To our families

Preface

We are in an information era where generating and storing large amounts of data are commonplace. A growing number of organizations routinely handle terabytes and exabytes of data, and individual digital data collections easily reach multiple gigabytes. Along with the increases in volume, the modality of digitized data that requires efficient management and the access modes to these data have become more varied. It is increasingly common for business and personal data collections to include images, video, voice, and unstructured text; the retrieval of these data comprises various forms, including structured queries, keyword search, and visual access. Data have become a highly valued asset for governments, industries and individuals, and the management of these data collections remains a critical technical challenge.

Database technology has matured over the past four decades and is now quite ubiquitous in many applications that deal with more traditional business data. The challenges of expanding data management to include other data modalities while maintaining the fundamental tenets of database management (data independence, data integrity, data consistency, etc.) are issues that the community continues to work on. The lines between database management and other fields such as information retrieval, multimedia retrieval, and data visualization are increasingly blurred.

This multi-volume *Encyclopedia of Database Systems* provides easy access to important concepts on all aspects of database systems, including areas of current interest and research results of historical significance. It is a comprehensive collection of over 1,250 in-depth entries (3,067 including synonyms) that present coverage of the important concepts, issues, emerging technology and future trends in the field of database technologies, systems, and applications. The content of the *Encyclopedia* was determined through wide consultations. We were assisted by an Advisory Board in coming up with the overall structure and content. Each of these areas were put under the control of Area Editors (70 in total) who further developed the content for each area, soliciting experts in the field as contributors to write the entries, and performed the necessary technical editing. Some of them even wrote entries themselves. Nearly 1,000 authors were involved in writing entries.

The intended audience for the *Encyclopedia* is technically broad and diverse. It includes anyone concerned with database system technology and its applications. Specifically, the *Encyclopedia* can serve as a valuable and authoritative reference for students, researchers and practitioners who need a quick and authoritative reference to the subject of databases, data management, and database systems. We anticipate that many people will benefit from this reference work, including database specialists, software developers, scientists and engineers who need to deal with (structured, semi-structured or unstructured) large datasets. In addition, database and data mining researchers and scholars in the many areas that apply database technologies, such as artificial intelligence, software engineering, robotics and computer vision, machine learning, finance and marketing are expected to benefit from the *Encyclopedia*.

We would like to thank the members of the Advisory Board, the Editorial Board, and the individual contributors for their help in creating this *Encyclopedia*. The success of the *Encyclopedia* could not have been achieved without the expertise and the effort of the many contributors. Our sincere thanks also go to Springer's editors and staff, including Jennifer Carlson, Susan Lagerstrom-Fife, Oona Schmid, and Susan Bednarczyk for their support throughout the project.

Finally, we would very much like to hear from readers for any suggestions regarding the *Encyclopedia's* content. With a project of this size and scope, it is quite possible that we may have missed some concepts. It is also possible that some entries may benefit from revisions and clarifications. We are committed to issuing periodic updates and we look forward to the feedback from the community to improve the *Encyclopedia*.

Ling Liu
M. Tamer Özsu

Editors-in-Chief

Ling Liu is a Professor in the School of Computer Science, College of Computing, at Georgia Institute of Technology. Dr. Liu directs the research programs in Distributed Data Intensive Systems Lab (DiSL), examining various aspects of data intensive systems, ranging from database and Internet data management, data storage, network computing, and mobile and wireless computing, with the focus on performance, availability, security, privacy, and energy efficiency in building very large database and data management systems and services. She has published over 200 international journal and conference articles in the areas of databases, data engineering, and distributed computing systems. She is a recipient of the best paper award of ICDCS 2003, the best paper award of WWW 2004, the 2005 Pat Goldberg Memorial Best Paper Award, and the best data engineering paper award of Int. Conf. on Software Engineering and Data Engineering (2008). Dr. Liu served on the editorial board of *IEEE Transactions on Knowledge and Data Engineering* and *International Journal of Very Large Databases* from 2004 to 2008 and is currently serving on the editorial board of several international journals, including *Distributed and Parallel Databases Journal, IEEE Transactions on Service Computing* (TSC), *International Journal of Peer-to-Peer Networking and Applications* (Springer), and *Wireless Network* (Springer). Dr. Liu's current research is primarily sponsored by NSF, IBM, and Intel.

M. Tamer Özsu is a Professor of Computer Science and Director of the David R. Cheriton School of Computer Science at the University of Waterloo. He holds a Ph.D. (1983) and an MS (1981) in Computer and Information Science from The Ohio State University (1983) and a B.S. (1974) and M.S. (1978) in Industrial Engineering from the Middle East Technical University, Turkey (1974).

Dr. Özsu's current research focuses on three areas: (a) Internet-scale data distribution that emphasizes stream data management, peer-to-peer databases, and Web data management; (b) multimedia data management, concentrating on similarity-based retrieval of time series and trajectory data; and (c) the integration of database and information retrieval technologies, focusing on XML query processing and optimization. His previous research focused on distributed databases, interoperable information systems, object database systems and image databases. He is the co-author of the book *Principles of Distributed Database Systems* (Prentice Hall), which is now in its second edition (third edition to publish in 2009).

He currently holds a University Research Chair and has held a Faculty Research Fellowship at the University of Waterloo (2000-2003), and a McCalla Research Professorship (1993-1994) at the University of Alberta where he was faculty member between 1984 and 2000. He is a fellow of the Association for Computing Machinery (ACM), a senior member of Institute of Electrical and Electronics Engineers (IEEE), and a member of Sigma Xi. He was awarded the ACM SIGMOD Contributions Award in 2006. He is also the 2008 recipient of Ohio State University College of Engineering Distinguished Alumnus Award.

He has held visiting positions at GTE Laboratories (USA), INRIA Rocquencourt (France), GMD-IPSI (Germany), University of Jyväskylä (Finland), Technical University of Darmstadt (Germany), University of Udine (Italy), University of Milano (Italy), ETH Zürich (Switzerland), and National University of Singapore (Singapore).

Dr. Özsu serves on the editorial boards of *ACM Computing Surveys*, *Distributed and Parallel Databases Journal*, *World Wide Web Journal*, *Information Technology and Management*, and Springer Book Series on *Advanced Information & Knowledge Processing*. Previously he was the Coordinating Editor-in-Chief of *The VLDB Journal* (1997-2005) and was on the Editorial Board of *Encyclopedia of Database Technology and Applications* (Idea Group). He has served as the Program Chair of VLDB (2004), WISE (2001), IDEAS (2003), and CIKM (1996) conferences and the General Chair of CAiSE (2002), as well as serving on the Program Committees of many conferences including SIGMOD, VLDB, and ICDE. He is also a member of Association for Computing Machinery's (ACM) Publications Board and is its Vice-Chair for New Publications.

Dr. Özsu was the Chair of *ACM Special Interest Group on Management of Data* (SIGMOD; 2001-2005) and a past trustee of the *VLDB Endowment* (1996-2002). He was a member and chair of the Computer and Information Science Grant Selection Committee of the Natural Sciences and Engineering Research Council of Canada during 1991-94, and served on the Management Committee of the Canadian Genome Analysis and Technology Program during 1992-93. He was Acting Chair of the Department of Computing Science at the University of Alberta during 1994-95, and again, for a brief period, in 2000.

A

Absolute Time

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

A temporal database contains time-referenced, or time-stamped, facts. A time reference in such a database is *absolute* if its value is independent of the context, including the current time, *now*.

Key Points

An example is "Mary's salary was raised on March 30, 2007." The fact here is that Mary's salary was raised. The absolute time reference is March 30, 2007, which is a time instant at the granularity of day.

Another example is "Mary's monthly salary was $ 15,000 from January 1, 2006 to November 30, 2007." In this example, the absolute time reference is the time period [January 1, 2006 – November 30, 2007].

Absolute time can be contrasted with *relative time*.

Cross-references

▶ Now in Temporal Databases
▶ Relative Time
▶ Time Instant
▶ Time Period
▶ Temporal Database
▶ Temporal Granularity

Abstract Versus Concrete Temporal Query Languages

Jan Chomicki[1], David Toman[2]
[1]State University of New York at Buffalo, Buffalo, NY, USA
[2]University of Waterloo, Waterloo, ON, Canada

Synonyms

Historical query languages

Definition

Temporal query languages are a family of query languages designed to query (and access in general) time-dependent information stored in temporal databases. The languages are commonly defined as extensions of standard query languages for non-temporal databases with *temporal features*. The additional features reflect the way dependencies of data on time are captured by and represented in the underlying temporal data model.

Historical Background

Most databases store time-varying information. On the other hand, SQL is often the language of choice for developing applications that utilize the information in these databases. Plain SQL, however, does not seem to provide adequate support for temporal applications.

Example. To represent the *employment histories* of persons, a common relational design would use a schema

`Employment(FromDate,ToDate, EID, Company)`,

with the intended meaning that a person identified by `EID` worked for `Company` continuously from `FromDate` to `ToDate`. Note that while the above schema is a standard relational schema, the additional assumption that the values of the attributes `FromDate` and `ToDate` represent *continuous periods* of time is itself *not* a part of the relational model.

Formulating even simple queries over such a schema is non-trivial. For example, the query GAPS: "*List all persons with gaps in their employment history, together* *with the gaps*" leads to a rather complex formulation in, e.g., SQL over the above schema (this is left as a challenge to readers who consider themselves SQL experts; for a list of appealing, but incorrect solutions, including the reasons why, see [9]). The difficulty arises because a single tuple in the relation is conceptually a *compact representation of a set of tuples*, each tuple stating that an employment fact was true on a particular day.

The tension between the conceptual abstract temporal data model (in the example, the property that employment facts are associated with individual *time instants*) and the need for an efficient and compact representation of temporal data (in the example, the representation of continuous periods by their start and end instants) has been reflected in the development of numerous temporal data models and temporal query languages [3].

Foundations

Temporal query languages are commonly defined using *temporal extensions* of existing non-temporal query languages, such as relational calculus, relational algebra, or SQL. The temporal extensions can be categorized in two, mostly orthogonal, ways:

- *The choice of the actual temporal values manipulated by the language.* This choice is primarily determined by the underlying temporal data model. The model also determines the associated operations on these values. The meaning of temporal queries is then defined in terms of temporal values and operations on them, and their interactions with *data* (non-temporal) values in a temporal database.
- *The choice of syntactic constructs to manipulate temporal values in the language.* This distinction determines whether the temporal values in the language are accessed and manipulated *explicitly*, in a way similar to other values stored in the database, or whether the access is *implicit*, based primarily on *temporally extending* the meaning of constructs that already exist in the underlying non-temporal language (while still using the operations defined by the temporal data model).

Additional design considerations relate to *compatibility* with existing query languages, e.g., the notion of temporal upward compatibility.

However, as illustrated above, an additional hurdle stems from the fact that many (early) temporal query languages allowed the users to manipulate a *finite underlying representation* of temporal databases rather than the actual temporal values/objects in the associated temporal data model. A typical example of this situation would be an approach in which the temporal data model is based on time instants, while the query language introduces interval-valued attributes. Such a discrepancy often leads to a complex and unintuitive semantics of queries.

In order to clarify this issue, Chomicki has introduced the notions of *abstract* and *concrete* temporal databases and query languages [2]. Intuitively, *abstract temporal query languages* are defined at the conceptual level of the temporal data model, while their *concrete* counterparts operate directly on an actual *compact encoding* of temporal databases. The relationship between abstract and concrete temporal query languages is also implicitly present in the notion of snapshot equivalence [7]. Moreover, Bettini et al. [1] proposed to distinguish between *explicit* and *implicit* information in a temporal database. The explicit information is stored in the database and used to derive the implicit information through *semantic assumptions*. Semantic assumptions related to fact persistence play a role similar to mappings between concrete and abstract databases, while other assumptions are used to address time-granularity issues.

Abstract Temporal Query Languages

Most temporal query languages derived by temporally extending the relational calculus can be classified as abstract temporal query languages. Their semantics are defined in terms of abstract temporal databases which, in turn, are typically defined within the point-stamped temporal data model, in particular *without* any additional hidden assumptions about the meaning of tuples in instances of temporal relations.

Example. The *employment histories* in an abstract temporal data model would most likely be captured by a simpler schema "`Employment(Date, EID, Company)`", with the intended meaning that a person identified by `EID` was working for `Company` on a particular `Date`. While instances of such a schema can potentially be very large (especially when a fine granularity of time is used), formulating queries is now much more natural.

Choosing abstract temporal query languages over concrete ones resolves the first design issue: the temporal values used by the former languages are time instants equipped with an appropriate temporal ordering (which is typically a linear order over the instants), and possibly other predicates such as temporal distance. The second design issue – access to temporal values – may be resolved in two different ways, as exemplified by two different query languages. They are as follows:

- Temporal Relational Calculus (TRC): a two-sorted first-order logic with variables and quantifiers explicitly ranging over the time and data domains.
- First-order Temporal Logic (FOTL): a language with an implicit access to timestamps using temporal connectives.

Example. The GAPS query is formulated as follows:

TRC: $\exists t_1, t_3 . t_1 < t_2 < t_3 \wedge \exists c.\texttt{Employment}(t_1, x, c) \wedge$
$(\neg \exists c.\texttt{Employment}(t_2, x, c)) \wedge$
$\exists c.\texttt{Employment}(t_3, x, c);$

FOTL: $\blacklozenge \exists c.\texttt{Employment}(x,c) \wedge$
$(\neg \exists c.\texttt{Employment}(x, c)) \wedge$
$\lozenge \exists c.\texttt{Employment}(x, c)$

Here, the explicit access to temporal values (in TRC) using the variables t_1, t_2, and t_3 can be contrasted with the implicit access (in FOTL) using the temporal operators ◆ (read "sometime in the past") and ◇ (read "sometime in the future"). The conjunction in the FOTL query represents an implicit temporal join. The formulation in TRC leads immediately to an equivalent way of expressing the query in SQL/TP [9], an extension of SQL based on TRC.

Example. The above query can be formulated in SQL/TP as follows:

```
SELECT t.Date, e1.EID
FROM Employment e1, Time t, Employment e2
WHERE e1.EID = e2.EID
AND e1.Date < e2.Date
   AND NOT EXISTS ( SELECT *
      FROM Employment e3
      WHERE e1.EID = e3.EID
      AND t.Date = e3.Date
        AND e1.Date < e3.Date
        AND e3.Date < e2.Date )
```

The unary constant relation `Time` contains all time instants in the time domain (in our case, all `Dates`) and is only needed to fulfill syntactic SQL-style requirements on attribute ranges. However, despite the fact that the instance of this relation is not finite, the query can be efficiently evaluated [9].

Note also that in all of the above cases, the formulation is *exactly the same* as if the underlying temporal database used the *plain* relational model (allowing for attributes ranging over time instants).

The two languages, FOTL and TRC, are the counterparts of the snapshot and timestamp models (cf. the entry Point-stamped Data Models) and are the roots of many other temporal query languages, ranging from the more TRC-like temporal extensions of SQL to more FOTL-like temporal relational algebras (e.g., the conjunction in temporal logic directly corresponds to a temporal join in a temporal relational algebra, as both of them induce an *implicit equality* on the associated time attributes).

Temporal integrity constraints over point-stamped temporal databases can also be conveniently expressed in TRC or FOTL.

Multiple Temporal Dimensions and Complex Values.

While the abstract temporal query languages are typically defined in terms of the point-based temporal data model, they can similarly be defined with respect to complex temporal values, e.g., pairs (or tuples) of time instants or even sets of time instants. In these cases, particularly in the case of set-valued attributes, it is important to remember that the set values are treated as *indivisible objects*, and hence truth (i.e., query semantics) is associated with the entire objects, but not necessarily with their components/subparts.

Concrete Temporal Query Languages

Although abstract temporal query languages provide a convenient and clean way of specifying queries, they are not immediately amenable to implementation. The main problem is that, in practice, the facts in temporal databases persist over periods of time. Storing all true facts individually *for every time instant* during a period would be prohibitively expensive or, in the case of infinite time domains such as *dense time*, even impossible.

Concrete temporal query languages avoid these problems by operating directly on the compact encodings of temporal databases. The most commonly used encoding is the one that uses *intervals*. However, in this setting, a tuple that associates a fact with such an interval is a compact representation of the association between the same fact and *all the time instants that belong to this interval*. This observation leads to the design choices that are commonly present in such languages:

- Coalescing is used, explicitly or implicitly, to consolidate representations of (sets of) time instants associated *with the same fact*. In the case of interval-based encodings, this leads to coalescing adjoining or overlapping intervals into a single interval. Note that coalescing only changes the *concrete representation* of a temporal relation, not its meaning (i.e., the abstract temporal relation); hence it has no counterpart in abstract temporal query languages.
- Implicit *set operations* on time values are used in relational operations. For example, conjunction (join) typically uses set intersection to generate a compact representation of the time instants attached to the facts in the result of such an operation.

Example. For the running example, a concrete schema for the employment histories would typically be defined as "`Employment(VT, EID, Company)`" where `VT` is a valid time attribute ranging over periods (intervals). The GAPS query can be formulated in a calculus-style language corresponding to TSQL2 (see the entry on TSQL2) along the following lines:

$$\begin{aligned}&\exists I_1, I_2.[\exists c.\mathtt{Employment}(I_1, x, c)] \wedge\\ &\quad [\exists c.\mathtt{Employment}(I_2, x, c)] \wedge I_1 \;\mathtt{precedes}\; I_2\\ &\quad \wedge I = [\mathtt{end}(I_1)+1, \mathtt{begin}(I_2)-1].\end{aligned}$$

In particular, the variables I_1 and I_2 range over periods and the `precedes` relationship is one of Allen's interval relationships. The final conjunct,

$$I = [\mathtt{end}(I_1)+1, \mathtt{begin}(I_2)-1],$$

creates a new period corresponding to the time instants related to a person's *gap in employment*; this interval value is explicitly constructed from the end and start points of I_1 and I_2, respectively. For the query to be correct, however, the results of evaluating the bracketed subexpressions, e.g., "$[\exists c.\mathtt{Employment}(I_1, x, c)]$," have to be *coalesced*. Without the insertion of the explicit coalescing operators, the query is *incorrect*. To see that, consider a situation in which a person p_0 is first employed by a company c_1, then by c_2, and finally by c_3, without any gaps in employment. Then without coalescing of the bracketed subexpressions of the above query, p_0 will be returned as a part of the result of the query, which is incorrect. Note also that it is not enough for the underlying (concrete) database to be coalesced.

The need for an explicit use of coalescing often makes the formulation of queries in some concrete SQL-based temporal query languages cumbersome and error-prone.

An orthogonal issue is the difference between explicit and implicit access to temporal values. This distinction also carries over to the concrete temporal languages. Typically, the various temporal extensions of SQL are based on the assumption of an explicit access to temporal values (often employing a built-in *valid time* attribute ranging over intervals or temporal elements), while many temporal relational algebras have chosen to use the implicit access based on temporally extending standard relational operators such as temporal join or temporal projection.

Compilation and Query Evaluation. An alternative to allowing users direct access to the encodings of temporal databases is to develop techniques that allow the evaluation of *abstract temporal queries* over these encodings. The main approaches are based on *query compilation* techniques that map abstract queries to concrete queries, while preserving query answers. More formally:

$$Q(\|E\|) = \|\mathtt{eval}(Q)(E)\|,$$

where Q an abstract query, eval(Q) the corresponding concrete query, E is a concrete temporal database, and ||.|| a mapping that associates encodings (concrete temporal databases) with their abstract counterparts (cf. Fig. 1). Note that a single abstract temporal database, D, can be encoded using several *different* instances of the corresponding concrete database, e.g., E_1 and E_2 in Fig. 1.

Most of the practical temporal data models adopt a common approach to physical representation of temporal databases: with every fact (usually represented as a tuple), a *concise encoding* of the set of time points at which the fact holds is associated. The encoding is commonly realized by *intervals* [6,7] or temporal elements (finite unions of intervals). For such an encoding it has been shown that both First-Order Temporal Logic [4] and Temporal Relational Calculus [8] queries can be *compiled* to first-order queries over a natural relational representation of the interval encoding of the database. Evaluating the resulting queries yields the interval encodings of the answers to the original queries, as if the queries were directly evaluated on the point-stamped temporal database. Similar results can be obtained for more complex encodings, e.g., periodic

Abstract Versus Concrete Temporal Query Languages. Figure 1. Query evaluation over interval encodings of point-stamped temporal databases.

sets, and for abstract temporal query languages that adopt the duplicate semantics matching the SQL standard, such as SQL/TP [9].

Key Applications

Temporal query languages are primarily used for querying temporal databases. However, because of their generality they can be applied in other contexts as well, e.g., as an underlying conceptual foundation for querying sequences and data streams [5].

Abstraction

BERNHARD THALHEIM
Christian-Albrechts University Kiel, Kiel, Germany

Synonyms

Component abstraction; Implementation abstraction; Association; Aggregation; Composition; Grouping; Specialization; Generalisation; Classification

Definition

Abstraction allows developers to concentrate on the essential, relevant, or important parts of an application. It uses a mapping to a model from things in reality or from virtual things. The model has the truncation property, i.e., it lacks some of the details in the original, and a pragmatic property, i.e., the model use is only justified for particular model users, tools of investigation, and periods of time. Database engineering uses construction abstraction, context abstraction, and refinement abstraction. Construction abstraction is based on the principles of hierarchical structuring, constructor composition, and generalization. Context abstraction assumes that the surroundings of a concept are commonly understood by a community or within a culture and focuses on the concept, turning away attention from its surroundings such as the environment and setting. Refinement abstraction uses the principle of modularization and information hiding. Developers typically use conceptual models or languages for representing and conceptualizing abstractions. The enhanced entity-relationship model schema are typically depicted by an EER diagram.

Key Points

Database engineering distinguishes three kinds of abstraction: construction abstraction, context abstraction, and refinement abstraction.

Constructor composition depends on the constructors as originally introduced by J. M. Smith and D.C.W. Smith. Composition constructors must be well founded and their semantics must be derivable by inductive construction. There are three main methods for construction: development of ordered structures on the basis of hierarchies, construction by combination or association, and construction by classification into groups or collections. The set constructors ⊂ (subset), × (product), and $\mathcal{P}$ (powerset) for subset, product and nesting are complete for the construction of sets.

Subset constructors support hierarchies of object sets in which one set of objects is a subset of some other set of objects. Subset hierarchies are usually a rooted tree. Product constructors support associations between object sets. The schema is decomposed into object sets related to each other by association or relationship types. Power set constructors support a classification of object sets into clusters or groups of sets – typically according to their properties.

Context abstraction allows developers to commonly concentrate on those parts of an application that are essential for some perspectives during development and deployment of systems. Typical types of context abstraction are component abstraction, separation of concern, interaction abstraction, summarization, scoping, and focusing on typical application cases.

Component abstraction factors out repeating, shared or local patterns of components or functions from individual concepts. It allows developers to concentrate on structural or behavioral aspects of similar elements of components. Separation of concern allows developers to concentrate on those concepts under development and to neglect all other concepts that are stable or not under consideration. Interaction abstraction allows developers to concentrate on parts of the model that are essential for interaction with other systems or users. Summarisation maps the conceptualizations within the scope to more abstract concepts. Scoping is typically used to select those concepts that are necessary for current development and removes those concepts which that do not have an impact on the necessary concepts.

Database models may cover a large variety of different application cases. Some of them reflect exceptional, abnormal, infrequent and untypical application situations. Focusing on typical application cases explicitly separates models intended for the normal or typical application case from those that are atypical. Atypical application cases are not neglected but can be folded into the model whenever atypical situations are considered.

The context abstraction concept is the main concept behind federated databases. Context of databases can be characterized by schemata, version, time, and security requirements. Sub-schemata, types of the schemata or views on the schemata, are associated with explicit import/export bindings based on a name space. Parametrization lets developers consider collections of objects. Objects are identifiable under certain assumptions and completely identifiable after instantiation of all parameters.

Interaction abstraction allows developers to display the same set of objects in different forms. The view concept supports this visibility concept. Data is abstracted and displayed in various levels of granularity. Summarization abstraction allows developers to abstract from details that are irrelevant at a certain point. Scope abstraction allows developers to concentrate on a number of aspects. Names or aliases can be multiply used with varying structure, functionality and semantics.

Refinement abstraction mainly concerns implementation and modularisation. It allows developers to selectively retain information about structures. Refinement abstraction is defined on the basis of the development cycle (refinement of implementations). It refines, summarizes and views conceptualizations, hides or encapsulates details, or manages collections of versions. Each refinement step transforms a schema to a schema of finer granularity. Refinement abstraction may be modeled by refinement theory and infomorphisms.

Encapsulation removes internal aspects and concentrates on interface components. Blackbox or graybox approaches hide all aspects of the objects being considered. Partial visibility may be supported by modularization concepts. Hiding supports differentiation of concepts into public, private (with the possibility to be visible as "friends") and protected (with visibility to subconcepts). It is possible to define a number of visibility conceptualizations based on inflection. Inflection is used for the injection of combinable views into the given view, for tailoring, ordering and restructuring of views, and for enhancement of views by database functionality. Behavioral transparency is supported by the glassbox approach. Security views are based on hiding. Versioning allows developers to manage a number of concepts which can be considered to be versions of each other.

Authorization verification

Definition

Access control deals with preventing unauthorized operations on the managed data. Access control is usually performed against a set of *authorizations* stated by Security Administrators (SAs) or users according to the *access control policies* of the organization. Authorizations are then processed by the *access control mechanism* (or *reference monitor*) to decide whether each access request can be authorized or should be denied.

Historical Background

Access control models for DBMSs have been greatly influenced by the models developed for the protection of operating system resources. For instance, the model proposed by Lampson [16] is also known as the *access matrix* model since authorizations are represented as a matrix. However, much of the early work on database protection was on inference control in statistical databases.

Then, in the 1970s, as research in relational databases began, attention was directed towards access control issues. As part of the research on System R at IBM Almaden Research Center, there was much work on access control for relational database systems [11,15], which strongly influenced access control models and mechanisms of current commercial relational DBMSs. Around the same time, some early work on multilevel secure database management systems (MLS/DBMSs) was reported. However, it was only after the Air Force Summer Study in 1982 [1] that developments on MLS/DBMSs began. For instance, the early prototypes based on the integrity lock mechanisms developed at the MITRE Corporation. Later, in the mid-1980s, pioneering research was carried out at SRI International and Honeywell Inc. on systems such as SeaView and LOCK Data Views [9]. Some of the technologies developed by these research efforts were transferred to commercial products by corporations such as Oracle, Sybase, and Informix. In the 1990s, numerous other developments were made to meet the access control requirements of new applications and environments, such as the World Wide Web, data warehouses, data mining systems, multimedia systems, sensor systems, workflow management systems, and collaborative systems. This resulted in several extensions to the basic access control models previously developed, by including the support for temporal constraints, derivation rules, positive and negative authorizations, strong and weak authorizations, and content and context-dependent authorizations [14]. Role-based access control has been proposed [12] to simplify authorization management within companies and organizations. Recently, there have been numerous developments in access control, mainly driven by developments in web data management. For example, standards such as XML (eXtensible Markup Language) and RDF (Resource Description Framework) require proper access control mechanisms [7]. Also, web services and the semantic web are becoming extremely popular and therefore research is currently carried out to address the related access control issues [13]. Access control is currently being examined for new application areas, such as knowledge management [4], data outsourcing, GIS [10], peer-to-peer computing and stream data management [8]. For example, in the case of knowledge management applications, it is important to protect the intellectual property of an organization, whereas when data are outsourced, it is necessary to allow the owner to enforce its access control policies, even if data are managed by a third party.

Foundations

The basic building block on which access control relies is a set of *authorizations*: which state, who can access which resource, and under which mode. Authorizations are specified according to a set of *access control policies*, which define the high-level rules according to which access control must occur. In its basic form, an authorization is, in general, specified on the basis of three components (*s,o,p*), and specifies that subject *s* is authorized to exercise privilege *p* on object *o*. The three main components of an authorization have the following meaning:

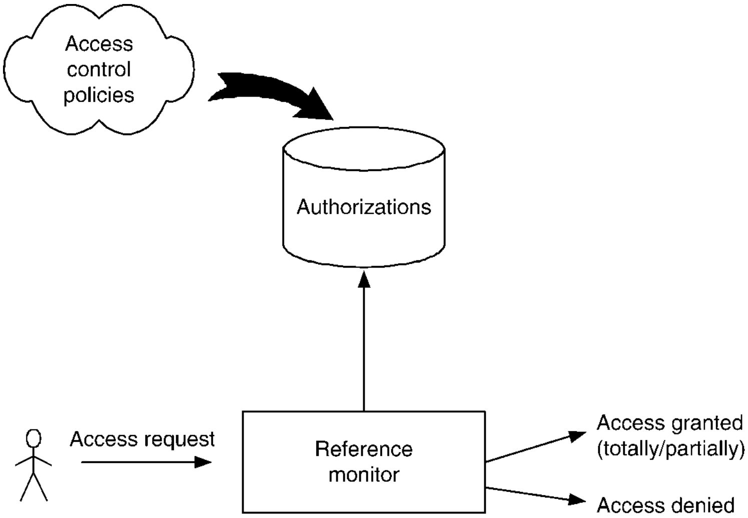
- *Authorization subjects*: They are the "active" entities in the system to which authorizations are granted. Subjects can be further classified into the following, not mutually exclusive, categories: *users*, that is, single individuals connecting to the system; *groups*, that is, sets of users; roles, that is, named collection of privileges needed to perform specific activities within the system; and *processes*, executing programs on behalf of users.
- *Authorization objects*: They are the "passive" components (i.e., resources) of the system to which protection from unauthorized accesses should be given. The set of objects to be protected clearly depends on the considered environment. For instance, files and directories are examples of objects of an operating system environment, whereas in a relational DBMS, examples of resources to be protected are relations, views and attributes. Authorizations can be specified at different granularity levels, that is, on a whole object or only on some of its components. This is a useful feature when an object (e.g., a relation) contains information (e.g., tuples) of different sensitivity levels and therefore requires a differentiated protection.
- *Authorization privileges*: They state the types of operations (or access modes) that a subject can exercise on the objects in the system. As for objects, the set of privileges also depends on the resources

to be protected. For instance, read, write, and execute privileges are typical of an operating system environment, whereas in a relational DBMS privileges refer to SQL commands (e.g., select, insert, update, delete). Moreover, new environments such as digital libraries are characterized by new access modes, for instance, usage or copying access rights.

Depending on the considered domain and the way in which access control is enforced, objects, subjects and/or privileges can be hierarchically organized. The hierarchy can be exploited to propagate authorizations and therefore to simplify authorization management by limiting the set of authorizations that must be explicitly specified. For instance, when objects are hierarchically organized, the hierarchy usually represents a "part-of" relation, that is, the hierarchy reflects the way objects are organized in terms of other objects. In contrast, the privilege hierarchy usually represents a subsumption relation among privileges. Privileges towards the bottom of the hierarchy are subsumed by privileges towards the top (for instance, the write privilege is at a higher level in the hierarchy with respect to the read privilege, since write subsumes read operations). Also roles and groups can be hierarchically organized. The group hierarchy usually reflects the membership of a group to another group. In contrast, the role hierarchy usually reflects the relative position of roles within an organization. The higher the level of a role in the hierarchy, the higher its position in the organization.

Authorizations are stored into the system and are then used to verify whether an access request can be authorized or not. How to represent and store authorizations depends on the protected resources. For instance, in a relational DBMS, authorizations are modeled as tuples stored into system catalogs. In contrast, when resources to be protected are XML documents, authorizations are usually encoded using XML itself. Finally, the last key component of the access control infrastructure is the *access control mechanism* (or *reference monitor*), which is a trusted software module in charge of enforcing access control. It intercepts each access request submitted to the system (for instance, SQL statements in case of relational DBMSs) and, on the basis of the specified authorizations, it determines whether the access can be partially or totally authorized or should be denied. The reference monitor should be *non-bypassable*. Additionally, the hardware and software architecture should ensure that the reference monitor is *tamper proof*, that is, it cannot be maliciously modified (or at least that any improper modification can be detected). The main components of access control are illustrated in Fig. 1.

A basic distinction when dealing with access control is between *discretionary* and *mandatory* access control. Discretionary access control (DAC) governs the access of subjects to objects on the basis of subjects' identity and a set of explicitly specified authorizations that specify, for each subject, the set of objects that



Access Control. Figure 1. Access control: main components.

he/she can access in the system and the allowed access modes. When an access request is submitted to the system, the access control mechanism verifies whether or not the access can be authorized according to the specified authorizations. The system is discretionary in the sense that a subject, by proper configuring the set of authorizations, is both able to enforce various access control requirements and to dynamically change them when needed (simply by updating the authorization state). In contrast, mandatory access control (MAC) specifies the accesses that subjects can exercise on the objects in the system, on the basis of subjects and objects security classification [14]. Security classes usually form a partially ordered set. This type of security has also been referred to as *multilevel security*, and database systems that enforce multilevel access control are called *Multilevel Secure Database Management Systems* (MLS/DBMSs). When mandatory access control is enforced, authorizations are implicitly specified, by assigning subjects and objects proper security classes. The decision on whether or not to grant an access depends on the access mode and the relation existing between the classification of the subject requesting the access and that of the requested object. In addition to DAC and MAC, role-based access control (RBAC) has been more recently proposed [12]. RBAC is an alternative to discretionary and mandatory access control, mainly conceived for regulating accesses within companies and organizations. In RBAC, permissions are associated with roles, instead of with users, and users acquire permissions through their membership to roles. The set of authorizations can be inferred by the sets of user-role and role-permission assignments.

Key Applications

Access control techniques are applied in almost all environments that need to grant a controlled access to their resources, including, but not limited, to the following: DBMSs, Data Stream Management Systems, Operat ing Systems, Workflow Management Systems, Digital Libraries, GIS, Multimedia DBMSs, E-commerce services, Publish-subscribe systems, Data warehouses.

Future Directions

Altough access control is a mature area with consolidated results, the evolution of DBMSs and the requirements of new applications and environments pose new challenges to the research community. An interesting discussion on open research issues in the field can be found in [6]. Some research issues which complement those presented in [6] are discussed below.

Social networks. Web-based social networks (WBSNs) are online communities where participants can establish relationships and share resources across the web with other users. In recent years, several WBSNs have been adopting semantic web technologies, such as FOAF, for representing users' data and relationships, making it possible to enforce information interchange across multiple WBSNs. Despite its advantages in terms of information diffusion, this raised the need for giving content owners more control on the distribution of their resources, which may be accessed by a community far wider than they expected. So far, this issue has been mainly addressed in a very simple way, by some of the available WBSNs, by only allowing users to state whether a specific information (e.g., personal data and resources) should be public or accessible only by the users with whom the owner of such information has a direct relationship. Such simple access control strategies have the advantage of being straightforward, but they are not flexible enough in denoting authorized users. In fact, they do not take into account the type of the relationships existing between users and, consequently, it is not possible to state that only, say, my "friends" can access a given information. Moreover, they do not allow to grant access to users who have an indirect relationship with the resource owner (e.g., the "friends of my friends"). Therefore, more flexible mechanisms are needed, making a user able to decide which network participants are authorized to access his/her resources and personal information. Additionally, since the number of social network users is considerably higher than those in conventional DBMSs, the traditional server-side way of enforcing access control, that is, the one relying on a centralized trusted reference monitor, should be revised and more efficient and distributed strategies should be devised for WBSNs. Until now, apart from [3], most of the security research on WBSNs has focused on privacy-preserving mining of social network data. The definition of a comprehensive framework for efficiently enforcing access control in social networks is therefore still an issue to be investigated.

- *Data streams*. In many applications, such as telecommunication, battle field monitoring, network monitoring, financial monitoring, sensor networks, data arrive in the form of high speed data streams. These data typically contain sensitive information (e.g., health information, credit card numbers) and thus unauthorized accesses should be avoided. Although many data stream processing systems have been developed so far (e.g., Aurora, Borealis, STREAM, TelegraphCQ, and StreamBase), the focus of these systems has been mainly on performance issues rather than on access control. On the other hand, though the data security community has a very rich history in developing access control models [9], these models are largely tailored to traditional DBMSs and therefore they cannot be readily applied to data stream management systems [8]. This is mainly because: (i) traditional data are static and bounded, while data streams are unbounded and infinite; (ii) queries in traditional DBMSs are one time and ad-hoc, whereas queries over data streams are typically continuous and long running; (iii) in traditional DBMSs, access control is enforced when users access the data; (iv) in data stream applications access control enforcement is data-driven (i.e., whenever data arrive), as such access control is more computational intensive in data stream applications and specific techniques to handle it efficiently should be devised; (v) temporal constraints (e.g., sliding windows) are more critical in data stream applications than in traditional DBMSs.

- *Semantic web*. The web is now evolving into the semantic web. The semantic web [5] is a web that is intelligent with machine-readable web pages. The major components of the semantic web include web infrastructures, web databases and services, ontology management and information integration. There has been much work on each of these areas. However, very little work has been devoted to access control. If the semantic web is to be effective, it is necessary to ensure that the information on the web is protected from unauthorized accesses and malicious modifications. Also, it must be ensured that individual's privacy is maintained. To cope with these issues, it is necessary to secure all the semantic web related technologies, such as XML, RDF, Agents, Databases, web services, and Ontologies and ensure the secure interoperation of all these technologies [13].

Access Control Administration Policies

Elena Ferrari
University of Insubria, Varese, Italy

Synonyms

Authorization administration policies; Authorization administration privileges

Definition

Administration policies regulate who can modify the authorization state, that is, who has the right to grant and revoke authorizations.

Historical Background

Authorization management is a an important issue when dealing with access control and, as such, research on this topic is strongly related to the developments in access control. A milestone in the field is represented by the research carried out in the 1970s at IBM in the framework of the System R project. In particular, the work by Griffiths and Wade [9] defines a semantics for authorization revocation, which had greatly influenced the way in which authorization revocation has been implemented in commercial Relational DBMSs. Administrative policies for Object-oriented DBMSs have been studied in [8]. Later on, some extensions to the System R access control administration model, have been defined [3], with the aim of making it more flexible and adaptable to a variety of access control requirements. Additionally, as the research on extending the System R access control model with enhanced functionalities progresses, authorization administration has been studied for these extensions, such as temporal authorizations [2], strong and weak and positive and negative authorizations [4]. Also, administrative policies for new environments and data models such as WFMSs [1] and XML data [12] have been investigated. Back in the 1990s, when research on role-based access control began, administration policies for RBAC were investigated [6,11,10,13]. Some of the ideas developed as part of this research were adopted by the current SQL:2003 standard [7].

Foundations

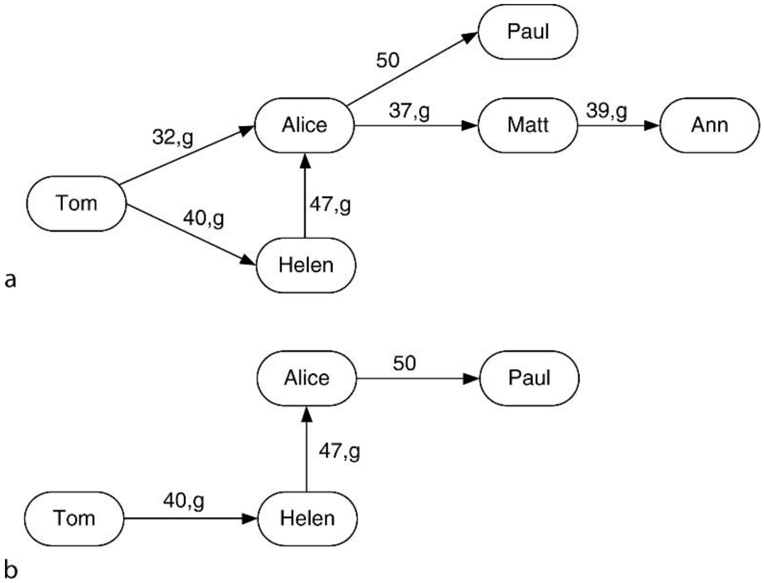
Access control administration deals with granting and revoking of authorizations. This function is usually regulated by proper *administration policies*. Usually, if mandatory access control is enforced, the adopted administration policies are very simple, so that the Security Administrator (SA) is the only one authorized to change the classification level of subjects and objects. In contrast, discretionary and role-based access control are characterized by more articulated administration policies, which can be classified according to the following categories [3]:

- *SA administration*. According to this policy, only the SA can grant and revoke authorizations. Although the SA administration policy has the advantage of being very simple and easily implemented, it has the disadvantage of being highly centralized (even though different SAs can manage different portions of the database) and is seldom used in current DBMSs, apart from very simple systems.
- *Object owner administration*. This is the policy commonly adopted by DBMSs and operating systems. Under this policy, whoever creates an object become its owner and he/she is the only one authorized to grant and revoke authorizations on the object.
- *Joint administration*. Under this policy, particularly suited for collaborative environments, several subjects are jointly responsible for administering specific authorizations. For instance, under the joint administration policy it can be a requirement that the authorization to write a certain document is given by two different users, such as two different job functions within an organization. Authorizations for a subject to access a data object requires that all the administrators of the object issue a grant request.

The object owner administration policy can be further combined with *administration delegation*, according to which the administrator of an object can grant other subjects the right to grant and revoke authorizations on the object. Delegation can be specified for selected privileges, for example only for read operations. Most current DBMSs support the owner administration policy with delegation. For instance, the `Grant` command provided by the SQL:2003 standard [7] supports a `Grant Option` optional clause. If a privilege p is granted with the grant option on an object o, the subject receiving it is not only authorized to exercise p on object o but he/she is also authorized to grant other subjects authorizations for p on object o with or without the grant option. Moreover, SQL:2003 provides an optional `Admin Option` clause, which has the same meaning as the Grant option clause but it applies to roles instead of to standard authorizations. If a subject is granted the authorization to play a role with the admin option he/she not only receives all the authorizations associated with the role, but he/she can also authorize other subjects to play that role.

If administration delegation is supported, different administrators can grant the same authorization to the same subject. A subject can therefore receive an authorization for the same privilege on the same object by different sources. An important issue is therefore related to the management of revoke operations, that is, what happens when a subject revokes some of the authorizations he/she previously granted. For instance, consider three users: Ann, Tom, and Alice. Suppose that Ann grants Tom the privilege to select tuples from the Employee relation with the grant option and that, by having this authorization, Tom grants Alice the same privilege on the Employee relation. What happens to the authorization of Alice when Ann revokes Tom the privilege to select tuples from the Employee relation? The System R authorization model [9] adopts the most conscious approach with respect to security by enforcing *recursive revocation*: whenever a subject revokes an authorization on a relation from another subject, all the authorizations that the revokee had granted because of the revoked authorization are recursively removed from the system. The revocation is iteratively applied to all the subjects that received an authorization from the revokee. In the example above, Alice will lose the privilege to select tuples from the Employee relation when Ann revokes this privilege to Tom.

Implementing recursive revocation requires keeping track of the *grantor* of each authorization, that is, the subject who specifies the authorization, since the same authorization can be granted by different subjects, as well as of its *timestamp*, that is, the time when it was specified. To understand why the timestamp is important in correctly implementing recursive revocation, consider the graph in Fig. 1a, which represents the authorization state for a specific privilege p on a specific object o. Nodes represent subjects, and an edge from node n_1 to node n_2 means that n_1 has granted privilege p on object o to n_2. The edge is labeled with the timestamp of the granted privilege and, optionally, with symbol "g," if the privilege has been granted with the grant option. Suppose that Tom revokes the authorization to Alice. As a result, the authorizations also held by Matt and Ann are recursively revoked because they could not have been granted if Alice did not receive authorization from Tom at time 32. In contrast, the authorization held by Paul is not revoked since it could have been granted even without the authorization granted by Tom to Alice at time 32, because of the privilege Alice had received by Helen at time



Access Control Administration Policies. Figure 1. Recursive revocation.

47. The authorization state resulting from the revoke operation is illustrated in Fig. 1b. Although recursive revocation has the advantage of being the most conservative solution with regard to security, it has the drawback of in some cases the unnecessarily revoking of too many authorizations. For instance, in an organization, the authorizations a user possesses are usually related to his/her job functions within the organization, rather than to his/her identity. If a user changes his/her tasks (for instance, because of a promotion), it is desirable to remove only the authorizations of the user, without revoking all the authorizations granted by the user before changing his/her job function. For this reason, research has been carried out to devise alternative semantics for the revoke operation with regard to recursive revocation. Bertino et al. [5] have proposed an alternative type of revoke operation, called *noncascading revocation*. According to this, no recursive revocation is performed upon the execution of a revoke operation. Whenever a subject revokes a privilege on an object from another subject, all authorizations which the subject may have granted using the privilege received by the revoker are not removed. Instead, they are restated as if they had been granted by the revoker.

SQL:2003 [7] adopts the object owner administration policy with delegation. A revoke request can either be issued to revoke an authorization from a subject for a particular privilege on a given object, or to revoke the authorization to play a given role. SQL:2003 supports two different options for the revoke operation. If the revoke operation is requested with the `Restrict` clause, then the revocation is not allowed if it causes the revocation of other privileges and/or the deletion of some objects from the database schema. In contrast, if the `Cascade` option is specified, then the system implements a revoke operation similar to the recursive revocation of the System R, but without taking into account authorization timestamps. Therefore, an authorization is recursively revoked only if the grantor no longer holds the grant/admin option for that, because of the requested revoke operation. Otherwise, the authorization is not deleted, regardless of the time the grantor had received the grant/admin option for that authorization. To illustrate the differences with regard to recursive revocation, consider once again Fig. 1a, and suppose that `Tom` revokes privilege p on object o to `Alice` with the `Cascade` option. With difference to the System R access control model, this revoke operation does not cause any other changes to the authorization state. The authorization granted by `Alice` to `Matt` is not deleted, because `Alice` still holds the grant option for that access (received by `Helen`).

Key Applications

Access control administration policies are fundamental in every environment where access control services are provided.

Access Control Policy Languages

ATHENA VAKALI
Aristotle University, Thessaloniki, Greece

Synonyms

Authorization policy languages

Definition

An access control policy language is a particular set of grammar, syntax rules (logical and mathematical), and operators which provides an abstraction-layer for access control policy specifications. Such languages combine individual rules into a single policy set, which is the basis for (user/subject) authorization decisions on accessing content (object) stored in various information resources. The operators of an access control policy language are used on attributes of the subject, resource (object), and their underlying application framework to facilitate identifying the policy that (most appropriately) applies to a given action.

Historical Background

The evolution of access control policy languages is inline with the evolving large-scale highly distributed information systems and the Internet, which turned the tasks of authorizing and controlling of accessing on a global enterprise (or on Internet) framework increasingly challenging and difficult. Obtaining a solid and accurate view of the policy in effect across its many and diverse systems and devices has guided the development of access control policy languages accordingly.

Access control policy languages followed the Digital Rights Management (DRM) standardization efforts, which had focused in introducing DRM technology into commercial and mainstream products. Originally, access control was practiced in the most popular RDBMSs by policy languages that were SQL based. Certainly, the access control policy languages evolution was highly influenced by the wide adoption of XML (late 1990s) mainly in the enterprise world and its suitability for supporting access control acts. XML's popularity resulted in an increasing need to support more flexible provisional access decisions than the initial simplistic authorization acts which were limited in an accept/deny decision. In this context, proposals of various access control policy languages were very active starting around the year 2000. This trend seemed to stabilize around 2005.

The historical pathway of such languages should highlight the following popular and general-scope access control policy languages:

- 1998: the Digital Property Rights Language (DPRL, Digital Property Rights Language, http://xml.coverpages.org/dprl.html) mostly addressed to commercial and enterprise communities was specified for describing rights, conditions, and fees to support commerce acts
- 2000: XML Access Control Language (XACL, XML Access Control Language, http://xml.coverpages.org/xacl.html) was the first XML-based access control language for the provisional authorization model
- 2001: two languages were publicized:
  - ► the eXtensible rights Markup Language (XrML, The Digital Rights Language for Trusted Content and Services, http://www.xrml.org/) promoted as the digital rights language for trusted content and services
  - ► the Open Digital Rights Language (ODRL, Open Digital Rights Language, http://odrl.net/) for developing and promoting an open standard for rights expressions for transparent use of digital content in all sectors and communities
- 2002: the eXtensible Media Commerce Language (XMCL, eXtensible Media Commerce Language, http://www.w3.org/TR/xmcl/) to communicate usage rules in an implementation-independent manner for interchange between business systems and DRM implementations
- 2003: the eXtensible Access Control Markup Language (XACML, eXtensible Access Control Markup Language, http://www.oasis-open.org/committees/xacml/) was accepted as a new OASIS, Organization for the Advancement of Structured Information Standards, http://www.oasis-open.org/, Open Standard language, designed as an XML specification with emphasis on expressing policies for information access over the Internet.
- 2005: Latest version XACML 2.0 appeared and policy languages which are mostly suited for Web services appear. These include WS-SecurityPolicy, http://www-128.ibm.com/developerworks/library/specification/ws-secpol/, which defines general security policy assertions to be applied into Web services security frameworks.

Foundations

Since Internet and networks in general are currently the core media for data and knowledge exchange, a primary issue is to assure authorized access to (protected) resources located in such infrastructures. To support access control policies and mechanisms, the use of an appropriate and suitable language is the core requirement in order to express all of the various components of access control policies, such as subjects, objects, constraints, etc. Initial attempts for expressing access control policies (consisting of authorizations) involved primary "participants" in a policy, namely the `subject` (client requesting access), the `object` (protected resource), and the `action` (right or type of access).

To understand the access control policy languages the context in which they are applied must be explained. Hence, the following notions which appear under varying terminology must be noted:

- *Content/objects*: Any physical or digital content which may be of different formats, may be divided into subparts and must be uniquely identified. Objects may also be encrypted to enable secure distribution of content.
- *Permissions/rights/actions*: Any task that will enforce permissions for accessing, using and acting over a particular content/object. They may contain constraints (limits), requirements (obligations), and conditions (such as exceptions, negotiations).
- *Subjects/users/parties*: Can be humans (end users), organizations, and defined roles which aim in consuming (accessing) content.

Under these three core entities, the policies are formed under a particular language to express offers and agreements. Therefore, the initial format of such languages authorization was (subject, object, and action) defining which subject can conduct what type of action over what object. However, with the advent of databases, networking, and distributed computing, users have witnessed (as presented in the section "Historical background") a phenomenal increase in the automation of organizational tasks covering several physical locations, as well as the computerization of information related services [6,7]. Therefore, new ideas have been added into modern access control models, like time, tasks, origin, etc. This was evident in the evolution of languages which initially supported an original syntax for policies limited in a

Access Control Policy Languages. Table 1. Summary of most popular access control policy languages

Language/ technology	Subject types	Object types	Protection granularity	Accessing core formats	Focus
DPRL/XML DTDs	Registered users	Digital XML data sources, stored on repositories	Fine-grained	Digital licenses assigned for a time-limited period	
XACL/XML syntax	Group or organization members	Particular XML documents	Fine-grained	Set of particular specified privileges	
XrML/XML schema	Registered users and/or parties	digital XML data sources	Fine-grained	Granted rights under specified conditions	
ODRL/open-source schema-valid XML syntax	Any user	Trusted or untrusted content	coarse-grained	Digital or physical rights	
XMCL/XML namespaces	Registered users	Trusted multimedia content	Coarse-grained	Specified keyword-based licenses	Particular business models
XACML/XML schema	Any users organized in categories	Domain-specific input	Fine-grained	Rule-based permissions	
WS-Security policy/ XML, SOAP	Any Web users/ Web services	Digital data sources	Fine-grained	Protection acts at SOAP Web services messages level	Web services security

3-tuple (subject, Subject primitive allows user IDs, groups, and/or role names. object, Object primitive allows granularity as fine as a single element within an XML document, and action, Action primitive consists of four kinds of actions: read, write, create, and delete.) which then was found quite simplistic and limited and it was extended to include non-XML documents, to allow roles and collections as subjects and to support more actions (such as approve, execute, etc).

Table 1 summarizes the most important characteristics of the popular general scope access control policy languages. It is evident that these languages differentiate on the subjects/users types, on the protected object/content type (which is considered as trusted when it is addressed to trusted audience/users) and on the capabilities of access control acts, which are presented under various terms and formats (rights, permissions, privileges, etc). Moreover, this table highlights the level at which the access control may be in effect for each language, i.e., the broad categorization into fine- and coarse-grained protection granularity, respectively, refers to either partitions/detailed or full document/object protection capability. Moreover, the extensibility of languages which support Web-based objects and content is noted.

To expand on the above, specific-scope languages have also emerged mainly to support research-oriented applications and tools. The most representative of such languages include:

- X-Sec [1]: To support the specification of subject credentials and security policies in Author-X and Decentral Author-X [2]. X-Sec adopts the idea of credentials which is similar to roles in that one user can be characterized by more than one credentials.

Access Control Policy Languages. Table 2. Specific-scope access control languages characteristics

	X-Sec	XACL	RBXAC	XAS syntax
Objects				
Protected resources	XML documents and DTDs	XML documents and DTDs	XML documents	XML documents and DTDs
Identification	XPath	XPath	XPath	XPath
Protection granularity	Content, attribute	Element	Content, attribute	Element
Subjects				
Identification	XML-expressed credentials	Roles, UIDs, groups	Roles	User ID, location
Grouping of subjects	No	Yes	No	Yes
Subjects hierarchy	No	Yes	Role trees	Yes
Support public subject	No	Yes	No	Yes
Policies				
Expressed in	Policy base	XACL policy file	Access control files	XAS
Closed/open	Closed	Both	Closed	Closed
Permissions/denials	Both	Both	Permissions	Both
Access modes	Authoring, browsing	Read, write, create, delete	RI, WI, RC, WC	Read
Propagation	No-prop, first-level, cascade	No/up/down	According to role tree	Local, recursive
Priority	Implicit rules	ntp, ptp, dtd	-	Hard, soft
Conflict resolution	Yes	According to priorities and implicit rules	-	Implicitly, explicitly
Other issues				
Subscription-based	Yes	Yes	Yes	Yes
Ownership	No	No	Yes	No

- XAS Syntax: Designed to support the ACP (Access Control Processor) tool [3]. It is a simplified XML-based syntax for expressing authorizations.
- RBXAC: A specification XML-based language supporting the role-based access control model [4].
- XACL: Which was originally based on a provisional authorization model and it has been designed to support ProvAuth (Provisional Authorizations) tool. Its main function is to specify security policies to be enforced upon accesses to XML documents.
- Cred-XACL [5]: A recent access control policy language focusing on credentials support on distributed systems and the Internet.

The core characteristics of these specific-scope languages are given in Table 2, which summarizes them with respect to their approach for objects and subjects management, their policies practicing and their subscription and ownership mechanisms. Such a summary is important in order to understand the "nature" of each such language in terms of objects and subjects identification, protection (sources) granularity and (subject) hierarchies, policies expression and accessing modes under prioritization, and conflict resolution constraints. Finally, it should be noted that these highlighted characteristics are important in implementing security service tasks which support several security requirements from both the system and the sources perspective.

Key Applications

Access control policy languages are involved in the transparent and innovative use of digital resources which are accessed in applications related to key nowadays areas such as publishing, distributing and consuming of electronic publications, digital images, audio and movies, learning objects, computer software and other creations in digital form.

Future Directions

From the evolution of access control policy languages, it appears that, in the future, emphasis will be given on languages that are mostly suited for Web-accessed repositories, databases, and information sources. This trend is now apparent from the increasing interest on languages that control accessing on Web services and Web data sources. At the same time, it manages the challenges posed by acknowledging and identifying users/subjects on the Web.

Access Methods

▶ Access Path

Access Path

Evaggelia Pitoura
University of Ioannina, Ioannina, Greece

Synonyms

Access path; Access methods

Definition

An access path specifies the path chosen by a database management system to retrieve the requested tuples from a relation. An access path may be either (i) a sequential scan of the data file or (ii) an index scan with a matching selection condition when there are indexes that match the selection conditions in the query. In general, an index matches a selection condition, if the index can be used to retrieve all tuples that satisfy the condition.

Key Points

Access paths are the alternative ways for retrieving specific tuples from a relation. Typically, there is more than one way to retrieve tuples because of the availability of indexes and the potential presence of conditions specified in the query for selecting the tuples. Typical access methods include sequential access of unordered data files (heaps) as well as various kinds of indexes. All commercial database systems implement heaps and B+ tree indexes. Most of them also support hash indexes for equality conditions.

To choose an access path, the optimizer first determines which matching access paths are available by examining the conditions specified by the query. Then, it estimates the selectivity of each access path using any available statistics for the index and data file. The *selectivity of an access path* is the number of pages (both index and data pages) accessed when the specific access path is used to retrieve the requested tuples. The access path having the smallest selectivity is called the most *selective access path*. Clearly, using the most selective access path minimizes the cost of data retrieval. Additional information can be found in [1].

ACID Properties

Gottfried Vossen
University of Münster, Münster, Germany

Synonyms

ACID properties; Atomicity; Isolation; Consistency preservation; Durability; Persistence

Definition

The conceptual *ACID properties* (short for atomicity, isolation, consistency preservation, and durability) of a transaction together provide the key abstraction which allows application developers to disregard irregular or even malicious effects from concurrency or failures of transaction executions, as the transactional server in charge guarantees the consistency of the underlying data and ultimately the correctness of the application [1–3]. For example, in a banking context where debit/credit transactions are executed this means that no money is ever lost in electronic funds transfers and customers can rely on electronic receipts and balance statements. These cornerstones for building highly dependable information systems can be successfully applied outside the scope of online transaction processing and classical database applications as well.

Key Points

The *ACID properties* are what a database server guarantees for transaction executions, in particular in the presence of multiple concurrently running transactions and in the face of failure situations; they comprise the following four properties (whose initial letters form the word "ACID"):

Atomicity. From the perspective of a client and an application program, a transaction is executed completely or not at all, i.e., in an all-or-nothing fashion. So the effects of a program under execution on the underlying data server(s) will only become visible to the outside world or to other program executions if and when the transaction reaches its "*commit*" operation. This case implies that the transaction could be processed completely, and no errors whatsoever were discovered while it was processed. On the other hand, if the program is abnormally terminated before reaching its commit operation, the data in the underlying data servers will be left in or automatically brought back to the state in which it was before the transaction started, i.e., the data appears as if the transaction had never been invoked at all.

Consistency preservation: Consistency constraints that are defined on the underlying data servers (e.g., keys, foreign keys) are preserved by a transaction; so a transaction leads from one consistent state to another. Upon the commit of a transaction, all integrity constraints defined for the underlying database(s) must be satisfied; however, between the beginning and the end of a transaction, inconsistent intermediate states are tolerated and may even be unavoidable. This property generally cannot be ensured in a completely automatic manner. Rather, it is necessary that the application is programmed such that the code between the beginning and the commit of a transaction will eventually reach a consistent state.

Isolation: A transaction is isolated from other transactions, i.e., each transaction behaves as if it was operating alone with all resources to itself. In particular, each transaction will "see" only consistent data in the underlying data sources. More specifically, it will see only data modifications that result from committed transactions, and it will see them only in their entirety, and never any effects of an incomplete transaction. This is the decisive property that allows to hide the fallacies and pitfalls of concurrency from the application developers. A sufficient condition for isolation is that concurrent executions are equivalent to sequential ones, so that all transactions appear as if they were executed one after the other rather than in an interleaved manner; this condition is made precise through serializability.

Durability: When the application program from which a transaction derives is notified that the transaction has been successfully completed (i.e., when the commit point of the transaction has been reached), all updates the transaction has made in the underlying data servers are guaranteed to survive subsequent software or hardware failures. Thus, updates of committed transactions are durable (until another transaction later modifies the same data items) in that they persist even across failures of the affected data server(s).

Therefore, a transaction is a set of operations executed on one or more data servers which are issued by an application program and are guaranteed to have the ACID properties by the runtime system of the involved servers. The "ACID contract" between the application program and the data servers requires the program to demarcate the boundaries of the transaction as well as the desired outcome – successful or abnormal termination – of the transaction, both in a dynamic manner. There are two ways a transaction can finish: it can commit, or it can abort. If it commits, all its changes to the database are installed, and they will remain in the database until some other application makes further changes. Furthermore, the changes will seem to other programs to take place together. If the transaction aborts, none of its changes will take effect, and the DBMS will rollback by restoring previous values to all the data that was updated by the application program. A programming interface of a transactional system consequently needs to offer three types of calls: (i) "*begin transaction*" to specify the beginning of a transaction, (ii) "*commit transaction*" to specify the successful end of a transaction, and (iii) "*rollback transaction*" to specify the unsuccessful end of a transaction with the request to abort the transaction.

The core requirement for a transactional server is to provide the ACID guarantees for sets of operations that belong to the same transaction issued by an application program requires that the server. This requires a *concurrency control* component to guarantee the isolation properties of transactions, for both committed and aborted transactions, and a *recovery* component to guarantee the atomicity and durability of transactions. The server may or may not provide explicit support for consistency preservation. In addition to the ACID contract, a transactional server should meet a number of technical requirements: A transactional data server (which most often will be a database system) must provide *good performance* with a given hardware/software configuration, or more generally, a good cost/performance ratio when the configuration is not yet fixed. Performance typically refers to the two metrics of *high throughput*, which is defined as the number of successfully processed transactions per time unit, and of *short response times*, where the response time of a transaction is defined as the time span between issuing the transaction and its successful completion as perceived by the client.

While the ACID properties are crucial for many applications in which the transaction concept arises, some of them are too restrictive when the transaction model is extended beyond the read/write context. For example, business processes can be cast into various forms of *business transactions*, i.e., long-running transactions for which atomicity and isolation are generally too strict. In these situations, additional or alternative guarantees need to be employed.

Right-time data warehousing

Definition

Active Data Warehousing is the technical ability to capture transactions when they change, and integrate them into the warehouse, along with maintaining batch or scheduled cycle refreshes. An active data warehouse offers the possibility of automating routine tasks and decisions. The active data warehouse exports decisions automatically to the On-Line Transaction Processing (OLTP) systems.

Real-time Data Warehousing describes a system that reflects the state of the warehouse in real time. If a query is run against the real-time data warehouse to understand a particular facet about the business or entity described by the warehouse, the answer reflects the state of that entity at the time the query was run. Most data warehouses have data that are highly latent – or reflects the business at a point in the past. A real-time data warehouse has low latency data and provides current (or real-time) data.

Simply put, a real-time data warehouse can be built using an active data warehouse with a very low latency constraint added to it. An alternate view is to consider active data warehousing as being a design methodology suited to tactical decision-making based on very current data while real-time data warehousing is a collection of technologies that refresh a data warehouse frequently. A real-time data warehouse is one that acquires, cleanses, transforms, stores, and disseminates information in real time. An active data warehouse, on the other hand, operates in a non-real-time response mode with one-or-more OLTP systems.

Historical Background

A *data warehouse* is a decision support database that is periodically updated by extracting, transforming, and loading operational data from several OLTP databases.

In the data warehouse, OLTP data is arranged using the (multi) dimensional data modeling approach (see [1] for a basic approach and [2] for details on translating an OLTP data model into a dimensional model), which classifies data into *measures* and *dimensions*. In recent years, several multidimensional data models have been proposed [3–6]. An in-depth comparison is provided by Pedersen and Jensen in [5]. The basic unit of interest in a data warehouse is a *measure* or *fact* (e.g., sales), which represent countable, semisummable, or summable information concerning a business process. An instance of a measure is called *measure value*. A measure can be analyzed from different perspectives, which are called the *dimensions* (e.g., location, product, time) of the data warehouse [7]. A dimension consists of a set of *dimension levels* (e.g., time: Day, Week, Month, Quarter, Season, Year, ALLTimes), which are organized in multiple hierarchies or *dimension paths* [6] (e.g., Time[Day] → Time[Month] → Time[Quarter] → Time[Year] → Time[ALLTimes]; Time[Day] → Time [Week] → Time[Season] → Time[ALLTimes]). The hierarchies of a dimension form a lattice having at least one top dimension level and one bottom dimension level. The measures that can be analyzed by the same set of dimensions are described by a *base cube* or *fact table*. A base cube uses level instances of the lowest dimension levels of each of its dimensions to identify a measure value. The relationship between a set of measure values and the set of identifying level instances is called *cell*. Loading data into the data warehouse means that new *cells* will be added to *base cubes* and new level instances will be added to *dimension levels*. If a dimension D is related to a measure m by means of a base cube, then the hierarchies of D can be used to aggregate the *measure values* of m using operators like SUM, COUNT, or AVG. Aggregating measure values along the hierarchies of different dimensions (i.e., *rollup*) creates a multidimensional view on data, which is known as *data cube* or *cube*. Deaggregating the measures of a cube to a lower dimension level (i.e., *drilldown*) creates a more detailed cube. Selecting the subset of a cube's cells that satisfy a certain selection condition (i.e., *slicing*) also creates a more detailed cube.

The data warehouses are used by analysts to find solutions for decision tasks by using OLAP (On-Line Analytical Processing) [7] systems. The decision tasks can be split into three, viz. *non-routine, semi-routine*, and *routine*. Non-routine tasks occur infrequently and/or do not have a generally accepted decision criteria. For example, strategic business decisions such as introducing a new brand or changing an existing business policy are non-routine tasks. Routine tasks, on the other hand, are well structured problems for which generally accepted procedures exist and they occur frequently and at predictive intervals. Examples can be found in the areas of product assortment (change price, withdraw product, etc.), customer relationship management (grant loyalty discounts etc.), and in many administrative areas (accept/reject paper based on review scores). Semi-routine tasks are tasks that require a non-routine solution – e.g., paper rated contradictory must be discussed by program committee. Since, most tasks are likely to be routine, it is logical to automate processing of such tasks to reduce the delay in decision-making.

Active data warehouses [8] were designed to enable data warehouses to support automatic decision-making when faced with routine decision tasks and routinizable elements of semi-routine decision tasks. The active data warehouse design extends the technology behind active database systems. Active database technology transforms passive database systems into reactive systems that respond to database and external events through the use of rule processing features [9,10]. Limited versions of active rules exist in commercial database products [11,12].

Real-time data warehousing captures business activity data as it occurs. As soon as the business activity is complete and there is data about it, the completed activity data flows into the data warehouse and becomes available instantly. In other words, real-time data warehousing is a framework for deriving information from data as the data becomes available. Traditionally, data warehouses were regarded as an environment for analyzing historic data, either to understand what has happened or simply to log the changes as they happened. However, of late, businesses want to use them to predict the future: e.g., to predict customers likely to churn; and thereby seek better control of the business. However, until recently, it was not practical to have *zero-latency* data warehouses – the process of extracting data had too much of an impact on the source systems concerned, and the various steps needed to cleanse and transform the data required multiple temporary tables and took several hours to run. However, the increased visibility of (the value of) warehouse data, and the take-up by a wider audience within the organization, has lead to a number of product developments by IBM [13], Oracle [14], and other vendors that make real-time data warehousing now possible.

Foundations

The two example scenarios below describe typical situations in which active rules can be used to automate decision-making:

Scenario 1: Reducing the price of an article. Twenty days after a soft drink has been launched on a market, analysts compare the quantities sold during this period with a standardized indicator. This indicator requires the total quantities sold during the 20-day period do not drop below a threshold of 10,000 sold items. If the analyzed sales figures are below this threshold, the price of the newly launched soft drink will be reduced by 15.

Scenario 2 : Withdrawing articles from a market. At the end of every quarter, high-priced soft drinks which are sold in Upper Austrian stores will be analyzed. If the sales figures of a high-priced soft drink have continuously dropped, the article will be withdrawn from the Upper Austrian market. Analysts inspect sales figures at different granularities of the time dimension and at different granularities of the location dimension. Trend, average, and variance measures are used as indicators in decision-making.

Rules that mimic the analytical work of a business analyst are called *analysis rules* [8]. The components of analysis rules constitute the *knowledge model* of an active data warehouse (and also a real-time data warehouse). The knowledge model determines *what* an analyst must consider when he specifies an active rule to automate a routine decision task.

An analysis rule consists of (i) the *primary dimension level* and (ii) the *primary condition*, which identify the objects for which decision-making is necessary, (iii) the *event*, which triggers rule processing, (iv) the *analysis graph*, which specifies the cubes for analysis, (v) the *decision steps*, which represent the conditions under which a decision can be made, and (vi) the *action*, which represents the rule's decision task. Below is a brief description of the components of an analysis rule. Detailed discussion is given in [8].

Event: Events are used to specify the timepoints at which analysis rules should be carried out. Active data warehouses provide three kinds of events: (i) OLTP method events, (ii) relative temporal events, and (iii) calendar events. OLTP method events describe basic happenings in the data warehouse's sources. Relative temporal events are used to define a temporal distance between such a basic happening and carrying out an analysis rule. Calendar events represent fixed points in time at which an analysis rule may be carried out. Structurally, every event instance is characterized by an occurrence time and by an event identifier. In its event part, an analysis rule refers to a calendar event or to a relative temporal event.

An *OLTP method event* describes a happening in the data warehouse's source systems that is of interest to analysis rules in the active data warehouse. Besides occurrence time and event identifier, the attributes of an OLTP method event are a reference to the dimension level for which the OLTP method event occurred and the parameters of the method invocation. To make OLTP method events available in data warehouses, a data warehouse designer has to define the schema of OLTP method events and extend the data warehouse's extract/transform/load mechanism. Since instances of OLTP method events are loaded some time after their occurrence, analysis rules cannot be triggered directly by OLTP method events.

Temporal events determine the timepoints at which decision-making has to be initiated. Scenario 1 uses the relative temporal event "twenty days after launch" while Scenario 2 uses the periodic temporal event "end of quarter." The *conditions* for decision-making are based on indicators, which have been established in manual decision-making. Each condition refers to a multidimensional cube and therefore "analyzing" means to evaluate the condition on this cube. Scenario 1 uses a quantity-based indicator, whereas scenario 2 uses value-based indicators for decision-making. The decision whether to carry out the rule's *action* depends on the result of evaluating the conditions. The action of scenario 1 is to reduce the price of an article, whereas the action of scenario 2 is to withdraw an article from a market.

Primary Condition: Several analysis rules may share the same OLTP method as their action. These rules may be carried out at different timepoints and may utilize different multidimensional analyses. Thus, a certain analysis rule usually analyzes only a subset of the level instances that belong to the rule's primary dimension level. The primary condition is used to determine for a level instance of the primary dimension level whether multidimensional analysis should be carried out by the analysis rule. The primary condition is specified as a Boolean expression, which refers to the describing attributes of the primary dimension level. If omitted, the primary condition evaluates to TRUE.

Action: The purpose of an analysis rule is to automate decision-making for objects that are available in OLTP systems and in the data warehouse. A *decision* means to invoke (or not to invoke) a method on a certain object in an OLTP system. In its action part, an analysis rule may refer to a single OLTP method of the primary dimension level, which represents a transaction in an OLTP system. These methods represent the *decision space* of an active data warehouse. To make the transactional behavior of an OLTP object type available in the active data warehouse, the data warehouse designer must provide (i) the specifications of the OLTP object type's methods together with required parameters, (ii) the preconditions that must be satisfied before the OLTP method can be invoked in the OLTP system, and (iii) a conflict resolution mechanism, which solves contradictory decisions of different analysis rules. Since different analysis rules can make a decision for the same level instance of the rules' primary dimension level during the same active data warehouse cycle, a *decision conflict* may occur. Such conflicts are considered as interrule conflicts. To detect interrule conflicts, a *conflict table* covering the OLTP methods of the decision space is used. The tuples of the conflict table have the form <*m*1, *m*2, *m*3> , where *m*1 and *m*2 identify two conflicting methods and *m*3 specifies the conflict resolution method that will be finally executed in OLTP systems. If a conflict cannot be solved automatically it has to be reported to analysts for manual conflict resolution.

Analysis Graph: When an analyst queries the data warehouse to make a decision, he or she follows an incremental topdown approach in creating and analyzing cubes. Analysis rules follow the same approach. To automate decision-making, an analysis rule must "know" the cubes that are needed for multidimensional analysis. These cubes constitute the *analysis graph*, which is specified once by the analyst. The *n* dimensions of each cube of the analysis graph are classified into one *primary dimension*, which represents the level instances of the primary dimension level, and $n - 1$ *analysis dimensions*, which represent the multidimensional space for analysis. Since a level instance of the primary dimension level is described by one or more cells of a cube, multidimensional analysis means to compare, aggregate, transform, etc., the measure values of these cells. Two kinds of multidimensional analysis are carried out at each cube of the analysis graph: (i) select the level instances of the primary dimension level whose cells comply with the decision-making condition (e.g., withdraw an article if the sales total of the last quarter is below USD 10,000) and (ii) select the level instances of the primary dimension level whose cells comply with the condition under which more detailed analysis (at finer grained cubes) are necessary (e.g., continue analysis if the sales total of the last quarter is below USD 500,000). The multidimensional analysis that is carried out on the cubes of the analysis graph are called decision steps. Each decision step analyzes the data of exactly one cube of the analysis graph. Hence, analysis graph and decision steps represent the knowledge for multidimensional analysis and decision-making of an analysis rule.

Enabling real-time data warehousing: As mentioned earlier, real-time data warehouses are active data warehouses that are loaded with data having (near) zero latency. Data warehouse vendors have used multiple approaches such as *hand-coded scripting* and data extraction, transformation, and loading (ETL) [15] solutions to serve the data acquisition needs of a data warehouse. However, as users move toward real-time data warehousing, there is a limited choice of technologies that facilitate real-time data delivery. The challenge is to determine the right technology approach or combination of solutions that best meets the data delivery needs. Selection criteria should include considerations for frequency of data, acceptable latency, data volumes, data integrity, transformation requirements and processing overhead. To solve the real-time challenge, businesses are turning to technologies such as enterprise application integration (EAI) [16] and transactional data management (TDM) [17], which offer high-performance, low impact movement of data, even at large volumes with sub-second speed. EAI has a greater implementation complexity and cost of maintenance, and handles smaller volumes of data. TDM provides the ability to capture transactions from OLTP systems, apply mapping, filtering, and basic transformations and delivers to the data warehouse directly. A more detailed study of the challenges involved in implementing a real-time data warehouse is given in [18].

Key Applications

Active and Real-time data warehouses enable businesses across all industry verticals to gain competitive advantage by allowing them to run *analytics* solutions over the most recent data of interest that is captured in the warehouse. This will provide them with the ability to make intelligent business decisions and better understand and predict customer and business trends based on accurate, up-to-the-second data. By introducing real-time flows of information to data warehouses, companies can increase supply chain visibility, gain a complete view of business performance, and increase service levels, ultimately increasing customer retention and brand value.

The following are some additional business benefits of active and real-time data warehousing:

- *Real-time Analytics:* Real-time analytics is the ability to use all available data to improve performance and quality of service at the moment they are required. It consists of dynamic analysis and reporting, right at the moment (or very soon after) the resource (or information) entered the system. In a practical sense, real time is defined by the need of the consumer (business) and can vary from a few seconds to few minutes. In other words, more frequent than daily can be considered real-time, because it crosses the overnight-update barrier. With increasing availability of active and real-time data warehouses, the technology for capturing and analyzing real-time data is increasingly becoming available. Learning how to apply it effectively becomes the differentiator. Implementing real-time analytics requires the integration of a number of technologies that are not interoperable off-the-shelf. There are no established best practices. Early detection of fraudulent activity in financial transactions is a potential environment for applying real-time analytics. For example, credit card companies monitor transactions and activate counter measures when a customer's credit transactions fall outside the range of expected patterns. However, being able to correctly identify fraud while not offending a well-intentioned valuable customer is a critical necessity that adds complexity to the potential solution.
- *Maximize ERP Investments:* With a real-time data warehouse in place, companies can maximize their Enterprise Resource Planning (ERP) technology investment by turning integrated data into business intelligence. ETL solutions act as an integral bridge between ERP systems that collect high volumes of transactions and business analytics to create data reports.
- *Increase Supply Chain Visibility:* Real-time data warehousing helps streamline supply chains through highly effective business-to-business communications and identifies any weak links or bottlenecks, enabling companies to enhance service levels and gain a competitive edge.
- *Live 360° View of Customers:* The active database solutions enable companies to capture, transform, and flow all types of customer data into a data warehouse, creating one seamless database that provides a 360° view of the customer. By tracking and analyzing all modes of interaction with a customer, companies can tailor new product offerings, enhance service levels, and ensure customer loyalty and retention.

Future Directions

Data warehousing has greatly matured as a technology discipline; however enterprises that undertake data warehousing initiatives continue to face fresh challenges that evolve with the changing business and technology environment. Most future needs and challenges will come in the areas of active and real-time data warehousing solutions. Listed below are some future challenges:

- *Integrating Heterogeneous Data Sources:* The number of enterprise data sources is growing rapidly, with new types of sources emerging every year. Enterprises want to integrate the unstructured data generated from customer emails, chat and voice call transcripts, feedbacks, and surveys with other internal data in order to get a complete picture of their customers and integrate internal processes. Other sources for valuable data include ERP programs, operational data stores, packaged and homegrown analytic applications, and existing data marts. The process of integrating these sources into a data warehouse can be complicated and is made even more difficult when an enterprise merges with or acquires another enterprise.
- *Integrating with CRM tools:* Customer relationship management (CRM) is one of the most popular business initiatives in enterprises today. CRM helps enterprises attract new customers and develop loyalty among existing customers with the end result of increasing sales and improving profitability. Increasingly, enterprises want to use the holistic view of the customer to deliver value-added services to

the customer based on her overall value to the enterprise. This would include, automatically identifying when an important life event is happening and sending out emails with necessary information and/or relevant products, gauging the mood of the customer based on recent interactions, and alerting the enterprise before it is too late to retain the customer and most important of all identifying customers who are likely to accept suggestions about upgrades of existing products/services or be interested in newer versions. The data warehouse is essential in this integration process, as it collects data from all channels and customer touch points, and presents a unified view of the customer to sales, marketing, and customer-care employees. Going forward, data warehouses will have to provide support for analytics tools that are embedded into the warehouse, analyze the various customer interactions continuously, and then use the insights to trigger *actions* that enable delivery of the above-mentioned value-added services. Clearly, this requires an active data warehouse to be tightly integrated with the CRM systems. If the enterprise has low latency for insight detection and value-added service delivery then a real-time data warehouse would be required.

- *In-built data mining and analytics tools:* Users are also demanding more sophisticated business intelligence tools. For example, if a telecom customer calls to cancel his call-waiting feature, real-time analytic software can detect this and trigger a special offer of a lower price in order to retain the customer. The need is to develop a new generation of data mining algorithms that work over data warehouses that integrate heterogeneous data and have self-learning features. These new algorithms must automate data mining and make it more accessible to mainstream data warehouse users by providing explanations with results, indicating when results are not reliable and automatically adapting to changes in underlying predictive models.

Active Database, Active Database (Management) System

Mikael Berndtsson, Jonas Mellin
University of Skövde, Skövde, Sweden

Definition

An active database (aDB) or active database (management) system (aDBS/aDBMS) is a database (management) system that supports reactive behavior through ECA-rules.

Historical Background

The term active database was first used in the early 1980s [12]. Some related active database work was also done within the area of expert database systems in the mid 1980s, but it was not until the mid/late 1980s that the research on supporting ECA rules in database systems took off, for example [10,12,18]. During the 1990s the area was extensively explored through more than twenty suggested active database prototypes and a large body of publications:

- Seven workshops were held between 1993 and 1997: RIDS [12,16,17], RIDE-ADS [20], Dagstuhl Seminar [5] and ARTDB [3,4].
- Two special issues of journals [8,9] and one special issue of ACM Sigmod Record [1].
- Two text books [13,19] and one ACM Computing Survey paper [15].

In addition, the groups within the ACT-NET consortium (A European research network of Excellence on active databases 1993–1996) reached a consensus on what constitutes an active database management system with the publication of the Active Database System Manifesto [2].

Most of the active databases are monolithic and assume a centralized environment, consequently, the majority of the prototype implementations do not consider distributed issues. Initial work on how active databases are affected by distributed issues are reported in [7].

Foundations

An active database can automatically react to events such as database transitions, time events, and external signals in a timely and efficient manner. This is in contrast to traditional database systems, which are passive in their behaviors, so that they only execute queries and transactions when they are explicitly requested to do so.

Previous approaches to support reactive behavior can broadly be classified into:

- Periodically polling the database.
- Embedding or encoding event detection and related action execution in the application code.

The first approach implies that the queries must be run exactly when the event occurs. The frequency of polling can be increased in order to detect such an event, but if the polling is too frequent, then the database is overloaded with queries and will most often fail. On the other hand, if the frequency is too low, the event will be missed.

The second approach implies that every application which updates the database needs to be augmented with condition checks in order to detect events. For example, an application may be extended with code to detect whether the quantity of certain items has fallen below a given level. From a software engineering point of view, this approach is inappropriate, since a change in a condition specification implies that every application that uses the modified condition needs to be updated.

Neither of the two previous approaches can satisfactorily support reactive behavior in a database context [10]. An active database system avoids the previous disadvantages by moving the support for reactive behavior inside the database (management) system. Reactive behavior in an active database is supported by ECA-rules that have the following semantics: when an event is detected, evaluate a condition, and if the condition is true, execute an action.

Similar to describing an object by its static features and dynamic features, an active database can be described by its knowledge model (static features) and execution model (dynamic features). Thus, by investigating the knowledge model and execution model of an active database, one can identify what type of ECA rules that can be defined and how the active database behave at run-time.

Key Applications

An aDB or aDBS/aDBMS is useful for any non-mission critical application that require reactive behavior.

Future Directions

Looking back, the RIDS'97 workshop marks the end of the active database period, since there are very few active database publications after 1997. However, the concept of ECA-rules has resurfaced and has been picked up by other research communities such as Complex Event Processing and Semantic Web. In contrast to typical active database approaches that assume a centralized environment, the current research on ECA rules within Complex Event Processing and Semantic Web assume that the environment is distributed and heterogeneous. Thus, as suggested within the REWERSE project [3], one cannot assume that the event, condition, and action parts of an ECA rule are defined in one single ECA rule language. For example, the event part of an ECA-rule can be defined in one language (e.g., Snoop), whereas the condition part and action part are defined in a completely different rule language.

The popularity of using XML for manipulating data has also led to proposals of ECA rule markup languages. These ECA rule markup languages are used for storing information about ECA rules and facilitates exchange of ECA-rules between different rule engines and applications.

One research question that remains from the active database period is how to model and develop applications that use ECA rules. Some research on modeling ECA rules has been carried out, but there is no widely agreed approach for modeling ECA rules explicitly in UML, or how to derive ECA rules from existing UML diagrams.

Active Database Management System Architecture

Jonas Mellin, Mikael Berndtsson
University of Skövde, Skövde, Sweden

Synonyms

ADBMS infrastructure; ADBMS framework; ADBMS

Definition

The active database management system (ADBMS) architecture is the software organization of a DBMS with active capabilities. That is, the architecture defines support for active capabilities expressed in terms of services, significant components providing the services as well as critical interaction among these services.

Historical Background

Several architectures has been proposed: HiPAC [5,8], REACH [4], ODE [14], SAMOS [10], SMILE [15], and DeeDS [1]. Each of these architectures emphasize particular issues concerning the actual DBMS that they are based on as well as the type of support for active capabilities. Paton and Diaz [18] provide an excellent survey on this topic. Essentially, these architectures propose that the *active capabilities* of an ADBMS require the services specified in Table 1. It is assumed that queries to the database are encompassed in transactions and hence transactions imply queries as well as database manipulation operations such as insertion, updates and deletion of tuples.

The services in Table 1 interact as depicted in Fig. 1. Briefly, transactions are submitted to the scheduling service that updates the dispatch table read by the transaction processing service. When these transactions are processed by the transaction processing service events are generated. These events are signaled to the event monitoring service that analyzes them. Events that are associated with rules (subscribed events) are signaled to the rule evaluation service that evaluates the conditions of *triggered rules* (i.e., rules associated with signaled events). The actions of the rules whose conditions are true are submitted for scheduling and are executed as dictated by the scheduling policy. These actions execute as part of some transaction according to the coupling mode and can, in turn, generate events. This is a general description of the service interaction and it can be optimized by refining it for a specific purpose, for example, in immediate coupling mode no queues between the services are actually needed.

In more detail, transactions are submitted to the scheduling service via a queue of schedulable activities; this queue of schedulable activities is processed and a dispatch table of schedulable activities is updated. This scheduling service encompasses scheduling of transactions as well as ECA rule actions in addition to other necessary schedulable activities. It is desirable for the scheduling service to encompass all these types of schedulable activities, because they impact each other, since they compete for the same resources. The next step in the processing chain is the monitored transaction processing service, which includes the transaction management, lock management, and log management [11, Chap. 5], as well as a database query engine (cf. query processor [20, Chap. 1]), but not the scheduling service. Another way to view the transaction processing service is as a passive database management system without the transaction scheduling service. The transaction processing service is denoted "monitored," since it generates events that are handled by the active capabilities. The monitored transaction processing service executes transactions and ECA rule actions according to the dispatch table. When transactions execute, event occurrences are signaled to the event monitoring service via a filtered event log. When event monitoring executes, it updates the filtered event log and submits subscribed events to the rule evaluation service. An example of event log filtering is that if a composite event occurrence is detected, then for optimization reasons (cf. dynamic programming) this event occurrence is stored in the filtered event log. Another example is that when events are no longer needed, then they are pruned; for example, when a transaction is aborted, then all event occurrences can be pruned unless intertransaction events are allowed (implying that dirty reads may occur). The rule evaluation service reads the

Active Database Management System Architecture. Table 1. Services in active database management systems

Service	Responsibility
Event monitoring	The event monitoring service is responsible for collecting events, analyzing events and disseminating results of the analysis (in terms of events) to subscribers, in particular, ECA rules.
Rule evaluation	The rule evaluation service is responsible for invoking condition evaluation of triggered ECA rules and submit actions for execution to the scheduler.
Scheduling service	The scheduling service is responsible for readying and ordering schedulable activities such as ECA rule actions, transactions etc. for execution.

Data flow: event occurrences, actions, transactions
Manipulation: insert, update, delete

Active Database Management System Architecture. Figure 1. Service interaction view of architecture (based on architecture by Paton and Diaz [18]).

queue of subscribed events, finds the triggered rules and evaluates their conditions. These conditions may be queries, logical expressions or arbitrary code depending on the active database system [9]. The rule evaluation results in a set of actions that is submitted to the scheduling service for execution.

The general view of active capabilities (in Fig. 1) can be refined and implemented in different ways. As mentioned, it is possible to optimize an implementation by removing the queues between the services if only immediate coupling mode is considered; this result in less overhead, but restricts the expressibility of ECA-rules significantly. A service can be implemented via one or more servers. These servers can be replicated to different physical nodes for performance or dependability reasons (e.g., availability, reliability).

In active databases, a set of issues have a major impact on refinement and implementation of the general service-oriented view depicted in Fig. 1. These issues are: (i) coupling modes; (ii) interaction with typical database management services such as transaction management, lock management, recovery management (both pre-crash such as logging and checkpointing and post-crash such as the actually recovery) (cf., for example, transaction processing by Gray and Reuter [11, Chap. 4]); (iii) when and how to invoke services; and (iv) active capabilities in distributed active databases.

The coupling modes control how rule evaluation is invoked in response to events and how the ECA rule actions are submitted, scheduled, dispatched and executed for rules whose conditions are true (see entry “Coupling modes” for more detailed description). There are different alternatives to interaction with a database system. One alternative is to place active database services on top of existing database management systems. However, this is problematic if the database management system is not extended with active capabilities [4]. For example, the deferred coupling mode require that when a transaction is requested to commit, then queued actions should be evaluated. This requires that the transaction management to interact with the rule evaluation and scheduling services during commit processing (e.g., by using back hooks in the database management system). Further, to be useful, the detached coupling mode has a set of significant varieties [4] that require the possibility to express constraints between transactions.

The nested transaction model [16] is a sound basis for active capabilities. For example, deferred actions can be executed as subtransactions that can be committed or aborted independently of the parent transaction. Nested transactions still require that existing services are modified. Alternatively rule evaluation can be performed as subtransactions.

To achieve implicit events the database schema translation process needs to automatically instrument the monitored systems. An inferior solution is to extend an existing schema with instrumented entities, for example, each class in an object-oriented database can be inherited to an instrumented class. In this example, there is no way to enforce that the instrumented classes are actually used. The problem is to modify the database schema translation process, since this is typically an intrinsic part in commercial DBMSs.

Concerning issue (iii), the services must be allocated to existing resources and scheduled together with the transactions. Typically, the services are implemented as a set of server processes and transactions are performed by transaction programs running as processes (cf., [11]). These processes are typically scheduled, dispatched and executed as a response to the requests from outside the database management system or as a direct or indirect response to a timeout. Each service is either invoked when something is stored in the queue or table or explicitly invoked, for example, when the system clock is updated to reflect the new time. The issues concerning scheduling are paramount in any database management system for real-time system purposes [2].

Event monitoring can either be (i) implicitly invoked whenever an event occurs, or it can be (ii) explicitly invoked. This is similar to coupling modes, but it is between the event sources (e.g., transaction processing service and application) and the event monitoring service rather than in between the services of the active capabilities. Case (i) is prevalent in most active database research, but it has a negative impact in terms of determinism of the result of event monitoring. For example, the problem addressed in the event specification and event detection entry concerning the unintuitive semantics of the disjunctive event operator is a result of implicit invocation. In distributed and real-time systems, explicit invocation is preferable in case (ii), since it provides the operating system with the control when something should be evaluated. Explicit invocation solves the problem of disjunction operator (see event specification and event detection entries), since the event expressions defining composite event types can be explicitly evaluated when all events have been delivered to event monitoring rather than implicitly evaluated whenever an event is delivered.

In explicit invocation of event monitoring, the different event contexts can be treated in different ways. For example, in recent event context, only the most recent result is of interest in implicit invocation. However, in terms of explicit invocation, all possible most recent event occurrences may be of interest, not only the last one. For example, it may be desirable to keep the most recent event occurrence per time slot rather than per terminating event.

Issue (iv) has been addressed in, for example, DeeDS [1], COBEA [15], Hermes [19], X2TS [5]. Further, it has been addressed in event based systems for mobile networks by Mühl et al. [17]. Essentially, it is necessary to perform event detection in a moving time window, where the end of the time window is the current time. All events that are older than the beginning of the time window can be removed and ignored. Further, the heterogeneity must be addressed and there are XML-based solutions (e.g., Common Base Events [6]).

Another issue that is significant in distributed active databases is the time and order of events. For example, in Snoop [8] it is suggested to separate global and local event detection, because of the difference in the time granularity of the local view of time and the global (distributed) view of time.

Foundations

For a particular application domain, common significant requirements and properties as well as pre-requisites of available resources need to be considered to refine the general architecture. Depending on the requirements, properties and pre-requisites, different compromises are reached. One example is the use of composite event detection in active real-time databases. In REACH [4], composite event detection is disallowed for real-time transactions. The reason for this is that during composite event detection, contributing events are locked and this locking affects other transaction in a harmful way with respect to meeting deadlines. A different approach is proposed in DeeDS [1], where events are stored in the database and cached in a special filtered event log; during event composition, events are not locked thus enabling the use of composite event detection for transaction with critical deadlines. The cost is that isolation of transactions can be violated unless it is handled by the active capabilities.

Availability is an example of a property that significantly affects the software architecture. For example, availability is often considered significant in distributed systems; that is, even though physical nodes may fail, communications links may be down, or the other physical nodes may be overloaded, one should get, at least, some defined level of service from the system. An example of availability requirements is that emergency calls in phone switches should be prioritized over non-emergency calls, a fact that entails that existing phone call connections can be disconnected to let an emergency call through. Another example to improve availability is pursued in DeeDS [1], where eventual consistency is investigated as a mean to improve availability of data. The cost is that data can temporarily be inconsistent.

As addressed in the aforementioned examples, different settings affect the architecture. Essentially, there are two approaches that can be mixed: (i) refine or invent new method, tools, techniques to solve a problem, and these method, tools, techniques can stem from different but relevant research areas; (ii) refine the requirements or pre-requisites to solve the problem (e.g., weaken the ACID properties of transactions).

Key Applications

The architecture of ADBMSs is of special interest to developers of database management systems and their applications. In particular, software engineering issues are of major interest. Researchers performing experiments can make use of this architecture to enable valid experiments, study effects of optimizations etc.

Concerning real examples of applications, only simple things such as using rules for implementing alerters, for example, when an integrity constraint is violated. SQL Triggers implement simple ECA rules in immediate coupling mode between event monitoring and rule evaluation as well as between rule evaluation and action execution.

Researchers have aimed for various application domains such as:

- Stock market
- Inventory control
- Bank applications

Essentially, any application domain in which there is an interest to move functionality from the applications to the database schema to reduce the interdependence between applications and databases.

Future Directions

There are no silver bullets in computer science or software engineering and each refinement of the architecture (in Fig. 1) is a compromise providing or enabling certain features and properties. For example, by allowing only detached coupling mode it is easier to achieve timeliness, an important property of real-time systems; however, the trade-off is that it is difficult to specify integrity rules in terms of ECA-rules, since the integrity checks are performed in a different transaction. The consequence is that dirty transactions as well as compensating transactions that perform recovery from violated integrity rules must be allowed.

It is desirable to study architectures addressing how to meet specific requirement of the application area (e.g., accounting information in mobile ad-hoc networks), the specific environment in which the active database are used (e.g., distributed systems, real-time systems, mobile ad-hoc networks, limited resource equipment). The major criteria for a successful architecture (e.g., by refining an existing architecture) is if anyone can gain something from using it. For example, Borr [3] reported that by refining their architecture by employing transaction processing they improved productivity, reliability as well as average throughput in their heterogenous distributed reliable applications.

An area that has received little attention in active database is optimization of processing. For example, how can queries to the database be optimized with condition evaluation if conditions are expressed as arbitrary queries? Another question is how to group actions to optimize performance? So far, the emphasis has been on expressibility as well as techniques how to enable active support in different settings. Another area that has received little attention is recovery processing, both pre-crash and post-crash recovery. For example, how should recovery with respect to detached but dependent transactions be managed?

Intertransaction events and rules has been proposed by, for example, Buchmann et al. [4]. How should this be managed with respect to the isolation levels proposed by Gray and Reuter [11, Chap. 7]?

There are several other areas with which active database technology can be combined. Historical examples include real-time databases, temporal databases, main-memory databases, geographical information systems. One area that has received little attention is how enable reuse of database schemas.

Active Database Coupling Modes

Mikael Berndtsson, Jonas Mellin
University of Skövde, Skövde, Sweden

Definition

Coupling modes specify execution points for ECA rule conditions and ECA rule actions with respect to the triggering event and the transaction model.

Historical Background

Coupling modes for ECA rules were first suggested in the HiPAC project [2,3].

Foundations

Coupling modes are specified for event-condition couplings and for condition-action couplings. In detail, the event-condition coupling specifies when the condition should be evaluated with respect to the triggering event, and the condition-action coupling specifies when the rule action should be executed with respect to the evaluated rule condition (if condition is evaluated to true).

The three most common coupling modes are: immediate, deferred, and decoupled. The immediate coupling mode preempts the execution of the transaction and immediately initiates condition evaluation and action execution. In the deferred coupling mode, condition evaluation and action execution is deferred to the end of the transaction (before transaction commit). Finally, in decoupled (also referred to as detached) coupling mode, condition evaluation and action execution is performed in separate transactions.

Specifying event-condition couplings and condition-action couplings in total isolation from each other is not a good idea. What first might seem to be one valid coupling mode for event-condition and one valid coupling mode for condition-action, can be an invalid coupling mode when used together. Thus, when combining event-condition couplings and condition-action couplings, not all combinations of coupling modes are valid. The HiPAC project [2,3] proposed seven valid coupling modes, see Table 1.

- *Immediate, immediate*: the rule condition is evaluated immediately after the event, and the rule action is executed immediately after the rule condition.
- *Immediate, deferred*: the rule condition is evaluated immediately after the event, and the execution of the rule action is deferred to the end of the transaction.
- *Immediate, decoupled*: the rule condition is evaluated immediately after the event, and the rule action is decoupled in a totally separate and parallel transaction.
- *Deferred, deferred*: both the evaluation of the rule condition and the execution of the rule action is deferred to the end of the transaction.
- *Deferred, decoupled*: the evaluation of the rule condition is deferred to the end of the transaction, and the rule action is decoupled in a totally separate and parallel transaction.
- *Decoupled, immediate*: the rule condition is decoupled in a totally separate and parallel transaction, and the rule action is executed (in the same parallel transaction) immediately after the rule condition.
- *Decoupled, decoupled*: the rule condition is decoupled in a totally separate and parallel transaction, and the rule action is decoupled in another totally separate and parallel transaction.

The two invalid coupling modes are:

- *Deferred, immediate*: this combination violates the semantics of ECA rules. That is, rule conditions must be evaluated before rule actions are executed. One cannot preempt the execution of the transaction immediately after the event and execute the rule action and at the same time postpone the condition evaluation to the end of the transaction.
- *Decoupled, deferred*: this combination violates transaction boundaries. That is, one cannot decouple the condition evaluation in a separate and parallel transaction and at the same time postpone the

Active Database Coupling Modes. Table 1. Coupling modes

	Condition-Action		
Event-Condition	*Immediate*	*Deferred*	*Decoupled*
Immediate	condition evaluated and action executed after event	condition evaluated after event, action executed at end of transaction	condition evaluated after event, action executed in a separate transaction
Deferred	not valid	condition evaluated and action executed at end of transaction	condition evaluated at end of transaction, action executed in a separate transaction
Decoupled	in a separate transaction: condition evaluated and action executed after event	not valid	condition evaluated in one separate transaction, action executed in another separate transaction

execution of the rule action to the end of the original transaction, since one cannot know when the condition evaluation will take place. Thus, there is a risk that the action execution in the original transaction will run before the condition has been evaluated in the parallel transaction.

Rule actions executed in decoupled transactions can either be dependent upon or independent of the transaction in which the event took place.

The research project REACH (REal-time ACtive Heterogeneous System) [1] introduced two additional coupling modes for supporting side effects of rule actions that are irreversible. The new coupling modes are variants of the detached casually dependent coupling mode: sequential casually dependent, and exclusive casually dependent. In sequential casually dependent, a rule is executed in a separate transaction. However, the rule execution can only begin once the triggering transaction has committed. In exclusive casually dependent, a rule is executed in a detached parallel transaction and it can commit only if the triggering transaction failed.

Active Database Execution Model

MIKAEL BERNDTSSON, JONAS MELLIN
University of Skövde, Skövde, Sweden

Definition

The execution model of an active database describes how a set of ECA rules behave at run time.

Key Points

The execution model describes how a set of ECA rules (i.e., active database rulebase) behave at run time [2,4]. Any execution model of an active database must have support for: (i) detecting event occurrences, (ii) evaluating conditions, and (iii) executing actions.

If an active database supports composite event detection, it needs a policy that describes how a composite event is computed. A typical approach is to use the event consumption modes as described in Snoop [1]: recent, chronicle, continuous, and cumulative. In the recent event context, only the most recent constituent events will be used to form composite events. In the chronicle event context, events are consumed in chronicle order. The earliest unused initiator/terminator pair are used to form the composite event. In the continuous event context, each initiator starts the detection of a new composite event and a terminator may terminate one or more composite event occurrences. The difference between continuous and chronicle event contexts is that in the continuous event context, one terminator can detect more than one occurrence of the composite event. In the cumulative event context, all events contributing to a composite event are accumulated until the composite event is detected. When the composite event is detected, all contributing events are consumed. Another approach to these event consumption modes is to specify a finer semantics for each event by using logical events as suggested in [3].

Once an event has been detected, there are several execution policies related to rule conditions and rule actions that must be in place in the execution model. Thus an execution model for an active database should provide answers to the following questions [2,4,5]:

- When should the condition be evaluated and when should the action should be executed with respect to the triggering event and the transaction model? This is usually specified by coupling modes.
- What happens if an event triggers several rules?
  - Are all rules evaluated, a subset, or only one rule?
  - Are rules executed in parallell, according to rule priority, or non-deterministically?
- What happens if one's rules trigger another set of rules?
  - What happens if the rule action of one rule negates the rule condition of an already triggered rule?
  - Can cycles appear? For example, can a rule trigger itself?

The answers to the above questions are important to know, as they dictate how a ECA rule system will behave at run time. If the answers to the above questions are not known, then the behavior of the ECA rule application becomes unpredictable.

Active Database Knowledge Model

Mikael Berndtsson, Jonas Mellin
University of Skövde, Skövde, Sweden

Definition

The knowledge model of an active database describes what can be said about the ECA rules, that is what type of events are supported, what type of conditions are supported, and what type of actions are supported?

Key Points

The knowledge model describes what types of events, conditions, and actions that are supported in an active database. Another way to look at the knowledge model is to imagine what type of features are available in an ECA rule definition language.

A framework of dimensions for the knowledge model is presented in [3]. Briefly, each part of an ECA rule is associated with dimensions that describe supported features. Thus, an event can be described as either a primitive event or a composite event, how it was generated (source), whether the event is generated for all instances in a given set or only for a subset (event granularity), what type (if event is a composite event) of operators and event consumption modes are used in the detection of the composite event.

Conditions are evaluated against a database state. There are three different database states that a rule condition can be associated with [3]: (i) the database state at the start of the transaction, (ii) the database state when the event was detected, and (iii) the database state when the condition is evaluated.

There are four different database states that a rule action can be associated with [3]: (i) the database state at the start of the transaction, (ii) the database state when the event was detected, and (iii) the database state when the condition is evaluated, and (iv) the database state just before action execution. The type of rule actions range from internal database updates (e.g., update a table) to external programs (e.g., send email).

Within the context of the knowledge model it is also useful to consider how ECA rules are represented, for example inside classes, as data members, or first class objects. Representing ECA rules as first class objects [1,2] is a popular choice, since rules can be treated as any other object in the database and traditional database operations can be used to manipulate the ECA rules. Thus, representing ECA rules as first class objects implies that ECA rules are not dependent upon the existence of other objects.

The knowledge model of an active database should also describe whether the active database supports passing of parameters between the ECA rule parts, for example passing of parameters from the event part to the condition part.

Related to the knowledge model is the execution model that describes how ECA rules behave at run time.

Active Database Rulebase

AnnMarie Ericsson[1], Mikael Berndtsson[2], Jonas Mellin[3]
University of Skövde, Skövde, Sweden

Definition

An active database rulebase is a set of ECA rules that can be manipulated by an active database.

Key Points

An active database rulebase is a set of ECA rules that can be manipulated by an active database. Thus, an ADB rulebase is not static, but it evolves over time. Typically, ECA rules can be added, deleted, modified, enabled, and disabled. Each update of the ADB rulebase can potentially lead to different behaviors of the ECA rules at run time, in particular with respect to termination and confluence.

Termination concerns whether a set of rules is guaranteed to terminate. A set of rules may have a non-terminating behavior if rules are triggering each other in a circular order, for example, if the execution of rule R1 triggers rule R2 and the execution of rule R2 triggers rule R1. A set of rules is confluent if the outcome of simultaneously triggered rules is unique and independent of execution order.

Active Disks; Intelligent Disks

Definition

Active Storage is a computer system architecture which utilizes processing power in disk drives to execute application code. Active Storage was introduced in separate academic papers [1–3] in 1998. The term Active Storage is sometimes identified merely with the computer systems proposed in these papers. Two synonyms, Active Disk and Intelligent Disk, are also used to refer to Active Storage. The basic idea behind Active Storage is to offload computation and data traffic from host computers to the disk drives themselves such that the system can achieve significant performance improvements for data intensive applications such as decision support systems and multimedia applications.

Key Points

A research group at Carnegie Mellon University proposed, in [3], a storage device called Active Disk, which has the capability of downloading application-level code and running it on a processor embedded on the device. Active Disk has a performance advantage for I/O bound scans, since processor-per-disk processing can potentially reduce data traffic on interconnects to host computers and yield great parallelism of scans. E. Riedel et al. carefully studied the potential benefits of using Active Disks for four types of data intensive applications, and introduced analytical performance models for comparing traditional server systems and Active Disks. They also prototyped ten Active Disks, each having a DEC Alpha processor and two Seagate disk drives, and demonstrated almost linear scalability in the experiments.

A research group at University of California at Berkeley discussed a vision of Intelligent Disks (IDISKs) in [2]. The approach of Intelligent Disk is similar to that of Active Disk. K. Keeton et al. carefully studied the weaknesses of shared-nothing clusters of workstations and then explored the possibility of replacing the cluster nodes with Intelligent Disks for large-scale decision support applications. Intelligent Disks assumed higher complexity of applications and hardware resources in comparison with CMU's Active Disks.

Another Active Disk was presented by a research group at the University of California at Santa Barbara and University of Maryland in [1]. A. Acharya et al. carefully studied programming models to exploit disk-embedded processors efficiently and safely and proposed algorithms for typical data intensive operations such as selection and external sorting, which were validated by simulation experiments.

These three works are often recognized as opening the gate for new researches of Intelligent Storage Systems in the post-"database machines" era.

Synonyms

Active document; AXML

Definition

Active XML documents (AXML documents, for short) are XML documents [12] that may include embedded calls to Web services [13]. Hence, AXML documents are a combination of regular "extensional" XML data with data that is defined "intensionally," i.e., as a description that enables obtaining data dynamically (by calling the corresponding service).

AXML documents evolve in time when calls to their embedded services are triggered. The calls may bring data once (when invoked) or continually (e.g., if the called service is a continuous one, such as a subscription to an RSS feed). They may even update existing parts of the document (e.g., by refreshing previously fetched data).

Historical Background

The AXML language was originally proposed at INRIA around 2002. Work around AXML has been going there in the following years. A survey of the research on AXML is given in [13]. The software, primarily under the form of an AXML system, is available as open source software. Resources on Active XML may be found on the project's Web site [11].

The notion of embedding function calls into data is old. Embedded functions are already present in relational systems as stored procedures. Of course, method calls form a key component of object databases. For the Web, scripting languages such as PHP or JSP have made popular the integration of processing inside HTML or XML documents. Combined with standard database interfaces such as JDBC and ODBC, functions are used to integrate results of (SQL) queries. This idea can also be found in commercial software products, for instance, in Microsoft Office XP, SmartTags inside Office documents can be linked to Microsoft's .NET platform for Web services.

The originality of the AXML approach is that it proposed to *exchange* such documents, building on the fact that Web services may be invoked from anywhere. In that sense, this is truly a language for distributed data management. Another particularity is that the logic (the AXML language) is a subset of the AXML algebra.

Looking at the services in AXML as queries, the approach can be viewed as closely related to recent works based on XQuery [14] where the query language is used to describe query plans. For instance the DXQ project [7] developed at ATT and UCSD emphasizes the distributed evaluation of XQuery queries. Since one can describe documents in an XQuery syntax, such approaches encompass in some sense AXML documents where the service calls are XQuery queries.

The connection with deductive databases is used in [1] to study the diagnosis problems in distributed networks. A similar approach is followed in [8] for declarative network routing.

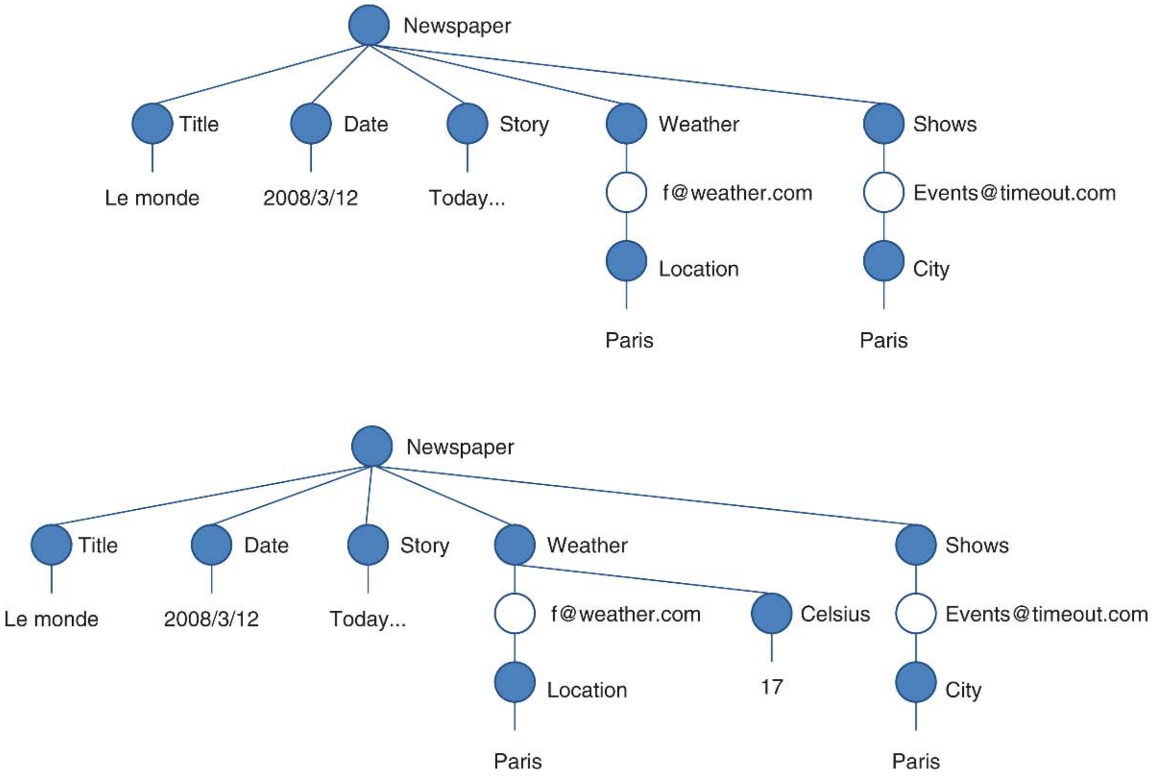
It should be observed that the AXML approach touches upon most database areas. In particular, the presence of intensional data leads to views, deductive databases and data integration. The activation of calls contained in a document essentially leads to active databases. AXML services may be activated by external servers, which relates to subscription queries and stream databases. Finally, the evolution of AXML documents and their inherent changing nature lead to an approach of workflows and service choreography in the style of business artifacts [10].

The management of AXML document raises a number of issues. For instance, the evaluation of queries over active documents is studied in [2]. The "casting" of a document to a desired type is studied in [9]. The distribution of documents between several peers and their replication is the topic of [4].

Foundations

An AXML document is a (syntactically valid) XML document, where service calls are denoted by special XML elements labeled *call*. An example AXML document is given in Fig. 1. The figure shows first the XML serialized syntax, then a more abstract view of the same document as a labeled tree. The document in the figure describes a (simplified) newspaper homepage consisting of (i) some extensional information (the name of the newspaper, the current date, and a news story), and (ii) some intensional information (service calls for the weather forecast, and for the current exhibits). When the services are called, the tree evolves. For example, the tree at the bottom is what results from a call to the service *f* at *weather.com* to obtain the temperature in Paris.

AXML documents fit nicely in a peer-to-peer architecture, where each peer is a persistent store of AXML



Active XML. Figure 1. An AXML document.

documents, and may act both as a client, by invoking the service calls embedded in its AXML documents, and as a server, by providing Web services over these documents.

Two fundamental issues arise when dealing with AXML documents. The first one is related to the exchange of AXML documents between peers, and the second one is related to query evaluation over such data.

Documents Exchange: When exchanged between two applications/peers, AXML documents have a crucial property: since Web services can be called from anywhere on the Web, data can either be materialized before sending, or sent in its intensional form and left to the receiver to materialize if and when needed. Just like *XML Schemas* do for standard XML, *AXML schemas* let the user specify the desired format of the exchanged data, including which parts should remain intensional and which should be materialized. Novel algorithms allow the sender to determine (statically or dynamically) which service invocations are required to "cast" the document to the required data exchange format [9].

Query evaluation: Answering a query on an AXML document may require triggering some of the service calls it contains. These services may, in turn, query other AXML documents and trigger some other services, and so on. This recursion, based on the management of intensional data, leads to a framework in the style of *deductive databases*. Query evaluation on AXML data can therefore benefit from techniques developed in deductive databases such as Magic Sets [6]. Indeed, corresponding AXML query optimization techniques where proposed in [1,2].

Efficient query processing is, in general, a critical issue for Web data management. AXML, when properly extended, becomes an algebraic language that enables query processors installed on different peers to collaborate by exchanging streams of (A)XML data [14]. The crux of the approach is (i) the introduction of generic services (i.e., services that can be provided by several peers, such as query processing) and (ii) some explicit control of distribution (e.g., to allow delegating part of some work to another peer).

Key Applications

AXML and the AXML algebra target all distributed applications that involve the management of distributed data. AXML is particularly suited for data integration (from databases and other data resources exported as Web services) and for managing (active) views on top of data sources. In particular, AXML can serve as a formal foundation for mash-up systems. Also, the language is useful for (business) applications based on evolving documents in the style of business artifacts, and on the exchange of such information. The fact that the exchange is based on flows of XML messages makes it also well-adapted to the management of distributed streams of information.

Activity

Nathaniel Palmer
Workflow Management Coalition, Hingham, MA, USA

Synonyms

Step; Node; Task; Work element

Definition

A description of a piece of work that forms one logical step within a process. An activity may be a manual activity, which does not support computer automation, or a workflow (automated) activity. A workflow activity requires human and/or machine resources to support process execution; where human resource is required an activity is allocated to a workflow participant.

Key Points

A process definition generally consists of many process activities which are logically related in terms of their contribution to the overall realization of the business process.

An activity is typically the smallest unit of work which is scheduled by a workflow engine during process enactment (e.g., using transition and pre/post-conditions), although one activity may result in several work items being assigned (to a workflow participant).

Wholly manual activities may form part of a business process and be included within its associated process definition, but do not form part of the automated workflow resulting from the computer supported execution of the process.

An activity may therefore be categorized as "manual," or "automated." Within this document, which is written principally in the context of workflow management, the term is normally used to refer to an automated activity.

Activity Diagrams

Luciano Baresi
Politecnico di Milano University, Milan, Italy

Synonyms

Control flow diagrams; Object flow diagrams; Flowcharts; Data flow diagrams

Definition

Activity diagrams, also known as control flow and object flow diagrams, are one of the UML (unified modeling language [11]) behavioral diagrams. They provide a graphical notation to define the sequential, conditional, and parallel composition of lower-level behaviors. These diagrams are suitable for business process modeling and can easily be used to capture the logic of a single use case, the usage of a scenario, or the detailed logic of a business rule. They model the workflow behavior of an entity (system) in a way similar to *state diagrams* where the different activities are seen as the states of doing something. Although they could also model the internal logic of a complex operation, this is not their primary use since tangled operations should always be decomposed into simpler ones [1,2].

An activity [3] represents a behavior that is composed of individual elements called *actions*. Actions have incoming and outgoing edges that specify control and data flow from and to other nodes. Activities may form invocation hierarchies invoking other activities, ultimately resolving to individual actions.

The execution of an activity implies that each contained action be executed zero, one, or more times depending on the execution conditions and the structure of the activity. The execution of an action is initiated by the termination of other actions, the availability of particular objects and data, or the occurrence of external events. The execution is based on token flow (like Petri Nets). A token contains an object, datum, or locus of control, and is present in the activity diagram at a particular node. When an action begins execution, tokens are accepted from some or all of its input edges and a token is placed on the node. When an action completes execution, a token is removed from the node and tokens are moved to some or all of its output edges.

Historical Background

OMG (Object Management Group, [10]) proposed and standardized *activity diagrams* by borrowing concepts from flow-based notations and some formal methods. As for the first class, these diagrams mimic *flowcharts* [6] in their idea of step-by-step representation of algorithms and processes, but they also resemble data and control flow diagrams [4]. The former provide a hierarchical and graphical representation of the "flow" of data through a system inspired by the idea of *data flow graph*. They show the flow of data from external entities into the system, how these data are moved from one computation to another, and how they are logically stored. Similarly, *object flow diagrams* show the relationships among input objects, methods, and output objects in object-based models. Control flow diagrams represent the paths that can be traversed while executing a program. Each node in the graph represents a basic block, be it a single line or an entire function, and edges render how the execution jumps among them.

Moving to the second group, activity diagrams are similar to state diagrams [8], where the evolution of a system is rendered by the identification of the states, which characterize the element's life cycle, and of the transitions between them. A state transition can be constrained by the occurrence of an event and by an additional condition; its firing can cause the execution of an associated action. Mealy et al. propose different variations: Mealy assumes that actions be only associated with transitions, Moore only considers actions associated with states, and Harel's *state charts* [7] merge the two approaches with actions on both states and transitions, and enhance their flat model with nested and concurrent states.

The dynamic semantics of activity diagrams is clearly inspired by Petri Nets [9], which are a simple graphical formalism to specify the behavior of concurrent and parallel systems. The nodes are partitioned into places and transitions, with arcs that can only connect nodes of different type. Places may contain any number of tokens and a distribution of tokens over the places of a net is called a marking. A transition can only fire when there is at least a token in all its input places (i.e., those places connected to the transition by means of incoming edges), and its firing removes a token for all these places and produces a new one in each output place (i.e., a place connected to the transition through an outgoing edge). P/T nets only consider tokens as placeholders, while colored nets augment them with typed data and thus with firing conditions that become more articulated and can predicate on the tokens' values in the input places.

Activity diagrams also borrow from SDL (Specification and Description Language, [5]) as event handling. This is a specification language for the unambiguous description of the behavior of reactive and distributed systems. Originally, the notation was conceived for the specification of telecommunication systems, but currently its application is wider and includes process control and real-time applications in general. A system is specified as a set of interconnected abstract machines, which are extensions of finite state machines. SDL offers both a graphical and a textual representation and its last version (known as SDL-2000) is completely object-orientated.

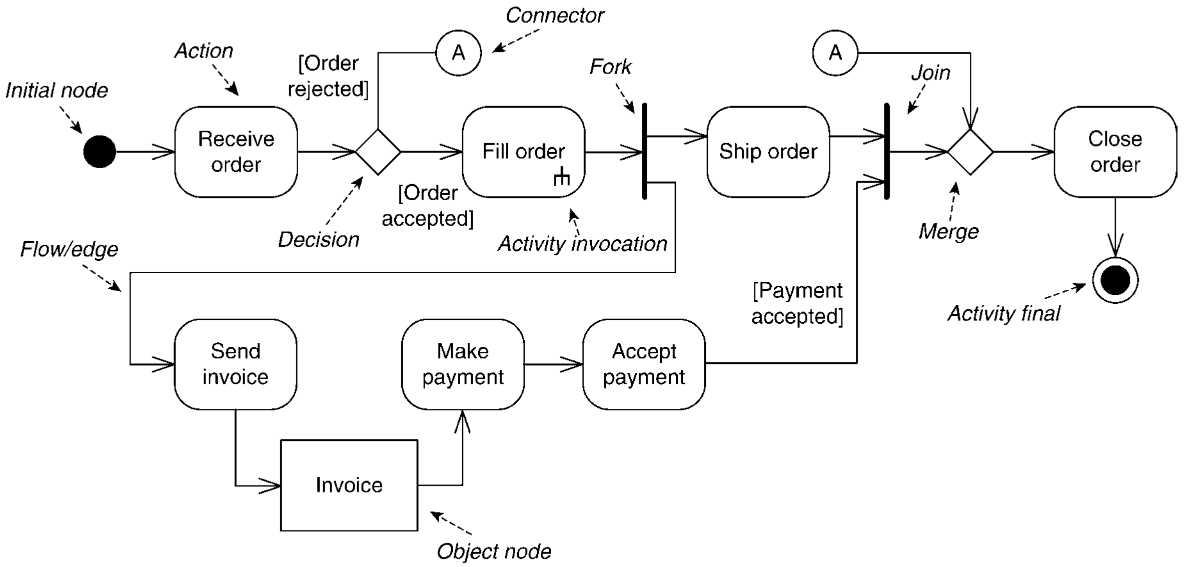
Foundations

Figure 1 addresses the well-known problem of order management and proposes a first *activity diagram* whose aim is twofold: it presents a possible formalization of the process, and it also introduces many of the concepts supplied by these diagrams.

Each atomic step is called *action*, with an *initial node* and *activity final* nodes to delimit their ordering as sequences, parallel threads, or conditional flows. A *fork* splits a single execution thread into a set of parallel ones, while a *join*, along with an optional *join specification* to constrain the unification, is used to re-synchronize the different threads into a single execution. Similarly, a *decision* creates alternative paths, and a *merge* re-unifies them. To avoid misunderstandings, each path must be decorated with the condition, in brackets, that must be verified to make the execution take that path.

The diagram of Fig. 1 also exemplifies the use of *connectors* to render *flows/edges* that might tangle the representation. This is nothing but an example, but the solution is interesting to avoid drawing flows that cross other elements or move all around the diagram. Another key feature is the use of a rake to indicate that action `Fill Order` is actually an *activity invocation*, and hides a hierarchical decomposition of actions into activities.

Besides the control flow, activity diagrams can also show the data/object flow among the actions. The use of *object nodes* allows users to state the artifacts exchanged between two actions, even if they are not directly connected by an edge. In many cases



Activity Diagrams. Figure 1. Example activity diagram.

control and object flows coincide, but this is not mandatory.

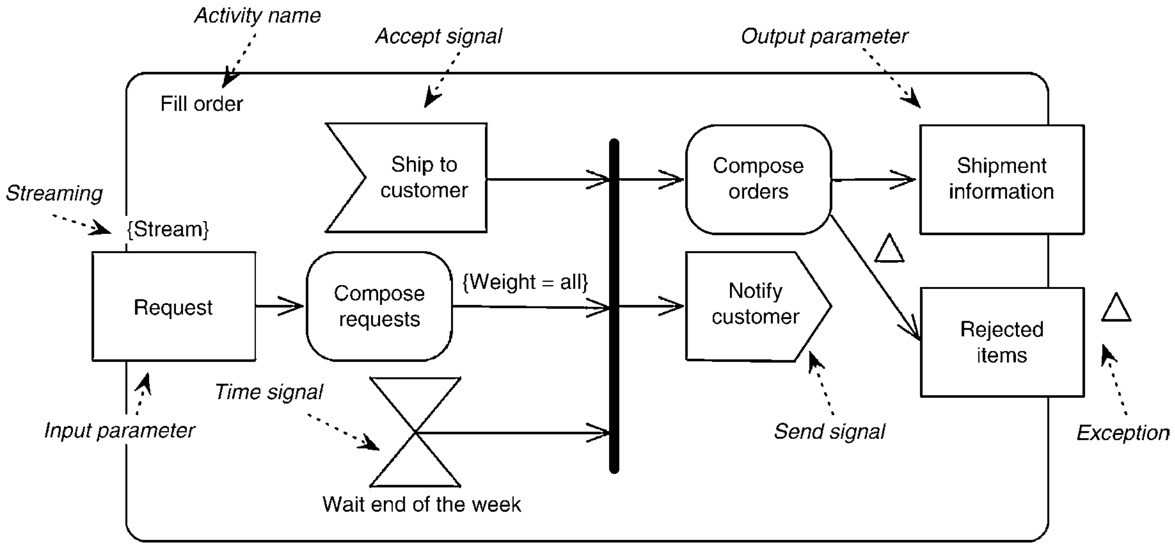
Activities can also comprise *input* and *output parameters* to render the idea that the activity's execution initiates when the inputs are available, and produces some outputs. For example, activity `Fill Order` of Fig. 2, which can be seen as a refinement of the invocation in Fig. 1, requires that at least one `Request` be present, but then it considers the parameter as a *stream*, and produces `Shipment Information` and `Rejected Items`. While the first outcome is the "normal" one, the second object is produced only in case of *exceptions* (rendered with a small triangle on both the object and the flow that produces it). In a stream, the flow is annotated from action `Compose Requests` to the join with its *weight* to mean that the subsequent processing must consider *all* the requests received when the composition starts.

The execution can also consider signals as enablers or outcomes of special-purpose actions. For example, Fig. 2 shows the use of an *accept signal*, to force that the composition of orders (`Compose Orders`) must be initiated by an external event, a *time signal*, to make the execution wait for a given timeframe (be it absolute or relative), and a *send signal*, to produce a notification to the customer as soon as the action starts.

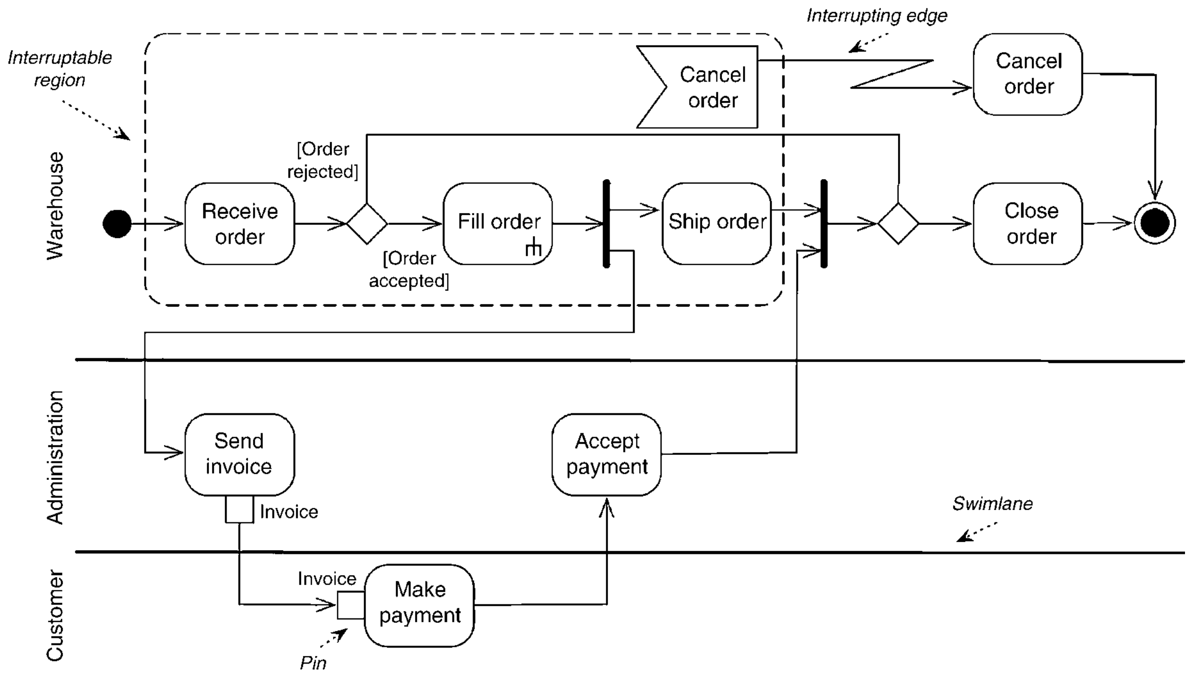
Basic diagrams can also be enriched with *swimlanes* to partition the different actions with respect to their responsibilities. Figure 3 shows a simple example: The primitive actions are the same as those of Fig. 1, but now they are associated with the three players in charge of activate the behaviors in the activity. The standard also supports hierarchical and multi-dimensional partitioning, that is, hierarchies of responsible actors or matrix-based partitions.

The `Warehouse` can also receive `Cancel Order` notifications to asynchronously interrupt the execution as soon as the external event arrivers. This is obtained by declaring an *interruptable region*, which contains the accept signal node and generates the interrupt that stops the computation in that region and moves the execution directly to action `Cancel Order` by means of an *interrupting edge*. More generally, this is a way to enrich diagrams with specialized *exception handlers* similarly to many modern programming and workflow languages. The figure also introduces *pins* as a compact way to render the objects exchanged between actions: empty boxes correspond to discrete elements, while filled ones refer to streams.

The discussion thus far considers the case in which the outcome of an action triggers a single execution of another action, but in some cases conditions may exist in which the "token" is structured and a single result triggers multiple executions of the same action. For example, if the example of Fig. 1 were slightly modified and after receiving an order, the user wants to check the items in it, a single execution of action



Activity Diagrams. Figure 2. Activity diagrams with signals.

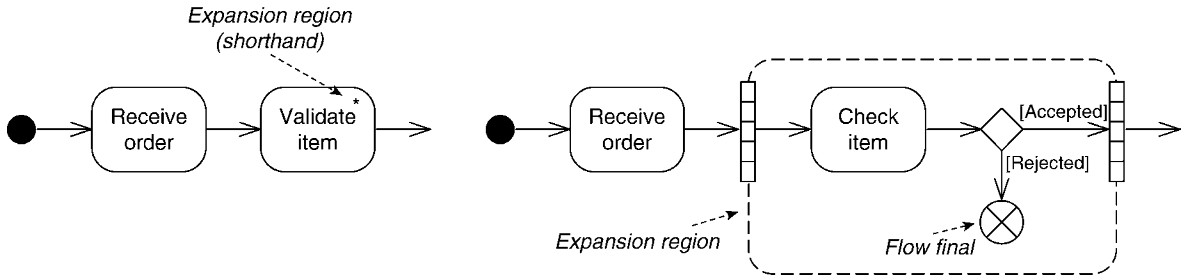


Activity Diagrams. Figure 3. Example swimlanes.

`Receive Order` would trigger multiple executions of `Validate Item`. This situation is depicted in the left-hand side of Fig. 4, where the star * conceives the information described so far.

The same problem can be addressed in a more complete way (right-hand side of figure) with an *expansion region*. The two arrays are supposed to store the input and output elements. In some cases, the number of input and output tokens is the same, but it might also be the case that the behavior in the region filters the incoming elements.

In the left-hand side of Fig. 4, it is assumed that some items are accepted and fill the output array, while others are rejected and thus their execution flow ends



Activity Diagrams. Figure 4. Expansion region.

there. This situation requires that a *flow final* be used to state that only the flow is ended and not the whole activity. Flow final nodes are a means to interrupt particular flows in this kind of regions, but also in loops or other similar cases.

The execution leaves an expansion region as soon as all the output tokens are available, that is, as soon as all the executions of the behavior embedded in the region are over. Notice that these executions can be carried out both concurrently (by annotating the rectangle with stereotype *concurrent*) or iteratively (with stereotype *iterative*). The next action considers the whole set of tokens as a single entity.

Further details about exceptions and other advanced elements, like pre- and post-conditions associated with single actions or whole activities, central buffers, and data stores are not discussed here, but the reader is referred to [11] for a thorough presentation.

Key Applications

Activity diagrams are usually employed to describe complex behaviors. This means that they are useful to model tangled processes, describe the actions that need to take place and when they should occur in use cases, render complicated algorithms, and model applications with parallel and alternative flows. Nowadays, these necessities belong to ICT specialists, like software engineering, requirements experts, and information systems architects, but also to experts in other fields (e.g., business analysts or production engineers) that need this kind of graphical notations to describe their solutions.

Activity diagrams can be used in isolation, when the user needs a pure control (data) flow notation, but they can also be adopted in conjunction with other modeling techniques such as interaction diagrams, state diagrams, or other UML diagrams. However, activity diagrams should not take the place of other diagrams. For example, even if the border between activity and state diagrams is sometimes blurred, activity diagrams provide a procedural decomposition of the problem under analysis, while state diagrams mostly concentrate on how studied elements behave. Moreover, activity diagrams do not give details about how objects behave or how they collaborate.

Actors/Agents/Roles

Nathaniel Palmer
Workflow Management Coalition, Hingham, MA, USA

Synonyms

Workflow participant; Player; End user; Work performer

Definition

A resource that performs the work represented by a workflow activity instance.

This work is normally manifested as one or more work items assigned to the workflow participant via the worklist.

Key Points

These terms are normally applied to a human resource but it could conceptually include machine-based resources such as an intelligent agent.

Where an activity requires no human resource and is handled automatically by a computer application, the normal terminology for the machine-based resource is Invoked Application.

An Actor, Agent or Role may be identified directly within the business process definition, or (more normally) is identified by reference within the process definition to a role, which can then be filled by one or more of the resources available to the workflow system to operate in that role during process enactment.

Adaptive Interfaces

Maristella Matera
Politecnico di Milano University, Milan, Italy

Synonyms

Context-aware interfaces; Personalized interfaces

Definition

A specific class of user interfaces that are able to change in some way in response to different characteristics of the user, of the usage environment or of the task the user is supposed to accomplish. The aim is to improve the user's experience, by providing both interaction mechanisms and contents that best suit the specific situation of use.

Key Points

There are a number of ways in which interface adaptivity can be exploited to support user interaction. The interaction dimensions that are adapted vary among functionality (e.g., error correction or active help), presentation (user presentation of input to the system, system presentation of information to the user), and user tasks (e.g., task simplification based on the user's capabilities). Adaptivity along such dimensions is achieved by capturing and representing into some models a number of characteristics: the user's characteristics (preferences, experience, etc.); the tasks that the user accomplishes through the system; the characteristics of the information with which the user must be provided.

Due to current advances in communication and network technologies, adaptivity is now gaining momentum. Different types of mobile devices indeed offer support to access – at any time, from anywhere, and with any media – services and contents customized to the users' preferences and usage environments. In this new context, *content personalization*, based on user profile, has demonstrated its benefits for both users and content providers and has been commonly recognized as fundamental factor for augmenting the overall effectiveness of applications. Going one step further, the new challenge in adaptive interfaces is now *context-awareness*. It can be interpreted as a natural evolution of personalization, addressing not only the user's identity and preferences, but also the environment that hosts users, applications, and their interaction, i.e., the *context*. Context-awareness, hence, aims at enhancing the application usefulness by taking into account a wide range of properties of the context of use.

Adaptive Middleware for Message Queuing Systems

Christophe Taton[1], Noel De Palma[1], Sara Bouchenak[2]
[1]INPG - INRIA, Grenoble, France
[2]University of Grenoble I - INRIA, Grenoble, France

Synonyms

Autonomous message queuing systems; Adaptive message-oriented middleware; Autonomous message-oriented middleware

Definition

Distributed database systems are usually built on top of middleware solutions, such as message queuing systems. Adaptive message queuing systems are able to improve the performance of such a middleware through load balancing and queue provisioning.

Historical Background

The use of message oriented middlewares (MOMs) in the context of the Internet has evidenced a need for highly scalable and highly available MOM. A very promising approach to the above issue is to implement performance management as an autonomic software. The main advantages of this approach are: (i) Providing a high-level support for deploying and configuring applications reduces errors and administrator's efforts. (ii) Autonomic management allows the required reconfigurations to be performed without human intervention, thus improving the system reactivity and saving administrator's time. (iii) Autonomic management is a means to save hardware resources, as resources can be allocated only when required (dynamically upon failure or load peak) instead of pre-allocated.

Several parameters may impact the performance of MOMs. Self-optimization makes use of these parameters to improve the performance of the MOM. The proposed self-optimization approach is based on a queue clustering solution: a *clustered queue* is a set of queues each running on different servers and sharing clients. Self-optimization takes place in two parts: (i) the optimization of the clustered queue load-balancing and (ii) the dynamic provisioning of a queue in the clustered queue. The first part allows the overall improvement of the clustered queue performance while the second part optimizes the resource usage inside the clustered queue. Thus the idea is to create an autonomic system that fairly distributes client connections among the queues belonging to the clustered queue and dynamically adds and removes queues in the clustered queue depending on the load. This would allow to use the adequate number of queues at any time.

Foundations

Clustered Queues

A queue is a staging area that contains messages which have been sent by message producers and are waiting to be read by message consumers. A message is removed from the queue once it has been read. For scalability purpose, a queue can be replicated forming a clustered queue. The clustered queue feature provides a load balancing mechanism. A clustered queue is a cluster of queues (a given number of queue destinations knowing each other) that are able to exchange messages depending on their load. Each queue of a cluster periodically reevaluates its load factor and sends the result to the other queues of the cluster. When a queue hosts more messages than it is authorized to do, and according to the load factors of the cluster, it distributes the extra messages to the other queues. When a queue is requested to deliver messages but is empty, it requests messages from the other queues of the cluster. This mechanism guarantees that no queue is hyper-active while some others are lazy, and tends to distribute the work load among the servers involved in the cluster.

Clustered Queue Performance

Clustered queues are standard queues that share a common pool of message producers and consumers, and that can exchange message to balance the load. All the queues of a clustered queue are supposed to be directly connected to each other. This allows message exchanges between the queues of a cluster in order to empty flooded queues and to fill draining queues.

The clustered queue Q_c is connected to N_c message producers and to M_c message consumers. Q_c is composed of standard queues $Q_i(i \in [1..k])$. Each queue Q_i is in charge of a subset of N_i message producers and of a subset of M_i message consumers:

$$\begin{cases} N_c = \sum_i N_i \\ M_c = \sum_i M_i \end{cases}$$

The distribution of the clients between the queues Q_i is described as follows: x_i (resp. y_i) is the fraction of message producers (resp. consumers) that are directed to Q_i.

$$\begin{cases} N_i = x_i \cdot N_c \\ M_i = y_i \cdot M_c \end{cases}, \begin{cases} \sum_i x_i = 1 \\ \sum_i y_i = 1 \end{cases}$$

The standard queue Q_i to which a consumer or producer is directed to cannot be changed after the client connection to the clustered queue. This way, the only action that may affect the client distribution among the queues is the selection of an adequate queue when the client connection is opened.

The clustered queue Q_c is characterized by its aggregate message production rate p_c and its aggregate message consumption rate c_c. The clustered queue Q_c also has a virtual clustered queue length l_c that aggregates the length of all contained standard queues:

$$l_c = \sum_i l_i = p_c - c_c, \begin{cases} p_c = \sum_i p_i \\ c_c = \sum_i c_i \end{cases}$$

The clustered queue length l_c obeys to the same law as a standard queue:

1. Q_c is globally stable when $\Delta l_c = 0$. This configuration ensures that the clustered queue is globally stable. However Q_c may observe local unstabilities if one of its queues is draining or is flooded.
2. If $\Delta l_c > 0$, the clustered queue will grow and eventually saturate; then message producers will have to wait.
3. If $\Delta l_c < 0$, the clustered queue will shrink until it is empty; then message consumers will also have to wait.

Now, considering that the clustered queue is globally stable, several scenarios that illustrate the impact of client distribution on performance are given below.

Optimal client distribution of the clustered queue Q_c is achieved when clients are fairly distributed among the k queues Q_i. Assuming that all queues and hosts have equivalent processing capabilities and that all producers (*resp.* consumers) have equivalent message production (*resp.* consumption) rates (and that all produced messages are equivalent: message cost is uniformly distributed), this means that:

$$\begin{cases} x_i = 1/k \\ y_i = 1/k \end{cases}, \begin{cases} N_i = \frac{N_c}{k}, \\ M_i = \frac{M_c}{k} \end{cases}$$

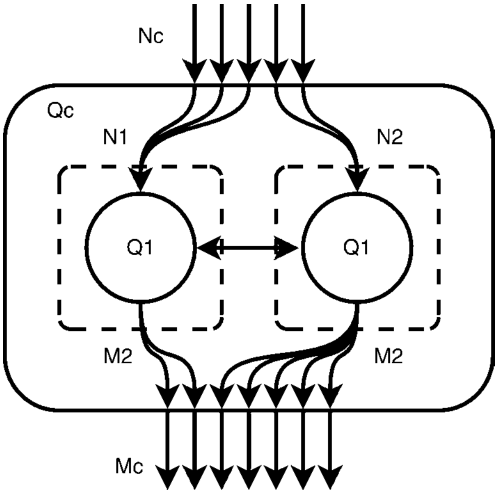
In these conditions, all queues Q_i are stable and the queue cluster is balanced. As a consequence, there are no internal queue-to-queue message exchanges, and performance is optimal. Queue clustering then provides a quasi-linear speedup.

The worst clients distribution appears when one queue only has message producers or only has message consumers. In the example depicted in Fig. 1, this is realized when:

$$\begin{cases} x_1 = 1 \\ y_1 = 0 \end{cases}, \begin{cases} x_2 = 0 \\ y_2 = 1 \end{cases}, \begin{cases} N_1 = N_c \\ M_1 = 0 \end{cases}, \begin{cases} N_2 = 0 \\ M_2 = M_c \end{cases}$$

Indeed, this configuration implies that the whole message production is directed to queue Q_1. Q_1 then forwards all messages to Q_2 that in turn delivers messages to the message consumers.

Local instability is observed when some queues Q_i of Q_c are unbalanced. This is characterized by a



Adaptive Middleware for Message Queuing Systems. Figure 1. Clustered queue Q_c.

mismatch between the fraction of producers and the fraction of consumers directed to Q_i:

$$x_i \neq y_i$$

In the example showed in Fig. 1, Q_c is composed of two standard queues Q_1 and Q_2. A scenario of local instability can be envisioned with the following clients distribution:

$$\begin{cases} x_1 = 2/3 \\ y_1 = 1/3 \end{cases}, \begin{cases} x_2 = 1/3 \\ y_2 = 2/3 \end{cases}$$

This distribution implies that Q_1 is flooding and will have to enqueue messages, while Q_2 is draining and will see its consumer clients wait. However the queue cluster Q_c ensures the global stability of the system thanks to internal message exchanges from Q_1 to Q_2.

A stable and unfair distribution can be observed when the clustered queue is globally and locally stable, but the load is unfairly balanced within the queues. This happens when the client distribution is non-uniform.

In the example presented in Fig. 1, this can be realized by directing more clients to Q_1 than Q_2:

$$\begin{cases} x_1 = 2/3 \\ y_1 = 2/3 \end{cases}, \begin{cases} x_2 = 1/3 \\ y_2 = 1/3 \end{cases}$$

In this scenario, queue Q_1 processes two third of the load, while queue Q_2 only processes one third. Suc situation can lead to bad performance since Q_1 may saturates while Q_2 is lazy.

It is worthwhile to indicate that these scenarios may all happen since clients join and leave the system in an uncontrolled way. Indeed, the global stability of a (clustered) queue is under responsability of the application developper. For instance, the queue can be flooded for a period; it is assumed that it will get inverted and draining after, thus providing global stability over time.

Provisioning

The previous scenario of stable and non-optimal distribution raises the question of the capacity of a queue. The capacity C_i of standard queue Q_i is expressed as an optimal number of clients. The queue load L_i is then expressed as the ratio between its current number of clients and its capacity:

$$L_i = \frac{N_i + M_i}{C_i}$$

1. $L_i < 1$: queue Q_i is underloaded and thus lazy; the message throughput delivered by the queue can be improved and resources are wasted.
2. $L_i > 1$: queue Q_i is overloaded and may saturate; this induces a decreased message throughput and eventually leads to thrashing.
3. $L_i = 1$: queue Q_i is fairly loaded and delivers its optimal message throughput.

These parameters and indicators are transposed to queue clusters. The clustered queue Q_c is characterized by its aggregated capacity C_c and its global load L_c:

$$C_c = \sum_i C_i, \; L_c = \frac{N_c + M_c}{C_c} = \frac{\sum_i L_i \cdot C_i}{\sum_i C_i}$$

The load of a clustered queue obeys to the same law as the load of a standard queue.

However a clustered queue allows to control k, the number of inside standard queues, and thus to control its aggregated capacity $C_c = \sum_{i=1}^{k} C_i$. This control is indeed operated with a re-evaluation of the clustered queue provisioning.

1. When $L_c < 1$, the clustered queue is underloaded: if the clients distribution is optimal, then all the standard queues inside the cluster will be underloaded. However, as the client distribution may be non-optimal, some of the single queues may be overloaded, even if the cluster is globally lazy. If the load is too low, then some queues may be removed from the cluster.

2. When $L_c > 1$, the clustered queue is overloaded: even if the distribution of clients over the queues is optimal, there will exist at least one standard queue that will be overloaded. One way to handle this case is to re-provision the clustered queue by inserting one or more queues into the cluster.

Control Rules for a Self-Optimizing Clustered Queue

The global clients distribution D of the clustered queue Q_c is captured by the fractions of message producers x_i and consumers y_i. The optimal clients distribution D_{opt} is realized when all queues are stable ($\forall i\ x_i = y_i$) and when the load is fairly balanced over all queues ($\forall i,\ j x_i = x_j,\ y_i = y_j$). This implies that the optimal distribution is reached when $x_i = y_i = 1/k$.

$$D = \begin{bmatrix} x_1 & y_1 \\ \vdots & \vdots \\ x_k & y_k \end{bmatrix},\ D_{opt} = \begin{bmatrix} 1/k & 1/k \\ \vdots & \vdots \\ 1/k & 1/k \end{bmatrix}$$

Local instabilities are characterized by a mismatch between the fraction of message producers x_i and consumers y_i on a standard queue. The purpose of this rule is the stability of all standard queues so as to minimize internal queue-to-queue message transfer.

1. $[(R_1)]$ $x_i > y_i$: Q_i is flooding with more message production than consumption and should then seek more consumers and/or fewer producers.
2. $[(R_2)]$ $x_i < y_i$: Q_i is draining with more message consumption than production and should then seek more producers and/or fewer consumers.

Load balancing rules control the load applied to a single standard queue. The goal is then to enforce a fair load balancing over all queues.

1. $[(R_3)]$ $L_i > 1$: Q_i is overloaded and should avoid accepting new clients as it may degrade its performance.
2. $[(R_4)]$ $L_i < 1$: Q_i is underloaded and should request more clients so as to optimize resource usage.

Global provisioning rules control the load applied to the whole clustered queue. These rules target the optimal size of the clustered queue while the load applied to the system evolves.

1. $[(R_5)]$ $L_c > 1$: the queue cluster is overloaded and requires an increased capacity to handle all its clients in an optimal way.
2. $[(R_6)]$ $L_c < 1$: the queue cluster is underloaded and could accept a decrease in capacity.

Key Applications

Adaptive middleware for message queuing systems helps building autonomous distributed systems to improve their performance while minimizing their resource usage, such as distributed Internet services and distributed information systems.

Definition

While in traditional query processing, a query is first optimized and then executed, *adaptive query processing* techniques use runtime feedback to modify query processing in a way that provides better response time, more efficient CPU utilization or more useful incremental results. Adaptive query processing makes query processing more robust to optimizer mistakes, unknown statistics, and dynamically changing data, runtime and workload characteristics. The spectrum of adaptive query processing techniques is quite broad: they may span the executions of multiple queries or adapt within the execution of a single query; they may affect the query plan being executed or just the scheduling of operations within the plan.

Key Points

Conventional query processing follows an optimize-then-execute strategy: after generating alternative query plans, the query optimizer selects the most cost-efficient among them and passes it to the execution engine that directly executes it, typically with little or no runtime decision-making. As queries become more complex, this strategy faces many limitations such as missing statistics, unexpected correlations, and dynamically changing data, runtime, and workload characteristics. These problems are aggregated in the case of long-running queries over data streams as well as in the case of queries over multiple potentially heterogeneous data sources across wide-area networks. Adaptive query processing tries to address these shortcomings by using feedback during query execution to tune query processing. The goal is to increase throughput, improve response time or provide more useful incremental results.

To implement adaptivity, regular query execution is supplemented with a control system for monitoring and analyzing at run-time various parameters that affect query execution. Based on this analysis, certain decisions are made about how the system behavior should be changed. Clearly, this may introduce considerable overheads.

The complete space of adaptive query processing techniques is quite broad and varied. Adaptability may be applied to query execution of multiple queries or just a single one. It may also affect the whole query plan being executed or just the scheduling of operations within the plan. Adaptability techniques also differ on how much they interleave plan generation and execution. Some techniques interleave planning and execution just a few times, by just having the plan re-optimized at specific points, whereas other techniques interleave planning and execution to the point where they are not even clearly distinguishable.

A number of fundamental adaptability techniques include:

- *Horizontal partitioning*, where different plans are used on different portions of the data. Partitioning may be explicit or implicit in the functioning of the operator.
- *Query execution by tuple routing*, where query execution is treated as the process of routing tuples through operators and adaptability is achieved by changing the order in which tuples are routed.
- *Plan partitioning*, where execution progresses in stages, by interleaving optimization and execution steps at a number of well-defined points during query execution.
- *Runtime binding decisions*, where certain plan choices are deferred until runtime, allowing the execution engine to select among several alternative plans by potentially re-invoking the optimizer.
- *In-operator adaptive logic,* where scheduling and other decisions are made part of the individual query operators, rather than the optimizer.

Many adaptability techniques rely on a symmetric hash join operator that offers a non-blocking variant of join by building hash tables on both the input relations. When an input tuple is read, it is stored in the appropriate hash table and probed against the opposite table, thus producing incremental output. The symmetric hash join operator can process data from either input, depending on availability. It also enables additional adaptivity, since it has frequent moments of symmetry, that is, points at which the join order can be changed without compromising correctness or losing work.

The eddy operator provides an example of fine-grained run-time control by tuple routing through operators. An eddy is used as a tuple router; it monitors execution, and makes routing decisions for the tuples. Eddies achieve adaptability by simply changing the order in which the tuples are routed through the operators. The degree of adaptability achieved depends on the type of the operators. Pipelined operators, such as the symmetric hash join, offer the most freedom, whereas, blocking operators, such as the sort-merge join, are less suitable since they do not produce output before consuming the input relations in their entirety.

Adaptive query processing

Definition

When querying long-lived data streams, the characteristics of the data may change over time or data may arrive in bursts – hence, the traditional model of optimizing a query prior to executing it is insufficient. As a result, most data stream management systems employ feedback-driven *adaptive stream processing*, which continuously re-optimizes the query execution plan based on data and stream properties, in order to meet certain performance or resource consumption goals. Adaptive stream processing is a special case of the more general problem of *adaptive query processing*, with the special property that intermediate results are bounded in size (by stream windows), but where query processing may have quality-of-service constraints.

Historical Background

The field of adaptive stream processing emerged in the early 2000s, as two separate developments converged. *Adaptive* techniques for database query processing had become an area of increasing interest as Web and integration applications exceeded the capabilities of conventional static query processing [10]. Simultaneously, a number of data stream management systems [1,6,8,12] were emerging, and each of these needed capabilities for query optimization. This led to a common approach of developing feedback-based re-optimization strategies for stream query computation. In contrast to Web-based adaptive query processing techniques, the focus in adaptive stream processing has especially been on maintaining quality of service under overload conditions.

Foundations

Data stream management systems (DSMSs) typically face two challenges in query processing. First, the data to be processed comes from remote feeds that may be subject to significant variations in distribution or arrival rates over the lifetime of the query, meaning that no single query evaluation strategy may be appropriate over the entirety of execution. Second, DSMSs may be *underprovisioned* in terms of their ability to handle bursty input at its maximum rate, and yet may still need to meet certain *quality-of-service* or resource constraints (e.g., they may need to ensure data is processed within some latency bound). These two challenges have led to two classes of adaptive stream processing techniques: those that attempt to *minimize the cost* of computing query results from the input data (the problem traditionally faced by query optimization), and those that attempt to manage query processing, possibly at reduced accuracy, in the presence of *limited resources*. This article provides an overview of significant work in each area.

Minimizing Computation Cost

The problem of adaptive query processing to minimize computation cost has been well-studied in a variety of settings [10]. What makes the adaptive stream processing setting unique (and unusually tractable) is the fact that joins are performed over *sliding windows* with size bounds: As the data stream exceeds the window size, old data values are expired. This means intermediate state within a query plan operator has constant maximum size; as opposed to being bounded by the size of the input data. Thus a windowed join operator can be modeled as a pair of filter operators, each of which joins its input with the bounded intermediate state produced from the other input. Optimization of joins in data stream management systems becomes a minor variation on the problem of optimizing selection or filtering operators; hence certain theoretical optimality guarantees can actually be made.

Eddies Eddies [2,11,14] are composite dataflow operators that model select-project-join expressions. An eddy consists of a *tuple router*, plus a set of primitive *query operators* that run concurrently and each have input queues. Eddies come in several variations; the one proposed for distributed stream management uses *state modules* (SteMs) [14,11]. Figure 1 shows an example of such an eddy for a simplified stream SQL query, which joins three streams and applies a selection predicate over them.

Eddy creation. The eddy is created prior to execution by an optimizer: every selection operation (σ_P in the example) is converted to a corresponding operator; additionally, each base relation to be joined is given a *state module*, keyed on the join attribute, to hold the intermediate state for each base relation [14] ($\bowtie_R$, $\bowtie_S$, $\bowtie_T$). If a base relation appears with multiple different join attributes, then it may require multiple SteMs. In general, the state module can be thought of as one of the hash tables within a symmetric or pipelined hash join. The optimizer also determines whether the semantics of the query force certain operators to execute before others. Such constraints are expressed in an internal routing table, illustrated on the right side of the figure. As a tuple is processed, it is annotated with a *tuple signature* specifying what input streams' data it contains and what operator may have last modified it. The routing table is a map from the tuple signature to a set of *valid routing destinations*, those operators that can successfully process a tuple with that particular signature.

Query execution/tuple routing. Initially, a tuple from an input data stream (R, S, or T) flows into the eddy router. The eddy (i) adds the data to the associated SteM or SteMs, and (ii) consults the routing table to determine the set of possible destination operators. It then chooses a destination (using a *policy* to be described later) and sends the tuple to the operator. The operator then either *filters* the tuple, or *produces* one or more output tuples, as a result of applying selection conditions or joining with the data within a SteM. Output tuples are marked as having been processed by the operator that produced them. If they have been processed by all operators, they will be sent to the query output, and if not, they will be sent back to the eddy's router and to one of the remaining operators.

Routing policies. The problem of choosing among alternate routing destinations has been addressed with a variety of strategies.

Tickets and lottery scheduling [2]. In this scheme, each operator receives a *ticket* for each tuple it receives from the router, and it returns the ticket each time it outputs a tuple to the router. Over time, each operator is expected to have a number of tickets proportional to $(1 - p)$ where p is the operator's selectivity. The router holds a *lottery* among valid routing destinations, where each operator's chance of winning is proportional to its number of tickets. Additionally, as a flow control mechanism, each operator has an input queue, and if this queue fills, then the operator may not participate in the lottery.

Deterministic with batching [9]. A later scheme was developed to reduce the per-tuple overhead of eddies by choosing destinations for batches of tuples. Here, each operator's selectivity is explicitly monitored and each predicate is assumed to be independent. Periodically, a *rank ordering* algorithm is used to choose a

Adaptive Stream Processing. Figure 1. Illustration of eddy with SteMs.

destination for a *batch* of tuples: the rank ordering algorithm sorts predicates in decreasing order of $c_i/(1 - p_i)$, where c_i is the cost of the applying predicate σ_i and p_i is its selectivity.

Content-based routing [7]. (CBR) attempts to learn correlations between attribute values and selectivities. Using sampling, the system determines for each operator the attribute most strongly correlated with its selectivity – this is termed the *classifier attribute*. CBR then builds a table characterizing all operators' selectivities for different values of each classifier attribute. Under this policy, when the eddy needs to route a tuple, it first looks up the tuple's classifier attribute values in the table and determines the destination operators' selectivities. It routes the tuple probabilistically, choosing a next operator with probability inversely proportional to its selectivity.

Other optimization strategies. An alternative strategy that does not use the eddies framework is the *adaptive greedy* [5] (A-greedy) algorithm. A-greedy continuously monitors the selectivities of query predicates using a *sliding window profile*, a table with one Boolean attribute for each predicate in the query, and sampling. As a tuple is processed by the query, it may be chosen for sampling into the sliding window profile – if so, it is tested against every query predicate. The vector of Boolean results is added as a row to the sliding window profile. Then the sliding window profile is then used to create a *matrix view* $V[i, j]$ containing, for each predicate σ_i, the number of tuples in the profile that satisfy $\sigma_1 ... \sigma_{i-1}$ but not σ_j. From this matrix view, the reoptimizer seeks to maintain the constraint that the *i*th operation over an input tuple must have the lowest cost/selectivity ratio $c_i/(1 - p(S_i|S_1,...,S_{i-1}))$. The overall strategy has one of the few performance guarantees in the adaptive query processing space: if data properties were to converge, then performance would be within a factor of 4 of optimal [5].

Managing Resource Consumption

A common challenge in data stream management systems is limiting the use of resources – or accommodating limited resources while maintaining quality of service, in the case of bursty data. We discuss three different problems that have been studied: load shedding to ensure input data is processed by the CPU as fast as it arrives, minimizing buffering and memory consumption during data bursts, and minimizing network communication with remote streaming sites.

Load Shedding. Allows the system to selectively drop data items to ensure it can process data as it arrives. Both the Aurora and STREAM DSMSs focused heavily on adaptive load shedding.

Aurora. In the Aurora DSMS [15], load shedding for a variety of query types are supported: the main requirement is that the user has a *utility function* describing the value of output data relative to how much of it has been dropped. The system seeks to place load shedding operators in the query plan in a way that maximizes the user's utility function while the system achieves sufficient throughput. Aurora precomputes conditional load shedding plans, in the form of a *load shedding road map* (LRSM) containing a sequence of plans that shed progressively more load; this enables the runtime system to rapidly move to strategies that shed more or less load.

LRSMs are created using the following heuristics: first, load shedding points are only inserted at data input points or at points in which data is split to two or more operators. Second, for each load shedding point, a *loss/gain ratio* is computed: this is the reduction in output utility divided by the gain in cycles, $R(p \cdot L - D)$, where R is the input rate into the drop point, p is the ratio of tuples to be dropped, L is the amount of system load flowing from the drop point, and D is the cost of the drop operator. Drop operators are injected at load shedding points in decreasing order of loss/gain ratio. Two different types of drops are considered using the same framework: *random drop*, in which an operator is placed in the query plan to randomly drop some fraction p of tuples; and *semantic drop*, which drops the p tuples of lowest utility. Aurora assumes for the latter case that there exists a utility function describing the relative worth of different attribute values.

Stanford STREAM. The Stanford STREAM system [4] focuses on aggregate (particularly SUM) queries. Again the goal is to process data at the rate it arrives, while minimizing the inaccuracy in query answers: specifically, the goal is to minimize the *maximum relative error across all queries*, where the relative error of a query is the difference between actual and approximate value, divided by the actual value.

A Statistics Manager monitors computation and provides estimates of each operator's selectivity and its running time, as well as the mean value and standard deviation of each query q_i's aggregate operator. For each q_i, STREAM computes an error threshold C_i, based on the mean, standard deviation, and number of values. (The results are highly technical so the reader is referred to [4] for more details.) A sampling rate P_i is chosen for query q_i that satisfies $P_i \geq C_i/\in_i$, where $\in_i$ is the allowable relative error for the query.

As in Aurora's load shedding scheme, STREAM only inserts load shedding operators at the inputs or at the start of shared segments. Moreover, if a node has a set of children who all need to shed load, then a portion of the load shedding can be "pulled up" to the parent node, and all other nodes can be set to shed some amount of additional load *relative* to this. Based on this observation, STREAM creates a query dataflow graph in which each path from source to sink initially traverses through a load shedding operator whose sampling rate is determined by the desired error rate, followed by additional load shedding operators whose sampling rate is expressed relative to that first operator. STREAM iterates over each path, determines a sampling rate for the initial load shedding operator to satisfy the load constraint, and then computes the maximum relative error for any query. From this, it can set the load shedding rates for individual operators.

Memory Minimization. STREAM also addresses the problem of minimizing the amount of space required to buffer data in the presence of burstiness [3]. The Chain algorithm begins by defining a *progress chart* for each operator in the query plan: this chart plots the relative size of the operator output versus the time it takes to compute. A point is plotted at time 0 with the full size of the input, representing the start of the query; then each operator is given a point according to its cost and relative output size. Now a *lower envelope* is plotted on the progress chart: starting with the initial point at time 0, the *steepest* line is plotted to any operator to the right of this point; from the point at the end of the first line, the next steepest line is plotted to a successor operator; etc. Each line segment (and the operators whose points are plotted beside it) represents a chain, and operators within a chain are scheduled together. During query processing, at each time "tick," the scheduler considers all tuples that have been output by any chain. The tuple that lies on the segment with *steepest slope* is the one that is scheduled next; as a tie-breaker, the earliest such tuple is scheduled. This Chain algorithm is proven to be near-optimal (differing by at most one unit of memory per operator path for queries where selectivity is at most one).

Minimizing Communication. In some cases, the constrained resource is the network rather than CPU or memory. Olston et al. [13] develop a scheme for reducing network I/O for AVERAGE queries, by using accuracy bounds. Each remote object O is given a *bound width* w_O: the remote site will only notify the central query processor if O's value V falls outside this bound. Meanwhile, the central site maintains a *bound cache* with the last value and the bound width for every object.

If given a *precision constraint* δ_j for each query Q_j, then if the query processor is to provide query answers within δ_j, the sum of the bound widths for the data objects of Q_j must not exceed δ_j times the number of objects. The challenge lies in the selection of widths for the objects.

Periodically, the system tries to tighten all bounds, in case values have become more stable; objects whose values fall outside the new bounds get reported back to the central site. Now some of those objects' bounds must be loosened in a way that maintains the precision constraints over all queries. Each object O is given a *burden score* equal to $c_O/(p_O w_O)$, where c_O is the cost of sending the object, w_O is its bound width, and p_O is the frequency of updates since the previous width adjustment. Using an approximation method based on an iterative linear equation solver, Olston et al. compute a *burden target* for each query, i.e., the lowest overall burden score required to always meet the query's precision constraint. Next, each object is assigned a *deviation*, which is the maximum difference between the object's burden score and any query's burden target. Finally, a queried objects' bounds are adjusted in decreasing order of deviation, and each object's bound is increased by the largest amount that still conforms to the precision constraint for every query.

Key Applications

Data stream management systems have seen significant adoption in areas such as sensor monitoring and processing of financial information. When there are associated quality-of-service constraints that might require load shedding, or when the properties of the data are subject to significant change, adaptive stream processing becomes vitally important.

Future Directions

One of the most promising directions of future study is how to best use a combination of offline modeling, selective probing (in parallel with normal query execution), and feedback from query execution to find optimal strategies quickly. Algorithms with certain optimality guarantees are being explored in the online learning and theory communities (e.g., the *k*-armed bandit problem), and such work may lead to new improvements in adaptive stream processing.

Administration Model for RBAC

Yue Zhang, James B. D. Joshi
University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

ARBAC97; SARBAC

Definition

The central ideal of administration model for RBAC is to use the role itself to manage roles. There are two well-known families of administration RBAC models.

Administrative RBAC

The Administrative RBAC family of models known as ARBAC97 [3] introduces administrative roles that are used to manage the regular roles. These roles can form a role hierarchy and may have constraints. ARBAC97 consists of three administrative models, the user-role assignment (URA97) model, the permission-role assignment (PRA97) model, and the role-role administration (RRA97) model. URA97 defines which administrative roles can assign which users to which regular roles by means of the relation: *can_assign*. Similarly, PRA97 defines which administrative roles can assign which permissions to which regular roles by means of the relation: *can_assignp*. Each of these relations also has a counterpart for revoking the assignment (e.g., *can_revoke*). RRA97 defines which administrative roles can change the structure (add roles, delete roles, add edges, etc.) of which range of the regular roles using the notion of *encapsulated range* and the relation: *can_modify*.

Scoped Administrative RBAC

The SARBAC model uses the notion of *administrative scope* to ensure that any operations executed by a role *r* will not affect other roles due to the hierarchical relations among them [1]. There are no special administrative roles in SARBAC, and each regular role has a *scope* of other regular roles called *administrative scope* that can be managed by it. Each role can only be managed by its administrators. For example, a senior-most role should be able to manage all its junior roles.

Key Points

ARBAC model is the first known role-based administration model and uses the notion of *range* and *encapsulated range*. Role *range* is essentially a set of regular roles. To avoid undesirable side effects, RRA97 requires that all role ranges in the *can_modify* relation be encapsulated, which means the range should have exactly one senior-most role and one junior-most role. Sandhu et al. later extended the ARBAC97 model into ARBAC99 model where the notion of mobile and immobile user/permission was introduced [4]. Oh et al. later extended ARBAC99 to ARBAC02 by adding the notion of organizational structure to redefine the user-role assignment and the role-permission assignment [2]. Recently, Zhang et al. have proposed an ARBAC07 model that extends the family of ARBAC models to deal with an RBAC model that allows hybrid hierarchies to co-exit [6].

SARBAC

The most important notion in SARBAC is that of the *administrative scope*, which is similar to the notion of *encapsulated range* in ARBAC97. A role *r* is said to be within to be the administrative scope of another role *a* if every path upwards from *r* goes through *a*, and *a* is said to be the administrator of *r*. SARBAC also consists of three models: SARBAC-RHA, SARBAC-URA, and SARBAC-PRA. In SARBAC-RHA, each role can only administer the roles that are within its own administrative scope. The operations include adding roles, deleting roles, adding permissions, and deleting permissions. The semantics for SARBAC-URA and SARBAC-PRA is similar to URA97 and PRA97. The administrative scope can change dynamically. Zhang et al. have extended SARBAC to also deal with hybrid hierarchy [5].

Administration Wizards

Philippe Bonnet[1], Dennis Shasha[2]
[1]University of Copenhagen, Copenhagen, Denmark
[2]New York University, New York, NY, USA

Definition

Modern database systems provide a collection of utilities and programs to assist a database administrator with tasks such as database installation and configuration, import/export, indexing (index wizards are covered in the self-management entry), and backup/restore.

Historical Background

Database Administrators have been skeptical of any form of automation as long as they could control the performance and security of a relatively straightforward installation. The advent of enterprise data management towards the end of the 1990s, where few administrators became responsible for many, possibly diverse database servers, has led to the use of graphical automation tools. In the mid-1990s, third party vendors introduced such tools. With SQL Server 6.5, Microsoft was the first constructor to provide an administration wizard.

Foundations

Installation and Configuration

Database servers are configured using hundreds of parameters that control everything buffer size, file layout, concurrency control options and so on. They are either set statically in a configuration file before the server is started, or dynamically while the server is running. Out-of-the-box database servers are equipped with a limited set of typical configurations.

The installation/configuration wizard is a graphical user interface that guides the administrator through the initial server configuration. The interface provides high-level choices (e.g., OLTP vs. OLAP workload), or simple questions (e.g., number of concurrent users) that are mapped onto database configuration values (log buffer size and thread pool size respectively).

Data Import/Export

Import/export wizards are graphical tools that help database administrators map a database schema with an external data format (e.g., XML, CSV, PDF), or generate scripts that automate the transfer of data between a database and an external data source (possibly another database server).

Back-up/Restore

Back-up/restore wizards automate the back-up procedure given a few input arguments: complete/incremental backup, scope of the back-up/restore operations (file, tablespace, database), target directory.

Key Applications

Automation of the central database administration tasks.

Aggregation: Expressiveness and Containment

Sara Cohen
The Hebrew University of Jerusalem, Jerusalem, Israel

Definition

An *aggregate function* is a function that receives as input a multiset of values, and returns a single value. For example, the aggregate function `count` returns the number of input values. An *aggregate query* is simply a query that mentions an aggregate function, usually as part of its output. Aggregate queries are commonly used to retrieve concise information from a database, since they can cover many data items, while returning few. Aggregation is allowed in SQL, and the addition of aggregation to other query languages, such as relational algebra and datalog, has been studied.

The problem of determining *query expressiveness* is to characterize the types of queries that can be expressed in a given query language. The study of query expressiveness for languages with aggregation is often focused on determining how aggregation increases the ability to formulate queries. It has been shown that relational algebra with aggregation (which models SQL) has a *locality property.*

Query containment is the problem of determining, for any two given queries q and q', whether $q(D) \subseteq q'(D)$, for all databases D, where $q(D)$ is the result of applying q to D. Similarly, the *query equivalence problem* is to determine whether $q(D) = q'(D)$ for all databases D. For aggregate queries, it seems that characterizing query equivalence may be easier than characterizing query containment. In particular, almost all known results on query containment for aggregate queries are derived by a reduction from query equivalence.

Historical Background

The SQL standard defines five aggregate functions, namely, `count`, `sum`, `min`, `max` and `avg` (average). Over time, it has become apparent that users would like to aggregate data in additional ways. Therefore, major database systems have added new built-in aggregate functions to meet this need. In addition, many database systems now allow the user to extend the set of available aggregate functions by defining his own aggregate functions.

Aggregate queries are typically used to summarize detailed information. For example, consider a database with the relations `Dept(deptId, deptName)` and `Emp(empId, deptId, salary)`. The following SQL query returns the number of employees, and the total department expenditure on salaries, for each department which has an average salary above $10,000.

```
(Q1) SELECT deptID, count(empID),
            sum(salary)
     FROM Dept, Emp
     WHERE Dept.deptID = Emp.deptID
     GROUP BY Dept.deptID
     HAVING avg(salary) > 10000
```

Typically, aggregate queries have three special components. First, the `GROUP BY` clause is used to state how intermediate tuples should be grouped before applying aggregation. In this example, tuples are grouped by their value of `deptID`, i.e., all tuples with the same value for this attribute form a single group. Second, a `HAVING` clause can be used to determine which groups are of interest, e.g., those with average salary above $10,000. Finally, the outputted aggregate functions are specified in the `SELECT` clause, e.g., the number of employees and the sum of salaries.

The inclusion of aggregation in SQL has motivated the study of aggregation in relational algebra, as an abstract modeling of SQL. One of the earliest studies of aggregation was by Klug [11], who extended relational algebra and relational calculus to allow aggregate functions and showed the equivalence of these two languages. Aggregation has also been added to Datalog. This has proved challenging since it is not obvious what semantics should be adopted in the presence of recursion [15].

Foundations

Expressiveness

The study of query expressiveness deals with determining what can be expressed in a given query language. The expressiveness of query languages with aggregation has been studied both for the language of relational algebra, as well as for datalog, which may have recursion.

Various papers have studied the expressive power of nonrecursive languages, extended with aggregation, e.g., [7,9,13]. The focus here will be on [12], which has the cleanest, general proofs for the expressive power of languages modeling SQL.

In [12], the expressiveness of variants of relational algebra, extended with aggregation, was studied. First, [12] observes that the addition of aggregation to relational algebra strictly increases its expressiveness. This is witnessed by the query `Q2`:

```
(Q2) SELECT 1
     FROM R1
     WHERE (SELECT COUNT(*) FROM R) >
               (SELECT COUNT(*) FROM S)
```

Observe that `Q2` returns 1 if `R` contains more tuples than `S`, and otherwise an empty answer. It is known that first-order logic cannot compare cardinalities, and hence neither can relational algebra. Therefore, SQL with aggregation is strictly more expressive than SQL without aggregation.

The language ALG_{aggr} is presented in [12]. Basically, ALG_{aggr} is relational algebra, extended by arbitrary aggregation and arithmetic functions. In ALG_{aggr}, non-numerical selection predicates are restricted to using only the equality relation (and not order comparisons). A *purely relational query* is one which is applied only to non-numerical data. It is shown that all purely relational queries in ALG_{aggr} are *local*. Intuitively, the answers to local queries are determined by looking at small portions of the input.

The formal definition of local queries follows. Let D be a database. The *Gaifman graph* $G(D)$ of D is the undirected graph on the values appearing in D, with $(a,b) \in G(D)$ if a and b belong to the same tuple of some relation in D. Let $\vec{a} = (a_1,\ldots,a_k)$ be a tuple of values, each of which appears in D. Let r be an integer, and let $S_r^D(\vec{a})$ be the set of values b such that $dist\ (a_i, b) \leq r$ in $G(D)$, for some i. The *r-neighborhood* $N_r^D(\vec{a})$ of $\vec{a}$ is a new database in which the relations of D are restricted to contain only the values in $S_r^D(\vec{a})$. Then, $\vec{a}$ and $\vec{b}$ are *(D, r)-equivalent* if there is an isomorphism $h : N_r^D(\vec{a}) \rightarrow N_r^D(\vec{b})$ such that $h(\vec{a}) = \vec{b}$. Finally, a q is *local* if there exists a number r such that for all D, if $(\vec{a})$ and $(\vec{b})$ are (D, r)-equivalent, then $\vec{a} \in q(D)$ if and only if $\vec{b} \in q(D)$.

There are natural queries that are not local. For example, transitive closure (also called reachability) is not local. Since all queries in ALG_{aggr} are local, this implies that transitive closure cannot be expressed in ALG_{aggr}.

In addition to ALG_{aggr}, [12] introduces the languages $\text{ALG}_{\text{aggr}}^{\leq,\mathbb{N}}$ and $\text{ALG}_{\text{aggr}}^{\leq,\mathbb{Q}}$. $\text{ALG}_{\text{aggr}}^{\leq,\mathbb{N}}$ and $\text{ALG}_{\text{aggr}}^{\leq,\mathbb{Q}}$ are the extensions of ALG_{aggr} which allow order comparisons in the selection predicates, and allow natural numbers and rational numbers, respectively, in the database. It is not known whether transitive closure can be expressed in $\text{ALG}_{\text{aggr}}^{\leq,\mathbb{N}}$. More precisely, [12] shows that if transitive closure is not expressible in $\text{ALG}_{\text{aggr}}^{\leq,\mathbb{N}}$, then the complexity class Uniform TC^0 is properly contained in the complexity class NLOGSPACE. Since the latter problem (i.e., determining strict containment of TC^0 in NLOGSPACE) is believed to be very difficult to prove, so is the former. Moreover, this result holds even if the arithmetic functions are restricted to $\{+,\cdot,<,0,1\}$ and the aggregate functions are restricted to $\{\texttt{sum}\}$. On the other hand, $\mathrm{ALG}^{\leq,\mathbb{Q}}_{\mathrm{aggr}}$ extended by arbitrary aggregation and arithmetic functions, can express all computable queries.

The languages $\mathrm{ALG}_{\mathrm{aggr}}$, $\mathrm{ALG}^{\leq,\mathbb{N}}_{\mathrm{aggr}}$ and $\mathrm{ALG}^{\leq,\mathbb{Q}}_{\mathrm{aggr}}$ are based on relational algebra, and therefore, do not allow recursion. The Datalog language allows queries to be defined as programs, containing recursion. The meaning of an aggregate function within a recursive program, is not always well-defined. One solution is to restrict the program to have only *stratified aggregation.* Stratification means that if a derived predicate p is defined by applying an aggregate function on a derived predicate q, then the definition of q does not depend, syntactically, upon the definition of p. For example, consider the following Datalog program, P_1.

$$\begin{aligned} p(X,\ \texttt{sum}(Y)) &\leftarrow q(X,Y)\\ q(X,Y) &\leftarrow a(X,Y)\\ q(X,Z) &\leftarrow q(X,Y), q(Y,Z) \end{aligned}$$

The program P_1 is stratified. Replacing the final rule in P_1 with

$$q(X,Z) \leftarrow q(X,Y), p(Y,Z)$$

would yield a program with nonstratified aggregation.

The expressiveness of stratified aggregation was studied in [14]. Only the aggregate functions `sum`, `avg`, `min`, `max` and `count` were allowed. It is shown that that stratified aggregation cannot express *summarized explosion* (i.e., the number of instances of a part needed to construct a bigger part). On the other hand, if the language is extended to allow the function +, as well as the constants 0 and 1, then all computable queries on the integer domain can be expressed. This is correct even if the only aggregate function allowed is `max`. Additional results of this type, i.e., expressibility of other fragments of stratified Datalog, also appear in [14].

Query Containment

The equivalence and containment problems for aggregate queries have been studied for nonrecursive Datalog programs. A survey of the containment and equivalence problems for aggregate queries, containing references to most works on this topic, appears in [2].

Deriving general characterizations of containment (or equivalence) for aggregate queries is difficult, since each aggregate function tends to have its own idiosyncrasies. For example, `count` is sensitive to the number of occurrences of each value, but not to the values themselves, whereas `max` ignores repeated values, but is sensitive to the exact values appearing. As another example, `sum` ignores the value 0, whereas `prod` ignores 1. In addition, `prod` always returns 0 if it is applied to a bag containing 0.

Due to aggregate function quirks, it is often the case that equivalent queries are no longer so, if the aggregate function appearing in their head changes. To demonstrate, consider the two pairs of queries q_1, q_1' and q_2, q_2'.

$$\begin{aligned} q_1(X,\texttt{count}) &\leftarrow a(X,Y)\\ q_1'(X,\texttt{count}) &\leftarrow a(X,Y), a(X,Z)\\ q_2(X,\texttt{max}(Y)) &\leftarrow a(X,Y)\\ q_2'(X,\texttt{max}(Y)) &\leftarrow a(X,Y), a(X,Z) \end{aligned}$$

The queries q_1 and q_2 (and similarly q_1' and q_2') have the same conditions in their body, and differ only on the output aggregate function. One may show that q_1 is not equivalent to q_1' (nor is there containment in either direction), as witnessed by the database

$$D_1 = \{a(\texttt{c},0), a(\texttt{c},1), a(\texttt{d},0)\}$$

over which $q_1(D_1) = \{(\texttt{c},2),(\texttt{d},1)\}$ and $q_1'(D_1) = \{(\texttt{c},4),(\texttt{d},1)\}$. On the other hand, $q_2 \equiv q_2'$ does hold.

The different oddities of aggregate functions make finding a general solution for the equivalence and containment problems very difficult. Thus, characterizations for equivalence of aggregate queries often are defined separately for each aggregate function. Most known characterizations for equivalence are based on checking for the existence of special types of mappings between the queries. For example, conjunctive queries (i.e., Datalog programs consisting of a single rule, and no negation) with the aggregate function `count`, are equivalent if and only if they are isomorphic [1,4].

For other types of aggregate functions, as well as for `count` queries with comparisons or disjunctions, isomorphism is not a necessary condition for equivalence. To demonstrate, each pair of queries q_i, q_i' below is equivalent, yet not isomorphic:

$$q_3(\texttt{count}) \leftarrow b(X), b(Y), b(Z), X < Y, X < Z$$
$$q_3'(\texttt{count}) \leftarrow b(X), b(Y), b(Z), X < Z, Y < Z$$

$$q_4(\texttt{sum}(Y)) \leftarrow b(Y), b(Z), Y > 0, Z > 0$$
$$q_4'(\texttt{sum}(Y)) \leftarrow b(Y), b(Z), Y \geq 0, Z > 0$$

$$q_5(\texttt{avg}(Y)) \leftarrow b(Y)$$
$$q_5'(\texttt{avg}(Y)) \leftarrow b(Y), b(Z)$$

$$q_6(\texttt{max}(Y)) \leftarrow b(Y), b(Z_1), b(Z_2), Z_1 < Z_2$$
$$q_6'(\texttt{max}(Y)) \leftarrow b(Y), b(Z), Z < Y$$

Characterizations for equivalence are known for queries of the above types. Specifically, characterizations have been presented for equivalence of conjunctive queries with the aggregate functions count, sum, max and count-distinct [4] and these were extended in [5] to queries with disjunctive bodies. Equivalence of conjunctive queries with avgand with percent were characterized in [8].

It is sometimes possible to define classes of aggregate functions and then present general characterizations for equivalence of queries with any aggregate function within the class of functions. Such characterizations are often quite intricate since they must deal with many different aggregate functions. A characterization of this type was given in [6] to decide equivalence of aggregate queries with *decomposable* aggregate functions, even if the queries contain negation. Intuitively, an aggregate function is decomposable if partially computed values can easily be combined together to return the result of aggregating an entire multiset of values, e.g., as is the case for count, sum and max.

Interestingly, when dealing with aggregate queries it seems that the containment problem is more elusive than the equivalence problem. In fact, for aggregate queries, containment is decided by reducing to the equivalence problem. A reduction of containment to equivalence is presented for queries with *expandable* aggregate functions in [3]. Intuitively, for expandable aggregate functions, changing the number of occurrences of values in bags B and B' does not affect the correctness of the formula $\alpha(B)=\alpha(B')$, as long as the proportion of each value in each bag remains the same, e.g., as is the case for count, sum, max, count-distinct and avg.

The study of aggregate queries using the count function is closely related to the study of nonaggregate queries evaluated under *bag-set semantics*. Most past research on query containment and equivalence for nonaggregate queries assumed that queries are evaluated under *set semantics*. In set semantics, the output of a query does not contain duplicated tuples. (This corresponds to SQL queries with the DISTINCT operator.) Under *bag-set semantics* the result of a query is a multiset of values, i.e., the same value may appear many times. A related semantics is *bag semantics* in which both the database and the query results may contain duplication.

To demonstrate the different semantics, recall the database D_1 defined above. Consider evaluating, over D_1, the following variation of q_1:

$$q_1''(X) \leftarrow a(X, Y)$$

Under set-semantics $q''_1(D_1)$ ={ (c),(d)}, and under bag-set semantics $q''_1(D_1)$ ={{ (c),(c),(d)}}. Note the correspondence between bag-set semantics and using the count function, as in q_1, where count returns exactly the number of duplicates of each value. Due to this correspondence, solutions for the query containment problem for queries with the countfunction immediately give rise to solutions for the query containment problem for nonaggregate queries evaluated under bag-set semantics, and vice-versa.

The first paper to directly study containment and equivalence for nonaggregate queries under bag-set semantics was [1], which characterized equivalence for conjunctive queries. This was extended in [4] to queries with comparisons, in [5] to queries with disjunctions and in [6] to queries with negation.

Key Applications

Query Optimization

The ability to decide query containment and equivalence is believed to be a key component in query optimization. When optimizing a query, the database can use equivalence characterizations to remove redundant portions of the query, or to find an equivalent, yet cheaper, alternative query.

Query Rewriting

Given a user query q, and previously computed queries $v_1,\ldots,v_n$, the query rewriting problem is to find a query r that (i) is equivalent to q, and (ii) uses the queries

$v_1,\ldots,v_n$ instead of accessing the base relations. (Other variants of the query rewriting problem have also been studied.) Due to Condition (i), equivalence characterizations are needed to solve the query rewriting problem. Query rewriting is useful as an optimization technique, since it can be cheaper to use past results, instead of evaluating a query from scratch. Integrating information sources is another problem that can be reduced to the query rewriting problem.

Future Directions

Previous work on query containment does not consider queries with HAVING clauses. Another open problem is containment for queries evaluated under bag-set semantics. In this problem, one wishes to determine if the bag returned by q is always sub-bag of that returned by q'. (Note that this is different from the corresponding problem of determining containment of queries with count, which has been solved.) It has shown [10] that bag-set containment is undecidable for conjunctive queries containing inequalities. However, for conjunctive queries without any order comparisons, determining bag-set containment is still an open problem.

Aggregation-Based Structured Text Retrieval

THEODORA TSIKRIKA
Center for Mathematics and Computer Science,
Amsterdam, The Netherlands

Definition

Text retrieval is concerned with the retrieval of documents in response to user queries. This is achieved by (i) representing documents and queries with indexing features that provide a characterisation of their information content, and (ii) defining a function that uses these representations to perform retrieval. *Structured text retrieval* introduces a finer-grained retrieval paradigm that supports the representation and subsequent retrieval of the individual document components defined by the document's *logical structure*. *Aggregation-based structured text retrieval* defines (i) the representation of each document component as the aggregation of the representation of its own information content and the representations of information content of its structurally related components, and

(ii) retrieval of document components based on these (aggregated) representations.

The aim of aggregation-based approaches is to improve retrieval effectiveness by capturing and exploiting the interrelations among the components of structured text documents. The representation of each component's own information content is generated at indexing time. The recursive aggregation of these representations, which takes place at the level of their indexing features, leads to the generation, either at indexing or at query time, of the representations of those components that are structurally related with other components.

Aggregation can be defined in numerous ways; it is typically defined so that it enables retrieval to focus on those document components more specific to the query or to each document's best entry points, i.e., document components that contain relevant information and from which users can browse to further relevant components.

Historical Background

A well-established Information Retrieval (IR) technique for improving the effectiveness of *text retrieval* (i.e., retrieval at the document level) has been the generation and subsequent combination of multiple representations for each document [3]. To apply this useful technique to the *text retrieval* of structured text documents, the typical approach has been to exploit their *logical structure* and consider that the individual representations of their components can act as the different representations to be combined [11]. This definition of the representation of a structured text document as the combination of the representations of its components was also based on the intuitive idea that the information content of each document consists of the information content of its sub-parts [2,6].

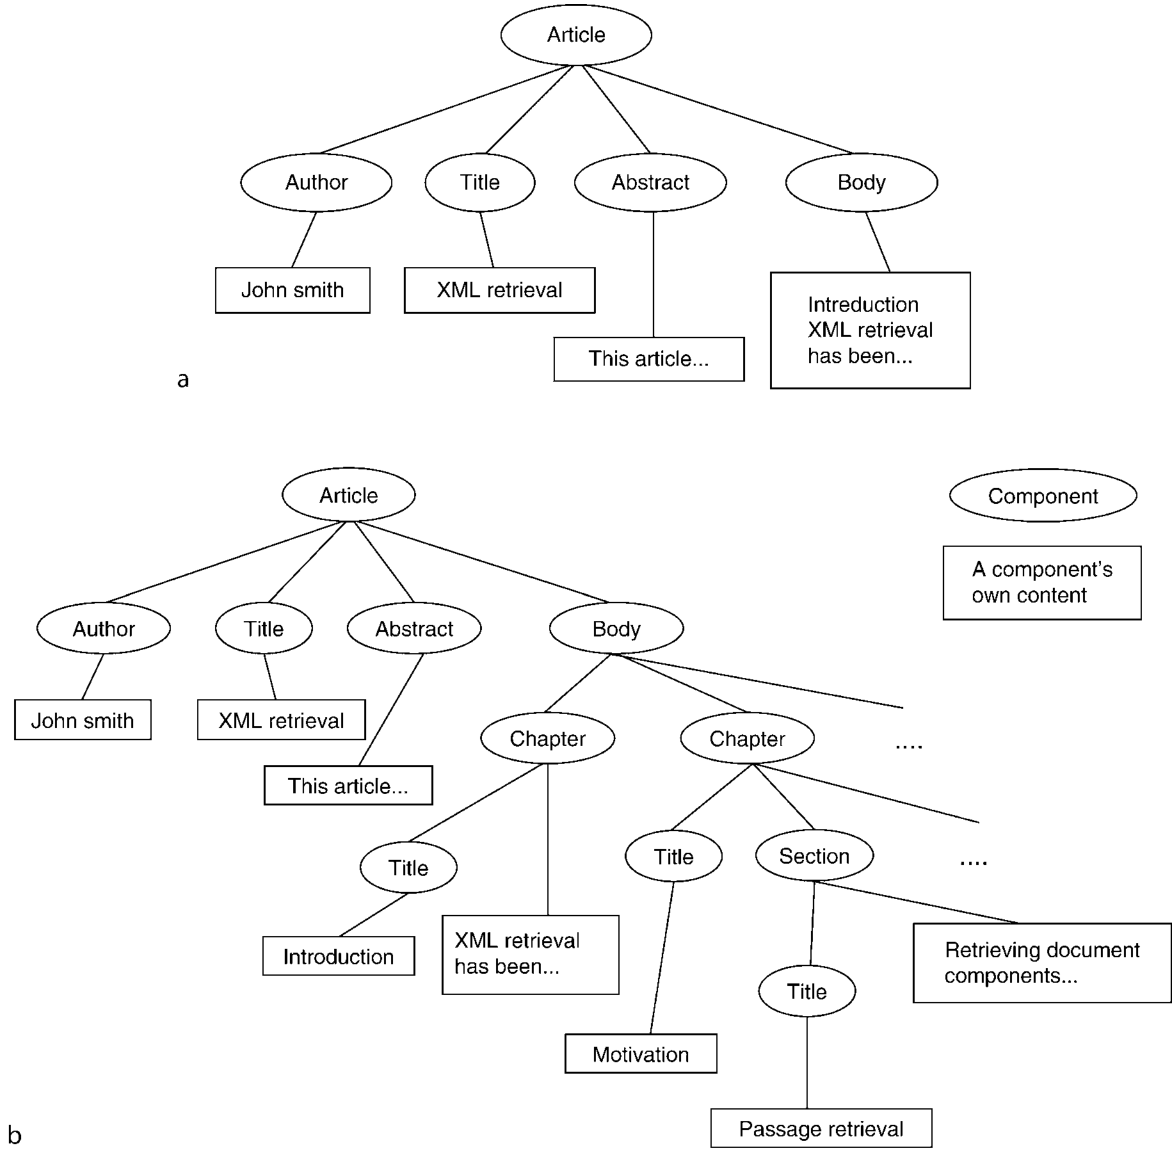
As the above description suggests, these combination-based approaches, despite restricting retrieval only at the document level, assign representations not only to documents, but also to individual document components. To generate these representations, structured text documents can simply be viewed as series of non-overlapping components (Figure 1a), such as title, author, abstract, body, etc. [13]. The proliferation of *SGML* and *XML* documents, however, has led to the consideration of hierarchical components (Figure 1b), and their interrelated representations [1]. For these (disjoint or nested) document components, the combination of their representations can take place (i) directly at the level of their indexing features, which typically correspond to terms and their statistics (e.g., [13]), or (ii) at the level of retrieval scores computed independently for each component (e.g., [15]). Overall, these combination-based approaches have proven effective for the *text retrieval* of structured text documents [11,13,15].

Following the recent shift towards the *structured text retrieval* paradigm [2], which supports the retrieval of document components (including whole documents), it was only natural to try to adapt these combination-based approaches to this new requirement for retrieval at the sub-document level. Here, the focus is on each document component: its representation corresponds to the combination of its own representation with the representations of its structurally related components, and its retrieval is based on this combined representation. Similarly to the case of combination-based approaches for *text retrieval*, two strands of research can be identified: (i) approaches that operate at the level of the components' indexing features (e.g., [12]), referred to as *aggregation-based structured text retrieval* (described in this entry), and (ii) approaches that operate at the level of retrieval scores computed independently for each component (e.g., [14]), referred to as *propagation*-based structured text retrieval.

Figure 2b illustrates the premise of aggregation- and propagated-based approaches for the simple structured text document depicted in Figure 2a. Since these approaches share some of their underlying motivations and assumptions, there has been a cross-fertilisation of ideas between the two. This also implies that this entry is closely related to the entry on *propagation*-based structured text retrieval.

Foundations

Structured text retrieval supports, in principle, the representation and subsequent retrieval of document components of any granularity; in practice, however, it is desirable to take into account only document components that users would find informative in response to their queries [1,2,4,6]. Such document components are referred to as *indexing units* and are usually chosen (manually or automatically) with respect to the requirements of each application. Once the *indexing*



Aggregation-Based Structured Text Retrieval. Figure 1. Two views on the logical structure of a structured text document.

units have been determined, each can be assigned a representation of its information content, and, hence, become individually retrievable.

Aggregation-based structured text retrieval approaches distinguish two types of *indexing units*: *atomic* and *composite*. Atomic components correspond to *indexing units* that cannot be further decomposed, i.e., the leaf components in Figure 1b. The representation of an atomic component is generated by considering only its own information content. Composite components, on the other hand, i.e., the non-leaf nodes in Figure 1b, correspond to *indexing units* which are related to other components, e.g., consist of sub-components. In addition to its own information content, a composite component is also dependent on the information content of its structurally related components. Therefore, its representation can be derived via the *aggregation* of the representation of its

retrieval_score (component$_3$) = f(w(t$_{13}$), w(t$_{23}$), w(t$_{33}$))

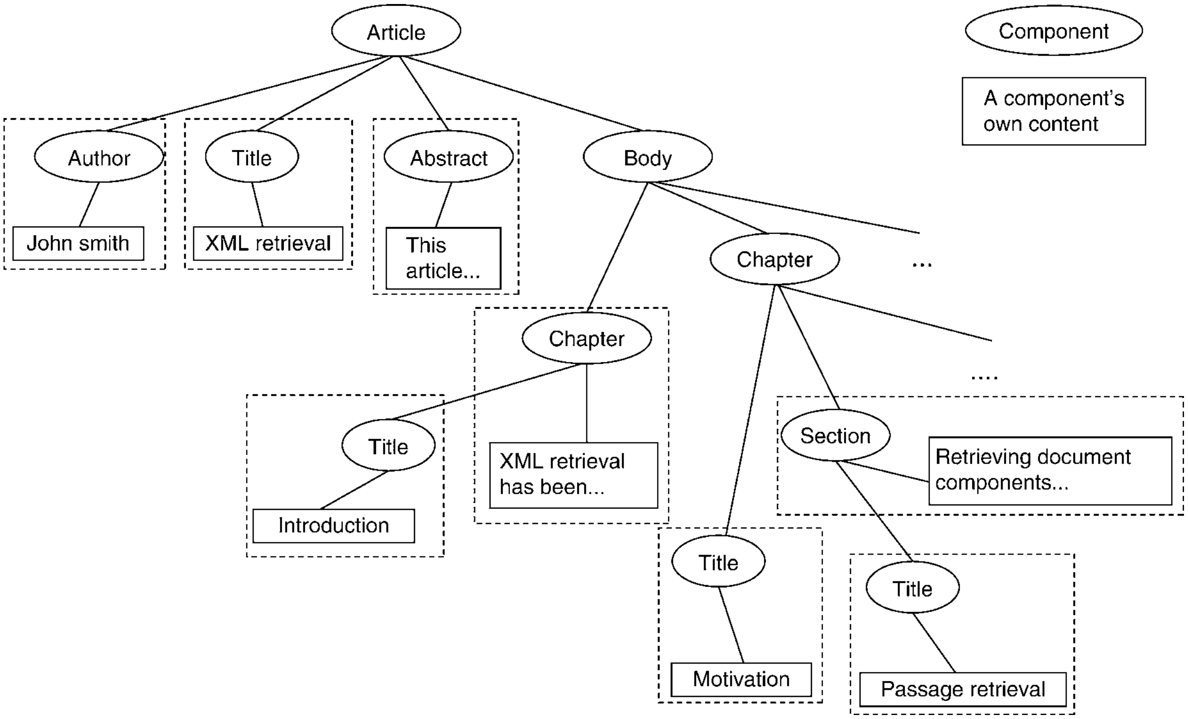
Aggregation-Based Structured Text Retrieval. Figure 2. Simple example illustrating the differences between aggregation- and propagation-based approaches.

own information content with the representations of the information content of its structurally related components; this aggregation takes place at the level of their indexing features. Given the representations of atomic components and of composite components' own information content, aggregation-based approaches recursively generate the aggregated representations of composite components and, based on them, perform retrieval of document components of varying granularity.

In summary, each aggregation-based approach needs to define the following: (i) the representation of each component's own information content, (ii) the aggregated representations of composite components, and (iii) the retrieval function that uses these representations. Although these three steps are clearly interdependent, the major issues addressed in each step need to be outlined first, before proceeding with the description of the key aggregation-based approaches in the field of *structured text retrieval.*

1. *Representing each component's own information content*: In the field of *text retrieval*, the issue of representing documents with indexing features that provide a characterisation of their information content has been extensively studied in the context of several *IR retrieval models* (e.g., Boolean, vector space, probabilistic, language models, etc.). For text documents, these indexing features typically correspond to term statistics. Retrieval functions produce a ranking in response to a user's query, by taking into account the statistics of query terms together with each document's length. The term statistics most commonly used correspond to the *term frequency tf* (t, d) of term t in document d and to the *document frequency df* (t, C) of term t in the document collection C, leading to standard $tf \times idf$ weighting schemes.

Structured text retrieval approaches need to generate representations for all components corresponding to *indexing units*. Since these components are nested, it is not straightforward to adapt these *term statistics* (particularly *document frequency*) at the component level [10]. Aggregation-based approaches, on the other hand, directly generate representations only for components that have their own information content,



Aggregation-Based Structured Text Retrieval. Figure 3. Representing the components that contain their own information.

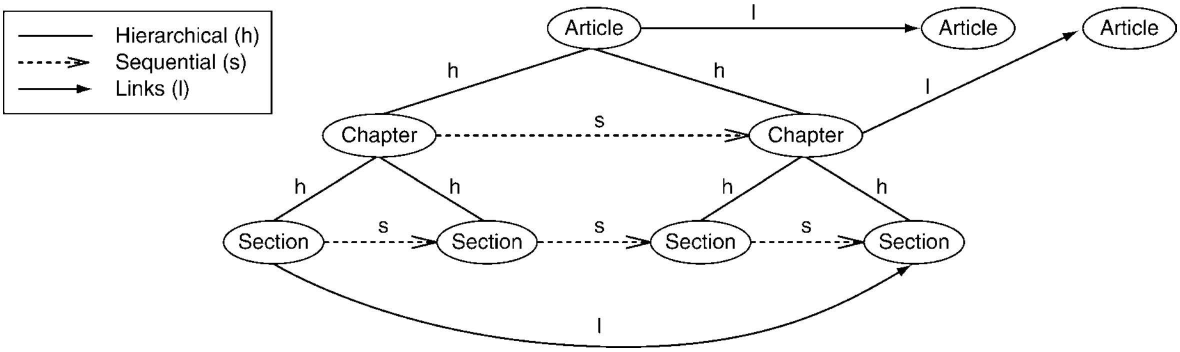
while the representations of the remaining components are obtained via the aggregation process. Therefore, the first step is to generate the representations of atomic components and of the composite components' own information content, i.e., the content not contained in any of their structurally related components. This simplifies the process, since only *disjoint* units need to be represented [6], as illustrated in Figure 3 where the dashed boxes enclose the components to be represented (cf. [5]).

Text retrieval approaches usually consider that the information content of a document corresponds only to its *textual content*, and possibly its metadata (also referred to as *attributes*). In addition to that, *structured text retrieval* approaches also aim at representing the information encoded in the logical structure of documents. Representing this *structural information*, i.e., the interrelations among the documents and their components, enables retrieval in response to both *content-only queries* and *content-and-structure queries.*

Aggregation-based approaches that only represent the textual content typically adapt standard representation formalisms widely employed in *text retrieval* approaches to their requirements for representation at the component level (e.g., [9,11]). Those that consider richer representations of information content apply more expressive formalisms (e.g., various logics [2,4]).

2. *Aggregating the representations*: The concept underlying aggregation-based approaches is that of *augmentation* [4]: the information content of a document component can be *augmented* with that of its structurally related components. Given the already generated representations (i.e., the representations of atomic components and of composite components' own information content), the augmentation of composite components is performed by the aggregation process.

The first step in the aggregation process is the identification of the structurally related components of each composite component. Three basic types of structural relationships (Figure 4) can be distinguished: hierarchical (*h*), sequential (*s*), and links (*l*). Hierarchical connections express the *composition* relationship among components, and induce the tree representing the *logical structure* of a structured



Aggregation-Based Structured Text Retrieval. Figure 4. Different types of structural relationships between the components of a structured text document.

document. Sequential connections capture the order imposed by the document's author(s), whereas links to components of the same or different documents reference (internal or external) sources that offer similar information. In principle, all these types of structural relationships between components can be taken into account by the aggregation process (and some aggregation-based approaches are generic enough to accommodate them, e.g., [7]). In practice, however, the hierarchical structural relations are the only ones usually considered. This leads to the aggregated representations of composite components being recursively generated in an ascending manner.

The next step is to define the *aggregation operator* (or *aggregation function*). Since the aggregation of the textual content of related components is defined at the level of the indexing features of their representations, the aggregation function is highly dependent on the model (formalism) chosen to represent each component's own content. This aggregation results in an (aggregated) representation modeled in the same formalism, and can be seen as being performed at two stages (although these are usually combined into one step): the aggregation of *index expressions* [2] (e.g., terms, conjunctions of terms, etc.), and of the *uncertainty* assigned to them (derived mainly by their statistics).

An aggregation function could also take into account: (i) *augmentation factors* [6], which capture the fact that the textual content of the structurally related components of a composite component is not included in that components own content and has to be "propagated" in order to become part of it, (ii) *accessibility factors* [4], which specify how the representation of a component is influenced by its connected components (a measure of the contribution of, say, a section to its embedding chapter [2]), and (iii) the overall importance of a component in a document's structure [7] (e.g., it can be assumed that a title contains more informative content than a small subsection [13]). Finally, the issue of the possible aggregation of the attributes assigned to related components needs to be addressed [2].

The above aggregation process can take place either at indexing time (*global aggregation*) or at query time (*local aggregation*). Global aggregation is performed for all composite *indexing units* and considers all indexing features involved. Since this strategy does not scale well and can quickly become highly inefficient, local aggregation strategies are primarily used. These restrict the aggregation only to indexing features present in the query (i.e., query terms), and, starting from components retrieved in terms of their own information content, perform the aggregation only for these components' ancestors.

3. *Retrieval*: The retrieval function operates both on the representations of atomic components and on the aggregated representations of composite components. Its definition is highly dependent on the formalism employed in modeling these representations. In conjunction with the definition of the aggregation function, the retrieval function operationalizes the notion of *relevance* for a *structured text retrieval* system. It can, therefore, determine whether retrieval focuses on those document components more specific to the query [2], or whether the aim is to support the users'

browsing activities by identifying each documents best entry points [7] (i.e., document components that contain relevant information which users can browse to further relevant components).

Aggregation-based Approaches

One of the most influential aggregation-based approaches has been developed by Chiaramella et al. [2] in the context of the FERMI project (http://www.dcs.gla.ac.uk/fermi/). Aiming at supporting the integration of IR, hypermedia, and database systems, the FERMI model introduced some of the founding principles of *structured text retrieval* (including the notion of retrieval focussed to the most specific components). It follows the logical view on IR, i.e., it models the retrieval process as inference, and it employs predicate logic as its underlying formalism. The model defines a generic representation of content, attributes, and structural information associated with the *indexing units*. This allows for rich querying capabilities, including support for both *content-only queries* and *content-and-structured queries*. The indexing features of structured text documents can be defined in various ways, e.g., as sets of terms or as logical expressions of terms, while the semantics of the aggregation function depend on this definition. Retrieval can then be performed by a function of the *specificity* of each component with respect to the query.

The major limitation of the FERMI model is that it does not incorporate the uncertainty inherent to the representations of content and structure. To address this issue, Lalmas [8] adapted the FERMI model by using propositional logic as its basis, and extended it by modeling the uncertain representation of the textual content of components (estimated by a *tf* × *idf* weighting scheme) using Dempster-Shafer's theory of evidence. The structural information is not explicitly captured by the formalism; therefore, the model does not provide support for *content-and-structured queries*. The aggregation is performed by Dempster's combination rule, while retrieval is based on the belief values of the query terms.

Fuhr, Gövert, and Rölleke [4] also extended the FERMI model using a combination of (a restricted form of) predicate logic with probabilistic inference. Their model captures the uncertainty in the representations of content, structure, and attributes. Aggregation of index expressions is based on a four-valued logic, allowing for the handling of incomplete information and of inconsistencies arising by the aggregation (e.g., when two components containing contradictory information are aggregated). Aggregation of term weights is performed according to the rules of probability theory, typically by adopting term independence assumptions. This approach introduced the notion of *accessibility factor* being taken into account. Document components are retrieved based on the computed probabilities of query terms occurring in their (aggregated) representations.

Following its initial development in [4], Fuhr and his colleagues investigated further this logic-based probabilistic aggregation model in [5,6]. They experimented with modeling aggregation by different Boolean operators; for instance, they noted that, given terms propagating in the document tree in a bottom-up fashion, a probabilistic-OR function would always result in higher weights for components further up the hierarchy. As this would lead (in contrast to the objectives of *specificity*-oriented retrieval) to the more general components being always retrieved, they introduced the notion of *augmentation factors*. These could be used to "downweight" the weights of terms (estimated by a *tf* × *idf* scheme) that are aggregated in an ascending manner. The effectiveness of their approach has been assessed in the context of the *Initiative for the Evaluation of XML retrieval (INEX)* [6].

Myaeng et al. [11] also developed an aggregation-based approach based on probabilistic inference. They employ Bayesian networks as the underlying formalism for explicitly modeling the (hierarchical) structural relations between components. The document components are represented as nodes in the network and their relations as (directed) edges. They also capture the uncertainty associated with both textual content (again estimated by *tf* × *idf* term statistics) and structure. Aggregation is performed by probabilistic inference, and retrieval is based on the computed beliefs. Although this model allows for document component scoring, in its original publication [11] it is evaluated in the context of *text retrieval* at the document level.

Following the recent widespread application of statistical language models in the field of *text retrieval*, Ogilvie and Callan [8] adapted them to the requirements of *structured text retrieval*. To this end, each document component is modeled by a language model; a unigram language model estimates the probability of a term given some text. For atomic components, the language model is estimated by their own text by employing a maximum likelihood estimate (MLE). For instance, the probability of term *t* given the language model θ_T of text *T* in a component can be estimated by: $P(t|\theta_T) = (1 - \omega)P_{MLE}(t|\theta_T) + \omega P_{MLE}(t|\theta_{collection})$, where ω is a parameter controlling the amount of smoothing of the background collection model. For composite components *comp$_i$*, the aggregation of language models is modeled as a linear interpolation: $P(t|\theta'_{comp_i}) = \lambda^{c'}_{comp_i} P(t|\theta_{comp_i}) + \sum_{j \in childern(comp_i)} \lambda^c_j$ $P(t|\theta_j)$, where $\lambda^{c'}_{comp_i} + \sum_{j \in childern(comp_i)} \lambda^c_j = 1$. These λs model the contribution of each language model (i.e., document component) in the aggregation, while their estimation is a non-trivial issue. Ranking is typically produced by estimating the probability that each component generated the query string (assuming an underlying multinomial model). The major advantage of the language modeling approach is that it provides guidance in performing the aggregation and in estimating the term weights.

A more recent research study has attempted to apply BM25 (one of the most successful *text retrieval* term weighting schemes) to *structured text retrieval*. Robertson et al. [13] initially adapted BM25 to structured text documents with non-hierarchical components (see Figure 1a), while investigating the effectiveness of retrieval at the document level. Next, they [9] adapted BM25 to deal with nested components (see Figure 1b), and evaluated it in the context of the *INitiative for the Evaluation of XML retrieval (INEX)*.

A final note on these aggregation-based approaches is that most aim at focusing retrieval on those document components more specific to the query. However, there are approaches that aim at modeling the criteria determining what constitutes a best entry point. For instance, Kazai et al. [7] model aggregation as a fuzzy formalisation of linguistic quantifiers. This means that an indexing feature (term) is considered in an aggregated representation of a composite component, if it represents *LQ* of its structurally related components, where *LQ* a linguistic quantifier, such as "at least one," "all," "most," etc. By using these aggregated representations, the retrieval function determines that a component is relevant to a query if *LQ* of its structurally related components are relevant, in essence implementing different criteria of what can be regarded as a best entry point.

Key Applications

Aggregation-based approaches can be used in any application requiring retrieval according to the structured text retrieval paradigm. In addition, such approaches are also well suited to the retrieval of multimedia documents. These documents can be viewed as consisting of (disjoint or nested) components each containing one or more media. Aggregation can be performed by considering atomic components to only contain a single medium, leading to retrieval of components of varying granularity. This was recognized early in the field of structured text retrieval and some of the initial aggregation-based approaches, e.g., [2,4], were developed for multimedia environments.

Experimental Results

For most of the presented approaches, particularly for research conducted in the context of the *INitiative for the Evaluation of XML retrieval (INEX)*, there is an accompanying experimental evaluation in the corresponding reference.

Data Sets

A testbed for the evaluation of structured text retrieval approaches has been developed as part of the efforts of the *INitiative for the Evaluation of XML retrieval (INEX)* (http://inex.is.informatik.uni-duisburg.de/).

URL to Code

The aggregation-based approach developed in [8] has been implemented as part of the open source *Lemur* toolkit (for language modeling and IR), available at: http://www.lemurproject.org/.

Air Indexes for Spatial Databases

Baihua Zheng
Singapore Management University, Singapore, Singapore

Definition

Air indexes refer to indexes employed in wireless broadcast environments to address scalability issue and to facilitate power saving on mobile devices [4]. To retrieve a data object in wireless broadcast systems, a mobile client has to continuously monitor the broadcast channel until the data arrives. This will consume a lot of energy since the client has to remain active during its waiting time. The basic idea of air indexes is that by including index information about the arrival times of data items on the broadcast channel, mobile clients are able to predict the arrivals of their desired data. Thus, they can stay in power saving mode during waiting time and switch to active mode only when the data of their interests arrives.

Historical Background

In spatial databases, clients are assumed to be interested in data objects having spatial features (e.g., hotels, ATM, gas stations). "Find me the nearest restaurant" and "locate all the ATMs that are within 100 miles of my current location" are two examples. A central server is allocated to keep all the data, based on which the queries issued by the clients are answered. There are basically two approaches to disseminating spatial data to clients: (i) *on-demand access*: a mobile client submits a request, which consists of a query and the query's issuing location, to the server. The server returns the result to the mobile client via a dedicated point-to-point channel. (ii) *periodic broadcast*: data are periodically broadcast on a wireless channel open to the public. After a mobile client receives a query from its user, it tunes into the broadcast channel to receive the data of interest based on the query and its current location.

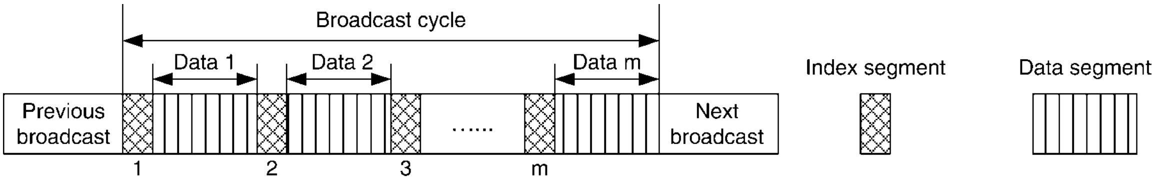
On-demand access is particularly suitable for light-loaded systems when contention for wireless channels and server processing is not severe. However, as the number of users increases, the system performance deteriorates rapidly. Compared with on-demand access, broadcast is a more scalable approach since it allows simultaneous access by an arbitrary number of mobile clients. Meanwhile, clients can access spatial data without reporting to the server their current location and hence the private location information is not disclosed.

In the literature, two performance metrics, namely *access latency* and *tuning time*, are used to measure access efficiency and energy conservation, respectively [4]. The former means the time elapsed between the moment when a query is issued and the moment when it is satisfied, and the latter represents the time a mobile client stays active to receive the requested data. As energy conservation is very critical due to the limited battery capacity on mobile clients, a mobile device typically supports two operation modes: *active mode* and *doze mode*. The device normally operates in active mode; it can switch to doze mode to save energy when the system becomes idle.

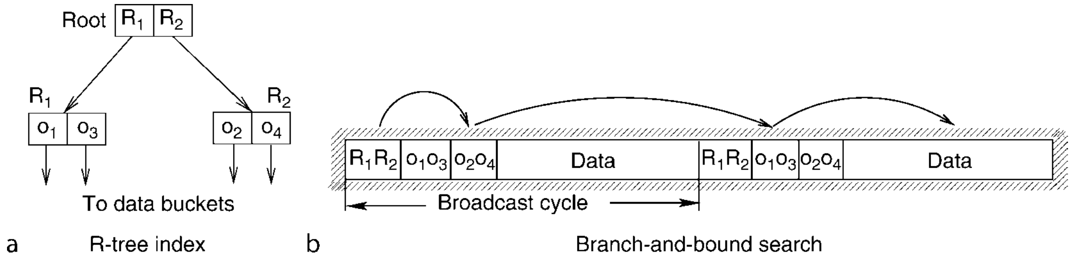
With data broadcast, clients listen to a broadcast channel to retrieve data based on their queries and hence are responsible for query processing. Without any index information, a client has to download all data objects to process spatial search, which will consume a lot of energy since the client needs to remain active during a whole broadcast cycle. A broadcast cycle means the minimal duration within which all the data objects are broadcast at least once. A solution to this problem is *air indexes* [4]. The basic idea is to broadcast an index before data objects (see Fig. 1 for an example). Thus, query processing can be performed over the index instead of actual data objects. As the index is much smaller than the data objects and is selectively accessed to perform a query, the client is expected to download less data (hence incurring less tuning time and energy consumption) to find the answers. The disadvantage of air indexing, however, is that the broadcast cycle is lengthened (to broadcast additional index information). As a result, the access latency would be worsen. It is obvious that the larger the index size, the higher the overhead in access latency.

An important issue in air indexes is how to multiplex data and index on the sequential-access broadcast channel. Figure 1 shows the well-known (1, *m*) scheme [4], where the index is broadcast in front of every 1/m fraction of the dataset. To facilitate the access of index, each data page includes an offset to the beginning of the next index. The general access protocol for processing spatial search involves following three steps: (i) *initial probe*: the client tunes into the broadcast channel and determines when the next index is broadcast; (ii) *index search*: The client tunes into the broadcast channel again when the index is broadcast. It selectively accesses a number of index pages to find out the spatial data object and when to download it; and (iii) *data retrieval*: when the packet containing the qualified object arrives, the client downloads it and retrieves the object.

To disseminate spatial data on wireless channels, well-known spatial indexes (e.g., R-trees) are candidates for air indexes. However, unique characteristics of wireless data broadcast make the adoption of existing spatial indexes inefficient (if not impossible). Specifically, traditional spatial indexes are designed to cluster data objects with spatial locality. They usually assume a resident storage (such as disk and memory) and adopt search strategies that minimize I/O cost. This is achieved by *backtracking* index nodes during search. However, the broadcast order (and thus the access order) of



Air Indexes for Spatial Databases. Figure 1. Air indexes in wireless broadcast environments.



Air Indexes for Spatial Databases. Figure 2. Linear access on wireless broadcast channel.

index nodes is extremely important in wireless broadcast systems because data and index are only available to the client when they are broadcast on air. Clients cannot randomly access a specific data object or index node but have to wait until the next time it is broadcast. As a result, each backtracking operation extends the access latency by one more cycle and hence becomes a constraint in wireless broadcast scenarios.

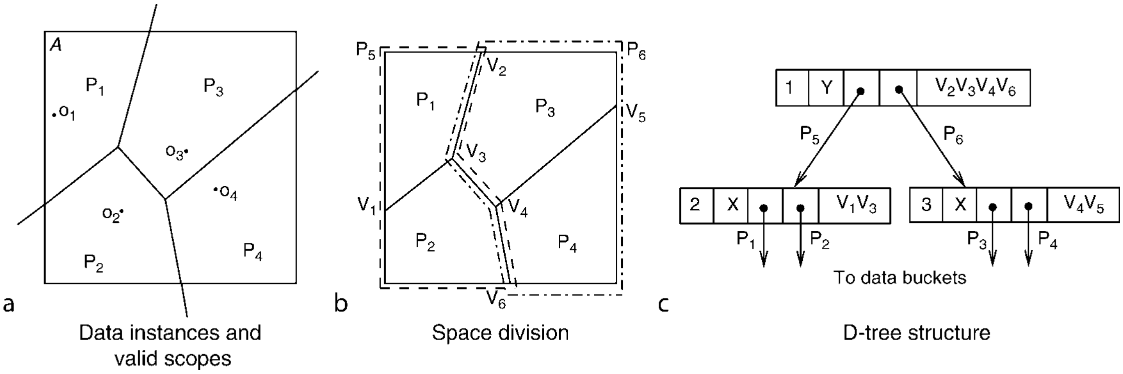
Figure 2 depicts an example of spatial query. Assume that an algorithm based on R-tree first visits root node, then the node R_2, and finally R_1, while the server broadcasts nodes in the order of root, R_1, and R_2. If a client wants to backtrack to node R_1 after it retrieves R_2, it will have to wait until the next cycle because R_1 has already been broadcast. This significantly extends the access latency and it occurs every time a navigation order is different from the broadcast order. As a result, new air indexes which consider both the constraints of the broadcast systems and features of spatial queries are desired.

Foundations

Several air indexes have been recently proposed to support broadcast of spatial data. These studies can be classified into two categories, according to the nature of the queries supported. The first category focuses on retrieving data associated with some specified geographical range, such as "Starbucks Coffee in New York City's Times Square" and "Gas stations along Highway 515." A representative is the index structure designed for *DAYS* project [1]. It proposes a location hierarchy and associates data with locations. The index structure is designed to support query on various types of data with different location granularity. The authors intelligently exploit an important property of the locations, i.e., containment relationship among the objects, to determine the relative location of an object with respect to its parent that contains the object. The containment relationship limits the search range of available data and thus facilitates efficient processing of the supported queries. In brief, a broadcast cycle consists of several sub-cycles, with each containing data belonging to the same type. A major index (one type of index buckets) is placed at the beginning of each sub-cycle. It provides information related to the types of data broadcasted, and enables clients to quickly jump into the right sub-cycle which contains her interested data. Inside a sub-cycle, minor indexes (another type of index buckets) are interleaved with data buckets. Each minor index contains multiple pointers pointing to the data buckets with different locations. Consequently, a search for a data object involves accessing a major index and several minor indexes.

The second category focuses on retrieving data according to specified distance metric, based on client's current location. An example is nearest neighbor (NN) search based on Euclidian distance. According to the index structure, indexes of this category can be further clustered into two groups, i.e., *central tree-based* structure and *distributed* structure. In the following, we review some of the representative indexes of both groups.

D-tree is a paged binary search tree to index a given solution space in support of planar point queries [6]. It assumes a data type has multiple data instances, and each instance has a certain *valid scope* within which this instance is the only correct answer. For example, restaurant is a data type, and each individual restaurant represents an instance. Take NN search as an example, Fig. 3a illustrates four restaurants, namely o_1, o_2, o_3, and o_4, and their corresponding valid scopes p_1, p_2, p_3, and p_4. Given any query location q in, say, p_3, o_3 is the restaurant to which q is nearest. D-tree assumes the valid scopes of different data instances are known and it focuses only on planar point queries which locate the



Air Indexes for Spatial Databases. Figure 3. Index construction using the D-tree.

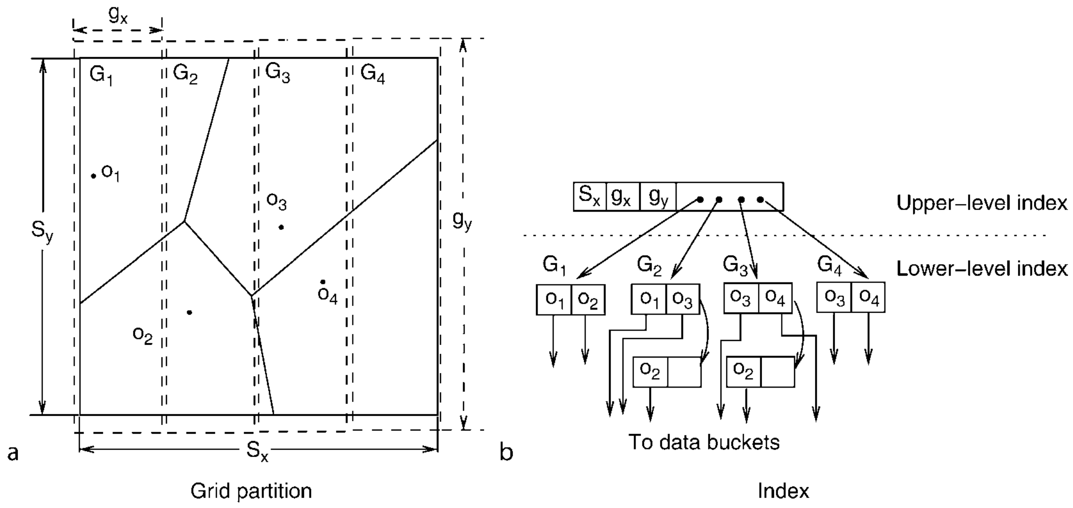
query point into a valid scope and return the client the corresponding data instance.

The D-tree is a binary tree built based on the divisions between data regions (e.g., valid scopes). A space consisting of a set of data regions is recursively partitioned into two complementary subspaces containing about the same number of regions until each subspace has one region only. The partition between two subspaces is represented by one or more polylines. The overall orientation of the partition can be either x-dimensional or y-dimensional, which is obtained, respectively, by sorting the data regions based on their lowest/uppermost y-coordinates, or leftmost/rightmost x-coordinates. Figure 3b shows the partitions for the running example. The polyline $pl(v_2, v_3, v_4, v_6)$ partitions the original space into p_5 and p_6, and polylines $pl(v_1,v_3)$ and $pl(v_4,v_5)$ further partition p_5 into p_1 and p_2, and p_6 into p_3 and p_4, respectively. The first polyline is y-dimensional and the remaining two are x-dimensional. Given a query point q, the search algorithm works as follows. It starts from the root and recursively follows either the left subtree or the right subtree that bounds the query point until a leaf node is reached. The associated data instance is then returned as the final answer.

Grid-partition index is specialized for NN problem [9]. It is motivated by the observation that an object is the NN only to the query points located inside its Voronoi Cell. Let $O = \{o_1, o_2,...,o_n\}$ be a set of points. $V(o_i)$, the *Voronoi cell* (VC) for o_i, is defined as the set of points q in the space such that $dist(q,o_i) < dist(q,o_j)$, $\forall j \neq i$. That is, $V(o_i)$ consists of the set of points for which o_i is the NN. As illustrated in Fig. 3a, p_1, p_2, p_3, and p_4 denote the VCs for four objects, o_1, o_2, o_3, and o_4, respectively. Grid-partition index tries to reduce the search space for a query at the very beginning by partitioning the space into disjoint grid cells. For each grid cell, all the objects that could be NNs of at least one query point inside the grid cell are indexed, i.e., those objects whose VCs overlap with the grid cell are associated with that grid cell.

Figure 4a shows a possible grid partition for the running example, and the index structure is depicted in Fig. 4b. The whole space is divided into four grid cells; i.e., G_1, G_2, G_3, and G_4. Grid cell G_1 is associated with objects o_1 and o_2, since their VCs, p_1 and p_2, overlap with G_1; likewise, grid cell G_2 is associated with objects o_1, o_2, o_3, and so on. If a given query point is in grid cell G_1, the NN can be found among the objects associated with G_1 (i.e., o_1 and o_2), instead of among the whole set of objects. Efficient search algorithms and partition approaches have been proposed to speed up the performance.

Conventional spatial index R-tree has also been adapted to support *k*NN search in broadcast environments [2]. For R-tree index, the *k*NN search algorithm would visit index nodes and objects sequentially as backtracking is not feasible on the broadcast. This certainly results in a considerably long tuning time especially when the result objects are located in later part of the broadcast. However, if clients know that there are at least k objects in the later part of the broadcast that are closer to the query point than the currently found ones, they can safely skip the downloading of the intermediate objects currently located. This observation motivates the design of the enhanced *k*NN search algorithm which caters for the constraints of wireless broadcast. It requires each index node to

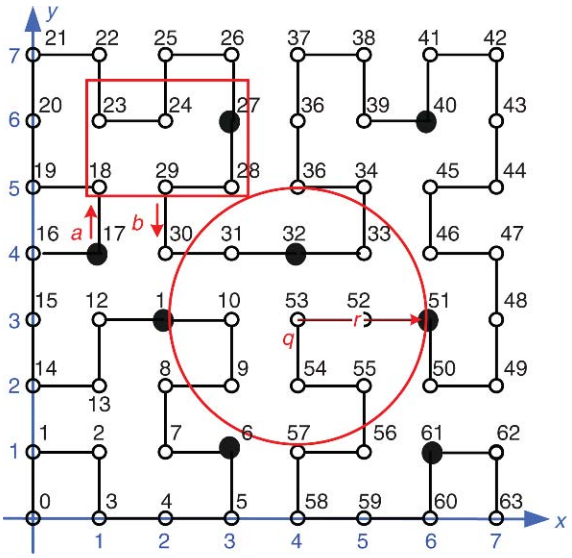


Air Indexes for Spatial Databases. Figure 4. Index construction using the grid-partition.

carry a count of the underlying objects (object count) referenced by the current node. Thus, clients do not blindly download intermediate objects.

Hilbert Curve Index (HCI) is designed to support general spatial queries, including window queries, *k*NN queries, and continuous nearest-neighbor (CNN) queries in wireless broadcast environments. Motivated by the linear streaming property of the wireless data broadcast channel and the optimal spatial locality of the Hilbert Curve (HC), HCI organizes data according to Hilbert Curve order [7,8], and adopts B^+-tree as the index structure. Figure 5 depicts a 8 × 8 grid, with solid dots representing data objects. The numbers next to the data points, namely *index value*, represent the visiting orders of different points at Hilbert Curve. For instance, data point with (1,1) as the coordinates has the index value of 2, and it will be visited before data point with (2,2) as the coordinates because of the smaller index value.

The *filtering and refining* strategy is adopted to answer all the queries. For window query, the basic idea is to decide a candidate set of points along the Hilbert curve which includes all the points within the query window and later to filter out those outside the window. Suppose the rectangle shown in Fig. 5 is a query window. Among all the points within the search range, the first point is point *a* and the last is *b*, sorted according to their occurring orders on the Hilbert curve, and both of them are lying on the boundary of the search range. Therefore, all the points inside this query window should lie on the Hilbert curve segmented by points *a* and *b*. In other words, data points with index values between 18 and 29, but not the others, are the candidates. During the access, the client can derive the coordinates of data points based on the index values and then retrieve those within the query window.



Air Indexes for Spatial Databases. Figure 5. Hilbert curve index.

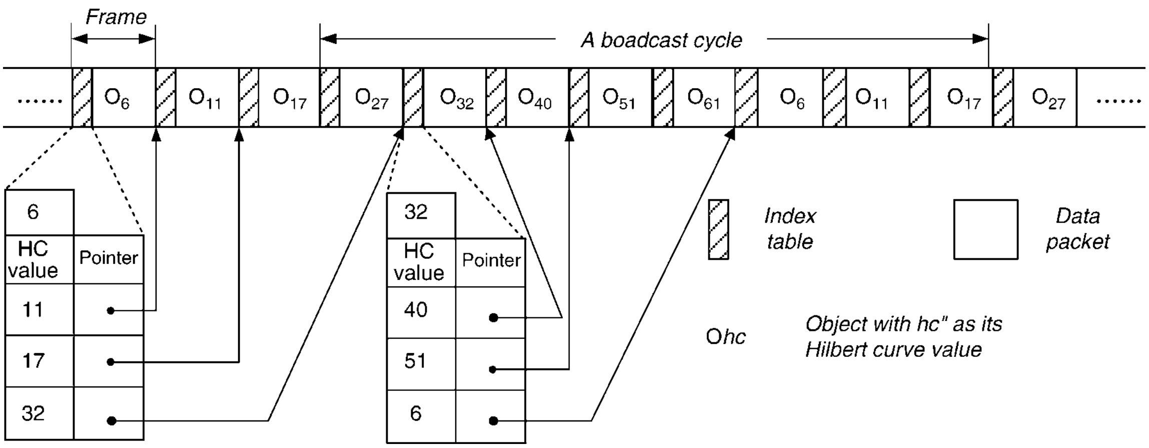
For *k*NN query, the client first retrieves those *k* nearest objects to the query point along the Hilbert curve and then derives a range which for sure bounds at least *k* objects. In the filtering phase, a window query which bounds the search range is issued to filter out those unqualified. Later in the refinement phase, *k* nearest objects are identified according to their distance to the query point. Suppose an NN query at point *q* (i.e., index value 53) is issued. First, the client finds its nearest neighbor (i.e., point with index value 51) along the curve and derives a circle centered at *q* with *r* as the radius (i.e., the green circle depicted in Fig. 5). Since the circle bounds point 51, it is certain to contain the nearest neighbor to point *q*. Second, a window query is issued to retrieve all the data points inside the circle, i.e., points with index values 11, 32, and 51. Finally, the point 32 is identified as the nearest neighbor. The search algorithm for CNN adopts a similar approach. It approximates a search range which is guaranteed to bound all the answer objects, issues a window query to retrieve all the objects inside the search range, and finally filters out those unqualified.

All the indexes mentioned above are based on a central tree-based structure, like R-tree and B-tree. However, employing a tree-based index on a linear broadcast channel to support spatial queries results in several deficiencies. First, clients can only start the search when they retrieve the root node in the channel. Replicating the index tree in multiple places in the broadcast channel provides multiple search starting points, shortening the initial root-probing time. However, a prolonged broadcast cycle leads to a long access latency experienced by the clients. Second, wireless broadcast media is not error-free. In case of losing intermediate nodes during the search process, the clients are forced to either restart the search upon an upcoming root node or scan the subsequential broadcast for other possible nodes in order to resume the search, thus extending the tuning time. *Distributed spatial index (DSI)*, a fully distributed spatial index structure, is motivated by these observations [5]. A similar distributed structure was proposed in [3] as well to support access to spatial data on air.

DSI is very different from tree-based indexes, and is not a hierarchical structure. Index information of spatial objects is fully distributed in DSI, instead of simply replicated in the broadcast. With DSI, the clients do not need to wait for a root node to start the search. The search process launches immediately after a client tunes into the broadcast channel and hence the initial probe time for index information is minimized. Furthermore, in the event of data loss, clients resume the search quickly.

Like HCI, DSI also adopts Hilbert curve to determine broadcast order of data objects. Data objects, mapped to point locations in a 2-D space, are broadcast in the ascending order of their HC index values. Suppose there are *N* objects in total, DSI chunks them into n_F *frames*, with each having n_o objects ($n_F = \lceil N/n_o \rceil$). The space covered by Hilbert Curve shown in Fig. 5 is used as a running example, with solid dots representing the locations of data objects (i.e., $N = 8$). Figure 6 demonstrates a DSI structure with n_o set to 1, i.e., each frame contains only one object.

In addition to objects, each frame also has an index table as its header, which maintains information



Air Indexes for Spatial Databases. Figure 6. Distributed spatial index.

regarding to the HC values of data objects to be broadcast with specific waiting interval from the current frame. This waiting interval can be denoted by delivery time difference or number of data frames apart, with respect to the current frame. Every index table keeps n_i entries, each of which, τ_j, is expressed in the form of $\langle HC'_j, P_j \rangle$, $j \in [0, n_i)$. P_j is a pointer to the r^j-th frame after the current frame, where r (> 1) is an exponential base (i.e., a system-wide parameter), and HC'_j is the HC value of the first object inside the frame pointed by P_j. In addition to τ_j, an index table also keeps the HC values HC_k ($k \in [1, n_o]$) of all the objects obj_k that are contained in the current frame. This extra information, although occupying litter extra bandwidth, can provide a more precise image of all the objects inside current frame. During the retrieval, a client can compare HC_ks of the objects against the one she has interest in, so the retrieval of unnecessary object whose size is much larger than an HC value can be avoided.

Refer to the example shown in Fig. 5, with corresponding DSI depicted in Fig. 6. Suppose $r = 2$, $n_o = 1$, $n_F = 8$, and $n_i = 3$. The index tables corresponding to frames of data objects O_6 and O_{32} are shown in the figure. Take the index table for frame O_6 as an example: τ_0 contains a pointer to the next upcoming (2^0-th) frame whose first object's HC value is 11, τ_1 contains a pointer to the second (2^1-th) frame with HC value for the first object (the only object) 17, and the last entry τ_2 points to the fourth (2^2-th) frame. It also keeps the HC value 6 of the object O_6 in the current frame. Search algorithm for window queries and kNN searches are proposed.

Key Applications

Location-based Service

Wireless broadcast systems, because of the scalability, provide an alternative to disseminate location-based information to a large number of users. Efficient air indexes enable clients to selectively tune into the channel and hence the power consumption is reduced.

Moving Objects Monitoring

Many moving objects monitoring applications are interested in finding out all the objects that currently satisfy certain conditions specified by the users. In many cases, the number of moving objects is much larger than the number of submitted queries. As a result, wireless broadcast provides an ideal way to deliver subscribed queries to the objects, and those objects that might affect the queries can then report their current locations.

AJAX

Alex Wun
University of Toronto, Toronto, ON, Canada

Definition

AJAX is an acronym for "Asynchronous JavaScript and XML" and refers to a collection of web development technologies used together to create highly dynamic web applications.

Key Points

AJAX does not refer to a specific technology, but instead refers to a collection of technologies used in conjunction to develop dynamic and interactive web applications. The two main technologies comprising AJAX are the JavaScript scripting language and the W3C open standard XMLHttpRequest object API. While the use of XML and DOM are important for standardized data representation, using neither XML nor DOM is required for an application to be considered AJAX-enabled since the XMLHttpRequest API actually supports any text format.

Using the XMLHttpRequest API, web applications can fetch data asynchronously while registering a callback function to be invoked once the fetched data is available. More concretely, the XMLHttpRequest object issues a standard HTTP POST or GET request to a web server but returns control to the calling application immediately after issuing the request. The calling application is then free to continue execution while the HTTP request is being handled on the server. When the HTTP response is received, the XMLHttpRequest object calls back into the function that was supplied by the calling application so that the response can be processed. The asynchronous callback model used in AJAX applications is analogous to the Operating System technique of using interrupt handlers to avoid blocking on I/O. As such, development using AJAX necessarily requires an understanding of multi-threaded programming.

There are three main benefits to using AJAX in web applications:

1. *Performance*: Since XMLHttpRequest calls are asynchronous, client-side scripts can continue execution after issuing a request without being blocked by potentially lengthy data transfers. Consequently, web pages can be easily populated with data fetched in small increments in the background.
2. *Interactivity*: By maintaining long-lived data transfer requests, an application can closely approximate real-time event-driven behavior without resorting to periodic polling, which can only be as responsive as the polling frequency.
3. *Data Composition*: Web applications can easily pull data from multiple sources for aggregation and processing on the client-side without any dependence on HTML form elements. Data composition is also facilitated by having data adhere to standard XML and DOM formats.

The functionality provided by AJAX allows web applications to appear and behave much more like traditional desktop applications. The main difference is that data consumed by the application resides primarily out on the Internet – one of the concepts behind applications that are labeled as being representative "Web 2.0" applications.

Qualitative relations between time intervals; Qualitative temporal constraints between time intervals

Definition

A (convex) *time interval* I is the set of all time points between a starting point (usually denoted by I^-) and an ending point (I^+). Allen's relations model all possible relative positions between two time intervals [1]. There are 13 different possibilities, depending on the relative positions of the endpoints of the intervals (Table 1).

For example, "There will be a guest speaker during the Database System class" can be represented by Allen's relation I_{Guest} *During* $I_{Database}$ (or by $I^-_{\text{Guest}} > I^-_{\text{Database}} \wedge I^+_{\text{Guest}} < I^+_{\text{Database}}$ considering the relative

Allen's Relations. Figure 1. Visualization of Allen's interval relations.

position of the endpoints. Moreover, any subset of the 13 relations, excluding the empty subset, is a relation in Allen's Interval Algebra (therefore, there are 2^{13}-1 relations in Allen's Algebra). Such subsets are used in order to denote ambiguous cases, in which the relative position of two intervals is only partially known. For instance, I_1 (Before, Meets, Overlaps) I_2 represents the fact that I_1 is before *or* meets *or* overlaps I_2.

Key Points

In many cases, the exact time interval when facts occur is not known, but (possibly imprecise) information on the relative temporal location of facts is available. Allen's relations allow one to represent such cases of *temporal indeterminacy*. For instance, planning in Artificial Intelligence is the first application of Allen's relations. A graphical representation of the basic 13 Allen's relations is shown in Fig. 1.

Allen's relations are specific cases of *temporal constraints*. Namely, they are qualitative temporal constraints between time intervals. Given a set of such constraints, *qualitative temporal reasoning* can be used in order to make inferences (e.g., to check whether the set of constraints is consistent).

Finally, notice that, in many entries of this Encyclopedia, the term *(time) period* has been used with the same meaning of *(time) interval* in this entry.

AMOSQL

Peter M. D. Gray
University of Aberdeen, Aberdeen, UK

Definition

AMOSQL [2] is a functional language having its roots in the functional query languages OSQL [1] and DAPLEX [5] with extensions of mediation primitives, multi-directional foreign functions, late binding, *active rules*, etc. Queries are specified using the select–from–where construct as in SQL. Furthermore, AMOSQL has aggregation operators, nested subqueries, disjunctive queries, quantifiers, and is relationally complete.

AMOSQL is a functional query language operating within the environment of Amos II , which is an open, light-weight, and extensible database management system (DBMS) with a functional data model. Each Amos II server contains all the traditional database facilities, such as a storage manager, a recovery manager, a transaction manager, and a query language. The system can be used as a single-user database or as a multi-user server to applications and to other Amos II peers. It has mainly been used for experiments with Mediators [4].

Key Points

AMOSQL is often used within a distributed mediator system where several mediator peers communicate over the Internet. Functional views provide transparent access to data sources from clients and other mediator peers. Amos II mediators are composable since a mediator peer can regard other mediator peers as data sources. In AMOSQL [2] the top-level language uses function application within an SQL-like syntax, for example to list children of a particular parent who like sailing:

```
create function sailch(person p) ->
string as
select name(c) from person c
where parent(c) = p and hobby(c) =
'sailing';
```

This is turned internally into a typed object comprehension.

```
sailch(p) == [name(c) | c <- person; par-
ent(c)=p; hobby(c) = 'sailing']
```

Some functions may be defined as views on other databases accessed through mediators. In the comprehension form, such functions may easily be substituted because of referential transparency, leading to a longer conjunction with extra clauses [3].

Suppose information about `hobby(c)` was held in connection with `sports-person`, a subclass of person with a `surname` attribute:

```
hobby(c) == [recreation(x) | x <- sports-
person; surname(x) = name(c)]
```

These comprehensions merge into the following which can be further simplified:

```
sailch(p) == [name(c) | c <- person; par-
ent(c)=p; x <- sportsperson;
surname(x) = name(c); recreation(x) =
'sailing']
```

Note that the internal form of comprehension does not explicitly distinguish the use of generators but simply use equality as in a filter. The conceptual advantage of this is that generators are not always a fixed role and some optimizations may reverse the role of filter and generator (systems with explicit generators use rewrite rules to do this).

AMS Sketch

ALIN DOBRA
University of Florida, Gainesville FL, USA

Synonyms

AGMS sketch; Sketch; Tug-of-war sketch

Definition

AMS sketches are randomized summaries of the data that can be used to compute aggregates such as the second frequency moment (the self-join size) and sizes of joins. AMS sketches can be viewed as random projections of the data in the frequency domain on ± 1 pseudo-random vectors. The key property of AMS sketches is that the product of projections on the same random vector of frequencies of the join attribute of two relations is an unbiased estimate of the size of join of the relations. While a single AMS sketch is inaccurate, multiple such sketches can be computed and combined using averages and medians to obtain an estimate of any desired precision.

Historical Background

The AMS sketches were introduced in 1996 by Noga Alon, Yossi Matias, and Mario Szegedy as part of a suit of randomized algorithms for approximate computation of frequency moments. The same authors, together with Phillip Gibbons, extended the second frequency moment application of AMS sketches to the computation of the size of join of two relations, a more relevant database application. The initial work on AMS sketches fostered a large amount of subsequent work on data streaming algorithms including generalizations and extensions of AMS sketches. Alon, Matias, and Szegedy received the Gödel Prize in 2005 for their work on AMS sketches.

Foundations

While the AMS sketches were initially introduced to compute the second frequency moment, since the reader might be more familiar with database terminology, the problem of estimating the size of join of two relations will be considered here instead. Notice that the size of the self join size of a relation coincides with the second frequency moment of the relation thus the treatment here is slightly more general but not more complicated.

Problem Setup

To set up the problem, assume access is provided to two relations F and G each with a single attribute a. Since it is convenient, denote with f_i and g_i the frequency of value i of attribute a in relation F and G, respectively. Assume that elements of F and G are streamed the result of the query: COUNT$(F \bowtie_a G)$ needs to be computed or estimated. Consider the following example:

$$\text{Stream } F\colon \boxed{\begin{array}{c|cccccc} \text{a} & 1 & 1 & 2 & 3 & 1 & 3 \end{array}},$$

$$\text{frequency vector } \mathbf{f}\colon \begin{array}{c|ccc} i & 1 & 2 & 3 \\ \hline f_i & 3 & 1 & 2 \end{array}$$

$$\text{Stream } G\colon \boxed{\begin{array}{c|ccccc} \text{a} & 3 & 1 & 3 & 1 & 1 \end{array}},$$

$$\text{frequency vector } \mathbf{g}\colon \begin{array}{c|ccc} i & 1 & 2 & 3 \\ \hline g_i & 3 & 0 & 2 \end{array}$$

Elements of F and G are assumed to arrive one by one (i.e., are streamed). If the frequency vectors **f** and **g** can be maintained, than the result of the query COUNT $(F \bowtie\ _aG)$ can be computed clearly in the following example:

$$\begin{aligned} \text{COUNT}(F \bowtie_\alpha G) &= \mathbf{f}\mathbf{g}^T \\ &= [3 \quad 1 \quad 2][3 \quad 0 \quad 2]^T \\ &= 3 \cdot 3 + 1 \cdot 0 + 2 \cdot 2 \\ &= 13 \end{aligned}$$

Observe that the size of join can be written as the dot product of the frequency vectors of the two relations. Expressing the size of the join in terms of frequencies of the join attribute is key for AMS sketch based approximation.

Main Idea

Assume now that the estimate COUNT$(F \bowtie\ _aG)$ needs to be computed but only less than linear space, in terms of the size of the frequency vectors, is available. As it turns out, exact computation is not possible with less space (in an asymptotic sense), but approximate computation is possible. The AMS sketches prove that they allow the approximation of the size of join using sub-linear space.

The main idea behind AMS sketches is to summarize the entire frequency table by projecting it on a random vector. The value thus obtained will be referred to as an elementary sketch. Then, use the two elementary sketches, one for each relation, to recover approximately the result of the query. Interestingly, a random vector $\xi = [\xi_1 \ldots \xi_n]$ of ± 1 values suffices to obtain projections with the desired properties. For simplicity, random vectors for which $\forall i$, $E[\xi_i] = 0$ are preferred. With this:

Sketch of F, $X_F = \text{f}\xi^T$

- Sketch of G, $X_G = \text{g}\xi^T$
- $X = X_F X_G$ estimates COUNT$(F \bowtie_a G)$ since

$$E[X] = E[\mathbf{f}\xi^T\xi\mathbf{g}^T] = \mathbf{f}E[\xi^T\xi]\mathbf{g}^T = \mathbf{f}I\mathbf{g}^T = \mathbf{f}\mathbf{g}^T$$

if $E[\xi^T \xi] = I$. To ensure this, property distinct elements of ξ must be pair-wise independent, i.e., $\forall i \neq i', \ \xi_i^2 = 1, \ E[\xi_i \xi_{i'}] = 0$

For the particular random vector $\xi = [\xi_1 \ \ \xi_2 \ \ \xi_3] = [-1 + 1 - 1]$, the value of the elementary sketches and the overall estimate will be:

$$X_F = \mathbf{f}\xi^T = -4$$
$$X_G = \mathbf{g}\xi^T = -5$$
$$X = X_F X_G = (-4)(-5) = 20 \approx 13$$

The error of the estimate X is due to its variance that can be shown to have the property:

$$\mathrm{Var(X)} \leq 2\mathbf{ff}^{\mathrm{T}}\mathbf{gg}^{\mathrm{T}} = 2 \ \mathrm{SJ(F)} \ \mathrm{SJ(G)}$$

as long as the random vector ξ is 4-wise independent, i.e., $\forall i_1 \neq i_2 \neq i_3 \neq i_4, \ E[\xi_{i_1} \xi_{i_2}] = 0, \ E[\xi_{i_1} \xi_{i_2} \xi_{i_3} \xi_{i_4}] = 0$

Since a higher degree of independence would not make the sketch more precise, 4-wise independence suffices. This is important since 4-wise independent ± 1 random vectors can be generated *on the fly* by combining a small seed s and the index of the entry using $\xi_i(s) = h(s,i)$ with h a special hash function that guarantees the 4-wise independence of the components of ξ. The fact that elements of ξ can be generated on the fly is important since space can be saved and, more importantly, because sketches X_F and X_G can be computed using constant storage. This is how this can be accomplished using the previous example:

$$X_F = \mathbf{f}\xi^T = \sum_i f_i \xi_i$$
$$= \sum_{t \in F} \xi_{t.a} = \xi_1 + \xi_1 + \xi_2 + \xi_3 + \xi_1 + \xi_3$$
$$= h(s,1) + h(s,1) + h(s,2) + h(s,3) + h(s,1) + h(s,3)$$

$$X_G = \mathbf{g}\xi^T = \sum_i g_i \xi_i$$
$$= \sum_{t \in G} \xi_{t.a} = \xi_3 + \xi_1 + \xi_3 + \xi_1 + \xi_1$$
$$= h(s,3) + h(s,1) + h(s,3) + h(s,1) + h(s,1)$$

From this example, it can be observed that, to maintain the elementary sketches over the streams F and G, the only operation needed is to increment X_F and X_G by the value of $\xi_{t.a}$ using the function $h(\cdot)$ and the seed s where $t.a$ is the value of attribute a of the current tuple t arriving on the data stream. The fact that the elementary sketches can be computed so easily by considering one element at the time in an arbitrary order is what makes the AMS sketches appealing as an approximation technique.

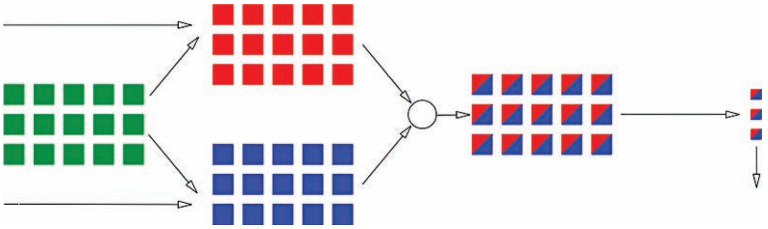
Improving the Basic Schema

Since the streams F and G are summarized by a single number X_F and X_G, respectively, it is not expected that the estimate will be very precise (this is suggested as well by the above example). In order to improve the accuracy of X, a standard technique in randomized algorithms can be used (i.e., generating multiple independent copies of random variable X). Copies of X are averaged in order to decrease the variance (thus the error). The median of such averaged values of X is used to estimate $\mathrm{COUNT}(F \bowtie_a G)$ since medians improve confidence. Multiple copies of X can be obtained using multiple seeds as depicted in Fig. 1.

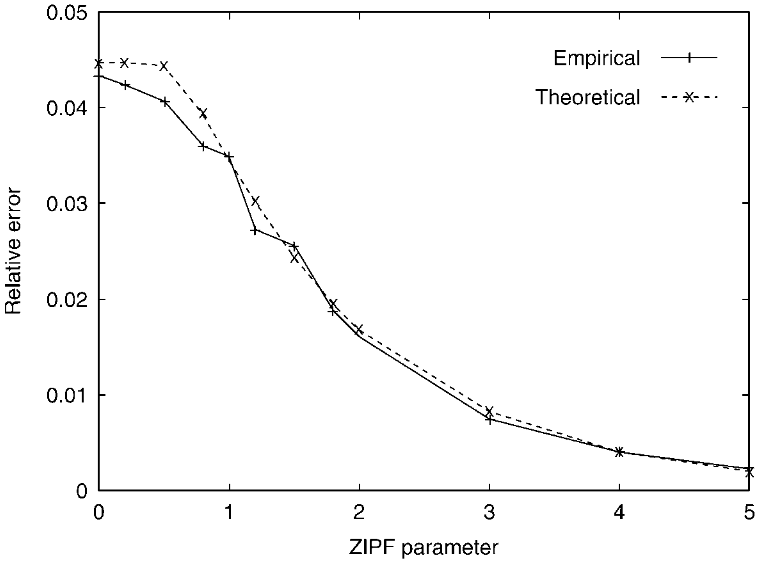
It can be shown that:

Average $\frac{8\mathrm{Var(X)}}{\epsilon^2 E^2[X]}$ independent copies of X to reduce error to $\in$

- Median of 2 log $1/\delta$ such averages increases the confidence to $1 - \delta$



AMS Sketch. Figure 1. Combining elementary sketches to estimate $\mathrm{COUNT}(F \bowtie_a G)$ with relative error at most $\in$ with probability at least $1 - \delta$.



AMS Sketch. Figure 2. Relative error of AMS sketches as a function of Zipf coefficient.

Key Applications

AMS sketches are particularly well suited for computing aggregates when data is either streamed (or a single pass over the data is allowed/desirable) or distributed at multiple sites. Thus, AMS sketches are relevant for processing large amount of data, as is the case in data warehousing, or processing distributed/streaming data, as is the case for computing networking statistics.

Experimental Results

To get an understanding of how the AMS sketches perform in the problem of estimating the self join size of a relation, consider the following setup. The domain of the attribute on which the self join size is computed is set to 16,384. The seize of the relation is fixed at 100,000 tuples. The distribution of the frequencies of join attribute values are generated according to a Zipf distribution with a varying Zipf coefficient. The number of medians is set to 1 (no median computation) and the number of elementary sketches averaged is set to 1,024.

The relative error, both theoretical and empirical, of AMS sketches is depicted in Fig. 2. The following observations confirm the intuition based on theory for the behavior of AMS sketches: (i) on the self join size problem the error is acceptable for sketches of size in the order of 2,000 words, (ii) the error decreases somewhat as the skew increases, and (iii) the theoretical prediction follows entirely the empirical behavior.

Synonyms

Anchor; Anchor text surrogate

Definition

Anchor text is the text associated with a hyperlink pointing from one Web document to another. Anchor text provides a concise description of a document, not necessarily written by the author of the document. It is very effective in Web search retrieval tasks, and in particular, in tasks where the aim is to find the home page of a given website.

Key Points

Hyperlink analysis algorithms explicitly employ the hyperlinks between Web documents to find high quality or authoritative Web documents. A form of implicit use of the hyperlinks in combination with content analysis is the use anchor text associated with the incoming hyperlinks of documents. Web documents can be represented by an anchor text surrogate, which is formed by collecting the anchor text associated with the hyperlinks pointing to the document.

The anchor text of the incoming hyperlinks provides a concise description for a Web document. The used terms in the anchor text may be different from the ones which occur in the document itself, because the author of the anchor text is not necessarily the author of the document. Eiron and McCurley [2] found similarities in the distribution of terms between the anchor text of Web documents and the queries submitted to an intranet search engine by users. Similarities were also found in the use of abbreviations and technical terms.

Craswell et al. [1] show that anchor text is effective for navigational search tasks and more specifically for finding home pages of Web sites. They report that searching for home pages of websites using an index of anchor text performs better than using an index of the document contents. Upstill et al. [3] also suggest that the anchor text of the incoming hyperlinks from documents outside a corpus of documents enhances the retrieval effectiveness for homepage finding.

Annotation

Amarnath Gupta
University of California, San Diego, La Jolla, CA, USA

Definition

An annotation is any form of additional information "superposed" on any existing data or document.

Example: If a scientist records her experimental data in a relational database and then marks some "cells" of a table with the comment "consistent with previous findings," this additionally "marked" information is an annotation.

Key Points

Often annotations are not originally intended to be part of the collected data, and hence no data or schema structure was designed to hold it. Annotating data is a very common practice in science, where scientists would literally "mark" experimental observation with comments, and often use annotations to share their opinions in a collaborative study. As larger scale experiments are conducted and larger collaborations are formed, management of the annotated data becomes a serious challenge. In recent times, the emerging importance of annotation in scientific data management has been recognized by the Information Management community, leading to a variety of research in annotation management.

Annotation-based Image Retrieval

Xin-Jing Wang, Lei Zhang
Microsoft Research Asia, Beijing, China

Synonyms

Semantic image retrieval; Text-based image retrieval; Tag-based image search; Tag-based image retrieval

Definition

Given (i) a textual query, and (ii) a set of images and their annotations (phrases or keywords), annotation-based image retrieval systems retrieve images according to the matching score of the query and the corresponding annotations. There are three levels of queries according to Eakins [7]:

- Level 1: Retrieval by primitive features such as color, texture, shape or the spatial location of image elements, typically querying by an example, i.e., "find pictures like this."
- Level 2: Retrieval by derived features, with some degree of logical inference. For example, "find a picture of a flower."
- Level 3: Retrieval by abstract attributes, involving a significant amount of high-level reasoning about the purpose of the objects or scenes depicted. This includes retrieval of named events, of pictures with emotional or religious significance, etc., e.g., "find pictures of a joyful crowd."

Together, levels 2 and 3 are referred to as semantic image retrieval, which can also be regarded as annotation-based image retrieval.

Historical BackGround

There are two frameworks of image retrieval [6]: annotation-based (or more popularly, text-based) and content-based. The annotation-based approach can be tracked back to the 1970s. In such systems, the images are manually annotated by text descriptors, which are used by a database management system (DBMS) to perform image retrieval. There are two disadvantages with this approach. The first is that a considerable level of human labor is required for manual annotation. The second is that because of the subjectivity of human perception, the manually labeled annotations may not converge. To overcome the above disadvantages, content-based image retrieval (CBIR) was introduced in the early 1980s. In CBIR, images are indexed by their visual content, such as color, texture, shapes. In the past decade, several commercial products and experimental prototype systems were developed, such as QBIC, Photobook, Virage, VisualSEEK, Netra, SIMPLIcity. Comprehensive surveys in CBIR can be found in [7,8].

However, the discrepancy between the limited descriptive power of low-level image features and the richness of user semantics, which is referred to as the "semantic gap" bounds the performance of CBIR. On the other hand, due to the explosive growth of visual data (both online and offline) and the phenomenal success in Web search, there has been increasing expectation for image search technologies. Because of these reasons, the main challenge of image retrieval is understanding media by bridging the semantic gap between the bit stream and the visual content interpretation by humans [3]. Hence, the focus is on automatic image annotation techniques.

Foundations

The state-of-the-art image auto-annotation techniques include four main categories [3,6]: (i) using machine learning tools to map low-level features to concepts, (ii) exploring the relations among image content and the textual terms in the associated metadata, (iii) generating semantic template (ST) to support high-level image retrieval, (iv) making use of both the visual content of images and the textual information obtained from the Web to learn the annotations.

Machine Learning Approaches

A typical approach is using Support Vector Machine (SVM) as a discriminative classifier over image low-level features. Though straightforward, it has been shown effective in detecting a number of visual concepts.

Recently there is a surge of interest in leveraging and handling relational data, e.g., images and their surrounding texts. Blei et al. [1] extends the Latent Dirichlet Allocation (LDA) model to the mix of words and images and proposed a Correlation LDA model. This model assumes that there is a hidden layer of topics, which are a set of latent factors and obey the Dirichlet distribution, and words and regions are conditionally independent on the topics, i.e., generated by the topics. This work used 7,000 Corel photos and a vocabulary of 168 words for annotation.

Relation Exploring Approaches

Another notable direction for annotating image visual content is exploring the relations among image content and the textual terms in the associated metadata. Such metadata are abundant, but are often incomplete and noisy. By exploring the co-occurrence relations among the images and the words, the initial labels may be filtered and propagated from initial labeled images to additional relevant ones in the same collection [3].

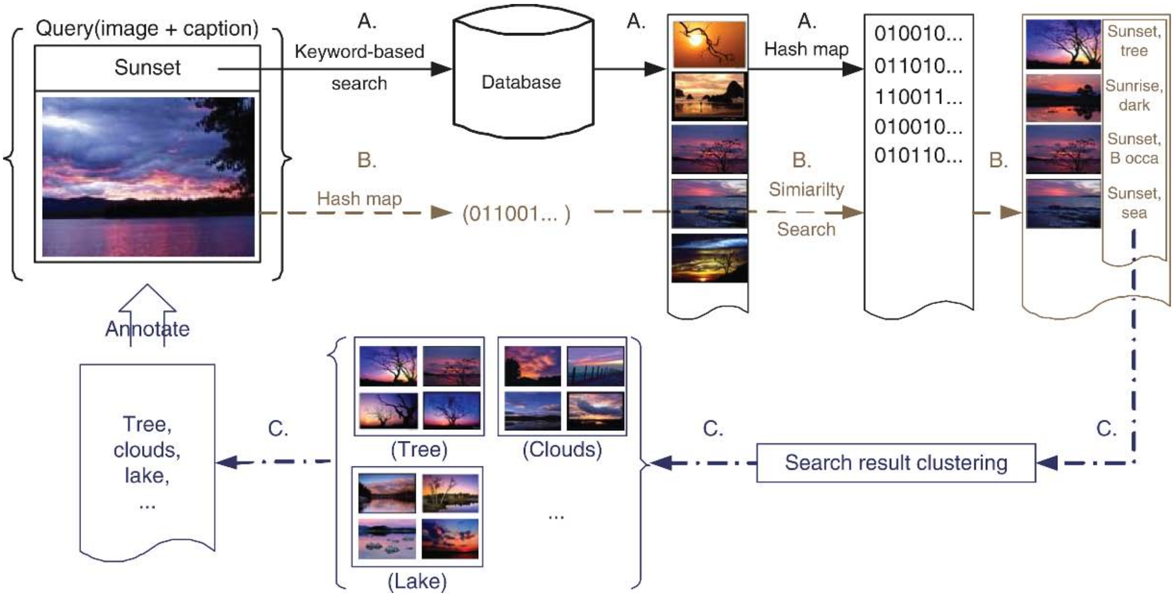
Jeon et al. [5] proposed a cross-media relevance model to learn the joint probabilistic distributions of the words and the visual tokens in each image, which are then used to estimate the likelihood of detecting a specific semantic concept in a new image.

Semantic Template Approaches

Though it is not yet widely used in the above mentioned techniques, Semantic Template (ST) is a promising approach in annotation-based image retrieval (a map between high-level concept and low-level visual features).

Chang and Chen [2] show a typical example of ST, in which a visual template is a set of icons or example scenes/objects denoting a personalized view of concepts such as meetings, sunset. The generation of a ST is based on user definition. For a concept, the objects, their spatial and temporal constraints, and the weights of each feature of each object are specified. This initial query scenario is provided to the system, and then through the interaction with users, the system finally converges to a small set of exemplar queries that "best" match (maximize the recall) the concept in the user's mind.

In contrast, Zhuang et al. [10] generates ST automatically in the process of Relevance Feedback, whose basic idea is to refine retrieval outputs based on interactions with the user. A semantic lexicon called WordNet is used in this system to construct a network of ST. During the retrieval process, once the user submits a query concept (keyword), the system can find a corresponding ST, and thus target similar images.



Annotation-based Image Retrieval. Figure 1. Framework of the search-based annotation system.

Large-Scale Web Data Supported Approaches

Good scalability to a large set of concepts is required in ensuring the practicability of image annotation. On the other hand, images from the Web repositories, e.g., Web search engines or photo sharing sites, come with free but less reliable labels. In [9], a novel search-based annotation framework was proposed to explore such Web-based resources. Fundamentally, it is to automatically expand the text labels of an image of interest, using its initial keyword and image content.

The process of [9] is shown in Fig. 1. It contains three stages: the text-based search stage, the content-based search stage, and the annotation learning stage, which are differentiated using different colors (black, brown, blue) and labels (A., B., C.). When a user submits a query image as well as a query keyword, the system first uses the keyword to search a large-scale Web image database (2.4 million images crawled from several Web photo forums), in which images are associated with meaningful but noisy descriptions, as tagged by “A.” in Fig. 1. The intention of this step is to select a semantically relevant image subset from the original pool. Visual feature-based search is then applied to further filter the subset and save only those visually similar images (the path labeled by “B.” in Fig. 1). By these means, a group of image search results which are both semantically and visually similar to the query image are obtained. To speed-up the visual feature-based search procedure, a hash encoding algorithm is adopted to map the visual features into hash codes, by which inverted indexing technique in text retrieval area can be applied for fast retrieval. At last, based on the search results, the system collects their associated textual descriptions and applies the Search Result Clustering (SRC) algorithm to group the images into clusters. The reason of using SRC algorithm is that (i) it is proved to be significantly effective in grouping documents semantically; and (ii) more attractively, it is capable of learning a name for each cluster that best represents the common topics of a clusters member documents. By ranking these clusters according to a ranking function, and setting a certain threshold, the system selects a group of clusters and merges their names as the final learnt annotations for the query image, which ends the entire process (C. in Fig. 1).

Key Applications

Due to the explosive growth of visual data (both online and offline), effective annotation-based image search becomes a highly-expected technique which facilitate human’s lives.

Anomaly Detection on Streams

Spiros Papadimitriou
IBM T.J. Watson Research Center, Hawthorne,
NY, USA

Definition

Anomaly detection generally refers to the process of automatically detecting events or behaviors which deviate from those considered normal. It is an unsupervised process, and can thus detect anomalies which have not been previously encountered. It is based on estimating a model of typical behavior from past observations and consequently comparing current observations against this model. It can be performed either on a single stream or among multiple streams. Anomaly detection encompasses outlier detection as well as change detection and therefore is closely related to forecasting and clustering methods.

Historical Background

Anomaly detection in streams has close connections to traditional outlier detection, as well as to change detection. The former is a common and widely studied topic in statistics [11]. The latter emerged in the context of statistical monitoring and control for continuous processes and the widely used CUSUM algorithm was proposed as early as 1954 [9]. With the emergence of data stream management systems, anomaly detection in this setting has received significant attention, with applications in network management and intrusion detection, environmental monitoring, and surveillance, to mention a few.

Foundations

Anomaly detection is closely related to outlier detection and change detection. After a review of the main ideas, the streaming case is presented.

Outlier Detection

The existing approaches to outlier detection can be broadly classified into the following categories. Typically, outlier detection relies on a model for the data. Model parameters are estimated based on appropriately chosen historical data. As new observations arrive, they are either compared directly against the model and are declared outliers if the fit is poor. Alternatively, a second set of model parameters may be estimated from recent observations. If there is a statistically significant difference among the two sets of parameters, the new observations are declared as outliers.

Clustering-Based and Forecasting-Based Approaches

Many clustering and forecasting algorithms detect outliers as by-products. However, not all clustering or forecasting procedures can be easily turned into outlier detection procedures.

Distribution-Based Approaches Methods in this category are typically found in statistics textbooks. They deploy some standard distribution model (e.g., Gaussian) and flag as outliers those objects which deviate from the model. These work well in many occasions, but may be unsuitable for high-dimensional data sets, or when reasonable assumptions about the distribution of data points cannot be made.

Distance-Based and Density-Based Approaches A point in a data set is a distance-based outlier if at least a fraction β of all other points are further than r from it. This outlier definition is based on a single, global criterion determined by the parameters r and β. This can lead to problems when the data set has both dense and sparse regions. Density-based approaches aim to remedy this problem, by relying on the local density of each point's neighborhood.

Change Detection

Sequential hypothesis testing and sequential change detection arose out of problems in statistical process control. Assume a collected sequence of observations, modeled as random variables $X_1, X_2,..., X_t,...$ Additionally, assume that X_t are drawn from a distribution with parameter θ and that a test of whether the true parameter is θ_0 or θ_1 is desired.

The Sequential Likelihood Ratio Test (SLRT) relies on the logarithm of likelihood ratios $z_t := \log(p(x_t;\ \theta_0)/p(x_t;\ \theta_1))$ and tests the cumulative sum $z_1 + ... + z_t$ to decide upon the true parameter.

This can be extended to other settings, such as detecting changes in other distribution parameters. For example, in its simplest form, CUSUM tests for a shift in the mean by essentially applying SLRT, assuming points independently drawn from a Gaussian distribution with known variance. Many other versions have appeared since the CUSUM test was first proposed [9], relaxing or modifying some of these assumptions.

In general, change detection is closely related to outlier detection; in fact, change detection may also be viewed as outlier detection along the time axis.

Streaming Algorithms

In a streaming setting, there are two key challenges that need to be addressed:

1. *Limited resources.* In a streaming setting, a large number of observations arrives over time and the total volume of data grows indefinitely. However processing and storage capacity are limited, in comparison to the amount of data. Therefore, data summarization or *sketching* techniques need to be applied, in order to extract a few, relevant features from the raw data.
2. *Concept drift.* In an indefinitely growing collection of observations, changes in the underlying features (e.g., distribution parameters) may not necessarily correspond to anomalies, but rather be part of normal changes in the behavior of the system. Thus, mechanisms to handle such non-stationarity or *concept drift* and adapt to changing behavior are necessary [12].

Next, several of the approaches that have been studied in the literature are reviewed.

Sketching techniques In the past several years, a number of techniques for *sketch* or *synopsis* construction have appeared, with applications to many stream processing problems. Some examples include CM sketches, AMS sketches, FM sketches, and Bloom filters [2]. Other summarization techniques specifically for data clustering on streams have appeared, such as those in [1,4], which can be easily extended for outlier detection on streams.

Burst Detection In many applications, the appearance of sudden bursts in the data often signifies an anomaly. For example, in a network monitoring application, a burst in the traffic volume to a particular destination may signify a denial of service (DoS) attack. Thus, *burst detection* on streams has received significant attention. Examples of such work include [7] and [14].

Correlation Dnalysis Often a collection of multiple streams is available and measurements from different streams may be highly correlated with each other. If the strength of correlations changes over time [13] or the number of correlated components varies [10], this often signifies changes in the underlying data-generating process that may be due to anomalies.

Change Analysis More generally, detecting significant changes has been studied in the context of stream processing [3].

Key Applications

Intrusion Detection With the widespread adoption of the internet, various forms of malware (e.g., viruses, worms, trojans, and botnets) have become a serious and costly issue. Most intrusion detection systems (IDS) rely on known signatures to identify malicious payloads or behaviors. However, there are several efforts underway for automatic detection of suspicious activity on the fly, as well as for automating the signature extraction process.

System Monitoring Maintenance costs for large computer clusters or networks is traditionally labor-intensive and contributes a large fraction of total cost of ownership. Hence, autonomic computing initiatives aim at automating this process. An important first step is the automatic, unsupervised detection of abnormal events (e.g., node or link failures) based on continuously collected system metrics. Streaming anomaly detection methods are used to address this problem.

Process Control Applications in quality control and industrial process control have traditionally provided much of the impetus for the development of change detection methods. Machinery used in a production chain (e.g., food preparation or chip fabrication) typically monitor a large number of process parameters at each step. Early detection of sudden changes in those parameters is important to identify potential flaws in the process which can severely affect end product quality.

Pervasive Healthcare Small and cheap sensors which can continuously monitor patient physiological data (e.g., temperature, blood pressure, heart rate, ECG measurements, glucose levels, etc.) are becoming widely available. Anomaly detection methods can prove essential in enabling early diagnosis of potential life-threatening conditions, as well as preventive healthcare.

Civil Infrastructure Early detection of faults by continuously monitoring civil infrastructure components (e.g., bridges, buildings, and roadways) can reduce maintenance costs and increase safety. Similarly, surveillance systems on urban environments rely on anomaly detection methods to spot suspicious activities and increase security.

Future Directions

Certain anomalies can be detected only by taking into account information collected from a large number of different sources. Even if data ownership issues are resolved, collecting all this information at a central site is often infeasible due to its large volume. A number of efforts have tackled this problem in the past few years, but much remains to be done, especially as the scale of information collected increases. Also related to this trend is anomaly detection on more complex data, such as time-evolving graphs.

Anonymity

Simone Fischer-Hübner
Karlstad University, Karlstad, Sweden

Synonyms

Namelessness; Nonidentifiability

Definition

The term anonymity originates from the Greek word “anonymia,” which means “without a name.”

In the context of computing, anonymity has been defined in [2] as follows: “Anonymity of a subject means that the subject is not identifiable within a set of subjects, the anonymity set.” The anonymity set is the set of all possible subjects, e.g., the set of all possible senders of a message or the set of all possible recipients of a message (dependent on the knowledge of an attacker). *Sender anonymity* means that a message cannot be linked to the sender, while *receiver anonymity* implies that a certain message cannot be linked to the receiver of that message. Relationship anonymity of a sender and recipient means that even though a sender and a recipient can be identified as participating in some communication, they cannot be identified as communicating with each other, i.e., sender and recipient are unlinkable. The definition above corresponds to the definition of anonymity in [1]: “Anonymity of a user means that the user may use a resource or service without disclosing the user’s identity.”

To reflect the possibility to quantify anonymity, a slightly modified definition has also provided by [2]: “Anonymity of a subject from the attacker’s perspective means that the attacker cannot sufficiently identify the subject within a set of subjects, the anonymity set.”

Data protection legislation usually defines data as anonymous if information concerning personal or material circumstances can no longer (or with disappropriate amount of time, expense, and labor) be attributed to an individual.

Key Points

Providing anonymity is the best strategy for achieving privacy. If individuals can act anonymously and if their data are kept in an anonymous form, their privacy is not affected (and consequently, data protection legislation is not applicable).

For providing anonymity, however, it has to be guaranteed that potential attackers cannot or not sufficiently identify the individuals. Proposals for measuring the degree of anonymity are usually based on Shannon’s entropy.

ANSI/INCITS RBAC Standard

YUE ZHANG, JAMES B. D. JOSHI
University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

RBAC standard

Definition

The ANSI/INCITS RBAC standard includes the *core*, *hierarchical*, and the *constraint RBAC* models [1]. The *core RBAC* includes the following entities:

- $USERS$, $ROLES$, OPS, and OBS are the sets of users, roles, operations and objects, respectively.
- $UA \subseteq USERS \times ROLES$ is a many-to-many mapping from $USERS$ to $ROLES$.
- $assigned\_users$: $(r{:}ROLES) \rightarrow 2^{USERS}$, is mapping of role r onto a set of users. Formally: $assigned\_users\ (r) = \{u \epsilon USERS \mid (u, r)\ \epsilon\ UA\}$
- $PRMS = 2^{(OBS\ \times\ OPS)}$ is the set of permissions.
- $PA \subseteq PERMS \times ROLES$ is a many-to-many mapping from $PERMISSIONS$ to $ROLES$.
- $assigned\_permissions(r{:}ROLES) \rightarrow 2^{\mathrm{PRMS}}$, is mapping of role r onto a set of permissions. Formally: $assigned\_permissions(r) = \{p \epsilon PRMS \mid (p, r)\ \epsilon\ PA\}$
- $Op(p{:}\ PRMS) \rightarrow \{op \subseteq OPS\}$, is the permission to operation mapping.
- $Ob(p{:}\ PRMS) \rightarrow \{ob \subseteq OBS\}$, is the permission to object mapping.
- $SESSIONS$ = the set of sessions
- $session\_users\ (s{:}SESSIONS) \rightarrow USERS$ is mapping of session s onto the corresponding user.

– *session_roles* (*s*:*SESSIONS*) → 2^{ROLES} is mapping of session *s* onto a set of roles.

– *avail_session_perms*(*s*:*SESSIONS*) → 2^{PRMS} gives the permissions available to a user in a session =

$$\left[\bigcup_{r\in session\_roles(s)} assigned\_permissions(r)\right]$$

The *hierarchical RBAC* model extends the core RBAC model with the *general* and *restricted* role hierarchies. The *general role hierarchy* is defined below:

- $RH \subseteq ROLES \times ROLES$ is a partial order on *ROLES*, written as ≥, where $r_1 \geq r_2$ only if all permissions of r_2 are also permissions of r_1, and all users of r_1 are also users of r_2.
- *authorized_users*(*r*: *ROLES*) → 2^{USERS}, is mapping of role *r* onto a set of users in the presence of a role hierarchy. Formally: $authorized\_users(r) = \{u \in USERS \mid r' \geq r, (u, r') \in UA\}$.
- *authorized_permissions*(*r*: *ROLES*) → 2^{PRMS}, is mapping of role *r* onto a set of permissions in the presence of a role hierarchy. Formally: $authorized\_permissions(r) = \{p \in PRMS \mid r' \geq r, (p, r') \in PA\}$

The *restricted hierarchy* is similar to the *general role hierarchies* with the following limitation:

$$\forall r,\ r_1,\ r_2 \in ROLES, \quad r \geq r_1 \wedge r \ \geq r_2 \Rightarrow r_1 = r_2$$

The *constraint RBAC* model extends the hierarchical RBAC with *Static Separation of Duty* (SSoD) and *Dynamic SoD* (DSoD) constraints.

SSoD Constraint: $SSD \subseteq (2^{ROLES} \times N)$ is a collection of pairs (*rs*, *n*) in *Static Separation of Duty*, where each *rs* is a role set, and *n* is a natural number ≥ 2, with the property that no user is assigned to *n* or more roles from the set *rs* in each (*rs*, *n*) *SSD*.

DSoD Constraint: $DSD \subseteq (2^{ROLES} \times N)$ is collection of pairs (*rs*, *n*) in *Dynamic Separation of Duty*, where each *rs* is a role set and *n* is a natural number ≥2, with the property that no subject may activate *n* or more roles from the set *rs* in each *dsd DSD*.

Key Points

The ANSI/INCTIS RBAC standard essentially evolved from the original RBAC96 model [2]. Several advanced features of RBAC such as cardinality constraints, hybrid hierarchy, much fine-grained SoD constraints, features related to the administration of RBAC, etc., are not covered in the standard. The link (http://csrc.nist.gov/groups/SNS/rbac/standards.html) includes the most updated information on ANSI RBAC.

Query rewriting using views

Definition

Answering queries using views refers to a data management problem and the set of related techniques, algorithms and other results to address it. The basic formulation of the problem is the following: Given a query *Q* over a database schema Σ, expressed in a query language L_Q and a set of views $V_1, V_2,..., V_n$ over the same schema, expressed in a query language L_V, is it possible to answer the query *Q* using (only) the views $V_1, V_2,..., V_n$?

The problem has a number of related formulations: What is the *maximal set* of tuples in the answer of *Q* that can be obtained from the views? If it is possible to access both the views and the database relations, what is the cheapest query execution plan for answering *Q*?

From the above, it is clear that this is more generally a family of problems. Problems of different complexity, often admitting different (or no) solutions and solution techniques, result from making choices about various "parameters" of the original problem. For example, one can choose the languages L_Q and L_V, the language L_R used to answer *Q* from the views, the ability to access the relations of the schema Σ, the possible existence of constraints, e.g., equality-generating or tuple-generating dependencies, as well as the semantics of the views (sound, complete, or both).

The problem is also referred to as query rewriting using views.

Historical Background

The problem of putting together information from multiple sources has a relatively long history within the database community. In the 1970s, distributed databases offered a controlled solution to the problem: the data are structured with a single schema and are put under the control of a single, albeit distributed, database system. In the early 1980s, the challenges of integrating full-fledged relational databases was studied in the context of multidatabases. An important direction of multidatabase research was static schema integration, i.e., creating in advance a single new schema with as much of the information of the original schemas as possible. Query processing could then be performed on the integrated schema. "Reusing" the original database tables also received some attention in the multidatabase context. In the early 1990s, techniques were developed in order to make use of existing materialized views to speed up the processing of queries that did not mention them explicitly. These techniques were precursors to the more general techniques developed a few years later for the problem of answering queries using views. The problem was cast in its current form in a seminal paper by Levy, Mendelzon, Sagiv, and Srivastava in 1995.

Foundations

Preliminaries

To fully specify the problem of answering queries using views one needs to decide on the languages used for the queries, the views and, in some cases, the rewritings. This entry presents the basic case of answering *conjunctive queries* using *conjunctive views*, possibly in the presence of constraints. The relevant definitions are presented next. Techniques developed for different languages or data models, such as bag queries (and views), XML queries, queries with aggregates, etc., can be found in the Recommended Reading list. Moreover, detailed presentations of the techniques discussed in the article, including exceptions, optimizations, and other technical issues, can be found in the research articles on the Recommended Reading list.

Conjunctive Queries A *conjunctive* query can be represented as:

$$q(\bar{X}) \leftarrow s_1(\bar{X}_1) \wedge \ldots \wedge s_n(\bar{X}_n)$$

where q and $s_1,\ldots,s_n$ are predicate names. In general, $s_1,\ldots,s_n$ refer to database relations. The atoms $s_1(\bar{X}_1),\ldots,$ $s_n(\bar{X}_n)$ that appear in the body of the query are called *subgoals* of the query, The atom $q(\bar{X})$ is called the *head* of the query and defines the answer relation. The tuples $\bar{X}$, $\bar{X}_1,\ldots,\bar{X}_n$ contain either variables or constants. The variables in $\bar{X}$ are the *distinguished* variables of the query, the rest of the variables are the *existential* variables. An important condition for a conjunctive query is *safety*: A query is safe if $\bar{X} \subseteq \bar{X}_1 \cup \ldots \cup \bar{X}_n$, i.e., every distinguished variable must also appear in a query subgoal.

Use $Vars(Q)$ and $Subg(Q)$ to refer to the set of variables (and constants) in Q and subgoals of Q respectively. $Q(D)$ refers to the result of evaluating the query Q over the database D.

Views A *view* is a query whose head defines a new database relation. If this relation is not stored, the view is called a *virtual* view. If the results of executing the view are stored, it is called a *materialized* view and the relation is the *extension* of the view. Denote by D_V the database D extended with the extensions of the views belonging to a view set V.

Containment & Equivalence The concepts of query containment and equivalence are central to query rewriting theory [ref Encyclopedia article Query Rewriting] as they are used to test the correctness of a rewriting of a query using a set of views.

Definition 1 *A query Q_1 is contained in a query Q_2, denoted $Q_1 \sqsubseteq Q_2$, if for all database instances D, the set of tuples computed for Q_1 is a subset of those computed for Q_2, i.e., $Q_1(D) \subseteq Q_2(D)$. The two queries are equivalent if $Q_1 \sqsubseteq Q_2$* and $Q_2 \sqsubseteq Q_1$.

Containment mappings provide a necessary and sufficient syntactic condition for testing query containment of conjunctive queries.

Definition 2 *A mapping τ from $Vars(Q_2)$* to $Vars(Q_1)$ is a *containment mapping if*

- *It is the identity on constants*
- *It maps every subgoal in$Subg(Q_2)$ to a subgoal in$Subg(Q_1)$, and*

- *It maps the head of Q_2 to the head of Q_1.*

A seminal result in semantic query optimization is that a query Q_1 is contained in Q_2 if and only if there is a containment mapping from Q_2 to Q_1.

Rewritings

Given a query Q and a set of views $V_1, V_2,..., V_n$ over the same database schema, the goal is to find an *equivalent rewriting* Q' of the query, i.e., a query Q' that uses one or more of the views in the body.

Definition 3 *A query Q' is an equivalent rewriting of query Q that uses the set of views $V = \{V_1, V_2,..., V_n\}$* if

- *Q and Q' are equivalent, and*
- *Q' refers to the views in V.*

For every database D, Q' is evaluated over D_V. A rewriting Q' is *locally minimal* if no literals from Q' can be removed while retaining equivalence to Q. A rewriting is *globally minimal* if there is no other rewriting with fewer literals. If the rewriting refers *only* to the views in V and to no other relations then the rewriting is called *complete*. When looking for rewritings, it is preferable to find those that are cheaper to evaluate than the original query. Below is an example of a query and a rewriting using views.

Example 1: Consider the following query Q and view V

$$Q : q(X, U) \leftarrow p(X, Y) \wedge p_0(Y, Z) \wedge p_1(X, W) \wedge p_2(W, U).$$

$$V : v(A, B) \leftarrow p(A, C) \wedge p_0(C, B) \wedge p_1(A, D).$$

Q can be rewritten using V as follows:

$$Q' : q(X, U) \leftarrow v(X, Z) \wedge p_1(X, W) \wedge p_2(W, U).$$

By substituting the view, the first two literals of the query can be removed. However, although the third literal in Q is guaranteed to be satisfied by V, it cannot be removed from the query, as the variable D is projected out in the head of V. Hence, if p_1 were removed from the query, the join condition between p_1 and p_2 could not be enforced.

In several settings, *maximally contained* rewritings need to be considered. Unlike equivalent rewritings, maximally contained rewritings may differ depending on the language used to express the rewritings. Therefore, the following definition depends on a particular query language:

Definition 3 *Let Q be a query and $V = \{V_1,..., V_m\}$ be a set of views over the same database schema, and L be a query language. The query Q' is a maximally contained rewriting of Q* using *V with respect to L* if:

- *Q' is a query in L that refers only to the views in V,*
- *$Q' \sqsubseteq Q$, and*
- *for every rewriting $Q_1 \in L$, such that $Q_1 \sqsubseteq Q$, $Q_1 \sqsubseteq Q'$.*

Characterizing Rewritings

Answering queries using views is closely related to the problem of query containment. The following proposition provides a necessary and sufficient condition for the existence of a rewriting of Q that includes a view V.

Proposition 1 *Let Q* and *V be conjunctive queries with built-in predicates. There is a rewriting of Q using V* if and only if $\pi_\emptyset(Q) \sqsubseteq \pi_\emptyset(V)$*, i.e., the projection of Q onto the empty set of columns is contained in the projection of V onto the empty set of columns.*

This proposition provides a complete characterization of the problem of using views for query answering. Two other important characteristics of the problem are that, for conjunctive queries and views, a rewriting that does not introduce new variables and does not include database relations that do not appear in the original query, can always be found. These characteristics allow significant pruning of the search space for a minimal rewriting of Q, but do not always hold for more expressive settings of the problem. Finally, a minimal rewriting of a query Q using a set of views V without built-in predicates does not need more than the number of literals in the query. In particular, *if the body of Q has p literals and Q' is a locally minimal and complete rewriting of Q using V, then Q' has at most p literals.*

The bound provided above does not hold when the database relations have functional dependencies. In such a case the size of a minimal rewriting is at most $p + d$ literals, where d is the sum of the arities of the literals in Q. In the presence of built-in predicates, the size of the rewritten query is at most exponential in the size of Q.

The above properties determine the complexity of the problem. In particular, if Q is a conjunctive query with built-in predicates and V is a set of conjunctive views *without* built-in predicates, then the problem of determining whether there exists a rewriting of Q that uses V is NP-complete. If the views in V have built-in predicates, the problem is Π_2^p-complete. If neither the query nor the views have built-in predicates, then finding a rewriting with at most k literals, where k is the number of literals in the body of Q, is NP-complete. Finally, if the query and the views have built-in predicates, then finding a rewriting with at most k literals is in Σ_3^p.

Techniques for Answering Queries Using Views

The above characterization suggests a two-step algorithm for finding rewritings of a query Q using a set of views V. At first, find some containment mapping from V to Q and add to Q the appropriate atoms of V, resulting in a new query Q'. Then, minimize Q' by removing literals from Q that are redundant. An algorithm needs to consider every possible conjunction of k or fewer view atoms, where k is the number of subgoals in the query. Algorithms that attempt to explore more effectively the search space to produce maximally contained rewritings include the Bucket Algorithm, the Inverse-Rules Algorithm and the MiniCon Algorithm.

The Bucket Algorithm The main idea underlying the algorithm is that the query rewritings that need to be considered can be significantly reduced if for each subgoal in the query the relevant views are identified.

To demonstrate the algorithm, the following query and views are used (The example used is from [10]):

$$\begin{aligned} Q_1(x) &\leftarrow \mathit{cites}(x,y) \wedge \mathit{cites}(y,x) \wedge \mathit{sameTopic}(x,y) \\ V_1(a) &\leftarrow \mathit{cites}(a,b) \wedge \mathit{cites}(b,a) \\ V_2(c,d) &\leftarrow \mathit{sameTopic}(c,d) \\ V_3(f,h) &\leftarrow \mathit{cites}(f,\ g) \wedge \mathit{cites}(g,\ h) \wedge \mathit{sameTopic}(f,\ g) \end{aligned}$$

Given a query Q, the Bucket Algorithm proceeds in two steps. In the first step, the algorithm creates a bucket for each subgoal in Q that is not in $C(Q)$, where by $C(Q)$ refers to the subgoals of comparison predicates of Q. Each bucket contains the views that are relevant to answering the particular subgoal. For the example, the following buckets are created:

cites(*x*, *y*)	*cites*(*y*, *x*)	*sameTopic*(*x*, *y*)
$V_1(x)$	$V_1(x)$	$V_2(x, y)$
$V_3(x, y)$	$V_3(x, y)$	$V_3(x, y)$

The algorithm also requires that every distinguished variable in the query should be mapped to a distinguished variable in the view. Hence, the algorithm does not include the entry $V_1(y)$ even though it is possible to map the subgoal $\mathit{cites}(x,y)$ in the query to the subgoal $\mathit{cites}(b,a)$ in V_1.

In the second step, for each element of the Cartesian product of the buckets, the algorithm constructs a conjunctive rewriting and checks whether it is contained (or can be made to be contained) in the query. If so, the rewriting is added to the answer. Therefore, the result of the Bucket Algorithm is a union of conjunctive rewritings.

In the example, the algorithm will try to combine V_1 with the other views and fail. Then it will consider the rewritings involving V_3 and V_2, and discover a contained rewriting. Finally, it will consider the rewritings involving only V_3, and find a contained rewriting by equating the variables in the head of V_3. It is possible to add an additional check that will determine whether a resulting rewriting will be redundant, as is the case here with the rewriting combining V_3 and V_2. Therefore, the only minimal rewriting in this example is: $Q_1'(x) \leftarrow V_3(x,\ x)$. This rewriting is in fact an equivalent one.

The Bucket Algorithm misses important interactions between view subgoals by considering each subgoal separately. Consequently, the buckets can contain unusable views and, as a result, the second step of the algorithm can become very expensive.

The Inverse Rules Algorithm The main idea of the Inverse-Rules Algorithm is to construct a set of rules that *invert* the view definitions, i.e., rules that compute tuples for the database relations from tuples of the views. The inverse rules together with a conjunctive query Q constitute a maximally contained rewriting for Q that is represented as a union of conjunctive queries. Considering the views of the previous example, the algorithm would construct the following inverse rules:

$$\begin{aligned} &R_1 : \mathit{cites}(a, f_{V_1}(a)) \leftarrow V_1(a) \\ &R_2 : \mathit{cites}(\ f_{V_1}(a), a) \leftarrow V_1(a) \\ &R_3 : \mathit{sameTopic}(c,d)) \leftarrow V_2(c,d) \\ &R_4 : \mathit{cites}(\ f, f_{V_3}(f,h)) \leftarrow V_3(f,h) \\ &R_5 : \mathit{cites}(\ f_{V_3}(f,h), h) \leftarrow V_3(f,h) \\ &R_6 : \mathit{sameTopic}(f, f_{V_3}(f,h)) \leftarrow V_3(f,h) \end{aligned}$$

For every view relation V with an existential variable Z_i, a function symbol $f_{V,i}$ is introduced. The above rules provide all the information about the database relations that can be extracted from the view extension. Intuitively, a tuple of the form (A) in the extension of the view V_1 is a *witness* of two tuples in the relation *cites*: a tuple of the form (A, Z), for some value of Z, and a tuple of the form (Z, A), for the same value of Z. The rules will generate from a tuple $V_1(A)$ two such tuples that will contain the unique functional term $f_{V_1}(A)$: it is a syntactic stand-in for the unknown (but known to exist) common value in the two tuples.

The rewriting of a query Q using the set of views V is simply the query consisting of Q and the inverse rules for V (There is a systematic way to eliminate the function symbols). Two important advantages of the algorithm are that the inverse rules can be constructed ahead of time, independent of a particular query, in polynomial time, and that the technique is also applicable virtually without change to recursive queries.

The rewritings produced by the Inverse-Rules Algorithm have some shortcomings when used for query evaluation. First, applying the inverse rules to the extension of the views may invert some of the computation done to produce the extent of the view. Second, they may access views that have no relevance to the query.

The MiniCon Algorithm The MiniCon Algorithm starts by considering, for each subgoal in the query, which view specializations contain subgoals that can "cover" it. A view specialization is created from a view by possibly equating some head variables. Once the algorithm finds a partial mapping φ from a subgoal g in the query to a subgoal g_1 in the view specialization V, it extends it to a minimal additional set of subgoals G of the query that must also be mapped to V. In particular, G includes all subgoals of the query that contain some variable of g mapped by ϕ to an existential variable of V. This set of subgoals and mapping information is call a *MiniCon Description* (MCD), and can be viewed as a generalized bucket. Having considered in advance how each of the variables in the query can interact with the available views, the second phase of the MiniCon Algorithm needs to consider significantly fewer combinations of these generalized buckets.

Using the query and views of the previous example, the MCDs formed during the first phase of the MiniCon Algorithm are:

$V(Y)$	h	φ	G
$V_2(c, d)$	$c \to c, d \to d$	$x \to c, y \to d$	3
$V_3(f, f)$	$f \to f, h \to f$	$x \to f, y \to f$	1, 2, 3

where h is a head homomorphism on V_i, $V(\bar{Y})$ is the result of applying h to V_i to create a view specialization, φ is a partial mapping from $Vars(Q_1)$ to $h(Vars(V_i))$ and G is a subset of the subgoals in Q_1 that are covered by some subgoal in $h(V_i)$ under the mapping φ.

In the second phase, the MCDs are combined to produce the query rewritings. In this phase the algorithm considers combinations of MCDs, and for each valid combination it creates a conjunctive rewriting of the query. There is no need for containment testing, as opposed to the Bucket algorithm. The combinations of MCDs considered by the MiniCon Algorithm are those that cover all the subgoals of the query with pairwise disjoint subsets of subgoals. The final maximally contained rewriting is a union of conjunctive queries.

As of 2008, MiniCon has been shown to be the most efficient current algorithm for answering conjunctive queries using conjunctive views.

Chase and Backchase In the presence of a set C of constraints on the relations and the views, Chase and Backchase is a powerful technique for finding *equivalent* rewritings using the views.

The chase [ref Encyclopedia entry Chase] is a well-known technique that can be used to decide containment of queries under constraints. If the chase of Q_1 with C terminates producing a query Q_c then $Q_1 \sqsubseteq_C Q_2$ if and only if $Q_C \sqsubseteq Q_2$. $Q_1 \sqsubseteq_C Q_2$ means that $Q_1 \sqsubseteq Q_2$ on every database instance that satisfies the constraint set C.

For the equivalent rewriting problem under constraints C, Q_1 is given and must effectively find Q_2 such that $Q_1 \equiv_C Q_2$. The algorithm proceeds in two steps. In the *chase* step, it chases Q_1 with C until no more chase steps are possible. This results in a query U called the *universal plan*. The universal plan is a query over the database relations and the views that conceptually incorporate all possible alternative ways to answer Q_1 in the presence of the constraints C. In particular, any minimal conjunctive query equivalent to Q_1 under C is isomorphic to a subquery of U. Hence, to find all minimal rewritings of Q_1, the backchase step of the algorithm searches the finite space of subqueries of U. Specifically, for each subquery Q_s it checks for equivalence with Q_1 by chasing Q_s with C. Q_s is equivalent to Q_1 if and only if there is a containment mapping from Q_1 into an intermediate chase result of Q_s.

Chase and Backchase applies if the constraint set C includes tuple-generating and equality-generating dependencies. It is sound and complete if C is *weakly acyclic*.

Key Applications

The conceptual framework and techniques developed for query rewriting using views have had significant impact in a number of areas of information systems, especially (but not exclusively) in the areas of information integration and data integration [ref Encyclopedia article Information Integration, ref Encyclopedia article Data Integration]. In particular, as of 2007, data integration theory and systems follow two main architectural approaches for defining and processing queries in a virtual (In a virtual integration system, as opposed to a data warehouse [ref entry Data Warehouse], data resides only in their original locations/sources. The integration system accesses them every time it needs to answer a query) integration system. In *global-as-view* the integrated *global view* (or views) of the disparate data sources is defined (using a standard query language or an ad hoc specification system) in terms of the *local* data sources, and queries are directly expressed in terms only of the global view(s). In this case, processing a query over this global view involves *view expansion*. In *local-as-view* data integration on the other hand, local data sources are expressed in terms of an a priori given *global schema*, i.e., they are expressed as views over the relations of the global schema. Queries are also expressed in terms of the global schema. Since in an integration system the only available data reside in the local sources, answering a query requires rewriting it in terms of the available sources, i.e., rewriting it using the views.

In the above context, sources describe their contents in terms of the local schema. In addition, for sources with limited processing power, their capabilities need to also be taken into account. Since integrated queries are answered by retrieving data from local sources, the data retrieval requests (i.e., the queries) submitted to the sources need to conform to their capabilities. Query rewriting using views has provided the conceptual framework and tools to address the *capability-based rewriting* problem.

Another area of application of the ideas of answering queries using views is query optimization. When the set of relations mentioned in queries overlaps with those mentioned in one or more views, and the views select one or more attributes selected by the query, the view may be *usable* by the query. Moreover, certain indices can also be modeled as materialized views. Using the materialized views may lower the cost of query processing, depending on the available access methods and the selectivity of the involved predicates. Answering queries using views is used to decide view usability and generate the appropriate query plans.

Finally, answering queries using views, especially in the presence of constraints, has influenced the theory of *data exchange*. Data exchange, or data translation, involves taking data described in one, *source*, schema and translating, without loss of information, into data structured under a different, *target*, schema.

Future Directions

Even though significant progress has been made in this area, the applicability and/or efficiency of the developed techniques is often limited. Future work is needed on rewriting techniques that can perform correctly and efficiently for "real" SQL views on real SQL queries, including queries with aggregates, nesting, bag semantics, and user-defined functions. Moreover, the conceptual framework of rewriting using views applies to problems in graph querying, Web service composition, and rewriting of XQuery.

Anti-monotone Constraints

Carson Kai-Sang Leung
University of Manitoba, Winnipeg, MB, Canada

Definition

A constraint C is *anti-monotone* if and only if for all itemsets S and S':

$$\text{if } S \supseteq S' \text{ and } S \text{ satisfies } C, \text{ then } S' \text{ satisfies } C.$$

Key Points

Anti-monotone constraints [1,2] possess the following nice property. If an itemset S satisfies an anti-monotone constraint C, then all of its subsets also satisfy C (i.e., C is downward closed). Equivalently, any superset of an itemset violating an anti-monotone constraint C also violates C. By exploiting this property, anti-monotone constraints can be used for pruning in frequent itemset mining with constraints. As frequent itemset mining with constraints aims to find itemsets that are frequent and satisfy the constraints, if an itemset violates an anti-monotone constraint C, all its supersets (which would also violate C) can be pruned away and their frequencies do not need to be counted. Examples of anti-monotone constraints include $min(S.Price) \geq \$20$ (which expresses that the minimum price of all items in an itemset S is at least \$20) and the usual frequency constraint $support(S) \geq minsup$ (i.e., $frequency(S) \geq minsup$). For the former, if the minimum price of all items in S is less than \$20, adding more items to S would not increase its minimum price (i.e., supersets of S would not satisfy such an anti-monotone constraint). For the latter, it is widely used in frequent itemset mining, with or without constraints. It states that (i) all subsets of a frequent itemset are frequent and (ii) any superset of an infrequent itemset is also infrequent. This is also known as the *Apriori property*.

Applicability Period

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

The *applicability period* (or *period of applicability*) for a modification (generally an insertion, deletion, or update) is the time period that modification is to be applied. Generally the modification is a sequenced modification and the period applies to valid time. This period should be distinguished from *lifespan*.

Key Points

The applicability period is specified within a modification statement. In constrast, the lifespan is an aspect of a stored fact.

This illustration uses the TSQL2 language, which has an explicit VALID clause to specify the applicability period within an INSERT, DELETE, or UPDATE statement.

For insertions, the applicability period is the valid time of the fact being inserted. The following states that Ben is in the book department for 1 month in 2007.

```
INSERT INTO EMPLOYEE
VALUES (‘Ben’, ‘Book’)
VALID PERIOD ‘[15 Feb 2007, 15 Mar 2007]’
```

For a deletion, the applicability period states for what period of time the deletion is to be applied. The following modification states that Ben in fact was not in the book department during March.

```
DELETE FROM EMPLOYEE
WHERE Name = ‘Ben’
VALID PERIOD ‘[1 Mar 2007, 31 Mar 2007]’
```

After this modification, the lifespan would be February 15 through February 28.

Similarly, the applicability period for an UPDATE statement would affect the stored state just for the applicability period.

A *current modification* has a default applicability period that either extends from the time the statement is executed to forever, or when now-relative time is supported from the time of execution to the ever-increasing current time.

[3]The Chinese University of Hong Kong, Hong Kong, China

Synonyms

Benchmark; Performance benchmark

Definition

An application benchmark is a suite of tasks that are representative of typical workloads in an application domain.

Key Points

Unlike a MICROBENCHMARK, an application benchmark specifies broader tasks that are aimed at exercising most components of a system or tool. Each individual task in the benchmark is assigned a relative *weight*, usually reflecting its frequency or importance in the application being modeled. A meaningful interpretation of the benchmark results has to take these weights into account.

The Transaction Processing Performance Council (TPC) is a body with a long history of defining and published benchmarks for database systems. For instance, it has defined benchmarks for Online Transaction Processing applications (TPC-C and TPC-E), Decision Support applications (TPC-H), and for an Application Server setting (TPC-App).

Other examples of application benchmarks are: the OO1 and OO7 benchmarks, developed for object-oriented databases, and XMark, XBench and TPoX, developed for XML applications.

Application Recovery

David Lomet
Microsoft Research, Redmond, WA, USA

Synonyms

Persistent applications; Fault tolerant applications; Transaction processing; Recovery guarantees; Exactly once execution

Definition

Systems implement application recovery to enable applications to survive system crashes and provide "exactly once execution" in which the result of executing the application is equivalent to a single execution where no system crashes or failures occur.

Historical Background

Application recovery was first commercially provided by IBM's CICS (Customer Information Control System). Generically, these kinds of systems became known as transaction processing monitors (TP monitors) [5,9]. With a TP monitor, applications are decomposed into a series of steps. Each step is executed within a transaction. A step typically consists of reading input state from a database or transactional queue, executing some business logic, perhaps processing user input or reading and writing to a database, and finally, writing state for the next step into database or queue [4]. If a step failure occurs, its transaction is aborted. Since the prior step results are stably stored, the step can be re-executed after system recovery.

Application recovery does not always involve transactions, however, as the early work by Borg et al. demonstrates [6]. More recently, in the web context, TP monitors have been renamed as application servers (app servers). App servers are similar to TP monitors, where state is explicitly managed, frequently by using transactions. Ongoing interest in application recovery is illustrated by the "recovery oriented computing" (ROC) project [3] and the Phoenix project [1].

Foundations

Introduction

Exactly-Once Applications: While application programmers are usually familiar with the problem area for which an application is written, they are frequently also faced with having to deal with "system problems" of reliability and availability. The system goal is to permit applications to achieve "exactly once execution" [2]. For example, an airline reservation system wants to issue exactly the number of tickets a customer requests, instead of no tickets or twice the number.

Types of Failures: Applications cannot survive all forms of failures. If an exactly-once execution produces a "deterministic" failure, then every execution of the application will lead to that same failure. Such deterministic failures are called "hard failures." The failures that software can deal with are called "soft failures." A subsequent execution of the system will usually avoid the state leading to the system failure. Soft failures arise in a number of ways.

1. *Software non-determinism*: A software system is non-deterministic if, when re-executed, it results in a different execution path than a prior execution. Non-determinism can arise when, for example, paths are determined by relative processor speed or the sequence of external events. Such software bugs have been called "Heisenbugs" (hard failures being "Bohrbugs").
2. *Soft hardware failures*: Hardware can also suffer from "Heisenbugs." For example, a transient hardware failure may be triggered by an environmental cause, such as a cosmic ray changing a memory bit, etc.
3. *Operator failures*: Systems occasionally require operator intervention. Operators, being human, make mistakes. An operator is unlikely to make the same mistake at the same point in a subsequent execution.

Recovery is effective because failures are usually "soft" [3,9], which is why database recovery is so successful.

Support for Application Persistence: Applications which guarantee "exactly once" execution are called "persistent applications" because application state persists across or despite system failures. The traditional method for providing application persistence has been to use a TP monitor. However, new approaches permit implicit state management, in which the application programmer delegates the problem of managing application state to the system infrastructure.

Implicit state management does not require application steps to execute within transactions. It permits applications to be coded more "naturally" (though restrictions exist). Application state is made stable "under the covers." Phoenix [1] does this via logging application non-determinism and replaying the captured non-determinism after a failure to recover application state. CORBA's approach [11], having shorter down time but more costly normal execution, replicates application state so that if part of the system fails, a copy of the state is available elsewhere for continued execution. Implicit state management is discussed here.

Application persistence (recovery) requires different techniques than database recovery: (i) Applications are usually single-threaded and "piece-wise deterministic," while databases execute highly concurrent code. (ii) Application state is frequently distributed, so dealing with distribution is essential. (iii) Databases change state entirely within a transaction, while application state may frequently change outside of a transaction.

Persisting Application State

Implicit state management requires the infrastructure supporting an application to capture application state and make it stable in some way, relieving the programmer of this task. Two approaches have been developed. The approaches are not as different as they appear. Both require that applications be piece-wise deterministic, with clearly identified non-deterministic events that can be "applied" at an application instance to be used in deterministic re-execution that can generate the same state as the original execution.

Recovery: Recovery technology usually assumes that a failing application will be re-activated after a system crash and its activities recovered on the original system. Thus recovery oriented approaches usually capture application state stably (e.g., "on disk") so that it survives a system failure. There are two parts to this:

1. Writing a "snapshot" of the state to stable storage from time to time. It matters when this snapshot, also called a checkpoint, occurs.
2. Stably logging non-deterministic events encountered by the application in arrival order.

Recovery, in which the state is re-created following a system failure, consists of re-installing the latest captured state (checkpoint) followed by re-executing the application by "feeding" events from the log to re-create application state as of the last logged event.

Logging can be either optimistic or pessimistic [7]. Pessimistic logging eagerly makes log records stable, usually as events occur in order to ensure that execution is "exactly once." Optimistic logging defers for a time making events stable, frequently sacrificing exactly once execution. Pessimistic logging can be greatly optimized. Optimistic logging can be constrained so that exactly once execution is assured. This brings these techniques toward some middle ground in performance, though important differences remain.

Replication: Replication technology usually assumes that an application executing on a failing system A will continue execution on a separate system B where a replica of its state has been maintained. The problem for replica oriented approaches is to capture and keep in sync an application's state on these separate systems. There are two generic approaches to this:

1. Designate one system as the primary system, the others as secondaries. Non-deterministic events are sent to the primary system, which then relays them to the secondary in the order that it received them. Replicas thus execute in response to the same sequence of events. A secondary becomes the primary on failure of the primary. If a secondary fails, the primary needs to know this and re-create another secondary.
2. Use atomic broadcast to send non-deterministic events to all systems maintaining replicas "simultaneously" [1]. Atomic broadcast guarantees that replicas receive all messages and in the same order. If there is a failure, then the remaining replicas participating in the atomic broadcast need to know the members of the new group so that the atomic broadcast protocol continues to work correctly, possibly including the creation of a new replica.

Intermediate Approaches: The line between replication and recovery approaches is not always crisp: (i) A recovery system can maintain its log by sending the log records to another system, hence using a second system as stable storage instead of a disk. This second site might then become the site where the application is subsequently executed should the original site fail. (ii) A second system for a replica might not execute the events forwarded to it immediately, but rather simply "log" them. Then, only if a primary replica fails would it perhaps then "catch up" by executing the stored events.

Thus a second system might serve as a cold standby system (retaining a log of events) or as a hot standby, immediately executing the application in response to the events. Warm standbys are also possible in which an application is executed at a secondary site in a lazy fashion, lagging the state of a primary site, but not by too much. Whether this is should be viewed as recovery or replication is not really important.

Distributed Applications

Many applications are distributed, e.g., a web application might consist of a client component providing the user interface, one or more middle tier components executing business logic, and back end components that typically provide transactions and database functionality. The new problem is to coordinate the states of multiple software components executing different parts of the application [6,7].

1. The state of the set of application components needs to be "causal," i.e., every message receive reflected in the state of some component must always be accompanied by a sender in a state where the message has been sent.
2. Messages (non-deterministic events in a distributed system) must result in an "exactly once" execution by the receiving component.
3. The application must be able to interact with users or other elements outside of the persistence infrastructure, which may not obey the required protocols.
4. The application must be able to interact with transactional elements like databases.
5. Different strategies have different costs and impact the balance between normal run time costs and recovery costs and time-to-recovery.

Contracts for Persistent Components: Providing persistence for components of a distributed application requires an agreed upon set of protocols or "contracts" [1,2] involving component state and message stability, repeated sending of messages, eliminating duplicate messages, etc. The basic contract between persistent components, called the "committed interaction contract" or CIC, places burdens on both sender and receiver of a message at the time it is sent.

The *sender of a message* ensures causality. The sender ensures that it's state as of the time of message send and the message will be persistent earlier than the receiver's state is persisted. Further, the sender must continue to send the message until the receiver acknowledges the message, in order to deal with unreliable networks and crashed receivers, etc. The CIC does not specify how to do this, but the recovery approach usually writes non-deterministic events to a log, and flushes the log when a message is sent should the state include previously received messages since the last log flush.

The *receiver of the message* ensures exactly once execution. The receiver eliminates duplicate messages the sender may send in its effort to provide reliable delivery. The receiver executes in response to a message only if receiver state does not already reflect having received the message and bypasses execution otherwise, returning the same result as produced by the original execution. Finally, the receiver ensures that the state resulting from the message receipt is stable at an appropriate moment. The CIC contract does not specify how to do this, but the receiver might use a table of messages received, or some high water mark for messages when the sender is known, to which it compares each incoming message.

External and Transactional Components: Many web applications involve users entering information at a keyboard, and a database that stores the results of business dealings, e.g., the purchase of a plane ticket. Hence, persistent components must interact with elements outside of the boundaries of the application and its supporting system. This requires new forms of "contracts" in which the main burden is placed on the persistent components to enable an ensemble of elements to achieve exactly once execution, e.g., one purchase of the plane ticket.

External components, including users, may not obey CIC requirements. Hence, external interactions must be limited to ensure exactly once execution. For users, both reads and writes might be exposed as having multiple occurrences. A failure in the middle of a user interaction may require entering data more than once or repeating an output if the system fails between the event and its stable logging. Systems typically minimize the problem window by immediate logging, with a log flush, in response to external events.

A transactional component only occurs at the edge of an application system, responding to requests for and updates to its data. Transactions can abort, with the transactional component's state reset to remove all effects of the aborted transaction. The persistent component must be prepared to handle transaction aborts at any time. Transactions actually reduce the burden for a persistent component as it need not ensure that its state is stable at each interaction within a transaction. A system crash will eventually lead to the abort of any interrupted transaction. However, at the point where the persistent component requests a transaction commit, it must obey the usual requirements for a sender in a CIC.

Optimizations: Optimizations can reduce the normal runtime cost of providing persistent applications. These exploit additional information known to the application programmer when the application is either written or being deployed.

1. Some components may be read-only, producing no external side effects. So a read only component need do no logging itself, while a calling persistent component can log lazily because the read can be repeated if needed. A functional call component in which the result depends only on the arguments of the call requires no logging as the call can be replayed idempotently.
2. If called components extend the time they stably remember prior calls and results for idempotence, then the calling component need not log to make its state stable prior to each call. It can depend upon the called components in a sequence of calls to capture the call results to enable its deterministic replay.
3. When a component is a "server" for exactly one client, the client can capture what would be nondeterministic calls and their order for the server component, relieving the server from needing to log calls messages. Combining this with item 2 enables persistent components without logging [8,10]. A logless component's state is regenerated by its client replaying the sequence of calls, and it re-executing its own series of calls to other components that have captured the call results. Logless components are easily deployed anywhere, can be freely replicated, and hence make persistence simple, flexible, and low cost.

Checkpoints: Recovery time is shortened via checkpoints. Component state consists of its variables and its execution time stack. By checkpointing component state when there is no execution within the component, the checkpoint can be accomplished solely by capturing its variable values, e.g., checkpoint might be taken transparently during the midst of a return from a call to a component. The cost of the checkpoint and the need for fast recovery time dictate checkpoint frequency.

Discussion

Making declarative the requirements for application persistence, as represented by interaction contracts, makes it easier to provide and optimize exactly once execution by expanding the range of implementation options, including interesting optimizations.

The level of the contract is also important. A CIC could have been derived from reliable messaging instead of more explicitly as repeated sending of messages with duplicate elimination. However, reliable messaging does not describe what happens to messages once they are delivered. By describing the requirements for state stability, etc., it becomes clear that delivery is not, by itself, sufficient. Further, were "persistent reliable messaging" used, this would requiring extra log forces that, can frequently be avoided with the "end-to-end" application persistence protocol.

System provided transparent application persistence is an example of delegating a serious problem to the "system," similar to how transactions delegate concurrency control and recovery to database systems. There is no need for special application programmer consideration, simplifying the application logic, and improving programmer productivity.

Key Applications

Application recovery (persistence) is used wherever exactly once semantics is required. Traditionally, this has been within transaction processing systems, but now more commonly, this involves web applications for e-business, whether for end user customers or business to business dealings. If there are financial or legal requirements for applications, they will be built using some form of application recovery to ensure exactly once execution.

Application Server

Heiko Schuldt
University of Basel, Basel, Switzerland

Synonyms

Web application server; Java application server

Definition

An *Application Server* is a dedicated software component in a three-tier or multi-tier architecture which provides application logic (business logic) and which allows for the separation of application logic from user interface functionality (client layer), delivery of data (web server), and data management (database server).

Key Points

Modern information systems, especially information systems on the web, follow an architectural paradigm that is based on a separation of concerns. In contrast to monolithic (single tier) architectures or two-tier client/server architectures where business logic is bundled with other functionality, three-tier or multi-tier architectures consider dedicated application servers which exclusively focus on providing business logic.

In three-tier or multi-tier architectures, application servers typically make use of several middleware services which enable the communication within and between layers. Application servers usually provide the basis for the execution of distributed applications with transactional guarantees on top of persistent data. In large-scale deployments, systems might encompass several instances of application servers (application server clusters). This allows for the distribution of client requests across application server instances for the purpose of load balancing.

Early application servers evolved from distributed TP Monitors. Over time, a large variety of application servers has emerged. The most prominent class consists of Java application servers, either as stand-alone servers or embedded in large software systems.

Application-Level Tuning

Philippe Bonnet[1], Dennis Shasha[2]
[1]University of Copenhagen, Copenhagen, Denmark
[2]New York University, Newyork, NY, USA

Synonyms

Query tuning; Tuning the application interface

Definition

An under-appreciated tuning principle asserts *start-up costs are high; running costs are low*. When applied to the application level, this principle suggests performance of a few bulk operations that manipulate and transport a lot of data rather than many small operations that act on small amounts of data. To make this concrete, this entry discusses several examples and draws lessons from each.

Historical Background

Application-level tuning is about changing the way a task is performed. This entails finding a better algorithm or finding a better way to handle the database. The first is difficult to automate, but the latter goes back to the very first use of the relational databases. Whether on disk or in main memory, databases have generally always performed best when a single statement accesses all and exactly the data needed for a task.

Foundations

Application-level tuning has the nice property that it often is a pure win. Whereas adding or removing indexes often entails a trade-off between insert/delete/update performance and query performance, application-level tuning for the most part improves the performance of certain queries without hurting the performance of others. Rewriting queries to use resources more efficiently also often gives a greater benefit than physical changes.

Assemble Object Collections in Bulk

Object-oriented encapsulation is the principle of shielding the user of an object from the object's implementation. Encapsulation sometimes is interpreted as *the specification is all that counts*. That interpretation can, unfortunately, lead to horrible performance.

The reason is simple. The first design that seems to occur to object-oriented implementers is to make relational records (or sometimes fields) into objects. This has the virtue of generality. Fetching one of these objects then translates to a fetch of a record or a field. So far, so good. But then the temptation is to build bulk fetches from fetches on little objects (the so-called "encapsulation imperative"). The net result is a proliferation of small queries instead of one large query.

Consider for example a system that delivers and stores trade information. Each document type (e.g., a report on a customer account) is produced according to a certain schedule that may differ from one trade type to another. "Focus" information relates trade types to risk analysts. That is, risk analysts may focus on one trade type or another. This gives a pair of tables of the form:

```
Focus(analyst, tradetype)
Tradeinstance(id, tradetype, tradedetail)
```

When an analyst logs in, the system gives information about the trade instances in which he or she would be interested. This can easily be done with the join:

```
select tradeinstance.id, tradeinstance.
tradedetail
from tradeinstance, focus
where tradeinstance.tradetype=focus.
tradetype
and focus.analyst={input analyst name}
```

But if each trade type is an object and each trade instance is another object, then one may be tempted to write the following code:

```
Focus focustypes=new Focus();
Focus.init({input analyst name});
for (Enumeration e=focustypes.elements(); e.hasMore-
Elements();)
{
TradeInstance tradeinst=new TradeInstance();
tradeinst.init(e.nextElement());
tradeinst.print();
}
```

This application program will first issue one query to find all the trade types for the analyst (within the init method of Focus class):

```
select tradeinstance.tradetype
from focus
where focus.analyst={input analyst name}
```

and then for each such type *t* to issue the query (within the init method of TradeInstance class):

```
select tradeinstance.id, tradeinstance.
tradedetail
from tradeinstance
where tradeinstance.tradetype=t
```

This is much slower than the previous SQL formulation. The join is performed in the application and not in the database server.

The point is not that object-orientation is bad–encapsulation contributes to maintainability. The point is that programmers should keep their minds open to the possibility that accessing a bulk object (e.g., a collection of documents) should be done directly rather than by forming the member objects individually (incurring a start-up cost each time) and then grouping them into a bulk object on the application side.

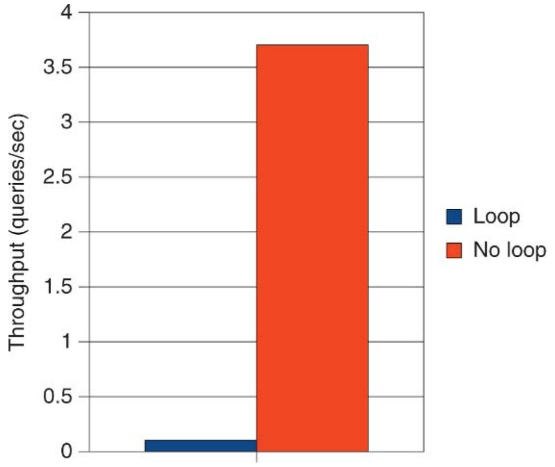
The Art of Insertion

This entry has discussed retrieving data so far. Inserting data rapidly requires understanding the sources of overhead of putting a record into the database:

- As in the retrieval case, the first source of overhead is an excessive number of round trips across the database interface. This occurs if the batch size of inserts is too small. A more radical approach is to assemble all the data to be inserted into a file, load that file into a temporary table, and then insert from that temporary table into the target table. This can improve performance by a factor of 100 or more when tables are large.
- The second issue has to do with the ancillary overhead that an insert causes: updating all the indexes on the table. Even a single index can hurt performance. For this reason, it is often a good idea to add indexes after loading the data.

Key Applications

Application-level tuning has proved useful in every setting where performance is an issue. Whereas index and physical layer tuning can be more easily automated, the benefits of application-level tuning are often greater.



Application-Level Tuning. Figure 1

Experimental Results

Looping hurts

This experiment illustrates the overhead of crossing the application interface. Two hundred tuples are fetched (these are small tuples composed of two integers) using a range query (no loop), or looping on the client-side to fetch one tuple at a time.

Figure 1 traces the throughput observed for this experiment on MySQL 6.0 with a warm buffer. There is an almost two orders of magnitude penalty when looping through the tuples. This is due to the overhead of crossing the application interface 200 times.

Applications of Emerging Patterns for Microarray Gene Expression Data Analysis

Guozhu Dong[1], Jinyan Li[2]
[1]Wright State University, Dayton, OH, USA
[2]Nanyang Technological University, Singapore, Singapore

Definition

This topic is related to applications of emerging patterns in the bioinformatics field, in particular for in-silico cancer diagnosis by mining emerging patterns from large scale microarray gene expression data.

Key Points

The contemporary gene expression profiling technologies such as cDNA microarray chips and Affymetrics DNA microarry chips can measure the expression levels of thousands even tens of thousands of genes simultaneously. This provides a great opportunity to identify specific genes or gene groups that are responsible for a particular disease, for example, the subtypes of childhood leukemia disease. Reference [3] proposed to use emerging patterns to capture the signature patterns between the gene expression profiles of colon tumor cells and normal cells. This was the first bioinformatics work studying how gene groups and their expression intervals signify the difference between diseased and normal cells. That paper also proposed to design treatment plans to cure the diseased cells by adjusting certain genes' expression level based on the discovered emerging patterns. Reference [2] reported simple rules underlying gene expression profiles of more than six subtypes of acute lymphoblastic leukemia (ALL) patients. The rules are converted from the mined emerging patterns. The rules are also used to construct a classifier (PCL) that reached a benchmark diagnosis accuracy of 96% on an independent test data set. As gene expression data sets contain many attributes, the discovery of emerging patterns by border-differential based algorithms is sometimes slow. To tackle this problem, reference [1] proposed a CART-based approach to discover a proportion of emerging patterns from the high-dimensional gene expression profiling data with a high speed. The ZBDD based approach discussed in the emerging patterns entry of this volume is also fast and can handle large number of genes.

Applications of Sensor Network Data Management

Farnoush Banaei-Kashani, Cyrus Shahabi
University of Southern California, Los Angeles, CA, USA

Synonyms

Applications of Sensor Networks, Applications of Sensor Databases, Applications of Sensor Network Databases

Definition

Sensor networks allow for micro-monitoring of different phenomena of interest in arbitrary physical environments. With this unique capability, sensor networks can capture the events in the real world as they happen in the form of high-resolution spatiotemporal data of various modalities, and provide the opportunity for real-time querying and analysis of the data for immediate response and control. Such functionality is desirable in many classic applications while enabling numerous other novel applications. From the data management perspective, there is a consensus among database researchers that management and analysis of the massive, dynamic, distributed and uncertain data in sensor network applications is going to be one of the new grand challenges for the database community:

> ▶ *Sensor information processing will raise many of the most interesting database issues in a new environment, with a new set of constraints and opportunities.*
>
> – Excerpt from the Lowell Database Research Self-Assessment (By a group of thirty senior

database researchers, *"The Lowell database research self-assessment"*, Communications of the ACM, Volume 48, Issue 5, May 2005.)

Historical Background

Shortly after the introduction of the sensor networks and their potential applications about a decade ago [6], management of the sensor data was recognized as one of the main challenges in realizing the sensor network applications [1].

Foundations

Sensor Databases

One can think of a sensor network as a distributed database that collects, stores and indexes the sensor data to answer the queries received from external users/applications as well as internal system entities. By considering a sensor network as a database, one envisions some of the benefits of the traditional databases potentially for sensor databases; e.g., reduced application development time, convenient multi-user data access and querying with a well-defined generic interface, efficient data reuse, and most importantly data independence. Physical data independence is a particularly beneficial advantage of the sensor database approach, because as compared to the physical layer of the traditional databases the physical infrastructure of the sensor networks is much more sophisticated. With physical data independence in sensor databases, the logical schema of the data exposed to the users is separated from the physical schema that defines the complex and probably changing implementation of the data structures and operations on the physical network. By separating the logical and physical schemas, users/applications are isolated from the typical complications of the distributed data processing in the volatile sensor networks and can focus on designing the logical structure of their queries. Hence, the use of the sensor data is significantly facilitated.

Sensor Database Distinctions

Sensor databases are different from traditional distributed databases in both physical specifications and data characteristics. At the physical level, nodes of the database (i.e., sensor nodes) are severely constrained in resources, such as memory space, storage space, CPU power, and most importantly energy. Moreover, in sensor databases nodes and links of the network are both highly volatile. On the other hand, with sensor devices continuously collecting measurements from the environment, sensor data is naturally very dynamic. Besides, due to inaccuracy of the sensor devices, signal interference, noise, etc., uncertainty is also an inherent characteristic of the sensor data. With such physical and data characteristics, maintaining the illusion of a database is arguably a more difficult objective with sensor databases as compared to that of the traditional distributed databases, and accordingly, requires new data management solutions:

- Database operators should be delay-tolerant, and tolerant to frequent updates of the data
- Query execution should be performed *in-network* for energy efficiency; similarly, data storage and access should be designed for energy efficiency
- Data acquisition plan is required to determine what data to collect
- Sensor query language should be augmented with new operators to specify duration and sampling rate of the data acquisition
- Query execution plan should be dynamically optimized to account for variable access delay and uncertain data availability
- Data uncertainty should be accounted for
- Volatility of the sensor network should be hidden to provide the illusion of a stable database
- Continuous queries should be supported, as sensor networks are primarily used for long-term monitoring
- Meaningful data digests should be maintained to allow for answering historical queries, since data is continuously collected despite the limited space for storage
- Aggregate spatiotemporal queries and range queries should be supported, for energy efficiency [13, 12]
- Approximate queries should be supported, as they are more meaningful with sensor data
- Triggers should be supported for the event-driven monitoring applications

One approach to implement sensor databases is to transfer all data to one or a small number of external base stations, where a traditional database system can be exploited. Alternatively, the data can be stored within the network itself with a balanced and optimal data storage plan. Although with the first approach one can more conveniently employ and extend the data management solutions applicable with the traditional databases, the second approach, termed *in-network storage*, allows for tighter coupling between query processing, on the one hand, and networking and application semantics, on the other hand. Tight coupling can potentially enable more energy efficient query processing in sensor databases. To evaluate the query processing performance with a particular sensor database implemented with either of these approaches, one can use the standard distributed database performance metrics such as incurred communication cost, query time, indexing time, throughput, load balance among nodes, data update overhead and storage requirements.

Key Applications

As compared to the traditional wireline sensor networks that have been in use for decades, the more recent wireless sensor networks enable low cost and rapid deployment of the sensing network while supporting mobility. With these desirable characteristics due to the wireless technology, recently the standard applications of the sensing networks are revived and new applications that were otherwise unthinkable are identified. The key classes of applications for sensor databases/networks are discussed below.

Environmental Monitoring

Environmental monitoring applications, specifically habitat monitoring [3], are among the earliest applications of the sensor networks. With the habitat monitoring applications, sensors are deployed to monitor animals or plants in their original habitats with most convenience for the scientists and least disturbance for the wildlife. With other environmental applications, sensors can be used to collect earth-science and atmospheric data for environmental explorations, such as the study of the air pollution, global warming, etc., and also early detection and prediction of the natural and man-made disasters, such as hurricanes, wildfires, earthquakes and biological hazards.

Military Intelligence

With rapid deployment, and inexpensive and untethered sensors, wireless sensor networks are well positioned as the tool to collect battlefield data for real-time battlefield intelligence [9]. For instance, wireless sensors can be utilized for geofencing (i.e., deploying a sensor network as a transparent fence to protect an area against unauthorized trespassing), enemy tracking, and battlefield exploration and condition assessment particularly in hazardous environments. In military intelligence applications, the small form-factor, reliability, interoperability and durability of the sensor nodes under severe environmental conditions are particularly critical requirements.

Asset Management

Businesses with large and high-turnover inventories of assets (such as construction companies, utility companies and trucking companies) can benefit from automated asset management systems in improving the utilization of their resources [10]. With automated asset management, sensor networks are deployed to collect real-time data about exact location and condition of an inventory of assets automatically. The collected data provides the opportunity for real-time analysis of the resource usage, which in turn enables timely and optimal decision-making on handling, supply, delivery, storage and other asset management tasks. Various types of sensing devices, such as GPS devices and passive RFID (Radio-Frequency Identification) tags, are applicable with the sensor networks used for asset monitoring.

Building Monitoring

The recent attempt aiming at optimizing the energy performance of the buildings by deep sensing of the building conditions, dubbed BIM (Building Information Modeling) (Federal BIM Program. URL: http://www.gsa.gov/bim/), heavily relies on the sensor network technology. With BIM energy tools enabled by sensing networks, one can monitor, e.g., the temperature and lighting conditions in the building, and accordingly regulate the heating and cooling systems, ventilators and lights dynamically for best energy performance [11]. Also as a safety tool, building sensor networks can detect and report threats, such as existence of the biological agents in the environment as well as physical intrusions.

Automotive

With the new standards such as Dedicated Short-Range Communication (DSRC) designated for vehicle communications, in the near future, cars will be able to communicate information to each other and to the roadside infrastructures. With this capability, while in traffic cars can form a so-called vehicular sensor network, where each car equipped with sensing devices (e.g., camera, thermometer, etc.) acts as a mobile sensor node. In a vehicular sensor network, cars can share information and analyze the aggregate information about the road conditions, congestions, nearby emergencies, etc., for applications such as collision prevention, congestion avoidance and flow optimization [8].

Healthcare

Sensor networks can effectively improve the accuracy of the patient care and, consequently, the safety of the patients when they become physically incapacitated and require immediate medical attention [7]. Sensor networks allow this by enabling close and automated monitoring of the patient's vital signs. When monitoring is coupled with real-time analysis of the signs, the sensor-enabled healthcare system can alert the right person at the right time to attend to the patient. Such healthcare systems are applicable both at homes of the elderly and at the hospitals.

Industrial Monitoring

Sensors can be used to monitor industrial processes for safety as well as manufacturing optimization [4]. One can also deploy sensors to monitor the condition of the industrial equipments for preventative maintenance and also safety of the operators. Wireline sensors have been in use for a long time in various industry sectors such as oil companies (both upstream and downstream) and chemical plants. Wireless technology and inexpensive sensors has greatly facilitated and extended the use of the sensing networks for process and equipment monitoring, encouraging oil companies, e.g., to develop smart oilfields by equipping the oil wells and other assets with wireless sensors (see e.g., [2]).

Future Directions

With the current trend, sensor networks are being applied with increasingly more complex, large-scale and distributed systems (e.g., the federal intelligent transportation system (Federal ITS Program. URL: http://www.its.dot.gov/)). Such applications demand deployment of large-scale sensor networks and, accordingly, require fully decentralized solutions for sensor data management to achieve scalability.

Approximate Queries in Peer-to-Peer Systems

Wolf Siberski, Wolfgang Nejdl

Synonyms

Top-*k* queries in P2P systems; Aggregate queries in P2P systems

Definition

Peer-to-peer (P2P) networks enable the interconnection of a huge amount of information sources without imposing costs for a central coordination infrastructure. Due to the dynamic and self-organizing nature of such networks, it is not feasible to guarantee completeness and correctness as in traditional distributed databases. Therefore, P2P systems are usually applied in areas where approximate query evaluation, i.e., the computation of a nearly complete and correct answer set, is sufficient. As the most frequent application of querying in P2P is search, many of these algorithms fall into the class of top-*k* query algorithms. Another important case is the approximation of aggregate query results.

Historical Background

P2P networks use approximate querying from the outset. In Gnutella, an unstructured network, the query is distributed in a limited neighborhood only, thus the result is usually not complete. The early top-*k* query algorithms for P2P are based on such unstructured networks. PlanetP [6], a P2P network for information retrieval, employs gossiping to replicate index information among all peers and sends queries to the best peers according to this replicated index. This approach has been extended to a super-peer network in [11]. While the first Distributed Hash Table (DHT) systems such as CHORD and Pastry aim at complete and correct answers, later structured networks approximate the result set, especially P2P networks for information retrieval [2,15]. Frequently, approximate P2P networks build upon algorithms for distributed databases or distributed IR. For example, for source selection PlanetP relies on an extended version of GlOSS [7], Minerva [15] on CORI [4]. Odissea [13] uses either Fagins Algorithm (FA) or a Threshold Algorithm (TA) as top-*k* algorithm, KLEE [9] extends TA, etc. (→*Top-k Selection Queries on Multimedia Datasets*).

Foundations

The main challenge in P2P approximate query processing is to select the optimal subset of peers to which the query is forwarded. However, the selection criteria for this subset are completely different for top-*k* and aggregate queries. While in top-*k* the goal is to identify the peers holding top objects, approximate aggregate querying algorithms need to find a representative sample of peers. In both cases, each selected peer evaluates the query locally; the respective responses are collected and merged to compute the final result set.

Approximation for Top-*k* Queries

Regardless of the chosen network topology, all distributed top-*k* algorithms consist of the following elements [14]:

Indexing. Determines what is indexed and how index information is collected within the network.

Source selection. Determines the peers a query is sent to.

Result merging. Determines how local result lists are merged to form the final result set.

Unstructured Networks In an unstructured P2P network peers form a random graph. In these networks, the only available routing strategy is *filtered flooding*, i.e., forwarding the query to selected neighbors. For effective filtering, the peers maintain content indexes. For each neighbor peer, the index allows to look up which kind of content is reachable via this peer. In the case of information retrieval, the index holds term frequencies of these subnets. This index information is built by gossiping: each peer periodically sends the content summaries it holds to its neighbors, where they are merged with the index. Thus, over time each peer gathers more and more accurate information about the whole network. Frequently, bloom filters or hash sketches are used to represent the content summaries. The typical representative for this approach is PlanetP [6]. Evaluations have shown that this algorithm type only scales to several thousands of peers, due to the limitations of filtered flooding. Even with complete index information, the query still usually has to be sent to a high fraction of all peers to reach the peers holding the top-*k* objects. Also, gossiping induces rather high index maintenance costs.

Hierarchical Networks Hierarchical topologies can overcome some of these limitations. In these topologies, particularly powerful peers form a super-peer backbone. Information sources are not connected with each other, but always assigned to one of the super-peers. This topology is especially suited for adaptation of traditional distributed top-*k* algorithms: each super-peer acts as coordinating node for its peers. In some systems the peers form a tree-shaped network; this has the advantage that the same aggregation algorithm can be used up to the root peer, but at the price of extremely uneven load distribution. Therefore, the usual approach is to restrict the hierarchy to two levels. In this case, filtered flooding is used to distribute queries within the super-peer backbone. Maintaining the index independently from the actual queries can impose a high overhead; this can be avoided by building a *query-driven index* [2].

Structured Networks Arguably the most efficient peer-to-peer networks are DHTs, where peers form highly structured network topologies. However, they only provide the usual hash table feature, storage and retrieval by key. The DHT maintains lists of top peers for each feature [3,13]. As in the case of hierarchical peers, the index can be improved by considering query statistics [12]. For a query, first these lists are retrieved, and then an established algorithm such as CORI or GlOSS is used for source selection. To retrieve the top-*k* objects, the TA family of algorithms are the state of the art. TPUT is especially suitable because it limits the retrieval process to three phases: first, the query initiator determines a lower bound for the object score by requesting scores of the top-*k* objects at each peer. Second, the initiator requests all objects having at least the threshold score. It is guaranteed that all top-*k* objects are in the returned sets. Finally, the initiator determines these objects and requests the actual content. TPUT has been evolved to an approximate algorithm with probabilistic guarantees in [9].

Approximation for Aggregate Queries

Efficient approximation of aggregate queries in unstructured P2P networks can be done by sampling. Starting at the peer issuing the query, the query travels along a random path to gather the sample. The challenge is to choose this path such that the query is indeed received by a uniform sample of the network. Note that the standard approach (*Markov-Chain random walk*) of selecting each outgoing edge with equal probability does not yield a uniform sample, but favors nodes with high degrees. This can be approximately compensated by scaling down the local peer value with the probability of this peer being selected. To reduce errors due to clustering within the network, the random walk can be modified such that only each *i*th peer on the path is considered for the sample. [1] shows how usual aggregate queries (COUNT, SUM, AVG) can be computed in this way with low error rates. While gossiping also has be proposed to compute aggregates in unstructured networks, this method does not scale to large networks [10].

An efficient method to compute COUNT queries in DHT networks has been proposed in [10]. This approach relies on locally computed hash sketches which are inserted into the DHT. For hash sketches of length k the actual counting requires $O(k)$ DHT lookups, resulting in $O(k \cdot logn)$ messages.

Key Applications

Top-*k* queries are used in distributed information retrieval scenarios, such as digital library networks.

An important application for aggregate queries in massively distributed networks is the gathering of network statistics, e.g., to identify security risks or to monitor performance [8]. Approximate aggregate queries are also gaining importance in the area of sensor network [5], where limitations of the sensor hardware (processor, memory, power supply) are key factors for query algorithm design.

Approximate query answering

Definition

Query processing in a database context is the process that deduces information that is available in the database. Due to the huge amount of data available, one of the main issues of query processing is how to process queries efficiently. In many cases, it is impossible or too expensive for users to get exact answers in the short query response time. Approximate query processing (AQP) is an alternative way that returns approximate answer using information which is similar to the one from which the query would be answered. It is designed primarily for aggregate queries such as count, sum and avg, etc. Given a SQL aggregate query Q, the accurate answer is y while the approximate answer is y'. The relative error of query Q can be quantified as:

$$Error(Q) = |\frac{y - y'}{y}|. \qquad (1)$$

The goal of approximate query processing is to provide approximate answers with acceptable accuracy in orders of magnitude less query response time than that for the exact query processing.

Historical Background

The earliest work on approximate answers to decision support queries appears in Morgenstein's dissertation from Berkeley [8]. And the approximate query processing problem has been studied extensively in the last 10 years. The main motivations [3] which drive the techniques being developed are summarized as follows.

First, with the advanced data collection and management technologies, nowadays there are a large number of applications with data sets about gigabytes, terabytes or even petabytes. Such massive data sets necessarily reside on disks or tapes, making even a few accesses of the base data sets comparably slow. In many cases, precision to "last decimal" is not required for a query answer. Quick approximation with some error guarantee (e.g., the resident population in Australia 21,126,700 +/− 200) is adequate to provide insights about the data.

Second, decision support system (DSS) and data mining are popular approaches to analyzing large databases for decision making. The main characteristic of the DSS is that aggregation queries (e.g., count, sum, avg, etc.) are executed on large portion of the databases, which can be very expensive and resource intensive even for a single analysis query. Due to the exploratory nature of decision making, iterative process involves multiple query attempts. Approximate answers with fast response time gives users the ability to focus on their explorations and quickly identify truly interesting data. It provides a great scalability of the decision support applications.

Third, approximate query processing is also used to provide query preview. In most cases, users are only interested in a subset of the entire database. Given a trial query, query preview provides an overview about the data distribution. The users can preview the number of hits and refine the queries accordingly. This prevents users from fruitless queries such as zero-hits or mega-hits. Figure 1 shows an example of query preview interface of NASA EOSDIS (Earth Observing System Data and Information System) project, which is attempting to provide online access to a rapidly growing archive of scientific earth data about the earth's land, water, and air. In the query preview, users select rough ranges for three attributes: area, topic (a menu list of parameters such as atmosphere, land surface, or oceans) and temporal coverage. The number of data sets for each topic, year, and area is shown on preview bars. The result preview bar, at the bottom of the interface, displays the total approximate number of data sets which satisfy the query.

Finally, sometimes network limitation or disk storage failure would cause the exact answers unaffordable or unavailable. An alternative solution is to provide an approximate answer based on the local cached data synopsis.

Foundations

Due to the acceptability of approximate answers coupled with the necessity for quick query response time, approximate query processing has emerged as a cost effective approach for dealing with the large amount of data. This speed-up is achieved by answering queries based on samples or other synopses (summary) of data whose size is orders of magnitude smaller than that of the original data sets.

Ioannidis presented the generic flow of approximate query process (Fig. 2) in [5]. Here, data analysis is the overall approach which derives the synopsis from original data to approximate the underlying data distribution. Typically, the *algorithm* partitions the data based on the *distance* function into groups of similar elements, called *buckets*, clusters, patterns, or several other names. The *data elements* that fall in each bucket are then represented by the synopses for *approximation use* which corresponds to the actual purpose of the whole data approximation process. The quality of approximation result can be measured by the *distance* between the synopses and the original data.

There are two basic approaches to achieve approximate query processing: pre-computed synopsis and online query processing.

Pre-Computed Synopsis

Approximate query processing using pre-computed synopsis includes two steps: construct synopsis prior to query time, answer query approximately using synopsis at query time.

To provide high accurate query answer, the key issue to construct synopsis is how to represent the underlying data distribution precisely and compactly. Generally, the data distribution can be classified into two groups: uniform distribution and non-uniform distribution. The synopsis for uniform data distribution assumes the objects are distributed uniformly in the data space. For point objects locating in two-dimensional

space $[{U^x}_{min}, {U^y}_{min}] \times [{U^x}_{max}, {U^y}_{max}]$, the query result size is estimated as $N \times area(Q)/(({U^x}_{max} - {U^x}_{min}) \times ({U^y}_{max} - {U^y}_{min}))$, where N is the data set size and $area(Q)$ is the area of window query Q.

There are various techniques developed for non-uniform data distribution. They can also be divided into two groups: parametric and non-parametric. The parametric techniques try to use parameters to catch the original data distributions. Although the models can summarize data distributions with a few descriptive parameters, if the underlying data do not follow any known distributions, or their linear combinations, the model fitting techniques produce inferior results.

The non-parametric techniques use different approaches to summarize the data distributions. Generally, it is possible to classify these techniques into three categories according to the strategies adopted:

1. Sampling techniques
2. Histogram techniques
3. Wavelet techniques

Sampling The basic idea of sampling is that a small random sample of the data often well-represent all the data. Therefore, query would be answered based on the pre-sampled small amount of data and then scaled up based on the sample rate. Figure 3 shows an example where 50% of data are sampled during the pre-computed stage. Given a query "how many Sony laptops are sold in *R*", the approximate result is "select 2 * sum(*) from *S* where *S.product* = '*SonyLaptop*'", which is 12. In *R*, the exact answer is 11.

The main issue of sampling method is to decide what sample criteria should be used to select data. The sampling techniques are classified into the following groups [1]:

1. *Uniform sampling*. Data is sampled uniformly
2. *Biased sampling*. A non-uniform random sample is pre-computed such that parts of the database deemed "more important" than the rest
3. *Icicles*. A biased sampling technique that is based on known workload information
4. *Outlier indexing*. Indexing outliers and biased sampling the remaining data
5. *Congressional sampling*. Targeting group by queries with aggregation and trying to maximize the accuracy for all groups (large or small) in each group-by query
6. *Stratified sampling*. Generalization of outlier indexing, Icicles and congressional sampling. It targets minimizing error in estimation of aggregates for the given workload

Sample-based procedures are robust in the presence of correlated and nonuniform data. Most importantly, sampling-based procedures permit both assessment and control of estimation errors. The main disadvantage of this approach is the overhead it adds to query optimization. Furthermore, join operation could lead to significant quality degradations because join operator applied on two uniform random sample can result in a non-uniform sample of the join result which contains very few tuples.

Histograms Histogram techniques are the most commonly used form of statistics in practice (e.g., they are used in DB2, Oracle and Microsoft SQL Server). This is because they incur almost no run-time overhead and

Approximate Query Processing. Figure 3. Example of sampling.

produce low-error estimates while occupying reasonably small space.

The basic idea is to partition attribute value domain into a set of buckets and query is answered based on the buckets. The main issues of histogram construction and query are as follows:

1. How to partition data into bucket
2. How to represent data in each bucket
3. How to estimate answer using the histogram

For one-dimensional space, a histogram on an attribute X is constructed by partitioning the data distribution of X into B ($B \geq 1$) buckets and approximating the frequencies and values in each bucket. Figure 4a is an example of original data set and Figure 4b shows its data distribution. Figure 4c is an example of histogram constructed accordingly, where $B = 3$.

If there are several attributes involved in a query, a multi-dimensional histogram is needed to approximate the data distribution and answer such a query. A multi-dimensional histogram on a set of attributes is constructed by partitioning the joint data distribution of the attributes. They have the exact same characteristics as one-dimensional histograms, except that the partition rule needs to be more intricate and cannot always be clearly analyzed because there cannot be ordering in multiple dimensions [9].

To represent data in each bucket, it includes value approximation and frequency approximation. Value approximation captures how attribute values are approximated within a bucket. And frequency approximation captures how frequencies are approximated within a bucket.

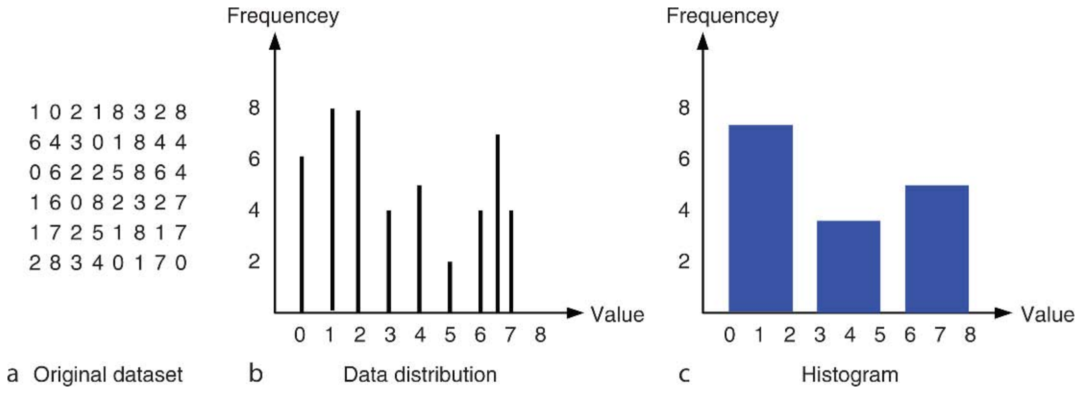
The two main approaches for value approximation are *continuous value assumption* and *uniform spread assumption* [10]. Continuous value assumption only maintains min and max value without indication of how many values there are or where they might be. Under the uniform spread assumption, one also maintain the number of values within each bucket and approximates the actual value set by the set that is formed by (virtually) placing the same number of values at equal distances between the min and max value in multi-dimensional space [6].

With respect to frequency approximation, almost all work deal with *uniform distribution assumption*.

The benefit of a histogram synopsis is that it can be easily used to answer many query types, including the aggregate and non-aggregate queries. However, one of the issues of histogram approach is it is hard to calculate a theoretical error bound. Thus the evaluations on the histogram synopsis usually rely heavily on the experiment results. Further more, histogram-based approaches become problematic when dealing with the high-dimensional data sets that are typical for modern decision support applications. This is because as the dimensionality of the data increases, both the storage overhead (i.e., number of buckets) and the construction cost of histograms that can achieve reasonable error rates increase in an explosive manner.

Wavelet Wavelet is a mathematical tool for hierarchical decomposition of functions using recursive pairwise averaging and differencing at different resolutions. It represents a function in terms of a coarse overall shape, plus details that range from broad to narrow. It is widely used in the signal and image processing.

Matias et al. [7] first proposed the use of Haar-wavelet coefficients as synopsis for estimating the selectivity of window queries. The basic idea is to apply wavelet decomposition to the input data collection to



1 0 2 1 8 3 2 8
6 4 3 0 1 8 4 4
0 6 2 2 5 8 6 4
1 6 0 8 2 3 2 7
1 7 2 5 1 8 1 7
2 8 3 4 0 1 7 0

Approximate Query Processing. Figure 4. Example of histogram.

obtain a compact data synopsis that comprises a select small collection of wavelet coefficients. Figure 5 shows an example of hierarchical decomposition tree of Haar-wavelet. The leaf nodes are original data and non-leaf nodes are wavelet coefficients generated by averaging and differencing from their two children.

Later, the wavelet concept was extended to answer more general approximate queries. The results of recent studies have clearly shown that wavelets can be very effective in handling aggregates over high-dimensional online analytical processing (OLAP) cubes, while avoiding the high construction costs and storage overheads of histogram techniques.

Another important part of the above three technologies for approximate query processing is synopsis maintenance. If the data distribution is not changed significantly, the data synopsis would be updated accordingly to reflect such change. Otherwise, a new data synopsis will be constructed and discard the old one. Refer to the specific techniques for more details.

There are a few other work that do not belong to the above three categories to approximate the underlying data distribution. For example, recently Das et al. [2] present a framework that is based on randomized projections. This is the first work in the context of spatial database which provides probability quality guarantees with respect to query result size approximation.

Online Query Processing

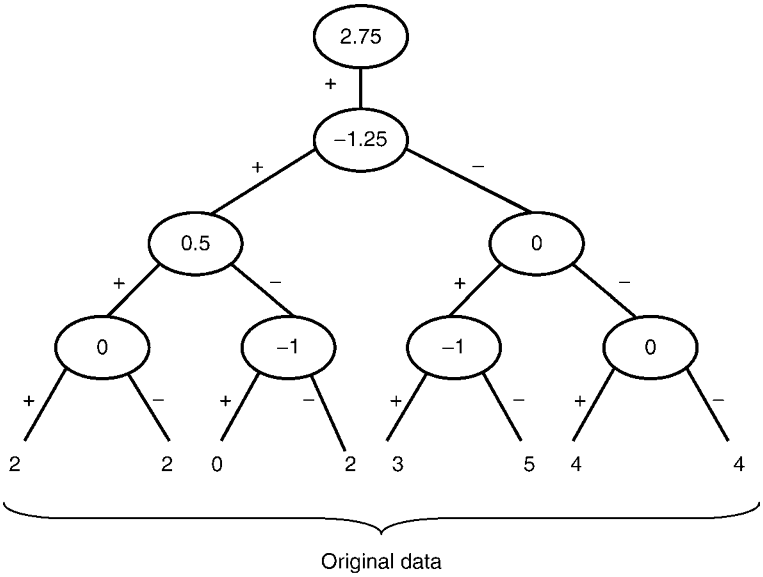
The motivation of online query processing is that the data analysis is to extract unknown information from data. It is an iterative process starting by asking broad questions and continually refining them based on approximate or partial results. Therefore, instead of optimizing for query response time, it needs to balance two conflicting performance goals: minimizing uneventful "dead time" between updates for the users, while simultaneously maximizing the rate at which partial or approximate answers approach a correct answer. Refer to [4] for details.

Compared with pre-computed synopses approach, the advantages of online query processing approach is it does not require pre-processing and progressive refinement of approximate results at runtime can quickly lead to a satisfied results. However, the main obstacles for this technique to be practical is it significantly changes the query processor of current commercial query processing system which is not desirable.

Key Applications

AQP in Relational Data Management

The AQUA system proposed by the Bell lab can support various kinds of approximate queries over the relational database.



Approximate Query Processing. Figure 5. Example of Haar-wavelet hierarchical decomposition.

AQP in Spatial Data Management

Alexandria Digital Library allows user to define spatial queries and returns the approximate number of hits quickly as the initial result and then user can refine the query accordingly.

AQP in Stream Data Management

MIT proposed Aurora as a data stream management system, which virtually supports answering approximate queries over the data stream.

AQP in Sensor Network

The techniques of TinyDB system, proposed by Massachusetts Institute of Technology and UC Berkeley, can lead to orders of magnitude improvements in power consumption and increased accuracy of query results over non-acquisitional systems that do not actively control when and where data is collected.

AQP in Semantic Web Search

For semantic web search, the viewpoints of users performing a web search, ontology designers and annotation designers do not match. This leads to missed answers. Research studies have shown AQP is of prime importance for efficiently searching the Semantic Web.

Approximate Reasoning

Vilém Novák
University of Ostrava, Ostrava, Czech Republic

Definition

Approximate reasoning is a deduction method which makes it possible to derive a conclusion on the basis of imprecisely characterized situation (quite often using linguistically specified fuzzy IF-THEN rules) and a new information that can also be imprecise. The basic scheme of approximate reasoning is the following:

$$\begin{array}{lcl} \text{Condition} & : & \text{IF } X \text{ is } \mathcal{A}_1 \text{ THEN } Y \text{ is } \mathcal{B}_1 \\ & & \dots\dots\dots\dots\dots\dots\dots\dots \\ & & \text{IF } X \text{ is } \mathcal{A}_m \text{ THEN } Y \text{ is } \mathcal{B}_m \\ \text{Premise} & : & X \text{ is } \mathcal{A}' \\ \hline \text{Conclusion} & : & Y \text{ is } \mathcal{B}' \end{array} \tag{1}$$

where "Condition" is a linguistic description consisting of a set of fuzzy/linguistic IF-THEN rules and $\mathcal{A}'$ is a possible modification of antecedent of some of the former rules. For example, "X is small" can be replaced by "X is very small."

Key Points

The mathematical model of approximate reasoning depends on the way how the linguistic description forming the condition is interpreted (see FUZZY/LINGUISTIC IF-THEN RULES AND LINGUISTIC DESCRIPTIONS).

Let X is $\mathcal{A}'$ be interpreted by a fuzzy set $A' \underset{\sim}{\subseteq} U$. If "Condition" is interpreted by a fuzzy relation $R \underset{\sim}{\subseteq} U \times V$ then the result of approximate reasoning is a fuzzy set $B' \underset{\sim}{\subset} V$ which interprets "Y *is* $\mathcal{B}'$" and which is obtained using the formula

$$B'(y) = \bigvee_{x \epsilon U} (A'(x) \otimes R(x,y)) \qquad (2)$$

where $\otimes$ is a t-norm (product in residuated lattice).

Alternative approximate reasoning method is *perception-based logical deduction*. Its idea consists of finding *perception* of the given measured value of the input $X = x_0$. The perception is an evaluative expression occurring among $\mathcal{A}_1, \ldots, \mathcal{A}_m$ that fits x_0 in the best way. Then the corresponding fuzzy IF-THEN rule is fired and the proper output is derived. More details can be found in [2,3].

Approximation of Frequent Itemsets

JINZE LIU
University of Kentucky, Lexington, KY, USA

Synonyms

AFI

Definition

Consider an $n \times m$ binary matrix D. Each row of D corresponds to a transaction t and each column of D corresponds to an item i. The (t, i)-element of D, denoted $D(t, i)$, is 1 if transaction t contains item i, and 0 otherwise. Let $T_0 = \{t_1, t_2, \ldots, t_n\}$ and $I_0 = \{i_1, i_2, \ldots, i_m\}$ be the set of transactions and items associated with D, respectively.

Let D be as above, and let $\varepsilon_r, \varepsilon_c \in [0,1]$. An itemset $I \subseteq I_0$ is an approximate frequent itemset AFI(ε_r, ε_c), if there exists a set of transactions $T \subseteq T_0$ with $|T| \geq minsup|T_0|$ such that the following two conditions hold:

1. $\forall i \in T, \dfrac{1}{|I|} \sum_{j \in I} D(i,j) \geq (1 - \epsilon_r);$
2. $\forall j \in I, \dfrac{1}{|T|} \sum_{i \in T} D(i,j) \geq (1 - \epsilon_c);$

Historical Background

Relational databases are ubiquitous, cataloging everything from market-basket data [1] to genomic data collected in biological experiments [2]. A binary matrix is one common representation of relational databases. Rows in the matrix often correspond to the objects, while columns represent attributes of the objects. The binary value of each matrix entry indicates the presence (1) or absence (0) of an attribute in the object. For example, in a market-basket database, rows represent transactions, columns represent product items, and a binary entry indicates whether an item is contained in the transaction [1]. Frequent itemset mining [1] is a key technique in the analysis of such data. In the binary representation, a *frequent itemset* corresponds to a sub-matrix of 1s, where the itemset (the set of columns) are supported by a sufficiently large number of transactions (set of rows).

While frequent itemsets and the algorithms to generate them have been well studied, the problem is that the data in real application is often imperfect. In a transaction database, frequent itemsets might be obscured by the vagaries of the market and human behaviors. Items expected to be purchased together by a customer might not appear together in some transactions when one of them is out of stock in the market or overstocked by the customer. In addition, empirical data is subject to measurement noise. For example, Microarray data is often error-prone due to variations in the experimental technology and the stochastic nature of biological processes.

The noise recorded in real applications undermines the ultimate goal of the classical frequent itemset algorithms, i.e., revealing the itemset that is present in a sufficient fraction of transactions (Fig. 1). In fact, when noise is present, the classical frequent itemset algorithms may discover multiple small fragments of the true itemset while missing the true itemset itself. The problem worsens for the most interesting large itemsets since they are more vulnerable to noise.

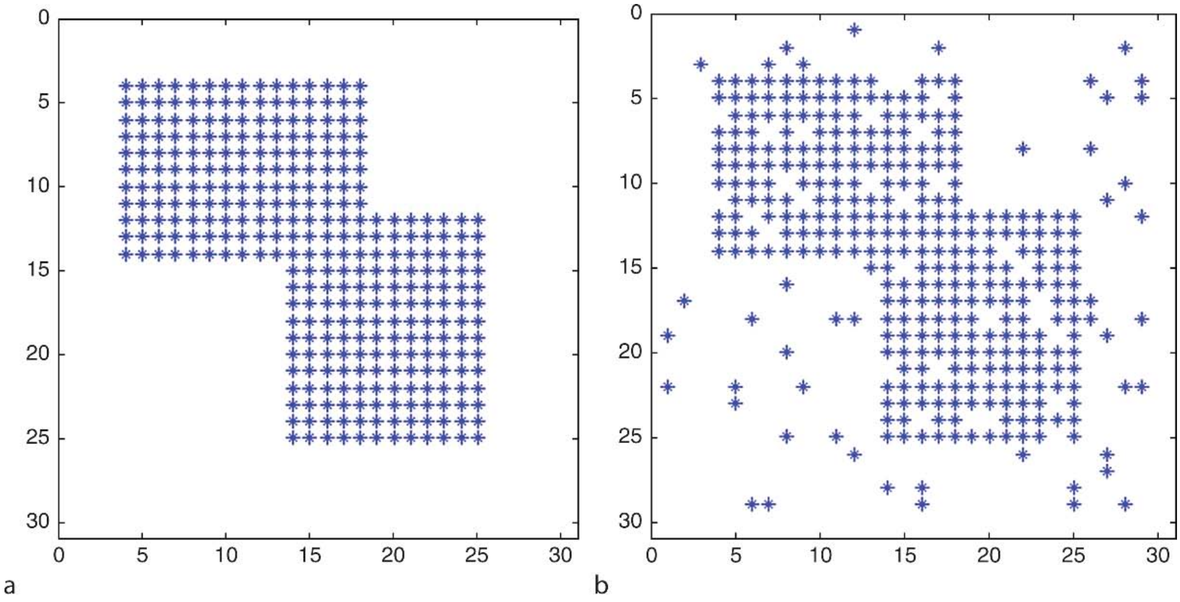
The approximate frequent itemset AFI(ε_r, ε_c) denotes a collection of submatrices of D where the row-wise and column-wise noise levels within each submatrix are below ε_r and ε_c respectively. The classical exact frequent itemset (EFI) is a member of AFI(ε_r, ε_c) where ε_r and ε_c are set to be 0 (Fig. 2). The noise thresholds ε_r and ε_c are usually below 30%. In cases when the noise in either row or column is not restricted, AFI(ε_r, $*$) or AFI($*$, ε_c) will be used to denote the corresponding families. AFI(ε_r, $*$) corresponds to the same family of itemsets, namely *Error Tolerant Itemset (ETI)*, defined by Yang et al. [8].

Foundations

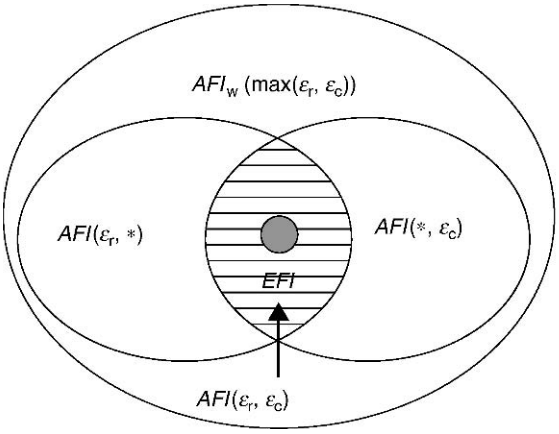
The AFI-mining algorithm [3,4] generalizes the framework of level-wise itemset enumeration. First, the Apriori property of exact frequent itemset mining doesn't hold for AFI when noise is allowed. Instead, conditions under which candidate itemsets can be pruned are established and employed in the AFI algorithm. Secondly, methods that systematically enumerate candidate itemsets without multiple scans of the database are also developed.

Noise-Tolerant Support Pruning

The anti-monotone property of exact frequent itemsets is the key to eliminating the exponential search space in frequent itemset mining [1]. In particular, the anti-monotone property ensures that a (k+1) exact itemset can be pruned if anyone of its k sub-itemsets is not sufficiently supported. However, the allowance of noise may lower the support necessary for the sub-itemsets of a noise-tolerant itemset. The following theorem suggests a lower bound of support for pruning the candidate itemsets in generating AFIs.



Approximation of Frequent Itemsets. Figure 1. Patterns with and without noise.



AFI_w (max(ε_r, ε_c))
$AFI(\varepsilon_r, *)$
$AFI(*, \varepsilon_c)$
EFI
$AFI(\varepsilon_r, \varepsilon_c)$

Approximation of Frequent Itemsets. Figure 2. Relationships of various AFI criteria.

Theorem 1. *Given a minsup threshold, If a length* $(k+1)$*-itemset* I' *is an AFI*(ε_r, ε_c), *for any of its k-sub-itemset* $I \subseteq I'$, *the number of transactions containing no more than* ε_r *fraction of noise must be at least*

$$n \cdot minsup \cdot (1 - \frac{k\epsilon_c}{\lfloor k\epsilon_r \rfloor + 1}) \qquad (1)$$

The noise-tolerant pruning support is defined as the following:

1 Definition

Given ε_c, ε_r and *minsup*, the **noise-tolerant support** for a length-k itemset.

$$minsup_I^k = minsup \cdot (1 - \frac{k\epsilon_c}{\lfloor k\epsilon_r \rfloor + 1})+ \qquad (2)$$

Here $(a)_+ = \max\{a, 0\}$.

The noise-tolerant support threshold is used as the basis of a pruning strategy for AFI mining. The strategy removes supersets of a given I from further consideration when I has support less than $minsup_I{}^k$. In the special case that $\varepsilon_r = \varepsilon_c = 0$, $minsup_I{}^k = minsup$, which is consistent with the anti-monotone property of exact frequent itemsets [1].

0/1 Extensions

A transaction t supports a k-itemset I if t contains at least a fraction $1 - \varepsilon_r$ of the items in I. The transaction set of I consists of all the transactions supporting I. Starting with singleton itemsets, the AFI algorithm generates $(k + 1)$-itemsets from k-itemsets in a breadth-first fashion. For each candidate itemset I, transactions t supporting I are generated. The transaction set of a $(k + 1)$ itemset is constructed from the transaction sets of its k-item subsets in one of two different ways, depending on the value of k and ε_r.

0-extension and 1-extension are the two basic steps to be taken for the efficient collection of the supporting transactions. They obtain the supports based on the support of its sub-itemset while avoiding the repeated database scans plaguing the algorithms proposed by [6,8].

Lemma 1 *(1-Extension) If* $\lfloor k \cdot \varepsilon_r \rfloor = \lfloor (k + 1) \cdot \varepsilon_r \rfloor$ *then any transaction that does not support a k-itemset will not support its* $(k + 1)$ *superset.*

The Lemma is based on the fact that if no additional noise is allowed when generating $(k + 1)$ itemset, a transaction does not support a (k-itemset won't support its $(k + 1)$ superset since the number of 1s it contains is always smaller than or equal or $\frac{\lfloor k_* \epsilon \rfloor - 1 + 1}{k+1} < \epsilon$. Thus if $\lfloor k \cdot \varepsilon_r \rfloor = \lfloor (k + 1) \cdot \varepsilon_r \rfloor$ then the transaction set of a $(k + 1)$ itemset I is the intersection of the transaction sets of its length k subsets. This is called a *1-extension.*

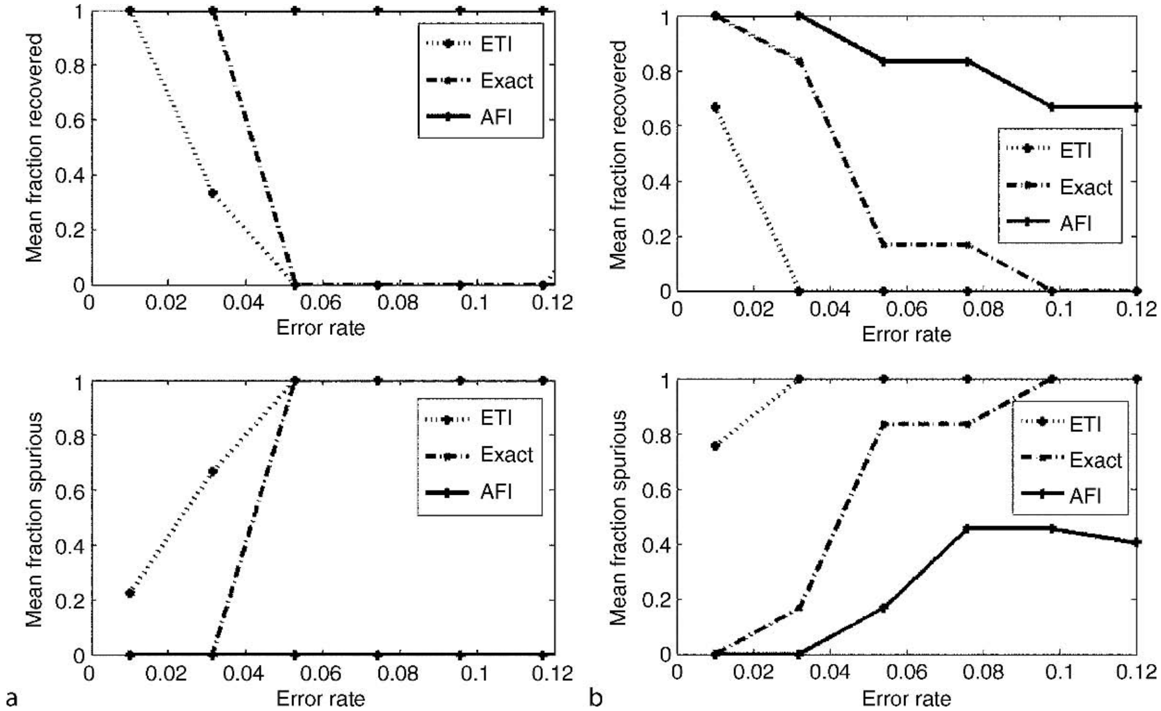
Lemma 2 *(0-Extension) If* $\lfloor k \cdot \varepsilon_r \rfloor + 1 = \lfloor (k + 1) \cdot \varepsilon_r \rfloor$ *then any transaction supporting a (k-itemset also supports its* $(k{+}1)$ *supersets.*

The procedure of 0-extension embodies how noise can be encompassed into a frequent itemset. If additional noise is allowed in a $(k + 1)$-itemset, it is intuitive that a transaction that supports a k-itemset will also support its $k + 1$-item superset, no matter whether the $k + 1$ entry is 1 or 0. To reflect this property, if $\lfloor k \cdot \varepsilon_r \rfloor + 1 = \lfloor (k + 1) \cdot \varepsilon_r \rfloor$, the transaction set of a $(k + 1)$ itemset I is the union of the transaction sets of its length k subsets. This is called a *0-extension.*

Experimental Results

In order to test the quality of the algorithm, data with an embedded pattern and overlaid random errors are generated. The discovered patterns are evaluated against the true patterns which are known in apriori. The methods, exact frequent itemset (EFI), ETI and AFI, are compared in terms of their capabilities in discovering the true patterns in the presence of noise.

Two measures jointly describing the quality are employed. They are "recoverability" and "spuriousness." Recoverability is the fraction of the embedded patterns recovered by an algorithm, while spuriousness is the fraction of the mined results that fail to



Approximation of Frequent Itemsets. Figure 3. Algorithm quality versus noise level.

correspond to any planted cluster. A truly useful data mining algorithm should achieve high recoverability with little spuriousness to dilute the results. A detailed description of the two measures is given in [3].

Multiple data sets were created and analyzed to explore the relationship between increasing noise levels and the quality of the result. Noise was introduced by bit-flipping each entry of the full matrix with a probability equal to p. The probability p was varied over different runs from 0.01 to 0.2. The number of pattern blocks embedded also varied, but the results were consistent across this parameter. The results when one or three blocks were embedded in the data matrix are presented in Fig. 3a,b, respectively.

In both cases, the exact method performed poorly as noise increased. Beyond $p = 0.05$ the original pattern could not be recovered, and all of the discovered patterns were spurious. In contrast, the error-tolerant algorithms, ETI and AFI, were much better at recovering the embedded matrices at the higher error rates. However, the ETI algorithm reported many more spurious results than AFI. Although it may discover the embedded patterns, ETI generates many more patterns that are not of interest, which may overshadow the real patterns of interest. The AFI algorithm consistently demonstrated higher recoverability of the embedded pattern while maintaining a lower level of spuriousness.

Application

AFI mining algorithm can be generally used to find dense 1s blocks in a large binary matrix. The following are example applications.

- E-commerce application: discover approximate frequent itemset in large transactional databases [3,4].
- Biogeographic application: discover regions associated with migration in biogeographic research [3].
- Microarray analysis: find noise tolerant co-expressed patterns.

Apriori Property and Breadth-First Search Algorithms

BART GOETHALS
University of Antwerp, Antwerp, Belgium

Synonyms

Monotonicity property; Downward closure property; Levelwise search

Definition

Given a large database of sets of items, called transactions, the goal of frequent itemset mining is to find all subsets of items, called itemsets, occurring frequently in the database, i.e., occurring in a given minimum number of transactions.

The search space of all itemsets is exponential in the number of different items occurring in the database. Hence, the naive approach to generate and count the frequency of all itemsets over the database can not be achieved within reasonable time. Also, the given databases could be massive, containing millions of transactions, making frequency counting a tough problem in itself.

Therefore, numerous solutions have been proposed to perform a more directed search through the search space, almost all relying on the well known Apriori-property. These solutions can be divided into breadth-first search and depth-first search, of which the first is discussed here.

Historical Background

The original motivation for searching frequent itemsets came from the need to analyze so called supermarket transaction data, that is, to examine customer behavior in terms of the purchased products. Frequent sets of products describe how often items are purchased together. In 1993, Agrawal, Imilienski, and Swami introduced this problem, and proposed a first algorithm to solve it. Shortly after that, in 1994, the algorithm was improved and named *Apriori*. The main improvement was to exploit the monotonicity property of the frequency of itemsets, later referred to as the *Apriori property*. The same technique was independently proposed by Mannila, Toivonen, and Verkamo, after which both works were combined in one book chapter [1]. Since then, hundreds of improvements and new algorithms have been developed, many of them relying on the breadth-first search strategy as proposed in the Apriori algorithm.

Foundations

A set of items $\mathcal{I}$ and a database $\mathcal{D}$ of subsets of $\mathcal{I}$, called *transactions*, is given. An *itemset* $I \subseteq \mathcal{I}$ is some set of items; its *support* in $\mathcal{D}$ is defined as the number of transactions in $\mathcal{D}$ that contain all items in I. An itemset is called *frequent* in $\mathcal{D}$ if its support in $\mathcal{D}$ is greater than or equal to a given minimum support threshold σ. The goal is now, given a minimal support threshold σ and a database $\mathcal{D}$, to find all frequent itemsets in $\mathcal{D}$.

Instead of naively generating and counting all possible itemsets, several collections of *candidate itemsets* are generated iteratively, and their supports computed until all frequent itemsets have been generated. Obviously, the size of a collection of candidate itemsets must not exceed the size of available main memory. Moreover, it is important to generate as few candidate itemsets as possible, since computing the supports of a collection of itemsets is a time consuming procedure. In the best case, only the frequent itemsets are generated and counted. Unfortunately, this ideal is impossible generally, which will be shown later in this section.

The main underlying property exploited by most algorithms is that support is monotone decreasing with respect to extension of an itemset.

Property 1. (Apriori Property) *Given a transaction database $\mathcal{D}$ over $\mathcal{I}$, let $X, Y \subseteq \mathcal{I}$ be two itemsets. Then,*

$$X \subseteq Y \Rightarrow support(Y) \leq support(X).$$

Hence, if an itemset is infrequent, all of its supersets must be infrequent. In the literature, this property is also called the monotonicity property, or also the downward closure property, since the set of frequent itemsets is closed with respect to set inclusion. This property is of crucial importance for all frequent itemset mining algorithms as it allows for pruning large parts of the search space. As soon as an itemset is known to be infrequent, none of its supersets has to be considered anymore.

The Apriori Algorithm

For simplicity, assume that items in transactions and itemsets are kept sorted in their lexicographic order unless stated otherwise.

The itemset mining phase of the Apriori algorithm is given in Figure 1. The notation *X[i]* is used to represent the *i*th item in *X*; the k-*prefix* of a set *X* is the *k*-set $\{X[1],\ldots,X[k]\}$, and $\mathcal{F}_k$ denotes the frequent *k*-sets.

The algorithm performs a breadth-first (levelwise) search through the search space of all sets by iteratively generating and counting a collection of candidate sets. More specifically, a set is candidate if all of its subsets are counted and frequent. In each iteration, the collection C_{k+1} of candidate sets of size $k + 1$ is generated, starting with $k = 0$. Obviously, the initial set C_1 consists of all items in $\mathcal{I}$ (line 1). At a certain level *k*, all candidate sets of size $k + 1$ are generated. This is done in two steps. First, in the *join* step, the union $X \cup Y$ of sets $X, Y \in \mathcal{F}_k$ is generated if they have the same $k - 1$-prefix (lines 13–15). In the *prune* step, $X \cup Y$ is inserted into C_{k+1} only if all of its *k*-subsets are frequent and thus, occur in $\mathcal{F}_k$ (lines 16–17).

Apriori Property and Breadth-First Search Algorithms. Figure 1. Apriori.

To count the supports of all candidate k-sets, the database is scanned one transaction at a time, and the supports of all candidate sets that are included in that transaction are incremented (lines 4–7). All sets that turn out to be frequent are inserted into $\mathcal{F}_k$ (line 11).

If the number of candidate sets is too large to remain in main memory, the algorithm can be easily modified as follows. The candidate generation procedure stops and the supports of all generated candidates are counted. In the next iteration, instead of generating candidate sets of size $k + 2$, the remaining candidate $k + 1$-sets are generated and counted repeatedly until all frequent sets of size $k + 1$ are generated and counted.

Although this is a very efficient and robust algorithm, its main drawback lies in its inefficient support counting mechanism. Fortunately, a lot of counting optimizations have been proposed for many different situations.

Optimizations

A lot of other algorithms proposed after the introduction of Apriori retain the same general structure, adding several techniques to optimize certain steps within the algorithm. Since the performance of the Apriori algorithm is almost completely dictated by its support counting procedure, most research has focused on that aspect of the Apriori algorithm. Here, only four out of more than hundreds of improvement proposals are outlined, but at least, these four represent the most influential and largest jumps forward.

Item Reordering One of the most important optimizations which can be effectively exploited by almost any frequent set mining algorithm, is the reordering of items.

The underlying intuition is to assume statistical independence of all items. Then, items with high frequency tend to occur in more frequent sets, while low frequent items are more likely to occur in only very few sets.

For example, in the case of Apriori, sorting the items in support ascending order improves the distribution of the candidate sets within the used data structure [4]. Also, the number of candidate sets generated during the join step can be reduced in this way. Unfortunately, until now, no results have been presented on an optimal ordering of all items for any given algorithm and only vague intuitions and heuristics are given, supported by practical experiments.

Partition As the main drawback of Apriori is its slow and iterative support counting mechanism, Savasere et al. [12] proposed the Partition algorithm.

The main novelty in the Partition algorithm, compared to Apriori, is that the database is partitioned into several disjoint parts and the algorithm generates for every part all sets that are relatively frequent within that part. The parts of the database are chosen in such a way that each part fits into main memory, allowing for much more efficient counting mechanisms. Then, the algorithm merges all relatively frequent sets of every part together. This results in a superset of all frequent sets over the complete database, since a set that is frequent in the complete database must be relatively frequent in one of the parts. Finally, the actual supports of all sets are computed during a second scan through the complete database.

Sampling Another technique to solve Apriori's slow counting is to use sampling as proposed by Toivonen [13].

The presented Sampling algorithm picks a random sample from the database that fits in main memory, then finds all relatively frequent patterns in that sample, and finally verifies the results with the rest of the database. In the cases where the sampling method does not produce all frequent sets, the missing sets can be found by generating all remaining potentially frequent sets and verifying their supports during a second pass through the database. The probability of such a failure can be kept small by decreasing the minimal support threshold. However, for a reasonably small probability of failure, the threshold must be drastically decreased, which can cause a combinatorial explosion of the number of candidate patterns. Nevertheless, in practice, finding all frequent patterns within a small sample of the database can be done very fast using fast in-memory support counting techniques. In the next step, all true supports of these patterns must be counted after which the standard levelwise algorithm could finish finding all other frequent patterns by generating and counting all candidate patterns iteratively. It has been shown that this technique usually needs only one more scan resulting in a significant performance improvement [13].

Concise Representations If the number of frequent sets for a given database is large, it could become infeasible to generate them all. Moreover, if the database is dense, or the minimal support threshold is set too low, then there could exist a lot of very large frequent sets, which would make sending them all to the output infeasible to begin with. Indeed, a frequent set of size k includes the existence of at least $2^k - 1$ frequent sets, i.e., all of its subsets. To overcome this problem, several proposals have been made to generate only a concise representation of all frequent sets for a given database such that, if necessary, the frequency of a set, or the support of a set not in that representation can be efficiently determined or estimated [2,5–11].

Key Applications

The Apriori property and the breadth-first search algorithms have broad applications in mining frequent itemsets and association rules. Please refer to the entries of frequent itemset mining and association rules. The Apriori property and the breadth-first search algorithms can be extended to mine sequential patterns. Refer to the entry of sequential patterns. Moreover, they can also be used to tackle other data mining problems such as density-based subspace clustering.

Experimental Results

So far, several hundreds of scientific papers present different techniques and optimizations for frequent set mining and it seems that this trend is keeping its pace. For a fair comparison of some of these algorithms, a contest was organized to find the best implementations in order to understand precisely why and under what conditions one algorithm would outperform another [3]. Although there were no clear winners, one of the rather surprising results of that contest was that the original Apriori algorithm often still performs among the best.

Architecture-Conscious Database System

John Cieslewicz, Kenneth A. Ross
Columbia University, New York, NY, USA

Synonyms

Architecture-sensitive database system; Architecture-aware database system; Hardware-conscious database system

Definition

Database systems designed with awareness of and a sensitivity to the underlying computer hardware are "architecture-conscious." In an architecture-conscious database system implementation, the performance characteristics of computer hardware guide algorithm and system design.

Historical Background

Database system implementation has been, in varying ways, architecture conscious from the advent of the relational database. For instance, System R [2], an early relational database system prototype included the number of I/Os as a cost metric in its optimizer. At a very high level, the implementers of System R included the characteristics of the underlying hardware in their analysis. This trend has continued with growing attention paid by the database research community to the effects of hardware technology on database performance. Architecture-conscious design took on greater importance as processor speeds improved by four orders of magnitude between 1980 and 2005, while memory latency improved by less than a single order of magnitude. Because of this performance gap, memory accesses, which are central to any database workload, became relatively expensive, requiring database researchers to design database algorithms with this hardware limitation in mind. New computational features have been added to microprocessors, including SIMD instructions, branch prediction, and memory prefetching. These techniques help to improve single threaded performance and instruction level parallelism (ILP), which is the simultaneous processing of instructions from the same thread. In order to take maximal advantage of many of these features, databases must be designed with them in mind.

The introduction of chip multiprocessors (CMP), in particular, has created new challenges and opportunities for improving database performance. Due to problems with power usage, heat dissipation, and diminishing single threaded performance returns from increasingly complex logic to exploit additional ILP, beginning early in the 2000s chip architects switched their design emphasis from faster clock rates to increased on chip parallelism. It is expected that the degree of parallelism supported by CMPs will continue to increase, making it imperative to design database operators for effective on-chip parallelism. In addition to single threaded performance, achieving good performance on chip multiprocessors requires awareness of thread level parallelism (TLP), the simultaneous processing of instructions from multiple instruction streams. All of these features provide additional opportunities for architecture-conscious database system design.

Foundations

The underlying hardware architecture of which an architecture-conscious database system must be aware includes all computer components. For database systems, the most critical components are persistent storage, the memory hierarchy, and the microprocessor. Research in this field is conducted using architecture simulators and with real hardware. Both are valuable tools, as simulators can test new techniques on hypothetical future hardware designs and using real hardware yields results that are applicable to systems in production now. This article focuses on identifying and explaining the architectural features that have performance implications for databases, and providing high-level design guidelines for database systems implementers using these architectures. A more detailed description of specific database implementation techniques is given in [6].

Persistent Storage

As mentioned above, the impact of storage subsystems has been part of database implementation from the beginning, and many database textbooks describe the costs of various relational operators in terms of the number of I/Os required. Accessing secondary storage incurs significant latency compared with accessing data in memory. For magnetic disk based storage systems, sequential access is favored because each read and write requires a large, fixed cost (rotational and seek latency) before the relatively fast reading or writing. Because of this property, databases are often optimized for sequential reads and writes to storage, e.g., reading entire buffer pages rather than individual records. Magnetic disks, however, are not the only type of persistent storage. Flash memory storage devices also provide high density persistent storage, but have different properties than magnetic disks. As of 2007, flash memory does not have density comparable to magnetic disks, but the technology is improving. Flash memory, unlike a magnetic disk, has no mechanical parts, uses less power, and supports a higher number of random I/Os per second. These different characteristics require new thinking about the way a database system uses persistent storage. For instance, the read, write, and erase properties of flash memory make is less suitable for update-in-place database operations than magnetic disks. Changes to page layout and logging have been introduced to overcome this difference [11]. Flash memory's support for more random I/Os per second, also leads to changes in cost-performance metrics such as the five-min rule [7].

Main Memory and Cache Optimizations

Memory density has increased while prices have fallen, resulting in affordable systems in which a database's entire working set can be held in memory. For such systems, I/O latency no longer dominates. At the same time, processor speeds have increased at a much faster rate than memory latency, making a data load from main memory relatively more expensive. Computer architects have combated this problem by adding caches to processors. A cache is a small, but very fast memory on the same chip as the processor. The cache provides a processor with fast access to frequently used data (temporal locality) or data that resides near recently used data (spatial locality). When data is found in the cache, it is called a *cache hit*, but when data is not found in the cache this is a *cache miss* and main memory must be accessed. Accessing main memory is a longer latency operation that can stall the processor's pipeline. On database workloads, cache misses for data and instructions have been shown to account for a significant portion of execution time [1]. Therefore, data structures and query execution techniques that make more efficient use of limited cache resources are complementary improvements that reduce cache misses and improve performance.

In addition to improving cache use, the challenge posed by the memory bottleneck can be overcome by overlapping memory latency with computation. Prefetching facilitates that overlapping by attempting to load data into the cache before it is needed. Prefetching can be controlled both in hardware and software. In hardware prefetching, the processor attempts to identify access patters, such as a sequential scan, and load data ahead of when it is needed. In software prefetching, the programmer inserts prefetch instructions into a program to provide the hardware with hints about what data should be loaded into the cache. Software prefetching must be used when there is no pattern to the memory accesses. Chen et al. have improved the performance of tree-based index searches and hash joins by using prefetch instructions [3,4].

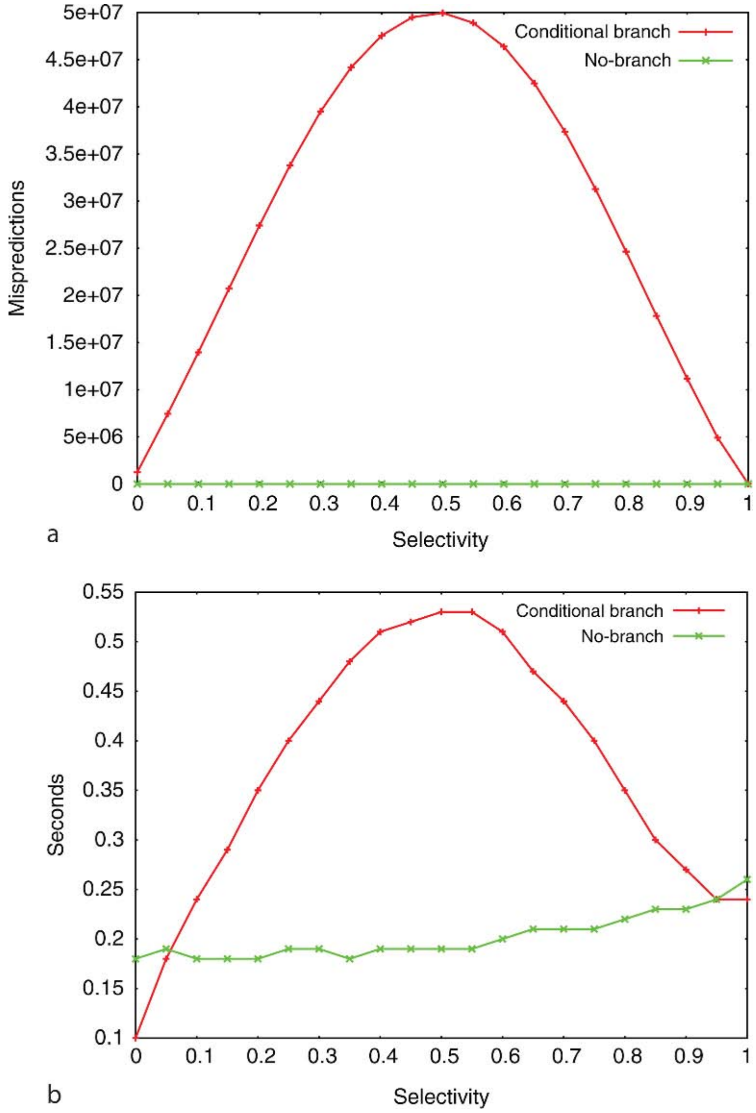
Microarchitecture Optimizations

Conditional branches are a performance hazard on many microarchitectures. A conditional branch represents a control dependency, after which the processor does not immediately know which instruction to execute. On architectures with long pipelines, the outcome of a conditional test is not known for many cycles. In the interim, the processor must either stop issuing instructions or guess the outcome of the condition. This control dependency can limit instruction level parallelism (ILP) because the compiler is limited in its ability to reorder instructions around a branch and the processor is unsure which instructions to issue after a branch instruction. Many modern processors attempt to guess the outcome of the branch using hardware branch prediction, so that instructions continue to be issued in spite of the branch. Branch prediction attempts to identify patterns in the recent history of branch outcomes in order to guess the present branch's outcome correctly. If the branch is predicted correctly, the branch causes no delay in the pipeline. When the prediction is incorrect, the pipeline must be flushed and restarted because invalid instructions have been issued. This cost is the "branch misprediction penalty" and is related to the depth of the pipeline. When there is no pattern to the branching, branch prediction fails up to half the time, and the misprediction penalty degrades performance. In database workloads, where branches are often data dependent, branch misprediction has a noticeable impact on performance [1]. Figure 1a shows the number of mispredictions of performing a simple range selection on an array of 100 million uniformly distributed four byte integers on a 2.4 GHz Intel Core 2 Duo processor. The graphs in Fig. 1 show data for a selection implementation using a conditional branch and a "no-branch" implementation in which the conditional branch's control dependency has been changed to a data dependency [12]. The maximum number of mispredictions occur in the conditional branch implementation when the selectivity is 0.5 because the branch prediction is wrong half of the time. This high rate of branch misprediction impacts performance, as shown in Fig. 1b. In contrast, the implementation with no conditional branch is less sensitive to the selectivity, with its modest rise in execution time (Fig. 1b) attributed to the cost of writing more output as the selectivity increases. Ross extends the query optimizer's cost model to take the cost of branch misprediction into account and demonstrates techniques for evaluating selection conditions using varying numbers of conditional branches [12].

Modern microarchitectures feature special vector operations, also known as *single instruction multiple data* (SIMD) instructions. These instructions operate on wide registers containing multiple variables, enabling data parallelism. For example, a 128 bit SIMD register can contain 16 `char` data types or four 32-bit integers. A wide range of mathematical, logical, and data movement operations can be applied in parallel to those variables using a single instruction. SIMD instructions can be used to improve the data parallelism present in database execution, resulting in higher performance [14]. For some architectures, such as the Cell Broadband Engine, which are highly optimized for SIMD processing, SIMD-izing database operations is crucial to achieving good performance [9]. SIMD instructions can be used to transform control dependencies into data dependencies. For instance, when using scalar instructions, selection is commonly performed with a comparison operation followed by a conditional branch. In contrast, with SIMD instructions, a selection is performed by applying a SIMD comparison operation to multiple elements in parallel. The result of this operation is a bit-mask that can be used to select the elements that pass the condition using other instructions. Transforming a control dependency into a data dependency can also be accomplished with predicated scalar instructions such as a *conditional move* instruction. Regardless of how the control dependency is eliminated, doing so will improve ILP, particularly if the branch is difficult to predict, as is the case in the example shown in Fig. 1.

On-Chip Parallelism

A chip multiprocessor (CMP) provides multiple on chip hardware thread contexts, often in the form of multiple



Architecture-Conscious Database System. Figure 1. Number of branch mispredictions and execution time for a one-sided range selection with varying selectivity. The red, ''Conditional Branch,'' line is an implementation using a conditional branch, while the green, ''No-Branch,'' line is an implementation where the conditional branch's control dependency has been replaced with a data dependency [8].

processor cores on a single die. A processor core's pipeline may be shared by different instruction streams, a design known as simultaneous multithreading (SMT). Some CMPs have both multiple cores and multiple threads per core. As of 2007, the most cores available on a commodity processor was eight, with each core supporting four threads for a total of 32 threads per CMP.

Hardware support for thread level parallelism (TLP) in a CMP differs from a symmetric multiprocessor (SMP) in that a CMP is one processor die with multiple processor cores and an SMP is a system composed of multiple processors sharing one main memory. This difference has two important implications. First, when data is shared among two or more processors in an SMP system, modifications to that data by any processor is coordinated by a cache coherency protocol, which uses the system bus to communicate information about changes to shared data. The system bus is significantly slower than the processors and if a large amount of data is shared among the processors or it is frequently updated, cache coherency overhead can significantly impact performance. In contrast, because all of the cores of a CMP are on the same die, communication between the cores can occur at chip speeds, greatly reducing the coherency overhead of shared data. Second, in a SMP system, although the main memory is shared, each processors' cache hierarchy is separate. In contrast, many CMPs share some cache levels among the processor cores or threads. Because some cache resources may be shared, designing threads to share data in the cache can be beneficial provided that coordinating the sharing does no introduce large amounts of overhead. These differences have implications for architecture-conscious database systems such as the challenge of designing core database operations that take advantage of the on-chip parallelism afforded by chip multiprocessors in a manner that will scale as CMPs provide more hardware thread contexts.

Chip multiprocessors present opportunities and challenges for improving database performance [8]. Finding parallelism in database systems is not difficult. Most database systems have long supported concurrent queries from different users. Other forms of parallelism can be found within a single query or within a single operator. Parallelism alone does not guarantee optimal performance on a CMP. An architecture-conscious database system on a CMP must exploit the on-chip parallelism in a manner that uses the parallel resources to maximum effect. For instance, Cieslewicz and Ross find that balancing parallelism, cache sharing, and thread communication is key to achieving good performance when computing aggregates using a CMP [5]. Chip multiprocessors can also help alleviate some of the problems associated with the memory bottleneck described previously. By having multiple concurrently executing thread contexts on one chip, a stall due to a cache miss in one thread does not stall the entire processor, leading to higher overall processor utilization. Similar to techniques using prefetch instructions described earlier, an on-chip thread can also be used to explicitly load data into the cache for other another thread [13].

Techniques that perform well on a uniprocessor may not be appropriate for a CMP. For instance, Johnson et al. found that work-sharing schemes for in-memory workloads on CMPs actually reduced performance [10]. This was because work-sharing created a bottleneck at the shared work, limiting the total parallelism. An important lesson is that in order to achieve optimal database performance on a CMP, database implementers must carefully evaluate design decisions that may limit parallelism.

Key Applications

Databases are crucial to a wide range of data storage and analysis activities. Optimizing core database operations to take advantage of all of the features and resources available on modern hardware will result in better performance, which in turn has the ability to directly improve the experience of all users of databases.

Future Directions

Adapting database operators to increased on-chip parallelism afforded by CMPs is one open problem. As the amount of on-chip parallelism increases, new bottlenecks and scaling challenges will emerge. Another area for future research includes using non-traditional architectures, such as the Cell Broadband Engine [9] and other future heterogeneous processors, for database operations. As long as computer architecture continues to evolve, architecture-conscious databases will need to adapt to new technologies.

Archiving Experimental Data

REAGAN W. MOORE
University of California, San Diego, La Jolla, CA, USA

Synonyms

Preservation; Reference collections

Definition

The archiving of data is the process by which a project preserves both data and representation information that is needed to interpret the data.

Historical Background

An increasing fraction of science research is based on the analysis of large data collections. Experimental data are collected from measurements by sensors on repeatable experiments conducted in laboratories. Observational data are collected from sensors that measure properties of the natural environment. Simulation output files are generated by applications that run on supercomputers. The size of each of these types of research data can be massive, measured in Petabytes (thousands of Terabytes), such that there is physically not enough room to keep the data on high-speed disk file systems.

The archiving of experimental data traditionally focused on the migration of data from high-performance (more costly) storage systems to the lowest cost media that were available (originally tape-based systems). Files were manually copied from disk onto the tape archive. The IEEE Mass Storage System Reference Model version 5 defines the properties that a tape archive should provide [4]. The properties include the ability to automate retrieval of the file, manage the name space used to identify the file, and manage migration of files between tapes. While these capabilities enable the long-term management of the files, each project was required to manage independently any representation information needed to interpret the file and the meaning of the data. The OAIS model defines representation information that should be provided for preservation of data [6]. This includes information about the source of the data, descriptions of the structures present within the data file, identification of the application that can manipulate the data structure, descriptions of the meaning of the data, and identification of a knowledge community that can interpret the meaning. Archiving of experimental data is successful when the data can be retrieved, interpreted, and manipulated by the project at an unspecified future time.

Foundations

The archiving of experimental data is facilitated through the development of standards for the descriptive terms used to describe meaning and provenance, standards for describing the structures present in the file, and standards for the services that manipulate the data structures.

- Standard semantics. The terms used to describe physical phenomena are created by each discipline. The meaning of these terms evolves over time as a better understanding is developed of the physical phenomena. A preservation environment will need to support evolution of the semantic meaning, through the mapping of prior vocabulary sets to the new vocabulary. This is typically done through use of ontologies that define logical mappings between terms, spatial correlation of terms to maps, assignment of temporal coordinates to processes, and specification of functional relationships between physical quantities.

- Standard formats. Each file is a linear string of bits, on which structure is imposed. A file format describes how to interpret the bit string into structures that can be named. Since the types of observational or experimental or simulation data vary extensively, each community chooses a standard format for specific physical phenomena. As new phenomena are measured, new data formats are created. Thus a preservation environment needs to manage either characterization of the file formats or migration of the file formats onto new standards. A promising approach to handle data format migration is based on Data Format Description Languages, that enable the description of the structure of the file using an XML syntax.
- Standard access methods. Each scientific community defines standard processing steps for manipulating the structures present within the standard data formats, using the standard semantic terms. These standard processing mechanisms can be ported on top of data grid technology to enable their use within the preservation environment [5]. An alternate approach is to port the required display application to each new operating system technology. This assumes the data can be retrieved from the preservation environment, and a copy is placed on the computer where the emulated application is executed.

The size of science data collections poses a major scalability challenge, and strongly impacts the implementation of the data archiving process. The large number of files and the large size of an individual file require support mechanisms that may not be provided by a specific storage system. The science research projects listed below use data grid technology to overcome limitations in current storage technology, and to simplify incorporation of new technology within the preservation environment. Data grids are software middleware that insulate the scientific collections from dependencies on current storage technology through the implementation of infrastructure independence [2]. The names used to describe the science data are managed by the data grid independently of the choice of storage system. This makes it possible to ensure consistent naming even when data is distributed across multiple storage systems or migrated from old technology to new technology.

Data grids provide standard operations for manipulating science data. The operations are executed at the remote storage system through interoperability mechanisms that can be applied on any choice of storage. Data grids also provide standard interfaces that enable the use of a preferred access mechanism. The result is the ability to use a particular research group's access interface to manipulate data stored on multiple types of remote storage systems.

The mechanisms provided by data grids to manage science data explicitly handle issues of scale:

- Large file size. An individual file can be multiple gigabytes in size. The time required to move such a file over a network to a storage system can be excessive. By using parallel I/O streams, the time can be decreased by multiple factors of two. Effectively, the data file is separated into multiple segments, each of which is transmitted over the network in parallel with the other segments. Large files are typically sent using four to eight parallel I/O streams.
- Large file size. The retrieval of a large file, even with parallel I/O streams may take multiple minutes. For cases where a small subset of the large file is needed, it is more efficient to filter the file at the remote storage system, and send only the desired subset back over the network. Data grids support remote manipulation of files through the execution of remote procedures at the location where the file resides.
- Large number of files. Each storage system has a maximum number of files that it is designed to handle. Large collections can exceed the number of files that can be written to a single storage system. To overcome this limitation, data grids aggregate small files into a single larger file called a container. The container is written to the storage system. The data grid maintains information that allows it to track the location in the container of each file. For example, the 2-Micron All Sky Survey [8] astronomy image collection containing 5 million images was archived on tape by aggregating the images into 147,000 containers. If the images in each container are from the same area on the sky, then retrieval of the container can result in multiple related images becoming accessible, improving bulk access to the collection.
- Large number of files. For the archived files to be useful, descriptive information is needed about

each file to support discovery. The descriptive information may be extractable from the file. However, if a discovery request is issued that requires the parsing of every file in the collection, the time to satisfy the request may be exceptionally long. Data grids manage metadata for each file in a metadata catalog. The metadata catalog is stored as tables in a relational database, enabling efficient searches. Data grids can use remote procedures to parse the descriptive metadata from the file, and bulk load the metadata into the metadata catalog.

- Large size of collections. The management of integrity across large collections may be viewed as an intractable problem. File integrity can be verified by reading each file, calculating a checksum, and then comparing the checksum with a previous value that was stored in the metadata catalog. If the file has become corrupted, the two checksums will not be equal. If a single tape drive is used to read a Petabyte collection, a sustained data transfer rate of 33 MB/s is needed to read the entire collection in a year. Thus integrity checking of large collections can require the dedication of significant hardware resources. If a problem is detected, a second copy is required to be able to repair the corruption. Data grids support the replication of data onto multiple storage systems that may be located at geographically remote locations. The geographic separation is needed to ensure recovery from natural disasters. Synchronization of replicas is done to verify integrity of the files.

Key Applications

Science disciplines are generating massive collections of experimental, observational, and simulation data. Single projects such as the Southern California Earthquake Center [7] plan to generate over 1.5 Petabytes of simulation data of seismic wave propagation from earthquakes on the San Andreas Fault. The Large Synoptic Survey Telescope (LSST) plans to capture more than 130 Petabytes of observational data [3]. The LSST project takes photographs of the sky to track near earth objects, supernovae, and micro-lensing events that can provide information on the structure of the Universe. The BaBar high-energy physics experiment has moved more than 400 Terabytes of experimental data from the Stanford Linear Accelerator in Palo Alto, California to Lyon, France for analysis by collaborating physicists [1]. In each case, the data are archived for comparison with future research results.

Future Directions

The ability to validate the trustworthiness of a digital repository is becoming an essential requirement for the archiving of experimental data. When scientific collections are archived, each community defines assessment criteria that they expect the preservation environment to maintain. The assessment criteria may be related to retention and disposition policies, or to time-dependent access controls, or to specifications of required descriptive metadata, or to required access mechanisms for data display and manipulation. An emerging requirement for scientific collections is the characterization of the management policies under which the desired collection properties are enforced.

Rule based data grids provide the mechanisms needed not only to enforce the application of the collection management policies, but also to automate the execution of data management policies. As scientific collections grow to the Petabyte size, the labor required to administer the collections can become onerous. This is driven by the use of distributed storage systems to manage the collections. Once the collection resides on multiple types of storage systems, located on multiple administrative domains at geographically remote sites, it becomes very hard to control what is happening. A network router or storage system may be taken down for maintenance, or an operational procedure may change, causing an unexpected result. Data grids provide mechanisms to recover from such problems through the use of replicas, checksums, and synchronization. A problem can be detected and repaired through an administrator-initiated action. When the number of detected problems becomes too large, the administrator is no longer able to keep up with the workload.

Rule based data grids minimize the labor required by the administrator by automating execution of management policies. Management policies are defined that control the preservation processes that are applied to the collection (e.g., validate checksum, verify presence of required metadata, implement the retention policy). Assessment criteria are specified that evaluate whether the management policies have been correctly applied. In a rule-based data grid, the preservation processes are expressed as sets of micro-services that are executed at the remote storage system. Each micro-service in turn is composed from standard operations that the data grid implements for each type of storage system. Management policies are expressed as sets of rules that control the execution of the micro-services. A rule engine is installed at each remote storage system to ensure that the policies are enforced, no matter which access mechanism is used to interact with the data grid. The assessment criteria are mapped to queries on persistent state information that is generated after the execution of each micro-service. Such a rule based data grid is capable of monitoring its own operations and verifying the trustworthiness of the digital repository that holds the archived scientific collection [2].

Armstrong Axioms

Solmaz Kolahi
University of British Columbia, Vancouver,
BC, Canada

Definition

The term *Armstrong axioms* refers to the sound and complete set of inference rules or axioms, introduced by William W. Armstrong [2], that is used to test logical implication of functional dependencies.

Given a relation schema $R[U]$ and a set of functional dependencies Σ over attributes in U, a functional dependency f is logically implied by Σ, denoted by $\Sigma \models f$, if for every instance I of R satisfying all functional dependencies in Σ, I satisfies f. The set of all functional dependencies implied by Σ is called the *closure* of Σ, denoted by Σ^+.

Key Points

Armstrong axioms consist of the following three rules:

Reflexivity: If $Y \subseteq X$, then $X \rightarrow Y$.
Augmentation: If $X \rightarrow Y$, then $XZ \rightarrow YZ$.
Transitivity: If $X \rightarrow Y$ and $Y \rightarrow Z$, then $X \rightarrow Z$.

Note that in the above rules XZ refers to the union of two attribute sets X and Z. Armstrong axioms are *sound* and *complete*: a functional dependency f is derivable from a set of functional dependencies Σ by applying the axioms if and only if $\Sigma \models f$ (refer to [1] for more information).

Association Rule Mining on Streams

Philip S. Yu[1], Yun Chi[2]
[1]IBM T.J. Watson Research Center, Yorktown Heights, NY, USA
[2]NEC Laboratories America, Cupertino, CA, USA

Definition

Let $I = \{ i_1,\ldots,i_m\}$ be a set of items. Let S be a stream of transactions in a sequential order, where each transaction is a subset of I. For an *itemsetX*, which is a subset of I, a transaction T in S is said to *contain* the itemset X if $X \subseteq T$. The *support* of X is defined as the fraction of transactions in S that contain X. For a given support threshold s, X is *frequent* if the support of X is greater than or equal to $s\%$, i.e., if at least $s\%$ transactions in S contain X. For a given *confidence* threshold c, an *association ruleX* $\Rightarrow Y$ holds if $X \cup Y$ is frequent and at least $c\%$ of transactions in S that contain X also contain Y. The problem of association rule mining on streams is to discover all association rules that hold in a stream of transactions.

Historical Background

In 1993, Rakesh Agrawal et al. [1] proposed the framework for association rule mining. Since this seminal work, a lot of researches have been done to improve the efficiency of association rule mining algorithms, to extend the definition of associations rule, and to apply association rule mining to other types of data such as time sequence data and structured data such as graphs. On the other hand, research on data streams started around 2000 when several data stream management systems were originated (e.g., the Brandeis AURORA project, the Cornell COUGAR project, and the Stanford STREAM project) to solve new challenges in applications such as network traffic monitoring, transaction data management, Web click streams monitoring, sensor networks, etc. Because association rule mining plays an important role in these data stream applications (e.g., the motivation in the first association rule paper [1] is to mine patterns from retail store transaction data), along with the development of data stream management systems, developing association rule mining algorithms for data streams has become an important research topic.

Foundations

Two Sub-problems

Algorithms for association rule mining usually consist of two steps. The first step is to discover frequent itemsets. In this step, all frequent itemsets that meet the support threshold are discovered. The second step is to derive association rules. In this step, based on the frequent itemsets discovered in the first step, the association rules that meet the confidence criterion are derived. Because the second step, deriving association rules, can be solved efficiently in a straightforward manner, most of researches focus mainly on the first step, i.e., how to efficiently discover all frequent itemsets in data streams. Therefore, in the rest of this article, the focus will be on frequent itemset mining in data streams.

Key Challenges

Frequent itemset mining in general is already a challenging problem. For example, due to combinatorial explosion, there may be huge number of frequent itemsets, and a main challenge is how to efficiently enumerate, discover, and store frequent itemsets. Data streams, because of their unique features, have further posed many new challenges to frequent itemset mining. Some of these new challenges are described as the following.

Single access of data In data streams, data are arriving continuously with high speed and in large volume. As a consequence, in many cases it is impractical to store all data in persistent media and in other cases, it is too expensive to (randomly) access data multiple times. The challenge is to discover frequent itemsets while the data can only be assessed once.

Unbounded data Another feature of data streams is that data are unbounded. In comparison, storage that can be used to discover or maintain the frequent itemsets is limited. Another consequence of unbounded data is that whether an itemset is frequent depends on time. The challenge is to use limited storage to discover dynamic frequent itemsets from unbounded data.

Real-time response Because data stream applications are usually time-critical, there are requirements on response time. For some restricted scenarios, algorithms that are slower than the data arriving rate are useless. The challenge is therefore to efficiently mine frequent itemsets in real time.

Data Models

Compared with finite data in traditional databases, data streams are unbounded and the number of transactions increase with time. Due to these characteristics, different data models have been proposed in different mining algorithms.

The first data model is an accumulative model. In this model, all data in the range from the beginning to the current time are considered in an equal fashion. Therefore, frequent itemsets are defined on the accumulated data where new data are appended continuously as time grows.

The second data model is based on a sliding window. That is, although the whole data stream is unbounded, the frequent itemsets are defined based on the most recent data that fall within a temporal sliding window whose ending time is the current time. One justification for such a sliding-window model is that due to concept drifts, the data distribution in streams is usually changing with time, and very often people are interested in the most recent patterns.

The third data model falls in between the first two models – while all data are considered in frequent itemset mining, they are weighted differently according to a predefined weighting function. A very commonly used weighting function is the exponentially decaying function, that is, for a transaction at time τ, its weight is $\alpha(\tau) = \exp(\tau - t)$, where t is the current time.

Algorithm Types

Based on the mining results, existing frequent itemsets mining algorithms on data streams can be roughly divided into two categories: the exact mining algorithms and the approximate mining algorithms.

Exact mining algorithms provide as results all the frequent itemsets in the data streams together with their accurate supports. Usually the focus of exact algorithms is to efficiently update frequent itemsets when new transactions arrive and (in the sliding-window data model) when old transactions expire.

Approximate mining algorithms, on the other hand, focus more on finite memory usage and single access of data, at the cost of the accuracy of the mining results. Approximate algorithms target low false positive rate, zero, or low false negative rate, and tight error bounds on the estimation for the supports of the frequent itemsets.

Representative Algorithms

Cheung et al. [6,7] proposed algorithms *FUP* and *FUP*$_2$ for incrementally updating frequent itemsets. Thomas et al. [13] presented a similar algorithm. Both Cheung's and Thomas's algorithms assume batch updates and take advantage of the relationship between the original database (*DB*) and the incrementally changed transactions (*db*). *FUP* is similar to the well-known Apriori algorithm [1], which is a multiple-step algorithm. The key observation of *FUP* is that by adding *db* to *DB*, some previously frequent itemsets will remain frequent and some previously infrequent itemsets will become frequent (these itemsets are called *winners*); at the same time, some previously frequent itemsets will become infrequent (these itemsets are called *losers*). The key technique of *FUP* is to use information in *db* to filter out some winners and losers, and therefore reduce the size of candidate set in the Apriori algorithm. Because the performance of the Apriori algorithm relies heavily on the size of candidate set, *FUP* improves the performance of Apriori greatly. *FUP*$_2$ extended *FUP* by allowing deleting old transactions from a database as well. Therefore *FUP* is restricted to the accumulative data model while *FUP*$_2$ can be used on the sliding-window data model as well. The algorithm proposed by Thomas et al. is similar to *FUP*$_2$ except that in addition to frequent itemsets, a negative border is maintained. In the algorithm, the frequent itemsets in *db* are mined first. At the same time, the counts of frequent itemsets (and itemsets on the negative border) in *DB* are updated. Then based on the change of the frequent itemsets in *DB*, the negative border in *DB*, and the frequent itemsets in *db*, the frequent itemsets in the updated database are computed with a possible scan of the updated database. Because the updated database is scanned at most once, Thomas's algorithm has very good performance. Thomas's algorithm can be used for both the accumulative and the sliding-window data models. In addition, *FUP*, *FUP*$_2$, and Thomas's algorithm all fall into the category of exact mining algorithms.

Veloso et al. [14] proposed an algorithm *ZIGZAG* for mining frequent itemsets in evolving databases. Later, Otey et al. [11] extended *ZIGZAG* into parallel and distributed algorithms. *ZIGZAG* is similar to Cheung's and Thomas's algorithms in that it achieves its speedup by using the relationship between *DB* and *db*. However, *ZIGZAG* has many distinct features. First, *ZIGZAG* mainly used *db* to speedup the support counting of frequent itemsets in the updated database and it does not discover the frequent itemsets in *db* itself. As a result, for a given minimum support, *ZIGZAG* can handle batch update with arbitrary block size. Second, *ZIGZAG* adapts the techniques proposed in the *GENMAX* algorithm [9] and in each update only maintains *maximal* frequent itemsets. Because the information on maximal frequent itemsets and their supports is not enough to generate association rules (because the support information of some non-maximal frequent itemsets may be missing), a second step is used in *ZIGZAG* in which the updated database is scanned to discover all frequent itemsets and their supports.

Chi et al. [5] developed an algorithm, *Moment*, to mine *closed* frequent itemsets over data stream sliding windows. In this work the authors introduced a compact data structure, the *closed enumeration tree* (CET), to maintain a dynamically selected set of itemsets over a sliding window. The selected itemsets contain a boundary between closed frequent itemsets and the rest of the itemsets. Concept drifts in a data stream are reflected by boundary movements in the CET, and can be efficiently captured. Both *ZIGZAG* and *Moment* are exact mining algorithms that use the sliding-window data model.

Charikar et al. [3] presented a one-pass algorithm, *Count Sketch*, that returns most frequent *items* whose frequencies satisfy a threshold with high probabilities. Manku et al. [10] developed a randomized algorithm, the *Sticky Sampling* algorithm, and a deterministic algorithm, the *Lossy Counting* algorithm, for maintaining frequent *items* over a data stream where for a given time *t*, the frequent items are defined over the *entire* data stream up to *t*. The algorithms guarantee no false negative and a bound on the error of estimated frequency (the guarantees are in a probabilistic sense for the randomized algorithm). The *Lossy Counting* algorithm is extended to handle frequent *itemsets*, where a trie is used to maintain all frequent itemsets and the trie is updated by batches of transactions in the data stream. The algorithms of Manku et al. strive for a tunable compromise between memory usage and error bounds. *Count Sketch*, *Sticky Sampling*, and *Lossy Counting* are all approximate mining algorithms that use the accumulative data model.

Teng et al. [12] presented an algorithm, *FTP-DS*, that mines frequent temporal patterns from data streams of itemsets. *FTP-DS* is an approximate mining algorithm that uses the sliding-window data model. Chang et al. [2] presented an algorithm, *estDec*, that mines recent frequent itemsets where the frequency is defined by an aging function. Giannella et al. [8] proposed an approximate algorithm for mining frequent itemsets in data streams during arbitrary time intervals. An in-memory data structure, *FP-stream*, is used to store and update historic information about frequent itemsets and their frequency over time and an aging function is used to update the entries so that more recent entries are weighted more. Both *estDec* and Giannella's algorithm are approximate mining algorithms on weighted transactions. However, Giannella's algorithm is a little different in that it can provide different error levels for data at multiple time granularities.

The above representative algorithms are summarized in Table 1. For a more detailed survey on algorithms for frequent itemset mining over data streams, refer to a recent survey by Cheng et al. [4].

Key Applications

For most data stream applications, there are needs for mining frequent patterns and association rules from data streams. Some key applications in various areas are listed in the following.

Performance monitoring Monitor network traffic and performance, detect abnormality and intrusion

Association Rule Mining on Streams. Table 1. The categorization of the representative algorithms according to their data models and algorithm types

	Data Model		
	Accumulative	Sliding-window	Weighted
Exact Mining Algorithm	*FUP* [2]	*FUP*$_2$ [3] Thomas's [4] *ZIGZAG* [5, 6] *Moment* [8	
Algorithm Mining Algorithm	*Count Sketch* [9] *Sticky Sampline* [10] *Lossy Counting* [10]	*FTP-DS* [11	*estDec* [12] Giannella's [13]

Transaction monitoring Monitor transactions in retail stores, ATM machines, and financial markets

Log record mining Mine patterns from telecommunication calling records, Web server log, etc.

Sensor network mining Mine patterns in streams coming from sensor networks or surveillance cameras

Experimental Results

In general, for each of the presented algorithms, there are supporting experimental studies in the corresponding references. The commonly compared performance metrics include memory usage, speed of the mining process, and (for the approximate algorithms) errors such as false positive rate, false negative rate, and support errors for the frequent itemsets.

Data Sets

A Linux version of the synthetic data generator originally developed by Agrawal et al. [1] is available at http://miles.cnuce.cnr.it/~palmeri/datam/DCI/datasets.php

Some other synthetic and real-life data sets are available from the Frequent Itemset Mining Dataset Repository at http://fimi.cs.helsinki.fi/data/

Furthermore, pointers to some related data sets are available at the KDnuggets Web site http://www.kdnuggets.com/datasets/

Association Rules

Jian Pei
Simon Fraser University, Burnaby, BC, Canada

Definition

Let $\mathcal{I}$ be a set of *items*, where each item is a literal. A *transaction* $T \subseteq \mathcal{I}$ is a subset of $\mathcal{I}$. Association rules are defined on a set of transactions $\mathcal{T}$.

An association rule R is in the form of $X \rightarrow Y$, where X and $Y$are two sets of items, that is, $X, Y \subseteq \mathcal{I}$. R is associated with two measures, the *support* $sup(R)$ and the confidence $conf(R)$. The support $sup(R)$ is the probability that X appears in a transaction in $\mathcal{T}$. The confidence $conf(R)$ is the conditional probability that when X appears in a transaction, Yalso appears.

Historical Background

The concept of association rules were firstly proposed by Agrawal et al. [1] for market basket analysis. A well known illustrative example of association rules is "Diaper → Beer" which can be explained by the fact that, when dads buy diapers for their babies, they also buy beer at the same time for their weekends game watching.

Apriori, an efficient algorithm for mining association rules, was developed by Agrawal and Srikant [3], while the similar idea was explored by Mannila et al. [13]. There have been many studies trying to improve the efficiency of Apriori (refer to entry "Apriori property and breadth-first search algorithms"). A pattern-growth approach for mining frequent itemsets without candidate generation was developed by Han et al. [8], and has been further improved by many studies since 2001 (see entry "Pattern-growth methods").

To remove redundancy in association rules, Pasquier et al. [15] proposed the notion of frequent closed itemsets using formal concept analysis. Several efficient algorithms have been developed (refer to entry "Closed itemset mining and non-redundant association rule mining").

Association rules have been extended in several ways, such as sequential patterns and sequential association rules (refer to entry "Sequential patterns"), spatial association rules [9], cyclic association rules [14], negative association rules [19], intertransaction association rules [12], multilevel generalized association rules [7,20], and quantitative association rules (refer to entry "Quantitative association rules").

In addition to support and confidence, some other interestingness measures for association rules were explored, such as [5,18].

Foundations

Let $\mathcal{I}$ be a set of *items*, where each item is a literal. An *itemset* X is a subset of items, that is, $X \subseteq \mathcal{I}$. A *transaction* $T \subseteq \mathcal{I}$ consists of a *transaction id* and an itemset. A *transaction database* $\mathcal{T}$ is a multiset of transactions.

An association rule R is in the form of $X \rightarrow Y$, where X and $Y$are two itemsets, that is, $X, Y \subseteq \mathcal{I}$. R is associated with two measures, the *support* $sup(R)$ and the confidence $conf(R)$. The support $sup(R)$, given by $sup(R) = Pr(X)$, is the probability that X appears in a transaction in $\mathcal{T}$. The confidence $conf(R)$, given by $conf(R) = \frac{sup(X \cup Y)}{sup(X)} = Pr(Y|X)$, is the conditional probability that when X appears in a transaction, Y also appears.

Given a transaction database $\mathcal{T}$, a minimum support threshold *minsup*, and a minimum confidence threshold *minconf*, the problem of *association rule mining* is to find the complete set of association rules whose supports are at least *minsup* and whose confidences are at least *minconf*.

Association rules can be mined in two steps. In the first step, the complete set of frequent itemsets are identified. An itemset is called *frequent* if $Pr(X) \geq minsup$. In the second step, frequent itemsets are used to generate association rules.

More often than not, to make association rule mining interesting, a user may specify a *minimum support threshold min_sup* and a *minimum confidence threshold min_conf*. Then, only the association rules whose supports and confidence pass those thresholds, respectively, should be returned. Alternatively, in some situations, a user may want to find the top-*k* association rules with the largest support and/or confidence. Some other kinds of constraints can also be specified. Such thresholds and constraints may be used by some association rule mining methods to speed up the mining procedure.

Key Applications

Association rules have been extensively mined and used in many applications. For example, mining association rules about customers' market baskets helps to identify the products that customers like to purchase together, or some products that may trigger the purchases of some other products. Such information can help business in one way or another. For example, knowing that the purchase of diapers may potentially lead to the purchase of beer, a store can put beer beside diapers so that the sales of beer can be boosted.

Association rules are also mined on biological data and clinic data. For example, mining the association rules among symptoms and disease can help to diagnose diseases.

An important application of association rules is to construct classifiers using association rules. Technically, association rules among features and the target class labels can be mined and the rules can be used to make prediction on cases with unknown class labels. Research has found that associative classifiers, classifiers using association rules, are accurate and highly understandable in a few applications such as those with many features [6,10,11].

Asymmetric Encryption

Ninghui Li
Purdue University, West Lafayette, IN, USA

Synonyms

Public-key encryption

Definition

Asymmetric encryption, also known as public-key encryption, is a form of data encryption where the encryption key (also called the public key) and the corresponding decryption key (also called the private key) are different. A message encrypted with the public key can be decrypted only with the corresponding private key. The public key and the private key are related mathematically, but it is computationally infeasible to derive the private key from the public key. Therefore, a recipient could distribute the public key widely. Anyone can use the public key to encrypt messages for the recipient and only the recipient can decrypt them.

Key Points

A public-key encryption algorithm requires a trapdoor one-way function, i.e., a function that is easy to compute but hard to invert unless one knows some secret trapdoor (i.e., the private key). Existing public-key encryption algorithms are based on computational problems in number theory.

The most well-known public-key encryption algorithms include RSA and El Gamal. RSA uses exponentiation modulo a product of two large primes to encrypt and decrypt, and its security is connected to the presumed difficulty of factoring large integers. The El Gamal cryptosystem relies on the difficulty of the discrete logarithm problem. The introduction of elliptic curve cryptography in the mid 1980s has yielded a new family of analogous public-key algorithms. Elliptic curves appear to provide a more efficient way to leverage the discrete logarithm problem, particularly with respect to key size.

[2]University of Arizona, Tucson, AZ, USA
[3]University of Turin, Turin, Italy

Synonyms

Snapshot data; Point-based temporal data

Definition

Atelic data is temporal data describing facts that do not involve a goal or culmination. In ancient Greek, *telos* means “goal,” and α is used as prefix to denote negation. In the context of temporal databases, atelic data is that data for which both *upward* and *downward* (temporal) *inheritance* holds. Specifically,

- *Downward inheritance*. The *downward inheritance* property implies that one can infer from temporal data *d* that holds at valid time *t* (where t is a time period) that *d* holds in any sub-period (and sub-point) of *t*.
- *Upward inheritance*. The *u pward inheritance* property implies that one can infer from temporal data *d* that holds at two consecutive or overlapping time

periods t_1 and t_2 that d holds in the union time period $t_1 \cup t_2$.

Atelic data is differentiated from telic data, in which neither upward nor downward inheritance holds.

Key Points

Starting from Aristotle [1], researchers in areas such as philosophy, linguistics, cognitive science and computer science have noticed that different types of facts can be distinguished according to their temporal behavior. Specifically, since atelic facts do not have any specific goal or culmination, they can be seen as "temporally homogeneous" facts, so that both upward and downward inheritance holds for them. For example, the fact that an employee (say, John) works for a company (say, ACME) would be considered atelic because of lack of goal or accomplishment. As a consequence, if John has worked for ACME from January 20, 2007 to September 23, 2007, it can be correctly inferred that John was working for ACME in May 2007 (or at any specific time point in May; therefore, downward inheritance does hold); furthermore, from the additional fact that John has also worked for ACME from September 23, 2007 to February 2, 2008, it can be correctly inferred that John worked for ACME from January 20, 2007 to February 2, 2008 (therefore, upward inheritance does hold).

In Aristotle's categorization, all possible facts are divided into two categories, telic and atelic; a telic fact, e.g., "John built a house" has goal or culmination [1].

Since both upward and downward inheritance properties hold for atelic data, such data supports the conventional "snapshot-by-snapshot" (i.e., point-based) viewpoint: the intended semantics of a temporal database is the set of conventional (atemporal) databases holding at each time point. As a consequence, most approaches to temporal databases support (only) atelic facts even if, in several cases, the representation allows, as a syntactic sugar, the use of periods to denote convex sets of time points. An integrated temporal database model that supports both telic and atelic data semantics has been developed [2].

Atomic Event

JONAS MELLIN, MIKAEL BERNDTSSON
University of Skövde, Skövde, Sweden

Synonyms

Primitive event

Definition

An atomic event is considered to be indivisible and instantaneous.

Key Points

If an event is non-instantaneous, then it is possible to divide into a beginning of this event (an initiator) and an ending of this event (a terminator). Therefore, atomic events must be instantaneous. In active database literature, the concept primitive event is typically used instead of atomic event. The major reason is probably that system primitives and application primitives are not distinguished.

Atomicity

GERHARD WEIKUM
Max-Planck Institute for Informatics, Saarbruecken, Germany

Definition

The *atomicity of actions* on a database is a fundamental guarantee that database systems provide to application programs. Whatever state modifications an atomic action may perform are guaranteed to be executed in an *all-or-nothing* manner: either all state changes caused by the action will be installed in the database or none. This property is important in the potential presence of failures that could interrupt the atomic action. The database system prepares itself for this case by *logging* state modifications and providing automated *recovery* as part of the failure handling or system restart. These implementation aspects are transparent to the application program and are thus a major relief for the programs' failure handling and boost the application development productivity.

Historical Background

Since the early 1970s (or even earlier), transaction processing systems for airline reservations and debit/credit banking had means for recovery and concurrency control that were similar to atomic actions. However, these implementation techniques were hardly documented in publicly available literature and still far from a principled, universal solution. The major credit for the modern concept of atomicity (and transactions) belongs to the 1998 Turing Award winner Jim Gray [6–8]. Closely related notions of atomic actions have been proposed by other authors at around the same time, including [11–13], which in turn were inspired by the informal work on "spheres of control" by Bjork and Davies [3,4].

Foundations

As an example for the importance of atomic actions, consider a sequence of steps that read and write two bank-account records, x and y, in order to transfer some amount of money from account x to account y:

$$R(x)W(x)R(y)W(y).$$

If there is a system failure after writing x but before writing y, the underlying database becomes inconsistent, with the transferred money seemingly lost in "mid-flight." Even worse, the application program may not even know if this problem actually occurred or not (the system may have succeeded in writing y just before it crashed but could not send a return code anymore). If, on the other hand, the database system executes the entire step sequence as an atomic action, the failure handling for the application program becomes much simpler as it can always restart on a clean, consistent database.

In database systems the atomic actions themselves can be flexibly defined by the application programs, by demarcating the begin and end of a *transaction* with explicit interface calls. For example, an entire sequence of SQL command invocations can be made atomic. By default, usually every individual SQL operation is guaranteed to be atomic. These guarantees are part of the *transactional ACID properites*: atomicity, consistency-preservation, isolation, durability [8]. In some scientific communities outside of database systems research, atomicity is meant to include the *isolation* guarantee. Atomic actions are then (alternatively) defined to be state-modification sequences whose effects are ensured (by the underlying run-time environment) to be equivalent to *indivisible actions* with all effect appearing to be instantaneous upon the completion of the entire sequence. In the presence of concurrent accesses to the same shared data, this combined atomicity/isolation property provides the illusion, despite the fact that in reality accesses by different programs are interleaved. Defining this principle in formal terms leads to the concept of *serializability* and methods for *concurrency control* as part of the database (or other run-time) system [2,6,14].

As an example for the importance of isolation (as an additional property of atomic actions), consider an extended variant of the earlier example. Assume to the the money-transfer process – now viewed as a transaction T1 – , a second transaction T2 reads both bank-account records x and y in order to analyze financial portfolios and perform some kind of risk assessment. The following concurrent execution, with time proceeding from left to right, could be possible:

T1:	R(x) W(x)		R(y) W(y)
T2:		R(x) R(y)	

With this step interleaving, transaction T2 would see an inconsistent database, namely, the state of x after money is withdrawn from x and the state of y before money is deposited there. This may lead to a distorted analysis and false conclusions in the decision making of a financial broker. Running both T1 and T2 as atomic and isolated transactions would prevent this particular interleaving and guarantees that only such executions are allowed that are provably equivalent to a sequential execution where such an anomaly is impossible.

The atomicity guarantee includes all "side effects" of an action as far as the database state is concerned. For example, the effects of a database trigger are covered by the guarantee, but effects outside of the database such as sending a message are outside the scope of the database system guarantees. Modern application servers and message brokers, on the other hand, may provide such guarantees about messages (e.g., atomic multicasts) and application state (e.g., specific program variables) beyond the database. A traditional implementation technique to this end is to support failure-resilient queues. Modern database systems have integrated such message queues and application state management and extend their atomic actions to them, providing more comprehensive *application recovery*. A new research trend in programming languages is to provide atomicity guarantees to arbitrary programs, not just database applications, in order to simplify exception handling and generally ease programmers' work. For example, method invocations in an object-oriented language could be made atomic by means of an underlying *transactional memory* as part of the language's run-time system (and possibly even hardware architecture).

The atomicity concept simplifies failure handling at the application program level, but it does not mask failures. Rather a typical approach is that the program notices the failing of an atomic action by a corresponding system return code (for the atomic action invocation itself, for the end-of-action demarcation call, or upon the next interaction with the database system if the previous call simply timed out without any response), and then has to retry the action. This paradigm still requires explicit coding for the retrying, and this may require special care about non-idempotent effects or additional system guarantees and state testing for ensuring *idempotence*. Some advanced methods for application recovery can automate these re-trials and testing for non-idempotence, thus strengthening the all-or-nothing guarantee for atomicity into an *exactly-once execution* guarantee with complete failure masking [1].

On the other hand, for some data-intensive applications outside of database systems, atomicity may be an overly strong property if applied to entire processes; this holds particularly for long-lived workflows and cooperative work. Although these applications still benefit from atomic actions for smaller-grained operations, additional forms of *relaxed atomicity* or extended atomicity would be desirable. The database research community has developed a variety of such models, most notably, the model of open nested transactions and the ACTA framework [5,9].

Future Directions

Atomicity is a ground-breaking, fundamental contribution that first emerged in database systems, but is increasingly pursued also by other research communities like programming languages, operating systems, dependable system design, and also formal reasoning and program verification [10]. There are several strategic reasons for this growing interest and extended application of atomic actions:

- Web Services, long-running workflows across organizations, large scale peer-to-peer platforms, and ambient-intelligence environments with huge numbers of mobile and embedded sensor/actor devices critically need support for handling or even masking concurrency and component failures, and may mandate rethinking the traditional atomicity concept.
- There is a proliferation of open systems where applications are constructed from pre-existing components. The components and their configurations are not known in advance and they can change on the fly. Thus, it is crucial that atomicity properties of components are composable and that one can predict and reason about the behavior of the composite system.
- Modern applications and languages like Java lead millions of developers into concurrent programming. This is a drastic change from the classical situation where only a few hundred "five-star wizard" system programmers and a few thousand programmers working in scientific computing on parallel supercomputers would have to cope with the inherently complex issues of concurrency and advanced failure handling.
- On an even broader scale, the drastically increasing complexity of the new and anticipated applications will require enormous efforts and care towards dependable systems or it may lead into a major "dependability crisis." Atomicity is an elegant basic asset to build on in the design, implementation, and composition of complex systems and the reasoning about system behavior and guaranteed properties.

Audible sound

Definition

Audio refers to audible sound – the sound perceivable by the human hearing system, or the sound of a frequency belonging to the *audible frequency range* (20-20,000 Hz). Audio can be generated from various sources and perceived as speech, music, voices, noise, or any combinations of these. The perception of an audible sound starts by the sound pressure waves hitting the eardrum of the outer ear. The generated vibrations are transmitted to the cochlea of the inner ear to produce mechanical displacements along the basilar membrane. These displacements are further transduced into electrical activity along the auditory nerve fibers, and finally "analyzed" and "understood" in the central auditory system [4,7].

Historical Background

The step from the fundamental definition of audio towards the concept of *audio signal* can be seen as a step towards the birth of the modern consumer electronics. An audio signal is a signal that contains audio information in the audible frequency range. The technology for generating, processing, recording, broadcasting and retrieving audio signals, first *analog* and later on *digital* ones, has rapidly grown for over a century, from the pioneering radio broadcasting and telephony systems to advanced mobile communication infrastructures, music players, speech recognition and synthesis tools, and audio content analysis, indexing and retrieval solutions. This growth may have been initiated by the research in the field of signal processing, but it has been maintained and has continuously gained in strength through an extensive interdisciplinary effort involving signal processing, information theory, human-computer interaction, psychoacoustics, psychology, natural language processing, network and wireless technology, and information retrieval.

Foundations

Digital Audio

An audio signal is an analog signal, which can be represented as a one-dimensional function $x(t)$, where t is a continuous variable representing time. To facilitate storage and processing of such signals in computers, they can be transformed into *digital signals* by *sampling* and *quantization*.

Sampling is the process in which one audio signal value (*sample*) is taken for each time interval (*sampling period*) T. This results in a *discrete audio* signal $x(n) = x(nT)$, where n is a numeric sequence. The sampling period T determines the *sampling frequency* that can be defined as $f = 1/T$. Typical sampling frequencies of digital audio are 8, 16, 32, 48, 11.025, 22.05, and 44.1 kHz (Hz represents the number of samples per second). Based on the Nyquist-Shannon sampling theorem, the sampling frequency must be at least 2 times larger than the band limit of the audio signal in order to be able to reconstruct the original analog signal back from its discrete representation. In the next step, each sample in the discrete audio signal is *quantized* with a bit resolution, which makes each sample be represented by a fixed limited number of bits. Common bit resolution is 8-bit or 16-bit per sample. The overall result is a digital representation of the original audio signal, that is referred to as *digital audio signal* or, if it is just considered as a set of bits, for instance for the purpose of storage and compression, as *digital audio data*.

Audio Coding and Compression

The digitization process described above leads to the basic standard of digital audio representation or *coding* named *Pulse Code Modulation* (PCM), which was developed in 1930-1940s. PCM is also the standard digital audio format in computers and Compact Disc (CD). PCM can be integrated into a widely used WAV format, which consists of the digital audio data and a *header* specifying the sampling frequency, bits per sample, and the number of audio channels.

As a basic audio coding format, PCM keeps all samples obtained from the original audio signal and all bits representing the samples. This format is therefore also referred to as *raw* or *uncompressed*. While it preserves all the information contained in the original analog signal, it is also rather expensive to store. For example, a one-hour *stereo* (A Cambridge Dictionary definition of stereo: a way of recording or playing sound so that it is separated into two signals and produces more natural sound) audio signal with 44.1 kHz sampling rate and 16 bits per sample requires 635MB of digital storage space. To save storage in computers and improve the efficiency of audio transmission, processing and management, *compression* theory and algorithms can be applied to decrease the size of a digital audio signal while still keeping the quality of the signal and communicated information at the acceptable level.

Starting with the variants of PCM, such as *Differential Pulse Code Modulation* (DPCM) and *Adaptive Differential Pulse Code Modulation* (ADPCM), a large number of audio compression approaches have been developed [5]. Some most commonly used approaches include MP3/ACC defined in the MPEG-1/2 standard [2,3], Windows Media Audio (WMA) developed by Microsoft, and RealAudio (RA) developed by RealNetworks. These approaches typically lead to a compressed audio signal being about 1/5 to 1/10 of the size of the PCM format.

Audio Content Analysis

Audio content analysis aims at extracting descriptors or *metadata* related to audio content and allowing content-based search, retrieval, management and other user actions performed on audio data. The research in the field of audio content analysis has built on the synergy of many scientific disciplines, such as signal processing, pattern recognition, machine learning, information retrieval, and information theory, and has been conducted in three main directions, namely *audio representation*, *audio segmentation*, and *audio classification*.

Audio representation refers to the extraction of audio signal properties, or *features*, that are representative of the audio signal composition (both in temporal and spectral domain) and audio signal behavior over time. The extracted features then serve as input into audio segmentation and audio classification. Audio segmentation aims at automatically revealing semantically meaningful temporal segments in an audio signal, which can then be grouped together (using e.g., a *clustering* algorithm) to facilitate search and browsing. Finally, an audio classification algorithm classifies a piece of audio signal into a predefined semantic class, and assigns the corresponding label (e.g., "applause," "action," "highlight," "music") to it for the purpose of text-based search and retrieval.

Audio Retrieval

Audio retrieval aims at retrieving sound samples from a large corpus based on their relation to an input query. Here, the query can be of different types and the expected results may vary depending on the application context. For example, in the *content-based retrieval* scenario, a user may use the text term "applause" to search for the audio clips containing the audio effect "applause." Clearly, the results obtained from audio classification can help annotate the corresponding audio samples, audio segments or audio tracks, and thus facilitate this search and retrieval strategy. However, audio retrieval can also be done by using an audio data stream as a query, i.e., by performing *query-by-example* [6]. For instance, one could aim at retrieving a song and all its variants by simply singing or humming its melody line.

In another retrieval scenario, the user may want to retrieve the exact match to the query or some information related to it. This typically falls into the application domain of *audio fingerprinting* [1]. An audio fingerprint is a highly compact feature-based representation of an audio signal enabling extremely fast search for a match between the signal and a large-scale audio database for the purpose of audio signal identification.

Key Applications

Audio technology is widely used in diverse applications areas, such as broadcasting, telephony, mobile communications, entertainment, gaming, hearing aids, and the management of large-scale audio/music collections.

Synonyms

Audio categorization; Audio indexing; Audio recognition

Definition

Audio classification aims at classifying a piece of audio signal into one of the pre-defined *semantic classes*. It is typically realized as a combination of a *learning* step to learn a statistical model of each semantic class, and an *inference* step to estimate which semantic class is closest to the given piece of audio signal.

Historical Background

Audio classification associates *semantic labels* with audio signals, and can also be referred to as *audio indexing, audio categorization* or *audio recognition.* As such, audio classification plays an important role in facilitating search and retrieval in large-scale audio collections (databases). Semantic labels are used to represent semantic classes or *semantic concepts*, which can be defined at different abstraction and complexity levels. Typical examples of basic semantic audio classes are *speech*, *music*, *environmental sounds*, and *silence*, which can be detected rather effectively using the methods like [8,9,10,17]. Examples of mid-level semantic concepts are *key audio effects*, like *applause*, *cheer*, *ball-hit*, *whistling*, *car-racing*, *siren*, *gun-shot*, and *explosion*. Finally, the detection of higher-level semantic concepts, such as sport highlights [1,14–16] and action scenes in movies [3,11], is usually performed by analyzing the sequence of detected key audio effects.

Foundations

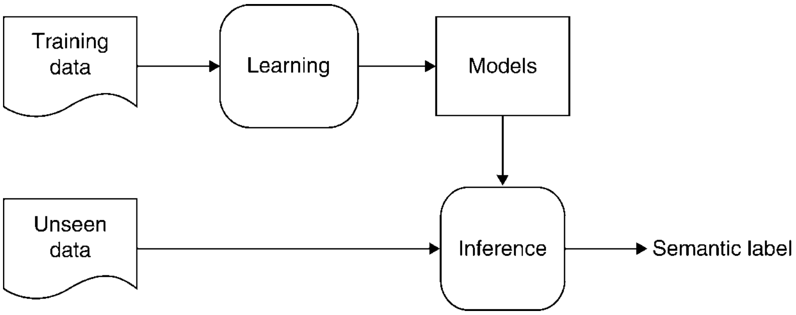
Figure 1 shows a general classification scheme, which is typically composed of two main steps: *learning* and *inference*. In the learning step, a model of each semantic class is built based on a set of training data, and with a specific learning scheme. Then, in the inference step, a new, unseen collection of data is associated with a semantic label, the model of which best resembles the properties of the data. Various schemes have been employed so far for realizing both the learning and inference steps. These schemes include sets of heuristic rules, vector Quantization (VQ), k-nearest neighbor (kNN), decision tree, Gaussian mixture model (GMM), support vector machine (SVM), boosting, Bayesian decision, hidden Markov model (HMM), and neural network. More information about these schemes can be found in [4,5].

While directly applying the previously mentioned learning and inference algorithms works well for straightforward classification tasks, there are a number of issues which should be taken into account when applying this scheme for audio classification. In the following sections, some critical issues are addressed that need to be considered when designing audio classification algorithms, and it is shown on the example of an existing approach how these issues can effectively be resolved. The classification cases discussed in the sections below concern the mid-level semantic concepts (key audio effects) and hierarchies of higher-level semantic concepts.

Key Audio Effect Detection

Several issues play a role in key audio effect detection in a continuous audio signal, and need to be resolved in order to secure reliable classification. The most important issues can be described as follows:

1. Key audio effect detection in a long, continuous audio signal, is typically approached by applying a sliding window of a given length (e.g., 0.5 s) to the signal. The audio segment captured by the window at a given time stamp is then used as the basic unit to associate with a key audio effect. An important implicit assumption here is that each segment corresponds to one and only one semantic class. However, a sliding window is often too short to capture one complete effect, which leads to over-segmentation. The sliding window could also be

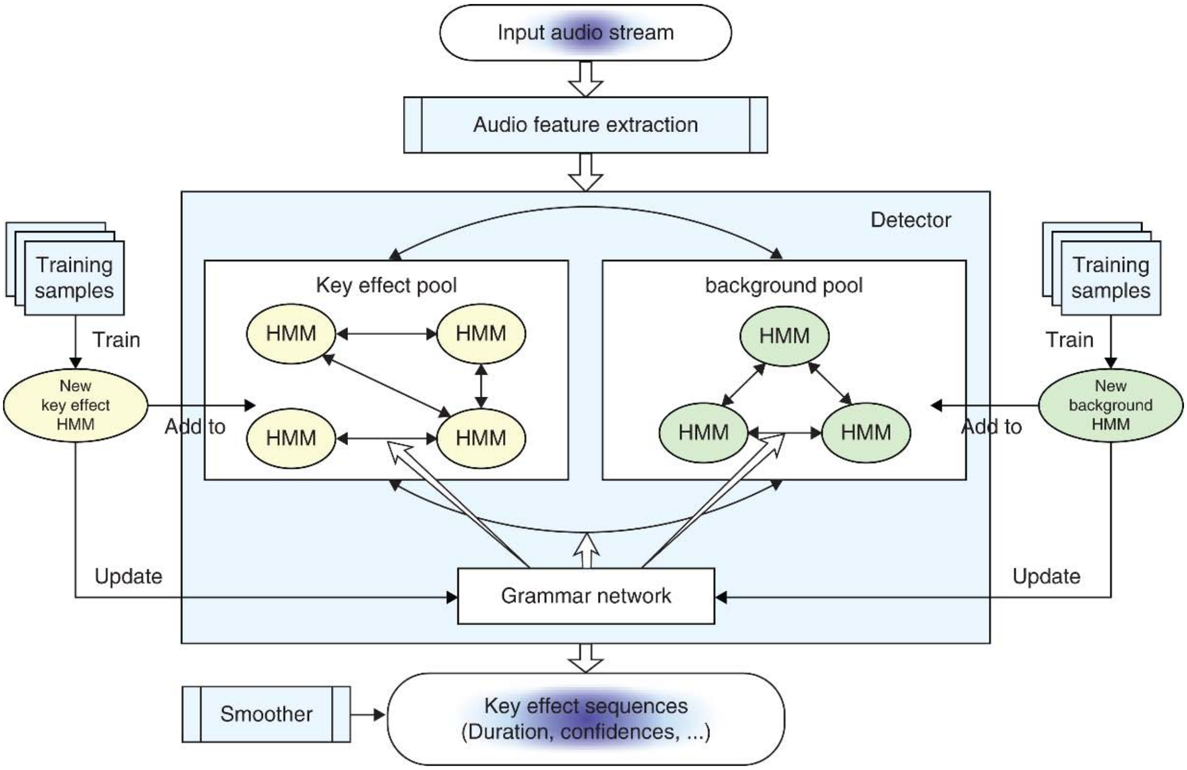


Audio Classification. Figure 1. An illustration of a general classification scheme.

too long and capture several effects within one segment.

2. The targeted audio effects are usually sparsely distributed over the signal, and there are plenty of non-target sounds that are to be rejected. Many existing approaches assume having a complete set of semantic classes available, and classify any audio segment into one of these semantic classes. Other methods use thresholds to discard the sounds with low classification confidence [3]. However, the threshold setting becomes troublesome for a large number of key effects.
3. Audio effects are usually related to each other. For example, some audio effects such as *applause* and *laughter* are likely to happen together, while others are not. Taking into account the transition relationships between audio effects is therefore likely to improve the detection of each individual effect.

To investigate the possibilities for effectively resolving the abovementioned issues when designing algorithms for key audio effect detection, the approach proposed in [2] will be discussed as an example. In this hierarchical, probabilistic framework, as illustrated in Fig. 2, an HMM model is first built for each key audio effect based on the complete set of audio samples, and the defined models are then used to compose the *Key Audio Effect Pool*. Then, comprehensive *background* models are also established to cover all non-target sounds that complement the targeted key effects. Thus, the non-target sounds would be detected as background sounds and excluded from the target audio effect sequence. Moreover, a higher-level probabilistic model is used to connect these individual models with a *Grammar Network*, in which the transition probabilities among various audio effects and background sounds are taken into account for finding the optimal audio effect sequence. Then, for a given input audio stream, the optimal audio effect sequence is found among the candidate paths using the Viterbi algorithm, and the location and duration of each key audio effect in the stream are determined simultaneously, without the need to pre-segment the audio



Audio Classification. Figure 2. The framework for audio effect detection [13], consisting of three main parts: key audio effect pool, background sound pool, and grammar network.

stream into audio segments. In the following both the learning and inference step from [2] are discussed in more detail.

Classifier Learning In the approach from [2], each key audio effect and background sound are modeled using HMMs, since HMM provides a natural and flexible way for modeling time-varying process [12]. The main issue that needs to be resolved for an HMM is the parameter selection, which includes (i) the optimal model size (the number of states); (ii) the number of Gaussian mixtures for each state, and (iii) the topology of the model.

To select the model size for a key audio effect category, one needs to balance the number of hidden states in the HMM and the computational complexity in the learning and inference processes. In general, a sufficient number of states are required to describe all the significant behavioral characteristics of a signal over time. However, when the number of states increases, the computational complexity grows dramatically and more training samples are required. Unlike speech modeling, in which the basic units such as tri-phones could be adopted to specify the number of states, general key audio effects lack such basic units, and thus make the choice of the state numbers difficult. As an example of an approach in this direction, a clustering-based method was proposed in [2,13,17] to estimate a reasonable number of states (model size) per audio effect. The clustering step was realized through an improved, unsupervised *k*-means algorithm, and the resulting number of clusters is taken as the model size.

The number of Gaussian mixtures per state is usually determined experimentally. For instance, the method from [2] adopts 32 Gaussian mixtures for each state in the HMM. This number is larger than those used in other related methods in order to secure a sufficient discriminative ability of the models to identify a large diversity of audio effects in general audio streams.

The most popular HMM topology is the left-to-right or the fully connected one. The left-to-right structure only permits transitions between adjacent states; while the fully connected structure allows transitions between any two states in the model. Different topologies can be used to model audio effects with different properties. For instance, for key audio effects with obvious time-progressive signal behavior, such as *car-crash* and *explosion*, the left-to-right structure should be adopted, while for audio effects without distinct evolution phases, such as *applause* and *cheer*, the fully connected structure is more suitable.

Regarding the background sound modeling, a straightforward approach is to build a large HMM, and train it with as many samples as possible. However, background sounds are very complex and diverse, and their feature vectors are typically widely scattered in the feature space, so that both the number of states and the Gaussian mixtures per state of such a HMM must be particularly large to secure a representation of all possible background sounds. As an alternative, the method from [2] modeled the background sounds as a set of subsets of basic audio classes. It is namely so that in most practical applications the background sounds can be further classified into a few basic categories, such as *speech*, *music*, and other *noise*. Thus, if background models could be trained from all these respective subsets, the training data would be relatively concentrated, and the training time would be reduced. Another advantage of building these subset models is that they could provide additional useful information in high-level semantic inference. For example, *music* is usually used in the background of movies, and *speech* is the most dominant component in talk shows. Following the discussion from above, three background models are built in [2] using the fully connected HMMs for *speech*, *music*, and *noise*. Here, *noise* is referred to as all background sounds except *speech* and *music*. To provide comprehensive descriptions of the background, 10 states and 128 Gaussian mixtures in each state are used in modeling.

The Grammar Network in Figure 2 is an analogy to a language model in speech processing. It organizes all the HMM models for continuous recognition. Two models are connected in the Grammar Network if the corresponding sounds are likely to occur after each other, both within and between the key audio effect pool and the background sound pool. For each connection, the corresponding transition probability is set and taken into account when finding the optimal effect sequence from the input stream.

The transition probabilities between two models can be statistically learned from a set of training data. If no sufficient training data are available, a heuristic approach can be deployed. For instance, the approach presented in [2] is based on the concept of *Audio Effect Groups*, and assumes that (i) only audio effects in the same group can happen subsequently, (ii) there should be background sounds between any two key audio effects belonging to different groups, and (iii) the transition probability is uniformly distributed per group. An audio effect group can be seen as a set of audio effects that usually occur together. An example Grammar Network with audio effect groups indicated as G_1-G_k is illustrated in Figure 3.

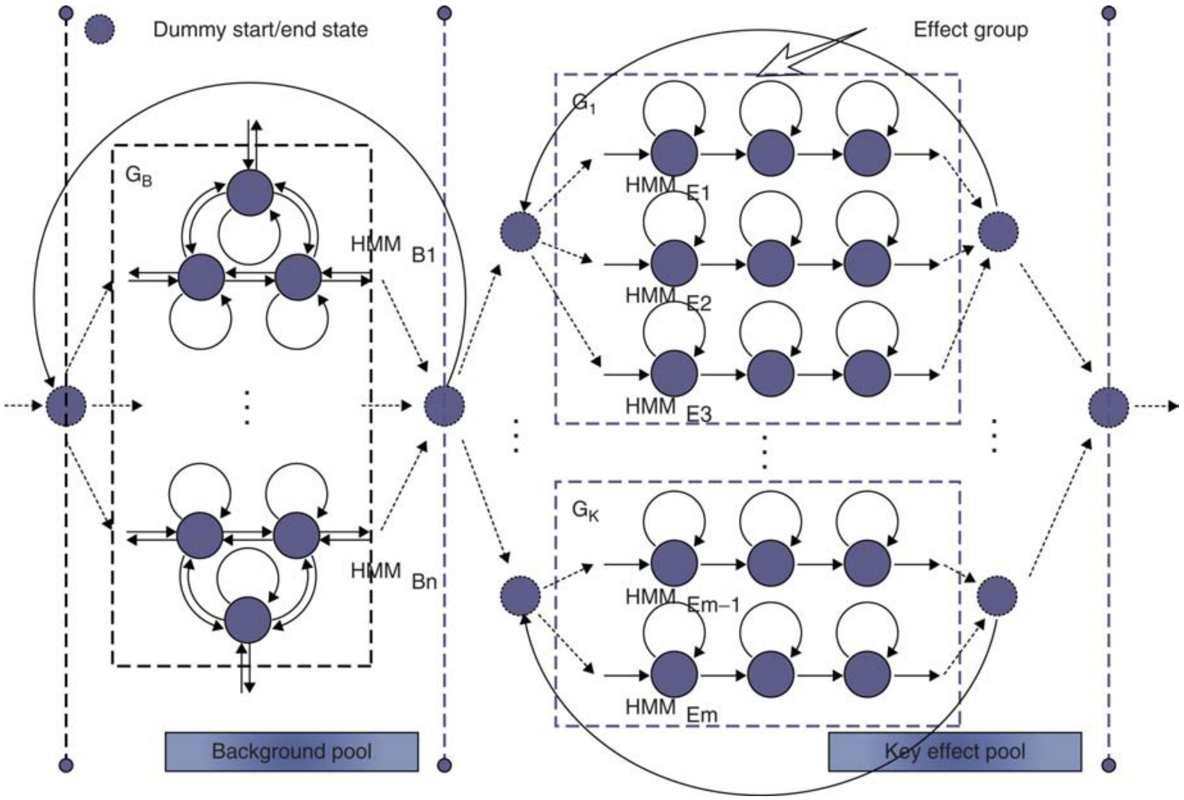
Probabilistic Inference Using the learned classification framework setup described above, the *Viterbi* algorithm can be used to choose the optimal state sequence from the continuous audio stream, as:

$$S_{optimal} = \arg\max_{s} \Pr(s|M, O). \qquad (1)$$

Here, s is the candidate state sequence, M represents the hierarchical structure, and O is the observation vector sequence of the input audio stream. In terms of practical realization of this classification scheme, the corresponding state and log-probability are obtained first for each audio frame. Then, a complete audio effect or background sound can be detected by merging adjacent frames belonging to the same sound model. Before this merging step, a smoothing filter can be applied to remove the classification outliers in the sequences of consecutive frames. The final classification confidence can be measured by averaging the log-probabilities of the classified audio frames. In addition, the starting time stamp and duration of each sound occurrence can be obtained simultaneously.

From Key Audio Effects to a Hierarchy of Semantic Concepts

Based on the obtained key audio effect sequence, methods can be developed to perform audio classification at a higher level, such as the level of audio events and scenes. While high-level semantic concepts can generally also be detected using the general scheme from Figure 1, using key audio effects as an



Audio Classification. Figure 3. An illustration of the *Grammar Network* with *Audio Effect Groups*, where G_k is the kth *Effect Group* and G_B is the *Background Sound Pool*. For convenience, all the key audio effect models are presented as 3-state left-to-right HMMs, and all the background models are denoted as 3-state fully connected HMMs. The dummy start and end states are used to link models, and make the structure more clear [2].

intermediate classification level has proved to be a more effective way to perform indexing at this level.

To infer high-level semantics from audio effects, most existing methods are rule-based [1,16], or employ a statistical classification [3,11]. Heuristic inference is straightforward and can be easily applied in practice. However, it is usually laborious to find a proper rule set if the situation is complex. For example, the rules usually involve many thresholds which are difficult to set; some rules may be in conflict with others, and some cases may not be well-covered. People are used to designing rules from a positive view but ignoring those negative instances, thus many false alarms are introduced although high recall can be achieved. Classification-based methods provide solutions from the view of statistical learning. However, the inference performance relies highly on the completeness and the size of the training samples. Without sufficient data, a positive instance not included in the training set will usually be misclassified. Thus these approaches are usually prone to high precision but low recall. Furthermore, it is inconvenient to combine prior knowledge into the classification process in these algorithms.

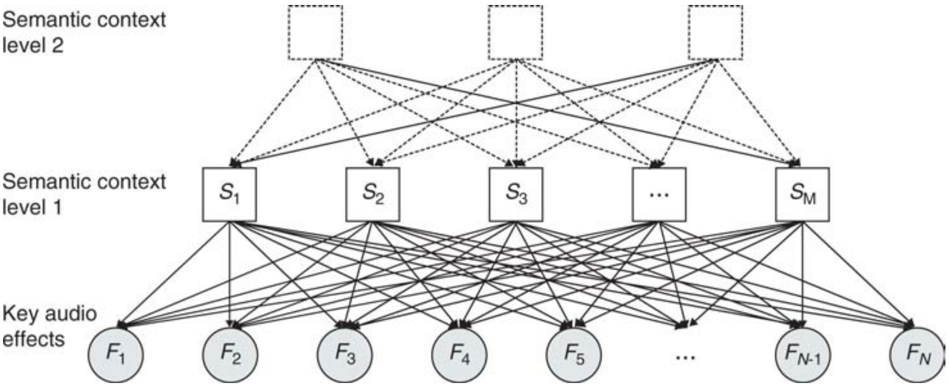
To integrate the advantages of heuristic and statistical learning methods, a Bayesian network-based approach is proposed in [2]. A Bayesian network [6] is a directed acyclic graphical model that encodes probabilistic relationships among nodes which denote random variables related to semantic concepts. A Bayesian network can handle situations where some data entries are missing, as well as avoid the overfitting of training data [6]. Thus, it weakens the influence from unbalanced training samples. Furthermore, a Bayesian network can also integrate prior knowledge by specifying its graphic structure.

Figure 4 illustrates the topology of an example Bayesian network with three layers. Nodes in the bottom layer are the observed audio effects. Nodes in the second layer denote high-level semantic categories such as scenes, while those in the top layer denote much higher semantic concepts. In Figure 4, the nodes in adjacent layers can be fully connected, or partially connected based on the prior knowledge of the application domain. For instance, if it is known *a priori* that some key effects have no relationships with a semantic category, the arcs from that category node to those key effect nodes could be removed. A Bayesian network with a manually specified topology utilizes human knowledge in representing the conditional dependencies among nodes, thus it can describe some cases which are not covered in the training samples.

The nodes in the upper layers are usually assumed to be discrete binaries which represent the presence or absence of a corresponding semantic category, while the nodes in the bottom layer produce continuous values of a Gaussian distribution

$$P(F_i|\mathbf{pa}_i) \sim N(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i)(1 \leq i \leq N) \tag{2}$$

where F_i is a 2-dimensional observation vector of the ith audio effect and is composed of the normalized duration of an effect and its detection confidence in a given semantic segment. The conditional argument $\mathbf{pa}_i$ denotes a possible assignment of values to the parent nodes of F_i, while $\boldsymbol{\mu}_i$ and $\boldsymbol{\Sigma}_i$ are the mean and



Audio Classification. Figure 4. An example of a Bayesian network for inference of a hierarchy of semantic concepts. Arcs are drawn from cause to effect. Following the convention, discrete variables are represented as squares while continuous variables are indicated as circles. Furthermore, observed variables are shaded, while hidden variables are not.

covariance of the corresponding Gaussian distribution respectively. In the training phase, all these conditional probability distributions are uniformly initialized and then updated by maximum likelihood estimation using the EM algorithm. In the inference process, the junction tree algorithm [7] can be used to calculate the occurrence probability of each semantic category. Thus, given the information on the audio effects, the semantics in each layer can be inferred based on the posterior probabilities. A semantic segment can be classified into the *c*th semantic category with the maximum marginal posterior probability:

$$c = \arg\max_{j} \Pr(S_j|F) \quad 1 \leq j \leq M$$
$$where \quad \mathbf{F} = \{F_1, F_2, \cdots, F_N\} \tag{3}$$

With this scheme, human knowledge and machine learning are effectively combined to perform high-level semantic inference. In other words, the topology of the network can be designed according to the prior knowledge of an application domain, and the optimized model parameters can then be estimated by statistical learning.

Key Applications

Audio classification is typically applied for content-based search and retrieval in and management of large-scale audio collections (databases).

Audio information retrieval; Semantic inference in audio

Definition

An *audio signal* is a signal that contains information in the audible frequency range. Audio content analysis refers to a set of theories, algorithms and systems that aim at extracting descriptors or metadata related to audio content and allowing search, retrieval and other user actions performed on audio signals.

Historical Background

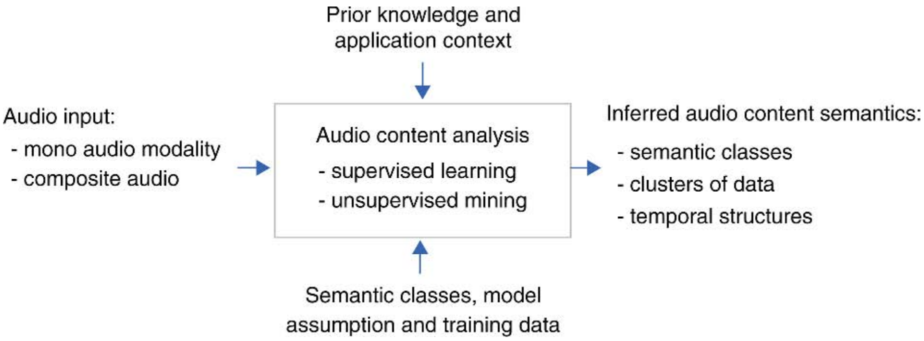
Multimedia content analysis has been one of the most booming research directions in the past years. With the objective of providing fast, natural, intuitive and personalized content-based access to vast multimedia data collections, and building on the synergy of many scientific disciplines, such as signal processing, pattern recognition, machine learning, information retrieval, information theory, natural language processing and psychology, the research initiative born around the end of the 1980s has succeeded in inspiring and mobilizing enormous number of researchers worldwide. This initiative turned into a broad research effort that has continuously gained in strength ever since. As an integrated part of multimedia (multimodal) documents, audio plays an important role in multimedia content analysis. In particular, audio content analysis can be combined with content analysis of visual information to jointly address semantic inference from *multimedia data* streams [5]. However, also taken separately, audio content analysis has been recognized as the key technology for providing easy access to rapidly growing audio archives, and in particular to music collections [3].

Foundations

The underlying problem of audio content analysis is to infer the information about the semantics of the content carried by an audio signal. Here, the audio signal can be a rather simple one consisting of one audio type only (e.g., pure speech, music), or a more complex audio signal (*composite audio*) resulting from a superposition of several audio types, like music, speech, audio effects, and noise. The audio content semantics includes the information on audio types (e.g., speech, music, noise, or any combination of these), on audio semantic classes (e.g., applause, solo instrument, guitar, speaker X or Y), and on audio content structure (e.g., the breaks between semantically coherent audio segments, clusters of *auditory scenes*).

The structure of a general audio content analysis system is illustrated in Figure 1. Depending on the levels at which prior knowledge is specified and the system is trained, this inference system can be realized by employing various approaches ranging from purely supervised to fully unsupervised ones. For example, if the scheme in Figure 1 is seen as a speech recognition system, the prior knowledge, such as the labeled audio data, dictionary and grammar, need to be pre-collected to train both an acoustic model and a language model in a supervised fashion [6]. Similarly, trained models of semantic classes such as car-racing, siren, gun-shot, and explosion can be used to detect the occurrences of these sounds in movie soundtracks [2,4]. Compared to these supervised realizations, an unsupervised approach can be employed to find clusters in audio data corresponding to auditory scenes [1,7], or to find "unusual" events in the sound track of a surveillance signal [9].

While the realizations of the Scheme in Figure 1 can be very different with respect to the types of input audio signals they handle, the prior knowledge and trained models they use, the types of inference techniques they employ (e.g., supervised versus unsupervised), and the inference results they are expected to provide (e.g., semantic categories versus clusters of data), the research targeting these realizations can be



Audio Content Analysis. Figure 1. A general audio content analysis scheme, specifying various possible types of input audio signals, prior knowledge and application context, the types of inference techniques and inference results.

said to follow three main directions that also roughly define the scope of the audio content analysis research field. These directions are *audio representation*, *audio segmentation*, and *audio classification*.

- Audio representation refers to the extraction of audio signal properties, or *features*, that are representative of the audio signal, such as short time energy, zero-crossing rate, pitch, or spectrum. Obtaining a compact feature-based representation of an audio signal can improve the efficiency of audio processing and benefit many applications based on such processing (e.g., audio retrieval).
- Audio segmentation aims to automatically reveal coherent and semantically meaningful temporal segments in an audio signal. Examples of such segments are those containing pure speech or music, or those corresponding to *auditory scenes* [7]. The segments discovered through segmentation can also be clustered together into semantically coherent groups [1] to provide the possibility for an easy content access (e.g., through browsing).
- While the abovementioned segmentation and clustering processes are typically *unsupervised*, audio classification classifies a piece of audio signal into one of the pre-defined semantic classes using *supervised* methods of machine learning and pattern classification. The semantic classes can be defined at the level of basic audio types (e.g., speech, music) [8], audio effects (e.g., applause, gun-shot, car chasing) [2,4], or auditory scenes (e.g., action, highlights, romance).

The term “audio” in the context of audio content analysis typically stands for general or *composite audio* signals [1]. When dealing with specific audio types, such as speech and music, and related applications, dedicated research has been deployed and led to a number of specific research directions like music information retrieval [3] and speech recognition [6].

Key Applications

Audio content analysis is typically applied for content-based search and retrieval in the management of large-scale audio (or multimedia) collections (databases).

Audio Metadata

Werner Kriechbaum
IBM Development Lab, Böblingen, Germany

Synonyms

Music metadata

Definition

Audio, first used in 1934 refers to "Sound, esp. recorded or transmitted sound . . . and signals representing this" [Oxford English Dictionary, Oxford 2005, Vol. 1, p, 780].

Metadata is data about data of any sort in any media, describing an individual datum, content item, or a collection of data including multiple content items. In that way metadata facilitates the understanding, characterization, use and management of data.

Audio metadata is structured, encoded data that describes content and representation characteristics of audio entities to facilitate the automatic or semiautomatic identification, discovery, assessment, interpretation, and management of the described entities, as well as their generation, manipulation, and distribution.

Historical Background

Audio metadata predate audio data by centuries. Since antiquity artists and theoreticians alike were interested to classify the effects that could be produced by the combination of different tones and to devise rules for the proper composition of music [12]. The baroque *Affektenlehre* (doctrine of the affections) provided the composers of music with rules and schemes to express affects like love, fear, or hate, and on the other hand gave the listeners a reference system to decode the emotional content of a piece of music. Falling into oblivion with the end of the baroque area similar classification schemes resurfaced with the advent of silent films. Score snippets classified this way enabled the pianist accompanying the film to select music appropriate to the mood of the film scene on the fly.

Like many other technological innovations the modern history of audio metadata started in Bell Labs with the vocoder, developed by Homer Dudley during the late 20s and early 30s of the last century [2]. As part of a speech analysis/synthesis system the vocoder was used to reduce the amount of storage needed to store human speech. The analysis part of the system computed a spectrogram (a variant of a short-term power spectrum) and extracted the fundamental frequency of the speech signal – the first low-level audio metadata. This paved the way for the development of an ever increasing stream of audio analysis techniques that can be traced for example in the "Transactions of the IRE Professional Group on Audio" and its IEEE follow-on and spin-off journals (Available at: http://ieeexplore.ieee.org/xpl/RecentIssue.jsp?punumber = 8340).

MPEG-7 Audio standard [7], finalized in 2002, selected and standardized a set of low- and high-level descriptors from the plethora of available signal processing techniques and tools. MPEG-7 low-level audio descriptors are derived from the time-frequency analysis of the audio signal and include:

- Basic descriptors: e.g., the audio waveform envelope
- Basic spectral descriptors: e.g., the centroid of the audio spectrum
- Signal parameters: e.g., the fundamental frequency
- Timbral temporal descriptors: e.g., the logarithmic attack time
- Timbral spectral descriptors: e.g., the harmonic spectral centroid
- Spectral basis descriptors: which are low-dimensional projections of the spectrum
- Silence

The MPEG-7 high-level descriptors, which are usually collections of further low-level descriptors with additional context, comprise:

- Audio signature
- Musical instrument timbre
- Monophonic melody
- HMM sound model
- Spoken content model

Markup languages and among those most notably HyTime [6], provided the second major force that influenced the development of audio metadata. The linking concepts introduced by HyTime provided mechanisms to connect (textual) symbolic representations and (non-textual) realizations of a media entity without embedding the link in either. The Standard Music Description Language (SMDL) [5] – developed as a HyTime application and up to now not promoted from a draft standard to an international standard – applied these techniques to standardize architecture for the representation of music. From an SMDL point of view a single musical work is comprised of four domains:

- Logical domain: "The logical domain is the basic musical content – the essence from which all performances and editions of the work are derived, including virtual time values, nominal pitches, etc. The logical domain is describable as 'the composer's intentions with respect to pitches, rhythms, harmonies, dynamics, tempi, articulations, accents, etc.,'" [5, p. 5]
- Gestural domain: Any number of performances of the logical domain, e.g., a digital audio recording capturing a concert
- Visual domain: Any visual rendering of the logical domain, e.g., a score
- Analytical domain: Any number of music-theoretical analyses like e.g., Schenkerian analysis [A. Cadwallader/D. Gagné, Analysis of Tonal Music: A Schenkerian Approach, Oxford 1998]

There is only a faint echo of this concept in the MPEG-7 Audio standard but the ideas are taken up again in the IEEE P1599 Recommended Practice for Definition of a Commonly Acceptable Musical Application using the XML Language (MX) which is as the time of this writing still a draft but should undergo ballot soon. In the terminology of MX, the SMDL domains are called layers and the aspects of music addressed are refined to six:

- General: Information that applies to the piece of music as a whole, e.g., the opus number
- Logic: The symbolic description of the music (equivalent to the SMDL logical domain)
- Structural: Description of music objects and their causal relationship
- Notational: The score (similar to the SMDL visual domain)
- Performance: An audible rendering of the piece of music like e.g., MIDI, CSound, etc
- Audio: Links to and description of digital audio

The great success of the compact disc and the almost ubiquitous availability of tools to create own copies or compilations from digital audio in MP3 format spawned a further community-based audio metadata "standardization" initiative. Since according to the original Red Book specification [IEC 60908 Ed. 2.0 b:1999 Audio recording – Compact disc digital audio system] the compact discs did not include metadata like disc name, track names or author information the need arose to add this information from a supplemental database and to embed at least part of this information in an MP3 file generated from the audio disc. The basic idea to bind the audio disc to its database entry used by all such systems is to compute a hash based on the track information available in the CD's table of contents. This hash is used as key for the metadata stored in the database. An entry in the open-source GPL-licensed audio metadata database freedb [http://www.freedb.org/] contains the following information:

- DISCID: the hash key
- DTITLE: Artist and disc title separated by "/"
- DYEAR: Year the compact disc was released
- DGENRE: The genre in textual form. In addition to this genre entry the database is split into eleven different categories (blues, classical, country, data, folk, jazz, newage, reggae, rock, soundtrack, misc) to minimize hash collisions. The information in the genre field can conflict with the category and will do so when two discs from the same category produce the same hash key. The recommended resolution for the key collision is to put the second disc in another category.
- TTITLEN: The title of track N
- EXTD: Extended data (i.e., any interesting information) for the audio disc
- EXTTN: Extended data for track N

Like the original audio disc the MP3 standard [ISO/IEC 11172–3:1993 Information technology – Coding of moving pictures and associated audio for digital storage media at up to about 1,5 Mbit/s – Part 3: Audio] did not provide for the inclusion of textual material as part of the encoded audio. This did not deter the user community from enhancing MP3 files with textual information. One result of these efforts is the (informal) ID3 standard [http://www.id3.org/id3v2.4.0-structure and http://www.id3.org/id3v2.4.0-frames] which specifies how to prepend metadata to an MP3 file. There is a rich set of predefined ID3 frames for example:

- Text information frames: Information like album, author, artist(s), etc.
- URL link frames: Links to e.g., the web page of a performer.
- Event timing codes: Time stamps for events in the audio like e.g., verse start, refrain start, theme start, key change, theme end, profanity, profanity end.

- Unsynchronized lyrics or text transcription
- Synchronized lyrics or text.
- Equalization: Equalizer settings for the encoded audio.
- Attached picture

The tag set can be extended since ID3 parsers – like HTML parsers – have to ignore unknown tags.

Foundations

From a metadata point of view, audio is rather ill-defined. All but the basic technical metadata describing the recording setup and the physical metadata characterizing the recorded signal, are specific for the recorded material and require content specific expertise. What makes sense for the description of the recording of a starting airplane is quite different from the data needed to describe birdsong or an opera recording. And even the description of the audio signal on the physical level is not without problems when the metadata are collected for human usage. On their way from the eardrum to the brain, auditory signals undergo a non-linear transformation caused by one's sound perception system [3,9] and all the concepts our cognition forms about audio events are based on this transformed signal. The perceived intensity (loudness) of a signal, for example, is quite different from the physical intensity of the signal. Low-level descriptors of audio signals have to take these differences into account, especially when they are used to derive more complex cognitive descriptors.

Since the domain of the recorded material has a marked influence on the metadata useful and necessary to describe the audio recording, the following discussion is restricted to the recording of music. Almost all music, except monophonic works, is realized by the co-operation of musicians that perform in parallel different subsets of the music. But in many cases, grouping mechanisms in one's auditory perception transform even monophonic music in two or more perceived separate streams [1]. Therefore even pure music not accompanying a stage play can be understood and described as multimedia data and the scientific fundamentals discussed in the entry on multimedia metadata apply to music as well. Furthermore all music can exist in two different forms: a symbolic representation (the score), and a realization (the audio recording). Information like metrum or key that is hard to derive from the analysis of the recorded audio is readily available from the score. In addition a score is accessible for music theoretical analysis that leads to further metadata [8]. Whenever one of the two, score or realization, is missing, it can, at least in principle, be derived from the other. The realizations generated by performing a score vary to a considerable degree. First of all most scores do not give an absolute reference point for the frequency. To map the note A4 (the A above the middle C) to a frequency of 440 Hertz, now an ISO standard [ISO 16:1975 Acoustics – Standard tuning frequency (Standard musical pitch)], is a rather new convention established by an international conference in 1936. Throughout history a variety of reference frequencies for A4 have been used, varying from as low as 392 Hertz up to 466 Hertz. Prior to the acceptance of equal temperament as tuning standard in the second half of the eighteenth century, a variety of tuning standards were in use and rendering baroque music on historic instruments with a historic temperament leads to a quite different performance than the one produced by a modern orchestra with well-tempered tuning. Similar variability exists for the global tempo (at least prior to the use of the metronome ticks to specify absolute time values) and the dynamic. And of course each individual performer or orchestra has its personal style of phrasings and embellishments. Therefore one score gives rise to a variety of realizations and at least when one is interested in identifying music all metadata derived from the realization of the score should in the end lead to the same piece of music. But scores themselves are by no means static; throughout history they have been transformed to adapt them to different needs. Examples of such transformations are transpositions (shifts in pitch) to adapt the score to the ambitus of an instrument, or piano reductions where an orchestral piece is simplified in such a way that its "essence" can be rendered on a piano. Like with the variation in realizations metadata for the description of music should be able to cope with this variability. Both types of variation exist not only in classical western music but in popular music or non-western music like Indonesian gamelan or Indian ragas as well.

Music has a complex temporal organisation and a rich semantic structure that defines a natural segmentation for the audio stream. Like in images, in music many features are characteristic for segments, vary from segment to segment, and become meaningless when averaged over all segments. Musical structure is not arbitrary but conforms to a set of possible patterns: The sonata form [10] for example is one of the most influential structural patterns during the classical era of western music. The structure of the sonata form is built from three to five pieces: an optional introduction, an exposition, a middle part (*Durchführung*), a repeat, and an optional coda. Usually these five elements are not atomic but further structured and some segments of this substructure are derived from each other by transformations like e.g., transposition, inversion, reflection, or tempo changes. Besides being metadata in its own right, structural information linked with the audio material allows a natural navigation of the recorded performance. As outlined above, the approach to document structure is prescriptive. As in nineteenth century music theory it is assumed that there is an ideal architecture for a sonata form, and that a piece of music not conforming to these rules is in error. In the twentieth century this concept has come under considerable criticism [e.g., 11] and a descriptive approach has been advocated. As a consequence, each musical work is likely to have more than one semantic segmentation, depending on the analysis approaches chosen. To be of any use, both a controlled vocabulary describing the structures and an ontology describing the relationships among them are needed. But this is by no means specific to the structure of music. For many other audio metadata standardized controlled vocabularies and ontologies are still lacking. For example without amendment the Dublin Core [http://www.dublincore.org/] term creator, “An entity primarily responsible for making the resource” [http://purl.org/dc/terms/creator], attached to a piece of music makes it hard if not impossible to recognize the specific role of the creator. Felix Weingartner as creator could refer to his role as conductor (he conducted what is believed to be the first complete recording of Beethoven’s symphonies), or his role as composer (symphonies, string quartets, operas) or his role as editor (he edited the complete works of Berlioz).

Key Applications

Audio metadata are essential for any search for audio data. In addition music metadata help to reveal similarities in style or structure between different compositions or different realisations of a piece of music. There are many frameworks for the analysis and manipulation of music, two GPLed packages that allow easy experimentation with different metadata concepts for music are CLAM [http://www.clam.iua.upf.edu/] and RUBATO® [http://www.rubato.org/].

Audio feature extraction; Audio characterization

Definition

An *audio signal* is a signal that contains information in the audible frequency range. Audio representation refers to the extraction of audio signal properties, or *features*, that are representative of the audio signal composition (both in temporal and spectral domain) and audio signal behavior over time. *Feature extraction* is typically combined with *feature selection*, through which the best set of features for the intended operation on the audio signal is defined.

Historical Background

Audio feature extraction typically leads to a strongly reduced audio signal representation. Obtaining such representation can improve the efficiency of audio processing and benefit many applications based on such processing. For example, a compact representation of an audio signal in the form of a *fingerprint* can enable extremely fast search for a match between this signal and a large-scale audio database for the purpose of audio signal identification. Further, if audio features are carefully chosen, they can capture the information from the original data that is relevant to subsequent audio signal analysis and processing steps, while leaving out the redundant and irrelevant (noisy) information parts. This possibility to simultaneously improve the efficiency and robustness of audio signal analysis and processing indicates the importance of the *feature selection* step as the basis step in *audio content analysis*, and in particular in *audio segmentation* and *audio classification*.

Foundations

Audio features can be divided into *temporal* and *spectral* features that capture the temporal and spectral characteristics of an audio signal, respectively. In terms of the way the features are extracted, a division into *frame-level* and *window-level* features can be made. An audio *frame* is the elementary temporal segment of the signal, from which features are extracted. The length of an audio frame typically varies between 10 and 50 ms. Due to its short duration, a frame can be said to contain (close-to) stationary signal behavior. The window-level features are extracted from a longer audio segment, comprising a number of consecutive frames, and are typically marked by applying a sliding window to the signal. While most audio features are extracted at the frame level, window-level features are mainly derived from the frame-level features by investigating their variation along the frames within the window, e.g., the mean and standard deviation of frame-level features. This expansion of the frame-level feature consideration from an individual frame to a series of consecutive frames proved to be useful in many applications, which indicates the importance of window-level features.

Table 1 gives an overview of the typical features proposed in literature to perform various operations on audio, and in particular, the audio segmentation and classification. The features in the table are ranked according to the frequency of their usage in literature. Multiple names indicated per row of the table stand for one and the same feature and/or its variants. Also, the notation ***t***, ***s***, ***fl*** and ***wl*** is used to indicate whether a feature is temporal, spectral, frame-level or a window-level feature. The table is followed by detailed descriptions of a subset of the most prominent frame-level and window-level features. Finally, information is provided about the processes of feature normalization and selection to generate optimal feature sets (vectors) for audio representation.

Zero-Crossing Rate

Zero-crossing rate (*ZCR*) is defined as the relative number of times the audio signal crosses the zero-line within a frame. It can be computed using the following expression:

$$ZCR = \frac{1}{2(N-1)} \sum_{m=1}^{N-1} |\mathrm{sgn}[x(m+1)] - \mathrm{sgn}[x(m)]| \qquad (1)$$

Here, sgn[] is a sign function, *x(m)* is the discrete audio signal, *m* = *1...N*, and *N* is the frame length.

The *ZCR* is a computationally simple measure of the general frequency content of a signal, and as such it is particularly useful in characterizing audio signals in terms of the *voiced* and *unvoiced* sound categories. As speech signals are generally composed of alternating voiced and unvoiced sounds, which is not the case in music signals, the variation in the *ZCR* values is expected to be larger for speech signals than for music signals. Due to its discriminative power in separating speech, music and various audio effects, *ZCR* is often employed in audio content analysis algorithms. An illustration of its practical usage can be found in [7,8,10–12,15].

Short Time Energy

Short Time Energy (*STE*) is the total spectral power of a frame. It can be computed from the audio signal directly, as

Audio Representation. Table 1. An overview of audio features most frequently used in literature for the purpose of audio segmentation and classification

Features	Level	Temporal/spectral
Short time energy, root mean square (RMS), spectrum power, volume, loudness	*fl*	*t, s*
Zero crossing rate (ZCR)	*fl*	*t*
Mel-frequency cepstral coefficient (MFCC)	*fl*	*s*
Spectral centroid, brightness, frequency centroid	*fl*	*s*
Bandwidth	*fl*	*s*
Sub-band energy (distribution), sub-band power, band-energy ratio	*fl*	*s*
Short time fundamental frequency, pitch, harmonic frequency	*fl*	*s*
LPC-derived cepstral coefficients (LPCC)	*fl*	*s*
Linear predictive coding (LPC)	*fl*	*s*
Spectral rolloff	*fl*	*s*
Spectral peak	*fl*	*s*
Spectral moments	*fl*	*s*
Spectral flatness	*fl*	*s*
Harmonicity	*fl*	*s*
Harmonicity prominence	*fl*	*s*
Sub-band partial prominence	*fl*	*s*
Wavelet decomposition	*fl*	*s*
MPEG-7 audio features	*fl*	*s*
Spectrum flux	*wl*	*s*
Percentage of low-energy frames, low short-time energy ratio (LSTER), non-silence ratio	*wl*	*t, s*
High ZCR ratio (HZCRR)	*wl*	*t*
Noise frame ratio, noise or non-voice ratio	*wl*	*t*
4 Hz modulation energy	*wl*	*t, s*
Pulse metric	*wl*	*t*

$$STE = \frac{1}{N}\sum_{m=1}^{N} |x(m)|^2, \qquad (2)$$

or from its *Discrete Fourier Transform* (*DFT*) coefficients, as

$$STE = \sum_{k=0}^{K/2} |F(k)|^2. \qquad (3)$$

Here, $F(k)$ denotes the *DFT* coefficients, $|F(k)|^2$ is the signal power at the discrete frequency k, and K is the order of *DFT*. In [7,14], this energy is computed using the logarithmic expression, to get a measure in (or similar to) decibels.

Similar to *ZCR*, *STE* is also an effective feature for discriminating between speech and music signals. For example, there are more silence (or unvoiced) frames in speech than in music. As a result, the variation of *STE* in speech is in general much higher than in music. An illustration of the practical usage of this feature can be found in [7,10,12,14,15].

Sub-Band Energy Distribution

To further exploit the energy information based on the *STE* feature defined above, the *sub-band energy distribution* (*SBED*) can be computed. This distribution can be obtained by dividing the frequency spectrum into sub-bands, and by computing for each sub-band j the ratio D_j between the energy contained in that sub-band and the total spectral power of the frame:

$$D_j = \frac{1}{STE}\sum_{L_j}^{H_j} |F(k)|^2 \qquad (4)$$

Here, L_j and H_j are the lower and upper bound of sub-band j respectively. The sub-band division can be done in various ways, such as in octave-scale [7] or in mel-scale [1].

Since the spectrum characteristics are rather different for sounds produced by different sources (e.g., human voice, music, environmental noise) the *SBED* feature has often been used for general audio classification [5,10], and, in particular, for discriminating between different sound effects [1,14].

Brightness and Bandwidth

Brightness and *bandwidth* are related to the first- and second-order statistics of the spectrum, respectively. The brightness is the centroid of the spectrum of a frame, and can be defined as:

$$w_c = \frac{\sum_{k=0}^{K/2} k|F(k)|^2}{\sum_{k=0}^{K/2} |F(k)|^2} \tag{5}$$

Bandwidth is the square root of the power-weighted average of the squared difference between the spectral components and the centroid:

$$B = \sqrt{\frac{\sum_{k=0}^{K/2} (k - w_c)^2 |F(k)|^2}{\sum_{k=0}^{K/2} |F(k)|^2}} \tag{6}$$

Brightness and Bandwidth characterize the shape of the spectrum, and roughly indicate the timbre quality of a sound. From this perspective, brightness and bandwidth can provide useful information for audio classification processes [11,14].

Mel-Frequency Cepstral Coefficient (MFCC)

The set of *Mel-Frequency Cepstral Coefficients* [10] is a cepstral representation of the audio signal obtained based on the mel-scaled spectrum. The log spectral amplitudes are first mapped onto the perceptual, logarithmic *mel-scale*, using a triangular band-pass filter bank. Then, the mel-scaled spectrum is transformed into MFCC using the Discrete Cosine Transform (*DCT*).

$$c_x = \sqrt{\frac{2}{K}} \sum_{k=1}^{K} (\log S_k) \cos[n(k - 0.5)\pi/K] \qquad n = 1, 2, \ldots, L \tag{7}$$

Here, c_n is the n-th MFCC, K is the number of band-pass filters, S_k is the mel-scaled spectrum after passing the k-th triangular band-pass filter, and L is the order of the cepstrum.

MFCC is commonly used in speech recognition and speaker recognition systems. However, *MFCC* also proved to be useful in discriminating between speech and other sound classes, such as music, which explains its wide usage in the audio analysis and processing literature [3,6,12].

Sub-Band Partial Prominence and Harmonicity Prominence

The *Sub-Band Partial Prominence* (*SBPP*) is used to measure whether there are salient frequency components (i.e., *partials*) in a sub-band. In other words, the *SBPP* estimates the existence of prominent partials in sub-bands [1]. It is computed by accumulating the variation between adjacent frequency bins in each sub-band, that is

$$S_p(i) = \frac{1}{H_i - L_i} \sum_{j=L_i}^{H_i - 1} \left| \hat{F}(k+1) - \hat{F}(k) \right| \tag{8}$$

Here, L_i and H_i are the lower and upper boundaries of the ith sub-band respectively, and the value of $S_p(i)$ indicates the corresponding prominence of salient partial components. The *SBPP* value $S_p(i)$ for sub-bands containing salient components is expected to be large. In order to reduce the impact induced by the energy variation over time, the original *DFT* spectral coefficient vector $\boldsymbol{F}$ is first converted to the decibel scale and constrained to the unit L_2-norm [2] to yield the new spectral coefficient vector used on (8):

$$\overset{\wedge}{\boldsymbol{F}} = \frac{10 \log_{10}(\boldsymbol{F})}{\left\| 10 \log_{10}(\boldsymbol{F}) \right\|} \tag{9}$$

If now the property of an ideally harmonic sound (with one dominant fundamental frequency f_0) is considered, its spectral energy is highly concentrated and precisely located at those predicted harmonic positions which are the multiples of the fundamental frequency f_0. To detect this situation, the following three factors could be measured: (i) the energy ratio between the detected harmonics and the whole spectrum; (ii) the deviation between the detected harmonics and predicted positions; and (iii) the concentration degree of the harmonic energy. Based on the above, the *Harmonicity Prominence* (*HP*) was defined in [14] to estimate the harmonic degree of a sound. The *HP* measure takes into account the above three factors and can be defined as

$$H_p = \frac{\sum_{n=1}^{N} E^{(n)} \left(1 - |B_r^{(n)} - f_n| \middle/ 0.5 f_0\right)\left(1 - B_w^{(n)} \middle/ B\right)}{E} \qquad (10)$$

Here, $E^{(n)}$ is the energy of the detected nth harmonic contour in the range of $[f_n - f_0/2, f_n + f_0/2]$ and the denominator E is the total spectral energy. The ratio between $E^{(n)}$ and E stands for the first of the three factors identified above. Further, f_n is the nth predicted harmonic position and is defined as

$$f_n = n f_0 \sqrt{1 + \beta(n^2 - 1)} \qquad (11)$$

where β is the *inharmonicity modification factor*, and $B_y^{(n)}$and $B_w^{(n)}$ are the brightness and bandwidth of the nth harmonic contour, respectively. The brightness $B_y^{(n)}$ is used instead of the detected harmonic peak in order to estimate a more accurate frequency center. The bandwidth $B_y^{(n)}$ describes the concentration degree of the nth harmonic. It is normalized by a constant B, which is defined as the bandwidth of an instance where the energy is uniformly distributed in the search range. Thus, the components $\left(1 - |B_y^{(n)} - f_n|/0.5 f_0\right)$ and $\left(1 - B_w^{(n)}/B\right)$ in the numerator of (10) represent the second and the third factor defined above.

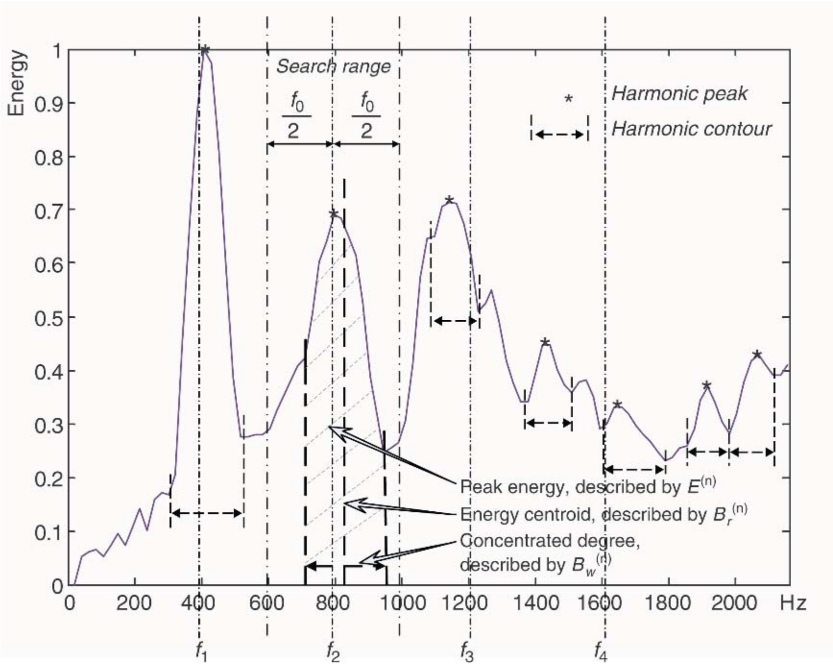
An illustration of the definition of *harmonicity prominence* is shown in Fig. 1. Detailed explanation of the computation and usage of this feature can be found in [1]. The harmonic audio analysis using the *SBPP* and *HP* features enables sophisticated audio classification, like for instance, the discrimination between *cheer* and *laughter*. This is possible because *laughter*, as opposed to *cheer*, usually contains prominent harmonic partials.

High ZCR Ratio

High ZCR Ratio (*HZCRR*) [6] is defined as the fraction of frames in the analysis window, whose *ZCR* values are 50% higher than the average *ZCR* computed in the window, that is

$$HZCRR = \frac{1}{2N} \sum_{n=0}^{N-1} [\mathrm{sgn}(ZCR(n) - 1.5 avZCR) + 1] \qquad (12)$$

Here, n is the frame index, $ZCR(n)$ is the zero-crossing rate at the n-th frame, N is the total number of frames,



Audio Representation. Figure 1. Definition of *harmonicity prominence*. The horizontal axis represents the frequency, and the vertical axis denotes the energy. The harmonic contour is the segment between the adjacent valleys separating the harmonic peaks. Based on the harmonic contour, three factors, that is, the peak energy, energy centroid (*brightness*) and degree of concentration (*bandwidth*), are computed to estimate the *harmonicity prominence*, as illustrated at the second harmonic in this example.

avZCR is the average *ZCR* in the analysis window, and sgn[] is a sign function. The variation of *HZCRR* is expected to be higher in speech signals than in music. Fig. 2(I) shows the probability distribution curves of *HZCRR* computed for a large number of speech and music signals. Using the cross-point of two displayed *HZCRR* curves as the threshold to discriminate speech and music leads to the classification error of 19.36%, as shown in [6].

Low Short-Time Energy Ratio

As an analogy for selecting *HZCRR* to model the variations of the ZCR within the analysis window, the *low short-time energy ratio* (*LSTER*) [6,11] can be defined to model the variation of the *short-time energy* (*STE*) in this window. *LSTER* is defined as the fraction of the frames within the analysis window, whose *STE* values are less than a half of the average *STE* measured in the window, that is,

$$LSTER = \frac{1}{2N}\sum_{n=0}^{N-1}[\mathrm{sgn}(0.5avSTE - STE(n)) + 1] \tag{13}$$

Here, N is the total number of frames in the analysis window, $STE(n)$ is the short time energy at the n-th frame, and *avSTE* is the average *STE* in the window. The *LSTER* measure of speech is expected to be much higher than that of music. This can be seen clearly from the probability distribution curves of *LSTER* obtained for a large number of speech and music signals, as illustrated in the Fig. 2(II). Using the cross-point of two displayed *LSTER* curves as the threshold to discriminate speech and music leads to the classification error of 8.27%, as presented in [6].

Spectrum Flux

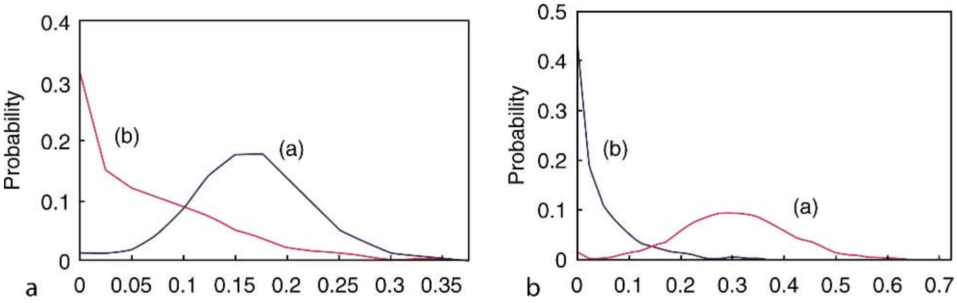
Spectrum Flux (*SF*) is defined as the average variation of the spectrum between adjacent two frames in the analysis window, that is

$$SF = \frac{1}{(N-1)(K-1)}\sum_{n=1}^{N-1}\sum_{k=1}^{K-1}[\log(A(n,k)+\delta) - \log(A(n-1,k)+\delta]^2 \tag{14}$$

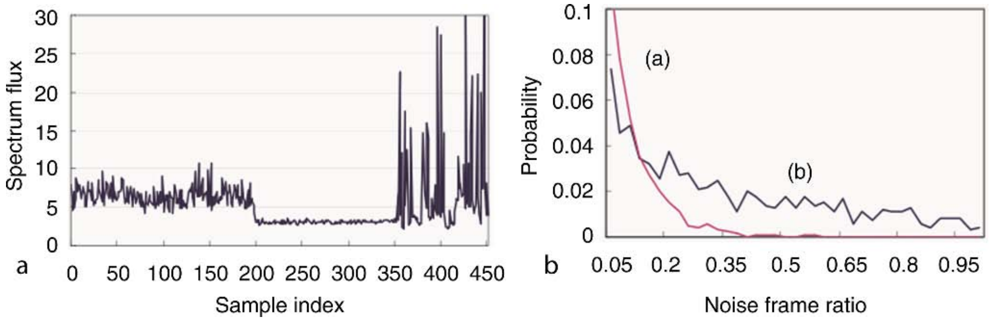
Here, $A(n, k)$ is the absolute value of the k-th *DFT* coefficient of the n-th frame, K is the order of DFT, δ is a very small value used to avoid computation overflow, and N is the number of frames in the analysis window. The *SF* of speech is expected to be larger than that of music. It was also found that the spectrum flux of environmental sounds is generally very high, and that it changes more dynamically than for speech and music [6]. To illustrate this, Fig. 3(I) shows the *SF* computed for an audio segment consisting of speech (0–200 s), music (201–350 s) and environmental sounds (351–450 s). Usage examples of this feature are provided in [8,6,11].

Noise Frame Ratio

Noise frame ratio (*NFR*) is defined as the ratio of noise frames in a given audio clip. A frame is considered as a noise frame if the maximum local peak of its normalized correlation function is lower than a pre-set threshold. The *NFR* is usually used to discriminate environmental sound from music and speech, and to detect noisy sounds. For example, the *NFR* value of a noise-like environmental sound is higher than that of music, because it contains many more noise frames. As can be observed in Fig. 3(II), considering higher NFR values can prove quite discriminative



Audio Representation. Figure 2. An illustration of probability distribution curves of (I) *HZCRR* (a) speech and (b) music, and (II) *LSTER* (a) speech and (b) music.



Audio Representation. Figure 3. (I) The spectrum flux curve of speech (0-200 s), music (201-350 s) and environmental sounds (351-450 s); (II) The probability distribution curves of *NFR*: (a) music and (b) environmental sound.

in separating these two types of audio. An illustration of the usage of this feature can be found in [5,6].

Feature Vector Generation

After they are extracted, features need to be combined together to form a complete audio representation and to provide input into audio analysis and processing steps. Since the values and dynamics of these features may vary considerably over the feature set, simply concatenating them all into a long feature vector is not likely to lead to good results. Therefore, a *normalization* needs to be performed on the features first to equalize their scales. The normalization is usually performed using the mean and standard deviation per feature, namely as $x_i^{'} = (x_i - \mu_i)/\sigma_i$, where x_i is the *i*-th feature, and where the corresponding mean μ_i and standard deviation σ_i can be obtained from the analyzed data set. Next to the normalization, *feature selection* is usually performed to improve the effectiveness of the feature vector while minimizing its dimension. While feature selection can be realized in many ways [4], a typical approach involves the *principle component analysis* (*PCA*) [13]. Technically, *PCA* is an orthogonal linear transformation that transforms the data to a new coordinate system to reveal the main characteristics (*principal components*) of the data that contribute most to the variance in data, and therefore best explain the data. The principal components can be obtained by performing a covariance analysis or *singular value decomposition* (*SVD*) [13]. If X' is a set of *N*-dimensional normalized feature vectors from *M* segments (usually $M >> N$), then X' can be written as an $M \times N$ matrix, where each row corresponds to a feature vector of one audio segment. By applying the *SVD*, the matrix X' can be written as

$$X' = USV^T \tag{15}$$

In terms of *SVD*, *V* and *U* are, respectively, an $N \times N$ and $M \times N$ matrix containing the right and left singular vectors, while the diagonal $N \times N$ matrix $S = \text{diag}\{\lambda_1,\ldots,\lambda_N,\}$ contains singular values, with $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_N$. In terms of *PCA*, singular vectors (columns) of the matrix *V* can be seen as principal components of X', each of which has its corresponding singular value. The larger this singular value is, the more principal (or more important) the component is. Assuming that V_m is a matrix keeping the first *m* principal components (by keeping the first *m* columns from *V*), the original feature set X' can be replaced by a reduced, PCA-transformed feature set

$$X'' = X'V_m \tag{16}$$

which only preserves those features that are relevant to subsequent audio signal analysis and processing steps, while leaving out the redundant and irrelevant (noisy) features.

Key Applications

Audio representation provides fundamentals for audio classification and audio segmentation.

Audio Segmentation

Lie Lu[1], Alan Hanjalic[2]
[1]Microsoft Research Asia, Beijing, China
[2]Delft University of Technology, Delft,
The Netherlands

Synonyms

Audio parsing; Auditory scene detection

Definition

Audio segmentation refers to the class of theories and algorithms designed to automatically reveal semantically meaningful temporal segments in an audio signal, also referred to as *auditory scenes* [7]. These scenes can be seen as equivalents of paragraphs in text, and can serve as input into audio categorization processes, either supervised (audio classification) or unsupervised (audio clustering). Through these processes, semantically similar auditory scenes can be grouped together and/or labeled using semantic indexes to provide multi-level, non-linear content-based access to large audio documents and collections.

Historical Background

Automatic detection of *auditory scenes* is an important step in enabling high-level semantic inference from general audio signals, and can benefit various content-based applications involving both audio and multimodal (multimedia) data sets. Traditional approaches to audio segmentation usually rely on a direct analysis of low-level audio features, that is, the targeted audio segments were often defined to coincide with a consistent low-level feature behavior [2,10,11]. This idea served as a basis for numerous approaches for audio segmentation. For example, in [10], a method for scene segmentation was presented that uses low-level features, such as cepstral and cochlear decomposition, combined with the listener model and various time scales. Motivated by the known limitations of traditional low-level feature based approaches, an approach was proposed in [7] to discover auditory scenes based on an analysis of *audio elements*, which can be seen as equivalents to the words in a text document. In this approach that draws an analogy to text document analysis, an audio track is described as a sequence of audio elements, and auditory scenes are segmented based on the semantic affinity among these audio elements and their co-occurrence.

Foundations

Traditional approaches to audio parsing relying directly on audio features have proved effective for many applications, and in particular for those where knowledge on the basic audio modalities (speech, music, and noise) is critical. However, for other applications, like those where higher-level content categories, e.g., semantic concepts, become interesting, the low-level feature based approaches have shown deficiencies due to their incapability of capturing the entire content diversity of a typical semantic concept. The audio segments obtained by typical feature-based approaches are short and of no higher semantic meaning, if compared to the true semantic segments, like, for instance, *logical story units* targeted by the algorithms of high-level video parsing [3], or the paragraphs in a text document.

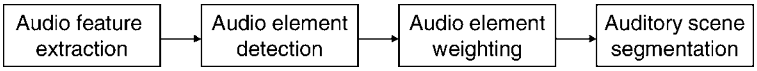
To come closer to the level of auditory scenes, a promising alternative is to design and employ suitable mid-level audio content representations. Figure 1 shows the framework for audio segmentation [6] where the input audio is first decomposed into various *audio elements* such as speech, music, various audio effects and any combination of these. Then, *audio element weighting* is performed to reveal the importance of an audio element to represent an audio document or any of its parts. The audio elements with highest weights can be adopted as the *key audio elements*, being the most characteristic for the semantics of the analyzed audio data [1,4,5,8,9,12–14]. Finally, auditory scenes can be characterized and detected based on the audio elements they contain, just as the paragraphs of a text document can be characterized and detected using a vector of words and their weights. As shown in [7], introducing the mid-level audio content representation in the form of audio elements enables splitting the semantics inference process into two steps, which leads to more robustness compared to inferring the semantics from low-level features directly.

The usefulness of audio elements for audio content analysis was already recognized, e.g., in [13], where the audio elements such as *applause*, *ball-hit*, and *whistling*, are extracted and used to detect the highlights in sports videos. However, this and similar methods usually adopted supervised data analysis and classification methods. There, the scene categories and the corresponding audio elements need to be predefined, which is usually difficult to do for general audio documents. Further, the effectiveness of supervised approaches relies heavily on the quality and quantity of the training data. This makes such approaches difficult to generalize. In view of this, a number of unsupervised approaches were proposed, including the approach to audio element discovery [1], and an approach to auditory scene segmentation [7]. The latter exploits the co-occurrence phenomena among audio elements to realize the segmentation scheme from Fig. 1. This is based on the rationale that, in general, some audio elements will rarely occur together in the same semantic context. On the other hand, the auditory scenes with similar semantics usually contain similar sets of typical audio elements. For example, many action scenes may contain *gunshots* and *explosions*, while a typical scene in a situation comedy may be characterized by a combination of *applause*, *laughter*, *speech*, and *light music*.

Audio Elements Detection and Weighting

As proposed in [1], an iterative *spectral clustering* method can be used to decompose an audio document into audio elements. Spectral clustering can be seen as an optimization problem of grouping similar data based on eigenvectors of a (possibly normalized) affinity matrix. Ng et al. [9] proposed a method to use k eigenvectors simultaneously to partition the data into k clusters, and successfully applied this to a number of complicated clustering problems. To further improve the robustness of the clustering process, the self-tuning strategy [14] can be adopted to set the context-based scaling factors for different data densities. This removes the need for the assumption that each cluster in the input data has a similar distribution density in the feature space, which is inherent in the standard spectral clustering algorithm, but usually not satisfied in complex audio data. Using this clustering method, short audio segments (e.g., one second in length [1]) can be grouped into natural semantic clusters that can then be adopted as audio elements.

In the next step, the obtained audio elements are assigned the importance weights to indicate their prominence in characterizing the content of audio data. Here, two cases can be considered. The first case assumes that only one audio document is available for weight computation. Then, a number of heuristic importance indicators, including *Element Frequency, Element Duration*, and *Average Element Length*, are



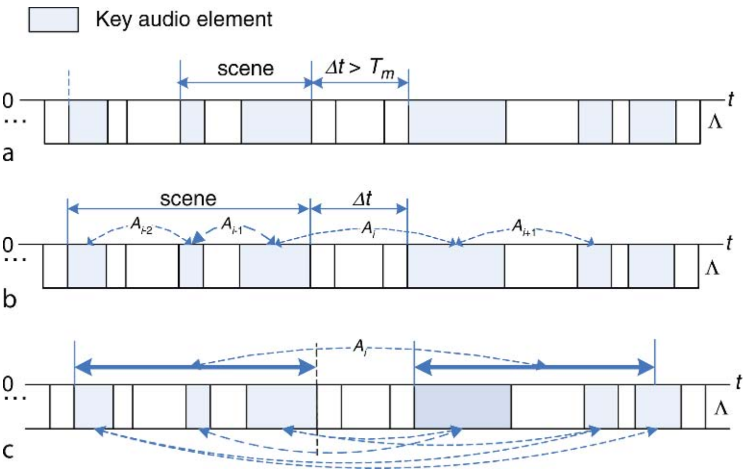
Audio Segmentation. Figure 1. The framework for audio segmentation based on audio elements [6].

proposed in [1] to compute the weight. The second case assumes that multiple audio documents are available to learn the weights. In this case, inspired by the effectiveness of *term frequency* (*TF*) and *inverse document frequency* (*IDF*) used for word weighting in text document analysis, the equivalents of these measures can be defined and employed for the case of audio segmentation. As described in [1,4,5,8,9,12–14], four factors, including *expected term frequency* (*ETF*), *expected inverse document frequency* (*EIDF*), *expected term duration* (*ETD*), and *expected inverse document duration* (*EIDD*), can be defined and combined together to give the importance weight of each audio element. These factors take into account the discriminative power of the occurrence frequency and the duration of a particular audio element to characterize the semantics of an audio document.

Auditory Scene Segmentation

In view of the way it is defined, an auditory scene may consist of multiple, concatenated and semantically related audio elements. An example of such an auditory scene is a *humor* scene consisting of several interleaved segments of *speech*, *laughter*, *cheer*, and possibly also some *light music*. In [6], a simple segmentation scheme was presented that employs crisply defined key audio elements. As shown in Figure 2a, two adjacent key audio elements are assumed to be in the same auditory scene if the time interval between them is sufficiently short. Then the scene boundaries are aligned to the key audio elements, while the background audio elements between two scenes are discarded. Clearly, the algorithm is quite naive and does not fully exploit the relationship between audio elements and auditory scenes. To improve the detection performance, the notion of *semantic affinity* between two contiguous key audio elements was introduced in [1]. This affinity takes into account both the co-occurrence statistics of these key audio elements and the time interval between them, and was employed in [1] to locate the auditory scene boundaries. As shown in Figure 2b, auditory scene boundaries are found between two key audio elements if their semantic affinity is low.

The performance of the segmentation methods discussed above strongly depends on the definition of a key audio element and the reliability of its detection. Crisply defining key audio elements and detecting them in composite audio documents may be rather difficult due to multiple superimposed audio modalities. Therefore, a more reliable solution would be to work with all audio elements instead, and rely on their importance weights. This idea also follows the analogy to the classical text [4] and video scene segmentation approaches [3,5]. As illustrated in Figure 2c, an approach in this direction would decide about the presence of a scene boundary at the observed time stamp



Audio Segmentation. Figure 2. An illustration of previous approaches to auditory scene segmentation, where a vertical line indicates a detected scene boundary: (a) using time interval between key audio elements; (b) using semantic affinity between neighboring key audio elements; and (c) investigating the relationship of (key) audio elements on a large temporal scale.

based on an investigation of the semantic affinity between audio elements taken from a broader range and surrounding this time stamp.

The possibilities for realizing the audio segmentation idea from Figure 2c are now illustrated on the example of the method proposed in [7]. Here, just like in text document analysis, the measure for semantic affinity is not based on the feature-based similarity between two audio segments, but on their joint ability to represent a semantically coherent piece of audio. With this in mind, the definition of semantic affinity in [7] is based on the following intuitive assumptions:

- Affinity between two audio segments is high if the corresponding audio elements usually occur together.
- The larger the time interval between two audio segments, the lower their affinity.
- The higher the importance weights of the corresponding audio elements, the more important is the role these elements will play in the auditory scene segmentation process, and therefore the more significant the computed semantic affinity value will be.

Figure 3 shows an example audio element sequence, where each temporal block belongs to an audio element and where different classes of audio elements are represented by different colors/grayscales. The semantic affinity between the segments s_i and s_j can now be computed as a function consisting of three components, each of which reflects one of the assumptions stated above. The following measure is proposed in [1]:

$$A\left(S_i, S_j\right) = Co\left(e_i, e_j\right) e^{-T\left(S_i, S_j\right)/T_m} p_{e_i} p_{e_j} \qquad (1)$$

Here, the notation e_i and e_j is used to indicate the audio element identities of the segments s_i and s_j, that is, to describe their content (e.g., speech, music, noise, or any combination of these). P_{ei} and P_{ej} are the importance weights of audio elements e_i and e_j, while $T(s_i,s_j)$ is the time interval between the audio segments s_i and s_j. Further, T_m is a scaling factor which can be set to 16 s, following the discussions on human memory limit [3]. The exponential expression in (1) is inspired by the content coherence computation formula introduced in [12]. Further, $Co(e_i, e_j)$ stands for the co-occurrence between two audio elements, e_i and e_j, in the entire observed audio document, and measures their joint ability to characterize a semantically coherent auditory scene.

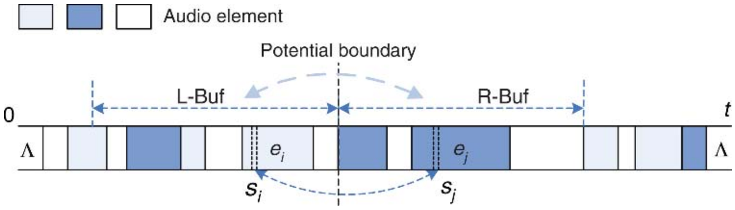
To estimate the co-occurrence between two audio elements, one can rely on the average time interval between two audio elements. The shorter the time interval, the higher the co-occurrence probability is. The procedure for estimating the value $Co(e_i, e_j)$ can then be summarized in the following three steps [1]:

1. First, compute D_{ij}, the average time interval between audio elements e_i and e_j, which is obtained by investigating the co-occurrences of the observed audio elements in the audio signal. For each segment belonging to audio element e_i, the nearest segment corresponding to e_j is located, and then D_{ij} is obtained as the average temporal distance between e_i and e_j.
2. D_{ji} is computed as an analogy to D_{ij}. One should note that D_{ij} is not always equal to D_{ji}.
3. The co-occurrence value can now be found as

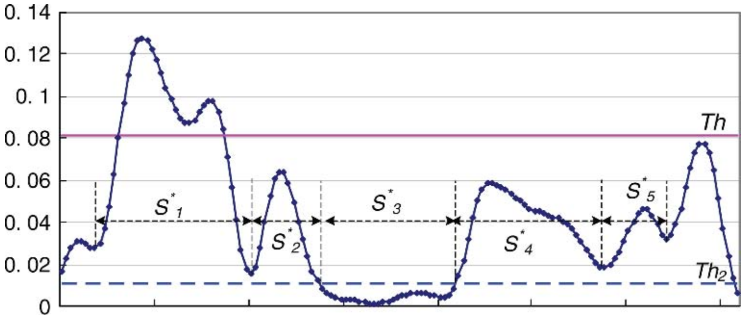
$$Co\left(e_i, e_j\right) = e^{-\frac{D_{ij} + D_{ji}}{2\mu_D}} \qquad (2)$$

where μ_D is the average of all D_{ij} and D_{ji} values. The choice for an exponential formula in (2) is made to keep the influence of audio element co-occurrence on the overall semantic affinity comparable with the influence of the time interval between the audio segments (1).

Based on the semantic affinity (1), the confidence of being within an auditory scene at the time stamp t can now be computed by averaging the affinity values



Audio Segmentation. Figure 3. An illustration of an approach to audio segmentation [7], where s_i and s_j are two audio segments, and e_i and e_j are their corresponding audio element identities.



Audio Segmentation. Figure 4. An example of the smoothed confidence curve and the auditory scene segmentation scheme, where S_1^*~S_5^* are five obtained auditory scenes and *Th* and Th_2 are two thresholds.

obtained for all pairs of segments s_i and s_j surrounding the *t*, that is,

$$C(t) = \frac{1}{N_l N_r} \sum_{i=1}^{N_l} \sum_{j=1}^{N_r} A(S_i, S_j)$$
$$= \frac{1}{N_l N_r} \sum_{i=1}^{N_l} \sum_{j=1}^{N_r} Co(e_1, e_j)\, e^{-T(S_i, S_j)/T_m} P_{e_i} P_{e_j} \qquad (3)$$

where N_l and N_r are the numbers of audio segments considered left and right from the potential boundary (as captured by the intervals *L-Buf* and *R-Buf* in Figure 3). Using this expression, a confidence curve can be obtained over the timeslots of potential boundaries, as illustrated in Figure 4. The boundaries of auditory scenes can now be detected simply by searching for local minima of the curve. In the approach from [1], the curve is first smoothed by using a median filter and then the auditory scene boundaries are found at places at which the following criteria are fulfilled:

$$C(t) < C(t+1);\;\; C(t) < C(t-1);\;\; C(t) < Th \quad (4)$$

Here, the first two conditions secure a local valley, while the last condition prevents high valleys from being detected. The threshold *Th* is set experimentally as $\mu_a + \sigma_a$, where μ_a and σ_a are the mean and standard deviation of the curve, respectively.

The obtained confidence curve is likely to contain long sequences of low confidence values, as shown by the segment S^*_3 in Figure 4. These sequences typically consist of the background audio elements which are weakly related to each other and also have low importance weights. Since it is not reasonable to divide such a sequence into smaller segments, or to merge them into neighboring auditory scenes, one could choose to isolate these sequences by including all consecutive audio segments with low affinity values into a separate auditory scene. Detecting such scenes is an analogy to detecting pauses in speech. Inspired by this, the corresponding threshold (Th_2 in Figure 4) can be set by using an approach similar to background noise level detection in speech analysis [12].

Key Applications

Audio segmentation is typically applied for content-based search and retrieval in and management of large-scale audio collections (databases).

Auditing and Forensic Analysis

Definition

The goal of *database auditing* is to retain a secure record of database operations that can be used to verify compliance with desired security policies, to trace policy violations, or to detect anomalous patterns of access. An audit log can contain the authorization ID and time stamp of read and write operations in the database, as well as a record of server connections, login attempts and authorization changes. Government and institutional regulations for the management of sensitive information often require auditing of data disclosure and data modification.

Database forensics is the analysis of the state of a database system to validate hypotheses about past events that are relevant to an alleged crime or violation of policy. Evidence supporting a forensic analysis may be found in an audit log (if available) but may also be recovered from any other component of a database system including table storage, the transaction log, temporary caches, or backup media. A challenge of working with forensically recovered evidence is that it is typically provides only a partial record of an event, possibly based on remnants of deleted information or on inference from incomplete information. On the other hand, it can be difficult to completely eradicate digital evidence from databases, which may be critical for preventing disclosure and complying with policy mandating limited data retention.

While auditing is focused on the preservation and analysis of specific data as required by law or internal corporate policy, digital forensics is broader in scope, potentially relating to any criminal or civil proceeding. Auditors and forensic analysts share some common goals, however the auditor usually relies on information retained intentionally by the system. The forensic analyst is more likely to rely on unintended remnants and inference about past events.

Historical Background

Auditing has been a common practice in settings where sensitive data is managed by computer systems, such as financial and military applications. Auditing has grown in importance as institutions are increasingly required to prove compliance with privacy regulations, or are mandated to discover and publicly respond to exploited vulnerabilities in their systems. Database forensics is an emerging subfield of digital forensics. Computer crime and investigations began receiving attention the late 1970s, but the realization that digital evidence is relevant to a spectrum of crimes has occurred within the last decade. Databases are common components of operating systems, web browers, and email programs and are an important focus of digital investigations.

Foundations

Database Auditing

The auditing component of a database system must support the collection, storage, and protection of sufficient historical data to enable desired auditing inquiries. Typical auditing queries might include the following:

- Display the query expression for all operations which modified more than ten rows.
- List the authorization IDs of users or client programs who performed SELECT queries on the Patients table between 10 P.M. and 5 A.M. last week.
- List any records in the Employee table whose salary field has been modified more than twice in the past 12 months.

In misuse detection or intrusion detection, the audit log may be used to assess more complex behavior such as: *Is today's workload of update operations similar to "normal" patterns of database usage?*

To support such inquiries, an audit log records the client programs and users who are executing operations, the data objects modified or disclosed, and the context of those operations. For each operation performed, an audit log could contain the SQL query string along with contextual information such as time of day, authorization ID, and network connection information. For update and deletion operations, the audit log may contain the removed values, and the previous values of modified data.

Analyzing database disclosure resulting from a sequence of SELECT queries can be more complex than analyzing the history of database modifications (inserts, updates, and deletes). Auditing disclosure has been the subject of intense research [1,2,4], but faces subtle challenges because a user may be able to infer information not directly released through an executed query. For example, a user's access to an individual database record can be hidden in a sequence of aggregate queries.

In establishing auditing policies, the credibility and completeness of the audit log must be carefully considered to ensure that all relevant events in the system are preserved. For example, the effects of an aborted transaction will be removed from the system for database consistency and atomicity. But a record of aborted transactions, and the reason for abort, could be important to an audit analysis [4].

Naturally, data that will never be relevant to the audit queries under consideration need not be recorded. Further, the retention of recorded audit data must be carefully determined and enforced. The log should be available for appropriate audit inquiries when they arise, but it also contains highly sensitive information and should be destroyed once the period of legitimate inquiry has passed.

Systems Issues and Performance Considerations To support auditing, database systems must efficiently collect required data and permit analysis. Modern commercial databases contain a range of native auditing features which usually include more than one type of log. Common features include a system log to record all connections to the database, and an query log to record each query expression submitted to the database. An auditing policy can be chosen to specify the level of detail that should be logged (e.g., all accesses to relations, or individual tuples; logging of first access in a session or all accesses, etc.).

Logged data may be written to files outside database storage, or to system tables within the database. In the former case, protection depends on operating system access control, while in the latter case protection of audit data depends on the access controls of the database. In particular, the DBA often has privileges to read or alter system tables. When audit data is stored in tables it can have a substantial performance impact on normal database operations.

Database users can implement their own auditing through user-level triggers. A trigger is a user-defined procedure that executes before or after designated events in the database. The triggering event can be an insert, delete, or update command, and most systems allow for tuple-level execution (in which the rule executes once for each tuple affected) or statement level (in which rule executes once for each statement). User-level triggers can be inefficient (especially tuple-level triggers) and the scope of events that can act as trigger events may be limited.

The database transaction log is designed to support critical ACID properties for the concurrent execution of transactions. The transaction log typically includes the before and after images of all database modifications to allow for rollback of aborted transactions and the redo of changes lost due to system failure. While the transaction log contains a wealth of information relevant to auditing, it has a number of limitations when used as an auditing mechanism. First, key data is missing from the transaction log: namely a record of read accesses to the database, as well as some operational context information. In addition, performing an audit analysis using the transaction log could require recovering the state of the database as of a past moment in time. Although a number of current systems provide such point-in-time recovery by reinstating backups and rolling transactions forward, using this mechanism for audit analysis is very inefficient. Finally, the retention period of transaction log data and audit log data may be substantially different. Transaction logs are often implemented as circular files in which old log records no longer needed for recovery are overwritten. Retention periods for auditing data may be much longer.

In a persistent database (also known as an archiving, or transaction-time database) the historical state of the database is purposely retained as modifications are applied. In such systems a deletion never destroys data and an update merely creates a new version of a tuple. It is possible to pose queries "as-of" any past point in time. Persistent databases have received considerable attention from the research community [5], motivated by both auditing and other applications. Combined with query logs and system logs, a persistent database can offer the most complete audit collection along with efficient audit analysis since the historical state of the database can be queried.

Support for persistence has not been widely implemented, and is not usually used to support auditing in commercial systems. A number of research projects have built persistent, temporal or transaction-time databases, many as extensions to existing systems like MySQL [8], BerkeleyDB [7], and SQL Server.

Protecting the Audit Log It is essential that the audit log be protected from unauthorized modification so that it accurately reflects history. The database administrator, and other privileged parties, should not be capable of tampering with the audit log. Typically there is no legitimate reason for records in an audit log to be modified. The log should be append-only and may be implemented using write-once media. Deletion of the audit log should occur only when it is clear that the log is no longer needed for audit inquiries. Cryptographic techniques have been proposed for detecting tampering of database audit logs and for efficiently tracing the location of illegally modified records once tampering has been discovered.

It is equally critical that the confidentiality of the audit log be protected. The audit log poses multiple privacy threats: the audit log contains records from database that may be sensitive, as well as a history of how the database was used (the users of the database, the queries that were executed, and times of day can all violate the privacy of individuals). Viewing audit logs is a highly privileged operation in most systems. Recent research has investigated the use of cryptography to permit searching over encrypted audit logs to minimize the disclosed data during an investigation [10].

Database Forensics

The goal of database forensics is the analysis of a database system's contents to validate hypotheses about past events that are relevant to an alleged crime or violation of policy. This is a challenge since recovered evidence is typically only a partial record of past events. The goal of the analysis is a formal presentation of recovered data in a court of law, and therefore it is critical for the investigator to also understand legal concepts, including evidence handling. Unlike auditing, there is no limitation on the type of data that can be of interest. Broadly, there are two types of evidence.

- Database evidence can be the direct subject of a crime. For example, records can store contraband, such as images of child pornography, copyrighted media, and stolen intellectual property.
- Evidence can be indirectly related to a crime, for example data from a log that verifies that a relationship exists between two users or computers. Or a log of database query terms can corroborate the notion that a user had knowledge of and intent to possess particular contraband content found in their file system.

Typically investigations cover not only databases but other computer systems (e.g., file systems, email stores, web history) as well as aspects of a crime scene beyond the computer. Evidence from the entire scope of a crime scene must be synthesized and reported as testimony that is persuasive to an adjudicator.

Harvesting Database Evidence Databases are among the most complicated systems found in modern computers. Investigators can harvest evidence from table storage, indexes, transaction and audit logs, temporary caches, database catalogs, or archived copies of records on backed up media.

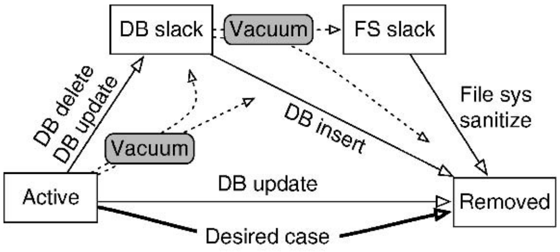
Data values have a complex lifetime with a database system. When input to a database, records begin in an active state, which means a database and its services need the record in order to function properly. Database operations can change or create active records or remove the purpose of active records. In the latter case, records become expired. For example, a record becomes expired when it is deleted and when there is no combination of operations left that would ever use the record again. Forensic investigators are interested in both active and recoverable expired records.

The lifetime of data is illustrated in Fig. 1 for the simple case of records in table storage. An insertion creates an active record, a deletion changes a record from being active to being expired and eventually the data may be overwritten by another database operation. After expiration, a tuple can be either removed, or it can continue to exist as recoverable slack data. Methods of removal are discussed below.

In the case of table storage, each paged file of storage is shared by many records. The database API enables users or investigators to retrieve all active values. When data is deleted by users, typically a single bit is flipped in the page file to indicate removal of the data. However, the record can be retrieved outside the mechanisms of the API.

Other database mechanisms can also leave recoverable records. Updates to records with variable lengths can replace one or more attribute values with smaller attribute values; the tail-end of the old record will remain partially recoverable until it is overwritten. Or an administrator may initiate a *vacuum* command to improve storage performance. When vacuum executes, on many systems, the reorganization is not performed completely in place. In addition to reorganizing records within and across pages, the size of the file used for table storage may be reduced, returning space to the file system, creating the possibility that the database records can be recovered through file system forensics.

Expired data can also be found in stored indexes if, for example, entries in B+tree nodes are deleted but not overwritten immediately. Temporary relations, materialized for improved query processing or used for external sorting, also contain data recoverable as filesystem slack. Data can be recovered from transaction logs, which are typically implemented sequentially written circular files where the newest data overwrites the oldest portion of the log. The amount of recoverable data is dependent on the file system space allocated to the log and characteristics of the database, including the rate and size of updates and checkpoints. Similarly, the amount of data stored in backups varies with policy, storage capacity, and use.



Auditing and Forensic Analysis. Figure 1. The flow of data during its lifetime. It begins in the active state. Before it is deleted and becomes expired it will often be retained as database slack or filesystem slack [9].

System Transparency and Privacy Forensic analysis is not restricted to active tuples because database designs do not strive to eliminate unintended retention of data accessible through interfaces that are not controlled by the database. This incongruence between what the database presents to users and what is actually stored represents a threat to privacy and confidentiality.

For example, as stated above, businesses can unintentionally violate privacy regulations when deleted data is left in table or file storage. Adversaries that investigate databases recovered from lost or stolen computers can reveal sensitive information that was thought to be deleted.

From this point of view, it is desirable for a database to operate in a forensically *transparent way* [9]. Stahlberg et al. have proposed a set of desiderata to determine the extent to which a database system is forensically transparent. A database system is forensically transparent if it satisfies all three desiderata.

Clarity: The impact of each operation on the state of records, whether active or expired, is clear to the user.
Purposeful retention: Only *active* records should be retained by the database.
Complete removal: Expired records must be *removed* by the system within a short, fixed time from when they become expired. In other words, there must be a small upper bound on the time that slack data exists in the database.

Databases that satisfy these desiderata provide a reliable interface to the user in terms of what data is actually stored in the system.

Removal of Data Ensuring that removed data is unrecoverable from a database system is difficult. Records can be removed by overwriting storage with a standard pattern (e.g., all zeros) or through the use of encryption.

Deletion through overwriting can be costly in terms of performance and therefore should be limited to small records or files. Asynchronous overwriting during idle periods can ameliorate performance degradation while opening a window of opportunity for recovering data. Secure removal of data can also be accomplished by storing data in encrypted form and using overwriting to remove the decryption key. This technique was first proposed for efficient simultaneous removal of data from files and backup logs. Stahlberg et al. [9] present an extended discussion of the use of encryption keys and overwriting in the different internal database mechanisms.

Key Applications

Auditing and forensic analysis are critical operations in any setting where sensitive or high-value data is exposed to untrusted users. For example, database applications that manage financial, national intelligence, or medical information must maintain audit records of past data and operations, and may be the subject of forensic analysis if policy violations occur.

Future Directions

A frequent outcome of auditing and forensic analysis is the detection of a malicious or mistaken operation in the past. Correcting the corrupted database, especially after many valid transactions have been applied, is a significant challenge receiving recent attention by the research community [3,6].

Also note that the above discussion has focused on a single database server. In modern applications, a comprehensive audit or forensic analysis is likely to involve many integrated systems where data objects are derived from diverse sources and follow a complex workflow. In such settings auditing inquiries share some similarities with data provenance (or lineage), which is a record of how a data item has come to exist in a database or view.

Authentication

Marina Blanton
University of Notre Dame, Notre Dame, IN, USA

Definition

Authentication is a broad term, which is normally referred to mechanisms of ensuring that entities are who they claim to be or that data has not been manipulated by unauthorized parties. Thus, *entity authentication* or *identification* refers to the means of verifying user identity, after which the user will be granted appropriate privileges. *Data origin authentication* refers to the means of ensuring that the data comes from an authentic source and has not been tampered with during the transmission.

Historical Background

The need for user authentication in early computer systems arose once it became possible to support multi-user environments. Similarly, data base systems that can be accessed by multiple users with different privileges have to rely on user authentication to enforce proper access control. There is a variety of mechanisms that allow users to authenticate themselves, but password-based authentication is currently the most widely used form of identification.

Data origin authentication (or *data authentication* for short) is also an old concept which gained importance with the adoption of inter-computer communications. With respect to data base systems, data authentication is crucial in distributed environments and when data bases are disseminated to other entities.

Foundations

Identification

The purpose of *entity authentication* or *identification* is to allow one party (the *verifier*) to gather evidence that the identity of another party (the *claimant*) is as claimed. Thus, authentication protocols should permit honest parties to successfully finish the protocol with the claimant's identity being accepted as authentic and make it difficult for dishonest parties to impersonate an identity of another user. Impersonation must remain difficult even for an adversary who can observe a large number of successful executions of the authentication protocol by another entity.

Identification mechanisms can normally be divided into the following types depending on how the identity evidence is gathered:

1. *The user knows a secret.* Such types of identification include passwords, personal identification numbers (PINs), or secret keys.
2. *The user possesses a token.* This is normally based on a hardware token such as magnetic-striped cards (or smartcards) or other custom-designed devices that generate time-variant passwords.
3. *The user has a physical characteristic.* Identification can be based on characteristics inherent to the user being authenticated such as biometrics, handwritten signatures, keystroke dynamics, facial and hand geometries, voice, and others.

Note that for added security often different mechanisms can be combined together. For example, PIN-based authentication is almost always used in conjunction with a physical device that stores information about its owner (i.e., user ID, credit card number, etc.). Likewise, biometric-based recognition can be used in combination with a password or a physical token.

Before a user will be able to engage in an authentication protocol, she needs to *register* with the system and store the data (e.g., a password, keys, biometric data) that will thereafter aid the system in the authentication process. Password-based authentication is treated next, followed by stronger forms of entity authentication.

Password-Based Authentication

Identification based on conventional time-invariant passwords is the most widely used form of identification even though such approaches do not provide strong authentication. A password is a string of (normally 8 or more) characters associated with a certain user, which serves the purpose of a shared secret between the user and the system. When a user initiates the identification process, she supplies the system with the pair (*userid, password*), where *userid* identifies the user and *password* provides the necessary evidence that the user possesses the secret.

The most straightforward approach for the system to store passwords is in the clear text. This, however, allows the system administrator, or an adversary in case of system compromise, to recover passwords of individual users leading to security concerns. Thus, most systems first apply a one-way *hash function* to each password and store the output in the system. Then when a user supplies the password during the identification process, the password is first hashed and then compared to the string stored in the system. This security measure no longer allows cleartext passwords to be recovered, but other attacks on passwords are still possible. In particular, the following attacks can be carried out:

- *Replay of passwords.* Since passwords are reusable, an adversary who obtains password information (by either seeing the user type the password, using a keylogger program, or capturing the password in transit from the user to the system) will be able to reuse it and successfully impersonate the user.
- *Exhaustive search.* An adversary might attempt to guess user passwords by trying all possible strings as potential passwords (on the verifier itself or by obtaining a copy of the password file and performing this attack off-line). Generally it is infeasible for an adversary to try all passwords if they are chosen from a sufficiently large space, but it is

possible to exhaust short passwords (e.g., of length 6 characters or less).

- *Dictionary attack.* It is well known that users tend to choose passwords that they can easily remember but which are considered weak from the security point of view. Thus, an adversary might try to guess a user password using words from a dictionary and variations thereof. If a user makes a poor password choice, such an attack can have a high probability of success. Dictionary attacks become increasingly complicated, testing for combinations of words, common substitutions and misspellings, insertion of additional symbols, words from foreign languages, etc.

To decrease the vulnerability of the system to these attacks, additional measures are normally employed, some of which are:

- *Salting passwords.* In order to make guessing attacks less effective, many systems use an additional random string, called *salt*, with each password. Before a password is stored, it is augmented with a random salt, hashed, and then stored in the system along with the salt. This prevents an attacker who is in possession of a file with many user passwords to launch a dictionary attack against all of them at the same time, and requires each user's password to be tested individually.
- *Slowing down password verification.* To defeat against attacks that perform trials of a large number of passwords, the function that computes the hash of the password can be made more computationally extensive. This, for example, can be done by iterating the computation n times. When increasing the computation for password mapping, a care, however, must be taken not to impose a burden on legitimate users.
- *Limiting the number of unsuccessful password guesses.* It is common for a user account to be locked after the number of unsuccessful authentication attempts exceeds a certain threshold. The owner of a locked account must then contact an administrator and have the account activated.
- *Password rules.* To protect against guessing attacks, often certain rules are imposed on user choice of passwords such as the minimal password length and/or usage of capital letters, numbers, and special symbols. Such rules normally strengthen the password choices but they also limit the password search space. Also, a technique called *password aging* is often employed to force users to choose a new password after a certain period of time. If such a period is rather short, however, users will be unable to remember a newly chosen strong password, thus weakening the security of the system with bad password choices.

It is always a challenge to find a balance between memorability of passwords (passwords that are hard to remember tend to be written down) and their resistance to dictionary attacks (i.e., passwords with enough randomness in them). Thus to aid users in choosing less predictable passwords which they can remember, techniques exist to create computer-generated *pronounceable passwords* which are based on mnemonics. Also, recently various solutions have been developed to use images for authentication (a user is given a number of images and is asked to identify the set of pre-selected images), graphical interfaces (a user draws a pattern on a grid that has to match a previously chosen pattern), etc. Such systems, however, are not widely deployed and have not been thoroughly evaluated to determine the level of security they provide.

Since a major security concern with fixed passwords is the possibility of replaying them, a natural way to improve their security is to consider *one-time passwords.* As the name suggests, in such systems each password is used only once and there are different ways to realize them, which is briefly outlined next.

- The user and the system initially agree on a sequence of secret passwords. Each time the user authenticates to the system, a new password is used. This solution is simple but requires maintenance of the shared list.
- The user updates her password with each instance of the authentication protocol. For instance, the user might send the new password encrypted under a key derived from her current password. This method crucially relies on the correct communication of the new password to the system.
- The new password is derived with each instance of the authentication protocol using a one-way *hash function.* As an example, consider the scheme called S/Key due to Lamport [2]. The user begins with a secret k and applies a one-way *hash function* h to produce a sequence of values $k, h(k), h(h(k)), \ldots, h^t(k)$. The password for ith identification session

is $k_i = h^{t-i}(k)$. When the user authenticates $(i+1)$ st time with k_{i+1}, the server (which has k_i for that user stored) checks whether $h(k_{i+1}) = k_i$ and, if so, accepts the authentication and replaces k_i with k_{i+1}. This check convinces the server because the function h is considered to be infeasible to invert and only the legitimate user will be able to construct k_{i+1} that passes the check.

Challenge-Response Identification

Challenge-response techniques provide a strong form of entity authentication as they are not vulnerable to replay attacks. The main idea behind such protocols is that the claimant possesses a secret. During an identification session, the server sends to the claimant a unique randomly chosen *challenge*. The claimant computes a *response* which is a function of her secret and the server's challenge and sends it to the server. It is important to note that the response does not provide information about the user secret, and cannot be used to successfully compute responses to server's challenges in the future by someone who monitors the message exchange.

A variety of cryptographic challenge-response techniques exist which could be based on (i) symmetric encryption, (ii) one-way *hash functions*, or (iii) public-key encryption. A more detailed explanation of such techniques is beyond the scope of this article and can be found in standard textbooks on cryptography such as [3,7].

Data Origin Authentication

The purpose of *data origin authentication* is to ensure that the data comes from a trusted source and has not been tampered with during the transmission. Techniques that permit verifying data authenticity can be divided in two categories: (i) the communicating parties *share a common secret* and (ii) the communicating parties *do not share a secret.*

Consider that in a distributed database environment two systems communicate often and there is a need to ensure data integrity. Then such systems can share a secret S that permits them to use *message authentication codes* (MAC) for data authentication. That is, prior to transmitting the data, the sender constructs the MAC using S and sends it along with the data. After obtaining the data, the receiver uses the shared secret to reconstruct the MAC and compare it with the MAC received. If the check succeeds, the data is accepted as authentic, and it is discarded otherwise.

In cases when the sender and the receiver do not already have a secret which is known to both of them, *digital signatures* can be used to verify the authenticity of the sender and integrity of the data. This mechanism assumes that the sender has a public-private key pair, which is used to sign the data. Then the sender uses her private key to sign the message and the receiver uses the corresponding public key to verify the fact that the message arrived intact.

The standard way of producing a digital signature on data is first to apply a one-way *hash function* on the data to compute its digest and then sign the digest. The purpose of computing the digest first is to compress the data to a short string, which then can be efficiently signed to produce a fixed-size signature. In cases when integrity of a database needs to be verified with some regularity while only parts of it change, more advanced techniques can be used. In particular, Merkle hash tree is commonly used to produce a digital signature on a hierarchically structured set of documents (e.g., an XML tree of documents). In such a tree, digests of individual nodes are computed and then combined in a bottom-up fashion to result in a single short digest of the tree. The owner of the data produces a signature on the root node only. Verification of data integrity in such trees can normally be done faster than recomputing digests of the entire tree if the user would like to verify the integrity of only a part of the tree.

Key Applications

The main application of authentication is access control. Namely, in multi-user systems a user authenticates to the system and is granted access to specific resources determined by her access privileges. The mechanisms used to determine user access rights vary drastically from one system to another and are based on the type of access control (e.g., role-based, discretionary, etc.,) and access control policies.

Also, authentication applications and services such as Kerberos, X.509 Authentication Service, or Public-Key Infrastructure (PKI) can be used to aid in the authentication process.

In case of data authentication, verification of data integrity and authenticity is essential in determining trustworthiness of the data. For example, updated database records that are coming from a trusted source can be safely used to modify the current contents of the database. If, on the other hand, data integrity and authenticity of the modifications cannot be verified, in many cases such data will not be trusted.

Multimedia content enrichment; Image classification; Object detection and recognition;Auto-annotation

Definition

The widespread search engines, in the professional as well as the personal context, used to work on the basis of textual information associated or extracted from indexed documents. Nowadays, most of the exchanged or stored documents have multimedia content. To reduce the technological gap so that these engines still can work on multimedia content, it is very convenient developing methods capable to generate automatically textual annotations and metadata. These methods will then allow to enrich the upcoming new content or to post-annotate the existing content with additional information extracted automatically if ever this existing content is partly or not annotated.

A broad diversity in the typology of manual annotation is usually found in image databases. Part of them is representing contextual information. The author, date, place or technical shooting conditions are quite frequent. Some semantic or subjective annotations, like emotions that flow out from images, can be found. Some other annotations could be related to the visual content of images. They provide information on a given image such as indicating whether it is a drawing, a map or a photograph... For photographs, the global aspect is often specified (vertical/horizontal, color/black and white, indoor/outdoor, landscape, portrait...), as well as the presence of remarkable objects or persons.

The aim of automatic image annotation approaches is to provide efficient methods that extract automatically the visual content of pictures allowing semantic labeling of images. This is generally achieved by learning algorithms that, once being trained on annotated sub-corpora, are able to suggest keywords to the archivist through object detection/recognition and image classification methods.

Historical Background

The exploration of visual content databases and their querying to retrieve some specific content usually rely on textual annotations that have been previously provided manually by human operators. The outcome of the tremendous improvements in digitization and acquisition devices is the availability of exponentially growing content. Usual annotation techniques then became more and more difficult to apply because they are time and cost consuming. Moreover, manual annotations are far from being perfect. They are often focused on the context, subjective, partial and driven by the needs of the end-users at the time they are produced. As these needs are evolving, part of the existing annotations becomes irrelevant and others are missing. This is especially true with the arising of Internet and the availability of all kind of databases online. An other issue lies in the lack of controlled vocabularies for most of the databases making difficult for the end-user to guess what query words he has to use in order to retrieve the content he has in mind.

Visual content indexing and retrieval community have achieved significant progress in the recent years [13] toward efficient approaches for visual features extraction and visual appearance modeling together with developing advanced mechanism for interactive visual information retrieval. One of the major issues was and remains the semantic gap [4,8].

Two main types of images databases could be distinguished. Specific databases are focused on a given restricted field. In the scientific domain, one can cite satellite images for weather forecast or cultivation study, medical images or botanical databases for species recognition. They are also found in the cultural heritage domain (e.g., paintings databases) or the military and security domain (e.g., fingerprints and faces databases). On the other side, generic databases contain very different images, without any *a priori* on their content. This is usually the case for professional news agencies, illustration photo stock collections and personal family and holiday photo albums. Only methods for generic content databases labeling will be addressed.

By analyzing automatically images and characterizing them with low-level features (mainly colors, textures and shapes) CBIR systems [3] provided new query paradigms that enable users to express their needs. The main one is "query by example" where the system retrieves images of the database that are the most similar to a given example. The scientific community has been facing the well known semantic gap problem for a while which remain the major concern of the research community. Since the late 90s, relevance feedback mechanism is one of possible solutions to this difficult problem.

The early papers on automatic annotation that have been published tackled image orientation detection or the classical indoor versus outdoor and city versus landscape classifications of photographs [14,15]. Recently, relevance feedback allows moreover helping for interactive mass-annotation of image collections. This approach is often referred to as semi-automatic image annotation.

Foundations

Despite some of its drawbacks, the query by keyword is still very useful and quite natural for the end-user [6]. Automatic annotation generates such keywords to enrich the images semantic descriptions and ease further querying. Because of the computational costs of all current approaches, the existing systems are always composed of two parts. An offline part is in charge of indexing the visual content and generating the annotations. Eventually, a human operator can help the system during the process or after it to validate/invalidate the produced annotations. In such cases, one talks of semi-automatic annotation systems. The second part, online and real-time, is a query by keywords module.

As the main purpose is to describe the visual content, the term "visual concept" is preferred over keyword to describe the labels a system has to discover in images. As previously mentioned, these visual concepts could be related to either global appearance of the image or presence of some objects. Objects detection can also be refined in generic object class detection or specific object instance detection. For example, one can ask a system to label only the "vehicle" concept, or more precisely to distinguish cars, motorbikes, boats and airplanes, and, at a very specific level, being able to recognize different makes of cars. This is the same problem with annotating persons. Being able to detect the presence of a person in an image is a different procedure and result than recognizing him. As face recognition is a well studied problem which is tackled by a specific research community. The ability to generalize from a few examples and to reach higher abstraction levels is natural for humans but it is very challenging task to achieve with current state-of-the-art's annotation systems [5,7,10,12].

One of the fundamental hypotheses of automatic annotation is that what looks similar is probably semantically similar. Most of the approaches rely on this assumption. The main generic steps of automatic annotation are described below. First, visual features are extracted automatically from images in order to obtain representations in a visual space. The second step is to build models that will link the visual concepts to the relevant information in the visual space. When new content is proposed, models are then able to predict the corresponding visual concepts.

The performances evaluation of such methods may rely on the usage of the annotations by the final users. As in most of information retrieval systems, precision and recall measures are used. Precision emphasizes the retrieval of relevant documents earlier and recall focuses on the retrieval of the full set of relevant documents. Precision and recall are complementary to judge the quality of a system. But for some applications, precision is the only important measure. This is especially the case when a huge image database is available (like Internet). When doing a query, a user is more interested in the first satisfying results than in the complete relevant result set.

Images Description with Low-Level Features

The visual description of images is of great importance as it is the raw material on which further models are built. There is not a universally good low-level features extractor. In specific databases, *a priori* on the content of images can be used to extract specialized features that will better describe their special nature. For example, numerous features can be found in the literature for faces or fingerprints description. In generic databases, compromises have to be made between exhaustiveness, fidelity to the content, ability to generalize and different invariance degrees (illumination changes, rotations, scales, occlusions. . .). The use of inappropriate features leading to poor performances of a system has often been described as semantic gap. In this case, one rather faces the numerical gap, meaning that the visual information is present in images but it has not been extracted correctly.

Due to their ability to generalize to content in different conditions, statistical features are often used. They gather color, shape and texture information in histograms, separately or jointly. Color histograms are among the first features used to describe images. They vary depending on the underlying color space that is used, the quantization parameters, different weighting schemes or the use of co-occurrences of colors. Shapes can be described by properties of edges found in images like their types, orientations or lengths. Textures are focusing on the analysis of frequencies in images. They often rely on Fourier transform, Gabor filter banks or wavelets. Some features also combine different types of information, mixing for example color and texture in a single representation. Typically, these visual features are represented by vectors in high-dimensional spaces (generally between a few tens and a few hundreds dimensions) [9,15].

Initially, the features were extracted over the full image. This approach is well suited to describe the global aspect of the content but is too coarse to represent small details and objects. Features need to be extracted locally. First, a support region has to be determined. Once its location, shape and size are known, features are computed on this small portion of the image. These features can be of the same types as those extracted at a global level or they can be specialized according to the nature of the support regions. Several strategies are used to select the support regions. Segmentation algorithms try to find the boundaries between homogeneous regions in images [2]. Segmentation is a difficult problem in itself that is not well defined. Unfortunately, the general trend has always been to focus on segmentation that detects objects, which is already a highly semantic task and, thus, not really achievable through automatic processes. Alternative approaches consist on sliding windows and fixed grid, with varying sizes and spacing, are common ways of obtaining dense sampling of the visual content [9,14]. Another popular region selection approach is based on local features detectors via point-of-interest. They were originally designed for image registration. These detectors are generally attracted to specific areas of images that have high variation in the visual signal, such as the vicinity of edges and corners of regions. They allow the selection of a very small proportion of image locations having the highest visual variance [11,16]. Typically, when using dense sampling, point-of-interest or when mixing them, between a few hundreds and a few thousands features are extracted per image. The computational cost is then much higher than with global features. Some representations also try to carry other information, like geometrical relations between features locations or contextual information [1].

With global features, the image representation is straightforward. However, even when local features are to be used, learning algorithms may sometimes require a global image representation that encompasses all the local visual information. The bag-of-visual-words representation, very much inspired by the classical bag-of-words representation for text, is one of the most popular for images. A visual vocabulary composed of visual words (some representative features) is generated. An image is then represented by a coordinate vector, each value of which expresses the degree of importance of a feature with respect to the image and/or the database as a whole. The creation of a visual vocabulary is an important step in the full process. The selected visual words (a few hundreds to a few thousands) have to be representative of the database content as they will serve as a basis for further representation. Creating a good vocabulary will avoid the loss of too much local information. Generally, clustering algorithms either supervised or not, are used with a sample of the database. This step can be seen as a quantization of the local features.

Whatever the selected representation, the similarity between images is measured by a distance functional in the visual space. A broad variety has been developed: classical Euclidean distance (L2), L1, earth mover distance (EMD), chi-squared (χ^2), vector angle, histogram intersection,. . .

Learning and Models

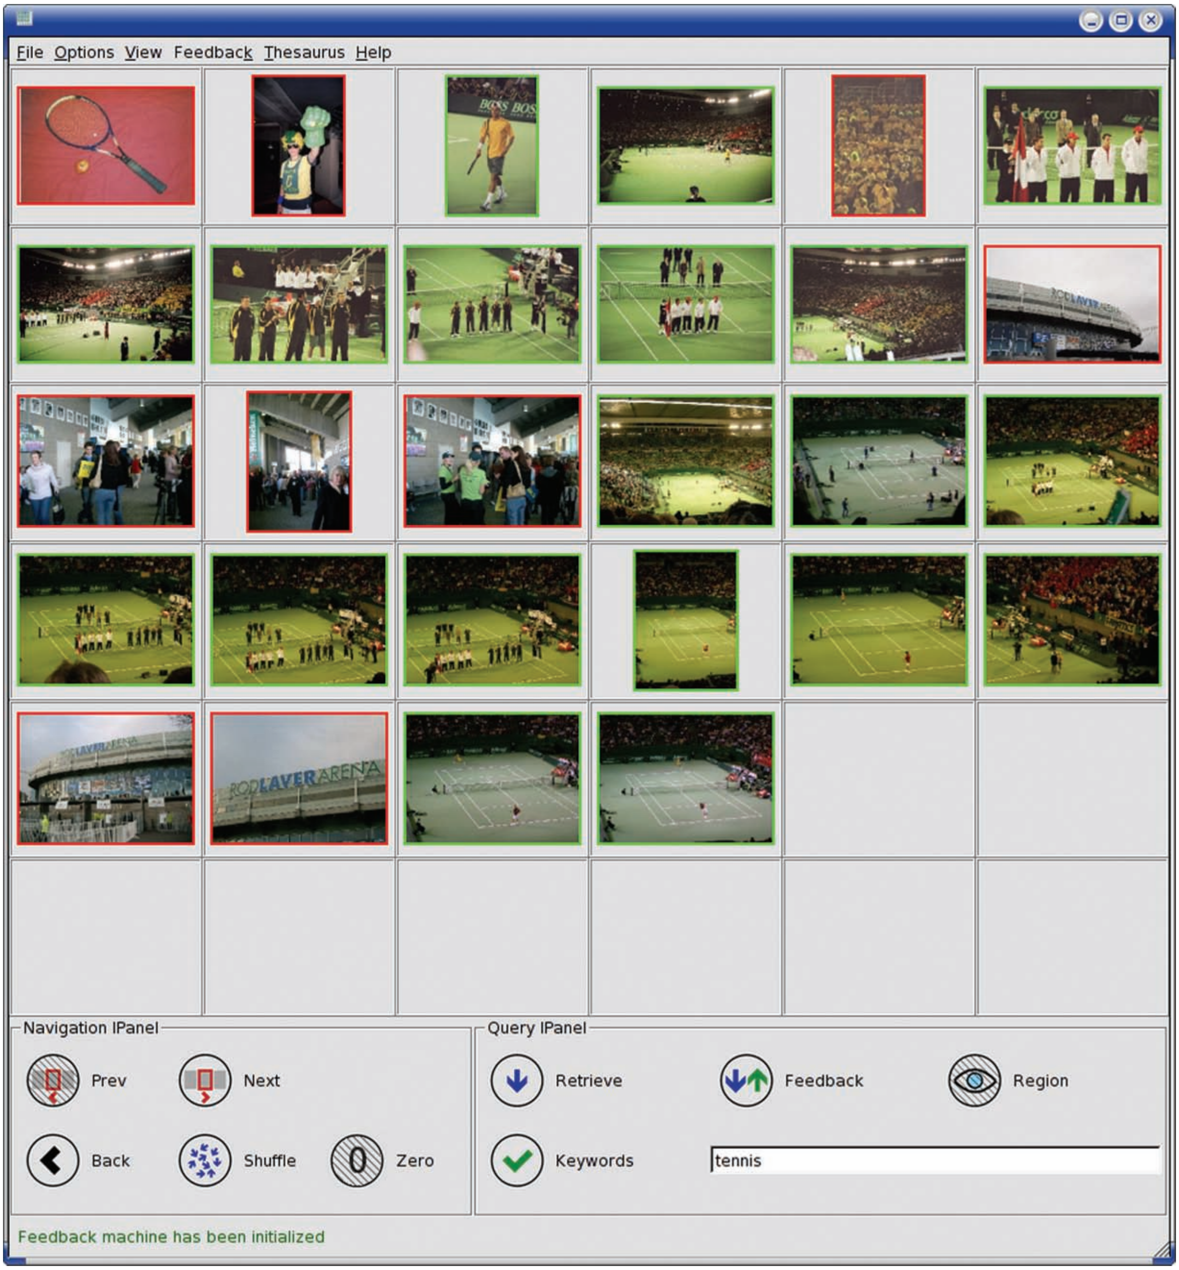
Although several formulations have been proposed, the main purpose of building models for visual concepts is to associate them with the visual space regions that best represent them. This problem is at the crossroads of computer vision, data mining and machine learning. Usually, the models are built through a supervised learning process. For given visual concepts, an algorithm is fed with a training dataset containing both positive and negative images regarding the concepts to learn. This algorithm has to find the discriminant information from the visual space that best models the concepts. Generally, the available annotations for the training set are not localized. The presence of a visual concept for an image is known, but its exact location is not provided. This is the case for almost all professional and personal databases. In the same way, annotating new images does not require to locate exactly the visual concept, but only to predict its presence. This is the main distinction that can be made with object detection tasks.

Two main learning algorithm families are used:

- *Generative*: the system tries to estimate density distribution of concepts in the visual space or other hidden variables [2]. Popular examples include Gaussian Mixture Models, Hidden Markov Models, Bayesian networks, Latent Semantic Analysis and translation models from the text processing community. The Expectation-Maximization algorithm is often used to train these models.
- *Discriminative*: instead of trying to model the distributions, discriminative approaches are focusing on detecting the boundaries between classes. For each visual concept, the annotation process is then often formalized as a two-class classification problem (present/not present). Although appearing to be a little bit more effective, discriminative approaches do not have the elegance of generative ones. They act more as black boxes and relationships between the different variables are not explicit, and thus difficult to analyze. The most famous algorithms are Support Vector Machine (SVM) [9,16], boosting (e.g., adaboost) [11] and all flavors of discriminant analysis (linear – LDA, biased – BDA, multiple – MDA, Fisher – FDA).

Both approaches may use global or local representations. Methods using bag-of-words representations are also called "multiple instance learning." Sometimes, pre-processes may also be used to prepare the data in order to enhance the performances or to reduce the computational costs: feature selection, dimensionality reduction, scaling or normalization. Current systems are often composed of several components, using different low-level features, combining them according to different schemes and training models with multiple learning strategies.

Once the models have been learned, they can be used to predict the visual concepts. Two types of predictions are possible. Hard decision simply indicates the presence or absence of the concept. Soft decision also provides a degree of confidence in the prediction, allowing ranking more easily the results when answering an end-user query and thus improving the retrieval of pertinent images earlier.



tennis

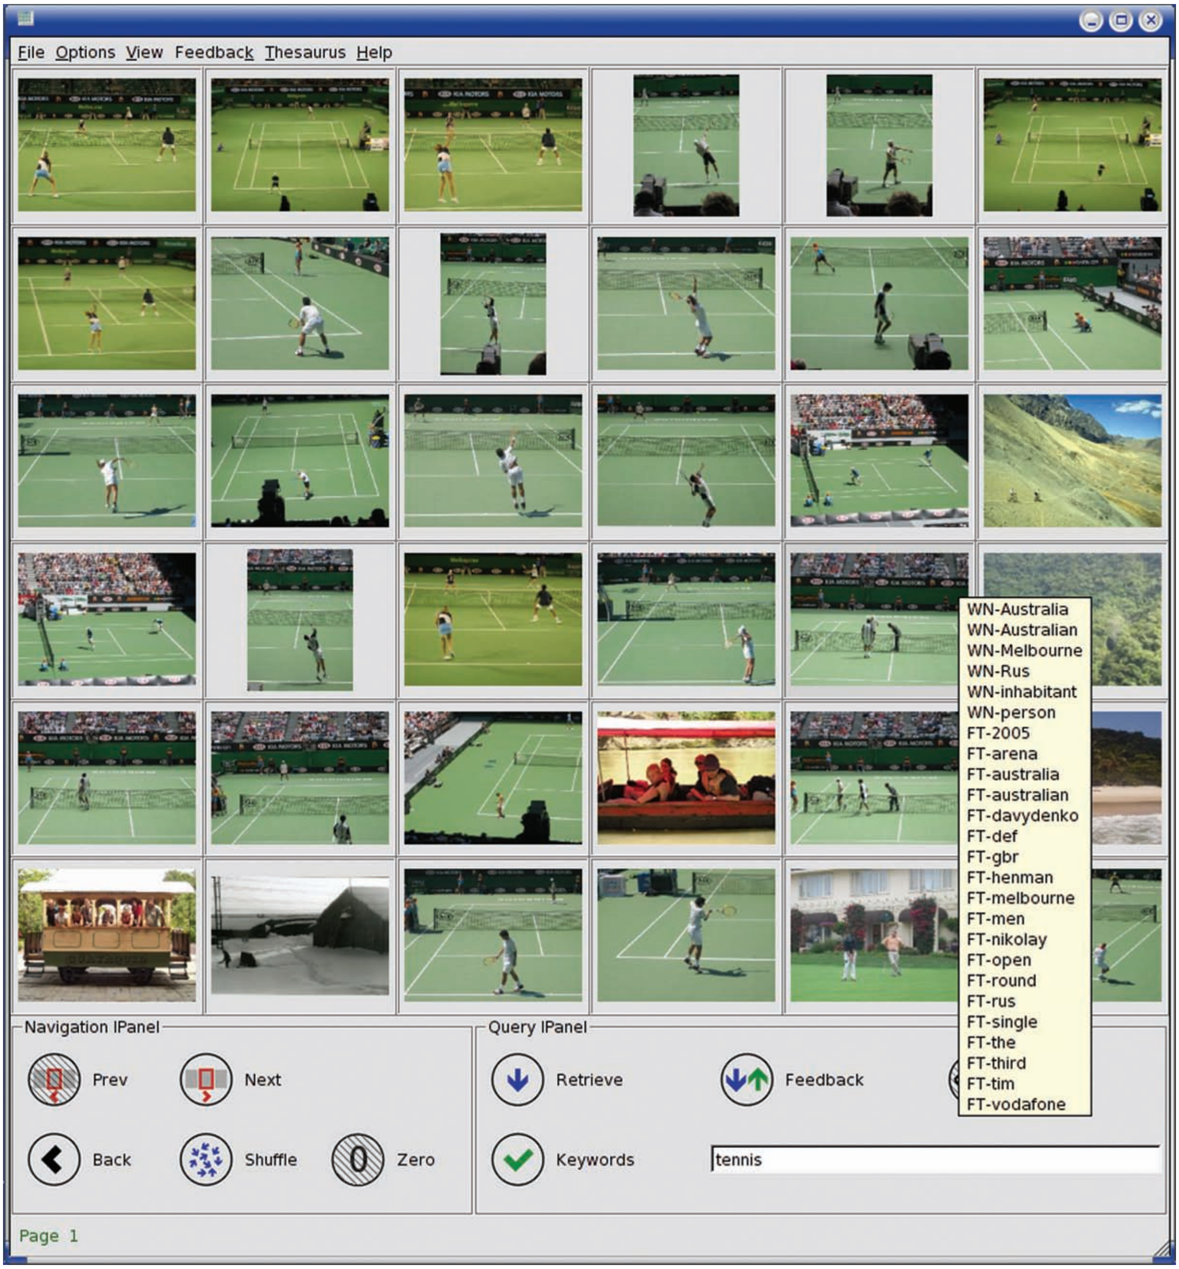
Feedback machine has been initialized

Automatic Image Annotation. Figure 1. Pictures annotated with the "tennis" keyword.

Current Results

The different methods are actually mature enough to predict global visual concepts like image types and scene categories. Regarding local concepts, huge improvements still need to be made in order to provide useful applications to real users. Both dense sampling and point-of-interest have shown to perform quite well on research databases, but results on real databases are quite poor [9,12]. A good indication of state-of-the-art performances can be obtained in the results of official benchmark campaigns like ImagEval, Pascal VOC, Imageclef or Trecvid. In all cases, the contextual information (visual or from the existing metadata) has shown to be of great importance in the results.

When the availability of correctly annotated images for a given visual concept is not guaranteed, the offline



Automatic Image Annotation. Figure 2. Pictures displayed after two iterations.

learning approach is not possible. One of the solutions is then to interact with a user through relevance feedback, also called interactive learning. In a few iterations, the user will provide the system positive and negative examples and guide it to recognize the visual concept. Part of the mechanism involved are the same as offline learning, but the training labels are provided online by a user. As an example, the following screen captures from Ikona [3] are showing the IAPR-TC12 database, used for the Imageclef benchmark. The first screen displays all the images annotated with the "tennis" keyword. The user is only interested in pictures where a tennis court is visible. He indicates positive (green border) and negative (red border) examples. After two iterations, one can see on the second screen that a lot of tennis court pictures have been retrieved. None of them was annotated with the "tennis" keyword. After a few more iterations, when no more correct pictures are retrieved from the database, the user is able to annotate massively all the pictures gathered through the iterations that were kept in a specific basket (third screen) (Figs. 1–3.)

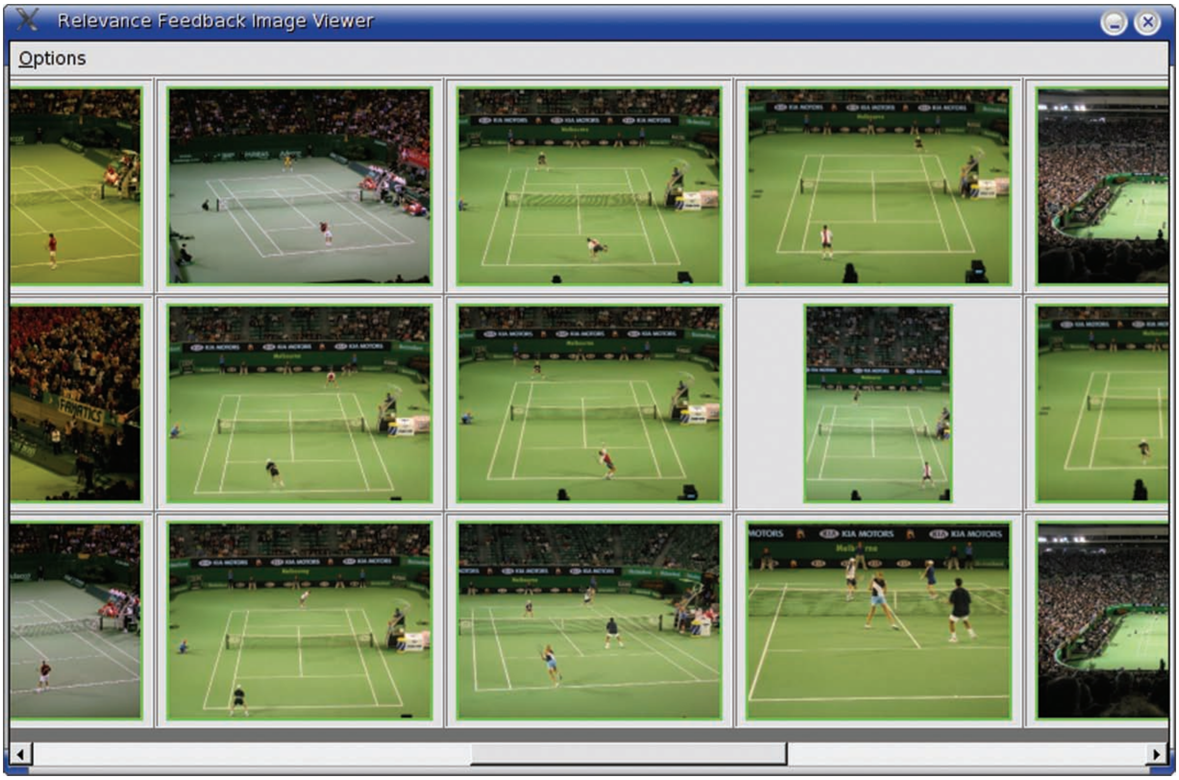
Key Issues and Future Research

The lack of generalization ability for both visual features and learning algorithms has to be compensated by a huge number of training examples. Depending on the complexity of the visual concept, a good estimation is around a hundred positive examples and ten times more negatives examples for the training set. Paradoxically, despite the tremendous amount of images available nowadays, finding content that has been reliably annotated for training dataset is hard.

The computational complexity is also still too high for real-time annotation when dealing with several thousands of visual concepts. Research is made on scalability issues in machine learning and is linked to existing high-dimensional data indexing structures.

Progresses for better description and integration of all types of available information need to be achieved.

There are also some questions arising: will the problem be solved with more computational power when one is able to process images at every scale and location in real-time? Are massive collaborative annotation websites, like Flickr, going to change the annotation paradigm



Automatic Image Annotation. Figure 3. All positive pictures basket allowing mass-annotation.

by transforming Internet in a giant common repository? What is the impact of GPS metadata, and more generally all the new information captured directly when a photograph is taken?

Key Applications

- Professional content owners: post-editing
- Personal family and holiday photo albums
- Web image search
- Searching into poorly human-made annotated corpora enhancing the quality of search results

Autonomous Replication

Cristiana Amza
University of Toronto, Toronto, ON, Canada

Synonyms

Database provisioning; Adaptive database replication; Autonomic database replica allocation

Definition

Autonomous database replication refers to dynamic allocation of servers to applications in shared server clusters, in such a way to meet per-application performance requirements. Autonomous database replication enables the service provider to efficiently multiplex data center resources across applications in order to save per-server costs related to human management, power and cooling.

Historical Background

The concept of Autonomic Computing and the associated research area of automated, adaptive self-management in data centers was introduced by IBM as a grand-challenge project in the early 2000s. Other companies, which have responded or have had similar proposals of their own include Microsoft, Intel, Sun and HP. Related industry efforts in this area have been on developing open standards for resource monitoring tools e.g., as available on IBM's Alphaworks, (http://www.alphaworks.ibm.com.) and academic or collaborative industry-academia efforts related to applying machine learning techniques for automated adaptation in cluster systems [6,8,13].

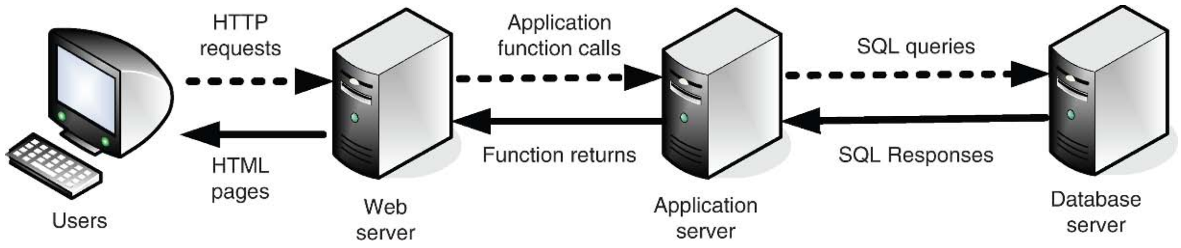
Foundations

Dynamic content servers, such as Amazon.com and eBay.com, commonly use a three-tier architecture (see Fig. 1) that consists of a front-end web server tier, an application server tier that implements the business logic, and a back-end database tier that stores the dynamic content of the site.

Large data centers may host multiple applications concurrently, such as e-commerce, auctions, news and games. The cooling and power costs of gross hardware over-provisioning for each application's estimated peak load are making efficient resource usage crucial. Furthermore, the excessive personnel costs involved in server management motivate an automated approach to resource allocation for applications in large sites.

Dynamic resource allocation techniques, i.e., dynamic provisioning of servers to multiple applications in each tier of the dynamic content site, have been recently introduced to address the increasing costs of ownership for large dynamic content server clusters. These automatic solutions add servers to an application's allocation based on perceived or predicted performance bottlenecks caused by either load spikes or component failures; they remove resources from a application's allocation when in underload.

If services experience daily patterns with peak loads for each service type at a different time (e.g., daytime for e-commerce, evening for auctions, morning for news sites, night for gaming), there are opportunities for re-assigning hardware resources from one service



Autonomous Replication. Figure 1. Three-tier architecture.

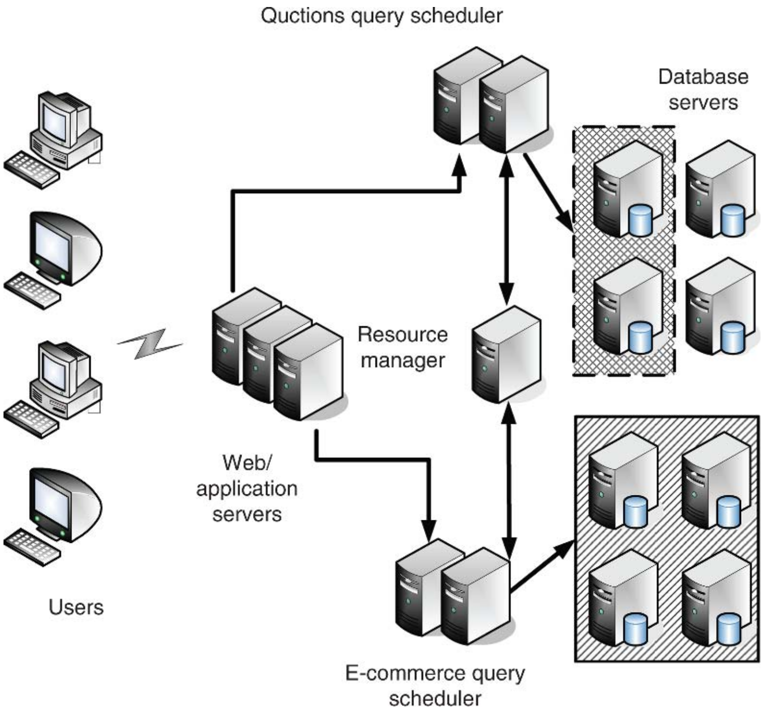
to another. Thus, instead of gross hardware overprovisioning for each application's estimated peak load, dynamic resource provisioning techniques enable the service provider to efficiently multiplex data center resources across applications.

Common Architecture for Database Replica Provisioning

Figure 2 shows the common architecture of sites with dynamic provisioning in the database server tier. A resource manager makes the replica allocation decisions for each application hosted on the site based on the application requirements and the current system state. The requirements are expressed in terms of a service level agreement (SLA) that consists of a latency requirement on the application's queries. The current system state includes the current performance of this application and the system capacity. The resource manager operates in two modes, underload and overload. During underload, the number of replicas exceeds overall demand and allocation decisions per application are made independently. During overload, the manager uses either a utility-based scheme, e.g., profit-based, or a fairness scheme, e.g., equal share, to allocate replicas to applications.

The allocation decisions are communicated to a set of schedulers, one per application, interposed between the application and the database tiers. Each scheduler fulfills the following functions. (i) It keeps track of the current *database set* allocated to its application and allocates or removes replicas from its managed set according to the resource manager's decisions. (ii) It distributes the corresponding incoming requests onto the respective database replicas. (iii) It periodically samples various system and application metrics, e.g., the average application latency from its *database set* in order to perceive or predict resource bottlenecks. (iv) It provides consistent replication, e.g., one-copy serializability [5], at all the replicas allocated to the application it manages.

Strong consistency is desirable for dynamic provisioning in the database tier of a multi-tier data center, for transparency reasons; the replicated nature of the database back-end and its configuration adaptations are thereby hidden from the application server, which interacts with the replicated back-end as with a single database. Any eager replication scheme with strong consistency guarantees, such as, 1-copy-serializability or 1-copy-snapshot-isolation



Autonomous Replication. Figure 2. Cluster architecture.

[5] can be used within each application's replica set. However, existing dynamic provisioning schemes typically leverage the presence of the scheduler and the synchronous, one query at a time, nature of the communication between the application and database tiers in a data center to implement a middleware replication solution in the scheduler itself. Upon receiving a query from the application server, the scheduler sends the query using a read-one, write-all replication scheme to the replica set allocated to the application. The scheduler assigns a global serialization order to all transactions pertaining to its application, e.g., based on conservatively-perceived table-level conflicts between transactions, and ensures that transactions execute in this order at all the corresponding database replicas. Table-level concurrency control affords optimizations based on conflict awareness in the scheduler [2,3], which offset any penalties due to the coarse-grain control for read-intensive e-commerce applications [11].

The scheduler is also in charge of bringing a new replica up to date by a process called *data migration*, during which all missing updates are applied on that replica. Integrating a stale replica into an application's allocation occurs through an on-line reconfiguration technique [10,11] without stalling on-going transactions on already active replicas for that application. Finally, each scheduler may itself be replicated for availability [2,3].

Overview of Dynamic Provisioning Solutions

Several fully-transparent provisioning solutions [4,9,12] have been recently introduced to address the increasing cost of management problem. Many of these approaches [4,9,12] investigate dynamic provisioning of resources within the (mostly) stateless web server and application server tiers. This entry focuses on the dynamic resource allocation solutions within the stateful database tier, which commonly becomes the bottleneck [1].

Regardless of the tier it applies to, a dynamic provisioning solution can be either *proactive* or *reactive* depending on its capabilities for predicting performance bottlenecks in the dynamic content server. *Proactive* solutions use sophisticated system models for prediction, such as, queuing models [4], utility models [12], machine learning models [6,8,13] or marketplace approaches [7]. *Proactive* provisioning techniques use the system model predictions for triggering allocations in advance of expected need. This is especially important for tiers with a higher adaptation delay, such as the database tier. In contrast, *reactive* approaches do not use prediction, but rather detect and react to existing resource bottlenecks. They rely on predefined thresholds for application-level or system metrics, such as latency or CPU usage for triggering changes in application allocation.

Challenges for Database Replica Provisioning

Adapting to a bottleneck caused by either a workload spike or a failure, by allocating additional replicas to the application, poses a set of challenges, which is summarized next.

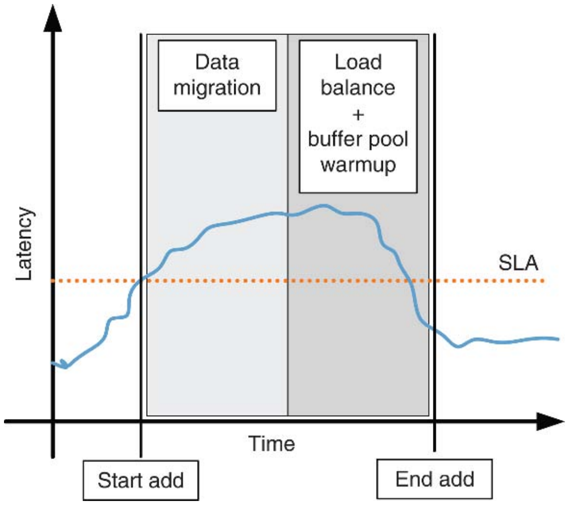
Adaptation Delay

Adding a database replica to an application's allocation is not an immediate process. The database state of the new replica(s) for that application will be stale and must be brought up-to-date, or a new instance of that application may need to be installed before it can be used. Furthermore, load balancing for the old and new replicas needs to occur and the buffer pool at the new replica(s) needs to be warm before the new replica(s) can be used effectively.

Oscillations in Allocation

Oscillations in database allocations to applications may occur during system instability induced by adaptations. As discussed earlier, the replica addition process can be long. *During* the adaptation phases, i.e., data migration, buffer pool warmup and load stabilization, the latency will remain high or may even temporarily continue to increase as shown in Figure 3. Latency sampling during this potentially long time is thus not necessarily reflective of a continued increase in load, but of system instability after an adaptation is triggered. If the system takes further decisions based on sampling latency during the stabilization time, it may continue to add further replicas which are unnecessary, hence will need to be removed later. This is an oscillation in allocation which carries performance penalties for other applications running on the system due to potential interference.

Both reactive and proactive policies that measure application-level metrics periodically, including during the replica addition process, can suffer from allocation instability. Allocation oscillations, in their turn, cause cross-application interference due to the



Autonomous Replication. Figure 3. Latency instability during replica addition.

price paid for warming up the buffer pool as part of the "context-switch" between applications on the machines involved.

While rapid load fluctuations may induce similar behavior, simple smoothing or filtering techniques can offer some protection to very brief load spikes. All existing dynamic provisioning schemes use some form of smoothing or filtering, to dampen brief load fluctuations.

Accurate and Lightweight Modeling

As previously mentioned proactive provisioning is desirable in the database back-end tier due to the higher adaptation delay inherent in this tier. The challenge for proactive database tier provisioning lies in accurately modeling the behavior of a replicated database back-end tier. Many factors, such as the wide range of query execution times typical in e-commerce workloads, the load balancing policy, caching effects, the replica consistency maintenance algorithm, etc. may influence performance. The derivation of a classic analytical model taking into account even a subset of these factors can be time consuming, hence unsuitable for on-line modeling and adaptation. Therefore, typically, pro-active provisioning schemes use machine learning approaches, such as K-Nearest-Neighbors (KNN) [6], or Support Vector Machine Regression (SVM) [8] to estimate performance models used for on-line adaptation. KNN-based approaches, or similar table-driven provisioning approaches [14] use off-line measurements and simple interpolation of response time values for various database server configurations and workloads. SVM-based approaches collect similar measurements[8] on-line to derive a regression function approximating the performance model dynamically.

Design Choices and Trade-offs for Database Provisioning

In designing a dynamic provisioning solution for the database back-end, it is necessary to consider the design trade-off between allocating replicas to applications in a *disjoint* versus *overlapping* manner. Consider the case where a *disjoint* set of machines is allocated to host the replicas of each application and dynamically adjusted to each application's cluster partition. When an application requires an additional replica, it must use an unallocated machine or a machine allocated to another application. In either case, the full *adaptation delay* for replica addition is incurred to the application.

Replica addition delay can be avoided altogether with *fully-overlapped* replicas, where all the database applications are replicated across all the available cluster machines. In this case, there is no replica addition delay because replicas do not have to be added or removed. However, this approach causes interference due to resource sharing. For example, when multiple database applications run on the same machine their performance can degrade due to buffer pool interference. This discussion shows that there is a trade-off between using disjoint and fully-overlapped replica allocation strategies. Disjoint allocation reduces interference and thus improves steady-state performance. Fully-overlapped allocation avoids replica addition delay and thus can speed up the system's response to load spikes and failures.

A compromise solution is to use a *partial overlap* strategy [11], where the application allocations are disjoint, but, for each application, batched updates are periodically executed on a set of database machines outside of that application's allocation, thus keeping them partially up-to-date.

Key Applications

Autonomic database replication is used for dynamic resource allocation in the database back-end of dynamic content web sites hosting e-commerce applications. Write queries in dynamic content applications are typically more lightweight and have a much lower memory footprint compared to read queries [2]. For instance, in e-commerce applications, an update query typically updates only the record pertaining to a particular customer or product, while read queries caused by browsing involve expensive database joins as a result of complex search criteria. Moreover, read queries are much more frequent than write queries. Hence, a *partial overlap* replication solution, which causes minimal resource interference, is typically used in order to reduce the adaptation delay [11].

Average Precision

Ethan Zhang[1,2], Yi Zhang[1]
[1]University of California, Santa Cruz, CA, USA
[2]Yahoo! Inc., Santa Clara, CA, USA

Definition

Average precision is a measure that combines recall and precision for ranked retrieval results. For one information need, the average precision is the mean of the precision scores after each relevant document is retrieved.

$$Average\ Precision = \frac{\sum_r P@r}{R}$$

where r is the rank of each relevant document, R is the total number of relevant documents, and $P@r$ is the precision of the top-r retrieved documents.

Key Points

The average precision is very sensitive to the ranking of retrieval results. The relevant documents that are ranked higher contribute more to the average than the relevant documents that are ranked lower. Changes to the ranking of relevant documents have a significant impact on the average precision score. Average precision is considered a reasonable evaluation measure for emphasizing returning more relevant documents earlier.

Average Precision at n

Nick Craswell, Stephen Robertson
Microsoft Research Cambridge, Cambridge, UK

Synonyms

AP@n

Definition

Average Precision at n is a variant of Average Precision (AP) where only the top n ranked documents are considered (please see the entry on Average Precision for its definition). AP is already a top-heavy measure, but has a recall component because it is normalized according to R, the number of relevant documents for a query. In AP@n there are a number of options for normalization, for example, normalize by n or normalize by min(n,R).

Key Points

The well-known measure Average Precision has a number of lesser-known variants, used in TREC [3] and elsewhere. Before and during TREC-1, it was usual to calculate an 11-point interpolated Precision-Recall curve, and take the average of these 11 precision values, giving an "interpolated AP." In TREC-2 and beyond, the modern non-interpolated AP was introduced. It calculates precision at each relevant document.

A number of other AP variants arise in a precision-oriented setting, where it is possible to calculate Average Precision at n. AP@n takes into account both the number of relevant documents in the top n and the positions of those documents. This is in contrast to Precision at n (P@n), which ignores position. It is defined as:

$$AP@n = \sum_{i=1}^{n} \frac{rel(i) \times P@i}{NF}$$

where rel(i) = 1 if the ith retrieved document is relevant and rel(i) = 0 otherwise, and NF is the normalization factor. In Average Precision it is usual to normalize by the number of relevant documents, i.e., NF = R. In a precision-oriented setting, this presents two problems. First, in precision-oriented evaluation one may not have judged enough documents to know R, or estimate it accurately. Second, if R is greater than n, a ceiling of n/R is imposed on the measure. For example, if one knows R = 100 relevant documents, then the best possible top-20, containing 20 relevant documents, will score an AP@20 of 0.2.

Three alternate normalization factors (NF) have been considered, only one of which has been used in TREC. Here, r is the number of relevant documents retrieved and n is the number of documents retrieved.

- *Normalize by r:* Baeza-Yates and Ribeiro-Neto [1] includes this variant, calling it "Average Precision at Seen Relevant Documents." This measure has the property that it may decrease when a relevant document is promoted into the top-n, because this increases the normalization factor. This seems counter-intuitive.
- *Normalize by n:* This variant was introduced for use in Web search evaluation [2]. In cases where R is less than n, this variant has a ceiling of less than 1. The scale of the measure is 0 ≤ AP@n ≤ min (R/n,1). It may be considered undesirable that the scale of the measure varies from query to query, for example when measuring the mean.
- *Normalize by min(n,R):* This is the "modified average precision" from the TREC-7 Very Large Collection track [3]. The ceiling is always 1 for this variant.

The normalization NF = min(n,R) allows AP@n scores to have the full range of 0.1, while retaining the property that promoting a relevant document always increases the score.

The arithmetic mean of AP@n over a set of queries can be called Mean Average Precision at n (MAP@n), in the same way that Average Precision relates to Mean Average Precision.

Average Precision Histogram

Steven M. Beitzel[1], Eric C. Jensen[2], Ophir Frieder[3]
[1]Telcordia Technologies, Piscataway, NJ, USA
[2]Twitter, Inc., San Fransisco, CA, USA
[3]Georgetown University, Washington, DC, USA

Definition

The average precision histogram plots the performance of a single run produced by an information retrieval system on a per-query basis. Each data point on the abscissa represents a query used in the evaluation process. The corresponding points on the ordinate measures the difference in this run's performance on the given topic relative to the median average precision of other runs on that topic.

Key Points

Average precision histograms are often used to illustrate the performance differences that an information retrieval system may exhibit across different queries in an evaluation set in relation to other systems or runs that are evaluated on the same set of queries. These histograms can be used to identify the queries in an evaluation set which pose the most difficulty for information retrieval systems. Various tracks in the NIST Text Retrieval Conference (TREC) have used average precision histograms in the post-competition analysis of submitted runs [1]. An example average precision histogram for 25 queries is shown in Fig. 1.

Average R-Precision

Steven M. Beitzel[1], Eric C. Jensen[2], Ophir Frieder[3]
[1]Telcordia Technologies, Piscataway, NJ, USA
[2]Twitter, Inc., San Fransisco, CA, USA
[3]Georgetown University, Washington, DC, USA

Definition

The Average R-precision is the arithmetic mean of the R-precision values for an information retrieval system over a set of n query topics. It can be expressed as follows:

$$ARP = \frac{1}{n}\sum_{n} RP_n$$

where RP represents the R-Precision value for a given topic from the evaluation set of n topics. R-Precision is defined as the precision after R documents have been retrieved by the system, where R is also the total number of judged relevant documents for the given topic. Precision is defined as the portion of retrieved documents that are truly relevant to the given query topic.

Key Points

R-precision places lower emphasis on the exact ranking of the relevant documents returned by an information retrieval system. This can be useful when a topic has a large number of judged relevant documents, or when an evaluator is more interested in measuring aggregate performance as opposed to the fine-grained quality of the ranking provided by the system.

As an example, consider two query topics: topic A has ten relevant documents, and topic B has six relevant documents. Suppose further that an information retrieval system returns five relevant documents in the top ten retrieved for topic A, two relevant documents in the top six retrieved for topic B. For this case, Average R-precision for this run would be:

$$ARP = \frac{\frac{5}{10} + \frac{2}{6}}{2} \approx 0.4167$$

B+-Tree

Donghui Zhang[1], Kenneth Paul Baclawski[1],
Vassilis J. Tsotras[2]
[1]Northeastern University, Boston, MA, USA
[2]University of California-Riverside, Riverside,
CA, USA

Synonyms

B-tree

Definition

The B+-tree is a disk-based, paginated, dynamically updateable, balanced, and tree-like index structure. It supports the exact match query as well as insertion/deletion operations in $O(\log_p n)$ I/Os, where n is the number of records in the tree and p is the page capacity in number of records. It also supports the range searches in $O(\log_p n + t/p)$ I/Os, where t is the number of records in the query result.

Historical Background

The binary search tree is a well-known data structure. When the data volume is so large that the tree does not fit in main memory, a disk-based search tree is necessary. The most commonly used disk-based search trees are the B-tree and its variations. Originally invented by Bayer and McCreight [2], the B-tree may be regarded as an extension of the balanced binary tree, since a B-tree is always balanced (i.e., all leaf nodes are on the same level). Since each disk access retrieves or updates an entire block of information between memory and disk rather than a few bytes, a node of the B-tree is expanded to hold more than two child pointers, up to the block capacity. To guarantee worst-case performance, the B-tree requires that every node (except the root) has to be at least half full. Because of this requirement, an exact match query, insertion or deletion operation must access at most $O(\log_p n)$ nodes, where p is the page capacity in number of child pointers, and n is the number of objects. The most popular variation of the B-tree is the B+-tree [3,4]. In a B+-tree, objects are stored only at the leaf level, and the leaf nodes are organized into a double linked list. As such, the B+-tree can be seen as an extension of the Indexed Sequential Access Method (ISAM), a static (and thus possibly unbalanced if updates take place) disk-based search tree proposed by IBM in the mid 1960's.

Foundations

Structure

The B+-tree is a tree structure where every node corresponds to a disk block and which satisfies the following properties:

- The tree is balanced, i.e., every leaf node has the same depth.
- An internal node stores a list of keys and a list of pointers. The number of pointers is one more than the number of keys. Every node corresponds to a key range. The key range of an internal node with k keys is partitioned into k+1 sub-ranges, one for each child node. For instance, suppose that the root node has exactly two keys, 100 and 200. The key range of the root node is divided into three sub-ranges $(-\infty, 100)$, $(100, 200)$ and $(200, +\infty)$. Note that a key in an internal node does not need to occur as the key of any leaf record. Such a key serves only as a means of defining a sub-range.
- A leaf node stores a list of records, each having a key and some value.
- Every node except the root node is at least half full. For example suppose that an internal node can hold up to p child pointers (and p-1 keys, of course) and a leaf node can hold up to r records. The half full requirement says any internal node (except the root) must contain at least $\lceil p/2 \rceil$ child pointers and any leaf node (except the root) must contain at least $\lceil r/2 \rceil$ records.
- If the root node is an internal node, it must have at least two child pointers.

- All the leaf nodes are organized, in increasing key order, into a double linked list.

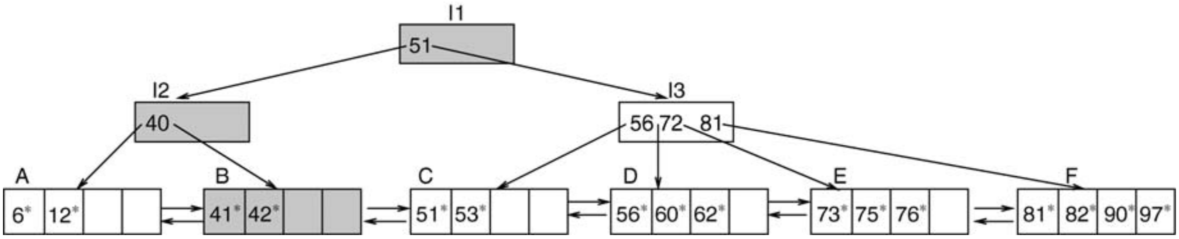
An example B+-tree is given in Fig. 1. It is assumed that every node has between two and four entries. In a leaf node, an entry is simply a record. In an internal node, an entry is a pair of (key, child pointer), where the key for the first entry is NULL. To differentiate a leaf entry (which corresponds to an actual record) from a key in an index entry, each leaf entry is followed by a "*".

Query Processing

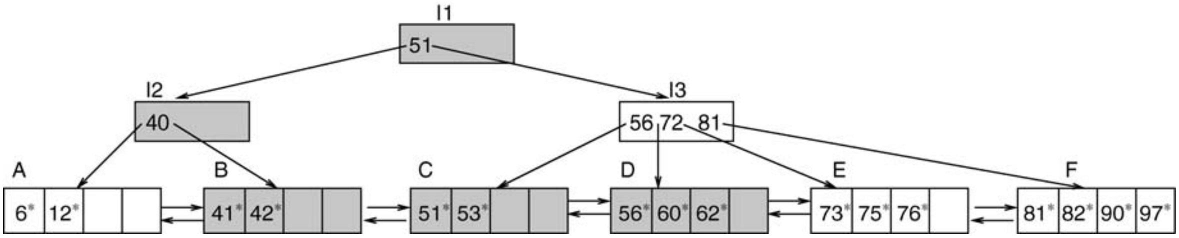
The B+-tree efficiently supports not only *exact-match queries*, which find the record with a given key, but also *range queries*, which find the records whose keys are in a given range. To perform an exact-match query, the B+-tree follows a single path from the root to a leaf. In the root node, there is a single child pointer whose key range contains the specified key. If one follows the child pointer to the corresponding child node, inside the child node there is also a single child pointer whose key range contains the desired key. Eventually, one reaches a leaf node. The desired record, if it exists, must be located in this node. As an example, Fig. 1 shows the search path if one searches for the record with key = 41. Besides exact-match queries, the B+-tree also supports range queries. That is, one can efficiently find all records whose keys belong to a range *R*. In order to do so, all the leaf nodes of a B+-tree are linked together. To search for all records whose keys are in the range *R* = [*low*, *high*], one performs an exact match query for key = *low*. This leads to a leaf node. One examines all records in this leaf node, and then follows the sibling link to the next leaf node, and so on. The algorithm stops when a record with key > *high* is encountered. An example is shown in Fig. 2.

Insertion

To insert a new record, the B+-tree first performs an exact-match query to locate the leaf node where the record should be stored, then the record is stored in the leaf node if there is enough space available. If there is not enough space, the leaf node is split. A new node is allocated, and half of the records, the ones with the larger keys in the overflowing node, are moved to the new node. A new index entry (the smallest key in the new node and a pointer to the new node) is inserted into the parent node. This may, in turn, cause



B+-Tree. Figure 1. Illustration of the B+-tree and exact-match query processing. To search for a record with key = 41, nodes I_1, I_2 and *B* are examined.



B+-Tree. Figure 2. Illustration of the range query algorithm in the B+-tree. To search for all records with keys in the range [41,60], the first step is to find the leaf node containing 41* (I_1, I_2 and *B* are examined). The second step is to follow the right-sibling pointers between leaf nodes and examine nodes *C* and *D*. The algorithm stops at *D* because a record with key >60 is found.

the parent node to overflow, and so on. In the worst case, all nodes along the insertion path are split. If the root node is split into two, a new root node is allocated and therefore the height of the tree increases by one.

As an example, Fig. 3 shows an intermediate result of inserting record 92* into Fig. 1. In particular, the example illustrates that splitting a leaf node results in a *"copy up"* operation. The result is intermediate because the parent node I_3 will also be split.

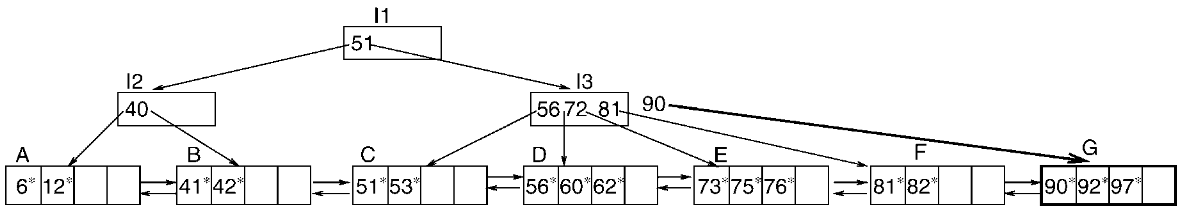
The complete result after inserting 92* is shown in Fig. 4. Here the overflowing internal node I_3 is split. In particular, the example illustrates that splitting an internal node can result in a *"push up"* operation.

Deletion

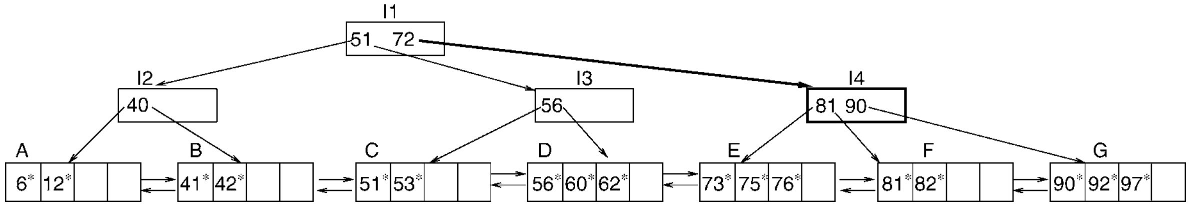
To delete a record from the B+-tree, one first uses the exact-match query algorithm to locate the leaf node that contains the record, and then the record is removed from the leaf node. If the node is at least half full, the algorithm finishes. Otherwise, the algorithm tries to re-distribute records between an immediate sibling node and the underflowing node. If redistribution is not possible, the underflowing node is merged with an immediate sibling node. Note that this merge is always possible.

As an example, Fig. 5 shows the intermediate result of deleting record 41* from the B+-tree shown in Fig. 4. Note that when merging two leaf nodes, a key in the parent node is *discarded*, which is the reverse operation of *copy up*. The result is intermediate because node I_2 is also underflowing.

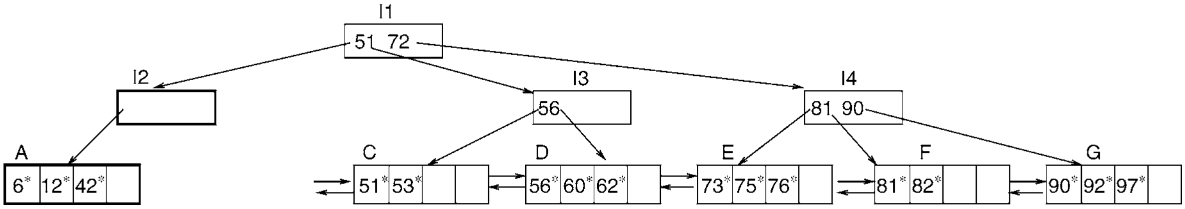
Figure 6 illustrates the final result of deleting 41*. The underflow of node I_2 is handled by merging I_2 with I_3. This merge causes key 51 from the parent node to be *dragged down* to I_2. It is the reverse operation of *push up*.



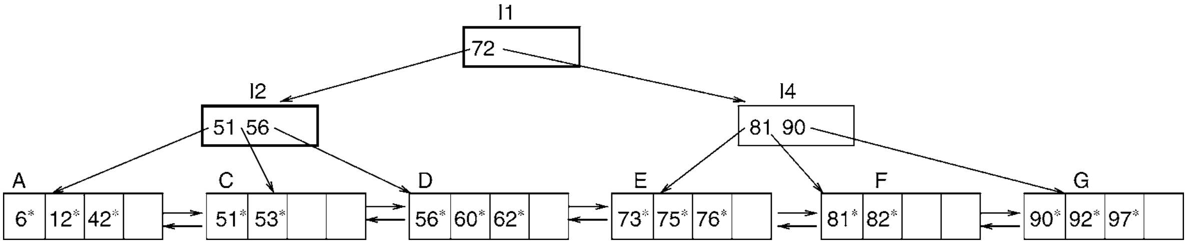
B+-Tree. Figure 3. Intermediate result of inserting record 92* into Fig. 1. The leaf node *F* is split. The smallest key in the new node *G*, which is 90, is *copied up* to the parent node.



B+-Tree. Figure 4. Continued from Fig. 3. Final result of inserting record 92*. The overflowing internal node I_3 is split. The middle key, 72, is *pushed up* to the parent node.



B+-Tree. Figure 5. Intermediate result of deleting 41* from Fig. 4. Node *B* is merged with node *A*. Key 40 (as well as the pointer to node *B*) is *discarded* from the parent node.



B+-Tree. Figure 6. Continued from Fig. 5. Final result of deleting 41*. Node I_2 is merged with node I_3. Key 51 from the parent node is *dragged down.*

Comparison with Some Other Index Structures

Compared with the B-tree, the B+-tree stores all records at the leaf level, and organizes the leaf nodes into a double linked list. This enables efficient range queries. Compared with ISAM, the B+-tree is a fully dynamic structure that balances itself nicely as records are inserted or deleted, without the need for overflow pages. Compared with external hashing schemes such as Linear Hashing and Extendible Hashing, the B+-tree can guarantee logarithmic query cost in the worst case (while hashing schemes have linear worst-case cost, although this is very unlikely), and can efficiently support range queries (whereas hashing schemes do not support range queries).

Key Applications

The B+-tree index has been implemented in most, if not all, relational database management systems such as Oracle, Microsoft SQL Server, IBM DB2, Informix, Sybase, and MySQL. Further, it is implemented in many filesystems including the NTFS filesystem (for Microsoft Windows), ReiserFS filesystem (for Unix and Linux), XFS filesystem (for IRIX and Linux), and the JFS2 filesystem (for AIX, OS/2 and Linux).

Future Directions

The impact of the B+-tree index is very significant. Many disk-based index structures, such as the R-tree [4] and k-d-B-tree [5] or their variants, are extensions of the B+-tree. Concurrency in B+-trees was studied in [6]. The Universal B-tree, which extends the B+-tree to index multi-dimensional objects, was studied in [1].

Backup and Restore

Kenichi Wada
Hitachi Limited, Tokyo, Japan

Synonyms

Backup copy

Definition

Backup is the action of collecting data stored on non-volatile storage media to aid recovery in case the original data are lost or becomes inaccessible due to corruption or damage caused by, mainly, a failure in storage component hardware (such as a hard disk drive or controller), a disastrous event, an operator's mistake, or intentional alteration or erasure of the data. In addition, the data collected by this action are called a backup. Restore is the action of copying a backup to on-line storage for use by applications in a recovery. The term "back up and restore" indicates both actions.

Key Points

The purpose of backup includes recovering data from storage media failure. For this reason, it is common to make backup to different storage media. Removable storage media is used because it is relatively less expensive than online storage media like hard disk drive, and it is easy to bring it offsite in case of site failure. Hard disk drives are becoming popular as backup storage media, because of its decreasing bit cost and quick restore capability.

There are many ways to take backup. A full backup is the way to make a full copy of data. It requires equal capacity of original data, unless data compression is not used. If full backup is taken daily from Monday to Friday and they are kept for the following week, five times capacity is required for backup.

The following two kinds of backup are used to reduce the size of backup data:

Incremental backup: A backup that copies all data modified since the last full backup. Modified data can be copied many times until next full backup is taken. To restore data when incremental backups are in use, the latest full backup and the latest incremental backup are required.

Differential backup: A backup that copies all data modified since the last backup. Modified data are not copied more than once. To restore data when differential backups are used, the latest full backup and all differential backups or all backups are required.

Bag Semantics

Duplicate Semantics; Multiset Semantics

Definition

In the ordinary relational model, relations are sets of tuples, which by definition do not contain "duplicate" entries. However, RDBMSs typically implement a variation of this model where relations are *bags* (or *multisets*) of tuples, with duplicates allowed. Formally, a bag is a mapping of tuples to natural number *multiplicities*; a set can be viewed as a special case of a bag where all tuple multiplicities are 0 or 1. The operations of the relational algebra are extended to operate on bags by defining their action on tuple multiplicities. RDBMSs based on bags rather than sets are said to implement *bag semantics* (rather than *set semantics*). Duplicates may occur at multiple levels: in source relations, in materialized views, or in query answers. A variation of bag semantics called *bag-set semantics* is obtained by requiring source relations to be sets, while allowing views and query answers to contain duplicates. Bag-set semantics represents a practical compromise between bag semantics and set semantics.

Historical Background

In the ordinary relational model, relations are sets of tuples, which by definition do not contain "duplicate" entries. However, RDBMS implementations, beginning with System R and INGRES, deviated from the "pure" relational model by allowing duplicate tuples in query answers, thus making bags (multisets), rather than sets, the primary collection type in query processing. The primary motivation for allowing duplicate tuples was the need to avoid expensive duplicate elimination in query processing. Instead, duplicate elimination would only be performed if explicitly requested by the user, e.g., via the SQL `DISTINCT` keyword. In their use of bag relations, RDBMS implementations were ahead of theory, and the precise semantics of relational algebra on bags was not studied until the 1980s [6,11,12]. Klug [12] pointed out the failure of certain algebraic identities under bag semantics, and also gave a precise semantics of aggregate functions that did not depend on bag semantics. Dayal et al. initiated the study of query optimization under bag semantics in [6]. Bag containment of unions of conjunctive queries (UCQs) was shown to be undecidable by Ioannidis and Ramakrishan [9], while bag equivalence of conjunctive queries (CQs) was shown to be decidable, in fact the same as isomorphism, by Chaudhuri and Vardi [3]. The $\Pi_2{}^p$-hardness of checking bag containment of CQs was also established in [3], but the decidability of the problem remains open (see Future Directions). The same paper introduced the terminology "bag-set semantics" to describe the semantics obtained by requiring source relations to be sets while allowing views and query answers to contain duplicates, and established the decidability of bag-set equivalence of CQs. For conjunctive queries with inequalities ($\mathrm{CQ}^{\neq}$), bag containment and bag-set containment were both shown to be undecidable by Jayram et al. [10]. Bag equivalence of UCQs was shown to be decidable (and like CQs, the same as isomorphism) by Cohen et al. [5]. Cohen [4] studied query equivalence for a generalization of bag-semantics called *combined semantics*, which captures user-specified elimination of duplicates at intermediate stages of query processing. A bag semantics for Datalog was proposed by Mumick et al. [14], and Mumick and Shmueli [15] studied computational problems related to infinite multiplicities (which may occur in query answers because of recursion). Going beyond the relational model, several papers have studied bag semantics in the context of query languages for nested relations; see [2,8] and references therein.

Foundations

Bag relational algebra. For simplicity, the definitions here assume the unnamed perspective [1] of the relational model. Fix a countable domain $\mathbb{D}$ of database values. A *bag relation* of arity k is a mapping R: $\mathbb{D}^k \to \mathbb{N}$ associating *tuples* with their *multiplicities.* Conceptually, a tuple not present in the bag relation is mapped to zero. It is typically required that bag relations have *finite support*, i.e., R is zero on all but finitely many tuples. A *duplicate tuple* is a tuple whose multiplicity is greater than 1. From the perspective of bag semantics, an ordinary set relation of arity k is a mapping $R : \mathbb{D}^k \to \{0,1\}$ (again of finite support), in other words, a bag relation with no duplicate tuples. The relational algebra can be extended to bag relations by defining the action of the relational operators on tuple multiplicities:

Selection. If R is a bag relation of arity k and the selection predicate P maps each k-tuple to either 0 or 1 then $\sigma_P R$ is the bag relation of arity k defined by

$$(\sigma_P R)(t) \overset{\text{def}}{=} R(t) \cdot P(t).$$

Projection. If R is a bag relation of arity k and $V = (v_1,...,v_n)$ is a list of indices, $1 \leq v_i \leq k$, then π_V R is a bag relation of arity n, defined by

$$(\pi_V R)(t) \overset{\text{def}}{=} \sum_{t'\text{s.t.}t'=\pi_V(t)} R(t').$$

Cross product. If R_1 is a bag relation of arity k_1 and R_2 is a bag relation of arity k_2, then $R_1 \times R_2$ is a bag relation of arity k_1+k_2, defined by

$$(R_1 \times R_2)(t) \overset{\text{def}}{=} R_1(t_1) \cdot R_2(t_2),$$

where t is a (k_1+k_2)-tuple obtained by concatenating t_1 and t_2.

Union. If R_1 and R_2 are bag relations of arity k, then $R_1 \cup R_2$ is a bag relation of arity k, defined by

$$(R_1 \cup R_2)(t) \overset{\text{def}}{=} R_1(t) + R_2(t).$$

Intersection. If R_1 and R_2 are bag relations of arity k, then $R_1 \cap R_2$ is a bag relation of arity k, defined by

$$(R_1 \cap R_2)(t) \overset{\text{def}}{=} \min(R_1(t), R_2(t)).$$

Difference. If R_1 and R_2 are bag relations of arity k, then $R_1 - R_2$ is a bag relation of arity k, defined by

$$(R_1 - R_2)(t) \overset{\text{def}}{=} \max(R_1(t) - R_2(t), 0),$$

in other words, the calculation uses *proper subtraction* of natural numbers.

Example 1.

$$R = \begin{array}{|cc|c|}\hline a & b & 2 \\ c & b & 3 \\ c & d & 1 \\ \hline\end{array}\,, \qquad S = \begin{array}{|cc|c|}\hline b & c & 5 \\ b & d & 1 \\ d & d & 2 \\ \hline\end{array}\,,$$

$$R \circ S = \begin{array}{|cc|c|}\hline a & c & 2 \cdot 5 = 10 \\ a & d & 2 \cdot 1 = 2 \\ c & c & 1 \cdot 5 = 5 \\ c & d & 3 \cdot 1 + 1 \cdot 2 = 5 \\ \hline\end{array}$$

where $R \circ S$ *denotes relational composition, i.e.,* $R \circ S \overset{\text{def}}{=} \pi_{1,4}\, \sigma_{2=3}(R \times S)$.

Example 2.

$$R = \begin{array}{|cc|c|}\hline a & b & 1 \\ c & b & 1 \\ c & d & 1 \\ \hline\end{array}\,, \qquad S = \begin{array}{|cc|c|}\hline b & c & 1 \\ b & d & 1 \\ d & d & 1 \\ \hline\end{array}\,,$$

$$\pi_{1,3}\ (R \times S) = \begin{array}{|cc|c|}\hline a & b & 1 \cdot 1 + 1 \cdot 1 = 2 \\ a & d & 1 \cdot 1 = 1 \\ c & b & 1 \cdot 1 + 1 \cdot 1 + 1 \cdot 1 + 1 \cdot 1 = 4 \\ c & d & 1 \cdot 1 + 1 \cdot 1 = 2 \\ \hline\end{array}$$

Note that the use of projection results in duplicate tuples in the query output, even though the source tables R and S are duplicate-free. Duplicates may also be introduced by the union operator.

Bags and SQL. Practical query languages such as SQL are based on bag semantics rather than set semantics, since eliminating duplicates typically requires an expensive sort. However, SQL provides a way to emulate set semantics by the use of an explicit *duplicate elimination* operator, which is specified using the `DISTINCT` keyword. This operator converts a bag relation into the corresponding set relation. For example, to execute the SQL query

```
SELECT DISTINCT R.A, S.C
FROM R, S
WHERE R.B = S.B
```

the RDBMS will compute the bag join of R and S, then eliminate duplicates to produce a set relation. The result is the same as the join of R and S under set semantics.

SQL also provides alternate versions of the union, intersection, and difference operators which differ in their handling of duplicates. In particular, `UNION ALL`, `INTERSECT ALL`, and `EXCEPT ALL` correspond to the bag operations as defined above, i.e., they retain duplicates and produce bag relations as output. Meanwhile, `UNION`, `INTERSECT`, and `EXCEPT` perform duplicate elimination and produce set relations as output. For `UNION`, duplicate elimination is performed after the bag union, while for `INTERSECT` and `EXCEPT`, the duplicate elimination is performed beforehand on the operands.

Query reformulation with bag semantics. The context of bag semantics poses unique challenges in query reformulation and optimization, as classical optimization techniques such as query minimization do not necessarily transfer to bag semantics. For example, under set semantics, the query $R \bowtie R$ can be minimized by removing the redundant self-join to produce the equivalent query R. However, under bag semantics, the resulting query is not equivalent to the original, as the "redundant" self-join may increase the multiplicity of some output tuples. The rest of this section summarizes some of the theoretical results which are known regarding containment and equivalence of queries under bag semantics. In studying query reformulation, it is convenient to assume queries are expressed in a Datalog-style syntax. Thus, the algebraic query $R \bowtie R$ corresponds to the CQ

$$Q(x, y){:}\ -R(x, y), R(x, y),$$

while the query R corresponds to the CQ

$$Q'(x, y){:}\ -R(x, y).$$

As the example illustrates, repetitions of an atom in the body of a CQ are significant. As with set semantics, the bag semantics of CQs is defined in terms of *valuations* which assign the variables in the CQ values from the domain $\mathbb{D}$. The multiplicity of an output tuple is computed by summing over all valuations which produce that output tuple, and for each valuation, taking the product of the source multiplicities of the tuples corresponding to the body. Thus, for a CQ

$$Q(\bar{x}){:}\ -A_1(\bar{z}_1), \ldots, A_n(\bar{z}_n),$$

the multiplicity of an output tuple t is given by

$$Q(t) \overset{\text{def}}{=} \sum_{v} \prod_{i=1}^{n} A_i(v(\bar{z}_i)), \tag{1}$$

where the sum is over valuations $v : \text{vars}(Q) \rightarrow \mathbb{D}$ such that $v(\bar{x}) = t$. Note that this definition agrees with the bag relational algebra definition for SPJ queries (using selection, projection, and cross product).

Example 3. *The relational algebra query from Example 1 corresponds to the CQ*

$$Q(x,z) : -R(x,y), S(y,z).$$

Applying Q to the bag relations R and S from Example 1 yields $Q(c,d) = 3 \cdot 1 + 1 \cdot 2 = 5$, *where the* $3 \cdot 1$ *is produced by the valuation v which sends* $x \mapsto c, y \mapsto b$, *and* $z \mapsto d$, *and the* $1 \cdot 2$ *is produced by the valuation* v' *which sends* $x \mapsto c, y \mapsto d$, *and* $z \mapsto d$.

For a UCQ $\bar{Q} = (Q_1,\ldots,Q_n)$ the multiplicity of an output tuple is computed by summing over all the CQs in $\bar{Q}$:

$$\bar{Q}(t) \overset{\text{def}}{=} \sum_i^n Q_i(t). \tag{2}$$

This definition agrees with the bag relational algebra definition for SPJU queries (using selection, projection, cross product, and union).

Example 4. *Applying the UCQ* Q' *defined by the CQs*

$$Q'(x,z): -R(x,y), S(y,z)$$

$$Q'(z,y): -R(x,y), S(x,z)$$

to the set relations R and S from Example 2, the multiplicity of (c,d) *in the output is* $1 \cdot 1 + 1 \cdot 1 = 2$, *with each of the CQs contributing a term to the sum.*

A query P is *bag-contained* in a query Q, denoted $P \sqsubseteq_b Q$, if for all bag instances I, for every output tuple t, $P(I)(t) \leq Q(I)(t)$. When $P \sqsubseteq_b Q$ and $Q \sqsubseteq_b P$, P and Q are said to be *bag-equivalent*, denoted $P \equiv_b Q$. The analogous notions of set-containment and set-equivalence are denoted $P \sqsubseteq_s Q$ and $P \equiv_s Q$, respectively. With set semantics, it is well-known that a CQ Q can be optimized by deleting atoms in the body of Q, producing a minimal *core* of Q which is set-equivalent to Q. However, under bag semantics, this optimization no longer works, as deleting an atom in the body of a CQ always produces an inequivalent query, in fact:

Theorem 1 ([3]). *For CQs* P, Q, $P \equiv_b Q$ *iff* $P \cong Q$.

Here, $P \cong Q$ denotes that P and Q are *isomorphic*. Two CQs P and Q are isomorphic if there is a (bijective) renaming of variables $\theta : \text{vars}(P) \rightarrow \text{vars}(Q)$ which transforms P into Q. Checking isomorphism of directed graphs (i.e., Boolean CQs over a single binary predicate), is known to be in *NP*, but is not known or believed to be either in *P* or *NP*-complete. This holds also for general relational structures (and arbitrary CQs). Thus, although there are fewer opportunities for optimization of CQs under bag semantics, checking bag-equivalence is presumably computationally easier than checking set-equivalence (which is known to be *NP*-complete). It turns out that Theorem 1 can be generalized to UCQs:

Theorem 2 ([5]). *For UCQs* $\bar{P}$, $\bar{Q}$, $\bar{P} \equiv_b \bar{Q}$ *iff* $\bar{P} \cong \bar{Q}$.

Bag-equivalence of unions of conjunctive queries with inequalities (UCQ$^{\neq}$s) is also known to be decidable:

Theorem 3 ([5]). For *UCQ$^{\neq}$ s* P, Q, *checking* $P \equiv_b Q$ *is in PSPACE.*

The same result was obtained earlier for CQ$^{\neq}$s by Nutt et al. [16]. The exact complexity in each case (CQ$^{\neq}$s or UCQ$^{\neq}$s) seems to be open. (Theorem 1 implies a graph isomorphism-hard lower bound).

In contrast to equivalence, which seems to only become easier to check for bag semantics than for set semantics, containment can become much harder. For CQs, the following lower bound on the complexity of bag containment is known:

Theorem 4 ([3]). For *CQs* P, Q, *checking* $P \sqsubseteq_b Q$ *is* $\Pi_2{}^P$-*hard.*

However, this is only a lower bound, and as of 2008, it is not known whether the problem is even decidable. For UCQs, the question has been resolved negatively:

Theorem 5 ([9]). For *UCQs* $\bar{P}, \bar{Q}$, *checking* $\bar{P} \sqsubseteq_b \bar{Q}$ *is undecidable.*

The reduction used to prove this result highlights a close connection between checking bag containment of UCQs and Hilbert's Tenth Problem, which concerns checking for the existence of solutions to Diophantine equations. Another (non-trivial) reduction from the same problem was used to establish a similar result for CQ$^{\neq}$s:

Theorem 6 ([10]). *For CQ$^{\neq}$ s* P, Q, *checking* $P \sqsubseteq_b Q$ *is undecidable.*

Query reformulation with bag-set semantics. Recall that with bag-set semantics, all source tuples are assumed to have cardinality 1 (or 0, if not present). For query optimization, the main ramification compared to bag semantics is that redundant (repeated) atoms in the body of a CQ are immaterial under bag-set semantics and can be simply deleted from the body, producing an *irredundant* CQ. For example, the CQs

$$Q_1(x,z){:}-R(x,y),S(y,z)$$

$$Q_2(x,z){:}-R(x,y),R(x,y),S(y,z)$$

are bag-set equivalent, denoted $Q_1 \equiv_{bs} Q_2$, and Q_1 is irredundant. The following result states that eliminating repeated atoms is essentially the only optimization possible for CQs under bag-set semantics:

Theorem 7 ([3]). *For irredundant CQs* P, Q, $P \equiv_{bs} Q$ *iff* $P \equiv_b Q$ *(hence* $P \equiv_{bs} Q$ *iff* $P \cong Q$*).*

This result was essentially a rediscovery of a well-known result in graph theory due to Lovász [13], who showed that for finite relational structures F, G, if $|\mathrm{Hom}(F,H)| = |\mathrm{Hom}(G,H)|$ for all finite relational structures H, where $\mathrm{Hom}(A,B)$ is the set of homomorphisms $h: A \to B$, then $F \cong G$. In database terminology, this says that bag-set equivalence of irredundant Boolean CQs is the same as isomorphism.

Theorem 7 was extended to UCQs in [5], and the PSPACE upper bound of Theorem 3 was also shown to hold for bag-set equivalence of UCQ$^{\neq}$s in [5].

In general, results on bag-set semantics correspond to results on bag semantics via the following *transfer lemma*:

Lemma 1 ([7]). *There exists a mapping* $\varphi : CQ \to CQ$ *(which extends to UCQs by applying it componentwise on CQs), a mapping f from bag instances to set instances, and a mapping g from set instances to bag instances, such that for any UCQ* $\bar{Q}$*, bag instance I, and set instance J:*

1. $\bar{Q}(I) = \varphi(\bar{Q})(f(I))$
2. $\varphi(\bar{Q})(J) = \bar{P}(g(J))$

In particular this lemma shows that bag-containment of CQs (UCQs) is polynomial time reducible to bag-set containment, as shown for CQs in [3]. Thus Theorem 5 also implies that bag-set containment of UCQs is undecidable. Also, Lemma 1 generalizes to queries with inequality predicates, hence Theorem [10] also implies also the undecidability of bag-set containment of CQ$^{\neq}$s, as shown in [10]. Finally, note that for UCQs $\bar{P}, \bar{Q}$ the transformation ϕ can be defined such that $\bar{P} \cong \bar{Q}$ iff $\varphi(\bar{P}) \cong \varphi(\bar{Q})$. Theorem 2 thus follows from a similar result for bag-set equivalence, also shown in [5]:

Theorem 8 ([5]). *For unions of irredundant CQs* $\bar{P}, \bar{Q}$*, we have* $\bar{P} \equiv_{bs} \bar{Q}$ *iff* $\bar{P} \cong \bar{Q}$.

Bag semantics of datalog queries. As with the relational algebra, the semantics of Datalog queries can be extended operate on bag instances. This is done by defining how *derivation trees* for an output tuple contribute to the multiplicity of the tuple. The *fringe* of a derivation tree τ of an output tuple t, denoted $\mathrm{fringe}(\tau)$, is the bag of leaves (source tuples) in the derivation tree. The count of an output tuple is computed by summing over all derivation trees, and taking the product of the multiplicities of the source tuples in the fringe. If a source tuple appears several times in the fringe, it is counted that many times in the product. Formally, for a Datalog program Q and source bag instance I, the multiplicity of a tuple t in the output is defined by

$$Q(t) \overset{\mathrm{def}}{=} \sum_{\tau} \prod_{A(t') \in \mathrm{fringe}(\tau)} A(t') \qquad (3)$$

where the sum is over all derivation trees for t. Note that when Q is a CQ or UCQ, the above definition agrees with definitions (1.1) and (1.2). However, a basic difference is that for recursive queries, there may be *infinitely many* derivation trees for an output tuple. In this case, its count is defined to be ∞.

Example 5. *For the transitive closure query TC and bag relation R defined by*

$$\begin{array}{lcl} TC(x,y) & :- & R(x,y) \\ TC(x,z) & :- & TC(x,y), R(y,z) \end{array} \qquad R = \begin{array}{ccc} a & b & 1 \\ a & c & 2 \\ c & b & 1 \\ c & d & 1 \\ d & d & 3 \end{array}$$

evaluating the query yields $TC(a,\, b) = 1 + 2 \cdot 1 = 3$ *but* $TC(c,\, d) = \infty$.

Computational problems related to infinite counts are therefore of central interest for Datalog programs with bag semantics. The most basic problem is to check whether or not a count for a given output tuple is ∞. Clearly, computing the set of all derivation trees, and then checking whether or not the set is finite, is not feasible. However, it turns out that the problem is decidable in polynomial time (data complexity), even for Datalog extended with safe stratified negation [15]. The related problem of checking statically whether answer counts are finite for all possible source bag instances is also decidable, even for Datalog extended with and negation on unary edb's [15]. However, checking this property is undecidable for Datalog extended with safe stratified negation [15].

Key Applications

The use of bag semantics in practical RDBMS implementations has led to a reexamination of fundamental issues in query optimization, namely, query containment and query equivalence. The switch from classical set semantics to bag semantics turns out to have a radical impact on these issues. Bag semantics also poses challenges for processing of recursive Datalog programs, where infinite multiplicities may arise in the output.

Future Directions

The most salient open problem involving bag semantics concerns containment of conjunctive queries. This was shown to be Π_2^p-hard in [3], but the decidability of the problem remains open. In contrast, for set semantics, the problem is known to be *NP*-complete.

Bootstrap aggregating

Definition

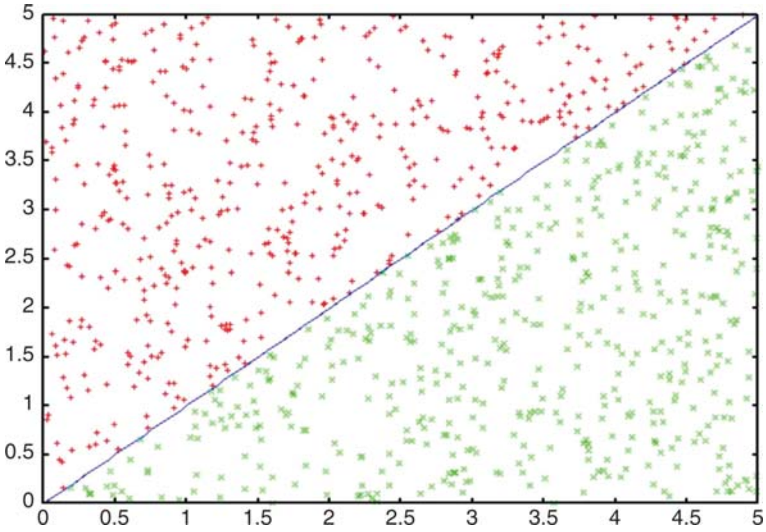
Bagging (**B**ootstrap **Agg**regating) uses "majority voting" to combine the output of different inductive models, constructed from bootstrap samples of the same training set. A bootstrap has the same size as the training data, and is uniformly sampled from the original training set with replacement. That is, after an example is selected from the training set, it is still kept in the training set for subsequent sampling and the same example could be selected multiple times into the same bootstrap sample. When the training set is sufficiently large, on average, a bootstrap sample has 63.2% unique examples from the original training set, and the rest are duplicates. In order to make full use of bagging, typically, one need to generate at least 50 bootstrap samples and construct 50 classifiers using these samples. During prediction, the class label receiving the most votes or most predictions from the base level 50 classifiers will be the final prediction. Normally, Bagging is more accurate than a single classifier trained from the original training set. Statistically, this is due to multiple classifiers' power to reduce the effect of overfitting on the training data and statistical variance. Bagging works the best for non-stable inductive models, such as decision trees, and its advantage is limited for stable methods such as logistic regression, SVM, naive Bayes, etc.

Historical Background

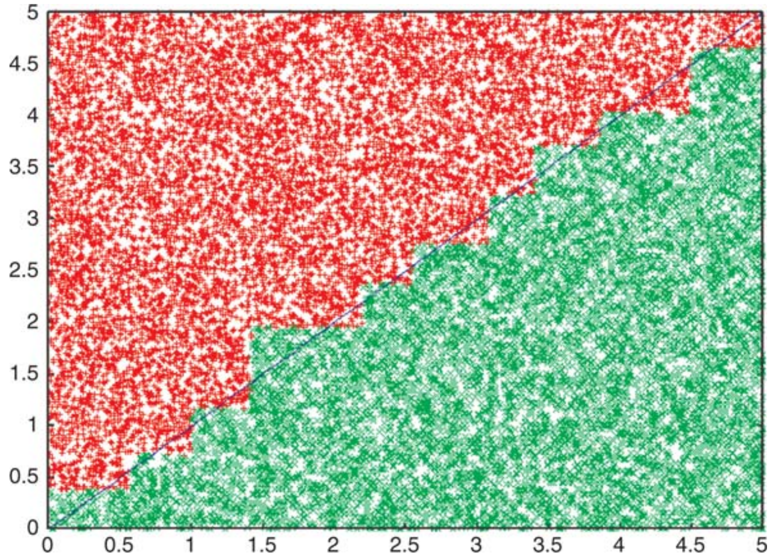
Bagging was originally proposed by Leo Breiman in 1996 [3]. The motivation comes from the fact that unstable inductive learners such as decision trees tend to generate very different models with just a slight change in the training data, for example, the inclusion or exclusion of one example. This is due to the "greedy-based" search heuristics of these methods to find the best hypothesis to fit the labeled training data. Statistically, the effect is that the variance in bias and variance decomposition of error is large. Bias is the systematic error of the chosen learning technique, and variance is due to variations in the training data, i.e., different training data produce different models. Bagging was proposed to remedy these problems. In order to overcome variations of a single training set, multiple bootstrap samples are used to replace the single original training set. Since each bootstrap sample is randomly selected from the original training data, it still "preserves" the main concept to be modeled. However, each bootstrap sample is different, thus offsetting the "individuality" of any single training set that contributes to variance. In the same time, any possible over-sample or "non-sample" of particular labeled examples from the training data (recall that 63.2% are unique examples and the rest are duplicates) that could reduce learning accuracy is resolved by majority voting or choosing the predicted labels with the most number of votes from base line models. The simple observation is that the probability for most models to make the same mistakes is much less than any single model itself.

Foundations

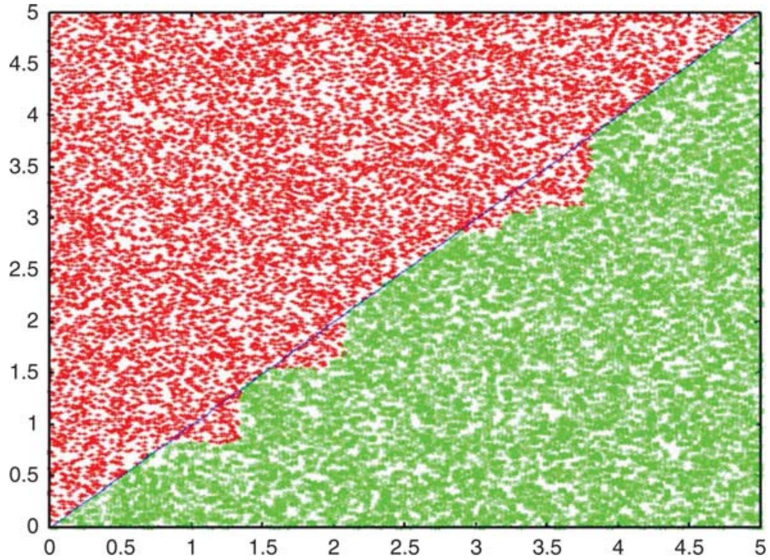
The key idea of Bagging can be illustrated by a simple synthetic example. In Fig. 1, the true decision boundary that separates two classes of examples is a simple linear function, $y = x$, where examples above the line belongs to one class and examples below the line belongs to another class. The labeled training examples are randomly sampled from the universe of examples and is obviously not exhaustive. When a decision tree algorithm is applied to the sampled training data, it will construct a tree model particular to that sample set. Figure 2 shows the decision boundary of a single tree constructed by C4.5 algorithm [12]. As observed, the "stair-step" shape of the decision boundary is due to "bias" or systematic error of decision tree algorithm, where the splits are always perpendicular to the axes. Once an algorithm is chosen, its bias is hard to avoid. At the same time, the exact position and size of each step is due to variations in individually sampled training data, and it contributes to "variance" term in the prediction error. Next, this entry studies how "variance" can be effectively reduced by applying Bagging. Figure 3 demonstrated the decision boundary of Bagging generated from 50 bagged C4.5 trees. It is clear



Bagging. Figure 1. Training data for a simple linear function.



Bagging. Figure 2. Decision boundary constructed by a single tree.



Bagging. Figure 3. Decision boundary constructed by bagging.

that the decision boundary is much closer to the perfect "$y = x$" line, and only three steps are left.

Formally, the reduction in variance can be approximated by the following equation:

$$\epsilon = \beta + \frac{\sigma}{\sqrt{n}}, \tag{1}$$

where the error ε is decomposed into bias β and variance σ. The reduction in variance is scaled by $\sqrt{n}$ where n is the number of bagging models. Additionally, the idea of Bagging can be applied to both classification problem or discrete variable prediction (such as the synthetic example given above) and regression problems or continuous variable prediction. In regression problems, the estimated value of different models are averaged as the final prediction.

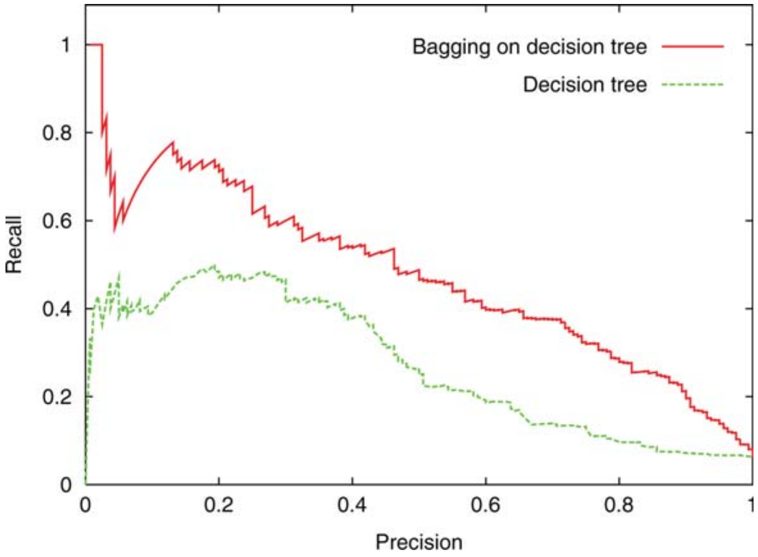
For further reading and understanding of Bagging and its various applications, refer to the 15 papers in the "Recommended Reading" section. For theories to explain how and why Bagging works, the best source is the original paper by Leo Breiman [3], that explains the statistical fundamentals that Bagging is built upon. Additionally, [5] explains the appropriate understanding of overfitting and how overfitting plays a role in classifers' generalization power. In essence, Bagging helps to correct the overfitting problem of unstable learners, such as decision trees. For various information on how to build an accurate decision tree, the base model where Bagging normally combines, the following list of papers contain solid information [2,4,9,11,12,13]. For state-of-the-art and future works of Bagging, one of the most novel ideas is "randomization" and different treatment on this subject can be found in various papers [1,6,7,14]. During the time when Bagging was proposed, an alternative method called "Boosting" was proposed to resolve the instability of inductive learners and some papers that theoretically describe its motivation and practice can be found in [8,10]. For a detailed and systematic comparison of Bagging and many other state-of-the art algorithms on a difficult application problem "skewed and stochastic ozone day forecasting", the works in [15] contain useful information.

Key Applications

Bagging is most suitable for applications where both the training set is not too big, i.e., the number of training examples can fit into main memory of the machine, and the chosen inductive learner is unstable, such as decision trees. This is mainly because generating multiple bootstrap sample involves multiple scans of the training data and can be a bottleneck if most operations rely on disk. At the same time, if the number of examples does not fit into main memory of the machine, learning can incur swapping cost and take a long time to complete. As discussed previously, bagging's success is mainly limited to unstable learners that normally have large variance.

As a good example, "ozone day prediction" [15] illustrates how well Bagging can perform in practice. What makes this problem interesting is that there are 72 continuous features in the collected dataset, only about 3% of 2,500+ collected days are positive. It is important to understand that for a problem with 72 dimensions, 2,500 training examples are trivial in size. Even if these 72 features are binary in values, the total problem size is an astronomical number 2^{72}, and obviously, 2,500 samples from this space is "really nothing".

Applying non-stable inductive learning method, such as decision tree, on this problem is unlikely to obtain satisfactory result. The simple reason is that these methods tend to "overfit" or build unnecessarily detailed models to fit well on the given 2,500 examples, but do not generalize well on unseen testing data in the problem space of 2^{72}. As illustrated in a precision-recall plot in Fig. 4, Bagging consistently obtains higher "precision" than its comparable single tree methods. Recall is the percentage of "true ozone days" that are correctly predicted as ozone days, and precision is the



Bagging. Figure 4. Bagging versus single decision tree.

percentage of "predicted ozone days" that are actually ozone days. By reading the consistently higher precision numbers by Bagging on the same recall number, it clearly demonstrates that Bagging is more accurate than single decision trees.

Future Directions

Most recently, a completely counter-intuitive method called "Random Decision Tree" [7,6,14] has been proposed to reduce both bias and variance in inductive learning. Each tree in a random tree ensemble is used as a structure to summarize the training data, and importantly, the structure of the tree is semi-randomly constructed, and data are "filled-in" the tree structure to summarize statistics of the training data. During prediction, the estimated probability from each tree is averaged as the final conditional probability $P(\mathbf{y}|\mathbf{x})$ and the class label with the highest probability is chosen as the predicted label. Since it does not incur any overhead of producing bootstraps or using information gain to perform feature selection as Bagging does, random decision tree can be highly efficient. One application on difficult skewed and high dimensional ozone day forecast can be found in [15]. Similar to Bagging, Random Decision Tree is applicable to both classification and regression problems.

Bayes classifier

Definition

In classification, the objective is to build a classifier that takes an unlabeled example and assigns it to a class. Bayesian classification does this by modeling the probabilistic relationships between the attribute set and the class variable. Based on the modeled relationships, it estimates the class membership probability of the unseen example.

Historical Background

The foundation of Bayesian classification goes back to Reverend Bayes himself [2]. The origin of Bayesian belief nets can be traced back to [15]. In 1965, Good [4] combined the independence assumption with the Bayes formula to define the Naïve Bayes Classifier. Duda and Hart [14] introduced the basic notion of Bayesian classification and the naïve Bayes representation of joint distribution. The modern treatment and development of Bayesian belief networks is attributed to Pearl [8]. Heckerman [13] later reformulated the Bayes results and defined the probabilistic similarity networks that demonstrated the practicality of Bayesian classification in complex diagnostic problems.

Foundations

Bayesian classification is based on Bayes Theorem. It provides the basis for probabilistic learning that accommodates prior knowledge and takes into account the observed data.

Let X be a data sample whose class label is unknown. Suppose H is a hypothesis that X belongs to class Y. The goal is to estimate the probability that hypothesis H is true given the observed data sample X, that is, P(Y|X).

Consider the example of a dataset with the following attributes: Home Owner, Marital Status, and Annual Income as shown in Fig. 1. Credit Risks are Low for those who have never defaulted on their payments and credit risks are High for those who have previously defaulted on their payments.

Assume that a new data arrives with the following attribute set: X = (Home Owner = Yes, Marital Status = Married, Annual Income = High). To determine the credit risk of this record, it is noted that the Bayes classifier combines the predictions of all alternative hypotheses to determine the most probable classification of a new instance. In the example, this involves computing P(High|X) and P(Low|X) and to determine whether P(High|X) > P(Low|X)?

However, estimating these probabilities is difficult, since it requires a very large training set that covers every possible combination of the class label and attribute values. Instead, Bayes theorem is applied and it resulted in the following equations:

$$\mathrm{P(High|X) = P(X|High)P(High)/P(X)} \text{ and}$$

$$\mathrm{P(Low|X) = P(X|Low)P(Low)/P(X)}$$

P(High), P(Low), and P(X) can be estimated from the given dataset and prior knowledge. To estimate the class-conditional probabilities P(X|High), P(X|Low), there are two implementations: the Naïve Bayesian classifier and the Bayesian Belief Networks.

In the Naïve Bayesian classifier [13], the attributes are assumed to be conditionally independent given the class label y. In other words, for an n-attribute set X = (X_1, X_2,...,X_n), the class-conditional probability can be estimated as follows:

$$P(Y|X) = \alpha P(Y)\prod_i P(X_i|Y)$$

Customer ID	Home owner	Marital status	Annual income	Credit risks
1	Yes	Married	High	Low
2	No	Single	Medium	High
3	No	Married	Medium	High
4	Yes	Divorced	Low	High
5	No	Married	High	Low
6	No	Divorced	High	Low
7	Yes	Single	Low	Low
8	No	Single	High	Low
9	No	Married	Medium	High
10	Yes	Single	Medium	Low

Bayesian Classification. Figure 1. Dataset example.

In the example,

$$\begin{aligned}&(\mathrm{X}|\mathrm{Low}) = \mathrm{P}(\text{Home Owner}\\&\qquad = \text{Yes}|\text{Credit Risk} = \text{Low})\times\\&\mathrm{P}(\text{Marital Status} = \text{Married}|\text{Credit Risk}\\&\qquad = \text{Low})\times\\&\mathrm{P}(\text{Annual Income} = \text{High}|\text{Credit Risk}\\&\quad = \text{Low} = 3/4 \times 2/4 \times 4/4 = 3/8\\&\mathrm{P}(\mathrm{X}|\text{High}) = \mathrm{P}(\text{Home Owner}\\&\qquad = \text{Yes}|\text{Credit Risk} = \text{High})\times\\&\mathrm{P}(\text{Marital Status}\\&\quad = \text{High})\times\\&\mathrm{P}(\text{Annual Income} = \text{High}|\text{Credit Risk}\\&\qquad = \text{High}) = 0\end{aligned}$$

Putting them together, $\mathrm{P(High|X)} = \mathrm{P(X|High)P(High)/P(X)} = 0$

$$\mathrm{P(Low|X) = P(X|Low)P(Low)/P(X)} > 0$$

Since $\mathrm{P(Low|X)} > \mathrm{P(High|X)}$, X is classified as having Credit Risk = Low.

In other words,

$$\mathit{Classifiy}(X) = \arg\max_{y} P(Y = y)\prod_{i} P(X_i|Y = y)$$

In general, Naïve Bayes classifiers are robust to isolated noise points and irrelevant attributes. However, the presence of correlated attributes can degrade the performance of naïve Bayes classifiers as they violate the conditional independence assumption. Fortunately, Domingos and Pazzani [3] showed that even when the independence assumption is violated in some situations, the naïve Bayesian classifier can still be optimal. This has led to a wide spread use of naïve Bayesian classifiers in many applications. Jaeger [9] also further clarifies and distinguishes the concepts that can be recognized by naïve Bayes classifiers and the theoretical limits on learning the concepts from data.

There are many extensions to the naïve Bayes classifier that impose limited dependencies among the feature/attribute nodes, such as tree-augmented naïve Bayes [6], and forest-augmented naïve Bayes [11].

Bayesian belief network [10] overcomes the rigidity imposed by this assumption by allowing the dependence relationships among a set of attributes to be modeled as a directed acyclic graph. Associated with each node in the directed acyclic graph is a probability table. Note that a node in the Bayesian network is conditionally independent of its non-descendants, if its parents are known.

Refer to the running example. Suppose the probabilistic relationships among Home Owner, Marital Status, Annual Income, and Credit Risks are shown in Fig. 2. Associated with each node is the corresponding conditional probability table relating the node to its parent node(s).

In the Bayesian belief network, the probabilities are estimated as follows:

$$P(Risk|X) = \alpha \sum_{I} P(Risk|Income) \sum_{O} P(Owner) \sum_{S} P(Status)P(Income|Owner, Status)$$

In the above example,

$$\begin{aligned}\mathrm{P(Low|X)} =& \mathrm{P(Low|Income = High)}\\&*\mathrm{P(Income = High|Owner}\\&= \mathrm{Yes, Status = Married)} = 1 * 1 = 1\end{aligned}$$

Alternatively, by recognizing that given Annual Income, Credit Risks is conditionally independent of Home Owner and Marital status, then

$$\mathrm{P(Low|X) = P(Low|Income = High)} = 1$$

This example illustrates that the classification problem in Bayesian networks is a special case of belief updating for any node (target class) Y in the network, given evidence X.

While Bayesian belief network provides an approach to capture dependencies among variables using a graphical model, constructing the network is time consuming and costly. Substantial research has been and is still continuing to address the inference as well as the automated construction of Bayesian networks by learning from data. Much progress has been made recently. So applying Bayesian networks for classification is no longer as time consuming and costly as before, and the approach is gaining headway into the mainstream applications.

Key Applications

Bayesian classification techniques have been applied in many applications. Here, a few more common applications of Bayesian classifiers are mentioned.

Text Document Classification

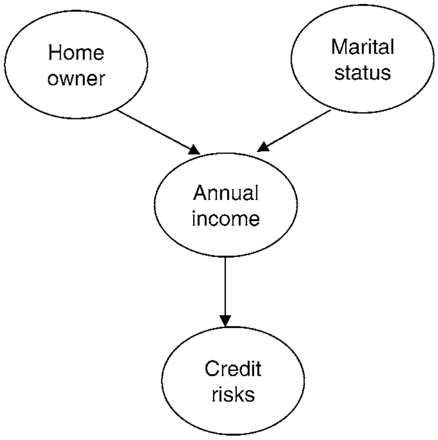
Text classification refers to the grouping of texts into several clusters so as to improve the efficiency and effectiveness of text retrieval. Typically, the text documents are pre-processed and the key words chosen. Based on the selected keywords of the documents, probabilistic classifiers are built. Dumais et al. [5] show naïve Bayes classifier yields surprisingly good classifications for text documents.

Image Pattern Recognition

In image pattern recognition, a set of elementary or low level image features are selected which describe some characteristics of the objects. Data extracted based on this feature set are used to train Bayesian classifiers for subsequent object recognition. Aggarwal et al. [1] did a comparative study of three paradigms for object recognition – Bayesian Statistics, Neural Networks and Expert Systems.

Medical Diagnostic and Decision Support Systems

Large amounts of medical data are available for analysis. Knowledge derived from analyzing these data can be used to assist the physician in subsequent diagnosis. In this area, naïve Bayesian classifiers performed exceptionally well. Kononenko et al. [12] showed that



Owner = Yes
0.4

(Table associated with node owner)

Status	
Married	0.4
Single	0.4
Divorced	0.2

(Table associated with node status)

	Income = High	Income = Medium	Income = Low
HO = Yes, MS = Married	1	0	0
HO = Yes, MS = Divorced	0	0	1
HO = Yes, MS = Single	0	0.5	0.5
HO = No, MS = Married	0.33	0.67	0
HO = No, MS = Divorced	1	0	0
HO = No, MS = Single	0.5	0.5	0

(Table associated with node income)

	Risk = High	Risk = Low
Income = High	0	1
Income = Medium	0.75	0.25
Income = Low	0.5	0.5

(Table associated with node credit risks)

Bayesian Classification. Figure 2. Bayesian belief network of the credit risks dataset.

the naïve Bayesian classifier outperformed other classification algorithms on five out of the eight medical diagnostic problems.

Email Spam Filtering

With the growing problem of junk email, it is desirable to have an automatic email spam filters to eliminate unwanted messages from a user's mail stream. Bayesian classifiers that take into consideration domain-specific features for classifying emails are now accurate enough for real world usage.

[4]University Paris-Sud, Orsay Cedex, France

Definition

Metadata characterize biological resources by core information including a name, a description of its input and its output (parameters or format), its address, and various additional properties. Resources are organized with respect to metadata that characterize their content (for data sources), their semantics (in terms of ontological classes and relationships), their characteristics (syntactical properties), their performance (with metrics and benchmarks), their quality (curation, reliability, trust), etc.

Historical Background

Digital resources for the Life Sciences include a variety of data sources and applications whose number increases dramatically every year [4]. Although this rich and valuable offering provides scientists with multiple options to implement and execute their scientific protocols (i.e., pipelines, dataflows, workflows), selecting the resources suitable for implementing each scientific step remains a difficult task. Scientific protocols are typically implemented using the resources a scientist is most familiar with, instead of the resources that may best meet the protocol's needs. The number of resources a scientist uses regularly, knowing their structure, the quality of data and annotations they offer, the capabilities made available by the provider to access, analyze, and display the data are ridiculously small compared to the thousands of resources made available on the Web [3]. Metadata are not only critical in selecting suitable resources for implement scientific protocols, but they are essential to the proper composition and integration of resources in a platform such as a workflow system or wrapped into a database mediation system. They also play a decisive role in the analysis of data, in particular to track data provenance. Finally, they contribute to data curation and the management of Life Sciences resources in a global and linked digital biological maze.

Foundations

Metadata management relies on the description of resources including the resource name, identification, and all additional information that may be relevant to locating, evaluating, and using the resource. A *resource identifier* is a sequence of characters that uniquely identifies a resource and is globally shared and understood over a network. A resource is analogous to a node on the Web. The ubiquitous Uniform Resource Locator (URL) is an example of a resource identifier, which uses the location, the local directory path, and the local file name of the resource to locate it on the Web. Unique Resource Identifiers (URIs) include URLs that not only identify the resource but describe its primary access mechanism or network location, and Uniform Resource Names (URN) that identify a resource by name in a particular namespace. The unique identification of resources is an unresolved problem in the life sciences community. Different protein, gene, and molecular interaction databases often assign separate identifiers to the same resource, a phenomenon known as *coreference*. Leveraging the information from all these databases becomes problematic, leading to duplicate records and inconsistency. To alleviate this problem, many Life Sciences databases cross reference their identifiers.

Metadata are data that describe a resource. Metadata include a wide range of information from attribution metadata, such as those attributes defined in the Dublin Core, to detailed policy metadata indicating who can access the resource under what conditions. *Semantic metadata* include the description of a resource with respect to the domain knowledge (e.g., a data source provides information about proteins, a tool computes the translation of a RNA sequence into an AA sequence). *Syntactic metadata* provide the description of the resource interface. *Summary metadata* describe the actual contents of the resource. These metadata include free text summaries and statistical summaries of the instances (values) contained in the database. Summary metadata can be classified along several axes: (i) textual versus quantitative, (ii) structured versus unstructured, and (iii) manually generated versus automatically generated. By far the most common type of summary metadata are textual. For example, NAR [4] maintains a listing of hundreds of biomedical resources. For each resource, they provide a brief description of the contents of that resource. Textual metadata allow an application developer or end-user to search for resources using keywords or phrases. The success of existing approaches seems to show that it is a familiar and intuitive operation, which works well when searching for reasonably well-defined concepts. Textual metadata are unstructured (i.e., free text) and manually curated. Alternatively, summary metadata can take the form of keywords drawn from a *controlled vocabulary*, such as Medical Subject Headings (MeSH) terms. A controlled vocabulary makes it easier to search for resources, assuming the vocabulary is sufficiently expressive and used consistently to annotate the resources. In most cases, textual metadata are generated manually, although there is some research in automatically extracting keywords from a resource for its annotation.

Quantitative metadata describe resources in terms of numeric datatypes. In the simplest case, these metadata specify the range of values that can be found in the resource. For example, all of the subjects in a pediatric database would be younger than 18. More detailed summaries are also possible. In the case of quantitative metadata, unstructured metadata make little sense. The end user needs to know what a given number represents, including relevant units. Quantitative metadata can still be generated manually or automatically. The former is required if the resource does not contain the necessary raw data. For example, if a pediatric database does not contain the ages of its subjects, the relevant age range must be specified manually. However, when the resource does contain the necessary raw data, quantitative metadata can be generated automatically. Moreover, the amount of detail in the metadata can vary depending on the needs of the resource owners and community members searching for resources. A current research challenge is determining the appropriate granularity for quantitative metadata and using these metadata to estimate the extent to which a given resource matches the end user's search criteria. *Statistical metadata* and benchmarks provide an additional layer exploited when the scientist wishes to predict the outcome of an execution. These metadata are particularly useful when several resources are combined to evaluate alternative evaluation strategies and select the most efficient one with respect to the protocols' aim [5]. The domain and range of resources, as well as resource overlaps contribute to the statistical description of resources. Similarly, information related to the quality of the resource (e.g., curation) may be exploited to optimize the quality of the execution.

Structural metadata describe the resource interface and the intention of the resource provider. These metadata can take on many forms including database schemata, Unified Modeling Language (UML) diagrams or Web service descriptions. What structural metadata provide are a description of how the resource provider intends to organize and deliver data. Controlled vocabularies capture domain knowledge and clarify resource descriptions (e.g., identical concepts). Controlled vocabularies are naturally extended by logical or conceptual representations such as expressed in a domain ontology. More generally, a metadata registry containing structural metadata allows an application developer to search for resources that are intended to contain particular types of data. Moreover, once a developer discovers a useful resource, he has a good idea of how to interact with that resource, both in terms of formulating queries and processing results. Structural metadata only indicate what sorts of queries can be posed, not whether those queries will return meaningful results. For example, the structural metadata for a card catalog might indicate that it includes, for each entry, a list of authors. Thus, one could reasonably query the card catalog for all books authored by John Grisham. However, if the card catalog supports a medical (non-fiction) library, it is unlikely that this query will return any record.

Bioinformatics resources may be represented with formats and standards developed by various communities driven by disparate motivations including business, library, Web, etc. The Resource Description Framework (RDF) and the RDF Schema (RDFS) were the earliest adopted standards for representing metadata about Web resources. The Dublin Core Metadata Elements Set (DCMES) is a standard set of metadata elements that can be used to describe a generic resource to facilitate its discovery and use. RDF specifically provides a very simple "triples" syntax or Subject-Predicate-Object syntax to capture resource metadata. Universal Description, Discovery and Integration (UDDI) is the XML-based format to register businesses on the Web proposed by OASIS. Dublin Core is a standard (NISO Standard Z39.85-2007) for cross-domain information resource description. The Web Ontology Language OWL, based on earlier languages OIL and DAML+OIL, is a W3C recommendation that extends XML, RDF, and RDF Schema (RDF-S) by providing additional vocabulary along with a formal semantics with descriptions of classes, along with their related properties and instances. The Web Service Description Language (WSDL) and its extension WSDL-S are used respectively as resource description and semantic annotation. Resource description and registration developed for the life science include BioMoby, PISE/Mobyle, caBIG, and SOAPlab.

The Life Sciences community has a number of metadata annotation standards. The Darwin Core (DwC) is a metadata standard from the National Biological Information Infrastructure (NBII) for annotating the objects contained within natural history specimen collections and species observation databases. These annotations are used to retrieve records of natural history specimens and observation records from local libraries, integrating them with other collections across the United States and making them available on the Web. The Access to Biological Collections Data Schema (ABCD Schema) is a complementary, hierarchical metadata standard for the annotation of biological specimens. Mappings exist from the terms of Darwin Core to the ABCD Schema that illustrate the overlap between the two standards and the few differences. Organizations such as NBII, the Integrated Taxonomic Information System and the Global Biodiversity Information Facility leverage metadata standards such as ABCD Schema and DwC to discover and utilize information pertaining to species and natural history specimens that is distributed around the world.

The Minimum Information About a Microarray Experiment (MIAME) [1] from the Microarray Gene Expression Data (MGED) Society, is used to describe sufficient information about a microarray experiment to reproduce it unambiguously. An increasing number of data providers are embracing the MIAME standard and several journals including NAR, Cell, and Nature require MIAME compliant data as a condition for publishing microarray based papers. The Minimum Information About a Proteomics Experiment (MIAPE) [7] is a minimum information reporting requirement for proteomics experiments. It is analogous to the MIAME standard for transcriptomics data. MIAPE is distributed across several modules, each of which is useful to describe a different proteomics experiment. Example modules are the MIAPE Gel Electrophoresis module, the MIAPE Mass Spectrometry module and the MIAPE Column Chromatography module. The Minimum Information required for reporting a Molecular Interaction Experiment (MIMIx) [6] has been developed as a framework to capture metadata about molecular interaction experiments. MIAME, MIAPE and MIMIx are being developed under the auspices of the Proteomics Standards Initiative at the Human Proteomics Organization.

Metadata standards vary in complexity from the simple format of the Dublin Core to the complex requirements of MIAME. A number of organizations are currently involved in the development of metadata standards in various fields of study. The Federal Geographic Data Committee (FGDC) is involved in the creation of several metadata standards such as the Spatial Data Transfer Standard for the exchange of spatial data, the National Vegetation Classification Standard to support a national vegetation classification system, the Biological Data Profile for the documentation of biological data, and the Utilities Data Content Standard to standardize geospatial information for utility systems. In addition the FGDC publishes the Content Standard for Digital Geospatial Metadata (CSDGM) for the annotation of geospatial data in the form of maps, atlases and satellite images. The Ocean Biogeographic Information System as an initiative to make marine biogeographic data available to a worldwide audience. OBIS has developed a taxonomic hierarchy of metadata elements, called the OBIS taxonomy for annotation of marine species observations. GeoConnections is a Canadian initiative to make geospatial data in the form of maps and satellite images easily available to a worldwide audience. GeoConnections uses the CSDGM published by the FGDC, to annotate its geospatial data.

Key Applications

Resource discovery systems exploit metadata in order to map the user requirements to the resource characteristics. For example, caCORE is an n-tier data management and integration infrastructure that combines several interconnected software and services. The Cancer Bioinformatics Infrastructure Objects (caBIO) model is at the heart of caCORE. The caBIO model contains definitions of concepts and inter-concept relationships that are common to biomedical research. These concept definitions in caBIO are the basis upon which data from distributed repositories are integrated. These repositories include gene and homolog databases (e.g., UniGene and Homologene), pathway databases (e.g., BioCarta), vocabulary and terminology repositories (e.g., the National Cancer Institute (NCI) Thesaurus, NCI Metathesaurus, and the Gene Ontology). The PathPort framework developed at The Virginia Bioinformatics Institute, presents a Web based interface that makes it possible for end users to invoke local and distributed biological Web services that are described in WSDL, in a location and platform independent manner.

Metadata offer metrics that may be used to predict the outcome of the execution of a scientific protocol on selected resources [5]. Metadata provide resource characterization that allows their comparison with similar resources, thus addressing the need of combining multiple complementary resources to implement completely a single task (e.g., data coverage). Path-based systems such as BioNavigation exploit statistical metadata to predict the resources that are likely to return the most entries, the best characterized (most attributes) entries, etc. [3].

Although some degree of transparency is often needed in queries, scientists also expect to be aware of the provenance of the answers. In order to analyze the results obtained from the execution of their scientific protocols, they often need to understand the process that produced the dataset. In particular, they need to know which resources have been used, and how entries have been linked to generate the answer to their question. Data traceability is related to the degree of information pertaining to the resources used to implement the process as well as the integration used to combine them. Because of this, reasoning on data provenance may exploit scientific resource metadata repositories. For example, BioGuideSRS allows the user to visualize the correspondence between the graph of entities and the graph of sources-entities [2]. By selecting an entity, the user visualizes the sources which provide information about this entity; similarly, by selecting a relationship, the user visualizes the links between sources which achieve this relationship. Second, the data obtained as a result yielded by BioGuideSRS to the user is systematically associated with the path which has been used to obtain it. In this way, the user knows the exact sequence of sources and links used. This approach was demonstrated with the ZOOM*UserViews system.

Future Directions

Metadata management remains a critical issue for the Life Sciences. First, the community has not agreed on common metadata to publish together with a resource so that it is properly identified, located, and used by scientists. Multiple discussions related to the representation of scientific objects generate the design of a large number of ontologies as published by the Open Biomedical Ontology (OBO) group. Although this effort contributes significantly to the better understanding of scientific information, it produces ontologies that may overlap and that are difficult to integrate. This semantic gap is aggravated by the diversity of models and formats used by biological data providers. Moreover, the community shows reluctance to adopting recommendations from the W3C Semantic Web for the specification of resources. The lack of a common publishing process for resources affects their impact significantly. In particular, it challenges the development of resource repositories to support resource discovery. Consequently, it affects the ability for scientists to select resources suitable to implement the scientific tasks involved in their protocols. The development of adequate technology, still in its infancy, is rather limited by the lack of a *franca lingua* for metadata. Future developments include the identification of metrics that adequalety capture the characteristics of resources, the design of benchmarks to evaluate and compare similar resources, automated data curation approaches that exploit and update resource metadata, automated classification of resources, data provenance analysis, etc.

Biological Networks

AMARNATH GUPTA
University of California-San Diego, La Jolla, CA, USA

Synonyms

Biological pathways; Molecular interaction graphs; Signal transduction networks; Transcriptional networks; Protein-protein interaction networks

Definition

A biological network is a graph-structured representation of binarized interactions among biological objects. Typically, the nodes in such a graph represent biological molecules, and the edges are labeled to represent different forms of interactions between molecules.

Example: A transcriptional network is a directed graph where a node represents either a protein (a transcription factor) or a region of the chromosome such that the edges can be constructed from the protein node to the chromosomal region. The edge in the graph represents that the protein can initiate the transcription (production of messenger RNA) process.

Key Points

A biological network is typically a node and edge attributed graph, where the edges can have different semantics depending on the kind of network. In some networks, the edges may be weighted, denoting, for instance, the probability of the interaction taking place. In some networks, like the protein-protein interaction graph, the edges are undirected. In some cases, like signal transduction networks, the edges represent the flow of time. Querying, integrating, and simulating are typical operations performed on biological networks.

Definition

Resources for the Life Sciences include various expedients including (access to) data stored in flat files or databases (e.g., a query form or a textual search engine), links between resources (index or hyperlink), or services such as applications or tools. *Resource discovery* is the process of identifying and locating existing resources that have a particular property. Machine-based resource discovery relies on crawling, clustering, and classifying resources discovered on the Web automatically. Resource discovery systems allow the expression of queries to identify and locate resources that implement scientific tasks and have properties of interest.

Historical Background

Resource selection relies on the identification of the resources suitable to achieve each task and the ability to compose the selected resources into a meaningful and efficient executable protocol. Metadata constitute the core information requisite to evaluate the suitability of Life Sciences resources to achieve a scientific task. Metadata critical to resource discovery include (i) resource publication, identification, and location, and

(ii) semantic and (iii) syntactic descriptions. First scientists need to be aware of existing resources. If academic publications such as Nucleic Acids Research (NAR) [7] or BMC Source Code for Biology and Medicine have provided valuable media where bioinformaticians may publish their resources, they require significant manpower to identify and evaluate the potential of each resource and compile and record their location and description for future use. Core resource description in a unified format accessible to scientists and machines alike and resource repositories contribute greatly to ease the problem of resource identification and location.

Foundations

Resource discovery relates to the activity of identifying a resource suitable to implement a particular task. Resource discovery relies on various metadata that specify the characteristics of resources thus allowing the mapping of the requirements to the resource specifications. The type of metadata chosen to represent resources will constrain resource discovery. For example, textual metadata drawn from a controlled, hierarchical vocabulary, support resource discovery by automatically expanding search terms to include more-specific terms. However, textual metadata are not sufficient when searching on specific criteria; for example, consider a researcher interested in finding datasets of *"MRI images for subjects between the ages of 18 and 24"*. Syntactic (formats) and semantic (concepts) metadata describe how a resource is organized and provide some insight into what type of information might be found in the resource while summary metadata specify the content of the resource. Although structural metadata are normally generated to help application developers understand how to interact with the resource, they can also be collected to support resource discovery. For example, in the caBIG framework, structural metadata are represented as common data elements. Each common data element references a common terminology (the NCI thesaurus in this case) and may also contain free text documentation describing that data element both providing a semantic representation of the resource. The metadata registry also maps common data elements to resources that provide instances of that element. An application developer searches the metadata registry by providing a collection of keywords; the registry returns a list of data elements that contain those keywords.

Resource discovery is the interface between resource metadata on one side and resource integration to implement complex scientific protocols (or workflows, queries, pipelines) on the other. Indeed the motivation for discovering a resource is drawn from the need to implement a scientific task. Most approaches to support resource discovery only locate one resource at a time, regardless of their future composition to implement complex workflows. In contrast, path-based guiding systems such as BioNavigation and BioGuide provide the ability to express resource discovery queries to identify resources that can be composed to express scientific protocols expressed as connected scientific tasks [4].

Key Applications

BioMoby is an open source, extensible framework that enables the representation, discovery, retrieval, and integration of biological data from distributed data repositories and analysis services. By registering their analysis and data access services with BioMoby, service providers agree to use and provide service specifications in a shared semantic space. The BioMoby Central registry now hosts more than a thousand services in the United States, Canada, and several other countries across the world. BioMoby uses a datatype hierarchy to facilitate the automated discovery of Web services capable of handling specific input datatypes. As a minimal Web based interface, the Gbrowse Moby service browser can be used by biologists to discover and invoke biological Web services from the Moby registry and seamlessly chain these services to compose multi-step analytical workflows. The process is data centric, relying on input and output datatype specifications of the services. The Seahawk client interface can infer the datatype of the input data files directly and immediately presents the biologist with a list of Web services that can process the input file. Users of the Seahawk interface are relieved of the necessity to familiarize themselves with datatype hierarchies, and instead are free to concentrate on the analytical aspects of their work. The BioMoby service encyclopedia provides a query interface to the repository of services. MOBY-S Web Service Browser retrieves bioinformatics resources with respect to a data type. Additional interfaces to BioMoby services include registry browsers that provide access to the complete list of registered BioMoby services organized in a HTML page.

These interfaces are convenient when searching for services with respect to a specific data format (input), but they are not suitable when searching for services with respect to their scientific meaning rather than their format. Another critical limitation of the approaches occurs when no single service achieves the task. In order to allow the discovery of the services that can be used to express scientific protocols, combinations of services must be retrieved. Scientific data integration systems such as workflow systems [6] enable the composition and execution of bioinformatics services. Combining a workflow approach with a service representation that guarantees compatibility of data formats offers a great value to the scientist who has selected the services to use and wishes to combine them in an executable workflow. A resource is selected because it uses or produces the expected format (e.g., `FASTA`) rather than because it implements the expected scientific aim or because it is efficient. This is illustrated by the BioMoby plugin in Taverna. When a BioMoby service, e.g., '`DragonDB_TBlastN`', is included in a workflow its output format, e.g., `NCBI_BLAST_TEXT`, can be searched (brief search) against available formats to determine if it is an input to any other service registered in BioMoby [9]. The characterization of a resource provided by existing formats such as Web services does not include the level of metadata necessary to evaluate the suitability of resources beyond the description of its input and output. More advanced resource formats such as OWL-S, WSDL-S, SAWSDL, and BioMoby aim at providing a semantic layer to capture better what the resource does in addition to its input and output data formats. The semantic part of the resource registration allows the classification of resources into a hierarchy of classes thus enhancing resource discovery. For example, the semantic search method of the BioMoby plugin in Taverna traverses the object ontology and recursively extracts the parent nodes of that particular output object [9]. However existing approaches do not offer an interface that allows the discovery of services with respect to their scientific meaning expressed in an ontology. To overcome this difficulty, path-based guiding systems such as SemanticMap and BioGuide can be combined with integration platforms to allow the discovery of resources suitable to implement scientific workflows. For example, BioGuide extends SRS [5] to allow a unique interface to discover resources and express queries over integrated data sources [3].

Resource discovery can exploit further resource metadata to predict the outcome of a workflow execution and select the resource more likely to produce the expected output. For example, BioNavigation [4] exploits various statistical metadata combined with semantic data to rank resources with respect to the users' criteria. Resources are ranked with respect to their cardinality, the characterization of their entries (number of attributes), etc. A user interested in *retrieving as many genes involved in a particular disease* selects a path in a domain ontology together with the corresponding ranking criteria. BioNavigation returns a ranking of all implementations of the conceptual path [10].

BioSpider is a system that integrates biological and chemical online databases. Given a biological or chemical identifier, BioSpider produces a report containing physico-chemical, biochemical and genetic information about the identifier. Ngu et al. [11] proposed an approach to classify search interfaces by probing these interfaces and trying to match the control flow of the interface against a standard control flow. InfoSpiders is a multi-agent focused crawler specialized for biomedical information whose goal is to fetch information about diseases when given information about genes. The Adaptive Crawler for Hidden-Web Entry Points (ACHE) is a focused crawler specialized for locating searchable Web forms that serve as entry points to online databases and Web services. Context-Aware Form Clustering (CAFC) is a clustering approach that models Web forms as a set of hyperlinked objects and considers visible information in the form context – both within and in the neighborhood of forms – as the basis for similarity comparison. A repository of scientific resources was automatically compiled using the approach [1].

Future Directions

Biological resource discovery remains a critical issue for the Life Sciences. The development of a system to support resource discovery is directly constrained by the information pertaining to scientific resources made available to the users as well as the formats designed to represent these rich metadata. For these reasons research on resource discovery for Life Sciences still is in its infancy. Scientists dramatically need assistance at each level of the process from the identification of the resources that best would meet the experimental requirements to the actual composition of the resources in an executable workflow. Future developments include the design of systems that combine various orthogonal aims for resource selection such as semantics (what the resource does), statistics (prediction of the result), syntax (schema mapping for resource compsition), performance (efficiency), quality, etc.

Biological Sequences

Amarnath Gupta
University of California-San Digeo, La Jolla, CA, USA

Synonyms

DNA sequences; Protein sequence

Definition

A biological sequence is a sequence with a small fixed alphabet, and represents a naturally occurring or experimental generated fragment of genetic or protein material or any intermediate product (like the messenger RNA).

Example: A DNA fragment has the 4 character alphabet 'A', 'C', 'T', 'G'. Chromosomes are long strings over this alphabet.

Key Points

Biological sequences can be long. A full chromosome may have millions of characters. Therefore development of proper storing and indexing strategies is very important for fast retrieval. Suffix tree based indexes have been used successfully for long biological sequences. Further, approximate string matching techniques with potential deletions and insertions are important for biological sequences. BLAST is a well known algorithm used for approximate matching and ranking of biological sequences.

Biomedical data annotation

Definition

The largest source of biomedical knowledge is the published literature, where results of experimental studies are reported in natural language. Published literature is hard to query, integrate computationally or to reason over. The task of reading published papers (or other forms of experimental results such as pharmacogenomics datasets) and distilling them down into structured knowledge that can be stored in databases as well as knowledgebases is called curation. The statements comprising the structured knowledge are called annotations. The level of structure in annotation statements can vary from loose declarations of "associations" between concepts (such as associating a paper with the concept "colon cancer") to statements that declare a precisely defined relationship between concepts with explicit semantics. There is an inherent tradeoff between the level of detail of the structured annotations and the time and effort required to create them. Curation to create highly structured and computable annotations requires PhD level individuals to curate the literature. In the molecular biology research community, this task is performed primarily by curators employed by genome databases such as the saccharomyces genome database [7]. In the biomedical research community this task is performed by curators employed by community portals such as AlzForum for Alzheimer's research [9] and PharmGKB for pharmacogenomics [31]. In the medical community such curation is still an ignored task, with some groups, such as RCTBank [26], pioneering the effort to curate clinical trial reports.

Historical Background

In the biomedical domain, curation began with the formation of cDNA, EST and gene sequence databases such as GenBank. Initially, curation was restricted to the task of assigning a functional annotation (usually in free text) to a sequence being submitted to GenBank. Scientists performing the experiments and submitting the data performed the task on their own. With the rise in the amount of sequence data and subsequently data on the function, structure and cellular locations of gene products along with the formation of communities of researchers around specific model organisms, the task of curation gradually became centralized in the role of a curator at model organism databases. Interaction amongst the curators and leading scientists led to the creation of projects such as the gene ontology project [1] in 1998, which led to a systematic basis for creating annotations about the molecular function, biological process and cellular locations of gene products. In subsequent years, user groups formed around other kinds of data, such as microarray gene expression data, resulting in the creation of information models for structuring the metadata pertaining to high throughput experiments. Individual research groups, such as Ecocyc, have already maintained a high level of curation effort, particularly for Information about biological pathways; although it was the success of the gene ontology project that resulted in the widespread appreciation for the need of curated content. With the continued rise in the amount and diversity of biomedical data, the need for curation continues to increase; both in terms of the number of man-hours required and in the level detail desired in the resulting annotations.

Foundations

In the course of their work, biomedical investigators must integrate a growing amount of diverse information. It is not possible for scientists to bring together this large amount of information without the aid of computers. Researchers have turned to ontologies – which allow representation of experimental results in a structured form – to facilitate interoperability among databases by indexing them with standard terms as well as to create knowledge bases that store large amounts of knowledge in a structured manner. Ontologies provide researchers with both the structure into which experimental results, facts and findings have to be put into as well as the words (or terms) to be used in populating the structure with instances [8,14]. If the ontologies are well-designed, then the resulting knowledge bases can be used to retrieve relevant facts, to organize and interpret disparate knowledge, to infer non-obvious relationships, and to evaluate hypotheses posited by scientists.

Assertion annotations – assertions or statements about the relationships among biological entities and the processes in which they participate – are a crucial link between abstractions of experimental results and the theory (or theories) that explain the underlying results. The national center for biomedical ontology develops methods and tools that enable the easy creation of such assertion annotations [11]. However, even with tool support, the creation of assertion annotations is manual, hard and expensive. In addition to this annotation as assertion viewpoint, another predominant use of annotations is to provide metadata for datasets stored in databases. In this case, these metadata-annotations are not assertions about any biological entity but instead provide additional information about the experiment or dataset examining the biological entity. Such metadata-annotations provide information about experimental conditions, the disease that the dataset pertains to, the perturbation applied during the experiment, and so on. Metadata-annotations do not state a biological fact like an assertion based on interpretation of experimental results. These two kinds of annotations: (i) assertion annotations and (ii) metadata annotations, are highlighted in Fig. 1.

Curation is the process by which annotations (either assertions or metadata) are created. (The word "annotation" is also used by some as a verb to describe this process of curation to create annotations; this has lead to wide-spread confusion in the community about the meaning of annotation.) Until now curation has been largely a manual process requiring highly qualified individuals to read and interpret the text in published papers to create the annotations. It is important to note that even though curation is carried out by skilled personnel, different curators have different opinions on what "knowledge" is being reported in the paper. Increasingly, automated methods are being employed to assist in the curation task because of the fact that manual curation is unlikely to scale and keep pace with the growth of biomedical data and literature [3]. Curation is typically carried out using a tool that allows the curator to select relevant ontology terms and associate them with the entity being annotated. The same tool writes out the resulting annotations in a custom format.

Technical Issues

The Different Types of Expressivity of Ontologies/Vocabularies Used to Create the Annotations As discussed, annotations can range from simple terms that are "associated" with a particular resource to structured

Biomedical Data/Content Acquisition, Curation. Figure1. Shows the relationship of the assertion-annotations and metadata-annotations with datasets. The dataset is analyzed by a researcher to make a fine grained statement (a), which states the particular observation made in the dataset and reported in a publication. Several such statements get published in scientific papers. A curator, after reading a multitude of these papers creates an *assertion-annotation* (such as a GO annotation) as a summary statement (b) based on the fine grained statements. The dataset is also described by the researcher in terms of the disease studied, the cell lines used, the experimental conditions that existed etc. This description (c), comprises the *metadata-annotation* of the dataset, and is usually in natural language; although at times it is done using a CV. (d) shows the "tag" from a controlled vocabulary or ontology that can be assigned to this dataset upon processing the text description computationally.

assertions that use explicit logical relationships. Depending on the required use – that of creating assertion-annotations or creating metadata-annotations – the ontologies used in the annotation process need to have adequate expressivity in terms of the different relationships the user can use during the curation process. A detailed discussion on the kinds of relationships that are available in biomedical ontologies is can be found in [27]. The most widely used artifacts for annotation are controlled vocabularies (CVs). A CV provides a list of terms whose meanings are specifically defined. Terms from a CV are usually used for indexing records in a database. The Gene Ontology (GO) is the most widely used CV in databases serving biomedical researchers [1]. The GO provides terms that are "associated" with particular gene products for describing their molecular function (MF), biological process (BP) and cellular component (CC). Arguably, CVs provide the most return-on-effort in terms of facilitating database search and interoperability.

Storage Schemes and Data Models to Store These Annotations in Underlying Databases Most annotations when created initially are stored as flat text files. However in order for the annotations to be useful to researchers, they need to be stored in database systems that support efficient storage and querying. Naturally the database schema and the data model to which the annotations conform to becomes an important issue. Until recently the trend was to create a relational schema corresponding to the annotation model used for a particular curation workflow and each group created its own annotation model as well as schema. This lead to various "silo" databases that need to be mapped to one another. The need for such mapping lead to the creation of groups, such as BioPAX, which proposed "exchange formats" to map silo databases to one another [4]. Recently, semantic web technology is receiving a lot of attention in the biomedical community because of the promise of "automatic" interoperability if different groups use consistent identifier (URIs) as well as the Resource Description Framework (RDF) format to describe entities and resources in their annotations [22].

Techniques for Indexing the Curated Annotation for Retrieval Assuming the issue of creating annotations (manually or computationally) is adequately addressed, special attention needs to be paid to the appropriate indexing of annotations. For example, once a publication is annotated by associating it with the term *melanoma*, in order to ensure appropriate retrieval when someone searches for *skin neoplasms* it is essential to index the same paper with terms such as *skin neoplasm* (because *melanoma* is a kind of *skin neoplasm*). This can be accomplished by pre-computing all such inferred annotations or by real time query expansion using the hierarchy among the terms *melanoma* and *skin neoplasm*.

Workflow Aspects of the Curation Process As noted before, different curators can have different opinions on what "knowledge" is being reported in the paper. The level of this agreement is quantified by calculating inter-curator agreement using a variety of methods [6]. Using detailed curation guidelines, many projects achieve inter-curator agreement in the range of 85–90% and some as high as 94% [6]. Currently, curation is typically carried out using a tool, such as Phenote, (www.phenote.org.) that allows the curator to select relevant ontology terms and associate them with the entity being annotated. The same tool writes out the resulting annotations in a custom format. Usually the workflow for curation differs by organization and the kinds of source (such as published papers or medical records or clinical trials) being curated. Currently, there are no off-shelf workflow systems that provide a generic curation workflow. Increasingly curation is becoming web based and the tools used for curation are tied to a database which stores the annotations (See the Alzforum and SWAN projects for an example). There are also efforts to make curation collaborative, and several wiki-based projects such as wikipathways (www.wikipathways.org) are underway in the field.

Key Applications

The discovery process in biomedical research is cyclical; Scientists examine existing data to formulate models that explain the data, design experiments to test the hypotheses and develop new hypotheses that incorporate the data generated during experimentation. Currently, in order to advance this cycle, the experimentalist must perform several tasks: (i) gather information of many different types about the biological entities that participate in a BP, (ii) formulate hypotheses (or models) about the relationships among these entities, (iii) examine the different data to evaluate the degree to which his/her hypothesis is supported, and (iv) refine the hypotheses to achieve the best possible match with the data. In today's data-rich environment, this is a very difficult, time-consuming, and tedious task.

If existing data, information and knowledge are curated to create knowledge bases that store large amounts of knowledge in a structured manner [14,15] the resulting knowledge bases can be used to retrieve relevant facts, to organize and interpret disparate knowledge and to computationally evaluate hypotheses and model posited by scientists [2,18,19]. For example, EcoCyc is a comprehensive source of structured knowledge on metabolic pathways in E. Coli and can be used to reason about E. Coli metabolism. Reactome is a source of structured knowledge on BPs related to signal transduction, gene regulation and metabolism in eukaryotic organisms [13]. The creation of such knowledgebases requires that the task of curation be carried out with great detail and that the tradeoffs between the complexity of the annotation structure required and the curation overhead entailed by that be balanced. Understanding the curation cost is a significant factor in determining the feasibility of proposed knowledge-driven applications [12].

There are several public as well as private groups that curate biomedical literature and other data to create highly structured knowledge bases. A majority of these knowledge bases are centered on biological pathways and Ecocyc and Reactome are the leading examples. In Pharmacogenomics, PharmGKB is a resource that provides curated knowledge on the interactions between genotype and pharmacological effects of drugs [31]. The Semantic Web Applications in Neuroscience (SWAN) project is a resource providing curated knowledge on Alzheimer's research with a focus on capturing the evolving scientific discourse as the research progresses [16]. In the commercial sector, companies such as Ingenuity offer subscription access to curated literature content as well as curation-for-fee services.

Such curated and structured content is primarily used to interpret the results of high-throughput datasets in the light of prior knowledge. At the simplest level, coloring nodes of a pathway according the increase or decrease in their expression level in a particular assay is a widely used approach. Another widely used approach is that of counting the annotations, such as the association with a particular BP, assigned to a set of biological entities, such as genes deemed significant for a particular cancer, and analyzing for a statistically significant difference in the distribution of the annotation counts as compared to a reference such as the set of all the genes assayed.

The other key use of curated and structured content is to support computer aided reasoning; with the goal of inferring possible explanations for biological phenomena [25], for evaluating alternative explanations for biological phenomena[19], for automated question answering [29] and automatically constructing as well as extending existing structured descriptions of BPs such as pathways [23].

Future Directions

As the amount and diversity of data, information and knowledge rise in the biomedical domain, there is a recognized need to be able to compute with the existing knowledge [5]. As the use of ontology rises in the biomedical domain [30], the appreciation for the need of curated content is also rapidly increasing; along with the realization that manual curation is unlikely to keep pace with the needs of the community [3].

These trends have led several groups, such as the BioAI group at Arizona State University and the SWAN group, to propose the use of distributed and collaborative curation in an attempt to leverage the "wisdom of the masses" [10,17]. Collaborative curation holds tremendous promise for the field if the community can arrive at an agreed upon platform and formalism using which researchers can contribute structured content. The other clear future direction is the use of text-mining in the curation pipeline as a "force multiplier" to increase the productivity of existing curation efforts. The computational pharmacology group at University of Colorado is conducting exciting research in this direction. Both community-based collaborative curation as well as the use of text-mining to increase the efficiency of curation tools will be activities to follow closely for those interested in biomedical data acquisition and curation.

Biomedical Image Data Types and Processing

Sameer Antani
National Institutes of Health, Bethesda, MD, USA

Synonyms

Data Types: Image, Video, Pixel, Voxel, Frame; Conceptual data types: Pixel, Point, Edge, Volume, Region of interest, Shape, Color, Texture, Feature; Format: Joint photographic experts group (JPEG), Digital imaging and communications in medicine (DICOM), JPEG2000, Imaging Technique: X-Ray, Magnetic resonance imaging (MRI), Computerized tomography (CT), Ultrasound, Positron emission tomography (PET), Nuclear magnetic resonance (NMR), Microscopy, Single photon emission computerized tomography (SPECT), Fluoroscopy; Image Processing: Compression, Wavelet compression, Functional mapping, Image reconstruction, 2D image processing, Texture analysis, Edge detection, 3D image processing, Surface detection, Image content analysis; Storage and Retrieval: Image databases, Content-based image retrieval (CBIR), Visual similarity, Feature indexing, Multimedia information retrieval

Definition

The entry term describes biomedical image types (X-Ray, CT, MR, PET) stored in a particular format (DICOM, JPEG) that can be processed for visual enhancement (windowing, leveling) or extraction of features for further processing as needed in specific applications (generate 3D volumes from 2D slices, Content-Based Image Retrieval (CBIR)).

Historical Background

Both image processing and databases have been studied for over four decades. Biomedical processing and storage systems have received significant attention within the last two decades. Imaging and image processing has gained significant importance in clinical medicine, biomedical research and education and correspondingly, biomedical image databases have also found increasing use in recent years. Images are still largely stored as flat files on file servers and made accessible via links stored in revelant database records. Significant progress has been made in image types, formats, and content being computed and stored in these databases. This information can help in processing and further use of these data. Image and image feature indexing is a topic of significant research interest with some specialized types are already in practical use.

Foundations

Imaging has taken on a very important role in clinical medicine, biomedical research, and education. Biomedical visual data are acquired using a variety of techniques: single frame images; 3D volumes composed of single frame images; and made and as time-synchronized multiple frames as video data. In addition, these data are acquired at varying scales ranging from gross anatomy to the cellular level. Each image data type has specific acquisition methods, set of image processing methods for feature extraction that aid in analysis for targeted purposes, compression and storage methods, and particular data handling methods [1]. The image database primarily serves as a file storage mechanism with various processes for analysis and retrieval traditionally included in utility applications. Image databases are typically found in practical use as “multimedia databases” or “multimedia information systems” in the form of Radiological Information Systems (RIS), Hospital Information Systems (HIS), and Picture Archiving and Communication Systems (PACS). Such systems link textual data to image data through file links stored in database records. Image databases imply use of image feature indexing strategies such as metric index trees, multidimensional data trees, spatial databases, and R-trees, for specialized use such as Content-Based Image Retrieval (CBIR) [8].

Image data types are challenging to define in standard terms such as integers, characters, strings, etc. An image is composed of pixels or in case of 3D images may be considered to composed of a set of elements of conceptual data type called voxels. Wikipedia (http://www.wikipedia.org) defines voxel as a portmanteau of words volumetric and pixel representing a unit element on a 3D image. Each such element (pixel or voxel) can be considered a complex data type as its content may be expressed using *n*-bits where *n* may be 8, 12, 16, 24, or 32. Typically 8-, 12-, and 16-bit images are gray scale images. A color pixel is typically 24-bits in depth comprising of three 8-bit channels for the additive color primaries (RED, GREEN, BLUE), though it is possible to have color images with other bit depths. This information is not natively stored in the image but needs to be exposed to the application through image metadata that may be stored in particular formats, such as a DICOM (http://dicom.nema.org/) on JPEG image header [6].

The images can be generated using a variety of techniques. Radiographic or X-Ray images, Computerized Tomography (CT), Magnetic Resonance images (MRI), Positron Emission Tomography (PET) images are examples of various imaging techniques. Techniques such as CT and MRI image the desired anatomical region in closely spaced sections. These sectional images can then be processed to create views along desired axes (axial, coronal, sagittal, oblique) as well as generate 3D volumetric data rendering.

Image processing is a term that includes functions and methods that focus on enhancement of images for improved human visualization or computer analysis, such as windowing, leveling, object edge detection, among others [3,9]. It also is synonymous with application of methods whereby features such as edges, textures, and surfaces, among others, can be computed for making measurements, computer-aided diagnosis, visual enhancement, identifying anatomical structures, determining unique image content signature, etc. For instance, using the above example of generating 3D volumetric data from 2D image slices, for a data set of MRI slices of the brain, it would be necessary to segment the edges from each 2D MRI image slice and register them with corresponding edges from the same anatomy in other slices. The next step would be to convert these edges into surfaces formed across these slices in order to generate 3D volumetric data.

With the increasing use of images in medical care and research, it becomes necessary make this data connect with other image and non-image data. The resulting database systems have evolved as PACS, RIS, and HIS and are commonly found in modern hospitals and medical centers. These database systems are capable of storing and retrieving text data, for example, a patient record containing test results and other medical history, along with image data. The systems may exist on a single computer, a local network of computers, or distributed over a wide area network. Variants of these systems developed for medical research studies can also correlate between different study participant information and keep track of longitudinal information.

In database processing it is often necessary to define the image to be of a particular type. This can assist in data and type verification as well as communication of semantics to other applications that may be using the data. Some database systems require storage of images in their native form as undefined BLOB data types while others, including most PACS, prefer to maintain references to image data files that are stored in traditional directory (folder) file structures. The choice between these approaches is largely determined by storage and computational efficiency and dependent on particular applications and solutions. In either scenario it is efficient to store the image metadata as database records. While this information may be available in image header files, it requires the additional step of accessing and opening each image file for any database operation involving images.

Image processing steps often result in features extracted from images. These features could be regions of pixels, measurements of color, texture, edges forming a shape, surfaces, etc. Each of these features could be standardized to be a data type or could use standard data types, e.g., a 3-channel color histogram could be represented using 3D arrays that could represent 3D histograms. Each such conceptual type may be used as a predefined data type. Other operations could include transforming the image or extracted characteristics from the spatial domain several into other domains through Fourier analysis or Wavelet transforms. Selecting these or other image processing methods is heavily dependent on the nature of the images and several methods are covered in [1,3,9]. Further, it may be necessary to compress the images in order to minimize data storage requirements or improve transmission efficiency over networks. These decisions must be made carefully in light of possible data loss found in typical implementations of common image compression methods such as JPEG or JPEG2000 [6].

In summary, biomedical image processing is critical to analysis and use of biomedical images for clinical medicine, research and education. These images may also have other associated images as well as text data. All this information is stored in biomedical databases that use a combination of image types, header information, image units, and content through the extracted features as data types. Images may be indexed through multidimensional indexing trees or be linked to flat files stored in a folder or accessed via a file server.

Key Applications

Multimedia Medical Information Systems: Medical Information Systems, like the PACS, hold medical data about patients, medical research study participants, etc. This medical data is typically heterogeneous comprising of electronic medical records containing the medical history, clinical notes, lab reports, and any acquired images. The text data can be fielded or exist as a block of free text. The image data can be from various sources and in a variety of formats. As such, a PACS can be considered a special type of a Multimedia Medical Information System. Another example of a Multimedia Medical Information System is the Multimedia Database Tool (MDT) being developed at the National Library of Medicine (NLM), part of the National Institutes of Health (NIH). The MDT is a Web-based system [5] with a MySQL back-end database that enables retrieval of text and image data in response to specific queries. For example, from a database of a cervical cancer study being conducted by the National Cancer Institute (NCI) one could query for "all women with cervical intraepithelial neoplasia 3 whose cytologic results are atypical squamous cells of undetermined significance."

The MDT was developed to access, evaluate, and collect information from thousands of uterine cervix images or cervigrams for cancer studies. It is one of two systems developed to work with these images: the boundary marking tool (BMT) for marking areas of particular importance in the images and the MDT for Internet dissemination of the images and to relate them with text data and information collected with the BMT. The MDT has system architecture capable of deploying color images and related information on the Web with minimal reprogramming. It has the flexibility to accept new datasets with the required customization performed at the level of a database administrator, rather than a programmer. It also has the capability of querying a database of text and images over the Web, of showing the query results consisting of multiple images and text data, and of exporting these results for statistical analysis. Additionally, the MDT is designed for data collection from remote users; given adequate password protection and anonymized data to assure patient privacy, experts worldwide will be able to access the data resource. Through the Internet, they will evaluate images and test data, perform analysis of the information, and record their evaluations in a central database. Additionally, because of its architecture, the MDT system can support a broad class of text and image databases. Therefore, the MDT is designed to grow if additional groups wish to merge their data on cervical cancer or to use it to manage their own multimedia collections.

Content-Based Image Retrieval (CBIR): While the MDT allows querying of text and images using text keywords and structured SQL-like queries, an alternative complementary form of image-based querying has gained significant research interest in recent years. This approach, called Content-Based Image Retrieval (CBIR), uses distinguishing features extracted from images to serve as indices. These features are then used to find images similar to an image query. For example, in the Spine Pathology Image Retrieval System (SPIRS) [4], developed at NLM, the boundary edges of individual vertebra are used to query the X-ray images of the spine captured as a part of the Second National Health and Nutrition Examination Survey (NHANES II). This shape feature was chosen because the pathology of interest is expressed along the vertebral boundary seen in the spine imaged on the sagittal plane. Perturbations along the boundary are indicative of pathology. In contrast, the set of cervigrams from the NCI cancer study is an example of an image class where color, texture, and location information are much more important than edge information. In this latter case, the pathology of interest is acetowhitened regions [10] on the cervical wall.

Finding similar images tends to be a very subjective matter and is heavily dependent on the extracted features from the images. Additionally, it is also dependent on the level of detail extracted. For example, one measure of image similarity is overall appearance of the image, which in case of X-Ray images, can be characterized by a histogram of pixel intensity levels in the image. While this *global* measure may be sufficient for overall similarity, it is insufficient in expressing *local* pathology that can only be captured by feature extraction within the region of interest. An intelligently implemented hierarchical strategy works better in a heterogeneous collection of images.

Given the subjective nature of image content and human perception, it is challenging to evaluate systems through system characteristics or reported performance measures alone. These results are sensitive to the kinds of image data that the system is operating on, extracted features, query capability, and several other gaps that need to be overcome for developing an "ideal" system. A framework for these gaps is discussed in [2]. Other medical systems are reviewed in [7]. The Cross Language Evaluation Forum (CLEF) benchmarking competition has evaluates image classification and image retrieval in a biomedical setting on an annual basis (CLEF-Campaign, http://www.clef-campaign.org) and permits use of text data commonly found with medical images to improve usability. Due to the transient nature of academic systems, and lack of detail available in commercial systems, such a venue provides valuable metrics for comparing various systems and assessing the state-of-the-art.

Definition

Vast amounts of biomedical scientific information and knowledge are recorded in text [1,7]. Various scientific textual data in the biomedical domain may generally be disseminated through the following resources [7,11]: biomedical literature (e.g., original reports and summaries of research in journals, books, reports, and guidelines), biological databases (e.g., annotations in gene/protein databases), patient records (e.g., clinical narrative reports), and web content.

A variety of techniques have been applied to identify, extract, manage, integrate and exploit knowledge from biomedical text. Some researchers [11] divide biomedical scientific textual data processing into three major activities as shown in Figure 1: information retrieval (IR), information extraction (IE), and text mining (TM).

Information retrieval [2,11] is the science of indexing and searching for information particularly in text or other unstructured forms. The aim of IR is to identify relevant documents in response to a particular query, which forms the basis of any knowledge discovery process.

Information extraction [11] aims to identify and extract categorized or semantically well-defined data (entities, relations or events) from text documents in a certain domain, as well as to create structured knowledge bases that can be accessed by other informatics applications. Typical subtasks of IE are named entity, relation and event recognition (e.g., recognition of protein names and interactions between proteins), coreference (e.g., identifying whether a chain of noun phrases refer to the same object), and terminology extraction (e.g., finding the relevant terms for a given corpus).

Text mining (TM) [2,6] is the process of discovering and extracting interesting and non-trivial patterns and knowledge from unstructured text data. The primary goal of TM is to retrieve knowledge that is hidden in text, and to present the distilled knowledge to users in a concise form. Typical subtasks of TM may include pattern discovery, hypothesis generation, correlation discovery, etc. However, some researchers give a broader definition of TM which overlaps with IR and IE on certain tasks such as text classification, text clustering and named entity recognition.

Historical Background

Before the invention of computers, results of biomedical research have been published as journal or conference prints for a long time. Bibliographic databases that typically contained references to literature on library shelves was the first application of using computers to improve library service. MEDLINE (Medical Literature Analysis and Retrieval System Online) is the U.S. National Library of Medicine's (NLM) premier bibliographic database that contains over 16 million references to journal articles in life sciences with a concentration on biomedicine. As an online interactive searchable bibliographic database, MEDLINE was introduced in 1971 by NLM, to replace its previous version called MEDLARS (Medical Literature Analysis and Retrieval System). In 1997, PubMed was developed by the National Center for Biotechnology Information (NCBI) at the NLM, to provide free and efficient access to MEDLINE through the World Wide Web. Currently, MEDLINE/PubMed is probably the best-known biomedical literature reference database. The use of high-throughput experimental technologies has dramatically increased the pace of biomedical knowledge discovery. In 2006, over 623,000 references to published articles were added to the MEDLINE database. A large amount of effort has been spent on improving the performance of IR on the MEDLINE database. A distinctive feature of MEDLINE is that the records are indexed with NLM's Medical Subject Headings (MeSH).

Biomedical Scientific Textual Data Types and Processing. Figure 1. Major stages of processing biomedical scientific textual data and relevant subtasks [11].

During the past decade, more and more full-text biomedical publications have become available on the Internet, though most of them have restricted access. In 1999, a bold new initiative called PubMed Central (PMC) was designed at the U.S. National Institutes of Health (NIH) to provide a central repository for literature in the life sciences with open access. To date, there are more than 300 journals that have joined PMC and they provide free access to their publications. BioMed Central, a commercial publisher, also provides free access to papers published in their journals.

Various text processing methods, such as natural language processing (NLP) and machine learning (ML) technologies, have been extensively studied in the domain of computer and information science. However, they have not been widely applied to biomedical text before the 1990s, largely due to the lack of available biomedical text. Starting at the mid 1990s, text processing technologies have been gradually applied to biomedical text on different tasks, such as information retrieval, biomedical entity recognition, text clustering and classification, and knowledge discovery.

Foundations

As mentioned above, biomedical scientific textual data processing applies methods and technologies from multiple disciplines, including linguistics, computer science, statistics, and so on. In general, the major stages of processing scientific textual data to exploit rich knowledge include retrieval of relevant documents, extraction of named entities and relations, and discovery of new knowledge. However, some processes may not follow the exact steps. This entry adopts a classification by Natarajan et al. [11] on major constituent technologies for knowledge discovery in text (see Fig. 1). Scientific fundamentals for each stage will be discussed in the following sections.

Information Retrieval

Conventional IR methods are often based on keyword queries, using Boolean logic, vector space models or probabilistic models [1,7]. One of the simplest forms of IR is to search keywords in documents that are indexed by a set of keywords. Search algorithms are used to identify the relevant documents based on the number of index keywords that match query keywords. One disadvantage of this approach is that the documents are determined either relevant or irrelevant. There is no further ranking. Vector space model is an algebraic model for representing text documents. When applying the model to IR, both the query and documents are represented as vectors, whose dimensions correspond to different terms in the query or documents. There are different methods to compute the weight of terms in the vectors and the tf-idf weighting is one of the best known schemes. Relevancy rankings of documents to a query can be determined by calculating the document similarities between the query and documents, via measurements such as cosine similarity of two vectors. Probabilistic models treat the process of document retrieval as a probabilistic inference and similarities are computed as probabilities that a document is relevant for a given query. An advantage of probabilistic model is that documents are ranked in decreasing order of their probability of being relevant to the query.

Information Extraction

Approaches to named entity recognition generally fall into three categories: lexicon based, rule based and statistically-based [1]. For example, part-of-speech tagging, inductive rule learning, decision trees, Bayesian model, support vector machines, as well as combined methods have been applied to this problem. For discovering relationships among entities, variant techniques have been used. Shallow parsing is often used to focus on specific parts of the text to analyze predefined words such as verbs and nouns. Some systems combine natural language processing and co-occurrence techniques, while others apply machine learning techniques.

Text Mining

Text classification and clustering are the most widely used techniques in biomedical text mining. While text classification is a form of learning from pre-classified examples, text clustering is referred to as unsupervised learning. Bayesian models were widely used in the early days. In recent years, more advanced machine learning methods, such as k-nearest neighbors, artificial neural networks, support vector machines, expectation maximization, and fuzzy clustering have been used. Logical inference models [13] have been applied to hypothesis generation which attempts to uncover relationships that are not present in the text but instead are inferred by the other existing relationships. There are a variety of techniques for knowledge discovery from biomedical text using graphs and knowledge models.

Key Applications

Information retrieval technologies have been used extensively to help users to find relevant articles that they are interested in. MEDLINE/PubMed has used various methods to improve the performance of searches. It provides keyword-based Boolean search to allow users to search by keywords, as well as document-based search, which implements the vector space model and could find documents for similar topics. With the availability of full-text articles online, more IR applications have tried to search full-text articles for detailed information. For example, the focus of the 2006 genomics track of the Text Retrieval Conference (TREC) [8] was to retrieve answers for biological questions from full text articles. The European Bioinformatics Institute (EBI) at the European Molecular Biology Laboratory (EMBL) has developed a biomedical information retrieval system called "CiteXplore," which combines literature search with text mining tools for biology. It also links biomedical literature sources to existing bioinformatics databases, such as SwissProt.

Although most of biomedical text processing tools are still in the research stage, some of them have shown potential uses. Many information extraction systems have been used to build knowledge bases from biomedical literature. Different approaches have been reported to extract relations among biomedical entities of interest (e.g., gene/protein). GENIES (GENomic Information Extraction System) [4] is an NLP-based system that extracts molecular pathways from literature. It semantically parses sentences into a structured form for relation extraction. PASTA (Protein Active Site Template Acquisition) [5] is a system that uses manually created templates to extract relationships between amino acid residues and their functions within a protein. The PreBIND [3] system uses Support Vector Machine (SVM) technology to locate protein-protein interaction data in the literature, thus to facilitate the curation process for protein databases. IR and IE systems are also combined to build more sophisticated systems to help specific tasks in biology, such as biological database curation tools that can help curators find related articles and identify critical findings from biological articles [14]. The iHOP [9] system extracts protein-relationship from the literature. It also includes advanced search modes for discovery and visualization of protein-protein-interaction network [9].

Another potential application of text mining tools is to discover new knowledge from literature, for example, helping biomedical researchers to generate new research hypotheses. ARROWSMITH and BITOLA [9,14] are two online tools that provide the function of literature-based knowledge discovery. ARROWSMITH detects indirect associations between concepts that are not directly linked in the literature. BITOLA is designed for disease candidate gene discovery by mining the bibliographic database MEDLINE.

Biostatistics and Data Analysis

MEHMET M. DALKILIÇ
Indiana University, Bloomington, IN, USA

Definition

Biostatistics is the application of probability and statistical techniques to the biological sciences. Probability has played a significant role in areas like genetics where combinatorics validate conjectures about the relationships of genes and the environment. Recently, combinatorics has become one of the main approaches to solving problems *e.g.*, motif discovery in bioinformatics. In the nineteenth century, well-known biologists like Herman von Helmholtz advocated that biological phenomenon could be understood using techniques in the physical sciences (remnants of this view still are present today). That approach, together with the "vitalism" movement [3] impeded the use of statistics. By the beginning of this century, however, statistics has become *de rigueur* in virtually all biological publications.

Historical Background

Although statistics as a mathematical area can be traced further, biostatistics is often associated with the work of Francis Galton (1822–1911). His major contribution was demonstrating that statistical methods could be beneficial in biology. Carrying on this tradition were Karl Pearson (1857–1936) and R.A. Fisher (1890–1962). While a number of standard applications and techniques have not changed for more than half-a-century, the availability of computing has made some (heretofore infeasible) techniques available. The classic text in this area is by Sokal and Rohlf, "Biometry" [5] now in its third edition. It should be pointed out that the demarcation often cited between "frequentists" [6] and "Bayesians" [1] is fairly well evident in biostatistics. In the former, physical, repeatable, identical, and random experiments can be associated to a mathematical limit *e.g.*, $P(heads) = \lim_{flips\rightarrow\infty} \frac{\#heads}{flips} = 1/2$ is the probability of getting heads when flipping a coin. Bayesians, on the other hand presume probability to be a degree of belief (or subjective probability). This can be written as *posterior* $\propto$ *prior* $\times$ *likelihood*, in symbols $P(H|E) \propto P(H)$ $P(E|H)$. The distinctive feature is that Bayesian statisticians will associate values with the *posterior*, *hypothesis*, and *prior* (likelihood), whereas non-Bayesian statisticians will only consider the hypotheses in constrained settings. Classical statistics is often the primary choice. However, Bayesian techniques are becoming increasingly popular in systems biology–biology that integrates and evaluates disparate data usually in the form of very large graphs. In these graphs, nodes are typically genes and edges evidence of relationship.

Foundations

As explained eloquently in [5], there is a deeper philosophical debate centered on whether biological phenomena can ultimately be modeled using deterministic approaches. That debate aside, the use of statistics is continuing to grow as the amounts of biological data grow. Indeed, recent technologies (high-throughput) are producing several orders of magnitude more data in comparison to traditional approaches. Statistical tools, from this perspective, becomes a necessity. Furthermore, a growing number of biologists now believe that there is benefit in examining data normally not studied within one's own specialized domain–this is called a systems biology. While the foundations for systems biology are still under development it is clear that it will rely heavily on Bayesian reasoning. Typically the disparate experimental, textual, *etc.* data are structured as a directed, acyclic graph where nodes are random variables and edges are effects. The basic attempt is to discover sets of independent variables and form a better understanding of the joint probability. For example, one might take the some 14,000 *Drosophila m.* genes and presume a joint distribution $P(X_1,X_2,...,X_{14000})$ where X_i represents the probability that gene i has some expression level. Bayesians build large graphs relying on conditional probabilities and so-called "separations" that expose which random variables are independent of one another. They then examine the behavior of the graph under particular conditions. The interested reader is guided to [4]. Topics studied in biostatistics are too numerous to list (for example multivariate regression, analysis of covariance, linear discriminant analysis, principal component analysis, and so forth; therefore, a sample that reflects the kind of tools that are used and most prevalent techniques will be given. Most of the biostatistics used is parameteric; the models result from human expertise. This is opposed to nonparametric models (or data-driven) that rely on the data itself. With the availability of cheap, fast computation, however, the use of nonparametric models has exploded. Given a set of data $\mathbf{x} = x_1, x_2,...,x_n$, the probability $P(\mathbf{x}|\theta_1,\theta_2,...,\theta_m)$ is parametric if m is not dependent on n; otherwise it is non-parametric. Linear Regression is a parametric model that presumes a linear relationship between two random variables (rv) both having Gaussian distributed noise. It is presumed the variables are real valued. If rv Y is a function of rv X, then the phrase, "A regression of Y on X," is used. One is determining the optimal coefficients β_0,β_1 given data $D = \{\langle x_1,y_1\rangle,...,\langle x_n,y_n\rangle\}$ on function $Y = \beta_1 X + \beta_0$. Regression, though simple, provides a first step in understanding the relationship between to rvs. Regression can be used to predict, adjust, explain, *etc.* and is common in biostatistics. Regression produces an optimal linear relationship between rvs Y and X. Typically, one minimizes the squares of the residuals–the difference between the hypothetical point and observed point. The use is so ubiquitous that virtually every mathematical or statistical package has this available. As pointed out many times in the area, because two rvs are *not* linearly related, does not mean they are *not* functionally related.

Correlation, related to Linear Regression, is as often used. It is so similar in so many ways to Linear Regression that the literature will often have the use of one, when in fact, it is the other that is warranted or even makes sense. Succinctly, Regression examines how one rv depends on another; Correlation examines how two rvs behave together–in concert or more formally *covary*. Correlation is related to moments and is often called product-moments. One of the most popular is the Pearson product-moment $\rho = \frac{\sigma_{XY}}{\sigma_X\sigma_Y}$ where σ_i is the variance of the joint (numerator) and individual rvs (denominator). The value $\rho \in [-1,1]$ where as $|\rho| \approx 1$, the variables appear to have an association. As ρ approaches 0, this indicates they do not. The positive and negative score reflects the direction of the association. Another popular correlation examines how pairs of pairs of values behave called ranks. Kendall's τ examines two pairs of pairs $\langle x_i, y_y\rangle,\langle x_j, y_j\rangle$ observing if *both* values of one pair are greater or smaller than the other pair; if so, then the pair of pairs is called concordant. If this is not satisfied, then the pair of pairs is discordant. The formula for Kendall's $\tau = \frac{N}{n(n-1)}$ where N is the count of ranks and n the sample size. It should be pointed out this is a nonparametric statistic and value $\tau \in (-1,1)$.

A good deal of analysis is done with simple hypothesis testing of sample statistics. Because an entire population can be seldom checked, to establish a degree of certainty about a property we use sampling techniques (statistics). Sampling is done randomly to hopefully reflect the underlying distribution, especially if it is not known. If the sample is consistent with the conjecture about the existence of a property (called a hypothesis), then the hypothesis is said to be *accepted*; if not, it is *rejected*. There exists two disparate hypotheses that are simultaneously proposed when doing this analysis. The Null hypothesis, typically denoted H_0, is that the property was observed likely through chance. The Alternative hypothesis, typically denoted by H_a, is that the property is *not* due to chance. While recapitulating this process in its entirety is not appropriate here, we summarize the following sequence of standard steps that are typically followed for such analysis: **(0)** State the two hypotheses H_0 and H_a. It must be the case that only one can be true; **(1)** Establish the protocol for acquiring and using sample data. The decision usually depends on a chosen test statistic (a real-valued function of the sample); **(3)** Calculate the test statistic's value; **(4)** Check whether the statistic's value is likely to have occurred by chance or not typically using tables [2].

There are two types of errors that can result in this procedure. A Type I error will reject a null hypothesis when it is actually true. The significance level is the probability of committing this error and is often denoted by α. A Type II error is accepting a null hypothesis when it is actually false. The power of the test is the probability of not committing a Type II error. A P-value is, in a sense, an extreme case in examining H_0. It will reflect the strength of the evidence. P-values are very useful, since one can apply any number of significance levels reflecting confidence in the data.

ANOVA (analysis of variance), developed by Fisher almost a century ago remains a popular tool that examines differences in populations means $\mu = \Sigma_{i=1}^{N} \frac{X_i}{N}$, for values $X_1, X_2, \ldots, X_N$ one of the measures of central tendency of a population (*e.g.*, median, mode). Population variance, $\sigma^2 = \Sigma_{i=1}^{N} \frac{(X_i - \mu)^2}{N}$, measures the spread of values. There are two models of ANOVA, Model I and Model II, which form H_0 and H_a based on mean and variance, respectively. The interested reader is guided to [5] for an in-depth presentation.

Key Applications

The initial application of biostatistics was to study evolution and natural selection. It now plays an essential role in sequence and genome analysis, protein structure prediction, proteomics, phylogenetics, *etc.* A current challenge for data analysis is to consider extensions to relational data, to include probabilistic data and uncertainty, as they their roles in biological inquiry. Database researchers, one of the challenges is to move in thinking from a Boolean model (relational) to one that involves probability and uncertainty, conflicting data, non-replicable data, and data that has orders of magnitude more attributes than tuples. Data in biology is often un-normalized and may lack primary key identifiers normalization.

Future Directions

Biologists and computer scientists use different paradigms when considering data and analysis. Biologists are reductionists and focus on tightly constrained problems, whereas computer scientists pursue generic technological solutions that can be applied to multiple problems. Researchers in data management and biostatistics must keep these differences in mind as they move towards developing useful yet generic tools to serve biologists into the future. The future of biostatistics will depend directly on the computational resources available. Typically, two different approaches to problems are taken: combinatorial (or enumerative) or statistical. The former is usually very fast, but lacks the ability to discover nuanced relationships. Statistical approaches are computationally expensive, *e.g.*, Expectation-Maximization, but with increasingly powerful computers and clusters, this computational impediment is slowly eroding.

Bi-temporal access methods

Definition

A bi-temporal index is a data structure that supports both temporal time dimensions, namely, transaction-time (the time when a fact is stored in the database) and valid-time (the time when a fact becomes valid in reality). The characteristics of the time dimensions supported imply various properties that the bi-temporal index should have to be efficient. As traditional indices, the performance of a temporal index is described by three costs: (i) storage cost (i.e., the number of pages the index occupies on the disk), (ii) update cost (the number of pages accessed to perform an update on the index; for example when adding, deleting or updating a record), and (iii) query cost (the number of pages accessed for the index to answer a query).

Historical Background

Most of the early work on temporal indexing has concentrated on providing solutions for transaction-time databases. A basic property of transaction-time is that it always *increases*. Each newly recorded piece of data are time-stamped with a new, larger, transaction time. The immediate implication of this property is that previous transaction times *cannot* be changed. Hence, a transaction-time database can “rollback” to, or answer queries for, any of its previous states.

On the other hand, a valid-time database maintains the entire temporal behavior of an enterprise as best known now. It stores the current knowledge about the enterprise’s past, current or even future behavior. If errors are discovered about this temporal behavior, they are corrected by modifying the database. In general, if the knowledge about the enterprise is updated, the new knowledge modifies the existing one. When a correction or an update is applied, previous values are not retained. It is thus not possible to view the database as it was before the correction/update.

By supporting both valid and transaction time, a bi-temporal database combines the features of the other temporal database types. While it keeps its past states, it also supports changes anywhere in the valid time domain. Hence, the overlapping and persistent methodologies proposed for transaction-time indexing can be applied [5,6,9]. The difference with transaction-time indexing is that the underlying access method should be able to dynamically manage intervals (like an R-tree, a quad-tree etc.). For a worst-case comparison of temporal access methods, the reader is referred to [7].

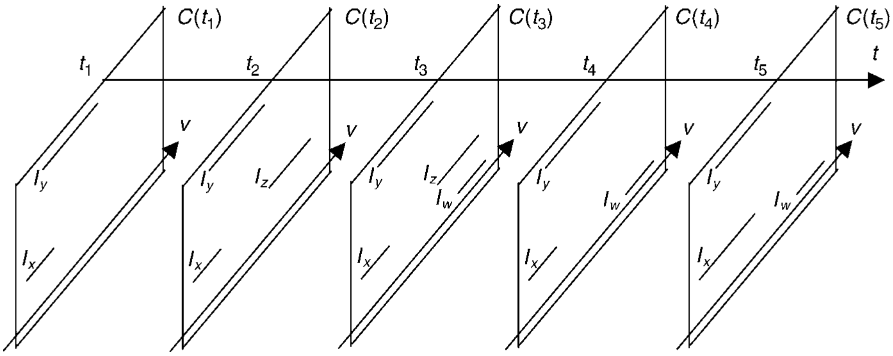
Foundations

When considering temporal indexing, it is important to realize that the valid and transaction time dimensions are *orthogonal* [3]. While in various scenarios it may be assumed that data about a fact is entered in the database at the same time as when it happens in the real world (i.e., valid and transaction time coincide), in practice, there are many applications where this assumption does not hold. For example, data records about the sales that occurred during a given day are recorded in the database at the end of the day (when batch processing of all data collected during the day is performed). Moreover, a recorded valid time may represent a later time instant than the transaction time when it was recorded. For example, a contract may be valid for an interval that is later than the (transaction) time when this information was entered in the database. The above properties are critical in the design of a bi-temporal access method since the support of both valid and transaction time affects directly the way records are created or updated. Note that the term "interval" is used here to mean a "convex subset of the time domain" (and not a "directed duration"). This concept has also been named a "period"; in this discussion however, only the term "interval" is used.

The reader is referred to the entry on Transaction-Time Indexing, in which a transaction time database was abstracted as an evolving collection of objects; updates arrive in increasing transaction-time order and are always applied on the latest state of this set. In other words, previous states cannot be changed. Thus a transaction-time database represents and stores the database activity; objects are associated with intervals based on this database activity. In contrast, in the chapter on Valid-Time Indexing, a valid-time database was abstracted as an evolving collection of interval-objects, where each interval represents the validity interval of an object. The allowable changes in this environment are the addition/deletion/modification of an interval-object. A difference with the transaction-time abstraction is that the collection's evolution (past states) is *not* kept. Note that when considering the valid time dimension, changes do not necessarily come in increasing time order; rather they can affect *any* interval in the collection. This implies that a valid-time database can correct errors in previously recorded data. However, only a single data state is kept, the one resulting after the correction is applied.

A bi-temporal database has the characteristics of both approaches. Its abstraction maintains the evolution (through the support of transaction-time) of a dynamic collection of (valid-time) interval-objects. Figure 1 offers a conceptual view of a bi-temporal database. Instead of maintaining a single collection of interval-objects (as a valid-time database does) a bi-temporal database maintains a sequence of such collections $C(t_i)$ indexed by transaction-time. Assume that each interval I represents the validity interval of a contract in a company. In this environment, the user can represent how the knowledge about company contracts evolved. In Fig. 1, the t-axis (v-axis) corresponds to transaction (valid) times. At transaction time t_1, the database starts with interval-objects I_x and I_y. At t_2, a new interval-object I_z is recorded, etc. At t_5 the valid-time interval of object I_x is modified to a new length.

When an interval-object I_j is inserted in the database at transaction-time t, a record is created with the object's surrogate (contract_no I_j), a valid-time interval (contract duration), and an initial transaction-time interval $[t, UC]$. When an object is inserted, it is not yet known if it (ever) will be updated. Therefore, the right endpoint of the transaction-time interval is filled with



Bi-Temporal Indexing. Figure 1. A bi-temporal database.

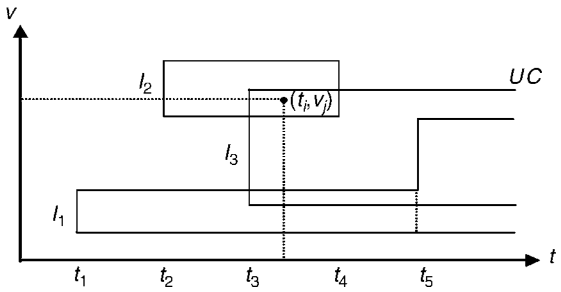
the variable *UC* (Until Changed), which will be changed to another transaction time if this object is later updated. For example, the record for interval-object I_z has transaction-time interval $[t_2, t_4]$, because it was inserted in the database at transaction-time t_2 and was "deleted" at t_4. Note that the collections $C(t_3)$ and $C(t_4)$ correspond to the collections C_a and C_b of Fig. 1 in the Valid-Time Indexing chapter, assuming that at transaction-time t_4 the erroneous contract I_z was deleted from the database.

Based on the above discussion, an index for a bi-temporal database should: (i) store past states, (ii) support addition/deletion/modification changes on the interval-objects of its current logical state, and (iii) efficiently access and query the interval-objects on any state.

Figure 1 summarizes the differences among the various database types. Each collection $C(t_i)$ can be thought of on its own, as a separate valid-time database. A valid-time database differs from a bi-temporal database since it keeps *only one* collection of interval-objects (the latest). A transaction-time database differs from a bi-temporal database in that it maintains the history of an evolving set of *plain*-objects instead of *interval*-objects. A transaction-time database differs from a conventional (non-temporal) database in that it also keeps its *past* states instead of only the latest state. Finally, the difference between a valid-time and a conventional database is that the former keeps *interval*-objects (and these intervals can be queried).

There are three approaches that can be used for indexing bi-temporal databases.

Approach 1: The first one is to have each bi-temporal object represented by a "bounding rectangle" created by the object's valid and transaction-time intervals, and to store it in a conventional multi-dimensional structure like the R-tree. While this approach has the advantage of using a single index to support both time dimensions, the characteristics of transaction-time create a serious overlapping problem [5]. A bi-temporal object with valid-time interval *I* that is inserted in the database at transaction time *t*, is represented by a rectangle with a transaction-time interval of the form $[t, UC]$. All bi-temporal objects that have not been deleted (in the transaction sense) will share the common transaction-time endpoint *UC* (which in a typical implementation, could be represented by the largest possible transaction time). Furthermore, intervals that remain unchanged will create long (in the transaction-time axis) rectangles, a reason for further overlapping. A simple bi-temporal query that asks for all valid time intervals that at transaction time t_i contained valid time v_j, corresponds to finding all rectangles that contain point (t_i, v_j).

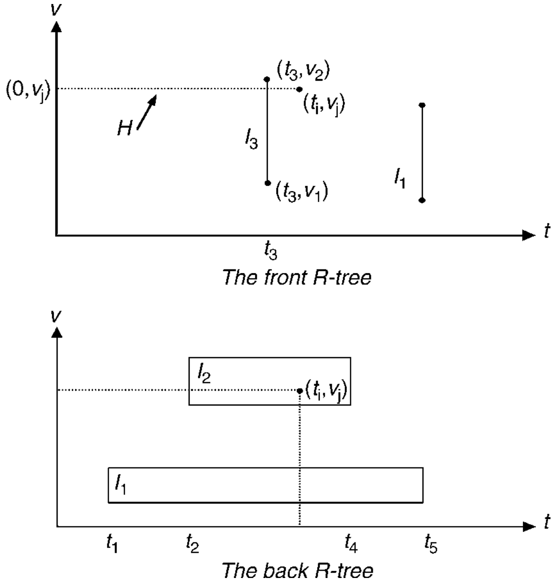


Bi-Temporal Indexing. Figure 2. The bounding-rectangle approach for bi-temporal objects.

Figure 2 illustrates the bounding-rectangle approach; only the valid and transaction axis are shown. At t_5, the valid-time interval I_1 is modified (enlarged). As a result, the initial rectangle for I_1 ends at t_5, and a new enlarged rectangle is inserted ranging from t_5 to *UC*.

Approach 2: To avoid overlapping, the use of two R-trees has also been proposed [5]. When a bi-temporal object with valid-time interval *I* is added in the database at transaction-time *t*, it is inserted at the *front* R-tree. This tree keeps bi-temporal objects whose right transaction endpoint is unknown. If a bi-temporal object is later deleted at some time $t' > t$, it is physically deleted from the front R-tree and inserted as a rectangle of height *I* and width from *t* to *t'* in the *back* R-tree. The back R-tree keeps bi-temporal objects with known transaction-time interval. At any given time, all bi-temporal objects stored in the front R-tree share the property that they are alive in the transaction-time sense. The temporal information of every such object is thus represented simply by a vertical (valid-time) interval that "cuts" the transaction axis at the transaction-time when this object was inserted in the database. Insertions in the front R-tree objects are in increasing transaction time while physical deletions can happen anywhere on the transaction axis.

In Fig. 3, the two R-trees methodology for bi-temporal data are divided according to whether their right transaction endpoint is known. The scenario of Fig. 2 is presented here (i.e., after time t_5 has elapsed). The query is then translated into an interval intersection and a point enclosure problem. A simple



Bi-Temporal Indexing. Figure 3. The two R-tree methodology for bi-temporal data.

bi-temporal query that asks for all valid time intervals which contained valid time v_j at transaction time t_i, is answered with two searches. The back R-tree is searched for all rectangles that contain point (t_i, v_j). The front R-tree is searched for all vertical intervals that intersect a horizontal interval H that starts from the beginning of transaction time and extends until point t_i at height v_j.

When an R-tree is used to index bi-temporal data, overlapping may also incur if the valid-time intervals extend to the ever-increasing *now*. One approach could be to use the largest possible valid-time timestamp to represent the variable *now*. In [2] the problem of addressing both the *now* and *UC* variables is addressed by using bounding rectangles/regions that increase as the time proceeds. A variation of the R-tree, the GR-tree is presented. The index leaf nodes capture the exact geometry of the bi-temporal regions of data. Bi-temporal regions can be static or growing, rectangles or stair-shapes. Two versions of the GR-tree are explored, one using minimum bounding rectangles in non-leaf nodes, and one using minimum bounding regions in non-leaf nodes. Details appear in [2].

Approach 3: Another approach to address bi-temporal problems is to use the notion of partial persistence [1,4]. This solution emanates from the abstraction of a bi-temporal database as a sequence of collections $C(t)$ (in Fig. 1) and has two steps. First, a good index is chosen to represent each $C(t)$. This index must support dynamic addition/deletion of (valid-time) interval-objects. Second, this index is made partially persistent. The collection of queries supported by the interval index structure implies which queries are answered by the bi-temporal structure. Using this approach, the Bi-temporal R-tree that takes an R-tree and makes it partially persistent was introduced in [5].

Similar to the transaction-time databases, one can use the "overlapping" approach [3] to create an index for bi-temporal databases. It is necessary to use an index that can handle the valid-time intervals and an overlapping approach to provide the transaction-time support. Multi-dimensional indexes can be used for supporting intervals. For example, an R-tree or a quad-tree. The Overlapping-R-tree was proposed in [6], where an R-tree maintains the valid time intervals at each transaction time instant. As intervals are added/deleted or updated, overlapping is used to share common paths in the relevant R-trees. Likewise, [9] proposes the use of quad-trees (which can also be used for spatiotemporal queries).

There are two advantages in "viewing" a bi-temporal query as a "partial persistence" or "overlapping" problem. First, the valid-time requirements are disassociated from the transaction-time ones. More specifically, the valid time support is provided from the properties of the R-tree while the transaction time support is achieved by making this structure "partially persistent" or "overlapping." Conceptually, this methodology provides fast access to the $C(t)$ of interest on which the valid-time query is then performed. Second, changes are always applied to the most current state of the structure and last until updated (if ever) at a later transaction time, thus avoiding the explicit representation of variable *UC*. Considering the two approaches, overlapping has the advantage of simpler implementation, while the partial-persistence approach avoids the possible logarithmic space overhead.

Key Applications

The importance of temporal indexing emanates from the many applications that maintain temporal data. The ever increasing nature of time imposes the need for many applications to store large amounts of temporal data. Accessing such data specialized indexing techniques is necessary. Temporal indexing has offered many such solutions that enable fast access.

Bitemporal Interval

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

Facts in a bitemporal database may be timestamped by time values that are products of time intervals drawn from two orthogonal time domains that model valid time and transaction time, respectively. A *bitemporal interval* then is given by an interval from the valid-time domain and an interval from the transaction-time domain, and denotes a rectangle in the two-dimensional space spanned by valid and transaction time.

When associated with a fact, a bitemporal interval then identifies an interval (valid time) during which that fact held (or holds or will hold) true in reality, as well as identifies an interval (transaction time) when that belief (that the fact was true during the specified valid-time interval) was held, i.e., was part of the current database state.

Key Points

In this definition, a time interval denotes a convex subset of the time domain. Assuming a discrete time domain, a bitemporal interval can be represented with a non-empty set of bitemporal chronons or granules.

Bitemporal Relation

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Temporal relation; Fully temporal relation; Valid-time and transaction-time relation

Definition

A *bitemporal relation* captures exactly one valid time aspect and one transaction time aspect of the data it contains. This relation inherits its properties from valid-time relations and transaction-time relations. There are no restrictions as to how either of these temporal aspects may be incorporated into the tuples.

Key Points

In this definition, "bi" refers to the capture of exactly two temporal aspects. An alternative definition states that a bitemporal relation captures one or more valid times and one or more transaction times. In this definition, "bi" refers to the existence of exactly two types of times.

One may adopt the view that the data in a relation represents a collection of logical statements, i.e., statements that can be assigned a truth values. The valid times of these so-called facts are the times when these are true in the reality modeled by the relation. In cases where multiple realities are perceived, a single fact may have multiple, different valid times. This might occur in a relation capturing archaeological facts for which there no agreements among the archaeologists. In effect, different archaeologists perceive different realities.

Transaction times capture when database objects are current in a database. In case an object migrates from one database to another, the object may carry along its transaction times from the predecessor databases, termed *temporal generalization*. This then calls for relations that capture multiple transaction times.

The definition of bitemporal is used as the basis for applying bitemporal as a modifier to other concepts such as "query language." A query language is bitemporal if and only if it supports any bitemporal relation. Hence, most query languages involving both valid and transaction time may be characterized as bitemporal.

Relations are named as opposed to databases because a database may contain several types of relations. Most relations involving both valid and transaction time are bitemporal according to both definitions.

Concerning synonyms, the term "temporal relation" is commonly used. However, it is also used in a generic and less strict sense, simply meaning any relation with time-referenced data.

Next, the term "fully temporal relation" was originally proposed because a bitemporal relation is capable of modeling both the intrinsic and the extrinsic time aspects of facts, thus providing the "full story." However, this term is no longer used.

The term "valid-time and transaction-time relation" is precise and consistent with the other terms, but is also lengthy.

Bitmap Index

Chee Yong Chan
National University of Singapore, Singapore,
Singapore

Definition

An index on an attribute provides an efficient way to access data records associated with a given range of values for the indexed attribute. Typically, an index stores a list of RIDs (called a RID-list) of all the records associated with each distinct value v of the indexed attribute. In a *bitmap index*, each RID-list is represented in the form of a bit vector (i.e., bitmap) where the size of each bitmap is equal to the cardinality of the indexed relation, and the ith bit in each bitmap corresponds to the ith record in the indexed relation. The simplest bitmap index design is the *Value-List index*, which is illustrated in Fig. 1b for an attribute A of a 12-record relation R in Fig. 1a. In this bitmap index, there is one bitmap E^v associated with each attribute value $v \in [0,9]$ such that the ith bit of E^v is set to 1 if and only if the ith record has a value v for the indexed attribute.

Bitmap Index. Figure 1. Examples of bitmap indexes. (a) indexed attribute *A* (b) equality-encoded index (or value-list index) (c) range-encoded index (or base-10 bit-sliced index) (d) interval-encoded index.

Historical Background

The idea of using bitmap indexes to speed up selection predicate evaluation has been recognized since the early 1970s [4]. Some early implementations of bitmap processing techniques include PC DBMSs (e.g., FoxPro, Interbase), a scientific/statistical database application developed at Lawrence Berkeley Laboratory [11], and Model 204, which is a commercial DBMS for the IBM mainframe [7].

The main advantage of using a bitmap index is the CPU efficiency of bitmap operations (AND, OR, XOR, NOT). Furthermore, compared to RID-based indexes, bitmap indexes are more space-efficient for attributes with low cardinality and more I/O-efficient for evaluating selection predicates with low selectivities. For example, assuming each RID requires four bytes of storage and ignoring any compression, bitmap indexes are more space-efficient if the attribute cardinality is less than 32, and reading a bitmap is more I/O-efficient than reading a RID-list if the selectivity factor of the selection predicate is more than $\frac{1}{32}(\approx 3.2\%)$. Another advantage of bitmap indexes is that they are very amenable to parallelization due to the equal-sized bitmaps and the nature of the bitwise operations.

A variety of bitmap index designs have been proposed since the early days. Besides the simple Value-List index illustrated in Fig. 1b, another early bitmap index design is the *Bit-Sliced index (BSI)* which is implemented in Model 204 and Sybase IQ [7]. A BSI for an attribute with a cardinality of C consists of $k = \lceil log_2(C) \rceil$ bitmaps, with one bitmap associated with each bit in the binary representation of C. Compared to the Value-List index, the BSI is more space-efficient with an attribute value v being encoded by a string of k bits corresponding to its binary representation. The BSI design can be generalized to use a non-binary base b such that it consists of $k(b - 1)$ bitmaps $\{B_i^j : 1 \leq i \leq k, 0 \leq j < b\}$, where $k = \lceil log_b(C) \rceil$. Each attribute value v is expressed in base b as a sequence of k base-b digits $v_k v_{k-1} ... v_2 v_1$, and each bitmap B_i^j represents the set of records with $v_i \leq j$. Using a larger base number improves the index's performance for evaluating range predicates at the cost of an increased space cost. An example of a base-10 BSI is shown in Fig. 1c. Both Model 204 and Sybase IQ implemented base-10 Bit-Sliced indexes [7].

Several bitmap index designs have also been implemented in a scientific/statistical database application at Lawrence Berkeley Laboratory [11]. These bitmap indexes include binary encoded indexes (equivalent to binary BSI), unary encoded indexes (equivalent to non-binary BSI), K-of-N encoded indexes (generalizations of Value-List indexes where each attribute value is encoded by a N-bit string with exactly K bits set to 1), and superimposed encoded indexes based on superimposed encoding which is useful for indexing set-valued attributes.

Interest in bitmap indexes was revived in the mid 1990s due to the emergence of data warehousing applications which are characterized by read-mostly query workloads dominated by large, complex ad hoc queries [7]. All the major DBMS vendors (IBM, Microsoft, Oracle, and Sybase) also started to support bitmap indexes in their products around this time.

Foundations

Chan and Ioannidis propose a two-dimensional framework to characterize the design space of bitmap indexes [2]. The two orthogonal parameters identified for bitmap indexes (with an attribute cardinality of C) are (i) the arithmetic used to represent attribute values; i.e., how an attribute value is decomposed into digits according to some base (e.g., base-C arithmetic is used in a Value-List index); and (ii) the encoding scheme of each decomposed digit in bits (e.g., each attribute value in a Value-List index is encoded by turning on exactly one out of C bits). Consider an attribute value $v \in [0,C)$ and a sequence of n base numbers $\mathcal{B} = <b_n, b_{n-1},\ldots,b_1>$, where $b_n = \left\lceil \frac{C}{\prod_{i=1}^{n-1} b_i} \right\rceil$ and $b_i \geq 2$, $i \in [1,n]$. Using $\mathcal{B}$, v can be decomposed into a unique sequence of n digits $<v_n,v_{n-1},\ldots,v_1>$ as follows: $v_i = V_i \; mod \; b_i$, where $V_1 = v$ and $V_i = \left\lfloor \frac{V_{i-1}}{b_{i-1}} \right\rfloor$, for $1 < i \leq n$. Thus, $v = v_n\left(\prod_{j=1}^{n-1} b_j\right) + \ldots + v_i\left(\prod_{j=1}^{i-1} b_j\right) + \ldots + v_2 b_1 + v_1$. Note that each v_i is a base-b_i digit (i.e., $0 \leq v_i < b_i$). Each choice of n and base-sequence $\mathcal{B}$ gives a different representation of attribute values, and therefore a different index (known as a Base-$\mathcal{B}$ index). The index consists of n *components* (i.e., one component per digit) where each component individually is now a collection of bitmaps. Figure 2b shows a base-<3,4> Value-List index that consists of two components: the first component has four bitmaps $\{E_1^3, E_1^2, E_1^1, E_1^0\}$, and the second component has three bitmaps $\{E_2^2, E_2^1, E_2^0\}$. Note that the kth bit in each bitmap E_i^j is set to 1 if and only if $v_i = j$, where $<v_2,v_1>$ is the <3,4>-decomposition of the kth record's indexed attribute value. For the encoding scheme dimension, there are two basic encoding schemes: equality encoding and range encoding. Consider the ith component of an index with base b_i, and a value $v_i \in [0,b_i - 1]$. In the *equality encoding scheme*, v_i is encoded by b_i bits, where all the bits are set to 0 except for the bit corresponding to v_i, which is set to 1. Thus, an equality-encoded component (with base b_i) consists of b_i bitmaps $\{E_i^{b_i-1},\ldots,E_i^0\}$ such that the kth bit in each bitmap E_i^j is set to 1 if and only if $v_i = j$, where v_i is the ith digit of the decomposition of the kth record's indexed attribute value. In the *range encoding scheme*, v_i is encoded again by b_i bits, with the v_i rightmost bits set to 0 and the remaining bits (starting from the one corresponding to v_i and to the left) set to 1. The kth bit in each bitmap R_i^j is set to 1 if and only if $v_i \leq j$, where v_i is the ith digit of the decomposition of the kth record's indexed attribute value. Since the bitmap $R_i^{b_i-1}$ has all bits set to 1, it does not need to be stored, so a range-encoded component consists of $(b_i - 1)$ bitmaps $\{R_i^{b_i-2},\ldots,R_i^0\}$. Value-List and Bit-Sliced indexes therefore correspond to equality-encoded and range-encoded indexes, respectively. Figures 1c and 2c show the range-encoded indexes corresponding to the equality-encoded indexes in Figs. 1b and 2b. Details of

Bitmap Index. Figure 2. Example of base- <3,4> indexes. (a) indexed attribute A (b) equality-encoded index (c) range-encoded index (d) interval-encoded index.

query processing algorithms and space-time tradeoffs of equality/range-encoded, multi-component bitmap indexes are given in [4].

A new encoding scheme, called *interval encoding*, was proposed in [5]. For an attribute with a cardinality of C, a value $v \in [0,C)$ is encoded using $\lceil \frac{C}{2} \rceil$ bits such that if $v < \lceil \frac{C}{2} \rceil$, then v is encoded by setting the $(v+1)$ rightmost bits to 1 and the remaining bits to 0; otherwise, v is encoded by setting the $(C-1-v)$ leftmost bits to 1 and remaining bits to 0. Thus, the interval encoding scheme consists of $\lceil \frac{C}{2} \rceil$ bitmaps $\{I^{\lceil \frac{C}{2} \rceil - 1},\ldots,I^0\}$, where each bitmap I^j is associated with a range of $(m+1)$ values $[j,j+m]$, $m = \lfloor \frac{C}{2} \rfloor - 1$, such that the kth bit in a bitmap I^j is set to 1 if and only if the kth record's indexed attribute value is in $[j,j+m]$. Figures 1d and 2d show the interval-encoded indexes corresponding to the equality-encoded indexes in Figs. 1b and 2b. Note that interval encoding has better space-time tradeoff than range encoding: it has the same worst-case evaluation cost of two bitmap scans as range encoding but its space requirement is about half that of range encoding.

Wu and Bachmann proposed a variant of binary BSI called *encoded bitmap index (EBI)* [12,13]. Instead of encoding each attribute value simply in terms of its binary representation, an EBI uses a lookup table to map each attribute value to a distinct bit string; this flexibility enables optimization of the value-to-bit-string mapping, by exploiting knowledge of the query workload, to reduce the number of bitmap scans for query evaluation. Thus, binary BSI is a special case of EBI. Another similar index design called *Encoded-Vector index (EVI)* is used in IBM DB2. Instead of storing the index as a collection of $\lceil log_b(C) \rceil$ bitmaps as in EBI, EVI is organized as a single vector of $\lceil log_b(C) \rceil$-bit strings, and the purpose of the lookup table optimization is to reduce the CPU cost of bit string comparisons when evaluating selection queries of the form "$A \in \{v_1,v_2,\ldots,v_n\}$." Another related index is the *Projection index* [7], which is implemented in Sybase IQ.

Complex, multi-table join queries (such as star-join queries) can also be evaluated very efficiently using *bitmapped join indexes* [6], which are indexes that combine the advantages of *join indexes* and bitmap representation. A *join index* for the join between two relations R and S is a precomputation of their join result defined by $\Pi_{R.rid,S.rid}(R \bowtie_p S)$, where p is the join predicate between R and S. Thus, a join index on $R \bowtie S$ can be thought of as a conventional index on the table R, where the attribute being indexed is the "virtual" attribute $S.rid$; i.e., each distinct $S.rid$ value v is associated with a list of all $R.rid$ values that are related to v via the join. A *bitmapped join index* [6] is simply a join index with the RID-lists represented using bitmaps. Bitmapped join indexes are implemented in Informix Red Brick Warehouse and Oracle. Bitmap indexes can also be applied to evaluate queries that involve aggregate functions (e.g., SUM, MIN/MAX, MEDIAN); evaluation algorithms for Value-List and Bit-Sliced indexes are discussed in a paper by O'Neil and Quass [7]. Efficient algorithms for performing arithmetic operations (addition and subtraction) on binary BSIs are proposed in [8].

As bitmap indexes become less efficient for larger attribute cardinality, a number of approaches have been developed to reduce their space requirement. Besides using multi-component bitmap indexes [2,11], another common space-reduction technique is to apply compression. In Model 204 [7], the bitmaps are compressed by using a hybrid representation; specifically, each individual bitmap is partitioned into a number of fixed-size segments, and segments that are dense are stored as verbatim bitmaps while sparse segments are converted into RID-lists. While generic compression techniques (e.g., LZ77) are effective in reducing both the disk storage and retrieval cost of bitmap indexes, the savings in I/O cost can be offset by the high CPU cost incurred for decompressing the compressed bitmaps before they can be operated with other bitmaps. A number of specialized compression techniques that enable bitmaps to be operated on without a complete decompression have been proposed: Byte-aligned Bitmap Code (BBC) (which is used by Oracle), and Word-Aligned Hybrid code (WAH) [14]. Some performance study of compressed bitmap indexes are reported in [1–3,14].

A different approach proposed to reduce the size of bitmaps is to use *range-based bitmaps (RBB)* [15], which have been applied to index large data sets in tertiary storage systems as well as large, multidimensional data sets in scientific applications [14]. Unlike Value-List indexes where there is one bitmap for each distinct attribute value, the RBB approach partitions the attribute domain into a number of disjoint ranges and constructs one bitmap for each range of values (this is also known as *binning*). Thus, RBB provides a form of lossy compression which requires additional post-processing to filter out false positives.

Koudas [5] has examined space-optimal RBBs for equality queries when both the attribute and query distributions are known; these results have been extended for range queries [9]. More recently, Sinha and Winslett have proposed *multi-resolution bitmap indexes* to avoid the cost of filtering out false positives for RBB [10]. For example, in a two-resolution bitmap index, it has a lower resolution index consisting of RBB (i.e., with each bitmap representing a range of attribute values) and a higher resolution index consisting of one bitmap for each distinct attribute value. By combining the efficiency of lower resolution indexes and the precision of higher resolution indexes, queries can be evaluated efficiently without false positive filtering.

Key Applications

Today, bitmap indexes are supported by all major database systems, and they are particularly suitable for data warehousing applications [7]. Bitmap indexes have also been used in scientific databases (e.g., [10,11,14]), indexing data on tertiary storage systems (e.g., [1]), and data mining applications.

Future Directions

The design space for bitmap indexes is characterized by four key parameters: levels of resolution (which affects the number of levels of bitmap indexes and the index granularity at each level), attribute value representation (which affects the number and size of the index components at each level) encoding scheme (which affects how the bitmaps in each component are encoded), and storage format (i.e., uncompressed, compressed, or a combination of compressed and uncompressed). While there are several performance studies that have examined various combinations of the above parameter space, a comprehensive investigation into the space-time tradeoffs of the entire design space is, however, still lacking and deserves to be further explored. The result of such a study can be applied to further enhance automated physical database tuning tools.

Bitmap Index; Projection Index

Definition

A bitmap-based index is a binary vector that represents an interesting property and indicates which objects in the dataset satisfy the given property. The vector has a 1 in position *i* if the *i*-th data object satisfies the property, and 0 otherwise. Queries are executed using fast bitwise logical operations supported by hardware over the binary vectors.t

Historical Background

Bitmap-based indexing was first implemented in Computer Corporation of America's Model 204 in the mid-1980s by Dr. Patrick O'Neil. The bitmap index from Model 204 was a hybrid between verbatim (uncompressed) bitmaps and RID lists. Originally, a bitmap was created for each value in the attribute domain. The entire bitmap index is smaller than the original data as long as the number of distinct values is less than the number of bits used to represent the attribute in the original data. For example, if an integer attribute has cardinality 10 and integers are stored using 32 bits, then the bitmap index for such an attribute, which only has 10 bit vectors, is 3.2 times smaller than the original data. For floating point attributes, the bitsliced index (BSI) [8] stores each bit of the binary representation of the attribute independently. Bitsliced indexes are never more than the size of the original data. However, in general, all bitslices need to be accessed to answer a query.

In order to reduce the number of bit vectors that needed to be read to answer a query, more complex encodings for bitmap-based indexes have been proposed, such as range encoded bitmaps [15,8], encoded bitmaps [16], and interval encoded bitmaps [4,5]. For attributes with high cardinality including floating point attributes, binning [7,13] was proposed to reduce the number of values in the domain, and therefore the number of bit vectors in the index. In addition, special compression techniques were developed to improve the performance of the bitmap indexes. The two most popular techniques are Byte-aligned Bitmap Code (BBC) [1], and Word Aligned Hybrid (WAH) [18] compression method. These compression techniques allow query execution over the compressed bitmaps. With compression, bitmap indexes have been proven to perform well with high cardinality attributes [17].

Foundations

Bitmap tables are a special type of binary matrices. Each binary row in the bitmap table represents one tuple in the database. The bitmap columns are produced by quantizing the attributes in the database into categories or bins. Each tuple in the database is then encoded based on which bin each attribute value falls into. Bitmap index encoding is based on the properties of physical row identifiers and there is a one-to-one correspondence between the data objects and the bits in the bitmap vector. Therefore, given a bit position, the location of its corresponding table row can be computed by simple arithmetic operations. For tables with a clustered-index or index-ordered tables, a mapping table is used to map bit positions to row locations.

Bitmap Encoding

For equality encoded bitmaps (also called simple encoding or projection index) [8], if a value falls into a bin, this bin is marked "1", otherwise "0". Since a value can only fall into a single bin, only a *single* "1" can exist for each row of each attribute. After binning, the whole database is converted into a large 0–1 bitmap, where rows correspond to tuples and columns correspond to bins. Figure 1 shows an example using a table with one attribute with cardinality 4. Columns

Tuple	Value	Equality				Eq w/binning		Range			Interval			Bitsliced		
		= 1	= 2	= 3	= 4	{1,2}	{3,4}	≤3	≤2	≤1	[1,2]	[2,3]	[3,4]	2^2	2^1	2^0
t_1	1	1	0	0	0	1	0	1	1	1	1	0	0	0	0	1
t_2	2	0	1	0	0	1	0	1	1	0	1	1	0	0	1	0
t_3	3	0	0	1	0	0	1	1	0	0	0	1	1	0	1	1
t_4	1	1	0	0	0	1	0	1	1	1	1	0	0	0	0	1
t_5	2	0	1	0	0	1	0	0	1	1	1	1	0	0	1	0
t_6	4	0	0	0	1	0	1	0	0	0	0	0	1	1	0	0
t_7	1	1	0	0	0	1	0	1	1	1	1	0	0	0	0	1
t_8	3	0	0	1	0	0	1	1	0	0	0	1	1	0	1	1

Bitmap-based Index Structures. Figure 1. Bitmap index examples for a table with one attribute with cardinality 4.

3–6 of Fig. 1 show the equality encoded bitmap for this table. The first tuple t_1 has value 1, therefore only the corresponding bit in the bitmap =1 is set. Columns 7 and 8, show the bitmaps for equality encoding with binning. In this example, the attribute was quantized into two bins.

For range encoded bitmaps [4], a bin is marked "1" if the value falls into it or a smaller bin, and "0" otherwise. Using this encoding, the last bin for each attribute is all 1s. Thus, this column is not explicitly stored. Columns 9–11 in Fig. 1 show the range encoding for the attribute. The first tuple t_1 has the smallest value 1, therefore all the bitmaps have the first bit set. For interval encoded bitmaps, every bitmap represents a range of $\lceil \frac{C}{2} \rceil$ values, where C is the cardinality of the attribute. This encoding allows to answer any range or point query on one attribute by reading at most two bit vectors [4,5]. Columns 12–14 in Fig. 1 show the interval encoded bitmap. The fifth tuple t_5 has value 2, therefore the fifth bit is set for the [1,2] and [2,3] interval bitmaps. Bit-sliced indexes (BSI) [8] can be considered as a special case of the encoded bitmaps [16]. With the bit-sliced index the bitmaps encode the binary representation of the attribute value. Columns 15–17 of Fig. 1 show the bit-sliced index of the table. The third tuple t_3 has value 3 which is represented by the binary number 011, therefore the corresponding bit in slices 2^1 and 2^0 are set. Encoded bitmaps encode the binary representation of the attribute bins. Therefore, only $\lceil \log_2 bins \rceil$ bitmaps are needed to represent all values.

With binning, several values are encoded in the same bitmap. However, the results from the queries are supersets of the actual results, therefore additional disk access may be needed to evaluate the candidates and retrieve the exact results. Several binning strategies, based on data distribution and query workloads, and several strategies for candidate evaluation have been proposed [10,11]. A binned bitmap index augmented with an auxiliary order-preserving bin-based Clustering (OrBiC) [19] can significantly reduce the I/O cost of candidate evaluation.

Query Execution

Bitmap indexes can provide efficient performance for point and range queries thanks to fast bitwise operations (AND, OR, NOT) which are supported by hardware. With equality encoded bitmaps a point query is executed by ANDing together the bit vectors corresponding to the values specified in the query conditions. For example, finding the data points that correspond to a query where Attribute 1 is equal to 3 and Attribute 2 is equal to 5 is only a matter of ANDing the two bitmaps together. Equality Encoded Bitmaps are optimal for point queries. Range queries are executed by first ORing together all the bit vectors specified by each range in the query conditions and then ANDing the answers together. If the query range for an attribute queried includes more than half of the cardinality then one executes the query by taking the complement of the ORed bitmaps that are not included in the query condition. The performance of queries with large-range query conditions can be improved by using multi-resolution bitmap indexes [12], i.e., bitmaps with different interval size: at the highest level one bit vector corresponds to an individual value and at lower levels each bit vector corresponds to a bin of values. Queries are executed using combined resolution bitmaps that minimize both the number of bitwise operations and the number of candidate points. With more complex encodings, the query evaluation strategy depends on the encoding and the range being queried.

Bitmap Compression

The goal of the bitmap index compression is twofold: to reduce the space requirement of the index and to maintain query execution performance by executing the query over the compressed index. The two most popular run-length compression techniques are the Byte-aligned Bitmap Code (BBC) [1] and the Word-Aligned Hybrid (WAH) compression method [18]. BBC stores the compressed data in bytes while WAH stores it in words. WAH is simpler because it only has two types of words, while BBC has four. Both techniques are based on the idea of run length encoding that represents consecutive bits of the same symbol (also called a fill or a gap) by their bit value and their length. The bit value of a fill is called the fill bit. BBC first divides the bit sequence into bytes and then group bytes into runs. A run consists of a fill word followed by a tail of literal bytes. A run always contains a number of whole bytes as it represents the fill length as number of bytes rather than number of bits. The byte alignment property limits a fill length to be an integer multiple of bytes. This ensures that during any bitwise logical operation a tail byte is never broken into individual bits. Similar to BBC, WAH is a hybrid between the run length encoding and the literal scheme. WAH stores compressed data in words rather than in bytes. The most significant bit of a word distinguishes between a literal word(0) and a fill word(1). Lower bits of a literal word contain the bit values from the bit sequence. The second most significant bit of a fill word is the fill bit and the lower (w-2) bits store the fill length. Imposing word alignment ensures that the logical operation functions only need to access words not bytes or bits. In general, bit operations over the compressed WAH bitmap file are faster than BBC while BBC gives better compression ratio.

Typically, complex encoded bitmaps do not compress well as the bit density of such bitmaps is relatively high. Recently, reordering has been proposed as a preprocessing step for improving the compression of bitmaps. The objective with reordering is to increase the performance of run length encoding. By reordering the data, the compression ratio of large boolean matrices can be improved [6]. However, optimal matrix reordering is NP-hard and the authors use traveling salesman heuristics to compute the new order. The idea of reordering is also applied to compression of bitmap indexes [9]. The authors show that the tuple reordering problem is NP-complete and propose a Gray code ordering heuristic.

Bitmap update is an expensive operation. The common practice is to drop the index, do a batch update, and recreate the index. For improved update performance, it is possible to add to each compressed bitmap a pad-word that encodes all possible rows using non-set bits [3]. For insertions, only the updated column needs to be accessed as opposed to all the bitmap columns. This technique is suitable for maintaining an online index when the update rate is not very high. An alternative to run-length compression proposed in the literature is the Approximate Bitmap Encoding [2], where hashing is used to encode the data objects in a bloom filter. This technique can offer improved performance for selection queries over small number of rows.

Key Applications

Bitmap indexing has been traditionally used in data warehouses to index large amount of data that are infrequently updated. More recently, bitmaps have found many other applications such as visualization and indexing of scientific data. Other works have applied bitmaps for term matching and similarity searches. In general, one could claim that bitmaps would outperform most approaches in the domains where full scan of the data are unavoidable and computations can be done using parallel bitwise operations.

Bitmap-based indexes are successfully implemented in commercial Database Management Systems. Oracle implements a version of the simple bitmap encoding compressed using BBC. Sybase IQ has two different types of bitwise indexes. IBM DB2 dynamically builds bitmaps from a single-column B-tree to join tables. Informix uses bitmapped indexes since version 8.21 released in 1998. PostgreSQL supports bitmap index scans since version 8.1 where dynamic bitmaps are created to combine the results of multiple index conditions using bitwise operations.

Blind Signatures

Barbara Carminati
University of Insubria, Varese, Italy

Definition

In blind signature schemes, the sender and the signer of the message are two distinguished entities. Given a message m, blind signatures have the property that the signer digitally signs a blinded version of m, i.e., m', without the disclosure of any information about the original message. The obtained blind signature can be verified by using the public key of the signer and the original message m, instead of m'.

Key Points

In 1982, David Chaum introduced the concept of blind signatures for protecting user privacy during electronic payment transactions [1]. This scheme has been devised for scenarios where the sender and the signer of the message are two distinguished entities, with the aim of preventing the signer from observing the message he or she signs. More precisely, given a message m generated by A, a signer B is able to digitally sign a blinded version of m', i.e., $DS_B(m')$, without the disclosure of any information about the original message. The key property of blind signatures is that the obtained signature $DS_B(m')$ can be verified by using the public key of B and the original message m, instead of m'. This property makes blind signatures particularly suitable for applications where sender privacy is the main concern, like for instance, in digital cash protocols and electronic voting systems.

Several digital signature schemes can be used to obtain a blind signature, like for instance RSA and DSA schemes. In the following to explain the generation and verification of a blind signature, the RSA algorithm is considered. Let $PK_B = (n, e)$ and $SK_B = (n, d)$ be the public and private keys of signer B.

Blinding. Let k be a random integer chosen by the sender A, such that $0 \leq k \leq n - 1$ and $gcd(n, k) = 1$. Thus, given a message m, the sender generates the blinded version of it, i.e., m', by combing m with k. According to RSA, the blinded version of m is computed as $m' = (mk^e) \bmod n$.

Blind signature generation. The signer digitally signs the blinded version m' using the RSA digital signature algorithm; that is, $DS_B(m') = (m')^d \bmod n$.

Signature unblinding. The intended verifier can obtain the signature of m, i.e., $DS_B(m)$, as follows $DS_B(m) = k^{-1}DS_B(m')$. This signature can be validated by the RSA verification algorithm, according to the standard process.

Bloom Filters

Michael Mitzenmacher
Harvard University, Boston, MA, USA

Hash filter

Definition

A Bloom filter is a simple, space-efficient randomized data structure based on hashing that represents a set in a way that allows membership queries to determine whether an element is a member of the set. False positives are possible, but not false negatives. In many applications, the space savings afforded by Bloom filters outweigh the drawbacks of a small probability for a false positive. Various extensions of Bloom filters can be used to handle alternative settings, such as when elements can be inserted and deleted from the set, and more complex queries, such as when each element has an associated function value that should be returned.

Historical Background

Burton Bloom introduced what is now called a Bloom filter in his 1970 paper [2], where he described the technique as an extension of hash-coding methods for applications where error-free methods require too much space and were not strictly necessary. The specific application he considered involved hyphenation: a subset of words from a standard dictionary require specialized hyphenation, while the rest could be handled by a few simple and standard rules. Keeping a Bloom filter of the words requiring specialized hyphenation dramatically cut down disk accesses. Here, false positives caused words that could be handled by the simple rules to be treated as special cases. Bloom filters were also used in early UNIX spell-checkers [12,13], where a false positive would allow a misspelled word to be ignored, and were suggested as a way of succinctly storing a dictionary of insecure passwords, where a false positive would disallow a potentially secure password [16].

Bloom filters were applied in databases to reduce the amount of communication and computation for join operations, especially distributed join operations [1,4,11]. The term Bloomjoin is sometimes used to describe a semijoin operation that utilizes Bloom filters. The Bloom filter is used to represent join column values, so that matching values can be found by querying the Bloom filter. False positives cause false matches of tuples that must later be removed. However, the communication and computation gains from using the filter can yield significant advantages even with these false positives.

Foundations

A Bloom filter for representing a set $S = \{x_1,x_2,...,x_n\}$ of n elements from a universe U consists of an array of m bits, initially all set to 0. The filter uses k independent hash functions $h_1,...,h_k$ with range $\{1,...,m\}$. For each element $x \in S$, the bits $h_i(x)$ are set to 1 for $1 \leq i \leq k$. (A location can be set to 1 multiple times.) To check if an item y is in S, one checks whether all $h_i(y)$ are set to 1. If not, then clearly y is not a member of S. If all $h_i(y)$ are set to 1, the data structure returns that y is in S. There is no possibility of a false negative, but it is possible that for $y \notin S$, all $h_i(y)$ are set to 1, in which case the data structure gives a false positive.

The fundamental issue in the analysis of the Bloom filter is the *false positive probability* for an element not in the set. In the analysis, generally it is assumed that the hash functions map each element in the universe to a random number independently and uniformly over the range. While this is clearly an optimistic assumption, it appears to be suitable for practical implementations. With this assumption, after all the elements of S are hashed into the Bloom filter, the probability that a specific bit is still 0 is

$$p' = (1 - 1/m)^{kn} \approx \mathrm{e}^{-kn/m}.$$

It is convenient to use the approximation $p = \mathrm{e}^{-kn/m}$ in place of p'. If ρ is the proportion of 0 bits after all the n elements are inserted in the table, then conditioned on ρ the probability f of a false positive is

$$f = (1-\rho)^k \approx (1-p')^k \approx (1-p)^k = \left(1 - \mathrm{e}^{-kn/m}\right)^k.$$

These approximations follow since $\mathrm{E}[\rho] = p'$, and ρ can be shown to be highly concentrated around p' using standard techniques [8].

The optimal number of hash function can be found by finding where $(1 - \mathrm{e}^{-kn/m})^k$ is minimized as a function of k. Simple calculus reveals the optimum occurs when $k = \ln 2 \cdot (m/n)$, giving a false positive probability f of

$$f = \left(1 - \mathrm{e}^{-kn/m}\right)^k = (1/2)^k \approx (0.6185)^{m/n}.$$

In practice, k must be an integer, and the choice of k might depend on application-specific questions.

Key Applications

Essentially any application that requires membership checks against a list or set of objects, and for which space is at a premium, is a candidate for a Bloom filter. In some applications, Bloom filters may also save computational resources. The consequences of false positives, however, need to be carefully considered in all circumstances.

Bloom filters enjoyed a recent resurgence in the networking community after their use in a paper by Fan et al. on distributed Web caches [9]. Instead of having caches distribute lists of URLs (or lists of their 16-byte MD5 hashes) corresponding to the cache contents, the authors demonstrate a system that saves in communication costs by sharing Bloom filters of URLs. False positives may cause a server to request a page from another nearby server, even when that server does not hold the page. In this case, the page must subsequently be retrieved from the Web. If the false positive probability is sufficiently low, the penalty from these occasional failures is dominated by the improvement in overall network traffic. Countless further applications in databases, peer-to-peer networks, overlay networks, and router architectures have arisen, and the use of Bloom filters and their many variants and extensions has expanded dramatically [5].

In databases, applications include the previously mentioned Bloomjoin variation of the semijoin. In a similar manner, Bloom filters can be effectively used to estimate the size of semijoin operations, using the fact that Bloom filters can be used to estimate the size of a set (and the size of set unions and intersections) [14]. Another early database application utilizes differential files [10]. In this setting, all changes to a database that occur during a given time period are processed as a batch job, and a differential file tracks changes that occur until the batched update occurs. To read a record then requires determining if the record has been changed by some transaction in the differential file. If not, the record can be read directly from the database, which is generally much quicker and more efficient than performing the necessary processing on the differential file. Instead of keeping a list of all records that have changed since the last update, a Bloom filter of the records that have been changed can be kept. Here, a false positive would force the database to check both the differential file and the database on a read even when a record has not been changed. If false positives are sufficiently rare, this cost is minimal.

Future Directions

Recent research related to Bloom filters has followed three major directions: alternative constructions, improved analysis, and extensions to more challenging questions. All three of these directions are likely to continue to grow.

Research in alternative constructions has focused on building data structures with the same capabilities as a Bloom filter or related data structures with improved efficiency, sometimes particularly for a specialized domain, such as router hardware. Improved analysis has considered reducing for example the amount of randomness required for a Bloom filter, or its performance under specific classes of hash functions.

The largest area of research has come from extending the basic idea of the Bloom filter to more general and more difficult problems. Arguably, the success of Bloom filters relies on their flexibility, and numerous variations on the theme have arisen. For example, counting Bloom filters extend Bloom filters by allowing sets to change dynamically via insertions and deletions of elements [9,15]. Spectral Bloom filters extend Bloom filters to handle multi-sets [7]. Count-min sketches extend Bloom filters to approximately track counts associated to items in a data stream, such as byte-counts for network flows [8]. Bloomier filters extend Bloom filters to the situation where each element of S is associated with a function value from a discrete, finite set of values, and the data structure should return that value [6]. Approximate concurrent state machines further extend Bloom filter to the setting where both the set can change due to insertions and deletions and the function values associated with set elements can change dynamically [3]. The list of variations continues to grow steadily as more applications are found.

BM25

Giambattista Amati

Ugo Bordoni Foundation, Rome, Italy

Synonyms

OKAPI retrieval function; Probabilistic model

Definition

BM25 is a ranking function that ranks a set of documents based on the query terms appearing in each document, regardless of the inter-relationship between the query terms within a document (e.g., their relative proximity). It is not a single function, but actually a whole family of scoring functions, with slightly different components and parameters. It is used by search engines to rank matching documents according to their relevance to a given search query and is often referred to as "Okapi BM25," since the Okapi information retrieval system was the first system implementing this function. The BM25 retrieval formula belongs to the BM family of retrieval models (BM stands for Best Match), that is the weight of a term **t** in a document **d** is:

$$\frac{\mathbf{tf}}{k+\mathbf{tf}}\ln\frac{(r_{\mathbf{t}}+0.5)\cdot(\mathbf{N}-R-\mathbf{n_t}+r_{\mathbf{t}}+0.5)}{(\mathbf{n_t}-r_{\mathbf{t}}+0.5)\cdot(R-r_{\mathbf{t}}+0.5)} \qquad [BM\text{'s family}]$$

where

- R is the number of documents known to be relevant to a specific topic,
- $r_{\mathbf{t}}$ is the number of relevant documents containing the term,
- **N** is the number of documents of the collection,
- $\mathbf{n_t}$ is the document frequency of the term,
- **tf** is the frequency of the term in the document,
- k is a parameter.

The BM25 document-query matching function is:

$$\sum_{\mathbf{t}\in\mathbf{q}} w_{\mathbf{t}}\cdot \mathrm{In}\frac{(r_{\mathbf{t}}+0.5)\cdot(\mathbf{N}-R-\mathbf{n_t}+r_{\mathbf{t}}+0.5)}{(\mathbf{n_t}-r_{\mathbf{t}}+0.5)\cdot(R-r_{\mathbf{t}}+0.5)} \; [BM25] \tag{1}$$

where

- **q** is the query,
- $w_{\mathbf{t}}=(k_1+1)\frac{\mathbf{tf}}{k+\mathbf{tf}}\cdot(k_3+1)\frac{\mathbf{tf}_q}{(k_3+\mathbf{tf_q})}$
- $\mathbf{tf}_q$ is the frequency of the term within the topic from which **q** was derived
- l and $\bar{\mathbf{l}}$ are respectively the document length and average document length.

- k is $k_1\left((1-b)+b(\frac{l}{\bar{\mathbf{l}}})\right)$.
- k_1, b and k_3 are parameters which depend on the nature of the queries and possibly on the database.
- k_1 and b are set by default to 1.2 and 0.75 respectively, k_3 to 1000.

By using these default parameters, the unexpanded BM25 ranking function, that is the BM25 applied in the absence of information about relevance ($R=r=0$), is:

$$\sum_{\mathbf{t}\in\mathbf{q}} \frac{2.2\cdot\mathbf{tf}}{0.3+0.9\frac{l}{\bar{\mathbf{l}}}+\mathbf{tf}}\cdot\frac{1001\cdot\mathbf{tf}_q}{1000+\mathbf{tf}_\mathbf{q}}\ln\frac{N-\mathbf{n_t}+0.5}{\mathbf{n_t}+0.5} \tag{2}$$

Historical Background

The successful formula of the BM family, the BM25, was introduced by Robertson and Walker in 1994 [1,3] and it has its root in Harter's 2-Poisson model of litheness for indexing. Before BM25, a direct exploitation of itheness for document retrieval was explored by Robertson, Van Rijsbergen, Porter, Williams and Walker [3,4] who plugged the Harter 2-Poisson model into the standard probabilistic model of relevance o Robertson and Spark Jones [2]. The evolution of the 2-Poisson model as designed by Robertson, Van Rijsbergen and Porter has thus motivated the birth of the BM family of term-weighting forms. The BM25 formula is the matching function of the Okapi information retrieval system of City University in London.

Foundations

BM25 derives from both the 2-Poisson model and the probabilistic binary independence model of relevance, that is as a combination of the probabilistic model

$$\mathrm{Prob}(rel,\mathbf{d}|\mathbf{q}) \propto \prod_{\mathbf{t}\in\mathbf{q}\cap\mathbf{d}} \frac{\mathrm{Prob}(\mathbf{t}|rel)\cdot\mathrm{Prob}(\bar{\mathbf{t}}|\overline{rel})}{\mathrm{Prob}(\mathbf{t}|\overline{rel})\cdot\mathrm{Prob}(\bar{\mathbf{t}}|\overline{rel})} \tag{3}$$

and the 2-Poisson model

$$\mathrm{Prob}(X=\mathbf{tf}) = p\cdot\frac{e^{-\lambda_{\mathbf{E_t}}}\lambda_{\mathbf{E_t}}{}^{\mathbf{tf}}}{\mathbf{tf}!}+(1-p)\cdot\frac{e^{-\lambda_{\overline{\mathbf{E_t}}}}\lambda_{\overline{\mathbf{E_t}}}{}^{\mathbf{tf}}}{\mathbf{tf}!} \tag{4}$$

where p is the probability of a document to belong to the Elite set.

However, the 2-Poisson has three parameters: the mean term frequency of the term in the elite set $\lambda_{\overline{\mathbf{E_t}}}$ (a set of documents with a large number of occurrences of the term), the mean term frequency of the term in the rest of the collection, $\lambda_{\overline{\mathbf{E_t}}}$, and the mixing parameter p. Therefore, the 2-Poisson model needs reasonable approximations in order to make the probabilistic mixture a workable retrieval model.

The combination of the notion of eliteness with that of relevance generates the Robertson, Van Rijsbergen and Porter's query term-document matching function:

$$w = \ln\frac{(p_1\lambda_{\mathbf{E_t}}{}^{\mathbf{tf}}e^{-\lambda_{\mathbf{E_t}}}+(1-p_1)\lambda_{\overline{\mathbf{E_t}}}{}^{\mathbf{tf}}e^{-\lambda_{\overline{\mathbf{E_t}}}})}{(p_2\lambda_{\mathbf{E_t}}{}^{\mathbf{tf}}e^{-\lambda_{\mathbf{E_t}}}+(1-p_2)\lambda_{\overline{\mathbf{E_t}}}{}^{\mathbf{tf}}e^{-\lambda_{\overline{\mathbf{E_t}}}})} \frac{(p_2e^{-\lambda_{\mathbf{E_t}}}+(1-p_2)e^{-\lambda_{\overline{\mathbf{E_t}}}})}{(p_1e^{-\lambda_{\mathbf{E_t}}}+(1-p_1)e^{-\lambda_{\overline{\mathbf{E_t}}}})} \tag{5}$$

where p_1 and p_2 are the conditional probabilities of a document to be or not in the elite set respectively, given the set of relevant documents. Since elite set (documents with high query-term frequency) and relevance (documents relevant to the query) are highly correlated then it can be assumed that $p_1 > p_2$.

With little algebra, (5) is equivalent to

$$w = \ln\frac{\left(p_1+(1-p_1)\left(\frac{\lambda_{\overline{\mathbf{E_t}}}}{\lambda_{\mathbf{E_t}}}\right)^{\mathbf{tf}}e^{\lambda_{\mathbf{E_t}}-\lambda_{\overline{\mathbf{E_t}}}}\right)}{\left(p_2+(1-p_2)\left(\frac{\lambda_{\overline{\mathbf{E_t}}}}{\lambda_{\mathbf{E_t}}}\right)^{\mathbf{tf}}e^{\lambda_{\mathbf{E_t}}-\lambda_{\overline{\mathbf{E_t}}}}\right)} \frac{\left(p_2e^{-\lambda_{\mathbf{E_t}}+\lambda_{\overline{\mathbf{E_t}}}}+(1-p_2)\right)}{\left(p_1e^{-\lambda_{\mathbf{E_t}}+\lambda_{\overline{\mathbf{E_t}}}}+(1-p_1)\right)} \tag{6}$$

Equation (6) can be rewritten as

$$w(\mathbf{tf}) = \ln C(\mathbf{tf}) + \ln C_0$$

where C_0 is the ratio of the two components of the cross-product ratio not containing the variable **tf**. The first derivative with respect to the variable **tf** is

$$\frac{dw}{d\mathbf{tf}} = \frac{(p_1-p_2)\cdot e^{\lambda_{\mathbf{E_t}}-\lambda_{\overline{\mathbf{E_t}}}}\cdot\left(\frac{\lambda_{\overline{\mathbf{E_t}}}}{\lambda_{\mathbf{E_t}}}\right)^{\mathbf{tf}}\cdot\ln\left(\frac{\lambda_{\mathbf{E_t}}}{\lambda_{\overline{\mathbf{E_t}}}}\right)}{C(\mathbf{tf})}$$

The derivative is always positive because $p_1 > p_2$, $\lambda_{\overline{\mathbf{E_t}}} \ll \lambda_{\mathbf{E_t}}$ and thus $\ln\left(\frac{\lambda_{\mathbf{E_t}}}{\lambda_{\overline{\mathbf{E_t}}}}\right) > 0$ in the 2-Poisson model. Therefore $w(\mathbf{tf})$ is a monotonically increasing function. The limiting form of (6) for **tf** $\rightarrow\infty$ is

$$w = \ln \frac{p_1\left(p_2 e^{-\lambda_{\mathbf{E_t}}+\lambda_{\overline{\mathbf{E_t}}}} + (1-p_2)\right)}{p_2\left(p_1 e^{-\lambda_{\mathbf{E_t}}+\lambda_{\overline{\mathbf{E_t}}}} + (1-p_1)\right)}$$

Since $e^{-\lambda_{\mathbf{E_t}}+\lambda_{\overline{\mathbf{E_t}}}} \sim 0$, this limit is very close to

$$w \sim \mathrm{In} \frac{p_1(1-p2)}{p_2(1-p1)} \tag{7}$$

Because (6) is monotonic with respect to the within–document term-frequency **tf**, document ranking is obtained by decreasing order of the **tf** value. Hence because for the highest values of the term frequency **tf** (i.e., for **tf** → ∞), the limiting form of (7) can be taken as the actual score of the topmost documents.

In 1994, Robertson and Walker defined as an approximation of w of (7) the product

$$w = \frac{\mathbf{tf}}{\mathbf{tf}+K} \cdot \mathrm{In} \frac{\mathrm{Prob}(\mathbf{t}|rel)\mathrm{Prob}(\bar{\mathbf{t}}|\overline{rel})}{\mathrm{Prob}(\mathbf{t}|\overline{rec})\mathrm{Prob}(\bar{\mathbf{t}}|\overline{rel})} \tag{8}$$

Indeed, both (6) and (8) have Formula 7 as their limit for large **tf**. Varying the parameter K and using equation

$$\frac{\mathrm{Prob}(\mathbf{t}|rec)\mathrm{Prob}(\bar{\mathbf{t}}|\overline{rec})}{\mathrm{Prob}(\mathbf{t}|\overline{rec})\mathrm{Prob}(\bar{\mathbf{t}}|rec)} = \frac{(r_{\mathbf{t}}+0.5)\cdot(\mathbf{N}-R-\mathbf{n_t}+r_{\mathbf{t}}+0.5)}{(\mathbf{n_t}-r_{\mathbf{t}}+0.5)\cdot(R-r_{\mathbf{t}}+0.5)} \tag{9}$$

the BM weighting formulas are derived.

Boolean Model

Massimo Melucci
University of Padua, Padua, Italy

Definition

In the Boolean Model for Information Retrieval, a document collection is a set of documents and an index term is the subset of documents indexed by the term itself. An index term can also be seen as a proposition which asserts whether the term is a property of a document, that is, if the term occurs in the document or, in other words, if the document is about the concept represented by the term.

The interpretation of a query is set-theoretical. In practice, a query is a Boolean expression where the set operators are the usual intersection, union and complement, and the operands are index terms. The document subsets which corresponds to the index terms of the query are combined through the set operators. The system returns the documents which belong to the subset expressed by the query.

Historical Background

The Boolean model for Information Retrieval was proposed as a paradigm for accessing large scale systems since the 1950s. The idea of composing queries as Boolean propositions was at that time considered advantageous for the end user and simple to implement, so that its use rapidly spread in the 1960s. The main reason for the rapid advent of the Boolean model was the presence of experienced end users who also were expert of the domain of the searched documents. These users were expected to be able to quite effectively express their own information needs by composing index terms and operators as propositions. More recently, some user studies suggested that even experienced users tended to employ the less Boolean operators as possible and to submit quite simple queries.

A possible reason for the potential success of the Boolean model was the controlled, coordinated and very often manual indexing of the collections; these terms were often quite homogeneous terms, namely, referred to a restricted domain, therefore, indexing carefully avoided ambiguous terms and correctly associated related terms. Since then, the Boolean model was adopted by various other information management systems, e.g., office information systems, library catalogue systems, and database systems.

Currently, the Boolean model is quite ubiquitous since the advanced search functions constitute a constant of almost every information management systems, Web search engines included. However, it is a matter of fact that the success of this model decreased over time because of the decreasing proportion of experienced end users, the increasing heterogeneity of the document collections and the lack of a support for ranking documents. The most glaring example is the World Wide Web, which fuels the search engine indexes with more and more heterogenous Web pages accessed by an increasing number of unexperienced end users. Various research works showed that the percentage of users who use advanced search functions is very limited, even when they are quite expert of the domain or in using the interface.

Foundations

A parallel can be established between database design and Boolean model. As far as database systems are concerned, the design process aims at structuring entities, relationships and attributes accessed through relational query languages. When Boolean Information Retrieval systems are considered, the document properties are index terms and the design process aims at selecting the index terms of the document through an indexing process. Once every document has been indexed, the document collection is described by an index whose terms are associated to the documents in which they occur. The basic information retained by the system is the membership of the document to the index term.

Suppose, for example, some authors are writing their own documents, say, d_1,d_2,d_3 using, say, three terms, namely, A,B,C. The terms *unambiguously* describe one concept each – the absence of ambiguity of the natural language is an important assumption so as to make this model effective. As a document may be about one or two concepts, a document may belong to more subsets. Suppose, for example, that the collection stores the documents d_1,d_2,d_3, which respectively contains the following index terms: $\{A,C\}$, $\{A,B\}$, $\{B\}$. According to the Boolean model, three subsets $A = \{d_1,d_2\}$, $B = \{d_2,d_3\}$, $C = \{d_1\}$ are defined after indexing the collection. (It is customary to label the subset with the index term.)

The example shows that a concept is addressed by one or more documents and a term is associated to a single document subset. These document subsets are the extensional expressions of the concept described by an index term. In other words, the enumeration of the document subset is the description of the concept labeled by the index term. Indeed, the Boolean model was thought as a means for describing concepts without recurring to ontological description, but to a simple, yet powerful logical language.

The index terms and the associated document subsets are decided at indexing time by a human indexer or an automated process driven by an indexing algorithm. If the set operators were not available, the end user could use one index term at a time for formulating his own query thus having a very few degrees of freedom for formulating his own information need. Thanks to the set-based view imposed by the Boolean model, the end user can utilize the Boolean algebra for constructing new subsets. These new subsets are what results from Boolean expressions based on the classical operators, namely, intersection, union and complement. Suppose, for example, A,B,C are the document subsets associated to three index terms; let $A = \{d_1,d_2\}$, $B = \{d_2,d_3\}$, $C = \{d_1\}$ and A AND NOT C be a new subset. This subset contains d_2 only thus expressing the fact that d_2 is about A AND NOT C.

What is important here is that the construction of document subsets through the Boolean algebra allows the end user for expressing new concepts which were not explicitly thought by the authors. Indeed, the author of d_2 did not think that d_2 was about A AND NOT C. With this respect, the Boolean model is a powerful language because would permit to represent the knowledge stored in a document collection by means of an algebra. A system based on the Boolean model can efficiently answer these queries by performing some simple algorithms which implement set operations and process sets.

Despite its strengths and simplicity, the Boolean model has some weaknesses. Understanding the main weaknesses of the Boolean model is crucial for making the application of this model to realistic contexts effective. The weaknesses of the Boolean model can be summarized as follows (see also Cooper, 1988):

- Set operator confusion
- Expressiveness gap
- Index term ambiguity
- Null output
- Output overload

Null output and output overload are due to the lack of support for ranking documents.

Set operator confusion occurs whenever intersection and union, namely, `AND` and `OR` are exchanged when composing a query. Because of the imprecision of the natural language, humans often use "or" for saying "and," and viceversa. This confusion causes a similar exchange when using the artificial Boolean language. Suppose, for example, the collection is $\{d_4,d_5\}$, d_4 is about *A* and d_5 is about *B*. Using the natural language, end user's information need might be "the documents about *A and B*" to mean the whole document collection. To obtain the whole collection as a result, the user should use *A* `OR` *B*. However, if the user translated the "and" of his own natural language request into an `AND` operator, the translation of the request into an artificial language would be *A* `AND` *B*, which returns the empty set. Things are more difficult as the query is more complex.

Expressiveness gap is the loss of expressiveness encountered whenever an information need has to be translated to an artificial language like the Boolean language from a more expressive natural language. Suppose, for example, the end user wants to retrieve documents about the Boolean language in Information Retrieval or Database Systems. The use of the Boolean query language requires that each word or group of words is corresponded to an index term, namely, to a document subsets, and that some set operators are applied to these sets; for example, a query might be `(boolean AND information retrieval) OR database systems`. The problem of the expressiveness gap is amplified by the multiplicity of queries which can be formulated as a representation of the same information need. As a consequence, a variety of document subsets not all being the same can be retrieved. Suppose, for example, the end user wants to retrieve documents about the Boolean language in Information Retrieval or Database Systems. Potential Boolean queries are, for example:

- `(boolean AND information retrieval) OR database systems`
- `boolean AND (information retrieval OR database systems)`

The expressiveness gap occurs because the request expressed in natural language does not indicate if and where the parentheses are located, whereas the location of the parentheses is crucial when using the Boolean algebra. Although both are valid expressions, they provide different results.

Index term ambiguity occurs whenever a term has two distinct meanings (polysemy) or two terms have the same meaning (synonymy). When a term is polysemous, documents about two distinct concepts co-occur in the same subset. As a consequence, irrelevant documents may be retrieved when the end user employs the term in his own query. Suppose, for example, `bank` = $\{d_6,d_7\}$, but d_6 is about bank as river bank and d_7 is about bank as bank branch. When the user expresses his own Boolean query using `bank` as term, both documents are retrieved. If, however, the user needs information about river banks, one irrelevant document, i.e., d_7, is retrieved. In this event, precision is lower than the precision measured if ambiguity does not occur. When two terms are synonyms, two distinct document subsets are defined, yet the documents are about the same concept. As a consequence, relevant documents may be missed when the end user employs only one of the two terms in his own query. Suppose, for example, `personalcomputer` = $\{d_8,d_9\}$ and `PC` = $\{d_{10}\}$, but `PC` is the acronym of `personal computer` and therefore d_{10} should be retrieved, but it is not. When the user expresses his own Boolean query using `PC` as term, only d_{10} is retrieved. If, however, the use needs information about personal computers, two relevant documents, i.e., d_8,d_9, are missed. In this event, recall decreases.

Null output occurs whenever the end user submits a very restrictive query to the system to an extent to make the returned document subset very small, if not even empty. Limit examples are terms being absent from the index, which are associated to the empty document set or two index terms whose intersection is empty because there are no common documents. The event of intersecting disjoint document subsets is very probable since the document subsets are usually small if compared with the document collection. Moreover, Boolean systems do not usually keep track of the semantic relationships between terms, and therefore connecting by AND two semantically related terms whose document subsets are disjoint would give the empty set as result. To reduce null output, some query terms can be related by OR or some AND should be removed by the user.

Output overload occurs whenever the result document subset is too large for being effectively browsed by the end user. This drawback often happens when too many ORs or too few ANDs are utilized for formulating the query. Even though a document subset is small if compared with the document collection, a subset of, say, 1,000 documents is very large for the end user who is required to inspect all of them. A strategy for avoiding output overload is reducing the number of OR or adding some AND.

Overall, the side effects of null output and output overload are hardly controlled by the end user who is requested to add and delete terms or Boolean operators so as to make the query an effective description of his own information need. This task, which is called Query Expansion, would overload the cognitive effort of the end user, if performed using a Boolean systems.

To overcome the problems of null output and output overload, the notion of level of coordination was introduced. The level of coordination is a measure of the degree to which each returned document matches the query. In this way, the level of coordination provides a score for ranking the documents. This ranking allows the user for deciding how many documents to inspect and the system for cutting the bottom ranked documents off the list.

The level of coordination is calculated as follows. A Boolean query is transcribed in conjunctive normal form, namely, as a list of propositions related by AND – each proposition is a disjunction of terms. The level of coordination of a document is the number of propositions satisfied by the document. Suppose, for example, A,B,C are the document subsets associated to three index terms; let $A = \{d_1,d_2\}$, $B = \{d_2,d_3\}$, $C = \{d_3\}$ and A AND (C OR B) be the query; the level of coordination of d_1 is 1 because only the first proposition is satisfied by d_1, the level of d_2 is 2 and that of d_3 is 1 – d_1,d_3 would have not been retrieved if the level of coordination were not been calculated because they do not satisfy the query.

A variation of the level of coordination was introduced for taking the variable size of document subsets into account – indeed, the document subsets are of arbitrary size and therefore a small subset may be treated as a large subset. This variation has been called weighted level of coordination: instead of assigning a constant weight to each proposition made true by a document, a different weighted is assigned depending on the proposition; for example, an IDF may be used. The weighed level of coordination is then the sum of the weights assigned to every proposition.

Key Applications

The research papers and articles on the Boolean model flourished until when other models, e.g., the probabilistic models and the vector-space model, appeared on the scene of the Information Retrieval theater and the Web search engines drastically changed the audience and the document collections. The knowledge of this model, however, is a basic element of an Information Retrieval system because the Boolean query language is provided by many if not all information management systems. Of course, this model is the starting point for facing the non-classical logic models for Information Retrieval.

Boosting

Zhi-Hua Zhou

Nanjing University, Nanjing, China

Definition

Boosting is a kind of ensemble method which produces a strong learner that is capable of making very accurate predictions by combining rough and moderately inaccurate learners (which are called as *base learners* or *weak learners*). In particular, Boosting sequentially trains a series of base learners by using a *base learning algorithm*, where the training examples wrongly predicted by a base learner will receive more attention from the successive base learner. After that, it generates a final strong learner through a weighted combination of these base learners.

Historical Background

In 1988, Kearns and Valiant posed an interesting question for the research of computational learning theory, i.e., whether a *weak* learning algorithm that performs just slightly better than random guess can be "boosted" into an arbitrarily accurate *strong* learning algorithm. In other words, whether two complexity classes, *weakly learnable* and *strongly learnable* problems, are equal. In 1989, Schapire [9] proved that the answer to the question is "yes", and the proof he gave is a construction, which is the first Boosting algorithm. One year later, Freund developed a more efficient algorithm. However, both algorithms suffered from some practical drawbacks. Later, in 1995, Freund and Schapire [4] developed the AdaBoost algorithm

```
Input: Data set $\mathcal{D} = \{(x_1, y_1), (x_2, y_2), \cdots, (x_m, y_m)\}$;
       Base learning algorithm $\mathcal{L}$;
       Number of learning rounds $T$.
Process:
  $D_1(i) = 1/m$.        % Initialize the weight distribution
  for $t = 1,\cdots,T$:
      $h_t = \mathcal{L}(\mathcal{D}, D_t)$;        % Train a base learner $h_t$ from $\mathcal{D}$ using distribution $D_t$
      $\epsilon_t = \Pr_{i \sim D_i}[h_t(x_i \neq y_i)]$;      % Measure the error of $h_t$
      $\alpha_t = \frac{1}{2}\ln\left(\frac{1-\epsilon_t}{\epsilon_t}\right)$; % Determine the weight of $h_t$
      $D_{t+1}(\mathrm{i}) = \frac{D_t(i)}{Z_t} \times \begin{cases} \exp(-\alpha_t) & \text{if } h_t(x_i) = y_i \\ \exp(\alpha_t) & \text{if } h_t(x_i) \neq y_i \end{cases}$
               $= \frac{D_t(i)\exp(-\alpha_t y_i h_t(x_i))}{Z_t}$   % Update the distribution, where $Z_t$ is
                     % a normalization factor which enables $D_{t+1}$ be a distribution
  end.
Output: $H(x) = \mathrm{sign}\,(f(x)) = \mathrm{sign}\left(\Sigma_{t=1}^{T} \alpha_t h_t(x)\right)$
```

Boosting. Figure 1. The AdaBoost algorithm.

which is effective and efficient in practice, and then a hot wave of research on Boosting arose.

Foundations

AdaBoost is the most influential Boosting algorithm. Let $\mathcal{X}$ and $\mathcal{Y}$ denote the instance space and the set of class labels, respectively, and assume $\mathcal{Y} = \{-1, +1\}$. Given a training set $\mathcal{D} = \{(x_1, y_1), (x_2, y_2), \ldots, (x_m, y_m)\}$ where $x_i \in \mathcal{X}$ and $y_i \in \mathcal{Y}$ $(i = 1, \ldots, m)$, and a base learning algorithm which can be decision tree, neural networks or any other learning algorithms, the AdaBoost algorithm works as follows.

First, it assigns equal weights to all the training examples (x_i, y_i) $(i \in \{1, \ldots, m\})$. Denote the distribution of the weights at the tth learning round as D_t. From the training set and D_t the algorithm generates a base learner $h_t : \mathcal{X} \to \mathcal{Y}$ by calling the base learning algorithm. Then, it uses the training examples to test h_t, and the weights of the incorrectly classified examples will be increased. Thus, an updated weight distribution D_{t+1} is obtained. From the training set and D_{t+1} AdaBoost generates another base learner by calling the base learning algorithm again. Such a process is repeated for T times, each of which is called a *round*, and the final learner is derived by weighted majority voting of the T base learners, where the weights of the learners are determined during the training process. In practice, the base learning algorithm may be a learning algorithm which can use weighted training examples directly; otherwise the weights can be exploited by sampling the training examples according to the weight distribution D_t. The pseudo-code of AdaBoost is shown in Fig. 1.

Freund and Schapire [4] proved that the training error of the final learner H is upper-bounded by

$$\epsilon_D = \Pr_{i \sim \mathcal{D}}[H(x_i) \neq y_i] \leq 2^T \prod_{t=1}^{T} \sqrt{\epsilon_t (1 - \epsilon_t)},$$

which can be written as

$$\epsilon_D \leq \prod_{t=1}^{T} \sqrt{1 - 4\gamma_t^2 \leq \exp} \left(-2 \sum_{t=1}^{T} \gamma_t^2 \right),$$

where $\gamma_t = 1/2 - \epsilon_t$. Thus, if each base learner is slightly better than random so that $\gamma_t \geq \gamma$ for some $\gamma > 0$, the training error will drop exponentially fast in T since the upper bound is at most $e^{-2T\gamma^2}$.

Freund and Schapire [4] also gave a generalization error bound of H in terms of its training error $\epsilon_{\mathcal{D}}$, the size m of the training set, the VC-dimension d of the base learner space, and the number of rounds T, by

$$\epsilon \leq \epsilon_{\mathcal{D}} + \tilde{O}\left(\sqrt{\frac{Td}{m}} \right)$$

with high probability, where $\tilde{O}(\cdot)$ is used to hide all logarithmic and constant factors [10] instead of using $O(\cdot)$ which hides only constant factors.

The above generalization error bound suggests that AdaBoost will overfit if it runs for many rounds since T is in the numerator. However, empirical observations show that AdaBoost often does *not* overfit even after a large number of rounds, and sometimes it is even able to reduce the generalization error after the training error has already reached zero. Thus, later, Schapire et al. [11] presented another generalization error bound,

$$\epsilon \leq \Pr_{i \sim \mathcal{D}}\left[\text{margin}_f (x_i, y_i) \leq \theta \right] + \tilde{O}\left(\sqrt{\frac{d}{m\theta^2}} \right)$$

for any $\theta > 0$ with high probability, where the *margin* of f on (x_i, y_i) was defined as

$$\text{margin}_f(x_i, y_i) = \frac{y_i f(x_i)}{\sum_{t=1}^{T} |\alpha_t|} = \frac{y_i \sum_{i=1}^{T} \alpha_t h_t(x)}{\sum_{t=1}^{T} |\alpha_t|},$$

whose value is in $[-1, +1]$ and is positive only if H classifies (x_i, y_i) correctly. In fact, the magnitude of margin can be explained as a measure of confidence in prediction. The larger the magnitude of margin, the higher confidence of prediction. Note that when $H(x_i) = y_i$, $\text{margin}_f(x_i, y_i)$ can still be increased as t increases. Thus, the above margin-based generalization bound gives an answer to the question of why AdaBoost is able to reduce the generalization error even after the training error reaches zero, that is, the confidence in prediction can be increased further. However, Breiman [2] showed that improving the margin does not necessarily lead to the improvement of generalization, which doubted the above margin-based explanation to AdaBoost.

In addition to the previously mentioned studies, the behavior of AdaBoost has been explained from the views of game theory [2,3], additive model [5], etc. Many variants or extensions of AdaBoost have been developed [6,10], which makes Boosting become a big family of ensemble methods.

In contrast to another famous ensemble method, Bagging (which reduces *variance* significantly but has little effect on *bias*), Boosting can significantly reduce bias in addition to reducing variance. So, on weak learners such as decision stumps, which are one-level decision trees, Boosting is usually more effective.

Key Applications

The first application of Boosting was on Optical Character Recognization by Drucker et al. Later, Boosting was applied to diverse tasks such as text categorization, speech recognization, image retrieval, medical diagnosis, etc. [6,10]. It is worth mentioning that AdaBoost has been combined with a cascade process for face detection [12], and the resulting face detector was 15 times faster than state-of-the-art face detectors at that time but with comparable accuracy, which was recognized as one of the major breakthroughs in computer vision (in particular, face detection) during the past decade.

Future Directions

The margin-based explanation to why Boosting often does not overfit was seriously challenged by Breiman's indication that larger margin does not necessarily mean better generalization [2]. Recently, Reyzin and Schapire [8] found that Breiman considered minimum margin instead of average or median margin. If the margin-based explanation can survive, it may be possible to establish a unified theoretical framework for the two powerful learning approaches, i.e., Boosting and support vector machine, since it is well-known that support vector machine works by maximizing the margin in a feature space.

It has been observed that Boosting performs poorly when abundant noise exists. Making Boosting more robust to noise is an important task. Moreover, Boosting suffers from some general deficiencies of ensemble methods, such as the lack of comprehensibility, i.e., the knowledge learned by Boosting is not understandable to the user. Trying to overcome those deficiencies is an important future direction.

Experimental Results

Empirical studies on Boosting have been reported in many papers, such as [1,7].

Bootstrap

Hwanjo Yu
University of Iowa, Iowa City, IA, USA

Synonyms

Bootstrap sampling; Bootstrap estimation

Definition

The bootstrap is a statistical method for estimating the performance (e.g., accuracy) of classification or regression methods. The bootstrap is based on the statistical procedure of sampling *with replacement*. Unlike other estimation methods such as cross-validation, the same object or tuple can be selected for the training set more than once in the boostrap. That is, each time a tuple is selected, it is equally likely to be selected again and re-added to the training set.

Historical Background

The bootstrap sampling was developed by Bradley Efron in 1979, and mainly used for estimating the statistical parameters such as mean, standard errors, etc. [2]. A meta-classification method using the bootstrap called *bootstrap aggregating* (or *bagging*) was proposed by Leo Breiman in 1994 to improve the classification by combining classifications of randomly generated training sets [1].

Foundations

This section discusses a commonly used bootstrap method, *.632 bootstrap*. Given a dataset of N tuples, the dataset is sampled N times, with replacement, resulting in a *bootstrap sample* or training set of N tuples. It is very likely that some of the original data tuples will occur more than once in the training set. The data tuples that were not sampled into the training set end up forming the test set. If this process is repeated multiple times, on average 63.2% of the original data tuples will end up in the training set and the remaining 36.8% will form the test set (hence, the name, .632 bootstrap).

The figure, 63.2%, comes from the fact that a tuple will not be chosen with probability of 36.8%. Each tuple has a probability of $1/N$ of being selected, so the probability of not being chosen is $(1 - 1/N)$. The selection is done N times, so the probability that a tuple will not be chosen during the whole time is $(1 - 1/N)^N$. If N is large, the probability approaches $e^{-1} = 0.368$. Thus, 36.8% of tuples will not be selected for training and thereby end up in the test set, and the remaining 63.2% will form the training set.

The above procedure can be repeated k times, where in each iteration, the current test set is used to obtain an accuracy estimate of the model obtained from the current bootstrap sample. The overall accuracy of the model is then estimated as

$$Acc(M) = \sum_{i=1}^{k} (0.632 \times Acc(M_i)_{test\_set} + 0.368 \times Acc(M_i)_{train\_set}), \tag{1}$$

where $Acc(M_i)_{train\_set}$ and $Acc(M_i)_{test\_set}$ are the accuracy of the model obtained with bootstrap sample i when it is applied to training set and test set respectively in sample i.

Key Applications

The bootstrap method is preferably used for estimating the performance when the size of dataset is relatively small.

Boyce-Codd Normal Form

Marcelo Arenas
Pontifical Catholic University of Chile, Santiago, Chile

Synonyms

BCNF

Definition

Let $R(A_1,\ldots,A_n)$ be a relation schema and Σ a set of functional dependencies over $R(A_1,\ldots,A_n)$. Then (R, Σ) is said to be in Boyce-Codd Normal Form (BCNF) if for every nontrivial functional dependency $X \rightarrow A$ implied by Σ, it holds that X is a superkey for R.

Key Points

In order to avoid update anomalies in database schemas containing functional dependencies, BCNF was introduced by Codd (In [2], Codd pointed out that this normal form was developed by Raymond F. Boyce and himself.) in [2]. This normal form is defined in terms of the notion of superkey as shown above. For example, given a relation schema $R(A, B, C)$ and a set of functional dependencies $\Sigma = \{AB \rightarrow C, C \rightarrow B\}$, it does not hold that $(R(A, B, C), \Sigma)$ is in BCNF since C is not a superkey for R. On the other hand, $(S\ (A, B, C), \Gamma)$ is in BCNF if $\Gamma = \{A \rightarrow BC\}$, since A is a superkey for S in this case.

It should be noticed that relation schema $R(A, B, C)$ above is in 3NF if $\Sigma = \{AB \rightarrow C, C \rightarrow B\}$, although this schema is not in BCNF. In fact, BCNF is strictly stronger than 3NF; every schema in BCNF is in 3NF, but there exist schemas (as the one shown above) that are in 3NF but not in BCNF.

For every normal form two problems have to be addressed how to decide whether a schema is in that normal form, and how to transform a schema into an equivalent one in that normal form. As opposed to the case of 3NF, it can be tested efficiently whether a relation schema is in BCNF. A relation schema (R, Σ) is in BCNF if and only if for every nontrivial functional dependency $X \rightarrow Y \in \Sigma$, it holds that X is a superkey. Thus, it is possible to check efficiently whether (R, Σ) is in BCNF by using the linear-time algorithm for functional dependency implication developed by Beeri and Bernstein [1]. On the negative side, given a relation schema S, it is not always possible to find a database schema S' such that S' is in BCNF and S' is a lossless and dependency preserving decomposition of S. In fact, relation schema $R(A, B, C)$ and set of functional dependencies $\{AB \rightarrow C, C \rightarrow B\}$ does not admit a dependency preserving decomposition in BCNF.

BP-Completeness

Dirk Van Gucht
Indiana University, Bloomington, IN, USA

Synonyms

Instance-completeness; Relation-completeness

Definition

A relational query language Q is BP-complete if for each relational database D, the set of all relations defined by the queries of Q on D is equal to the set of all first-order definable relations over D. More formally, fix some infinite universe **U** of atomic data elements. A *relational database schema* S is a finite set of relation names, each with an associated arity. A *relational database* D with schema S assigns to each relation name of S a *finite* relation over **U** of its arity. The domain of D, $dom(D)$, is the set of all atomic data elements occurring in the tuples of its relations. Let FO^S be the set of first-order formulas over signature S and the equality predicate, and let $FO^S(D) = \{\varphi(D) | \varphi \in FO^S\}$. (For a formula $\varphi \in FO^S$ with free variables $(x_1,...,x_m)$, $\varphi(D)$ denotes the m-ary relation over $dom(D)$ defined by φ, where the variables in φ are assumed to range over $dom(D)$.) Let Q^S denote those queries of Q defined over schema S, and let $Q^S(D) = \{q(D)|q \in Q^S\}$, i.e., the set of relations defined by queries of Q applied to D. Then, Q is *BP- complete* if for each relational database D over schema S,

$$Q^S(D) = FO^S(D).$$

In the words of Chandra and Harel, "BP-completeness can be seen to be a measure of the power of a language to express relations and *not* of its power to express functions having relations as outputs, i.e., queries." In fact, there exist BP-complete languages that do not express the same queries.

Key Points

Chandra and Harel introduced the concept of BP-completeness and attributed it to Bancilhon and Paredaens who were the first to study it. Bancilhon and Paredaens considered the following decision problem: given a relational database D and a relation R defined over $dom(D)$, does there exists a first-order formula φ such that $\varphi(D) = R$? (Paredaens considered this problem for the relational algebra, but by Codd's theorem on the equivalence of first-order logic and the relational algebra, these decision problems are the same.) They gave an algebraic, language-independent characterization of this problem by showing that such a first-order formula exists if and only if for each bijection $h : dom(D) \rightarrow dom(D)$, if $h(D) = D$ then $h(R) = R$. Equivalently, if h is an automorphism of D then it is also an automorphism of R. (Here, $h(D)$ and $h(R)$ are the natural extensions of h to D and R, respectively.) For a relational database D over schema S and a relation R, denote by $Aut(D)$ and $Aut(R)$ the sets of automorphisms of D and R, respectively, and let $R^S(D) = \{R \mid R$ is a relation over $dom(D)$ such that $Aut(D) \subseteq Aut(R)\}$. Then, an alternative characterization for the BP-completeness of Q is to require that for each relational database D over schema S,

$$Q^S(D) = R^S(D).$$

Van den Bussche showed that this characterization follows from Beth's Theorem about the explicit and implicit definability of first-order logic. The concept of BP-completeness has been generalized as well as specialized to query languages over other database models.

Bpref

Nick Craswell
Microsoft Research Cambridge, Cambridge, UK

Definition

Bpref is a preference-based information retrieval measure that considers whether relevant documents are ranked above irrelevant ones. It is designed to be robust to missing relevance judgments, such that it gives the same experimental outcome with incomplete judgments that Mean Average Precision would with complete judgments.

Key Points

In a test collection where all relevant documents have been identified, experiments using bpref and MAP should give the same outcome, for example both systems should agree that system A is better than system B. However, if the relevance judgments are incomplete, for example where only half the pool has been judged, MAP becomes unstable and may incorrectly show that system B is better than system A. The bpref measure was developed to maintain the correct ordering of systems (A better than B) even with incomplete judgments.

Given a ranked list of search results and a set of R known relevant documents and N known irrelevant documents, bpref first identifies the top-R irrelevant documents in the list. For these irrelevant documents n and relevant documents r the measure is:

$$bpref = \frac{1}{R}\sum_{r}\left(1 - \frac{|n\ ranked\ higher\ than\ r|}{\min(R,N)}\right)$$

The bpref paper [1] found good agreement between full-judgment MAP and reduced-judgment bpref even if the judged set was reduced by 80%. Later work has introduced other measures with similar or better properties, notably Inferred Average Precision [2].

Browsing

Kent Wittenburg
Mitsubishi Electric Research Laboratories, Inc., Cambridge, MA, USA

Synonyms

Perusal; Scanning

Definition

"Browsing" has two definitions in the context of visual interfaces for database systems:

1. The human activity of visual perception and interpretation of electronic content when there is no specific target object being sought.
2. The human activity of clicking or tapping on a sequence of elements in an information display that results in a sequence of screens of information state.

Definition (1) implies something about the mental intent of the user performing the act of information processing. The intent can be to learn the gist of "what is there." It may be to take in information in order to be entertained or informed. Or it may simply be a part of involuntary visual scanning within an environment. In the physical world, examples include flipping through the pages of a book, scanning quickly through a menu, or glancing down a store aisle.

Definition (2) is used in the context of contrasting the human-computer interaction paradigm of link-following in World Wide Web applications versus searching, which entails forming queries. "Browsing" in this context refers to a sequence of clicking or tapping behaviors on highlighted elements (hyperlinks) in order to go directly to a subsequent state of the information display. In contrast, "searching" entails specifying and then executing a query. The interaction paradigms of browsing and searching are independent of the intentional state of the user – the individual may or may not be looking for something specific in either case.

Key Points

A branch of research in visual interfaces for browsing in the first sense is Rapid Serial Visual Presentation (RSVP) [2, Sect. 4.2]. The human psychology of visual perception, specifically models of short-term visual memory, can inform the design of visual interfaces for browsing. Visual information can be presented in space or in time or in some combination thereof. For image presentation specifically, is it better to utilize screen real estate to present multiple images concurrently or to present them over time? If over time, should images move in some specified path or remain motionless? What are the best controls to give to the user in order to support the tasks of rapid perusal in order to get a gist of the content within that information space or to help in making a selection for further detailed investigation? These are some of the questions being asked by researchers and designers in the context of RSVP interfaces.

An important aspect of browsing as link-following has to do with information "scent." Just as animals' scent can be used as an indicator of their territory or former presence, the presentation of information links provides hints of what a user would find were he or she to follow the link. The theory of information foraging [1] provides insight into human behavior in information seeking that can help inform the design for interfaces and electronic documents. According to Pirolli, humans tend to make decisions about what links to follow and how long to continue along certain paths based on resource-limited assessments of the costs of such activities relative to a judgment of payoff.

Synonyms

Exploring; Surfing; Looking over/through

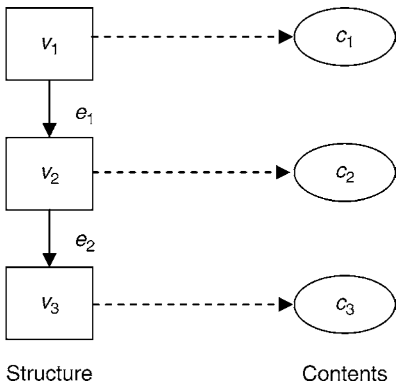
Definition

Informally, browsing is a process that involves looking through a collection of information. Thus, in a traditional library, one may wander about the stacks, glancing at titles of works, in regions where one expects to find interesting material. In the broadest sense, browsing is considered as one type of exploration, typically less directed or purposeful than searching, in that the goal or result is not always precisely known in advance. In the World Wide Web, this is very common, making use of "browsers" like Firefox or Internet Explorer. Sometimes the colorful term "surfing" is used when it seems appropriate to emphasize the excitement that some feel when exploring new Web content, or the thrill of getting closer to some desirable result. Yet, the WWW is but one example of a hypertext (or, if multiple media types are considered, hypermedia) environment. Accordingly, in a digital library, which many believe must include a hypertext [4], browsing involves moving from one information object to another according to some connections or links or structures.

Historical Background

A hypertext is a high level interactive navigational structure which allows non-sequential exploration of and access to information [3]. In the most general case, it consists of nodes connected by directed links in a graph structure. A directed link in the hypertext graph is called a hyperlink. Today's most famous hypertext system is the World Wide Web. The Web's structure contains hyperlinks connecting nodes that each can be associated with either a complete document (e.g., HTML page) or with a location in a document (e.g., a start tag in an HTML page).

Three models for Web browsing defined by Baeza-Yates and Ribeiro-Neto [1] are flat browsing, structure guided browsing, and utilizing the hypertext model. If a document collection is organized as a one dimensional list, exploring the document space is an example of flat browsing; if the organization is hierarchical instead of flat, then browsing is structure guided. The first two models have a hypertext graph that is made up of a disconnected bipartite graph and a tree, respectively, so they are special cases of the third model.



Browsing in Digital Libraries. Figure 1. A simple hypertext.

Browsing and searching are two paradigms for finding things on the Web. Some Web search engines provide Web directories used for browsing (and also for searching). Web directories are hierarchical taxonomies that classify human knowledge. Although a taxonomy can be considered as a tree, there can be cross references. One of the advantages of browsing a Web directory, in most cases, is that if a user finds what she is looking for in the taxonomy, then the answer that is found classified under that category almost certainly will be useful. In Web directories, a search can be reduced to a sub-tree of the taxonomy. However, searching may miss related pages that are not in that part of the taxonomy, if a user cannot formulate her information need sufficiently broadly.

Foundations

Browsing and searching are two methods of pursuing information on the Web; they also are two major paradigms for exploring digital libraries. The Web has no maintenance organization. Individuals add and delete pages at will. On the other hand, digital libraries require proper collection maintenance, and they will succeed only if their content is well organized [2].

The 5S (Streams, Structures, Scenarios, Spaces, and Societies) framework [4], which is used as a formal base upon which to describe digital libraries, defines structures to specify the way in which parts of a whole are managed or organized. In such digital libraries, structures can represent hypertexts.

For example, Fig. 1 illustrates a simple hypertext designed to provide access to objects in a digital library, in chronological order. It is made up of structural hyperlinks that follow chronological order (see solid

Thus, a formal and precise definition of browsing is illustrated in Fig. 1: Given a hypertext of a digital library, with vertex set *V* and edge set *E*, browsing is a set of sequences of traverse link events over the hypertext, such that event *e* of traversing from node v_k to v_t is associated with a function which retrieves the contents of node v_t. Hence, browsing a digital library is the

Browsing in Digital Libraries. Figure 4. Equus records are retrieved through basic searching.

procedure of navigating the hypertext, and it also can be understood as a traversal of a directed linked graph.

Returning to the previous example, one can observe that the left part of Fig. 1 is a directed linked graph (V, E), where each the right part is a set of contents $C = \{c_1, c_2, c_3\}$, and where c_i $(1 <= i <= 3)$ is the contents of a Web page associated with node v_i. An event of traversing along edge $e_1 = (v_1, v_2)$ is associated with a function: $E \rightarrow C$, which retrieves the contents of node v_2, i.e., c_2.

Note that (sorted) lists and hierarchical trees can be represented as hypertexts, so browsing can be over common organizations, such as alphabetical lists of authors, or indented lists of categories and subcategories; these are familiar from books with author indexes or tables of contents.

Key Applications

Modeling and analyzing browsing in digital libraries helps ease development and maintenance in those digital libraries. Some domain specific digital libraries have heterogeneous data that should be organized using several schemes. Thus, digital objects in an archaeological digital library may fit into various categories of archaeological data such as figurine images, bone records, locus sheets, and site plans. They can be organized according to different hierarchical structures (e.g., animal bone records are organized based on sites where they are excavated, temporal sequence, and animal names). These hierarchical structures contain one or more hierarchically arranged categories. In addition, they can be refined based on taxonomies existing in botany and zoology, or through classification and description of artifacts by archaeologists.

Thus, an archaeological digital library may provide multi-dimensional browsing (see Fig. 2) to allow users to move along any of the navigational dimensions, or a combination thereof. Navigational dimensions correspond to hierarchical structures used to browse digital objects, as mentioned above.

For example, an archaeologist might browse through three dimensions: space, object, and time. She can start from any of these dimensions and move along by clicking. The scenario shown in Fig. 2 tells that she is interested in the artifact records from the tomb numbered 056 in area A of the Bab edh-Dhra site. The clickstream representing her navigation path is

denoted "Site=Bab edh-Dhra>>PARTITION=A>> SUBPARTITION=056." While this navigation path is within the first dimension, it also is associated with the other dimensions. The second dimension shows there is only one type of object, i.e., pottery, from that particular location. The third dimension presents the two time periods associated with those pottery records. Hence, the dynamic coverage and hierarchical structure of those dimensions yields a tool supporting learning and exploring. The user can navigate across dimensions. By clicking "EARLY BRONZE II" in the third dimension, she can view all of the interesting artifact records from the EARLY BRONZE II period.

Browsing may present a useful starting point for active exploration of an answer space. Subsequent browsing and searching, in any combination, also can be employed to refine or enhance users' initial, possibly under-specified, information needs.

Browsing context is associated with a user's navigation path. Browsing results within a certain browsing context typically are a set of records (web pages), e.g., there are 35 pottery records within the browsing context represented by the navigation path denoted "Site=Bab edh-Dhra>>PARTITION=A>>SUBPARTITION=056." For example, assume a user wants to find saucer records in the set of thirty five pottery records. She types "saucer" in the search box as shown in Fig. 3. She switches from browsing to searching, so searching then is a natural extension of browsing.

Browsing may be provided as a post-retrieval service to organize searching results hierarchically in digital libraries. For example, in Fig. 4 one can see that eighty eight equus records are retrieved through the basic searching service, in response to a query "equus". They are organized into three dimensions after the user clicks the button "View search results hierarchically" (see Fig. 5).

Browsing may be supported by visualization to provide a starting point for users. Graphic overviews of a digital library collection can display category labels hierarchically based on the facets. Categories can be visualized as a hyperbolic tree [5] as well as through a traditional node-link representation of a tree.

A hyperbolic tree in Fig. 6 shows hierarchical relationships among excavation data in an archaeological digital library based on spatial, temporal, and artifact-related taxonomies. A node name represents a category, and a bubble attached to a node represents a set of archaeological records. The size of a bubble attached to a node reflects the number of records belonging to that category. The hyperbolic tree supports "focus + context" navigation; it also provides an overview of records organized in the archaeological digital library. It shows that the records are from seven archaeological sites (the Megiddo site has the most) and are of twelve different types.

Future Directions

Browsing and searching are often provided by digital libraries as separate services. Developers commonly see these functions as having different underlying mechanisms, and they follow a functional, rather than a task-oriented, approach to interaction design. While exhibiting complementary advantages, neither paradigm alone is adequate for complex information needs. Searching is popular because of its ability to identify information quickly. On the other hand, browsing is useful when appropriate search keywords are unknown or unavailable to users. Browsing also is appropriate when a great deal of contextual information is obtained along the navigation path. Therefore, a synergy between searching and browsing is required to support users' information seeking goals. Browsing and searching can be converted and switched to each other under certain conditions [5]. This suggests some new possibilities for blurring the dividing line between browsing and searching. If these two services are not considered to have different underlying mechanisms, they will not be provided as separated functions in digital libraries, and may be better integrated.

Text mining and visualization techniques provide digital libraries additional powerful exploring services, with possible beneficial effects on browsing and searching. Digital library exploring services such as browsing, searching, clustering, and visualization can be generalized in the context of a formal digital library framework [5]. The theoretical approach may provide a systematic and functional method to design and implement exploring services for domain focused digital libraries.

B-Tree Locking

GOETZ GRAEFE
Hewlett-Packard Laboratories, Palo Alto, CA, USA

Synonyms

B-tree concurrency control; Row-level locking; Key value locking; Key range locking; Lock coupling; Latching; Latch coupling; Crabbing

Definition

B-tree locking controls concurrent searches and updates in B-trees. It separates transactions in order to protect the B-tree contents and it separates threads in order to protect the B-tree data structure. Nowadays, the latter is usually called latching rather than locking.

Historical Background

Bayer and Schkolnick [1] presented multiple locking (latching) protocols for B^*-trees (all data records in the leaves, merely separator keys or "reference keys" in upper nodes) that combined high concurrency with deadlock avoidance. Their approach for insertion and deletion is based on deciding during a root-to-leaf traversal whether a node is "safe" from splitting (during an insertion) or merging (during a deletion), and on reserving appropriate locks (latches) for ancestors of unsafe nodes.

Lehman and Yao defined B^{link}-trees by relaxing the B-tree structure in favor of higher concurrency [8]. Srinivasan and Carey demonstrated their high performance using detailed simulations [13]. Jaluta et al. recently presented a detailed design for latching in B^{link}-trees, including a technique to avoid excessive link chains and thus poor search performance [7].

IBM's System R project explored multiple transaction management techniques, including transaction isolation levels and lock duration, predicate locking and key value locking, multi-granularity and hierarchical locking, etc. These techniques have been adapted and refined in many research and product efforts since then. Research into multi-level transactions [14] and into open nested transactions [3,12] enables crisp separation of locks and latches – the former protecting database contents against conflicts among transactions and the latter protecting in-memory data structures against conflicts among concurrent threads.

Mohan's ARIES/KVL design [10,11] explicitly separates locks and latches, i.e., logical database contents versus "structure maintenance" in a B-tree. A key value lock covers both a gap between two B-tree keys and the upper boundary key. In non-unique indexes, an intention lock on a key value permits operations on separate rows with the same value in the indexed column. In contrast, other designs include the row identifier in the unique lock identifier and thus do not need to distinguish between unique and non-unique indexes.

Lomet's design for key range locking [4] attempts to adapt hierarchical and multi-granularity locking to keys and half-open intervals but requires additional lock modes, e.g., a "range insert" mode, to achieve the desired concurrency. Graefe's design [9] applies traditional hierarchical locking to keys and gaps (open intervals) between keys, employs ghost (pseudo-deleted) records during insertion as well as during deletion, and permits more concurrency with fewer special cases. The same paper also outlines hierarchical locking exploiting B-trees' hierarchical structure or multi-field B-tree keys.

Foundations

The foundations of B-tree locking are the well-known transaction concepts, including multi-level transactions and open nested transactions, and pessimistic concurrency control, i.e., locking. Multiple locking concepts and techniques are employed, including two-phase locking, phantom protection, predicate locks, precision locks, key value locking, key range locking, multi-granularity locking, hierarchical locking, and intention locks.

Preliminaries

Most work on concurrency control and recovery in B-trees assumes what Bayer and Schkolnick call B^*-trees [1] and what Comer calls B^+-trees [2], i.e., all data records are in leaf nodes and keys in non-leaf or "interior" nodes act merely as separators enabling search and other operations but not carrying logical database contents. Following this tradition, this entry ignores the original design of B-trees with data records in interior nodes.

Also ignored are many other variations of B-trees here. This includes what Comer, following Knuth, calls B^*-trees, i.e., attempting to merge an overflowing node with a sibling rather than splitting it immediately. Among the ignored techniques are whether or not underflow is recognized and acted upon by load balancing and merging nodes, whether or not empty nodes are removed immediately or ever, whether or not leaf nodes form a singly or doubly linked list using physical pointers (page identifiers) or logical boundaries (fence keys equal to separators posted in the parent node during a split), whether suffix truncation is employed when posting a separator key, whether prefix truncation or any other compression is employed on each page, and the type of information associated with B-tree keys. Most of these issues have little or no bearing on locking in B-trees, with the exception of sibling pointers, as indicated below where appropriate.

Two Forms of B-Tree Locking

B-tree locking, or locking in B-tree indexes, means two things. First, it means concurrency control among concurrent database transactions querying or modifying database contents and its representation in B-tree indexes. Second, it means concurrency control among concurrent threads modifying the B-tree data structure in memory, including in particular images of disk-based B-tree nodes in the buffer pool.

These two aspects have not always been separated cleanly. Their difference becomes very apparent when a single database request is processed by multiple parallel threads. Specifically, two threads within the same transaction must "see" the same database contents, the same count of rows in a table, etc. This includes one thread "seeing" updates applied by the other thread. While one thread splits a B-tree node, however, the other thread should not observe intermediate and incomplete data structures. The difference also becomes apparent in the opposite case when a single operating system thread is multiplexed to serve all user transactions.

These two purposes are usually accomplished by two different mechanisms, locks and latches. Unfortunately, the literature on operating systems and programming environments usually uses the term locks for the mechanisms that in database systems are called latches, which can be confusing.

Locks separate transactions using read and write locks on pages, on B-tree keys, or even gaps (open intervals) between keys. The latter two methods are called key value locking and key range locking. Key range locking is a form of predicate locking that uses actual key values in the B-tree and the B-tree's sort order to define predicates. By default, locks participate in deadlock detection and are held until end-of-transaction. Locks also support sophisticated scheduling, e.g., using queues for pending lock requests and delaying new lock acquisitions for lock conversions, e.g., an existing shared lock to an exclusive lock. This level of sophistication makes lock acquisition and release fairly expensive, often thousands of CPU cycles, some of those due to cache faults in the lock manager's hash table.

Latches separate threads accessing B-tree pages, the buffer pool's management tables, and all other in-memory data structures shared among multiple threads. Since the lock manager's hash table is one of the data structures shared by many threads, latches are required while inspecting or modifying a database system's lock information. With respect to shared data structures, even threads of the same user transaction conflict if one thread requires a write latch. Latches are held only during a critical section, i.e., while a data structure is read or updated. Deadlocks are avoided by appropriate coding disciplines, e.g., requesting multiple latches in carefully designed sequences. Deadlock resolution requires a facility to roll back prior actions, whereas deadlock avoidance does not. Thus, deadlock avoidance is more appropriate for latches, which are designed for minimal overhead and maximal performance and scalability. Latch acquisition and release may require tens of instructions only, usually with no additional cache faults since a latch can be embedded in the data structure it protects.

Latch Coupling and B^{link}-Trees

Latches coordinate multiple concurrent threads accessing shared in-memory data structures, including images of on-disk storage structures while in the buffer pool. In the context of B-trees, latches solve several problems that are similar to each other but nonetheless lend themselves to different solutions.

First, a page image in the buffer pool must not be modified (written) by one thread while it is interpreted (read) by another thread. For this issue, database systems employ latches that differ from the simplest implementations of critical sections and mutual exclusion only by the distinction between read-only latches and read-write latches, i.e., shared or exclusive access. Latches are useful not only for pages in the buffer pool but also for the buffer pool's table of contents or the lock manager's hash table.

Second, while following a pointer (page identifier) from one page to another, e.g., from a parent node to a child node in a B-tree index, the pointer must not be invalidated by another thread, e.g., by deallocating a child page or balancing the load among neighboring pages. This issue requires retaining the latch on the parent node until the child node is latched. This technique is traditionally called "lock coupling" or better "latch coupling."

Third, "pointer chasing" applies not only to parent-child pointers but also to neighbor pointers, e.g., in a chain of leaf pages during a scan. This issue is similar to the previous, with two differences. On the positive side, asynchronous read-ahead may alleviate the frequency of buffer faults. On the negative side, deadlock avoidance among scans in opposite directions requires that latch acquisition code provides an immediate failure mode.

Fourth, during a B-tree insertion, a child node may overflow and require an insertion into its parent node, which may thereupon also overflow and require an insertion into the child's grandparent node. In the most extreme case, the B-tree's root node splits and a new root node is added. Going back from the leaf towards the B-tree root works well in single-threaded B-tree implementations, but in multi-threaded code it introduces the danger of deadlocks. This issue affects all updates, including insertion, deletion, and even record updates, the latter if length changes in variable-length records can lead to nodes splitting or merging. The most naïve approach, latching an entire B-tree with a single exclusive latch, is obviously not practical in multi-threaded servers.

One approach latches all nodes in exclusive mode during the root-to-leaf traversal. The obvious problem in this approach is the potential concurrency bottleneck, particularly at a B-tree's root. Another approach performs the root-to-leaf search using shared latches and attempts an upgrade to an exclusive latch when necessary. A third approach reserves nodes using "update" or "upgrade" latches. A refinement of these three approaches retains latches on nodes along its root-to-leaf search only until a lower, less-than-full node guarantees that split operations will not propagate up the tree beyond the lower node. Since most nodes are less than full, most insertion operations will latch no nodes in addition to the current one.

A fourth approach splits nodes proactively during a root-to-leaf traversal for an insertion. This method avoids both the bottleneck of the first approach and the failure point (upgrading a latch) of the second approach. Its disadvantage is that it wastes some space by splitting earlier than truly required. A fifth approach protects its initial root-to-leaf search with shared latches, aborts this search when a node requires splitting, restarts a new one, and upon reaching the node requiring a split, acquires an exclusive latch and performs the split.

An entirely different approach relaxes the data structure constraints of B-tress and divides a node split into two independent steps. Each node has a high fence key and a pointer to its right neighbor, thus the name B^{link}-trees. The right neighbor might not yet be referenced in the node's parent and a root-to-leaf search might need to proceed to the node's right neighbor. The first step of splitting a node creates the high fence key and a new right neighbor. The second, independent step posts the high fence key in the parent. The second step should happen as soon as possible yet it may be delayed beyond a system reboot or even a crash. The advantage of B^{link}-trees is that allocation of a new node and its initial introduction into the B-tree is a local step, affecting only one preexisting node. The disadvantages are that search may be a bit less efficient, a solution is needed to prevent long linked lists among neighbor nodes during periods of high insertion rates, and verification of a B-tree's structural consistency is more complex and perhaps less efficient.

Key Range Locking

Locks separate transactions reading and modifying database contents. For serializability, read locks are retained until end-of-transaction. Write locks are always retained until end-of-transaction in order to ensure the ability to roll back all changes if the transaction aborts. High concurrency requires a fine granularity of locking, e.g., locking individual keys in B-tree indexes. The terms key value locking and key range locking are often used interchangeably.

Key range locking is a special form of predicate locking. The predicates are defined by intervals in the sort order of the B-tree. Interval boundaries are the key values currently existing in the B-tree, which form half-open intervals including the gap between two neighboring keys and one of the end points.

In the simplest form of key range locking, a key and the gap to the neighbor are locked as a unit. An exclusive lock is required for any form of update of this unit, including modifying non-key fields of the record, deletion of the key, insertion of a new key into the gap, etc. Deletion of a key requires a lock on both the old key and its neighbor; the latter is required to ensure the ability to re-insert the key in case of transaction rollback.

High rates of insertion can create a hotspot at the "right edge" of a B-tree index on an attribute correlated with time. With next-key locking, one solution verifies the ability to acquire a lock on $+\infty$ but does not actually retain it. Such "instant locks" violate two-phase locking but work correctly if a single acquisition of the page latch protects both verification of the lock and creation of the new key on the page.

In those B-tree implementations in which a deletion does not actually erase the record and instead merely marks the record as invalid, "pseudo-deleted," or a "ghost" record, each ghost record's key participates in key range locking just like a valid record's key. Another technique to increase concurrency models a key, the appropriate neighboring open interval, and the combination of key and open interval as three separate items [9]. These items form a hierarchy amenable to multi-granularity locking. Moreover, since key, open interval, and their combination are all identified by the key value, additional lock modes can replace multiple invocations of the lock manager by a single one, thus eliminating the execution costs of this hierarchy.

Multi-granularity locking also applies keys and individual rows in a non-unique index, whether such rows are represented using multiple copies of the key, a list of row identifiers associated with a single copy of the key, or even a bitmap. Multi-granularity locking techniques exploiting a B-tree's tree structure or a B-tree's compound (multi-column) key have also been proposed. Finally, "increment" locks may be very beneficial for B-tree indexes on materialized summary views [5].

Both proposals need many details worked out, e.g., appropriate organization of the lock manager's hash table to ensure efficient search for conflicting locks and adaptation during structure changes in the B-tree (node splits, load balancing among neighboring nodes, etc.).

Key Applications

B-tree indexes have been called ubiquitous more than a quarter of a century ago [2], and they have become ever more ubiquitous since. Even for single-threaded applications, concurrent threads for maintenance and tuning require concurrency control in B-tree indexes, not to mention online utilities such as online backup. The applications of B-trees and B-tree locking are simply too numerous to enumerate them.

Future Directions

Perhaps the most urgently needed future direction is simplification – concurrency control and recovery functionality and code are too complex to design, implement, test, tune, explain, and maintain. Elimination of any special cases without a severe drop in performance or scalability would be welcome to all database development and test teams.

At the same time, B-trees are employed in new areas, e.g., Z-order UB-trees for spatial and temporal information, various indexes for unstructured data and XML documents, in-memory and on-disk indexes for data streams and as caches of reusable intermediate query results. It is unclear whether these application areas require new concepts or techniques in B-tree concurrency control.

Online operations – load and query, incremental online index creation, reorganization & optimization, consistency check, trickle load and zero latency in data warehousing including specialized B-tree structures.

Scalability – granularities of locking between page and index based on compound keys or on B-tree structure; shared scans and sort-based operations including "group by," merge join, and poor man's merge join (index nested loops join); delegate locking (e.g., locks on orders cover order details) including hierarchical delegate locking.

B-tree underpinnings for non-traditional database indexes, e.g., blobs, column stores, bitmap indexes, and master-detail clustering.

Confusion about transaction isolation levels in plans with multiple tables, indexes, materialized and indexed views, replicas, etc.

URL to Code

Gray and Reuter's book [6] shows various examples of sample code. In addition, the source of various open-source database systems is readily available.

Buffer Management

GIOVANNI MARIA SACCO
University of Torino, Torino, Italy

Definition

The database buffer is a main-memory area used to cache database pages. Database processes request pages from the buffer manager, whose responsibility is to minimize the number of secondary memory accesses by keeping needed pages in the buffer. Because typical database workloads are I/O-bound, the effectiveness of buffer management is critical for system performance.

Historical Background

Buffer management was initially introduced in the 1970s, following the results in virtual memory systems. One of the first systems to implement it was IBM System-R. The high cost of main-memory in the early days forced the use of very small buffers, and consequently moderate performance improvements.

Foundations

The buffer is a main-memory area subdivided into frames, and each frame can contain a page from a secondary storage database file. Database pages are requested from the buffer manager. If the requested page is in the buffer, it is immediately returned to the requesting process with no secondary memory access. Otherwise, a fault occurs and the page is read into a free frame. If no free frames are available, a "victim" page is selected and its frame is freed by clearing its content, after writing it to secondary storage if the page was modified. Usually any page can be selected as a victim, but some systems allow processes actively using a page to fix or pin it, in order to prevent the buffer manager from discarding it [5]. Asynchronous buffered write operations have an impact on the recovery subsystem and require specific protocols not discussed here.

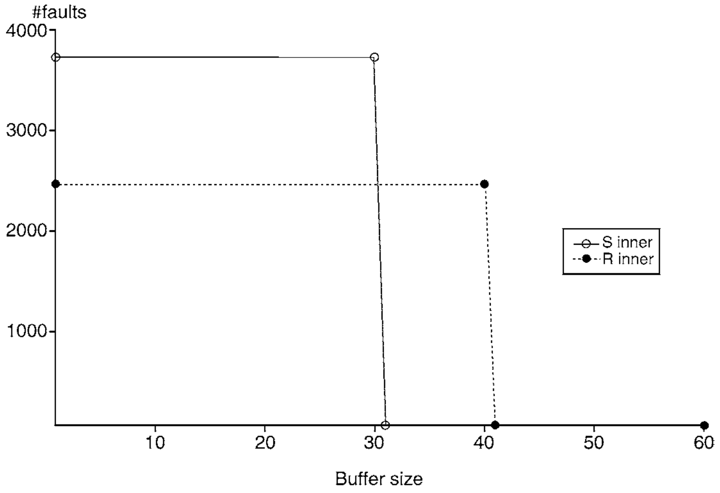
There are obvious similarities between buffer management and virtual memory (VM) systems [3]. In both cases, the caching system tries to keep needed pages in main-memory in order to minimize secondary memory accesses and hence speed up execution. As in VM systems, buffer management is characterized by two policies: the *admission policy*, which determines when pages are loaded into the buffer, and the *replacement policy*, which selects the page to be replaced when no empty frames are available. The admission policy normally used is demand paging (i.e., a missing page is read into the buffer when requested by a process), although prefetching (pages are read before processes request them) was studied (e.g., [1]). Since the interaction with the caching system is orders of magnitude less frequent in database systems than in VM systems, "intelligent" replacement policies such as LRU [3] (the Least Recently Used page is selected for replacement) can be implemented in software, with no performance degradation. Inverted page tables are used because their space requirement is proportional to the buffer size rather than to the entire database space as in normal page tables. Finally, database pages in the buffer can be shared among different processes, whereas the amount of sharing in VM systems is usually negligible.

The VM Approach

Besides minor architectural differences, the buffer manager can be used exactly as a virtual memory system for database pages, so that buffer management is transparent for the database system. In this VM approach, research is focused on effective replacement policies, which include GCLOCK and LRD (Least Reference Density) [5], LRU, and, more recently, efficient policies that account for page popularity, such as LRU-K [11].

LRU does not discriminate between frequently and infrequently referenced pages, and once a page is admitted in a buffer of B frames, it will stay there for at least B-1 references, even if not referenced again. Therefore, a potentially large portion of the buffer can be wasted by caching useless (i.e., infrequent) pages. *LRU-K* dynamically estimates the interreference distance for each page in the buffer by keeping the history of the last K references for each page in the buffer. A shorter interreference distance means a more frequently accessed page. Consequently, the page selected for replacement is the one with the largest interreference distance, i.e., the one with the maximum backward K-distance. The backward K-distance $b_t(p, K)$ at time t is defined as the distance backward to the Kth most recent reference the page p. When K = 1, only the last reference is considered, and LRU-1 is equivalent to LRU. As K grows, so do space and time overheads, because longer histories must be stored and kept ordered. At the same time, larger values of K improve the estimate of the interreference distance, but make the algorithm less responsive to dynamic changes in page popularity, so that, in practice, LRU-2 is normally used. The *2Q* (two queues) [7] algorithm provides an efficient, constant-time algorithm equivalent to LRU-2 replacement.

Although LRU-K improves LRU replacement through additional information about page access frequency, it is fundamentally different from the Least Frequently Used (LFU) replacement, because LFU does not adapt its estimate to evolving access patterns. The idea of exploiting both recency and frequency of access (also present in LRD replacement [5]) is extended by *LRFU* (least recently/frequently used) replacement [9], to model a parametric continuum of replacement policies ranging from LRU to LFU. The Combined Recency and Frequency (CRF) information is associated to each page in the buffer. CRF weights page references giving higher weights to more recent references, and combines frequency and recency information through a parameter λ ($0 \leq \lambda \leq 1$). The page to be replaced is the one with minimum CRF. When $\lambda = 0$, LRFU becomes LFU; when $\lambda = 1$, it becomes LRU. The optimal λ depends on the actual workload, but a self-tuning strategy can be used. An efficient implementation of LRFU exists, and experiments show this replacement strategy to outperform LRU-K with small buffer sizes.



Buffer Management. Figure 1. Number of faults as a function of the available buffer space, under LRU replacement.

A known problem in the VM approach is that processes with fast sequential scans over large relations tend to fill the buffer with useless pages accessed in the scan and flush the active pages of other processes out of memory, thereby significantly increasing the overall fault rate [12]. In a sequential scan, the current page is (i) rapidly accessed several times in order to read all the tuples on it, (ii) once the last tuple in the page is read, the page will never be reaccessed again. Reaccess in (i) makes VM strategies to incorrectly estimate that the current page is likely to be reaccessed in the future, and therefore to keep it in the buffer at the expense of other pages. In order to avoid this problem, some strategies use parametric correctives. LRU-K, for instance, uses the Correlated Reference Period. During this period, a page freshly admitted to the buffer cannot be replaced because additional references are expected. At the same time, subsequent references during this period are not tracked because they are expected to be correlated and do not give a reliable indication of future behavior. The length of such period is at the same time critical and difficult to estimate.

The Predictive Approach

A completely different, predictive approach was proposed with the *hot set model* [12,13]. In database systems with non-procedural data manipulation languages (such as relational or object-relational database systems), it is not the programmer but the system query optimizer that determines the access plan for a query. Such access plan is based on a small number of access primitives, such as sequential scans, nested loop joins, etc., whose reference string is known or can be estimated before actual execution. As an example, consider the execution of a tuplewise nested loop join between relation R (3 tuples/page, 40 pages) and relation S (2 tuples/page, 30 pages). Assuming S inner and indicating by Xi the i-th page of relation X, and by $\{a\}^N$ N repetitions of string a, the reference string is exactly $\{R1, \{S1\}^2,\ldots,\{S30\}^2\}^3, \{R2, \{S1\}^2,\ldots,\{S30\}^2\}^3,\ldots,\{R40, \{S1\}^2,\ldots,\{S30\}^2\}^3$. Figure 1 plots the number of faults as a function of the available buffer space, under LRU replacement.

Figure 1 shows that, differently from what happens in VM systems where fault curves tend to be smooth, the fault curve here is discontinuous. If the buffer is not large enough to contain all the pages in the inner relation plus one frame for the current page in the outer one, no reusal occurs and the fault rate is the same as for 1 frame. If sufficient space exists, all the needed pages are kept in the buffer, and the cost becomes linear in the number of pages of the two relations. In this case, the entire behavior of the plan in which S is inner is completely characterized by two *hot points* and their corresponding fault rate:

- hp1 = 1, faults(hp1) = |R|(1 + pages(S))
- hp2 = 1 + pages(S), faults(hp2) = pages (R) + pages(S)

The number of frames needed by a plan is called its hot set size, and usually is the largest hot point no larger than the total buffer size. Note that the length of the loop on the inner relation is exactly known at the database level, but it is very hard to discover in the VM approach.

The basic idea of the hot set model is that, given an access plan and a replacement policy, the number of faults as a function of the available buffer space can be predicted. Three main types of reusal, modeled upon primitive strategies, are considered:

1. Simple reusal. It models the sequential scan of a relation: the current page is accessed several times in order to read all the tuples on it, but once the last tuple in the page is read, the page will never be reaccessed again. There is only one hot point at 1 frame.
2. Loop reusal. Used in the example in Fig. 1. There are as many hot points as there are loops.
3. Index reusal. It includes both clustered and unclustered index access. Reusal can occur when indices are used in a join, or when an index is accessed by several processes. In unclustered index access, data pages are accessed randomly, and the hot set is estimated through Yao's function.

It must be stressed that LRU replacement is not required, and that other replacement strategies can be adopted [2,13]. As a matter of fact, both simple and loop reusal do not benefit from LRU replacement at all. The *query locality set model* (QLSM) [2] extends the hot set model by determining the hot set size on a file-instance basis rather than on a primitive operation basis, and by adopting replacement policies appropriate for each type of reusal. As an example, a nested loop join between R and S (S inner) is characterized by two different access patterns: a simple reusal (sequential scan) on R, requiring 1 frame, and a loop reusal on S, requiring 1 to pages(S) frames. MRU (most recently used) replacement can be used for loop reusal, since it is optimal for this type of reference string.

Since the reference string of the application is known, optimal replacement policies can be used. This opportunity is exploited in *OLRU* [14], which derives an optimal replacement policy for clustered index reusal, e.g., repeated access to clustered B+ trees. In this case, the Independent Reference Model (IRM) [3] is used. IRM was originally proposed as a theoretical evaluation model for VM systems, and assumes, in extreme synthesis, that the probability of reaccess for each page is known and stationary. Under this assumption, it can be proven that the optimal buffering strategy for a buffer of B frames consists of ordering the pages by decreasing reaccess probabilities, fixing the first B-1 high-probability pages in the buffer and using the remaining frame to access all the other low-probability pages. Since the optimal strategy only requires a ranking among pages, it can be straightforwardly applied to a B+ tree of order m and height h by assuming a uniform distribution of access to the leaf level. In this case, the probability of reaccessing a page at level j ($0 \leq j < h$) is $1/m^j$. The optimal policy is then an allocation by levels, i.e., fixing the first levels in the tree in the buffer. LRU replacement allocates the buffer by traversal stacks and is therefore suboptimal, unless severe deviations from uniformity in data page access occur, in which case OLRU and LRU are similar in performance. LRU-K, which assumes IRM as well, can be seen as a run-time approximation of OLRU.

A complete characterization of query buffer requirements and corresponding access costs is required for two major reasons. First, query optimizers need to have a precise *cost estimate* as a function of the available buffer size, in order to discriminate execution plans. This is especially important because (i) cost curves can intersect as shown in Fig. 1: R inner is cheaper in the interval [1,30], whereas S inner is better or no worse for buffer sizes of at least 31 frames; (ii) many query evaluation strategies (e.g., nested loops) do not explicitly account for memory, and they must be compared with other strategies (such as fragmentation/recursive hash partitioning join) in which available buffer space is fully accounted for and directly managed.

Second, *thrashing* phenomena [3] can occur in database buffers as in virtual memory systems, and become potentially more frequent as the number of concurrent active users increases. Thrashing occurs when the available memory is insufficient to keep all the pages each active process needs. Consequently, processes steal pages from each other and, if the available memory is severely overcommitted, the system collapses because all activity is devoted to swapping pages to and from main-memory. In VM systems, thrashing can be avoided by (i) monitoring the pagination device for excessive utilization or (ii) using the working set model [3] in order to estimate the memory requirements of active processes. In buffer management, there is no pagination device and accesses may be directed to a high number of secondary devices. In addition, the working set model, which is an expensive run-time estimator, cannot be efficiently used in database systems [13].

Thrashing avoidance, and the more general problem of *scheduling* queries for execution in order to optimally use buffer resources, is considerably simplified in the predictive approach because buffer requirements for each query are known before execution. The simplest policy [13] schedules queries for execution in such a way that the sum of their hot set sizes does not exceed the total buffer space. Each query can then be run in isolation in its own buffer partition, and this, by definition, avoids thrashing. However, page sharing, which is relatively frequent in database systems, is not accounted for. If two different processes request the same page, two faults occur. If sharing is considered these additional faults can be avoided, and the actual required buffer size can decrease because a page shared by several processes requires only one frame. For these reasons, hot set scheduling [12,13] maintains an additional global LRU chain to manage free pages, and, on a local page fault, scans the entire buffer for potential shared pages. In addition, a measure of buffer consumption is used in order to avoid unnecessarily inflating hot set sizes, which would result in serializing small queries behind queries with high buffer requirements. Variations of this scheduling algorithm include DBMIN [2] (where different local replacement policies can be used), scheduling with marginal gains [10], and scheduling with prefetching [1].

The VM Versus the Predictive Approach

When compared to the predictive approach, the VM approach has the advantage of placing all concerns on buffering into a single system component that can be seen as a black box from the rest of the system. In addition, the VM approach is more generally applicable since it does not require non-procedural interactions, and inherently implements page sharing.

However, for non-procedural systems, the predictive approach solves a number of important problems:

- Uniformity of estimated costs for query optimization. Query plans can be compared, regardless of whether methods directly manage memory or not.
- Thrashing avoidance, and efficient, low cost query scheduling. The predictive approach characterizes requirements before execution and does not require expensive run-time estimators.
- Resource planning for self-tuning databases. Predictive characterization of buffer requirements can be used to determine the optimal buffer size for actual workloads.
- Better performance. Since reference strings are known, optimal replacement policies can be used and buffer requirements carefully tuned.

There is a duality between detecting sequential scans and detecting page sharing. The VM approach has no problems in implementing page sharing. VM strategies work reasonably well for index access, but, despite correctives, they tend to break on simple and loop reusal. Conversely, sequential scan detection and inner loop size detection is trivial in the predictive approach, but, since prediction is based on a query run in isolation, run-time corrections are required for page sharing. This duality suggests that a combination of the two approaches might be beneficial.

Key Applications

The trend towards cheaper and larger main-memories does not make buffer management less important. In fact, the increase in available main-memory has been so far matched by a larger increase in secondary storage capacity and in the amount of data to be managed, in the complexity of queries, and in the number of users. Consequently, buffer management continues to be a fundamental topic for database systems, and indeed its results carry over to different areas, such as web caching.

Current research areas in database systems include automatic buffer sizing in self-tuning databases [15], extendibility of buffer management strategies [6], specific buffering strategies for object databases [8], XML databases and P2P data architectures, multidimensional databases, real-time databases where process priorities must be considered in scheduling, and, of course, new index structures or evaluation strategies for which buffer analysis is required [4]. In addition, challenging applications managing very large amounts of data such as sensor data, search engines, large digital libraries, etc. require high-performance buffer management.

Cache manager

Definition

If a buffer pool is employed in a database management system, the associated software must provide appropriate services for efficient query processing, correct transaction execution, and effective sharing and reuse of database pages. It must provide interfaces for page access including pinning and latching pages, and it must invoke primitives for disk I/O and synchronization.

Historical Background

Database buffer pool management was studied heavily in the 1970s and 1980s as the new relational database management system posed new challenges, in particular non-procedural queries with range scans. Reliance of virtual memory and file system buffer pool was investigated but rejected due to performance issues (read-ahead, prefetch) and correctness issues (transaction management, write-behind, write-through).

Buffer pool management is currently not a very active research area. It may be revived in order to serve deep storage hierarchies, e.g., slow disk, fast disk, flash memory, main memory, and CPU cache. It may also be revived in the context of very large memories, e.g., query optimization that considers residence in the buffer pool or physical database design that includes temporary or partial indexes that exist only in the buffer pool.

Foundations

This section describes a database system's buffer pool and its management by focusing on management of individual pages in the buffer pool, replacement policies, asynchronous I/O, and the requirements imposed by concurrency control and recovery.

Buffer Pool Interfaces

The principal methods provided by the buffer pool manager request and release a page. A page request fixes or pins a page, i.e., it protects it from replacement as well as movement within the buffer pool, thus permitting access to the page by in-memory pointers. Variants of requesting and releasing a page apply to disk pages immediately after allocation (no need to read the page contents from disk) and immediately after deallocation (no need to save the page contents).

In addition, a buffer pool may provide methods for concurrency control among threads in order to protect page contents, also known as latching. Pragmatically, the methods to pin and to release a page include parameters that control latching.

Concurrency control among transactions is usually not provided by the buffer pool. In aid of logging and recovery, a buffer pool must support a method to force a page to disk and may support a method to retain one page until another page has been written.

For performance, a buffer pool may support methods to hint asynchronous prefetch, read-ahead, and write-behind. If the buffer pool serves a memory pool for other software layers, it must support methods for memory allocation and deallocation.

The principal methods upon which a buffer pool manager relies are disk reading and writing, including asynchronous operations, and scheduling primitives to implement latching. If the buffer pool size is dynamic, memory allocation and deallocation are also required. If the buffer pool supports multiple page sizes, it requires fast methods for moving (copying) page contents from one memory address to another.

Replacement Policies

The goal of the replacement policy (or retention policy) is to speed up future page accesses. Prediction of future accesses can be based on past accesses (how recent, how frequent, whether read or write) or on hints from higher software layers within the database management system. Standard policies include LRU (least recently used, implemented using a doubly-linked list), LRU-K (least recent K uses), LFU (least frequently used), second chance (usually implemented following a clock metaphor), generalized clock (using counters instead of a single bit per page frame), and combinations of those. Many combinations have been proposed, including the hot set model, the query locality set model, adaptive replacement cache, etc.

They differ in their heuristics to separate pages used only once, e.g., in a large sequential scan, from pages likely to be reused, e.g., pages containing the database catalog or root pages of B-tree indexes. Alternative designs let higher software layers hint the likelihood of reuse, e.g., love/hate hints or keep/toss hints.

Dirty pages (containing recent updates) may be retained longer than clean ones because their replacement cost and delay are twice as high (write plus read instead of merely a read operation) and because correct preparation for recovery may impose restrictions on the order in which pages are written. For example, write-ahead logging requires writing the relevant log page to stable storage before overwriting old database contents. On the other hand, non-logged operations (e.g., index creation) require flushing dirty pages as part of transaction commit.

Asynchronous I/O

Rather than merely responding to requests from higher software layers, a buffer pool may employ or enable asynchronous I/O, in three forms:

Write-behind cleans the buffer pool of dirty pages in order to complete update transactions as fast as possible yet enable quick page replacement without needing a write operation prior to a read operation. However, most write-behind is driven by checkpoints rather than page faults, based on typical checkpoint intervals (very few minutes) and retention intervals as calculated or optimized using the five-minute rule (many minutes or even hours). A write-behind operation may leverage a disk seek forced by another read or write operation. Alternatively, a write-behind operation may move the data to achieve this effect, e.g., in log-structured file systems and write-optimized database indexes.

Read-ahead speeds up large scans, e.g., a range scan in a B-tree or a complete scan of a heap structure. The appropriate amount of read-ahead is the product of bandwidth and latency, i.e., the smallest of I/O bandwidth and processing bandwidth multiplied with the delay from initiation to completion of a read operation. Read-ahead may be triggered by observation of the access pattern or by a hint from a higher software layer, e.g., a table scan in a query execution plan.

Prefetch accelerates fetch operations by loading into the buffer pool precisely those pages that contain needed data records. Prefetch in heap structures is quite straightforward. In B-tree indexes, prefetch may apply to all tree levels or merely to the leaf level, combined with synchronous read operations or large read-ahead for interior B-tree nodes. Prefetch speeds up not only to ordinary forward processing but also to transaction rollback as well as system recovery.

Concurrency Control and Recovery

The buffer pool may participate in concurrency control, e.g., if multi-version concurrency control requires multiple versions of individual pages. The mechanisms for pinning and latching are essential for coordination of multiple threads accessing the same in-memory data structures, including in-memory images of on-disk pages.

The buffer pool always participates in the preparation for recovery including transaction rollback, media recovery, and system recovery. For example, by retaining all modified pages in the buffer pool until transaction commit, one can avoid logging *undo* information in the persistent log – this is called a “no steal” policy. By forcing merely log pages to stable storage, one can avoid writing all modified database pages back to disk – this is called a “no force” policy. Most database management systems use “steal – no force” by default. The log volume of index creation and similar operations is often minimized using a “force” policy.

Logging volume can be reduced by ensuring specific write sequences. For example, when a B-tree node is split and some records are moved to a new node, one can avoid logging the moved records by writing the new page before writing the modified old page.

The buffer pool also participates in checkpoint processing. In addition to recording active transactions, a checkpoint must write all dirty database pages to the log or to the database. Proactive asynchronous write-behind may lessen the number of write operations during the checkpoint.

Cooperative Buffer Pool Management

Multiple buffer pools may cooperate. Prototypical examples include client-server operation (in which the buffer pools form a hierarchy) and shared-disk database systems (in which the buffer pools are peers). Those environments require optimizations for both data traffic among buffer pools and control messages, in particular for concurrency control and lock management.

Key Applications

A buffer pool and its management software are required in any database management system that employ multiple levels in a memory hierarchy, process and store data at different levels, and do not rely other means for moving data between those levels. The main example is main memory and disks – the buffer pool manager manages which data pages are immediately available for access, e.g., from the query execution engine. A CPU cache is a level in the memory hierarchy above the main memory, but data movement between main memory and CPU cache are automatic. A database management system could rely on a file system and its buffer pool manager but usually does not due to performance issues (e.g., read-ahead, prefetch) and due to correctness issues (write-behind, write-through). A database management system could rely on virtual memory provided by the operating system but typically does not for the same reasons.

Future Directions

While basic buffer pool management in traditional database management systems is well understood, there are many developments that build upon it. For example, integration of database cache, mid-tier cache, and web cache may become imperative in order to maximize efficiency and thus minimize costs for hardware, management, power, and cooling.

Buffer pools and buffer management will become more pervasive with the increased virtualization of storage and processing. At the same time, it will become more complex due to missing information on the true cost and location of data. It will also become more pervasive and complex due to increasing use of peer-to-peer storage, communication, and processing.

Any buffer pool becomes more effective with data compression and co-location. Compression reduces the space required locally (in the buffer pool) and remotely. Co-location techniques such as master-detail clustering enable access to multiple related records or pieces of information within a single frame in the buffer pool and with a single access to the remote location.

In a very large buffer pool, one might create temporary on-disk structures that never even exist on disk. For example, a temporary index on a permanent table may be created yet retained in the buffer pool. During contention in the buffer pool, the index is dropped. Ideally, such an index is partitioned, created and dropped incrementally, and left behind as a free side effect of query execution.

The data structures that manage a buffer pool, both its contents descriptors and its replacement policy, can be complex yet require very high concurrency, in particular in forthcoming many-core processors. Hardware-assisted transactional memory may simplify the software implementation effort as well as increase concurrency and performance.

In deep memory hierarchies, e.g., a three-level hierarchy of traditional memory, flash memory, and disk, contents descriptors and data structures in aid of the replacement policy may be separate. For example, the contents descriptors may need to be persistent if the flash memory is part of the persistent database, but all data structures for the replacement policy (between flash memory and disk) might be in the traditional memory.

Buffer Pool

GOETZ GRAEFE
Hewlett-Packard Laboratories, Palo Alto, CA, USA

Synonyms

I/O cache, Page cache

Definition

Cost constraints (dollars per gigabyte) prohibit in-memory databases in most cases, but processors can access and manipulate data only while it is in memory. The in-memory buffer pool holds database pages currently in use and retains those deemed likely to be used again soon.

The buffer pool and the buffer management component within the storage layer of a database management system provide fast access and fast recall of on-disk pages using in-memory images of those pages. In addition to the size of individual pages and of the entire buffer pool, key issues are (i) page replacement in response to buffer faults, and (ii) page retention and update in aid of database recovery.

A database buffer pool differs from virtual memory as it contributes to correctness and efficiency of query and update processing, e.g., by pinning pages while in use and by ensuring a write sequence that guarantees the ability to recover. In some systems, the buffer pool permits "stealing" memory for query processing operations such as sorting and hash join, for utilities such as reorganization and consistency checks, etc.

Historical Background

Gray and Putzolo's paper introducing the five-minute rule makes a strong case for using multiple levels of the memory hierarchy for data collections that include both hot and cold data, i.e., data that are accessed with different frequencies. Hot data are kept at a high level of the memory hierarchy, whereas cold data are fetched as needed and buffered temporarily.

A buffer pool is also needed if the provided granularity of access is too coarse. Disks permit random page accesses, whereas query execution, predicate evaluation, etc. require accesses to individual records, fields, and bytes.

Early research demonstrated that virtual memory is not appropriate for use in database management systems, as observed by Härder, Stonebraker, Traiger, and their research teams for early relational database management systems. Reasons include both correctness, specifically with respect to recovery, and performance, specifically asynchronous read-ahead and write-behind.

In order to avoid double page faults, a buffer pool should not be subject to page replacement by virtual memory provided by the operating system. One means to achieve this is to vary the size of the buffer pool in response to paging rates of the virtual memory. The five-minute rule gives guidance for the appropriate sizing of memory and buffer pool.

Techniques to map on-disk database contents into virtual memory advanced in the context of object-oriented databases and persistent programming languages but did not result in wide adoption.

Flash memory still requires an in-memory buffer pool for access to bytes within pages, yet it can also serve as a buffer pool for pages that require faster access than rotating disks can provide. In fact, buffer pool management techniques such as replacement policies apply to all levels in a multi-level memory hierarchy, e.g., CPU caches, RAM, flash memory, disk caches, rotating disk, tape media, etc. In an extreme case, a fast disk may serve a buffer pool for a slower disk; alternatively, both disks may serve as permanent storage and buffer replacement policies may be adapted for page placement on those disks, possibly including frequent page migration.

Foundations

This section describes a database system's buffer pool, replacement policies, and the requirements imposed by concurrency control and recovery.

Buffer Frames

A buffer pool contains many frames, each capable of holding the image of an on-disk page. Pages can be fixed-length or variable-length, i.e., multiple base pages, typically a power of 2. Space management is complex for variable-length pages; one technique employed commercially relies on multiple buffer pools with a single page size in each, i.e., a fixed-length page frame in each buffer pool.

In addition to being idle or unused, buffer frames can be pinned to protect the page from replacement, latched (locked) to protect against concurrent readers or writers, or in transit from or to disk. Pinning and latching are important for performance; they enable the database's query execution software to inspect or update records directly in the buffer pool.

A buffer pool may hold multiple versions of the same on-disk page in aid of transaction isolation, compression, asynchronous write-behind, or protection from partial writes. Write-behind with a single copy inhibits further updates until the write operation completes. The copy step may compact free space between variable-length records.

A small descriptor data structure is used for each frame in the buffer pool. It identifies the on-disk page and its status with respect to pinning, latching, versioning, etc. The descriptor also participates in a look-up scheme, typically a hash table, and in data structures used for page replacement.

Buffer Pool Data Structures

In addition to page frames and their descriptors, a buffer pool needs data structures to locate buffered pages and to manage page replacement including page frames currently unused. Locating a buffered page, i.e., mapping from a disk address (page number) to an in-memory address, usually is implemented with a hash table.

The data structures needed for page replacement depend on the page replacement policy – one method that is simple but not ideal is to employ a doubly linked list of page descriptors with pages ordered the time since they were last used. When a page is pinned, it is removed from the list. When it is unpinned, it is inserted at the head of the list. When a page is needed for replacement, the page at the tail of the list is chosen.

Replacement Policies

The goal of the replacement policy (or retention policy) is to speed up future page accesses. Prediction of future accesses can be based on past accesses (how recent, how frequent, whether read or write) or on hints from higher software layers within the database management system. Standard policies include LRU (least recently used, implemented using a doubly-linked list), LRU-K (least recent K uses), LFU (least frequently used), second chance (usually implemented following a clock metaphor), generalized clock (using counters instead of a single bit per page frame), and combinations of those. Many combinations have been proposed, including the hot set model, the query locality set model, adaptive replacement cache, etc.

They differ in their heuristics to separate pages used only once, e.g., in a large sequential scan, from pages likely to be reused, e.g., pages containing the database catalog or root pages of B-tree indexes. Alternative designs let higher software layers hint the likelihood of reuse, e.g., love/hate hints or keep/toss hints.

Dirty pages (containing recent updates) may be retained longer than clean ones because their replacement cost and delay are twice as high (write plus read instead of merely a read operation) and because correct preparation for recovery may impose restrictions on the order in which pages are written. For example, write-ahead logging requires writing the relevant log page to stable storage before overwriting old database contents. On the other hand, non-logged operations (e.g., index creation) require flushing dirty pages as part of transaction commit.

Key Applications

A buffer pool and its management software are required in any database management system that employ multiple levels in a memory hierarchy, process and store data at different levels, and do not rely other means for moving data between those levels. The main example is main memory and disks – the buffer pool manager manages which data pages are immediately available for access, e.g., from the query execution engine. A CPU cache is a level in the memory hierarchy above the main memory, but data movement between main memory and CPU cache are automatic. A database management system could rely on a file system and its buffer pool manager but usually does not due to performance issues (e.g., read-ahead, prefetch) and due to correctness issues (write-behind, write-through). A database management system could rely on virtual memory provided by the operating system but typically does not for the same reasons.

Future Directions

In deep memory hierarchies, e.g., a three-level hierarchy of traditional memory, flash memory, and disk, contents descriptors and data structures in aid of the replacement policy may be separate. For example, the contents descriptors may need to be persistent if the flash memory is part of the persistent database, but all data structures for the replacement policy (between flash memory and disk) might be in the traditional memory.

Business Intelligence

Stefano Rizzi
University of Bologna, Bologna, Italy

Definition

Business intelligence is a business management term that indicates the capability of adding more intelligence to the way business is done by companies. More precisely, it refers to a set of tools and techniques that enable a company to transform its business data into timely and accurate information for the decisional process, to be made available to the right persons in the most suitable form. Business intelligence systems are used by decision makers to get a comprehensive knowledge of the business and of the factors that affect it, as well as to define and support their business strategies. The goal is to enable data-based decisions aimed at gaining competitive advantage, improving operative performance, responding more quickly to changes, increasing profitability and, in general, creating added value for the company.

Key Points

Though business intelligence has its roots in reporting systems, it was born as a term within the industrial world in the early 1990's, to indicate a set of technologies aimed at satisfying the managers' request for efficiently and effectively analyzing the enterprise data in order to better understand the situation of their business and improving the decision process. In the mid-1990's business intelligence became an object of interest for the academic world, and ten years of research managed to transform a bundle of naive techniques into a well-founded approach to information extraction and processing that led to defining the modern architectures of data warehousing systems. Currently, business intelligence includes not only the tools to gather, provide access to, and analyze data and information about company operations, but also a wide array of technologies used to support a closed decisional loop (known as *Business Performance Management*) where the company performance is measured by a set of indicators (commonly called *Key Performance Indicators, KPIs*) whose target values are determined by the company strategy, and where the actions taken are aimed at matching current and target values for these indicators.

From an architectural point of view, the core of a business intelligence system is usually a data warehouse that stores the corporate historical data in a consistent and integrated form. A number of applications may be built around the data warehouse, for instance aimed at supporting OLAP analysis, data mining, what-if analysis, forecasting, balanced scorecards preparation, geospatial analysis, click-stream analysis. The architecture may be completed by a reactive data flow, more suited for monitoring the time-critical operational processes by supporting real-time applications.

Business Process Execution Language

W. M. P. van der Aalst
Eindhoven University of Technology, Eindhoven,
The Netherlands

Synonyms

BPEL; BPEL4WS

Definition

The *Business Process Execution Language for Web Services* (BPEL) has emerged as a standard for specifying and executing processes. It is supported by many vendors and positioned as the "process language of the Internet." BPEL is XML based and aims to enable "programming in the large," i.e., using BPEL new services can be composed from other services.

Key Points

BPEL [2,3] supports the modeling of two types of processes: executable and abstract processes. An *abstract*, (not executable) *process* is a business protocol, specifying the message exchange behavior between different parties without revealing the internal behavior for any one of them. This abstract process views the outside world from the perspective of a single organization or (composite) service. An *executable process* views the world in a similar manner. However, things are specified in more detail such that the process becomes executable, i.e., an executable BPEL process specifies the execution order of a number of *activities* constituting the process, the *partners* involved in the process, the *messages* exchanged between these partners, and the *fault* and *exception handling* required in cases of errors and exceptions.

A BPEL process itself is a kind of flow-chart, where each element in the process is called an *activity*. An activity is either a primitive or a structured activity. The set of *primitive activities* contains: `invoke`, invoking an operation on a web service; `receive`, waiting for a message from an external source; `reply`, replying to an external source; `wait`, pausing for a specified time; `assign`, copying data from one place to another; `throw`, indicating errors in the execution; `terminate`, terminating the entire service instance; and `empty`, doing nothing.

To enable the presentation of complex structures the following *structured activities* are defined: `sequence`, for defining an execution order; `switch`, for conditional routing; `while`, for looping; `pick`, for race conditions based on timing or external triggers; `flow`, for parallel routing; and `scope`, for grouping activities to be treated by the same fault-handler. Structured activities can be nested and combined in arbitrary ways. Within activities executed in parallel the execution order can further be controlled by the usage of `links` (sometimes also called control links, or guarded links), which allows the definition of directed graphs. The graphs too can be nested but must be acyclic.

The terminology above is based on BPEL 1.1 which was introduced in 2003 [3]. A new version of the standard [2] was published in 2007. This version has been approved as an OASIS Standard. This new version resolves many semantical issues [1,5]. Moreover, new activity types such as `repeatUntil`, `validate`, `forEach` (parallel and sequential), `rethrow`, `extensionActivity`, and `compensateScope`, have been added and some of the existing activities have been renamed (`switch/case` renamed to `if/else` and `terminate` renamed to `exit`). Currently, many extensions are under development, including BPEL4People which enables BPEL activities to be executed by human resources [4].

Workflow management; Process management; Case handling

Definition

Information technology has changed business processes within and between enterprises. Traditionally, information technology was mainly used to support individual tasks ("type a letter") and to store information. However, today business processes and their information systems are intertwined. Processes heavily depend on information systems and information systems are driven by the processes they support [1]. *Business Process Management* (BPM) is concerned with the interactions between processes and information systems. An important element of BPM is the modeling and analysis of processes. Processes can be designed using a wide variety of languages ranging from BPMN to Petri nets. Some of these languages allow for analysis techniques (e.g., model checking and simulation) to answer questions related to correctness and performance. Models can be used to configure generic software tools, e.g., middleware, workflow management systems, ERP systems, etc. These systems, also referred to as *Business Process Management Systems* (BPMS), are used to enact relevant business processes. A business process management system can be defined as: *a generic software system that is driven by explicit process designs to enact and manage operational business processes.* The system should be "process-aware" and "generic" in the sense that it is possible to modify the processes it supports. The process designs are often graphical and the focus is on structured processes that need to handle many cases. Workflow management systems are typical examples of such "process-aware" systems. An important technological enabler for business process management systems is the Service Oriented Architecture (SOA). The partitioning of processes into services makes it easier to isolate the process-logic.

Historical Background

Traditionally, information systems are viewed from either a *process-centric* or an *information-centric* perspective. The information-centric view focuses on the information managed by the system. Database management systems provide the functionality required to store and retrieve data. Since the 1970's, there have been consensus on the modeling of data. Although there are different languages and different types of database management systems, the fundamental concepts are quite stable for the information-centric view of information systems. The process-centric view on information systems on the other hand can be characterized by the term "divergence." There is little consensus on the fundamental concepts. Despite the availability of established formal languages (e.g., Petri nets and process calculi) industry has been pushing ad-hoc/domain-specific languages. As a result there is a plethora of systems and languages available today.

An good starting point from a scientific perspective is the early work on office information systems. In the 1970's, people like Skip Ellis, Anatol Holt, and Michael Zisman already worked on so-called office information systems, which were driven by explicit process models [6]. It is interesting to see that the three pioneers in this area independently used Petri-net variants to model office procedures. During the 1970's and 1980's, there was great optimism about the applicability of office information systems. Unfortunately, few applications succeeded. As a result of these experiences, both the application of this technology and research almost stopped for a decade. Consequently, hardly any advances were made in the 1980's. In the 1990's, there again was a huge interest in these systems [7]. The number of workflow management systems developed in the period 1995–2005 and the many papers on workflow technology illustrate the revival of office information systems. Today workflow management systems are readily available. However, their application is still limited to specific industries such as banking and insurance. In fact, workflow technology is often hidden inside other systems. For example, ERP systems like SAP and Oracle provide workflow engines. Many other platforms include workflow-like functionality. For example, integration and application infrastructure software such as IBM's Websphere provides extensive process support.

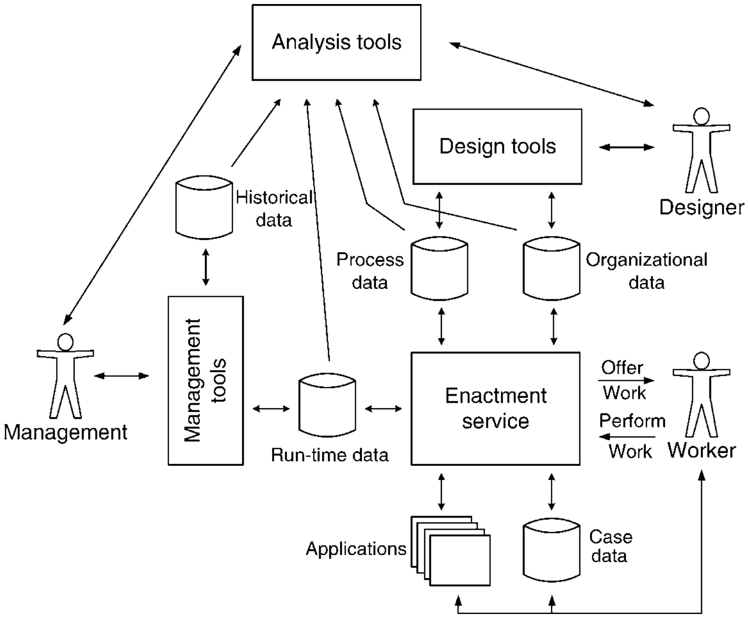
When comparing today's business process management systems to the workflow management systems of the nineties two things can be noted. First of all, the focus is no longer exclusively on automation and enactment, e.g., process analysis (simulation, process mining, verification, etc.) is increasingly important. Second, the use of web technology makes it easier to realize such systems even if processes are scattered over multiple organizations.

Foundations

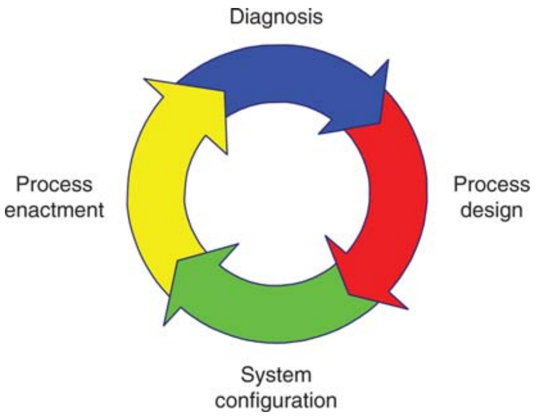
Business process management looks at the relationships between business processes and information systems. Using information systems in an innovative way enables new types of business processes. For example, making paper documents electronic may enable the concurrent execution of tasks thus shortening flow times. Moreover, characteristics of business processes lead to requirements for business process management systems (cf. workflow patterns). Business process management is *not* limited to the automation of business processes. For example, it is vital to *analyze* processes before and after they are enacted. During the design phase it is vital to use verification techniques to assess the correctness of the process design. Moreover, simulation techniques can be used to estimate the performance of the process once it is realized. While the processes is running, the information system needs to record information about actual events and realized performance. Using process mining techniques and other types of business intelligence, the event logs of systems can be analyzed. Based on such a diagnosis, the process can be improved.

The modeling and analysis of processes plays a central role in business process management. Therefore, the choice of language to represent an organization's processes is essential. Three types of languages can be identified:

1. *Formal languages*: Processes have been studied using theoretical models. Mathematicians have been using Markov chains, queueing networks, etc. to model processes. Computer scientists have been using Turing machines, transition systems, Petri nets, and process algebras to model processes.



Business Process Management. Figure 1. Architecture of a business process management system.



Business Process Management. Figure 2. BPM life-cycle.

All of these languages have in common that they have *unambiguous semantics* and allow for *analysis*.

2. *Conceptual languages*: Users in practice have problems using formal languages. They prefer to use higher-level languages. Examples are BPMN (Business Process Modeling Notation), EPCs (Event-Driven Process Chains), UML activity diagrams, etc. These language are typically *informal*, i.e., they do not have a well-defined semantics and do not allow for analysis. Moreover, the lack of semantics makes it impossible to directly execute them.
3. *Execution languages*: Formal language typically abstract from "implementation details" (e.g., data structures) and conceptual languages only provide an approximate description of the desired behavior. Therefore, more technical languages are needed for enactment. An example is the BPEL (Business Process Execution Language) language. Most vendors provide a proprietary execution language.

The existence and parallel use of these three types of languages causes many problems. The lack of consensus makes it difficult to exchange models. The gap between conceptual languages and execution languages leads to re-work and a disconnect between users and implementers. Moreover, both types of languages are not supported by advanced analysis tools.

Figure 1 shows the typical architecture of a business process management system. The figure also shows three roles of people involved: management, designer, and worker. The "heart" of the business process management system is the enactment service also known as "workflow engine" [4,7]. This engine is offering the right pieces of work (work-items) to workers at the right point in time. In order to do this, it needs to have detailed descriptions of the processes and organizations involved. Using design tools one can model processes and organizations. Note that Fig. 1 presents an idealized view. As indicated before there may be different languages (formal, conceptual, and execution languages) involved. The designer may first model the process in an informal manner. This model is then converted into a model that can be enacted or analyzed. The enactment service is driven by models in order to offer the right piece of work to the right persons at the right time. Moreover, the enactment service is starting applications and provides access to case data. During execution all kinds of information are recorded and at any time there is a (partial) history (i.e., audit trails, event logs, etc.) and a current state (run-time data). This information can be used for all kinds of analysis. Some types of analysis focus on the process design (e.g., verification and simulation). Other types of analysis focus on the actual behavior of the process (e.g., process mining).

As indicated before, different types of people are involved (management, designers, and workers). Moreover, business process management systems have a characteristic *life-cycle*. Figure 2 shows the four phases of such a life-cycle [7]. In the *design phase*, the processes are (re)designed. In the *configuration phase*, designs are implemented by configuring a process aware information system (e.g., a BPMS). After configuration, the *enactment phase* starts where the operational business processes are executed using the system configured. In the *diagnosis phase*, the operational processes are analyzed to identify problems and to find things that can be improved. The focus of traditional workflow management (systems) is on the lower half of the BPM life-cycle. As a result there is little support for the diagnosis phase. Moreover, support in the design phase is limited to providing an editor while analysis and real design support are missing. It is remarkable that few systems provide good support simulation, verification, and validation of process designs. Another problem of conventional workflow systems is the lack of flexibility. Fortunately, the emphasis is shifting from automation of highly structured processes to issues such as flexibility and analysis. Case handling systems such as FLOWer and academic prototypes such as DECLARE, YAWL/worklets, and ADEPT offer innovative ways of supporting flexible processes. Process mining tools such as ProM, ARIS PPM, etc. allow for the analysis of actual behavior. This supports the diagnosis phase and triggers process improvement.

The architecture demonstrated in Fig. 1 does not show any organizational boundaries. In the traditional setting it was very difficult to support inter-organizational processes. Web services and the Service Oriented Architecture (SOA) simplify the distribution of processes over different organizations [8]. Moreover, the paradigm shift towards services has also changed the architecture within a single organization. When focusing on processes, two terms are important: (i) choreography and (ii) orchestration.

Choreography is concerned with the exchange of messages between those services. *Orchestration* is concerned with the interactions of a single service with its environment. While choreography can be characterized by reaching an agreement and the monitoring of the overall progress, the focus of orchestration is more on the implementation of a particular service by describing the process logic and linking this to neighboring services. Orchestration languages are close to traditional workflow languages (BPMN, BPEL, Petri nets, etc.). An important characteristic of such languages is the ability to compose a service by using other services. The role of choreography languages (e.g., WS-CDL) is less clear.

Business process management is clearly related to management science. For example, topics such as operations research, operations management, business process re-engineering are highly relevant [9]. There are also clear links with coordination languages and theory. Coordination can be defined as "managing dependencies between activities." Process modeling languages and concepts such as choreography and orchestration are obviously related to coordination.

Key Applications

Banking

The financial industry has changed dramatically using both business process re-engineering and workflow-like technologies. Many processes have been rationalized using business process management techniques. The rise of e-banking led to a dramatic reduction of people and offices. Banking processes are supported and monitored by business process management systems.

Government

Government organizations need to react quickly to new legislation, i.e., the corresponding processes need to be modified based on changes in tax laws, customs procedures, immigration laws, corporate governance, safety regulations, etc. Business process management assists in dealing with these changes and further improving the processes.

Business-to-Business

Mergers and virtual enterprises trigger the need for cross-organizational workflows. Web services and business process management techniques can assist in connecting process fragments from different organizations. The SOA combined with languages like BPEL provides a good basis for cross-organizational workflows.

Health-care

Business process management techniques have mainly been applied to structured processes. Given the nature of care processes, it is not easy to streamline these processes and to support them with workflow-like systems. However, they only way to reduce costs and improve effectively is to provide better support for such processes. Hence, the health-care domain poses an interesting and relevant challenge for business process management.

BPMN

Definition

The Business Process Modeling Notation (BPMN) is a graphical notation for drawing business processes. It is proposed as a standard notation for drawing models understandable by different business users. BPMN aims to bridge the communication gap that frequently occurs between business process design and implementation. The language is similar to other informal notations such as UML activity diagrams and extended event-driven process chains.

Key Points

BPMN was initially developed by Business Process Management Initiative (BPMI). It is now being maintained by the Object Management Group (OMG) who released a “Final Adopted Specification” in 2006 [3]. The intent of BPMN is to standardize a business process modeling notation in the face of many different modeling notations and viewpoints.

A model expressed in terms of BPMN is called a Business Process Diagram (BPD). A BPD is essentially a flowchart composed of different elements. There are four basic categories of elements: (i) *Flow Objects*, (ii) *Connecting Objects*, (iii) *Swimlanes*, and (iv) *Artifacts* [3]. Flow objects are the main graphical elements to define the behavior of a process. There are three types of flow objects: *Events*, *Activities*, and *Gateways*. Events are comparable to places in a Petri net, i.e., they are used to trigger and/or connect activities. There are different types of activities. Atomic activities are referred to as tasks. Gateways are used to model splits and joins. The flow objects can be connected to establish a control-flow. Swimlanes are just a means to structure processes. Artifacts are used to add data or to further annotate process models.

Figure 1 shows the basic set of symbols used by BPMN. These symbols can be combined to construct a BPD. On the left hand side, four types of events are shown. Three type of splits are shown. The data-based XOR gateway split passes control to exactly one of its output arcs. The parallel fork gateway passes control to all output arcs. The event-based XOR gateway selects one output arc based on the occurrence of the corresponding event. Note that Fig. 1 shows only a subset of all possible notations. The complete language is rather complex. The specification itself [3] is 308 pages without providing any formal semantics.

BPMN is an informal language aiming at the communication and not directly at execution. Therefore, the language is positioned as the design language for BPEL, i.e., BPMN diagrams are gradually refined into BPEL specifications. Given the lack of formal semantics this is not a trivial task [2,4]. Therefore, several attempts have been made to provide semantics for a subset of BPMN [1].

Business Process Redesign

Definition

Business process reengineering refers to a substantial change of a company's organizational processes that (i) is enabled by the implementation of new information technologies that were not previously used by the company, (ii) takes an interfunctional (or interorganizational) perspective, i.e., involves multiple organizational functions (or organizations) that cooperate along processes (iii) considers end-to-end processes, i. e., processes that deliver a service to a company's customers, (iv) emphasizes the integration of information and related information technologies to obtain seamless technological support along processes.

Historical Background

In 1993, Hammer and Champy [3] introduced the concept of business process reengineering as a radical and fast change of organizational processes that leverages information technology. Their work was the first of a wave of research contributions that analyzed the role and impact of information technologies in business process reengineering. This research was accompanied by a widespread use of the term business process reengineering in the industry to indicate large projects that involved the implementation of client-server architectures and the concurrent redesign of core business processes. Client-server enabled a more extensive sharing of organizational data within organizations by making server data accessible to personal computers through more user friendly client applications. In turn, this enabled a redesign of end-to-end business processes towards greater interfunctional cooperation. These changes primarily involved service companies, such as insurance companies, banks, research institutions, and so on, since client server had much broader application in service industries due to a more widespread use of personal computers by all employees and in all activities, both clerical and operating. More recently, the term has been extended to indicate any substantial redesign of business processes that is enabled by information technologies.

Foundations

The interfunctional integration of business processes has been recognized as a fundamental lever to improve organizational performance ever since the early studies within the information perspective of organizational theory. Going back to Galbraith's analysis [5], two complementary methods for increasing the information processing capacity of an organization are proposed. The first improves the communication of information within organizations along hierarchies of authority through *vertical* information systems. Information is gathered from lower hierarchical levels, consolidated, and conveyed to higher decision-making centers. While very effective for routine decision making, vertical information systems can quickly become overloaded in conditions of increasing uncertainty. In this case, firms can resort to direct *lateral* communication, Galbraith's second method. Liaison roles, task forces, project teams, and matrix structures are increasingly powerful mechanisms to facilitate this lateral interchange of information. While the first method reinforces the communication of information across levels of authority, the second consists of a set of organizational solutions allowing information exchanges orthogonal to the hierarchy.

Solutions for direct lateral communication permit higher organizational efficiency when hierarchies become inadequate information processors because of increasing coordination needs. This happens when dependencies between agents are difficult to foresee, as they continually change over time. In principle, within a hierarchy, lateral communication can take place only through levels of authority. Any two agents communicating through hierarchical levels experience an efficiency that is inversely proportional to their distance in the hierarchy. If dependencies between agents are stable and cause recurring paths of lateral communication, hierarchies of authority can be built by grouping agents who require most frequent interaction. By minimizing the distance between interacting agents, hierarchical coordination can be efficient. On the contrary, when organizations operate in conditions of high uncertainty, lateral information exchange becomes essential. Since demands for responsiveness and flexibility in today's business environment are raised as a result of increased uncertainty, the lateral exchange of information becomes critical to support overall information processing needs. Business process reengineering involves the redesign of organizational processes towards a higher degree of lateral communication.

Traditional Intra-Organizational Reengineering

Historically, mainframe-based architectures could support the implementation of vertical information systems, but were inherently inadequate for lateral communication. In centralized architectures, no distinction was made between data and applications. Data belonged to the application creating them and could be accessed only through that same application. Consistent with Galbraith's recommendations for the use of IT to support vertical communication, design methodologies witnessed a focus on the hierarchical conception and implementation of information systems. For example, the Normative Application Portfolio [9]

adopted a layered view of organizations, following Anthony's hierarchical framework of planning and control systems. Three main classes of applications were distinguished, supporting operations, management, and strategy, respectively. The application portfolio was created by building vertically from one level to the next, in order to guarantee that activities on lower levels supported higher level activities.

In the mid-1970s, databases and database management systems (DBMS) introduced significant changes in the design of IT architectures. Based on database technology, a new type of IT architecture was implemented, which can be broadly categorized as *centralized*. Centralized architectures allow the *logical separation* between data and applications. The layer of software services constituting the DBMS logically separated data and applications and permitted their independent design. Data common to different applications could be designed and managed as a unified resource. Database management systems exported data manipulation services that could be accessed by any application.

The management of data as a unified resource favored information sharing by integrating data common to different applications. Users running different applications could exchange information by storing and retrieving data in the central database. Conversely, designers could conceive new applications taking advantage of previously gathered and integrated information. A classical example is the use of accounting data by financial applications, allowing more precise financial analyses through detailed information on a firm's cash flows. Likewise, replenishment could be optimized through integration with order fulfillment data.

In the 1990s, client-server architectures allowed the *physical separation* between data and applications. Unlike the logical separation provided by databases in centralized architectures, the physical separation allowed the storage of data and the execution of applications on any computer. Within a client-server environment, shared data were typically stored on the server, but applications could be stored and run on local servers or personal computers.

The DBMS layer of centralized architectures was complemented by an additional layer of network services achieving the physical separation between data and applications. This made the number and the location of resources transparent to individual nodes in the architecture. By relying on peripheral processing and storage capacities of individual nodes, distributed architectures could grow incrementally. This provided the flexibility to continuously adjust to requirements and to implement a variety of applications according to individual needs. This greater flexibility enabled lateral organizational solutions that allowed different functions to take full advantage of organizational information with a variety of functionalities that could be more easily adjusted to changing requirements. These functionalities are now incorporated inside ERP (Enterprise Resource Planning) systems representing fully integrated software solutions that embed laterally integrated organizational processes.

Supply Chain Management Process Reengineering

More recently, the Web service paradigm is shifting reengineering activities towards interorganizational and interpersonal processes. Web service platforms are designed to wrap a company's information system and make selected functionalities available as web services to both internal and external users. This opens up a number of new opportunities. First, the Web service paradigm is causing a radical redesign of supply chain management processes (see Fig. 1). Supply chain management applications (SCM) support the integration of suppliers into a company's information system. This integration allows concurrent and efficient planning of production activities along the value chain. SCM involve a learning process, as shown in Fig. 1. This learning process starts from the monitoring of suppliers to measure their performance and, hence, optimize procurement activities. Then, a subset of efficient and reliable suppliers is selected for tighter integration, ranging from electronic orders to requirement management and electronic requirement management and codesign. If the supplier management process is effective, a company can build and evaluation and qualification system that can lead to official certifications that suppliers themselves can leverage as part of their brand equity. Overall, SCM involves a deep reengineering of supply management processes that represents the objective of a number of current projects.

Knowledge Management Process Reengineering

Knowledge management processes constitute a second important objective of current business process reengineering activities enabled by the Web and by the more recent Web service paradigm. Knowledge management systems (KMS) are "IT-based systems developed to support and enhance the organizational processes of knowledge creation, storage/retrieval, transfer, and application" ([1]: 114). KMS span a large and complex spectrum from help desk and customer care applications to those designed to develop employee skills. Virtual communities and collaborative environments are forms of KMS and KMS can also serve as corporate knowledge repositories and maps of expertise.

The literature on Knowledge Management Systems (KMS) largely assumes that an individual's knowledge can be captured and converted into group or organization-available knowledge. When individuals do not contribute to such systems, the knowledge creation capability of the firm is adversely affected. However, there is little clarity in the information systems literature on which mechanisms are necessary for conversion to take place. Many in the information systems literature (e.g., [6]) have argued for social influences (such as culture), hierarchical authority, and/or economic incentives, all of which are external influences that rely on the broader social context outside the KMS system. An alternative view to these external influences is internal or intrinsic motivation. This view assumes that there is little that a broader context outside of the person and the person's interactions with KMS can do to enhance contributions. "Creating and sharing knowledge are intangible activities that can neither be supervised nor forced out of people. They only happen when people cooperate voluntarily" [6]. Intrinsic motivation implies that the activity is performed because of the immediate satisfaction it provides in terms of flow, self-defined goal, or obligations of personal and social identity rather than some external factor or goal. The external factors can even undermine knowledge contributions if they interfere with intrinsic motivation. Although both views are likely to play a role in knowledge sharing, the internal view is important in organizations that take on characteristics of knowledge era (or postmodern) organizations. Such organizations require a more participative and self-managing knowledge worker compared to industrial era organizations. Knowledge-era organizations are associated with increased egalitarianism among positions, increased availability of information and knowledge resources, and increased self-management of knowledge workers. Wikipedia.org represents a typical example of postmodern self-organizing KMS, in which everyone in the world can contribute spontaneously with personal expertise and where control over contributions appropriateness is not based on any hierarchical structure, but is completely peer-based.

In a postmodern organization, an employee's commitment to his or her organization results from autonomous forms of organizing and the resulting self-expression and feelings of responsibility and control of the outputs of work. With knowledge workers, where work is associated with flows of knowledge and information, rather than flows of materials, self-expression, responsibility, and control are often targeted to knowledge outputs. Knowledge workers want to share their knowledge across the organization while preserving their association with these contributions. This type of psychological attachment, or emotional connection between the person and knowledge is well documented in open source initiatives. When given a choice to require or not require attribution to one's creative works (permit others to copy, distribute, display, modify the work but only if given credit without any economic implications), individuals invariably choose the requirement of future users of their knowledge to attribute knowledge to them (http://Creative commons.org/). The importance of psychological attachment to knowledge is no less important in commercial contexts.

KMS do not necessarily harness psychological attachment between knowledge embedded in the system and the individual who is the source of that knowledge. On one side, it is risky for the organization to let knowledge reside within the minds of individuals, in a form that can easily leak across the firm's boundaries and lead to a loss of competitive advantage. On the other hand, individual employees may perceive their personal goals to be poorly served by sharing knowledge unless the system helps to manage the knowledge worker's personal attachment to knowledge and make this attachment known in relevant organizational communities. In knowledge intensive organizations, people's distinctiveness depends upon their possessed knowledge. KMS that do not help construct, communicate, and defend the psychological attachment between the knowledge and the knowledge worker, and the rest of the organization can reduce the motivation to contribute knowledge to KMS. Fostering psychological attachment is likely to increase the knowledge workers quality of contributions, not only the quantity. In fact, the more complex and tacit the knowledge contributed to KMS, the higher the effort that knowledge workers are likely to put in their contributing activities. When the KMS fosters psychological attachment to contributions, knowledge workers increase their likelihood to engage also those knowledge sharing activities that require greater effort in order to be carried out.

Process Modeling Languages and Techniques

Reengineering initiatives typically involve a process modeling phase that supports the analysis of existing processes and the specification of new processes. UML (www.uml.org) represents a quasi-standard for process modeling and is widely used in business process reengineering.

Over the years, the scope of business processes and BPM has broadened. Initially, BPM, or workflow, was a technique that helped design largely human-based, paper-driven processes within a corporate department. For example, to handle a claim, an insurance claims process, taking as input a scanned image of a paper claims form, would pass the form electronically from the mailbox (or worklist) of one claims specialist to that of another, mimicking the traditional movement of interoffice mail from desk to desk. The contemporary process orchestrates complex system interactions, and is itself a service capable of communicating and conversing with the processes of other companies according to well-defined technical contracts. A retailer's process to handle a purchase order, for example, is a service that uses XML messages to converse with the service-based processes of consumers and warehouses.

A number of new modeling languages have recently been proposed to accommodate this complexity. For example, the i* model and its subsequent developments within the TROPOS project allow the representation of strategic relationships between organizations and their relationships with goals, resources and system components (cf.[10]). The impact of the structure of cooperation forms on the interactions among actors are modeled in the field of Multi-Agent Systems to determine an architectural solution based on typical software non-functional requirements (i.e., security, integrity, modularity, etc.). Moreover, the i* model supports the analysis of high-level goals together with non-functional requirements. The ability to move from high-level goals to sub-goals is also provided by KAOS (cf.[4]). KAOS is a formal approach for analyzing goals and for transforming goals into requirements for the software system. Finally, GBRAM (Goal Based Requirements Analysis Method, cf.[2]) proposes a method supporting the initial identification of high-level goals. Different from i* and KAOS, GBRAM does not assume that high-level goals are previously identified and provides a set of strategies to elicit goals from all available sources of information.

Key Applications

Cache-Conscious Query Processing

Kenneth A. Ross
Columbia University, New York, NY, USA

Synonyms

Cache-aware query processing; Cache-sensitive query processing

Definition

Query processing algorithms are designed to efficiently exploit the available cache units in the memory hierarchy. Cache-conscious algorithms typically employ knowledge of architectural parameters such as cache size and latency. This knowledge can be used to ensure that the algorithms have good temporal and/or spatial locality on the target platform.

Historical Background

Between 1980 and 2005, processing speeds improved by roughly four orders of magnitude, while memory speeds improved by less than a single order of magnitude. As a result, it is common (at the time of writing) for data accesses to RAM to require several hundred CPU cycles to resolve. Many database workloads have shifted from being I/O bound to being memory/CPU-bound as the amount of memory per machine has been increasing. For such workloads, improving the locality of data-intensive operations can have a direct impact on the system's overall performance.

Foundations

A cache is a hardware unit that speeds up access to data. Several cache units may be present at various levels of the memory hierarchy, depending on the processor architecture. For example, a processor may have a small but fast Level-1 (L1) cache for data, and another L1 cache for instructions. The same processor may have a larger but slower L2 cache storing both data and instructions. Some processors may even have an L3 cache. On multicore processors, the lower level caches may be shared among groups of cores.

Some initial analysis would typically be performed to determine the performance characteristics of a workload. For example, Ailamaki et al. [1] used hardware performance counters to demonstrate that several commercial systems were, at that time, suffering many L2 data cache misses and L1 instruction cache misses. Based on such observations, one can determine that the L2 data cache and L1 instruction cache are targets for performance tuning.

If the operating system does not provide direct access to system parameters such as the cache size, a database system can run a calibration test to estimate the relevant parameters [13].

To get good cache performance, algorithm designers typically utilize one or more of the following general approaches:

- Improve spatial locality, so that data items that are often accessed together are in the same cache lines.
- Improve temporal locality for data, so that after an initial cache miss, subsequent data item accesses occur while the item is still cache-resident.

- Improve temporal locality for instructions, so that code that needs to be applied to many data items is executed many times while the instructions reside in the cache.
- Hide the latency. Latency can be hidden in several ways. If the data access pattern is predictable, prefetching data elements into the cache can overlap the memory latency with other work. On architectures that support multiple simultaneous outstanding memory requests, cache miss latencies can be overlapped with one another.
- Sample the data to predict the cache behavior, and choose an algorithm accordingly.

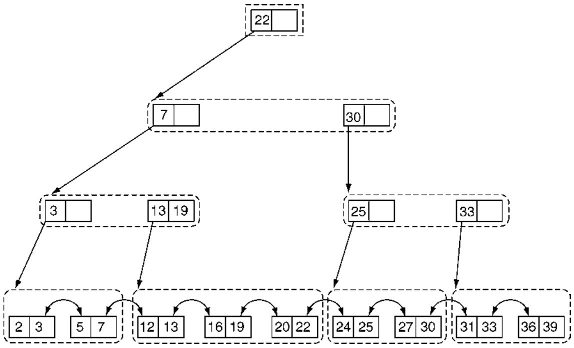
Examples of each of these approaches are given below.

Spatial Locality

In many query-processing contexts, only a few columns for a table are needed. In such cases, it pays to organize the table column-wise, so that column values from consecutive records are contiguous. Cache lines then contain many useful data elements. A row-wise organization would require more cache-line accesses, since each cache line would contain some data from unneeded columns. Examples of systems with column-wise storage are Sybase IQ [12], MonetDB [3], and C-Store [19]. The PAX storage model [6] allows for column-wise storage within each disk page. The main advantage of such an approach is that existing page-oriented database systems can improve cache behavior with limited changes to the whole system.

Chilimbi et al. [7] advocate placing multiple levels of a binary tree within a cache line, to reduce the number of cache misses per traversal. Chilimbi et al. also use cache coloring to place frequently accessed items in certain ranges of physical memory. The idea is to reduce the number of conflict misses by making sure that the low order bits of the addresses of certain items cannot be the same.

To reduce the number of cache lines needed to search for an item in an index, Rao and Ross proposed CSS-trees [16] and CSB+-trees [17]. CSS-trees eliminate pointers; a node contains only keys. Nodes are of fixed size, typically one cache line, aligned to the cache line boundaries. Nodes are stored in an array in such a way that the children of a node can be determined using simple arithmetic operations, making pointers unnecessary. CSB+-trees extend this idea, allowing just one pointer per node and requiring that all sibling nodes be contiguous. CSB+-trees have better update performance than CSS-trees, while retaining almost all of the cache-efficiency. The diagram below shows a CSB+-Tree of Order 1. Note that each node has only one child pointer and that each node's children are allocated contiguously.



Several other ways to compress B+-tree nodes for cache performance, such as key compression and key-prefix truncation, are discussed in [11].

Temporal Locality

Blocking is a general technique for ensuring temporal locality. Data is processed in cache-sized units, so that all data within the block stays cache-resident. The blocks are then combined in a later phase. Alpha-Sort [14] is an example of such a method: cache-sized units of input data are read and quick-sorted into runs. These runs are merged in a later phase. Padmanabhan et al. [15] modified a commercial database system to pass data between certain operators in blocks, and demonstrated improved cache behavior.

Buffering is a related strategy to improve temporal locality. Zhou and Ross [20] propose buffering to speed up bulk B-tree index lookups. By sending probes only one level at a time through the tree, in batches, one can amortize the cost of reading an index node over many probes. The savings in data cache misses usually outweigh the extra cost of reading and writing to intermediate buffers. Zhou and Ross also examine the code size of database operators, and propose to buffer data to ensure that the footprint of the active code is smaller than the size of the L1 instruction cache [21]. Again, the savings in instruction cache misses usually outweigh the cost of buffering.

Partitioning the data into cache-sized units for later processing is the dual of blocking. Examples include the partitioned hash join [18] and radix-join [3].

When multiple processors, or multiple threads within a single processor access a shared cache, cache interference can result. Even if each individual thread is cache-conscious, the total cache resources may be insufficient for all threads, and cache thrashing may result. To counter this interference, one could design cooperative threads that work together on a common task using common cache-conscious data structures. Multithreaded join operators [10,22] and aggregation operators [8] have been proposed.

Many divide-and-conquer style algorithms generate temporal locality at recursively smaller granularities. Such algorithms have been termed *cache oblivious* because they can achieve locality at multiple levels of the memory hierarchy without explicit knowledge of the cache parameters [9].

Prefetching

Prefetching involves reading data into the cache ahead of when it is to be used. When access patterns can be predicted in advance, and when memory bandwidth is not saturated, prefetching can effectively hide the memory latency. Some hardware platforms automatically recognize certain access patterns, such as regular fixed-stride access to memory. The hardware then automatically prefetches ahead in the access sequence. For access patterns that are not so easily recognized, or for hardware platforms that do not support hardware prefetching, one can explicitly prefetch memory locations using software.

Chen et al. [6] show how to prefetch parts of a B+-tree node or CSB+-tree node to get a bigger effective node size. For example, if the memory system can support n outstanding memory requests, then a node consisting of n cache lines could be retrieved in only slightly more time than a single cache line. Since wider nodes result in shallower trees, the optimal node size might be several cache lines wide.

Chen et al. [4] use prefetching to speed up hash joins. The internal steps for processing records are divided into stages. A memory access is typically required between stages. Stages for multiple records are scheduled so that while data for a forthcoming operation is being prefetched, useful work is being performed on other records.

Zhou et al. [22] define the notion of a work-ahead set, a data structure that describes a memory location and a computation stage for some data-intensive operation. One thread of a two-threaded system is devoted purely to prefetching the data into the cache, while the other thread does the algorithmic work.

Sampling

Inspector joins sample the data during an initial partitioning phase [5]. This information is used to accelerate a cache-optimized join algorithm for processing the partitions. Cieslewicz et al. [8] sample a stream of tuples for aggregation to estimate (among other things) the locality of reference of group-by values. Based on that information, an appropriate aggregation algorithm is chosen for the remainder of the stream.

Key Applications

Data intensive operators such as sorts, joins, aggregates, and index lookups, form the "assembly language" into which complex queries are compiled. By making these operators as efficient as possible on modern hardware, all database system users can effectively exploit the available resources.

Future Directions

Future processors are likely to scale by placing many cores on a chip, with only a modest increase in clock frequency. As a result, the amount of cache memory per processor may actually decrease over time, making cache optimization even more critical. For chips with shared caches, interference between cores will be a significant performance hazard. While locality is good for cache behavior, it can be bad for concurrency due to hot-spots of contention [8]. Cache performance will need to be considered together with parallelism to find appropriate performance trade-offs.

Calendar

Christian S. Jensen[1], Richard Snodgrass[2]

[1]Aalborg University, Aalborg, Denmark

[2]University of Arizona, Tucson, AZ, USA

Definition

A *calendar* provides a human interpretation of time. As such, calendars ascribe meaning to temporal values such that the particular meaning or interpretation provided is relevant to its users. In particular, calendars determine the mapping between human-meaningful time values and an underlying time line.

Key Points

Calendars are most often cyclic, allowing human-meaningful time values to be expressed succinctly. For example, dates in the common Gregorian calendar may be expressed in the form <*month*, *day*, *year*> where the month and day fields cycle as time passes.

The concept of calendar defined here subsumes commonly used calendars such as the Gregorian calendar, the Hebrew calendar, and the Lunar calendar, though the given definition is much more general. This usage is consistent with the conventional English meaning of the word.

Dershowitz and Reingold's book presents complete algorithms for fourteen prominent calendars: the present civil calendar (Gregorian), the recent ISO commercial calendar, the old civil calendar (Julian), the Coptic an Ethiopic calendars, the Islamic (Muslim) calendar, the modern Persian (solar) calendar, the Bahá'í calendar, the Hebrew (Jewish) calendar, the Mayan calendars, the French Revolutionary calendar, the Chinese calendar, and both the old (mean) and new (true) Hindu (Indian) calendars. One could also envision more specific calendars, such as an academic calendar particular to a school, or a fiscal calendar particular to a company.

Definition

A calendric system is a collection of calendars. The calendars in a calendric system are defined over contiguous and non-overlapping intervals of an underlying time-line. Calendric systems define the human interpretation of time for a particular locale as different calendars may be employed during different intervals.

Key Points

A calendric system is the abstraction of time available at the conceptual and logical (query language) levels. As an example, a Russian calendric system could be constructed by considering the sequence of six different calendars used in that region of the world. In prehistoric epochs, the Geologic calendar and Carbon-14 dating (another form of calendar) are used to measure time. Later, during the Roman empire, the lunar calendar developed by the Roman republic was used. Pope Julius, in the first century B.C., introduced a solar calendar, the Julian calendar. This calendar was in use until the 1917 Bolshevik revolution when the Gregorian calendar, first introduced by Pope Gregory XIII in 1572, was adopted. In 1929, the Soviets introduced a continuous schedule work week based on 4 days of work followed by 1 day of rest, in an attempt to break tradition with the 7-day week. This new calendar, the Communist calendar, had the failing that only eighty percent of the work force was active on any day, and it was abandoned after only 2 years in favor of the Gregorian calendar, which is still in use today.

The term "calendric system" has been used to describe the calculation of events within a single calendar. However, the given definition generalizes that usage to multiple calendars in a very natural way.

Cardinal Direction Relationships

Spiros Skiadopoulos
University of Peloponnese, Tripoli, Greece

Synonyms

Orientation relationships; Directional relationships

Definition

Cardinal direction relationships are qualitative spatial relations that describe how an object is placed relative to other objects utilizing a co-ordinate system. This knowledge is expressed using symbolic (qualitative) and not numerical (quantitative) methods. For instance, *north* and *southeast* are cardinal direction relationships. Such relationships are used to describe and constrain the relative positions of objects and can be used to pose queries such as "Find all objects *a*, *b* and *c* such that *a* is *north of b* and *b* is *southeast of c*".

Historical Background

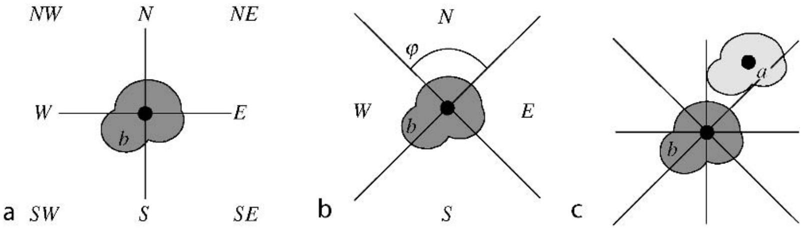
Qualitative spatial relationships (QSR) approach common sense knowledge and reasoning about space using symbolic rather than numerical methods [5]. QSR has found applications in many diverse scientific areas such as geographic information systems, artificial intelligence, databases, and multimedia. Most researchers in QSR have concentrated on the three main aspects of space, namely topology, distance and direction. The uttermost aim in these lines of research is to define new and more expressive categories of spatial operators, as well as to build efficient algorithms for the automatic processing of queries involving these operators.

Foundations

Several models capturing cardinal direction relationships have been proposed in the literature. Typically, a cardinal direction relationship is a binary relation that describes how a *primary object a* is placed relative to a *reference object b* utilizing a co-ordinate system (e.g., object *a* is *north of* object *b*). Early models for cardinal direction relationships approximate an extended spatial object by a representative point [3,6], e.g., objects in Fig. 1 are approximated by their centroid. Typically, such models partition the space around the reference object *b* into a number of mutually exclusive areas. For instance, the *projection* model partitions the space using lines parallel to the axes (Fig. 1a) while the *cone* model partitions the space using lines with an origin angle ϕ (Fig. 1b). Depending on the adopted model, the relation between two objects may change. For instance, consider Fig. 1c. According to the projection model, *a* is northeast of *b* while according to the cone model, *a* is north of *b*. Point based approximations may be crude [4], thus, later models more finely approximate an object using a representative area (most commonly the minimum bounding box (The minimum bounding box of an object *a* is the smallest rectangle, aligned with the axis, that encloses *a*.)) and express directions on these approximations [7,9]. Unfortunately, even with finer approximations, models that approximate both the primary and the reference object may give misleading directional relations when objects are overlapping, intertwined, or horseshoe-shaped [4].

Recently, more precise models for cardinal direction relationships have been proposed. Such models define directions on the exact shape of the primary object and only approximate the reference object (using its minimum bounding box). The *projection-based directional relations* ($\mathcal{PDR}$) model is the first model of this category [4,11,12]. The $\mathcal{PDR}$ model partitions the plane around the reference object into nine areas similarly to the projection model (Fig. 2a). These areas correspond to the minimum bounding box (*B*) and the eight cardinal directions. Intuitively, the cardinal direction relationship is characterized by the names of the reference areas occupied by the primary object. For instance, in Fig. 2b, object *a* is partly *NE* and partly *E* of object *b*. This is denoted by *a NE*:*E b*. Similarly in Fig. 2c, *a B*:*S*:*SW*:*W*:*NW*:*N*:*E*:*SE b* holds. In total, the $\mathcal{PDR}$ model identifies 511 (= $2^9 - 1$) relationships.

Clearly, the $\mathcal{PDR}$ model offers a more precise and expressive model than previous approaches that approximate objects using points or rectangles [4]. The $\mathcal{PDR}$ model adopts a projection-based partition using lines parallel to the axes (Fig. 2a). Typically, most people find it more natural to organize the surrounding space using lines with an origin angle similarly to the cone model (Fig. 3a). This partition of space is adopted by the *cone-based directional relations* ($\mathcal{CDR}$) model. Similarly to the $\mathcal{PDR}$ model, the $\mathcal{CDR}$ model uses the exact shape of the primary object and only approximates the reference object using its minimum bounding box

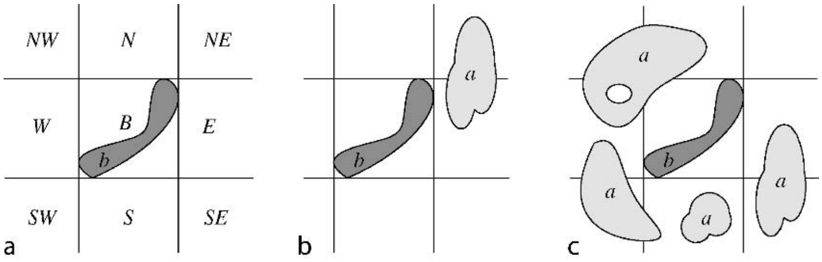


Cardinal Direction Relationships. Figure 1. Projection-based and cone-based point models.

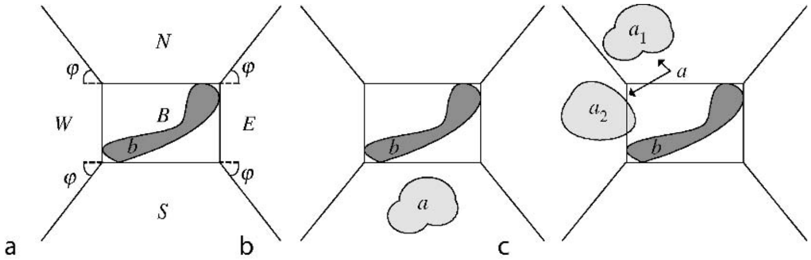
[14]. But, for the $\mathcal{CDR}$ model the space around the reference object is partitioned into five areas (Fig. 3a). The cardinal direction relationship is formed by the areas that the primary object falls in. For instance, in Fig. 3b, *a* is south of *b*. This is denoted by *a S b*. Similarly in Fig. 3c, *a B*:*W*:*N b* holds. In total, the $\mathcal{CDR}$ model identifies 31 ($= 2^5 - 1$) relationships.

In another line of research, cardinal direction relationships are modeled as ternary relationships [2]. Given three objects *a*, *b* and *c*, the ternary model expresses the direction relation of the primary object *a* with respect to a reference frame constructed by objects *b* and *c*. Specifically, the convex-hull, the internal and the external tangents of objects *b* and *c* divide the space into five areas as in Fig. 4a. These areas correspond to the following directions: right-side (*RS*), before (*BF*), left-side (*LS*), after (*AF*) and between (*BT*). Similarly to $\mathcal{PDR}$ and $\mathcal{CDR}$, the name of the areas that *a* falls into, determines the relation. For instance, in Fig. 4b, *a* is before and to the left-side of *b* and *c*. This is denoted by *LS*:*BF*(*a*,*b*,*c*). Notice that, if the order of the reference objects changes, the relationship also changes. For instance, in Fig. 4b, *RS*:*AF*(*a*,*c*,*b*) also holds.

For all the above models of cardinal direction relationships, research has focused on four interesting operators: (i) efficiently determining the relationships that hold between a set of objects, (ii) calculating the inverse of a relationship, (iii) computing the composition of two relationships and (iv) checking the consistency of a set of relationships. These operators are used as mechanisms that compute and infer cardinal direction relations. Such mechanisms are important as they are in the heart of any system that retrieves collections of objects similarly related to each other using spatial relations. Table 1 summarizes current research on the aforementioned problems.



Cardinal Direction Relationships. Figure 2. Extending the projection model.



Cardinal Direction Relationships. Figure 3. Extending the cone model.

Rectangle approximations	[9]	[9]	[9]	[9]
$\mathcal{PDR}$	[13]	[1]	[11]	[8, 12]
$\mathcal{CDR}$	Open problem	[14]	[14]	Open problem
Ternary	[2]	[2]	Open problem	Open problem

Key Applications

Cardinal direction relationships intuitively describe the relative position of objects and can be used to constrain and query spatial configurations. This information is very useful in several applications like geographic information systems, spatial databases, spatial arrangement and planning, etc.

Future Directions

There are several open and important problems concerning cardinal direction relations. For the models discussed in the previous section, as presented in Table 1, there are four operators that have not been studied (two for the $\mathcal{CDR}$ and two for the ternary model). Another open issue is the integration of cardinal direction relationships with existing spatial query answering algorithms and data indexing structures (like the R-tree). Finally, with respect to the modeling aspect, even the most expressive cardinal direction relationships models define directions by approximating the reference objects. Currently, there is not a simple and easy to use model that defines cardinal direction relationships on the exact shape of the involved objects.

Cartesian Product

Cristina Sirangelo
University of Edinburgh, Edinburgh, UK

Synonyms

Cross product

Definition

Given two relation instances R_1, over set of attributes U_1, and R_2, over set of attributes U_2 – with U_1 and U_2 disjoint – the cartesian product $R_1 \times R_2$ returns a new relation, over set of attributes $U_1 \cup U_2$, consisting of tuples $\{t | t(U_1) \in R_1 \text{ and } t(U_2) \in R_2\}$. Here $t(U)$ denotes the restriction of the tuple t to attributes in the set U.

Key Points

The cartesian product is an operator of the relational algebra which extends to relations the usual notion of cartesian product of sets.

Since the sets of attributes of the input relations are disjoint, in $R_1 \times R_2$ each tuple of R_1 is combined with each tuple of R_2; moreover the arity of the output relation is the sum of the arities of R_1 and R_2.

As an example, consider a relation *Students* over attributes (*student-number, student-name*), containing tuples {(1001, *Black*), (1002, *White*)}, and a relation *Courses* over attributes (*course-number, course-name*), containing tuples {(*EH*1, *Databases*), (*GH*5, *Logic*)}. Then *Students* × *Courses* is a relation over attributes (*student-number, student-name, course-number, course-name*) containing tuples (1001, *Black*, *EH*1, *Databases*), (1001, *Black*, *GH*5, *Logic*), (1002, *White*, *EH*1, *Databases*), (1002, *White*, *GH*5, *Logic*).

The cartesian product can also be viewed as a special case of natural join, arising when the set of attributes of the operands are disjoint. However, relations over non-disjoint sets of attributes can also be combined by the cartesian product, provided that the renaming operator is used to rename common attributes in one of the two relations.

In the presence of attribute names, the cartesian product is commutative. In the case that relation schemas do not come with attribute names, but are specified by a relation name and arity, the cartesian product $R_1 \times R_2$ returns the concatenation $t_1 t_2$ of all pairs of tuples such that $t_1 \in R_1$ and $t_2 \in R_2$. Moreover the output schema is specified by the sum of the arities of the input schemas. In this case the cartesian product is a non-commutative operator.

Cataloging in Digital Libraries

Mary Lynette Larsgaard
University of California-Santa Barbara, Santa Barbara, CA, USA

Synonyms

Cataloging; Classification

Definition

Cataloging is using standard rules to create a mainly text surrogate that describes an object sufficiently in detail so that the object is uniquely differentiated from all other objects. Without looking at the object, a user may know enough about the object to know if it suits the user's needs. It is generally considered to include bibliographic description, and the application of subjects, both as words and as classification.

Historical Background

Devising and using methods of arranging and describing information – respectively termed, within the standard library world, classification and cataloging – have been primary concerns of libraries ever since libraries began, in the ancient world of the Greeks and the Romans. A collection of information without classification and cataloging is not a library. The whole point of classification and cataloging is to make access quick and easy for users; it was discovered very early that putting like objects together (classification) and creating text or relatively speaking much smaller surrogates to describe an information object (cataloging) made finding information much quicker for the user.

Experiments in using digital records in libraries started in approximately the late 1960s. But it was only in the mid-1970s, with the success of what is called "shared cataloging" – many libraries using a catalog record contributed as "original cataloging" by the first library to catalog the item – that using digital systems for cataloging came into its own. This sharing of bibliographic records in online form began with OCLC, initially as a consortium of college libraries in Ohio (starting in 1967), but growing rapidly to become the most successful such library utility, currently with about 60,000 participating libraries in 112 countries and territories (http://www.oclc.org). The development of integrated library systems (ILS) or library management systems (LMS) – software, or a combination of software and hardware, that permits a library to perform multiple functions, such as acquisitions/ordering, cataloging and classification, circulation, preservation, and reference, using digital files in large databases with many tables – has continued to the present in the "Library of Congress Authorities" online authority system, http://authorities.loc.gov).

The inception and speedy growth of the World Wide Web (Web) since the mid-1990s has spread this interest in arrangement and description of, and access to, information objects to non-library communities, and within the library world to how specifically to arrange and describe digital objects made available over the Web in digital libraries. There have been many standards for the description of information objects. They are most often intended either to apply at least in theory to all materials (e.g., Anglo-American Cataloging Rules, hereafter referred to as AACR; Dublin Core, which began in 1995, http://www.dublincore.org/documents/dces/) or to apply to the description of a specific body of information (e.g., for digital geospatial data, "Content Standard for Digital Geospatial Metadata"; 2nd edition, 1998, http://www.fgdc.gov/standards/projects/FGDC-standards-projects/metadata/base-metadata/v2_0698.pdf and ISO Standard 19115, "Geographic Information, metadata; Information géographique, métadonnées," 2003).

Foundations

Classification

Classification and cataloging complement each other. Classification is a form of subject cataloging, which is where the major overlap between the two occurs. Classification tends to be hierarchical, breaking a given world of information or knowledge into broad divisions (e.g., Law) and then breaking that into smaller divisions (e.g., education for law; law of various countries; etc.). Classification is most often placing like items about like subjects (e.g., works by Shakespeare) and like genres or formats (e.g., maps) together. It also provides a physical location within a library for each object, be it digital or hardcopy. The most prominent systems used are the Dewey Decimal Classification (often used by public libraries and smaller libraries generally), and the Library of Congress Classification (most often used by university and other research libraries in the United States). There are many more systems, such as the Bliss Classification and the Colon Classification, and special and research libraries (such as the New York Public Library) devise and maintain their own systems. Devising a classification system is easy, but maintaining it is very difficult and time-consuming. Often a library maintaining a classification system unique to itself will find that it is far less work to convert to a rigorously maintained system that is used by many libraries than it is to maintain a unique system not used by any other collections.

Classification of digital objects at first glance seems unnecessary. Why not just assign an arbitrary number (e.g., a unique identifier that database software assigns to each separate catalog record) and be done with it? Libraries of digital objects have found that, for several reasons, it is very practical to assign classification to digital objects just as one would to hard-copy objects. The main one is that very often one needs to move around, or to perform the same operation (e.g., create distribution forms) on large numbers of digital objects in groups of items that are, e.g., the same file type. For example, the Alexandria Digital Library (ADL), a collection of digital geospatial data, with a catalog that includes catalog records both for digital and hard-copy geospatial data (http://webclient.alexandria.ucsb.edu), always gives a digital geospatial data object (e.g., a scan of a paper map; a born-digital object) the same classification number as the hardcopy geospatial data equivalent (e.g., the paper map that has been scanned). Classification of digital objects allows one file to be accessible from multiple classification numbers, an action that few libraries of hardcopy items have ever been able to afford. For example, a digital map of California and Nevada may have two classification numbers (either pointing toward one file, or storing the same file two separate places), one for California and one for Nevada. Few libraries of hardcopy items have financial resources available to buy multiple copies of an item and store a copy at each applicable classification number.

Cataloging

A catalog record (whether in hardcopy or in digital form) provides information on the thematic and physical nature of an item (whether hard-copy or digital) being cataloged. Libraries first used hard-copy catalogs, generally book-format catalogs, then cards, and then beginning in the late 1960s the use of databases as catalogs. This started with in 1969 the Library of Congress' MARC, MAchine-Readable Catalog format for the transmission of catalog-card information in digital form (http://www.loc.gov/marc/). While MARC may be used as the machine format for bibliographic records formulated using any set of cataloging rules, it is most often used for records based on the cataloging rules of the Anglo-American library community, AACR (Anglo-American Cataloging Rules) in its various editions, first issued in 1967. AACR itself is based on the International Standard Bibliographic Descriptions (ISBDs) as far as content of fields, and field order, are concerned.

The purpose of ISBDs is to standardize the form and content – including in what order information appears – for the bibliographic description of an object. ISBDs specifically do not include rules for fields for subject cataloging, added entries for additional authors, or classification. The idea of ISBDs arose at a conference of the International Meeting of Cataloging Experts held in 1969, with the first ISBD (for monographic publications) being issued in 1971. ISBDs were issued for numerous categories of publications (e.g., computer files; cartographic materials; serials; etc.; for full list, see http://www.ifla.org/VI/3/nd1/isbd-list.htm). In 2002, work began on a single consolidated ISBD, to supersede all existing ISBDs. The consolidated edition (available online at http://www.ifla.org/VII/s13/pubs/cat-isbd.htm) was published in 2007 (International standard bibliographic description (ISBD), 2007).

The same organization that issues ISBDS – the International Federation of Library Associations (IFLA) – has been a prime agent in the move toward an international cataloging standard. In the early 1990s, IFLA's Study Group on the Functional Requirements for Bibliographic Records (FRBR) began work on its report to recommend basic functionalities of a catalog and bibliographic-record data requirements. The Group's final report was issued in 1998 (Functional Requirements for Bibliographic Records (FRBR)).

While FRBR put forward several ideas, the one that most engaged the interest and discussion of the library community was the importance of incorporating into the bibliographic description the concept of the relationship between the work, the expression, the manifestation, and the item (called Group 1 Entities). A work is a distinct intellectual or artistic creation but a concept rather than an actual physical object. An expression is the intellectual or artistic realization of a work but still not generally an actual physical object. The manifestation is all copies of a published object (e.g., all copies of a printed map; all copies of a DVD of a specific piece of music), and the item is one copy of a manifestation. For example, all digital versions of one given map (one could be raster and the other could be vector; there could be more than one level of resolution of raster and of vector images), and all hard-copy versions of the same map (e.g., paper; microfiche; microfilm) are two expressions' the basic map itself is the work and the 1973 edition of all copies of the paper map is a specific manifestation, with each one of those printed maps being an item.

Key Applications

Key applications of classification and cataloging:

Classification: Arrangement of digital objects in digital libraries. See previous section

Cataloging: Creation of metadata for digital objects in digital libraries

While full-text searching is extremely useful and a major step forward in the history of information retrieval, it does have the following main problems: it may give the user very large numbers of hits; it is not as efficient as searching well-constructed text surrogates; and it does not work for what are primarily non-text materials (e.g., music; maps; etc.). The reason for creating metadata records for digital objects is the same as that for performing standard cataloging – constructing a surrogate for the item so that users may quickly and efficiently find resources that suit the users' needs. Metadata is constructed by non-library entities (e.g., federal government agencies) and by libraries. Metadata records include but are not limited to the information contained in what the standard library cataloging world terms "bibliographic records."

Metadata records tend to be considerably longer than catalog records, because they contain far more and generally more detailed technical information than a catalog record would. The latter is much more likely to simply include a URL that points to an online version of that technical information, quite possibly to a metadata record. The reasons for this are that metadata records tend to be constructed for very focused, often technically skilled audiences, and a geographic digital dataset (such as a geographic information system, more commonly known as a GIS) is often quite large and complicated, with many layers of information, and therefore is by no means as easily browsed – in order to determine its suitability for use – as is a hard-copy map. For example, the catalog record for Digital Orthophoto Quarter Quadrangles (DOQQs; mosaics of rectified aerial photographs) is relatively brief – about one standard printed page – when compared with the metadata record for DOQQs, which is seven pages. For example, see http://fisher.lib.virginia.edu/collections/gis/doq/helps/doqq_meta.html (Fig. 1).

A library generating metadata records has two major options: load the records into the library's ILS (integrated library system) online catalog; or create what is in effect another ILS, or at the very least an online catalog for the metadata records. The first technique generally requires that the records be in MARC format, since the alternative is that the online-catalog software must be capable of searching over multiple catalog-record databases in different formats.

For the second technique, the following is required: software (UNIX; a database manager; a user interface; and middleware to connect inquiries on the user interface with the data and return results); hardware; computer technical staff/programmers (for a digital library of any size, a minimum of three computer programmers to deal with adding new data and metadata and maintaining and improving the system, including the interface, plus one more programmer to deal with the operating system, disk storage, and manipulation and maintenance of the directories of digital material).

An example of this is the ADL (Alexandria Digital Library) Catalog, http://webclient.alexandria.ucsb.edu. The ADL webpage (http://www.alexandria.ucsb.edu) provides an outline as to what kind and how much work is required to start up, develop, and maintain such a library; software is free for download, and general instructions are given as to what work should be done in order to get the software working.

As previously indicated, there are numerous metadata standards. The following are major standards that digital libraries creating metadata records will probably need to deal with, at least in the United States: Dublin Core; XML; METS; and MODS.

Dublin Core

Dublin Core (DC) (http://dublincore.org/) is extremely heavily used by libraries cataloging digital content. Its adaptability to any form or type of digital data and its brevity (15 fields, what libraries term minimal-level cataloging) with no fields required and all fields repeatable, makes it very flexible. While DC may be used either as "qualified" (each of the 15 elements may be qualified in some way to make the information clear, e.g., for Coverage, one might state that the geographic area is given in decimal degrees), the experience in libraries over the nearly 15 years since DC was made available for use is that it is strongly advised only qualified DC be used. This is because unqualified DC results in metadata records that are so unstructured as to be nearly useless [12]. For digital libraries needing keep at least one foot solidly in the traditional library world, there is a DC-to-MARC2 crosswalk at http://www.loc.gov/marc/dccross.html, and also one the other direction.

XML

XML has achieved primacy as the format of choice for metadata for digital libraries and is of considerable importance to the standard library world, as evidenced by the Library of Congress having MARC21 in XML available over the Web at http://www.loc.gov/standards/marcxml/Sandburg/sandburg.xml. It was announced in April 2005 that the ISO

committee for Technical Interoperability – Information and Documentation was to vote on a proposal for a New Work Item concerning an XML schema to wrap MARC records. ISO 2709 had been used for many years and has worked well, but the library community needed a standard exclusively for MARC records (of which there are over 100 million worldw ide) in XML. The standard is to be published as ISO 25577 with the short name of MarcXchange; the temporary Webpage for the standard is http://www.bs.dk/marcxchange/.

METS and MODS

METS (Metadata Encoding and Transmission Standard) is a standard for encoding descriptive, administrative, and structural metadata of objects in a digital library (http://www.loc.gov/standards/mets/).

The "Metadata Object Description Schema" (MODS) is intended both to carry metadata from existing MARC21 records, and to be used to create new catalog records. It has a subset of MARC fields, and – unlike MARC21. It uses language-based tags rather than numeric tags. It occasionally regroups elements from the MARC21 bibliographic format (http://www.loc.gov/standards/mods/). METS and MODS are both expressed using XML, and are maintained by the Library of Congress's Network Development and MARC Standards Office.

Conclusion

Organizations creating metadata records and arranging digital files are best advised to follow well-maintained national or international standards. In no case should organizations just starting out on this work create their own standards. Instead, use of sturdy standards – some of which have an extensions feature, to enable customization of the records to the library users' needs – is recommended.

Creating metadata records is relatively easy compared with the difficult and expensive work of setting up what is in effect an ILS online catalog. Libraries need to consider this very carefully. If the library cannot sustain the programming effort required to develop and then to maintain and add to the catalog, then the library should not begin the project. If anything, digital libraries and their catalogs are, at the moment, at least as expensive and time-consuming to develop and maintain as are hard-copy libraries.

Definition

Let T be a finite theory expressed in a language L, and ϕ an L-sentence. Then T finitely entails ϕ, in notation $T \vDash \phi$, if all finite models of T also are models of ϕ. A theory T is said to be *complete in the finite* if for each L-sentence ϕ either $T \vDash \phi$ or $T \vDash \neg\phi$. In particular, if T is incomplete (not complete in the finite), then there is an L-sentence ϕ, such that $T \nvDash \phi$ and $T \nvDash \neg\phi$. It follows from classical logic that a first order theory is complete in the finite if and only if all its finite models are isomorphic. Consider now a theory

$$T_1 = \begin{cases} R(a,b) \wedge R(a,c), \\ \forall x, y : R(x,y) \rightarrow (x,y) = (a,b) \vee (a,c), \\ a \neq b, a \neq c, b \neq c. \end{cases}$$

where a, b, and c are constants. This theory is complete, and clearly for instance $T \vDash R(a, b)$, $T \vDash R(a, c)$, and $T \nvDash R(d, c)$, for all constants d different from a and b. Consider then the theory

$$T_2 = \begin{cases} R(a,b) \vee R(a,c), \\ \forall x, y : R(x,y) \rightarrow (x,y) = (a,b) \vee (a,c), \\ a \neq b, a \neq c, b \neq c. \end{cases}$$

This theory is incomplete, since for instance $T_2 \nvDash R(a, b)$, and $T_2 \nvDash \neg R(a, b)$. If "finitely entails" is equated with "certainly holds," it is possible to say that $R(a, b)$ and $R(a, c)$ *certainly* hold in T_1. Dually, it is possible to say that $R(a, b)$ *possibly* holds in T_2, since $T_2 \nvDash \neg R(a, b)$, and similarly that $R(a, c)$ possibly holds in T_2.

Key Points

An *incomplete database* is similar to a logical theory: it is defined using a finite specification, usually a *table* T (relation with nulls and conditions) of some sort, and a function *Rep* that associates a set of complete (ordinary, finite) databases $Rep(T)$ with T. Then each instance $I \in Rep(T)$ represents one isomorphism class (isomorphism up to renaming of the constants) of the finite models of the table T regarded as a logical theory. Depending on the interpretation of facts missing from T, either the *closed world assumption* is made [9], which postulates or axiomatizes (as in the middle "row" in T_1 and T_2) that any facts not deducible from T are *false*, or the *open world assumption* (omit the middle rows), in which there are certain and possible facts, but no false ones. There is actually a spectrum of closed world assumptions, ranging up to semantics best axiomatized in third order logic [4].

Having settled on a representation T, and an interpretation *Rep*, the *certain answer* to a query Q on an incomplete database T, is now defined as $\bigcap_{I \in Rep(T)} Q(I)$, sometimes also denoted $\bigcap Q(Rep(T))$. In database parlance the certain answer consists of those facts that are true in *every* possible database instance I that T represents. Likewise, the *possible answer* to a query Q on an incomplete database T, consists of those facts which are true in *some* possible database, i.e., $\bigcup_{I \in Rep(T)} Q(I)$. Needless to say, the possible answer $\bigcup Q(Rep(T))$ is interesting only under a closed world assumption, since otherwise every fact is possible.

These definitions are clear and crisp, but unfortunately it doesn't mean that they always have tractable computational properties. Consider the membership problem for the set

$$\textsc{Cert}(Q) = \{(t,T) : t \in \bigcap Q(Rep(T))\}.$$

If T actually is a complete instance I, it is well known that $\textsc{Cert}(Q)$ has polynomial time complexity, for any first order (relational algebra) or datalog query Q. Likewise, the set

$$\textsc{Poss}(Q) = \{(t,T) : t \in \bigcup Q(Rep(T)).$$

has PTIME complexity for first order and datalog queries Q, and tables T that actually are complete databases.

A table T with *unmarked nulls* is a classical instance containing existentially quantified variables (nulls), such that each existential quantifier has only one variable in its scope. This means that each occurrence of a null can be independently substituted by a constant for obtaining one possible database in $Rep(T)$.

If only simple incomplete databases with unmarked nulls are allowed, only existential first order queries Q need to be admitted, or alternatively algebraic expressions with operators from $\{\pi, \sigma, \cup, \bowtie\}$, in order for $\textsc{Cert}(Q)$ to become coNP-complete, and $\textsc{Poss}(Q)$ to become NP-complete [2]. The use of inequalities $\neq$ or disjunctions $\vee$ in Q is essential. If the use of inequalities and disjunctions is denied, $\textsc{Cert}$ (Q) and $\textsc{Poss}(Q)$ remain in PTIME. If one admits arbitrary first order or full relational queries Q, along with an open world assumption, $\textsc{Cert}(Q)$ and $\textsc{Poss}(Q)$ become undecidable. This follows from validity and satisfiability of a variant of first order logic known to be undecidable [3]. (Note that under the open world assumption $\textsc{Poss}(Q)$ equals all possible databases, assuming $\textsc{Poss}(Q) \neq \emptyset$. The problem then becomes to decide whether $\textsc{Poss}(Q)$ is non-empty or not.)

On the other hand, if the representation mechanism allowed for T is more powerful that the simple incomplete databases above, $\textsc{Cert}(Q)$ and $\textsc{Poss}(Q)$ again become coNP and NP complete, respectively, already with Q being the identity query. For this, the *conditional tables* of [6] are needed. As observed in [5], conditional tables can be obtained as a closure of simple incomplete databases by requiring that the exact result $\{q(I) : I \in Rep(T)\}$ of any relational algebra query on a any table T is representable by conditional table. In other words, for each T conditional table and Q relational algebra query, there exists a conditional table U, such that $Rep(U) = Q(Rep(T))$.

Another way of representing incomplete databases, is to consider an *information integration* scenario, where the basic facts are stored in *views* of a virtual *global schema*. For instance, in the integration scenario

$$T_3 = \begin{cases} V(a), \\ \forall x, y : R(x,y) \rightarrow V(x), \\ \forall x : V(x) \rightarrow x = a, \\ \forall x, y : R(x,y) \rightarrow x = a \end{cases}$$

gives (closed world) $Rep(T_3) = \{I : V^I = \pi_1(R^I) = \{(a)\}\}$. ($R^I$ means the value (interpretation) of predicate symbol R in instance/model I. The meaning of V^I is similar.) Open world (omit in T_3 the third and fourth rows) $Rep(T_3)$ would be defined as $\{I : V^I \supseteq \{(a)\}, \pi_1(R^I) \supseteq \{(a)\}$. If T is allowed to use conjunctive queries (such as the second row of T_3) to express the views V in terms of the global relations R, then $\textsc{Cert}(Q)$ is in PTIME for existential first order and datalog queries under the open world assumption, and coNP complete under the closed world assumption [1]. The latter is due to the negation implicit in the closed world assumption. If one allows inequalities $\neq$ in the query, $\textsc{Cert}(Q)$ is coNP complete also under the open world assumption. Undecidability of $\textsc{Cert}(Q)$ is achieved by allowing negation in the query or the view definitions, or, under the open world assumption by allowing view definitions in (recursive) datalog.

Finally, one can see the *data exchange* problem [7,8] as a variation of the integration problem. The data exchange problem consists of importing the data from a source database R_s to a target database R_t, using data dependencies (implicational sentences) to express the translation. For example, a (closed world) exchange scenario could be

$$T_4 = \{R_s(a), \forall x : [R_s(x) \leftrightarrow \exists y : R_t(x, y)].$$

The base facts are in a source database R_s, and the user query is expressed against the target database R_t. As T_4 obviously is incomplete, the certain answer of Q on T_4 is defined as $\cap Q(Rep(T_4)$, and the possible answer as $\cup Q(Rep(T_4)$. It is perhaps no big surprise that essentially the same complexity landscape for $\text{Cert}(Q)$ and $\text{Poss}(Q)$ as in the previous table- and integration-scenarios emerges: the boundaries between undecidability, intractability, and polynomial time depend on similar restrictions on the use of negation, of inequalities or unions in the exchange mappings, and on the open or closed world assumptions.

Change detection and explanation on streams

Definition

A *data stream* is a (potentially infinite) sequence of data items $x_1, x_2, \ldots$. As opposed to traditional data analysis, it is not assumed that the data items are generated independently from the same probability distribution. Thus *change detection* is an important part of data stream mining. It consists of two tasks: determining when there is a change in the characteristics of the data stream (preferably as quickly as possible) and explaining what is the nature of the change.

The nature of the data stream model means that it may be infeasible to store all of the data or to make several passes over it. For this reason, change detection algorithms should satisfy the following desiderata: the memory requirements should be constant or increase logarithmically, and the algorithm should require only one pass over the data.

Historical Background

There has been a lot of work on detecting change in time series data *after* all of the data has been collected. Change point analysis [5] is a statistical field devoted to detecting the point in time where the distribution of the data has changed. The description of the change is often concerned with how the parameters of the distributions (such as the mean) have changed. Scan statistics [11] can be used to detect and describe changes (not just along the time dimension) by identifying regions where the probability mass has changed the most. For examples of offline analysis of change in terms of data mining models see [6] for itemset mining, [10] for itemset mining and decision trees, and [14] for burst detection. Offline algorithms for describing change include [1] for hierarchical numerical data and [7,8] for semi-structured data.

The offline methods are useful for data analysis, but as data acquisition becomes easier and easier, the data stream model becomes more and more relevant. The assumptions behind this model are that there is so much data that it cannot all be stored on disk (let alone kept in memory) and that the data arrives at such a rate that expensive online computations are impractical. Often results are expected in real-time – for example, notification of change should occur as soon as possible. The data stream model is discussed in detail in [2].

In the data stream model, one can predefine a certain set of stochastic processes. One of these processes is initially active and the goal is to determine when a different process in that set becomes active [3]. The description of the change is then the identity of the new process. Alternative approaches [9,13] avoid making distributional assumptions by using ideas from nonparametric statistics. In these approaches the main idea is to divide the domain of the data into (possibly overlapping) regions, estimate the probability of the regions, and then determine whether the changes in probability in any of the regions are statistically significant. Alternate approaches for handling change include testing if the data are exchangeable (i.e., any permutation of the data is equally likely) [15] and developing data mining algorithms (such as decision tree construction) that adapt to change [12].

Foundations

Let $x_1,x_2,...,$ be a potentially infinite sequence of data points. To detect changes in the data stream, one first has to determine a plausible framework that describes how the data can be generated. In the simplest case, data are generated from one of two probability distributions S_1 and S_2 (for example a Gaussian with mean 0 and variance 1, and a Gaussian with mean 10 and variance 1). Initially, the data points are generated independently from S_1 and after some time the data are generated independently from S_2. The celebrated CUSUM algorithm by Page [4] can be used to detect that a change from S_1 to S_2 occurred by comparing the likelihoods that parts of the data were generated by S_1 or S_2. Suppose S_1 has density f_1 and S_2 has density f_2, and let $\delta > 0$ be a threshold.

A user of the change-detection system is interested in the first time k where. $\sum_{i=k}^{\text{now}} \log(f_2(x_i)/f_1(x_i)) > \delta$. When this happens, the system signals that a change has occurred and can return k as a plausible estimate of the change point. This test can be done in an online fashion by defining $T_0 = 0$ and $T_k = \max(T_{k-1} + \log(f_2(x_k)/f_1(x_k)),0)$ and signaling a change if $T_{\text{now}} > \delta$. Typically S_1 is chosen based on an initial sample of the data stream and S_2 is then chosen to represent the smallest change whose detection is desired. For example, suppose that S_1 is chosen to be a Gaussian with mean 0 and variance 1, and suppose that for the current application it is desirable to detect any change in mean greater than 10. Then a natural choice for S_2 is a Gaussian with mean 10 and variance 1.

This framework has been generalized by Bansal and Papantoni-Kazakos [3] to the case where S_1 and S_2 are stochastic processes that need not generate each point independently. Additional generalizations of the CUSUM algorithm, including the case of multiple data generating distributions, are discussed in [4].

The framework of the CUSUM algorithm is an example of a *parametric* framework: the set of possible data-generating distributions has been prespecified and elements in that set can be identified using a small number of parameters. Parametric approaches are powerful in cases where they can accurately model the data. In cases where the data is not well modeled by a parametric framework, performance may deteriorate in terms of more false change reports and/or fewer detection of changes.

Kifer, Ben-David, and Gehrke [13] showed how to avoid problems with parametric approaches by using a nonparametric framework. In this framework the data points $x_1,x_2,...,$ are k-dimensional vectors of real numbers. Point x_1 is generated by some (arbitrary) probability distribution F_1, x_2 is generated by F_2 (independently of x_1), x_3 is generated by probability distribution F_3 (independently of x_1 and x_2), etc. A change is defined as a change in the data-generating distribution; if the first change occurs at time n_1 then $F_1 = F_2 = ... = F_{n_1-1} \neq F_{n_1}$; if the second change occurs at time n_2 then $F_{n_1} = F_{n_1+1} = ... = F_{n_2-1} \neq F_{n_2}$, etc. This framework for detecting change consists of three parts: a collection of regions of interests, a method for estimating probabilities, and a statistical test.

Regions of Interest

A collection of regions of interest serves two purposes: to restrict attention to changes that are considered meaningful, and to provide a means for describing the change.

Ideally a change is said to have occurred whenever the data-generating distribution changes. However, for many practical applications not all changes are meaningful. For example, consider the case where F_1 is a probability distribution that assigns probability 1 to the set of real numbers between 0 and 1 whose seventeenth significant digit is odd and furthermore suppose that F_1 is uniform over this set. From time 1 up to $n - 1$ the data are generated independently from the distribution F_1. At time n a change occurs and from that point the data are generated independently from the distribution F_n defined as follows: F_n assigns probability 1 to the set of real numbers between 0 and 1 whose seventeenth significant digit is even and is uniform over this set. Letting f_1 be the probability density function for F_1 and f_n be the probability density function for F_n it can be seen that f_1 and f_n are very different according to some common similarity measures. Indeed, the L^1 distance between f_1 and f_n (i.e., $\int_0^1 |f_1(x) - f_n(x)|\, dx$), is as large as possible. However, in many applications it is of no practical consequence whether the true distribution is F_1 or F_n. This is because one may be interested only in questions such as "what is the probability that the next point is larger than 0.75" or "what is the probability that the next point is within the safety range of 0.14–0.95." For these types of questions one would only be interested in the probabilities of various intervals, so instead of receiving notification of arbitrary types of change, one would be happy to know only when some interval has become more or less probable. In this case, the intervals are said to be the *regions of interest*. In general, if the domain of each data element is $\mathcal{D}$ then the set of regions of interest is a collection of subsets of $\mathcal{D}$. Note that regions of interest can be overlapping, as in the case of intervals, or they can form a partition of the domain. Dasu et al. [9] also proposed to partition the domain based on an initial sample of the data.

Once the regions of interest have been specified, the goal is to report a change whenever the system detects that the probability of a region has changed. The region (or regions) with the largest change in probability are then given as the description of the change.

Estimating Probabilities

Since the true distributions F_i are unknown, it is necessary to estimate them. A *window of size m* is a set of m consecutive data points. The initial distribution is estimated using a window that contains the first m data points and the most recent distribution is estimated using a window containing the most recent m data points (in practice, several change detection algorithms can be run in parallel, each using a different value of m). In each window W_i, the probability of a particular region of interest R can be estimated by $\frac{|W_i \cap R|}{|W_i|}$, the fraction of points in the window that occur in the region. Alternatively, if the regions of interest form a partition of the domain into k regions, then a Bayesian-style correction $\frac{|W_i \cap R| + \alpha}{|W_i| + \alpha k}$ can also be used [9].

Statistical Testing

In this setting, a *statistic f* is a function that assigns a number to a pair of windows (W_1, W_2). The larger this number is, the more likely it is that the points in one window were generated from one distribution and the points in the other window were generated from a different distribution. A *statistical test* is a statistic f and a real number τ that serves as a threshold; when $f(W_1, W_2) \geq \tau$ then one can conclude that the points in W_1 were generated from a different distribution than the points in W_2.

For each $i \geq 1$ let W_i be the window that contains the points $x_i, \ldots, x_{i+m-1}$, so that W_1 is the set of the first m data points. To use a statistical test f with threshold τ, one computes the values $f(W_1, W_m)$, $f(W_1, W_{m+2})$, $f(W_1, W_{m+3}), \ldots$, and signals a change the first time i such that $f(W_1, W_i) \geq \tau$. At this time, the current window W_i is considered to be a set of m points generated from the new distribution. The distribution may change again in the future, so one proceeds by computing the values of $f(W_i, W_{i+m})$, $f(W_i, W_{i+m+1})$, $f(W_{i+m+2})$, etc., until another change is detected.

Note that in order for it to be useful, a statistic should be easy to compute since a new value must be computed every time a new data point arrives. The value of the threshold τ should also be carefully chosen to avoid incorrect detections of change. A *false positive* is said to have occurred if the algorithm reports a change when the underlying distribution has not changed. Since a stream is a potentially unbounded source of data, false positives will occur and so instead of bounding the probability of a false positive, the goal is to choose a value of τ that bounds the *expected rate* of false positives. Several statistics for detecting change and a method for choosing τ are presented next.

Let $\mathcal{A}$ be the collection of regions of interest. Let W and W' be two windows and let P and P' be the corresponding probability estimates: for any $A \in \mathcal{A}$, $P(A)$ is the estimated probability of region A based on window W and $P'(A)$ is the estimated probability of A based on window W'. The following statistics can be used in the change detection framework [13]:

$$d_{\mathcal{A}}(W, W') = \sup_{A \in \mathcal{A}} |P(A) - P'(A)|$$

$$\phi_{\mathcal{A}}(W, W') = \sup_{A \in \mathcal{A}} \frac{|P(A) - P'(A)|}{\sqrt{\min\left\{\frac{P(A)+P'(A)}{2}, 1 - \frac{P(A)+P'(A)}{2}\right\}}}$$

$$\Xi_{\mathcal{A}}(W, W') = \sup_{A \in \mathcal{A}} \frac{|P(A) - P'(A)|}{\sqrt{\frac{P(A)+P'(A)}{2}\left(1 - \frac{P(A)+P'(A)}{2}\right)}}$$

Note that when $\mathcal{A}$ is the set of intervals of the form $(-\infty, b)$ then $d_{\mathcal{A}}$ is also known as the Kolmogorov-Smirnov statistic. For any one of these statistics, the region $A \in \mathcal{A}$ which maximizes the statistic is the region where the change in observed probability is the most statistically significant; this region (or the ℓ most significant regions, depending on user preferences) and its change in probability is therefore the description of the change.

To use these statistics, one must determine the value of the threshold τ and the corresponding expected rate of false positives. To do this one can take advantage of the fact that for one-dimensional data, the worst-case behavior of the $d_{\mathcal{A}}$, $\phi_{\mathcal{A}}$, and $\Xi_{\mathcal{A}}$ statistics occur when the data are generated by continuous distributions and that the statistics behave in the same way for all continuous distributions [13]. This means that one can perform an offline computationally-intensive simulation to determine τ and then use this value for *any* one-dimensional stream afterwards.

To perform the simulation, a user must specify a test statistic f and four parameters: a window size m, a real number p between 0 and $\frac{1}{2}$, a large integer $q >= 2m$ (e.g., 1 million), and the number of repetitions B. For each repetition i, generate q points independently from any continuous distribution (e.g., from a Gaussian distribution with mean 0 and variance 1). Compute the value $\tau_i \equiv \max_{m \leq j \leq q-m+1} f(W_1, W_j)$ (this represents the largest value of the statistic f that would have encountered if this were the real data). After B repetitions, choose a value for the threshold τ such that τ is greater than $(1 - p)B$ of the values $\tau_1, \ldots, \tau_B$. This value of τ guarantees that the probability of a false positive in the first q points is approximately p.

To compute the expected rate of false positives corresponding to τ, one first notes that false reports of change should occur in pairs for the following reason. Once a false positive has occurred, one has a window with points that are considered anomalous (since they caused a change to be reported); as new data points arrive, one compares the m most recent points (which are still generated from the original distribution) with this anomalous window using the chosen test statistic and therefore a second report of change should soon occur. Thus one can upper bound the expected number H of false positives in the first q points using the following probability distribution: $P(H = 2) = p$, $P(H = 4) = p^2$, etc., and $P(H = 0) = \frac{1-2p}{1-p}$. The expected value is $\frac{2p}{(1-p)^2}$ and one can use this as an upper bound on the number of false positives in the first q points. One can approximate the expected number of errors in the next q points also by $\frac{2p}{(1-p)^2}$ so that the expected rate of false positives is approximated by $\frac{2p}{q(1-p)^2}$.

When the regions of interest form a partition of the domain into k regions, other statistics, such as the KL-distance can be used [9]:

$$KL_{\mathcal{A}}(W, W') = \sum_{A \in \mathcal{A}} P(A) \log \frac{P(A)}{P'(A)}$$

where the probabilities $P(A)$ and $P'(A)$ are estimated using the Bayesian correction (i.e., $P(A) = \frac{|W \cap A| + \alpha}{|W| + \alpha k}$). Dasu et al. propose using the KL-distance with the following scheme (which uses a user-defined parameter γ): initially collect m data points for the window W_1 and use these points to create the regions of interest which partition the (possibly high-dimensional) domain; then compute $KL_{\mathcal{A}}(W_1, W_m), KL_{\mathcal{A}}(W_1, W_{m+1}), KL_{\mathcal{A}}(W_1, W_{m+2})$, etc., and report a change whenever $n\gamma$ consecutive values of the statistic exceed a threshold τ. The value of τ depends on the points in W_1 and must be recomputed every time a change is detected. As before, τ is estimated via simulation.

To determine the value of τ, choose a parameter p $(0 < p < 1/2)$ and number of repetitions B. For each repetition i, use the probability distribution P estimated from W_1 to generate two windows V_1 and V_2 of m points each. Define τ_i to be $KL_{\mathcal{A}}(V_1, V_2)$. After B

repetitions, choose τ so that it is greater than $(1 - p)B$ of the $\tau_1,\ldots,\tau_B$.

Key Applications

Data mining, network monitoring.

Future Directions

Key open problems include efficiently detecting change in high-dimensional spaces (see also [9]) and detecting change in streams where data points are not generated independently.

Channel-Based Publish/Subscribe

Hans-Arno Jacobsen
University of Toronto, Toronto, ON, Canada

Synonyms

Event channel; Event service

Definition

Channel-based publish/subscribe is a communication abstraction that supports data dissemination among many sources and many sinks. It is an instance of the more general publish/subscribe concept. The communication channel mediates between publishing data sources and subscribing data sinks and decouples their interaction.

Key Points

Publishing data sources submit messages to the channel and subscribing data sinks listen to the channel. All messages published to the channel are received by all subscribers listening on the channel. The channel broadcasts a publication message to all listening subscribers.

The channel decouples the interaction among publishing data sources and subscribing data sinks. The same decoupling characteristics as discussed under the general publish/subscribe concept apply here as well. Realizations of this model found in practice vary in the exact decoupling offered. To properly qualify as publish/subscribe, at least the anonymous communication style must exist. That is publishing clients must not be aware of who the subscribing clients are and how many subscribing clients exist, and vice versa. Thus, channel-based publish/subscribe enables the decoupled interaction of n sources with m sinks for $n, m \geq 1$.

Channel-based publish/subscribe systems often allow the application developer to create multiple logical channels, where each channel can be configured to offer different qualities-of-service to an application. Furthermore, a channel can be dedicated to the dissemination of messages pertaining to a specific subject or type. The channel-based publish/subscribe model does not support message filtering, except through the use of various channels to partition the publication space. It is the clients' responsibility to select the right channel for the dissemination of messages, which are sent to all listeners on the channel. This enables a limited form of filtering by constraining messages to be disseminated on one channel to a given message type. Finally, channel-based publish/subscribe is often coupled with client-side filtering, where messages are still broadcast throughout the channel, but filtered upon arrival at the data sink before passing to the application. More fine-grained filtering functionalities are provided by the other publish/subscribe models, such as the topic-based model and the content-based model.

In channel-based publish/subscribe, the publication data model is defined by the type of message the channel-based communication abstraction supports. This is often closely tied to the programming language or the library that implements the model.

Similarly, the subscription language model is defined by the programming language or library that allows the application developer to select channels to listen to, unless special provisions for subscriber-side filtering are offered. If supported, subscriber-side filtering can be arbitrarily complex, even selecting messages based on their content, as offered by the content-based publish/subscribe model.

Matching in the sense of evaluating a publication message against a set of subscriptions, as is common in the other publish/subscribe instantiations, does not occur in channel-based publish/subscribe.

Channel-based publish/subscribe systems are often coupled with different client interaction styles. These are the *push-style* and the *pull-style*. In the push-style, data sources initiate the transfer of messages to the channel, which delivers the messages to all listening data sinks. In the pull-style, data sinks initiate the message transfer by requesting messages from the channel, which requests any available messages from all connected data sources. Both interaction styles can also be combined. That is on one channel some clients can connect to the channel through the push-style, while others connect via the pull-style.

Channel-based publish/subscribe systems are distinguished by the qualities-of-service the channel offers to its clients, such as various degrees of reliability, persistence, real-time constraints, and message delivery guarantees. Channel-based publish/subscribe relates to topic-based publish/subscribe in that publishing a message to a channel is similar to associating a message with a topic, which could be the name or identity of the channel. However, in topic-based publish/subscribe this association is reflected in the message itself, while in channel-based publish/subscribe the association is indirect, reflected by selecting a channel, not part of the message. Also, topics can go far beyond channel identities, as discussed under the topic-based publish/subscribe concept. Examples that follow the channel-based publish/subscribe model are the CORBA Event Service [2], IP multicast [?], Usenet newsgroups [?], mailing lists, and group communication [?]. Elements of channel-based publish/subscribe can also be found in the Java Messaging Service [1], the OMG Data Dissemination Service [3], and other messaging middleware. However, these approaches are not directly following the channel-based model as described above; rather these approaches are enriched with elements of message queuing, topic-based publish/subscribe, and content-based publish/subscribe.

There are many applications of channel-based publish/subscribe. Examples include change notification, update propagation, information dissemination, newsgroups, email lists, and system management. Channel-based publish/subscribe serves well, if one or more entities have to communicate date to an anonymous group of receivers that may change over time, without the need of filtering messages within the channel.

In the literature the term channel-based publish/subscribe is not used uniformly. Abstractions that exhibit the above described functionality are also often referred to as event services, event channels, and simply channels. Messages disseminated to listeners are also often referred to as events. Publishing data sources are often referred to as publishers, producers or suppliers, and subscribing data sinks are often referred to as subscribers, consumers or listeners.

Chart

Hans Hinterberger
ETH Zurich, Zurich, Switzerland

Synonyms

Chart; Map; Diagram; Information graphic; Graph

Definition

A chart is an instrument to consolidate and display information.

The term is applied to virtually any graphic that displays information, be it a map used for navigation, a plan for military operations, a musical arrangement, barometric pressure, genealogical data, and even lists of tunes that are most popular at a given time.

Definitions of specialized charts typically include the graphical method on which the chart is based (e.g., bar chart) and or its application area (e.g., CPM chart) but it does not specify design principles. Tufte [2] introduces the notion of "chartjunk" and defines it to be that part of the chart which functions only as decoration, all of which is considered to redundant data ink.

Sometimes charts are reduced to refer to maps and diagrams, excluding graphs and tables.

Key Points

Because charts are used for different purposes there exist almost as many different types of charts as there are applications. Some maps, however, are more general in their use and therefore assigned to one of the following four categories: Graphs, Maps, Diagrams, and Tables. Each of these categories is broken down further into subcategories. In the category Diagrams, one therefore finds pie charts as well as flow charts or organization charts. A detailed categorization can be found in [1].

Charts are not only used to visualize data. They serve as a useful tool for many tasks where information is the main ingredient such as planning, presentation, analysis, monitoring.

Chase

Alin Deutsch[1], Alan Nash[2]
[1]University of California-San Diego, La Jolla, CA, USA
[2]Aleph One LLC, La Jolla, CA, USA

Definition

The chase is a procedure that takes as input a set Σ of constraints and an instance I. The chase does not always terminate, but if it does it produces as output an instance U with the following properties:

1. $U \models \Sigma$; that is, U satisfies Σ.
2. $I \rightarrow U$; that is, there is a homomorphism from I to U.
3. For every instance J (finite or infinite), if $J \models \Sigma$ and $I \rightarrow J$, then $U \rightarrow J$.

In [7], an instance that satisfies (1) and (2) above is called a *model of* Σ *and* I and an instance that satisfies (3) above is called *strongly universal.*

In summary, the chase is a procedure which – whenever it terminates – yields a strongly-universal model.

Comments

1. The set Σ of constraints is usually a set of tuple-generating dependencies (tgds) and equality-generating dependencies (egds) [5], or, equivalently, embedded dependencies [5,10]. However, the chase has been extended to wider classes of constraints and to universality under functions other than homomorphisms [6,7,9]. In this case, the chase often produces a strongly-universal model *set* (see below), instead of a single model.

2. It was noted in [7] that in database applications, *weak universality* (condition 3 above restricted to finite instances) would suffice. Nevertheless, the chase gives strong universality.

Historical Background

The term "chase" was coined in [14], where it was used to test the logical implication of dependencies (i.e., whether all databases satisfying a set Σ of dependencies must also satisfy a given dependency σ). The implication problem was one of the key concerns of dependency theory, with applications to automatic schema design. The chase was defined in [14] for the classes of functional, join and multivalued dependencies. Related chase formulations for various kinds of dependencies were introduced in [15,17]. The work [5] unified the treatment of the implication problem for various dependency classes by introducing and defining the chase for tuple-generating and equality-generating dependencies (sufficiently expressive to capture all prior dependencies).

Ancestors of the chase (introduced as unnamed algorithms) appear in [2–4]. [4] introduces tableaux, a pattern-based representation for relational queries, and shows how to check the equivalence of tableau queries in the presence of functional dependencies, with applications to query optimization. To this end, the tableaux are modified using an algorithm that coincides with the chase with functional dependencies. The same algorithm is used in [3] for minimization of tableaux under functional dependencies. This algorithm is extended in [2] to include also multivalued dependencies, for the purpose of checking whether the join of several relations is lossless (i.e., the original relations can be retrieved as projections of the join result).

The chase was extended to include disjunction and inequality in [9], and to arbitrary ∀∃-sentences in [6]. Independently, [13] extended the chase to a particular case of disjunctive dependencies incorporating disjunctions of equalities between variables and constants (see also [12]). There are also extensions of the chase to deal with more complex data models beyond relational. The chase (and the language of embedded dependencies) is extended in [16] to work over complex values and dictionaries. For an excellent survey of the history of the chase prior to 1995, consult [1].

Foundations

A *tuple-generating dependency (tgd)* is a constraint σ of the form

$$\forall \bar{x}, \bar{y}\ (\alpha(\bar{x}, \bar{y}) \rightarrow \exists \bar{z} \beta(\bar{x}, \bar{z}))$$

where α and β are conjunctions of relational atoms. Furthermore, every variable in $\bar{x}$ appears in both α and β. The $\forall \bar{x}, \bar{y}$ prefix of universal quantifiers is usually omitted. If $\bar{z}$ is empty, then σ is *full*.

An *equality-generating dependency (egd)* is a constraint ϕ of the form

$$\forall x_1, x_2, \bar{y}\ (\alpha(x_1, x_2, \bar{y}) \rightarrow x_1 = x_2)$$

where α is a conjunction of relational atoms.

The chase is used on instances whose active domain consists of constants and *labeled nulls.* A *homomorphism* from A to B is denoted $A \rightarrow B$. It is a mapping h on the constants and nulls in A that (i) preserves constants (i.e., $h(c) = c$ for every constant c) and preserves relationships (i.e., for every tuple $R(x_1,...,x_n) \in A$, that is $R(h(x_1),...,h(x_n)) \in B$). Two instances A and B are *homomorphically equivalent* if $A \rightarrow B$ and $B \rightarrow A$.

The chase is a natural procedure for building strong universal models. Indeed, it turns out that checking for strong universality is undecidable as shown in [7]). In contrast, checking whether an instance is a model can be done efficiently. Therefore, it is natural to define any procedure for constructing strong universal models by steps which always preserve strong universality while attempting to obtain a model and then to check whether a model was indeed obtained. This is precisely what the chase does.

A tgd $\sigma \in \Sigma$ *fails* (or *applies*) on instance A and tuple $\bar{a}$ if there is tuple $\bar{b}$ in A such that the premise α of σ satisfies $A \vDash \alpha(\bar{a}, \bar{b})$, yet there is no tuple $\bar{c}$ in A such that the conclusion β of σ satisfies $A \vDash \beta(\bar{a}, \bar{c})$. Assume that the instance A' is obtained by adding to A the tuples in $\beta(\bar{a}, \bar{n})$ where $\bar{n}$ is a tuple of new nulls. Then A' is the result of *firing* σ on A, $\bar{a}$. Notice that $A \subseteq A'$ and that σ does not fail on A', $\bar{a}$. It is easy to verify that if A is strongly universal for Σ and I, then so is A' (towards this, it is essential that all the nulls in $\bar{n}$ be new and distinct).

An egd $\sigma \in \Sigma$ *fails* (or *applies*) on instance A and values a_1, a_2 if there is tuple $\bar{b}$ in A such that the premise α of σ satisfies $A \vDash \alpha(a_1, a_2, \bar{b})$, yet $a_1 \neq a_2$. If a_2 is a null a_2 is replaced everywhere in A with a_1

to obtain A', then say that A' is the result of *firing* σ on A, a_1, a_2. Notice that $A \rightarrow A'$ and that σ does not fail on A', a_1, a_1. It is easy to verify that if A is strongly universal for Σ and I, then so is A'. If a_2 is a constant, but a_1 is null, then it is possible to replace a_1 everywhere in A with a_2 instead. However, if both a_1 and a_2 are constants, then it is not possible to satisfy σ and preserve strong universality and the chase *fails.*

The standard chase procedure proceeds as follows.

1. Set $A_0 = I$.
2. Repeat the following:
   a. If A_n is a model of Σ and I, stop and return A_n.
   b. Otherwise, there must be either
      i. a tgd σ and $\bar{a}$ such that σ fails on A, $\bar{a}$, or
      ii. an egd σ' and a_1, a_2 such that σ' fails on A, a_1, a_2.

   Obtain A_{n+1} by picking one such σ and $\bar{a}$ and firing σ on A_n, $\bar{a}$, or by picking one such σ' and a_1, a_2 and firing σ' on A, a_1, a_2. (This is one *chase step* of the standard chase.)

Notice that, at every chase step, there may be a choice of σ and $\bar{a}$, respectively σ' and a_1, a_2. How these choices are picked is often left unspecified and in that case the standard chase is non-deterministic. The chase *terminates* if A_n is a model of Σ and I for some n.

The chase of instance I with tgds Σ produces a sequence of instances $I = A_0 \subseteq A_1 \subseteq A_2 \subseteq \ldots$ such that every A_i is strongly universal for Σ and I. The chase with tgds and egds produces a sequence $I = A_0 \rightarrow A_1 \rightarrow A_2 \rightarrow \ldots$ such that every A_i is strongly universal for Σ and I. In the presence of egds, it is no longer the case that $A_i \subseteq A_j$ for $i \leq j$ and there is the additional complication that a chase step may fail. The chase for tgds and egds is described in more detail in [1].

Example 1 Consider the schema consisting of two relations:

1. employee Emp(ss#, name, dept#), with social security, name, and dept. number, and
2. department Dept(dept#, name, location, mgr#), with dept. number, name, location, and its manager's social security number.

Assume that Σ consists of the constraints

σ_1: dept# is a foreign key in Emp,
σ_2: mgr# is a foreign key in Dept, and
σ_3: every manager manages his own department.

(This omits the constraints that say that ss# is a key for Emp and that dept# is a key for Dept to keep the example simple.) These constraints can be written as follows (where σ_1 and σ_2 are tgds and σ_3 is an egd):

σ_1: $\mathrm{Dept}(d, e, \ell, m) \rightarrow \exists n, d' \mathrm{Emp}(m, n, d')$,
σ_2: $\mathrm{Emp}(s, n, d) \rightarrow \exists e, \ell, m \mathrm{Dept}(d, e, \ell, m)$, and
σ_3: $\mathrm{Dept}(d, e, \ell, m), \mathrm{Emp}(m, n, d') \rightarrow d = d'$.

Consider the initial instance

$$I_0 = \mathrm{Dept}(1, ''\mathrm{HR}'', ''\mathrm{somewhere}'', 333 - 33 - 3333)$$

containing a single tuple. Then in the first step of the chase, σ_1 fires, giving

$$I_1 = \{\mathrm{Dept}(1,\}\mathrm{HR}\},\}\mathrm{somewhere}\}, 33), \\ \mathrm{Emp}(33, \alpha, \beta)\}$$

where α and β are labeled nulls. In the second step, both σ_2 and σ_3 apply. If σ_3 fires, then β is set to 1 and yields

$$I_2 = \{\mathrm{Dept}(1, ''\mathrm{HR}'', ''\mathrm{somewhere}'', 33), \mathrm{Emp}(33, \alpha, 1)\}.$$

Since I_2 satisfies Σ, the chase terminates. However, if instead at the second step σ_2 fires, then it gives

$$I'_2 = \{\mathrm{Dept}(1, ''\mathrm{HR}'', ''\mathrm{somewhere}'', 33), \\ \mathrm{Emp}(33, \alpha, \beta),\ \mathrm{Dept}(\beta, \gamma, \delta, \epsilon\}$$

where γ, δ, and ε are new nulls. In this case, it is possible to continue firing σ_1, σ_2, and σ_3 in such a way as to obtain a chase that does not terminate, perpetually introducing new nulls.

If the standard chase (or any other chase listed below) terminates, it yields a strongly-universal model of Σ and I and it is straightforward to verify that all such models are homomorphically equivalent. Therefore the result of the standard chase is unique up to homomorphic equivalence. However, the choice of what constraint to fire and on what tuple may affect whether the chase terminates or not.

There are several variations of the chase, which shall be called here the *standard* chase, the *parallel* chase, and the *core* chase. The standard chase was described above. In the *parallel chase*, at every chase step σ is fired on A_n, $\bar{a}$ for all pairs $(\sigma, \bar{a})$ such that σ fails on A, $\bar{a}$.

One writes I^{Σ} for the result of the chase on Σ and I, if the chase terminates. In that case, one says that I^{Σ} is defined. In general, it holds that if $A \rightarrow B$, then $A^{\Sigma} \rightarrow B^{\Sigma}$, whenever the latter are defined.

It was shown in [7] that the standard chase is incomplete, in the following sense: it may be that Σ and I have a strongly-universal model, yet the standard chase does not terminate. The parallel chase is also incomplete in this sense. In contrast, the *core chase* introduced in [7] is complete: if a strongly universal-model exists, the core chase terminates and yields such a model. A chase step of the core chase consists of one chase step of the parallel chase, followed by computing the core of the resulting instance.

Any of the above mentioned variations of the chase can be applied to sets of constraints which consist of

1. tgds only
2. tgds and egds
3. tgds and egds with disjunctions
4. tgds and egds with disjunctions and negation which are equivalent to general $\forall\exists$ sentences

The chase with tgds and egds has been described above. The chase has been extended to handle disjunction and negation. In this case, it gives not a single model, but a set S of models which is strongly universal, in the sense that for any model J (finite or infinite) of Σ and I, there is a model $A \in S$ such that $A \rightarrow J$. Such a set arises from a single initial model by branching due to disjunction. For example, consider the set Σ with the single disjunctive tgd

$$\sigma : R(x) \rightarrow S(x) \vee T(x)$$

and the instance I containing the single fact $R(1)$. Clearly every model of Σ and I, must contain either $S(1)$ or $T(1)$. It is easy to verify that the set $S = \{I_1, I_2\}$ where $I_1 = \{R(1), S(1)\}$ and $I_2 = \{R(1), T(1)\}$ is strongly universal for I and Σ, but no proper subset of S is. The disjunctive chase with Σ on I consists of a single step, which produces not a single model, but the set S of models. Intuitively, whenever a disjunctive tgd fires on a set W of models, it produces, for every instance $A \in W$, one instance for every disjunct in its conclusion. For details, to see how negation is handled, and to see how universality for functions other than homomorphisms is achieved, see [6,7].

It was shown in [7] that it is undecidable whether the standard, parallel, or core chase with a set of tgds terminates. A widely-applicable, efficiently-checkable condition on a set Σ of tgds, which is sufficient to guarantee that the chase with Σ on any instance I terminates, was introduced in [9,11]. A set of tgds satisfying this condition is called *weakly acyclic* in [11] and is said to have *stratified witnesses* in [9]. A more widely-applicable condition, also sufficient for chase termination, was introduced in [7], where a set of tgds satisfying this condition is called *stratified*.

Key Applications

The chase has been used in many applications, including

- Checking containment of queries under constraints (which in turn is used in such query rewriting tasks as minimization, rewriting using views, and semantic optimization)
- Rewriting queries using views
- Checking implication of constraints
- Computing solutions to data exchange problems
- Computing certain answers in data integration settings

To check whether a query P is contained in a query Q under constraints Σ, written $P \sqsubseteq_\Sigma Q$, it is sufficient to (1) treat P as if it was an instance in which the free variables are constants and the bound variables are nulls (this is known as the "frozen instance" or "canonical database" [1] corresponding to P) (2) chase it with Σ, and if this chase terminates to yield P^Σ (3) check whether the result of this chase is contained in Q, written $P^\Sigma \sqsubseteq Q$. In symbols, if the chase described above terminates, then

$$P \sqsubseteq_\Sigma Q \text{ iff } P^\Sigma \sqsubseteq Q.$$

That is, the chase reduces the problem of query containment under constraints to one of query containment without constraints.

To check whether a set Σ of tgds implies a tgd σ of the form

$$\forall \bar{x}, \bar{y}(\alpha(\bar{x}, \bar{y}) \rightarrow \exists \bar{z} \beta(\bar{x}, \bar{z}))$$

which is logically equivalent to

$$\forall \bar{x}\,(\underbrace{\exists \bar{y} \alpha(\bar{x}, \bar{y})}_{Q_\alpha(\bar{x})} \rightarrow \underbrace{\exists \bar{z} \beta(\bar{x}, \bar{z})}_{Q_\beta(\bar{x})}),$$

it suffices to check whether the query Q_α in the premise of σ is contained under the constraints Σ in the query Q_β in the conclusion of σ. That is, if $Q_\alpha{}^\Sigma$ is defined, then

$$\Sigma \models \sigma \text{ iff } Q_\alpha \sqsubseteq_\Sigma Q_\beta \text{ iff } Q_\alpha^\Sigma \sqsubseteq Q_\beta.$$

The chase was also employed to find equivalent rewritings of conjunctive queries using conjunctive query views, in the presence of constraints. Given a set $\mathcal{V}$ of conjunctive query views and a conjunctive query Q, one can construct, using the chase, a query R expressed in terms of $\mathcal{V}$, such that Q has some equivalent rewriting using $\mathcal{V}$ if and only if R is itself such a rewriting. Moreover, every minimal rewriting of Q is guaranteed to be a sub-query of R. The algorithm for constructing R and exploring all its sub-queries is called the *Chase&Backchase (CB)* [8], and it is sound and complete for finding all minimal rewritings under a set Σ of embedded dependencies, provided the chase with Σ terminates [9]. The CB algorithm constructs R by simply (i) constructing a set $\Sigma_{\mathcal{V}}$ of tgds extracted from the view definitions, and (ii) chasing Q with $\Sigma \cup \Sigma_{\mathcal{V}}$ and restricting the resulting query to only the atoms using views in $\mathcal{V}$.

In [11] is was shown that the certain answers to a union Q of conjunctive queries on a ground instance I under a set Σ of source-to-target tgds and target tgds and egds can be obtained by computing $Q(U)$ – where U is a *universal solution* for I under Σ – then discarding any tuples with nulls. Universal solutions, which are the preferred solutions to materialize in data exchange, are closely related to strongly-universal models [7] and it was shown in [11] that they can be obtained using the chase.

Cyclic Redundancy Check (CRC)

Definition

Checksum and CRC are schemes for detecting the errors of data which occur during transmission or storage. The data computed and appended to original data in order to detect errors are also referred as checksum and CRC.

A checksum consists of a fixed number of bits computed as a function of the data to be protected, and is appended to the data. To detect errors, the function is recomputed, and the result is compared to that appended to the data. Simple implementation of checksum is to divide the data into same length bits chunk and to make exclusive-or of all chunks. Cyclic redundancy check mechanism exploits mathematical properties of cyclic codes. Specifically, CRC uses polynomial devisor circuits with a given generator polynomial so as to obtain the remainder polynomial. The remainder is similarly appended to the original data for transmission and storage, and then utilized for error detection. CRC can be used as a kind of checksum.

Key Points

CRC is usually expressed by the use of binary polynomials due to mathematical convenience. When original data $M(x)$ is given, basic CRC mechanism calculates redundancy data $R(x)$ by using a pre-defined generator polynomial $G(x)$. That is, supposing the degree of $G(x)$ is m, a polynomial $M(x) * x^m$ is divided by $G(x)$ and the remainder is used for $R(x)$ such that a concatenated polynomial $T(x) = M(x) * x^m + R(x)$ is divisible by $G(x)$. The obtained $T(x)$ is used for transmission or storage. For error detection, CRC mechanism similarly checks the divisibility of $T(x)$ by $G(x)$. These encoding and detection processes can be implemented by using multi-level shift register circuits.

Given below is an example of CRC calculation. Assume that a generator polynomial and original data are given as follows.

$$\mathrm{G}(x) = x^3 + x + 1 \quad (\textit{binary expression}: 1011)$$

$$M(x) = x^4 + 1 \quad (10001)$$

In this case, a remainder polynomial $R(x)$ can be obtained by dividing $M(x) * x^3$ by $G(x)$.

$$R(x) = x \quad (010)$$

Therefore, the resulting data $T(x)$ can be obtained as follows.

$$T(x) = x^7 + x^3 + x \quad (10001010)$$

Theoretically, CRC is capable of detecting m-bit long or shorter bust errors. This property is suitable for communication infrastructure and storage infrastructure, which often introduce burst errors rather than random errors.

Choreography

W. M. P. van der Aalst
Eindhoven University of Technology, Eindhoven, The Netherlands

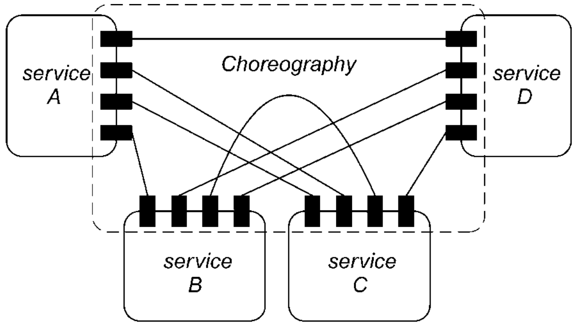
Definition

In a service oriented architecture (SOA) services are interacting by exchanging messages, i.e., by combining services more complex services are created. Choreography is concerned with the composition of such services seen from a global viewpoint focusing on the common and complementary observable behavior. Choreography is particulary relevant in a setting where there is not a single coordinator.

Key Points

The terms orchestration and choreography describe two aspects of integrating services to create business processes [1,3]. The two terms overlap somewhat and the distinction is subject to discussion. Orchestration and choreography can be seen as different "perspectives." Choreography is concerned with the exchange of messages between those services. Orchestration is concerned with the interactions of a single service with its environment.

Figure 1 illustrates the notion of choreography. The dashed area shows the focal point of choreography,



Choreography. Figure 1. Choreography.

i.e., the aim is to establish a “contract” containing a “global” definition of the constraints under which messages are exchanged. Unlike orchestration, the viewpoint is not limited to a single service. The Web Services Choreography Description Language (WS-CDL, cf. [2]) and the Web Service Choreography Interface (WSCI) are two languages aiming at choreography. Since the focus is on agreement rather than enactment, choreography is quite different from traditional workflow languages. The goal is not to control and enact but to coordinate autonomous parties. Some characterize choreography as “Dancers dance following a global scenario without a single point of control” to emphasize this distinction.

Chronon

Curtis Dyreson
Utah State University, Logan, UT, USA

Synonyms

Instant; Moment; Time quantum; Time unit

Definition

A chronon is the smallest, discrete, non-decomposable unit of time in a temporal data model. In a one-dimensional model, a chronon is a *time interval* or *period*, while in an *n*-dimensional model it is a non-decomposable region in *n*-dimensional time. Important special types of chronons include valid-time, transaction-time, and bitemporal chronons.

Key Points

Data models often represent a time line by a sequence of non-decomposable, consecutive time periods of identical duration. These periods are termed chronons. A data model will typically leave the size of each particular chronon unspecified. The size (e.g., one microsecond) will be fixed later by an individual application or by a database management system, within the restrictions posed by the implementation of the data model. The number of chronons is finite in a bounded model (i.e., a model with a minimum and maximum chronon), or countably infinite otherwise. Consecutive chronons may be grouped into larger intervals or segments, termed *granules*; a chronon is a granule at the lowest possible granularity.

Citation

Prasenjit Mitra
The Pennsylvania State University, University Park, PA, USA

Synonyms

Reference; Bibliography

Definition

A citation is a reference from one article to another article. A citation is a record that consists of the names of the authors, the title of the referred article, the time and place of publication, as well as various other fields. The fields in the citation should collectively specify unambiguously where the full text of the referred article could be obtained. Typically, all citations are presented at the end of the referring article. However, articles in certain domains list the citations as footnotes in the pages where the reference occurs. Citations can range from references to be to single articles or to entire books.

Key Points

Often, authors have to refer to knowledge that is derived from another work. For example, when quoting text from another article or book, the author must specify from which article or book the quotation is obtained. Authors need to refer to other works in order to point out preliminary information on the shoulders of which the current treatise stands, to refer to related work and contrast the current work with previous works, etc. A citation is used for primarily two purposes: (i) to provide a reference to an article or book such that the reader can retrieve the article or book easily and read the article to gain additional knowledge, and (ii) to provide credit (or discredit for "negative" citations) to the authors of the works that are being cited.

There are various widely used formats for citations. Citation formats vary by discipline; typically a discipline adheres to one (or a few) "style-guide" that indicates what fields should be mentioned in a citation and how the fields should be formatted and presented. Recently, with the proliferation of electronic documents published over the World-Wide-Web, citations to Uniform Resource Locators (URLs) of websites are increasingly common. Unlike printed articles and books, websites are dynamic and can change frequently. Therefore, in order to specify precisely which version of the webpage was being referred, apart from the publication date, authors usually provide the date on which the website was accessed.

Citations analysis has been performed to identify the impact of published articles. Because different authors use different formats, automatic analysis of citations requires *citation matching*. Citation matching helps identify which different citations formatted differently refer to the same article or book. The term *bibliometrics* is used to refer to metrics designed based on citation analysis. Citation indexing for academic journals was popularized by Eugene Garfield [1,2]. A citation index contains the information about which document cites which. The term *co-citation* refers to the frequency with which two documents are cited together [3]. Today, Google Scholar (http://scholar.google.com) provides a readily-available collection of indexed citations on the web.

Classification learning; Supervised learning; Learning with a teacher, Concept learning; Statistical decision techniques

Definition

In *Classification learning*, an algorithm is presented with a set of classified examples or "instances" from which it is expected to infer a way of classifying unseen instances into one of several "classes". Instances have a set of features or "attributes" whose values define that particular instance. Numeric prediction, or "regression," is a variant of classification learning in which the class attribute is numeric rather than categorical. Classification learning is sometimes called *supervised* because the method operates under supervision by being provided with the actual outcome for each of the training instances. This contrasts with clustering where the classes are not given, and with association learning which seeks any association – not just one that predicts the class.

Historical Background

Classification learning grew out of two strands of work that began in the 1950s and were actively pursued throughout the 1960s: statistical decision techniques and the Perceptron model of neural networks. In 1955, statisticians Bush and Mosteller published a seminal book *Stochastic Models for Learning* which modeled in mathematical terms the psychologist B. F. Skinner's experimental analyses of animal behavior using reinforcement learning [2]. The "perceptron" was a one-level linear classification scheme developed by Rosenblatt around 1957 and published in his book *Principles of Neurodynamics: Perceptrons and the Theory of Brain Mechanisms* [10]. In a response published in 1969, Minsky and Papert argued that perceptrons were simplistic in terms of their representational capability and had been greatly over-hyped as potentially universal learning machines [6]. This scathing response by widely-respected artificial intelligence pioneers dampened research in neural nets and machine learning in general. Meanwhile, in 1957 others were investigating the application of Bayesian decision schemes to pattern recognition; the general conclusion was that full Bayesian models were prohibitively expensive. In 1960 Maron investigated in the context of information retrieval what has since become known as the "naïve Bayes" approach, which assumes independence between attributes notwithstanding overwhelming evidence to the contrary [5]. Other early machine learning work was buried in cybernetics, the study of feedback and derived concepts such as communication and control in living and artificial organisms. Throughout the 1960s classification learning applied to pattern recognition was the central thread of the embryo field of machine learning, as underlined by the subtitle of Nilsson's 1965 landmark book *Learning Machines – Foundations of Trainable Pattern-Classifying Systems* [7].

Symbolic learning techniques began to recover from the doldrums in the late 1970s, with influential and almost simultaneous publications by Breiman et al. on *classification and regression trees* (the CART system) [1] and Quinlan on *decision tree induction* (the ID3 and later C4.5 systems) [8,9]. Whereas Breiman was a statistician, Quinlan was an experimental computer scientist who first used decision trees not to generalize but to condense large collections of chess end-games. Their work proceeded independently, and the similarities remained unnoticed until years later. CART (by default) produces multivariate trees whose tests can involve more than one attribute: these are more accurate and smaller than the univariate trees produced by Quinlan's systems, but take longer to generate.

The first workshop devoted to machine learning was held in 1980 at Carnegie-Mellon University. Further workshops followed in 1983 and 1985. These invitation-only events became an open conference in 1988. Meanwhile the journal *Machine Learning* was established in 1986. By the 1990s the subject had become the poster child of artificial intelligence – a successful, burgeoning, practical technology that eschewed the classical topics of general knowledge representation, logical deduction, theorem proving, search techniques, computational linguistics, expert systems and philosophical foundations that still characterize the field today. Classification learning, which forms the core of machine learning, outgrew its behaviorist and neurological roots and moved into the practical realm of database systems.

Early work focused on the *process* of learning – learning curves, the possibility of sustained learning, and the like – rather than the *results* of learning. However, with the new emphasis on applications, objective techniques of empirical testing began to supplant the scenario-based style of evaluation that characterized the early days. A major breakthrough came during the 1980s, when researchers finally realized that evaluating a learning system on its training data gave misleading results, and instead put the subject on a secure statistical footing.

Foundations

One of the most instructive lessons learned since the renaissance of classification in the 1980s is that simple schemes often work very well. Today, practitioners strongly recommend the adoption of a "simplicity-first" methodology when analyzing practical datasets. There are many different kinds of simple structure that datasets can exhibit. One dataset might have a single attribute that does all the work, the others being irrelevant or redundant. Alternatively, the attributes might contribute independently and equally to the final outcome. Underlying a third dataset might be a simple contingent structure involving just a few attributes. In a fourth, a few independent rules may govern the assignment of instances to classes. In a fifth, classifications appropriate to particular regions of instance space might depend on the distance between the instances themselves. A sixth might exhibit dependence among numeric attributes, determined by a sum of attribute values with appropriately chosen weights. This sum might represent the final output for numeric prediction, or be compared to a fixed threshold in a binary decision setting. Each of these examples leads to a different style of method suited to discovering that kind of structure.

Rules Based on a Single Attribute

Even when instances have several attributes, the classification decision may rest on the value of just one of them. Such a structure constitutes a set of rules that all test the same attribute (or, equivalently, a one-level decision tree). It can be found by evaluating the success, in terms of the total number of errors on the training data, of testing each attribute in turn, predicting the most prevalent class for each value of that attribute. If an attribute has many possible values – and particularly if it has numeric values – this may "overfit" the training data by generating a rule that has almost as many branches as there are instances. Minor modifications to the scheme overcome this problem.

A startling discovery published in 1993 was that "very simple classification rules perform well on most commonly used datasets" [3]. In an empirical investigation of the accuracy of rules that classify instances on the basis of a single attribute, on most standard datasets the resulting rule was found to be as accurate as the structures induced by the majority of machine learning systems – which are far more complicated. The moral? – always compare new methods with simple baseline schemes.

Statistical Modeling (see entry Bayesian Classification)

Another simple technique is to use all attributes and allow them to make contributions to the decision that are *equally important* and *independent* of one another, given the class. Although grossly unrealistic – what makes real-life datasets interesting is that the attributes are certainly not equally important or independent – it leads to a statistically-based scheme that works surprisingly well in practice. Employed in information retrieval as early as 1960 [5], the idea was rediscovered, dubbed "naïve Bayes," and introduced into machine learning 30 years later [4]. Despite the disparaging moniker it works well on many actual datasets. Over-reliance on the independence of attributes can be countered by applying attribute selection techniques.

Divide and Conquer Technique (see entry Decision Tree Classification)

The process of constructing a decision tree can be expressed recursively. First, select an attribute to use at the root, and make a branch for each possible value. This splits the instance set into subsets, one for every value of the attribute. Now repeat the process recursively for each branch, using only those instances that actually reach the branch. If all instances at a node have the same classification, stop developing that part of the tree. This method of "top-down induction of decision trees" was explored and popularized by Quinlan [8,9]. The nub of the problem is to select an appropriate attribute at each stage. Of many heuristics that have been investigated, the dominant one is to measure the expected amount of information gained by knowing that attribute's actual value. Having generated the tree, it is selectively pruned back from the leaves to avoid over-fitting. A series of improvements include ways of dealing with numeric attributes, missing values, and noisy data; and generating rules from trees.

Covering Algorithms (see entry Rule-Based Classification)

Classification rules can be produced by taking each class in turn and seeking a rule that covers all its instances, at the same time excluding instances not in the class. This bottom-up approach is called *covering* because at each stage a rule is identified that "covers" some of the instances. Although trees can always be converted into an equivalent rule set, and vice versa, the perspicuity of the representation often differs. Rules can be symmetric whereas trees must select one attribute to split on first, which can produce trees that are much larger than an equivalent set of rules. In the multiclass case a decision tree split takes account of all classes and maximizes the information gained, whereas many rule generation methods concentrate on one class at a time, disregarding what happens to the others.

Instance-Based Learning (see entry Nearest Neighbor Classification)

Another approach is to store training instances verbatim and, given an unknown test instance, use a distance function to determine the closest training instance and predict its class for the test instance. Suitable distance functions are the Euclidean or Manhattan (city-block) metric; attributes should be normalized to lie between 0 and 1 to compensate for scaling effects. For nominal attributes that assume symbolic rather than numeric values, the distance between two values is 1 if they are not the same and 0 otherwise. In the *k*-nearest neighbor strategy, some fixed number of nearest neighbors – say five – are located and used together to determine the class of the test instance by majority vote. Another way of proofing the database against noise is to selectively and judiciously choose the exemplars that are added. Nearest-neighbor classification was notoriously slow until advanced data structures like *k*D-trees were applied in the early 1990s.

Linear Models (see entry Linear Regression)

When the outcome and all attributes are numeric, linear regression can be used. This expresses the class as a linear combination of the attributes, with weights that are calculated from the training data. Linear regression has been popular in statistical applications for decades. If the data exhibits a nonlinear dependency, the best-fitting straight line will be found, where "best" is interpreted in the least-mean-squared-difference sense. Although this line may fit poorly, linear models can serve as building blocks for more complex learning schemes.

Linear Classification (see entry Neural Networks, Support Vector Machine)

The idea of linear classification is to find a hyperplane in instance space that separates two classes. (In the multiclass case, a binary decision can be learned for each pair of classes.) If the linear sum exceeds zero the first class is predicted; otherwise the second is predicted. If the data is linearly separable – that is, it can be separated perfectly using a hyperplane – the perceptron learning rule espoused by Rosenblatt is guaranteed to find a separating hyperplane [10]. This rule adjusts the weight vector whenever the prediction for a particular instance is erroneous: if the first class is predicted the instance (expressed as a vector) is added to the weight vector (making it more likely that the result will be positive next time around); otherwise the instance is subtracted.

There have been many powerful extensions of this basic idea. Support vector machines use linear decisions to implement nonlinear class boundaries by transforming the input using a nonlinear mapping. Multilayer perceptrons connect many linear models in a hierarchical arrangement that can represent nonlinear decision boundaries, and use a technique called "back-propagation" to distribute the effect of errors through this hierarchy during training.

Missing Values

Most datasets encountered in practice contain missing values. Sometimes different kinds are distinguished (e.g., unknown vs. unrecorded vs. irrelevant values). They may occur for a variety of reasons. There may be some significance in the fact that a certain instance has an attribute value missing – perhaps a decision was taken not to perform some test – and that might convey information about the instance other than the mere absence of the value. If this is the case, *not tested* should be recorded as another possible value for this attribute. Only someone familiar with the data can make an informed judgment as to whether a particular value being missing has some significance or should simply be coded as an ordinary missing value. For example, researchers analyzing medical databases have noticed that cases may, in some circumstances, be diagnosable strictly from the tests that a doctor decides to make, regardless of the outcome of the tests. Then a record of which values are "missing" is all that is needed for a complete diagnosis – the actual measurements can be ignored entirely!

Meta-Learning

Decisions can often be improved by combining the output of several different models. Over the past decade or so the techniques of *bagging*, *boosting*, and *stacking* have been developed that learn an ensemble of models and deploy them together. Their performance is often astonishingly good. Researchers have struggled to understand why, and during that struggle new methods have emerged that are sometimes even better. For example, whereas human committees rarely benefit from noisy distractions, shaking up bagging by adding random variants of classifiers can improve performance. Boosting – perhaps the most powerful of the three methods – is related to the established statistical technique of additive models, and this realization has led to improved procedures.

Combined models share the disadvantage of being rather hard to analyze: they can comprise dozens or even hundreds of individual learners and it is not easy to understand in intuitive terms what factors are contributing to the improved decisions. In the last few years methods have been developed that combine the performance benefits of committees with comprehensible models. Some produce standard decision tree models; others introduce new variants of trees that provide optional paths.

Evaluation

For classification problems, performance is naturally measured in terms of the *error rate*. The classifier predicts the class of each test instance: if it is correct, that is counted as a success; if not, it is an error. The error rate is the proportion of errors made over a whole set of instances, and reflects the overall performance of the classifier. Performance on the training set is definitely *not* a good indicator of expected performance on an independent test set. A classifier is *overfitted* to a dataset if its structure reflects that particular set to an excessive degree. For example, the classifier might be generated by rote learning without any generalization whatsoever. An overfitted classifier usually exhibits performance on the training set which is excellent but far from representative of performance on other datasets from the same source.

In practice, one must predict performance bounds based on experiments with whatever data is available. Labeled data is required for both training and testing, and is often hard to obtain. A single data set can be partitioned for training and testing in various different ways. In a popular statistical technique called *cross-validation* the experimenter first decides on a fixed number of "folds," or partitions of the data – say three. The data is split into three approximately equal portions, and each in turn is used for testing while the remainder serves for training. The procedure is repeated three times so that in the end every instance has been used exactly once for testing. This is called *threefold cross-validation*. "Stratification" is the idea of ensuring that all classes are represented in all folds in approximately the right proportions. *Stratified tenfold cross-validation* has become a common standard for estimating the error rate of a classification learning scheme. Alternatives include *leave-one-out* cross-validation, which is effectively *n*-fold cross-validation where *n* is the size of the data set; and the *bootstrap*, which takes a carefully-judged number of random samples from the data with replacement and uses these for training, combining the error rate on the training data (an optimistic estimate) with that on the test data (a pessimistic estimate, since the classifier has only been trained on a subset of the full data) to get an overall estimate.

Key Applications

Classification learning is one of the flagship triumphs of research in artificial intelligence. It has been used for problems that range from selecting promising embryos to implant in a human womb during in vitro fertilization to the selection of which cows in a herd to sell off to an abattoir. Fielded applications are legion. They include decisions involving judgment, such as whether a credit company should make a loan to a particular person; screening images, such as the detection of oil slicks from satellite images; load forecasting, such as combining historical load information with current weather conditions and other events to predict hourly demand for electricity; diagnosis, such as fault finding and preventative maintenance of electromechanical devices; marketing and sales, such as detecting customers who are likely to switch to a competitor.

URL to Code

The Weka machine learning workbench is a popular tool for experimental investigation and comparison of classification learning techniques, as well as other machine learning methods. It is described in [11] and available for download from http://www.cs.waikato.ac.nz/ml/weka.

Classification by Association Rule Analysis

Bing Liu
University of Illinois at Chicago, Chicago, IL, USA

Associative classification

Definition

Given a training dataset *D*, build a classifier (or a classification model) from *D* using an association rule mining algorithm. The model can be used to classify future or test cases.

Historical Background

In the previous section, it was shown that a list of rules can be induced or mined from the data for classification. A decision tree may also be converted to a set of rules. It is thus only natural to expect that association rules [1] be used for classification as well. Yes, indeed! Since the first classification system (called CBA) that used association rules was reported in [10], many techniques and systems have been proposed by researchers [2–4,6–8,13,15,16]. CBA is based on class association rules (CAR), which are a special type of association rules with only a class label on the right-hand-side of each rule. Thus, syntactically or semantically there is no difference between a rule generated by a class association rule miner and a rule generated by a rule induction system (or a decision tree system for that matter). However, class association rule mining inherits the completeness property of association rule mining [1]. That is, all rules that satisfy the user-specified minimum support and minimum conference are generated. Other classification algorithms only generate a small subset of rules existing in data for classification [9,10].

Most existing classification systems based on association rules (also called *associative classifiers*) employ CARs directly for classification, although their ways of using CARs can be quite different [3,7,8,10,15,16].

To deal with unbalanced class distributions, the multiple minimum class supports approach is proposed in [9,11], which gives each class a different minimum support based on its relative frequency in the data. In [2,4,6,13], the authors also proposed to use rules as features or attributes to augment the original data or even to replace the original data. That is, in these techniques, CARs are not directly used for classification, but are used only to expand or to replace the original data. Any classification technique can be used subsequently to build the final classifier based on the expanded data, e.g., naïve Bayesian and SVM. Since the number of class association rules can be huge, closed rule sets have been proposed for classification in [3]. This approach helps solve the problem that in many data sets the complete sets of CARs cannot be generated due to combinatorial explosion. The closed rule set is a smaller, lossless and concise representation of all rules. Thus, long rules (rules with many conditions) may be used in classification, which otherwise may not be generated but can be crucial for accurate classification. Finally, normal association rules may be used for prediction or classification as well.

This section thus introduces the following three approaches to using association rules for classification:

1. Using class association rules for classification
2. Using class association rules as features or attributes
3. Using normal association rules for classification

The first two approaches can be applied to tabular data or transactional data. The last approach is usually employed for transactional data only. Transactional data sets are difficult to handle by traditional classification techniques, but are very natural for association rules. Below, the three approaches are described in turn. Note that various sequential rules can be used for classification in similar ways as well if sequential data sets are involved [6].

Foundations

Classification Using Class Association Rules

As mentioned above, a class association rule (CAR) is an association rule with only a class label on the right-hand side of the rule. Any association rule mining algorithm can be adapted for mining CARs. For example, the Apriori algorithm [1] for association rule mining was adapted to mine CARs in [10].

There is basically no difference between rules generated from a decision tree (or a rule induction system) and CARs if only categorical (or discrete) attributes (more on this later) are considered. The differences are in the mining processes and the final rule sets. CAR mining finds all rules in data that satisfy the user-specified minimum support (minsup) and minimum confidence (minconf) constraints. A decision tree or a rule induction system finds only a subset of the rules (expressed as a tree or a list of rules) for classification. In many cases, rules that are not in the decision tree (or the rule list) may be able to perform the classification more accurately. Empirical comparisons reported by several researchers have shown that classification using CARs can perform more accurately on many data sets than decision trees and rule induction systems [7,8,10,15,16].

The complete set of rules from CAR mining is also beneficial from the rule usage point of view. In many applications, the user wants to act on some interesting rules. For example, in an application for finding causes of product problems in a manufacturing company, more rules are preferred to fewer rules because with more rules, the user is more likely to find rules that indicate causes of problems. Such rules may not be found by a decision tree or a rule induction system. A deployed data mining system based on CARs is reported in [12] for finding actionable knowledge from manufacturing and engineering data sets.

One should, however, also bear in mind of the following differences between CAR mining and decision tree construction (or rule induction):

1. Decision tree learning and rule induction do not use the minsup or minconf constraint. Thus, some rules that they find can have very low supports, which, of course, are likely to be pruned because the chance that they overfit the training data is high. Although a low minsup for CAR mining can be used, it may cause combinatorial explosion. In practice, in addition to minsup and minconf, a limit on the total number of rules to be generated may be used to further control the CAR generation process. When the number of generated rules reaches the limit, the algorithm stops. However, with this limit, long rules (with many conditions) may not be generated. Recall that the Apriori algorithm works in a level-wise fashion, i.e., short

rules are generated before long rules. In some applications, this may not be an issue as short rules are often preferred and are sufficient for classification or for action. Long rules normally have very low supports and tend to overfit the data. However, in some other applications, long rules can be useful.

2. CAR mining does not use continuous (numeric) attributes, while decision trees deal with continuous attributes naturally. Rule induction can use continuous attributes as well. There is still no satisfactory method to deal with such attributes directly in association rule mining. Fortunately, many attribute discretization algorithms exist that can automatically discretize the value range of a continuous attribute into suitable intervals [e.g., [5]], which are then considered as discrete values.

Mining Class Association Rules for Classification There are many techniques that use CARs to build classifiers. Before describing them, it is useful to first discuss some issues related to CAR mining for classification.

Rule pruning: CAR rules are highly redundant, and many of them are not statistically significant (which can cause overfitting). Rule pruning is thus needed. The idea of pruning CARs is basically the same as tree pruning in decision tree building or rule pruning in rule induction. Thus, it will not be discussed further (see [8,10] for some of the pruning methods).

Multiple minimum class supports: A single minsup may be inadequate for mining CARs because many practical classification data sets have uneven class distributions, i.e., some classes cover a large proportion of the data, while others cover only a very small proportion (which are called *rare* or *infrequent classes*).

For example, there is a data set with two classes, *Y* and *N*. 99% of the data belong to the *Y* class, and only 1% of the data belong to the *N* class. If the minsup is set to 1.5%, no rule for class *N* will be found. To solve the problem, the minsup needs to be lowered. Suppose the minsup is set to 0.2%. Then, a huge number of overfitting rules for class *Y* may be found because minsup = 0.2% is too low for class *Y*.

Multiple minimum class supports can be applied to deal with the problem. A different *minimum class support* $minsup_i$ for each class c_i can be assigned, i.e., all the rules of class c_i must satisfy $minsup_i$. Alternatively, one single total minsup can be provided, denoted by *t_minsup*, which is then distributed to each class according to the class distribution:

$$minsup_i = t\_minsup \times sup(c_i)$$

where $sup(c_i)$ is the support of class c_i in the training data. The formula gives frequent classes higher minsups and infrequent classes lower minsups. There is also a general algorithm for mining normal association rules using multiple minimum supports in [9,11].

Parameter selection: The parameters used in CAR mining are the minimum supports and the minimum confidences. Note that a different minimum confidence may also be used for each class. However, minimum confidences do not affect the classification much because classifiers tend to use high confidence rules. One minimum confidence is sufficient as long as it is not set too high. To determine the best $minsup_i$ for each class c_i, a range of values can be tried to build classifiers and then use a validation set to select the final value. Cross-validation may be used as well.

Classifier Building After all CAR rules are found, a classifier is built using the rules. There are many existing approaches, which can be grouped into three categories.

Use the strongest rule: This is perhaps the simplest strategy. It simply uses CARs directly for classification. For each test instance, it finds the strongest rule that covers the instance. A rule *covers* an instance if the instance satisfies the conditions of the rule. The class of the strongest rule is then assigned as the class of the test instance. The strength of a rule can be measured in various ways, e.g., based on confidence, χ^2 test, or a combination of both support and confidence values.

Select a subset of the rules to build a classifier: The representative method of this category is the one used in the CBA system [10]. The method is similar to the sequential covering method, but applied to class association rules with additional enhancements as discussed above.

Let the set of all discovered CARs be *S*. Let the training data set be *D*. The basic idea is to select a subset L ($\subseteq S$) of high confidence rules to cover *D*. The set of selected rules, including a default class, is then used as the classifier. The selection of rules is based on a total order defined on the rules in *S*.

Definition: *Given two rules, r_i and r_j, $r_i \succ r_j$(called r_i precedes r_j, or r_i has a higher precedence than r_j) if*

1. *The confidence of $r_i$is greater than that of r_j, or*
2. *Their confidences are the same, but the support of $r_i$is greater than that of r_j, or*
3. *Both the confidences and supports of $r_i$and r_j are the same, but r_i is generated earlier than r_j.*

A CBA classifier L is of the form:

$L = < r_1, r_2, \ldots, r_k, \textit{default-class}>$

where $r_i \in S$, $r_a \succ r_b$ if $b > a$. In classifying a test case, the first rule that satisfies the case classifies it. If no rule applies to the case, it takes the default class (*default-class*). A simplified version of the algorithm for building such a classifier is given in Fig. 1. The classifier is the *RuleList*.

This algorithm can be easily implemented by making one pass through the training data for every rule. However, this is extremely inefficient for large data sets. An efficient algorithm that makes at most two passes over the data is given in [10].

Combine multiple rules: Like the first approach, this approach does not have an additional step to build a classifier. At the classification time, for each test instance, the system first finds the subset of rules that covers the instance. If all the rules in the subset have the same class, the class is assigned to the test instance. If the rules have different classes, the system divides the rules into groups according to their classes, i.e., all rules of the same class are in the same group. The system then compares the aggregated effects of the rule groups and finds the strongest group. The class label of the strongest group is assigned to the test instance. To measure the strength of a rule group, there again can be many possible techniques. For example, the CMAR system uses a weighted χ^2 measure [8].

Class Association Rules as Features

In the above two approaches, rules are directly used for classification. In this approach, rules are used as features to augment the original data or simply form a new data set, which is then fed to a traditional classification algorithm, e.g., decision trees or the naïve Bayesian algorithm.

To use CARs as features, only the conditional part of each rule is needed, and it is often treated as a Boolean feature/attribute. If a data instance in the original data contains the conditional part, the value of the feature/attribute is set to 1, and 0 otherwise. Several applications of this method have been reported [2,4,6,13]. The reason that this approach is helpful is that CARs capture multi-attribute or multi-item correlations with class labels. Many classification algorithms do not find such correlations (e.g., the naïve Bayesian method), but they can be quite useful.

Classification Using Normal Association Rules

Not only can class association rules be used for classification, but also normal association rules. For example, association rules are commonly used in e-commerce Web sites for product recommendations, which work as follows: When a customer purchases some products, the system recommends him/her some other related products based on what he/she has already purchased.

Recommendation is essentially a prediction problem. It predicts what a customer is likely to buy. Association rules are naturally applicable to such applications. The classification process is as follows:

1. The system first uses previous purchase transactions (the same as market basket transactions) to mine association rules. In this case, there are no fixed classes. Any item can appear on the left-hand side or the right-hand side of a rule. For recommendation purposes, usually only one item appears on the right-hand side of a rule.
2. At the prediction (e.g., recommendation) time, given a transaction (e.g., a set of items already

```
Algorithm CBA(S, D)
S = sort(S);                       // sorting is done according to the precedence>
RuleList = ∅;                      // the rule list classifier
for each rule r ∈ S in sequence do
    if D ≠ ∅ AND r classifies at least one example in D correctly then
        delete from D all training examples covered by r;
        add r at the end of RuleList
    endif
endfor
add the majority class as the default class at the end of RuleList
```

Classification by Association Rule Analysis. Figure 1. A simple classifier building algorithm.

purchased by a customer), all the rules that cover the transaction are selected. The strongest rule is chosen and the item on the right-hand side of the rule (i.e., the consequent) is the predicted item and is recommended to the user. If multiple rules are very strong, multiple items can be recommended.

This method is basically the same as the "use the strongest rule" method described earlier. Again, the rule strength can be measured in various ways, e.g., confidence, χ^2 test, or a combination of both support and confidence. Clearly, the other two classification methods discussed earlier can be applied here as well.

The key advantage of using association rules for recommendation is that they can predict any item since any item can be the class item on the right-hand side. Traditional classification algorithms only work with a single fixed class attribute, and are not easily applicable to recommendations.

Finally, it should be noted that multiple minimum supports in rule mining [11] can be of significant help. Otherwise, *rare items* will never be recommended, which is called the *coverage* problem [14]. It is shown in [14] that using multiple minimum supports can dramatically increase the coverage.

Key Applications

The applications of associative classifiers are very wide. Three main scenarios are briefly described below.

1. Since classification using class association rules is a supervised learning technique, it can be (and has been) used as a classification algorithm just like any other classification algorithm from machine learning, e.g., decision trees, naïve Bayesian classifiers, SVM, and rule induction. In many cases, an associative classifier performs better than these classic machine learning techniques.
2. Apart from classification, individual class association rules themselves are very useful in practice due to the completeness property. In many practical applications (especially diagnostic data mining applications), the user wants to find interesting rules that are actionable. As discussed earlier, traditional classification algorithms (e.g., rule induction or any other technique) are not suitable for such applications because they only find a small subset of rules that exist in data. Many interesting or actionable rules are not discovered. A deployed data mining system, called Opportunity Map, for Motorola Corporation was based on class association rules [12]. When this entry was written, the system had been in use in Motorola for more than 2 years and further improvements were still being made. Although the system was originally designed for finding rules that indicate causes of phone call failures, it had been used in a variety of other applications in Motorola.
3. Using normal association rules for classification or prediction is also very common, especially for the transaction type of data. For such kind of data, as described above, traditional classification techniques are not easily applicable because they can only predict some fixed class items (or labels).

Classification in Streams

Charu C. Aggarwal
IBM T. J. Watson Research Center, Yorktown Heights, NY, USA

Synonyms

Learning in streams; Knowledge discovery in streams

Definition

The classification problem is a well defined problem in the data mining domain, in which a training data set is supplied, which contains several feature attributes, and a special attribute known as the class attribute. The class attribute is specified in the training data, which is used to model the relationship between the feature attributes and the class attribute. This model is used in order to predict the unknown class label value for the test instance.

A data stream is defined as a large volume of continuously incoming data. The classification problem has traditionally been defined on a static training or test data set, but in the stream scenario, either the training or test data may be in the form of a stream.

Historical Background

The problem of classification has been studied so widely in the classification literature, that a single source for the problem cannot be identified. Most likely, the problem was frequently encountered in practical commercial scenarios as a statistical problem, long before the field of machine learning was defined. With advances in hardware technology, data streams became more common, and most data mining problems such as clustering and association rule mining were applied to the data stream domain. Domingos and Hulten [2] were the first to model the problem in the context of data streams.

Foundations

There are numerous techniques available for classification in the classical literature [3]. However, most of these techniques cannot be used directly for the stream scenario. This is because the stream scenario creates a number of special constraints which are as follows:

- The data stream typically contains a large volume of continuously incoming data. Therefore the techniques for training or testing need to be very efficient. Furthermore, a data point may be examined only once over the course of the entire computation. This imposes hard constraints on the nature of the algorithms which may be used for stream classification. This constraint is generally true of almost all data mining algorithms.
- Often the patterns in the underlying data may evolve continuously over time. As a result, the model may soon become stale for data mining purposes. It is therefore important to keep the models current even when the patterns in the underlying data may change. This issue is known as concept drift.
- Many stream classification methods have considerable memory requirements in order to improve computational efficiency. The stream case is particularly resource constrained, since the memory may sometimes be limited, while the computational efficiency requirements continue to be very high.
- In many cases, the rate of incoming data cannot be controlled easily. Therefore, the classification process needs to be nimble enough in order to provide effective tradeoffs between accuracy and efficiency.

Most of the known classification methods can be made to work in the data stream scenario with a few modifications. These modifications are generally designed to deal with either the one-pass constraint, or the stream evolution scenario. The different types of classifiers which can be modified for the data stream scenario are as follows:

- Nearest Neighbor Classifiers: In these techniques, the class label of the nearest neighbor to the target record is used in order to perform the classification. Since the nearest neighbor cannot be defined easily over the entire stream, a stream sample is used in order to perform the classification. This stream sample can be dynamically maintained with the one-pass constraint with the use of a technique called *reservoir sampling*. In order to deal with issues of stream evolution, one can used *biased* reservoir sampling. In biased sampling, a time decay function is used in order to maintain a sample which is biased towards more recent data points.
- Decision Tree Classifiers: In this techniques, decision trees need to be built in one pass of the stream. A method known as Very Fast Decision Trees (VFDT) was proposed in [2] which uses probabilistic split methods in order to create decision trees with predictable accuracy. In particular, the Hoeffding inequality is used in order to ensure that the generated tree produces the same tree as a conventional learner. Several other techniques were proposed by the same authors subsequently, which deal with the time-changing aspect of the data streams.
- Cluster-based Classifiers: An on-demand stream classification model was proposed which uses clustering techniques in order to build the optimal model for a classifier on demand. In this technique, a micro-clustering technique is used in order to compress the underlying data into clusters. The data belonging to different classes are compressed into different clusters. For a given test example, the class of the closest cluster is used in order to predict the class label. One key aspect of this classifier is that it assumes that both the training and the test data are in the form of a stream. The technique calculates the optimal horizon for using the cluster statistics.
- Ensemble Classifiers: In this case, a combination of different models is used in order to deal with the issue of concept drift. This is because different kinds of models work better with different kinds of data patterns. Therefore, an optimal model is picked depending upon the current data pattern. The idea is that different classifiers are more effective for different kinds of data patterns. Therefore, by making an optimal choice of the classifier from the ensemble, it is possible to improve the classification accuracy significantly.
- Bayes Classifiers: The naive Bayes classifier computes the Bayes a-posteriori probabilities of a test instance belonging to a particular class using the inter-attribute independence assumption. The key in adapting such classifiers is to be able to effectively maintain the statistics used to compute conditional probabilities in one pass. In the case of an evolving data stream, the statistics need to be maintained over particular user-specific horizons.

A number of other methods for stream classification also exist which cannot be discussed within the scope of this entry. A detailed survey on classification methods may be found in [3].

Key Applications

Stream classification finds application to numerous data domains such as network intrusion detection, target marketing and credit card fraud detection. In many of these cases, the incoming data clearly has very large volume. For example, typical intrusion scenarios have a large volume of incoming data. Similarly, in the case of target-marketing, super-store transactions may have very large volumes of incoming data.

Many of the traditional classification applications are still used in the batch mode, since the stream technology is still in its infancy, and it is sometimes simpler to collect a sample of the data set and run a batch process on it. Most of the traditional problems for the classification domain will eventually be transformed to the data stream scenario. This is because more and more data domains are being converted to the stream scenario with advances in hardware technology.

Client-Server DBMS

M. Tamer Özsu
University of Waterloo, Waterloo, ON, Canada

Definition

Client-server DBMS (database management system) refers to an architectural paradigm that separates database functionality between client machines and servers.

Historical Background

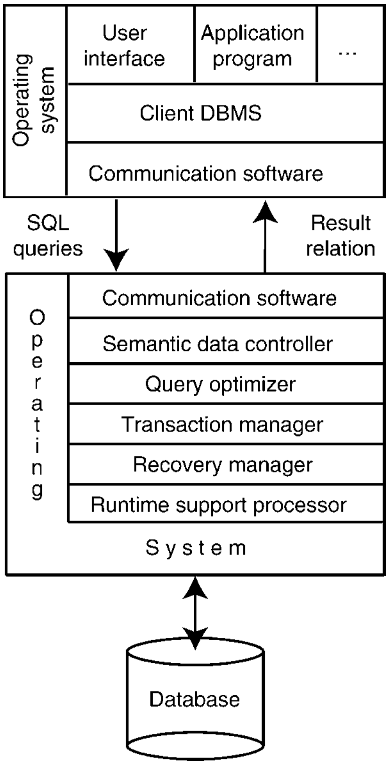
The original idea, which is to offload the database management functions to a special server, dates back to the early 1970s [1]. At the time, the computer on which the database system was run was called the *database machine*, *database computer*, or *backend computer*, while the computer that ran the applications was called the *host computer*. More recent terms for these are the *database server* and *application server*, respectively.

The client-server architecture, as it appears today, has become a popular architecture around the beginning of 1990s [2]. Prior to that, the distribution of database functionality assumed that there was no functional difference between the client machines and servers (i.e., an earlier form of today's peer-to-peer architecture). Client-server architectures are believed to be easier to manage than peer-to-peer systems, which has increased their popularity.

Foundations

Client-server DBMS architecture involves a number of database client machines accessing one or more database server machines. The general idea is very simple and elegant: distinguish the functionality that needs to be provided and divide these functions into two classes: server functions and client functions. This provides a *two-level architecture* that makes it easier to manage the complexity of modern DBMSs and the complexity of distribution.

In client-server DBMSs, the database management functionality is shared between the clients and the server(s) (Fig. 1). The server is responsible for the bulk of the data management tasks as it handles the storage, query optimization, and transaction management (locking and recovery). The client, in addition

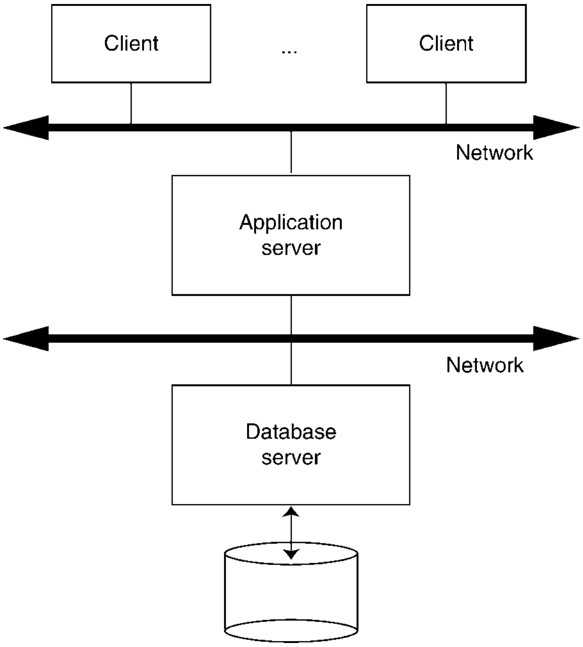


Client-Server DBMS. Figure 1. Client-server reference architecture.

to the application and the user interface, has a *DBMS client* module that is responsible for managing the data that are cached to the client, and (sometimes) managing the transaction locks that may have been cached as well. It is also possible to place consistency checking of user queries at the client side, but this is not common since it requires the replication of the system catalog at the client machines. The communication between the clients and the server(s) is at the level of SQL statements: the clients pass SQL queries to the server without trying to understand or optimize them; the server executes these queries and returns the result relation to the client. The communication between clients and servers are typically over a computer network.

In the model discussed above, there is only one server which is accessed by multiple clients. This is referred to as *multiple client-single server* architecture [3]. There are a number of advantages of this model. As indicated above, they are simple; the simplicity is primarily due to the fact that data management responsibility is delegated to one server. Therefore, from a data management perspective, this architecture is similar to centralized databases although there are some (important) differences from centralized systems in the way transactions are executed and caches are managed. A second advantage is that they provide predictable performance. This is due to the movement of non-database functions to the clients, allowing the server to focus entirely on data management. This, however, is also the cause of the major disadvantage of client-server systems. Since the data management functionality is centralized at one server, the server becomes a bottleneck and these systems cannot scale very well.

The disadvantage of the simple client-server systems are partially alleviated by a more sophisticated architecture where there are multiple servers in the system (the so-called *multiple client-multiple server* approach). In this case, two alternative management strategies are possible: either each client manages its own connection to the appropriate server or each client knows of only its "home server", which then communicates with other servers as required. The former approach simplifies server code, but loads the client machines with additional responsibilities, leading to what has been called "heavy client" systems. The latter approach, on the other hand, concentrates the data management functionality at the servers. Thus, the transparency of data access is provided at the server interface, leading to "light clients."



Client-Server DBMS. Figure 2. Database server approach.

The integration of workstations in a distributed environment enables an extension of the client-server architecture and provides for a more efficient function distribution. Application programs run on workstations, called *application servers*, while database functions are handled by dedicated computers, called *database servers*. The *clients* run the user interface. This leads to the present trend in three-tier distributed system architecture, where sites are organized as specialized servers rather than as general-purpose computers (Fig. 2).

The application server approach (indeed, a n-tier distributed approach) can be extended by the introduction of multiple database servers and multiple application servers, as can be done in client-server architectures. In this case, it is common for each application server to be dedicated to one or a few applications, while database servers operate in the multiple server fashion discussed above.

Key Applications

Many of the current database applications employ either a two-layer client-server architecture of the three-layer application-server approach.

Clinical Data Acquisition, Storage and Management

Chimezie Ogbuji
Cleveland Clinic Foundation, Cleveland, OH, USA

Synonyms

Electronic data capture; Case report forms; Clinical data management systems

Definition

The management of clinical data for supporting patient care and for supporting retrospective clinical research requires a means to acquire the clinical data and a repository that stores the data and provides the functions necessary for managing them over their lifetime. Typically, patient data are collected "at the point of care" (i.e., onsite where health care is being provided) and entered into a patient record system [2]. Data entry is typically the first line of precaution for maintaining a certain amount of quality on the data collected. Subsequently, a representative from an externally sponsoring organization or authorized personnel from within the health care institution then extracts a select set of medical record data into a Clinical Data Management System (*CDMS*). The entries in such systems are often referred to as secondary patient records since they are derived from a primary patient record and are used by personnel who are not involved in direct patient care [2]. These systems are also often referred to as *patient registries.*

The study committee of the Institute of Medicine (IOM) defined [2] a computer-based patient record (*CPR*) as

► an electronic patient record that resides in a system specifically designed to support users by providing accessibility to complete and accurate data, alerts, reminders, clinical decision support systems, links to medical knowledge, and other aids.

Such systems are also often referred to as Electronic Health Records (*EHR*s). The committee also defined a *primary* patient record as one used by health care professionals while providing patient care services to review patient data or document their own observations, actions, or instructions [2]. Finally, the committee emphasized the distinction between clinical data and the systems that capture and process this data by defining a patient record *system* as

► the set of components that form the mechanism by which patient records are created, used, stored, and retrieved.

A CDMS is the repository for the management of the data used for clinical studies or trials. One of the core services provided by a CDMS is to facilitate the identification (and correction) of errors due to human entry as well as errors that existed in the source from which the data was gathered. Data completeness implies that CDMS will accommodate an expected range and complexity for the data in the system [2]. In addition, the CDMS can employ the use and enforcement of one or more vocabulary standards.

Finally, a CDMS will also provide services for querying the data as well as generate reports from the data. The generated reports and results of such queries are typically transmitted to a centralized authority or normalized for use by statistical analysis tools.

Historical Background

Virtually every person in the United States who has received health care in the United States since 1918 has a patient record [2]. Most of these records consist of structured paper forms with sections that consist solely of narrative text. However, conventional patient records can also appear in other forms such as scanned media, microfilm, optical disk, etc.

They are created and used most frequently in health care provider settings. However, their use also extends to other facilities such as correctional institutions, the armed forces, occupational health programs, and universities [2].

The process of recording patient care information has primarily consisted of entry into a paper patient record. For the purpose of a clinical trial or study, data are manually transcribed into a paper Case Report Form (*CRF*). CRFs are typically in the form of a questionnaire formulated to collect information specific to a particular clinical trial. The ICH Guidelines for Good Clinical Practice define [4] the CRF as:

- ▶ A printed, optical, or electronic document designed to record all of the protocol required information to be reported to the sponsor on each trial subject.

CRFs are then collected by a representative from the sponsoring organization and manually entered into a CDMS. This secondary transcription is often called *double data entry*. In some cases, Optical Character Recognition (*OCR*) is used to semi-automate the transcription from a CRF into a CDMS [1].

Traditionally, clinical data management systems consist of infrastructure built on top of relational database management systems. Depending on the nature of the requirements for the creation of analysis data sets for biostatisticians, accuracy of the data, and speed of data entry, a wide spectrum of database management or spreadsheet systems are used as the underlying medium of storage for the CDMS.

Good database design and proper application of relational model theory for normalizing the data is typically used to ensure data accuracy. Traditional relational query languages such as SQL are used to identify and extract relevant variables for subsequent analysis or reporting purposes.

Foundations

Electronic Data Capture

There is a slow, but steady move by pharmaceutical companies towards the adoption of an electronic means of capturing patient record information directly from the source and at the point of care into an electronic system that submits the data relevant to the trial to the sponsor or to other consumers of electronic patient record data. This new shift of emphasis from paper to a direct electronic system is often referred to (in the health care industry) as Electronic Data Capture (*EDC*) [3].

Infrastructure and Standards for Data Exchange

Once patient record data are collected and stored in an electronic information system, the increasing need to transfer the machine-readable data to external systems emphasizes the importance of standardized formats for communication between these disparate systems [2]. Efforts to standardize a common format for communication between health care systems and other external consumers of health care data have settled on the adoption of Extensible Markup Language (*XML*) as the primary data format for the transmission of Health Level 7 (*HL7*) messages.

HL7 is an organization with a mission to develop standards that improve the delivery of care, optimize the management of workflow, reduce ambiguity in clinical terminology and facilitate efficient transfer of knowledge between the major stakeholders.

Document Models and Management Systems

As its name implies, XML is a markup language for describing structured data (or *documents*) in a manner that is both human- and machine-readable. It can be extended to support users who wish to define their own vocabularies. It is meant to be highly reusable across different information systems for a variety of purposes. It is recommended by the World Wide Web Consortium (*W3C*) and is a free and open standard.

XML is at the core of an entire suite of technologies produced by the W3C that includes languages for querying XML documents as well as describing their structure for the purpose of validating their content. This suite of technologies is meant to serve as infrastructure for a contemporary set of information systems each known more broadly as a Document Management System (*DMS*).

Common Components of Information Systems

Like most information systems, document management systems are comprised of a particular data model (XML in this case), one or more query languages, and a formal processing model for systems that wish to support queries written in language against the underlying data. Document management systems (and information systems in general) typically also offer security services that ensure limited access to the data. This is particularly important for clinical data management systems.

With respect to the kind of services they provide for the systems that are built on top of them (such as clinical data management systems), document management systems are very much like relational database management systems. However, whereas relational database management systems have an underlying relational model that is tabular and rigid, document management systems have a data model that is hierarchical with data elements that can be extended to support new terminology over the life of the data.

Text-Oriented Information Systems

Most modern computer-based patient record systems mainly adopt information systems with hierarchical, relational, or text-oriented data models. Text-based information systems typically store their content primarily as narrative text and often employ natural language processing for extracting structured data for transcription into a clinical data management system. Querying such systems usually involves keyword-based searches that use text indexes that are used to associate words with the sections of narrative in which they can be found.

Key Applications

Electronic data capture and clinical data management systems constitute the majority of the infrastructure necessary in the overall process of clinical research from the point of interaction with primary patient records all the way to the analysis of the curated clinical research data. The sections below describe the major areas where their application makes a significant difference.

Electronic Data Collection Options

There are a variety of ways in which data can be acquired electronically for transcription into a clinical data management system. The most desired means is one where the data are directly retrieved electronically from an existing source such as the primary patient record. This method is often referred to as *single entry* [1]. It requires that the primary patient record adopt or align with a set of consistent format standards such that they can facilitate the support of primary care as well as reuse for the purpose of (unanticipated) clinical research. Unfortunately the lack of adoption of computer-based patient records remains a primary impediment to this more direct means of acquiring clinical data [2,3].

Alternatively, clinical data can be transcribed from a primary patient record into a secondary patient record using some form of an electronic user interface on a particular device. Typically, such user interfaces are either web browser-based (i.e., they are built on top of an existing web browser such as Internet Explorer or Firefox) or they are written as independent applications that are launched separately. The latter approach is often referred to as a *thick-client system* [6].

Patient Registries

The set of functions associated with a secondary computer-based patient record system is often adopted from the underlying information system. Modern document and relational database management systems are equipped with a wide spectrum of capabilities each of which is directly relevant to the needs of users of these systems. This includes: content organization, archival, creation of documents, security, query services, disaster recovery, and support for web-based user interfaces.

Clinical Workflow Management

Equally important to the clinical data is the management of the pattern of activity, responsibilities, and resources associated with a particular clinical study or trial. These patterns are often referred to as *workflow*. Orchestrating the overall process can also have a significant impact on the success of a clinical study. Clinical data management systems sometimes have off-the-shelf capabilities for managing workflow. These usually support some amount of automation of the workflow process. Document management systems that include capabilities for building customized application are well-suited for supporting workflows that are either specific to a particular study protocol or capable of supporting multiple (or arbitrary) protocols.

Quality Management, Report Generation, and Analysis

Finally, document management and relational database management systems include capabilities for monitoring error in the data collected. This is often supported through the application of a set of common constraints that are relevant to the research protocol. Typically, these systems have an automated mechanism for indicating when the underlying data does not adhere to the constraints specified.

In addition, document management and relational database management systems include services for generating reports and extracting variables for statistical analysis.

Future Directions

Modern information management systems are adopting standards for representation formats that push the envelope of machine-readability. In particular, the W3C has recently been developing a suite of technologies that build on the standards associated with the World Wide Web and introduce a formal model for capturing knowledge in a manner that emphasizes the meaning of terms rather than their structure. Such approaches to modeling information are often referred to as knowledge representation or conceptual models. This particular collection of standards is commonly referred to as *semantic web technologies* [5].

Semantic web technologies are built on a graph-based data model known as the Resource Description Framework (*RDF*) as well as a language for describing conceptual models for RDF data known as Ontology Web Language (*OWL*). RDF leverages a highly-distributable addressing and naming mechanism known as Uniform Resource Identifiers (*URIs*) that is the foundation of the current web infrastructure.

Semantic web technologies also include a formal mechanism for rendering or transforming XML document dialects into RDF known as Gleaning Resources Descriptions from Dialects of Languages (*GRDDL*). Finally a common query language has been defined for accessing data expressed in RDF known as *SPARQL*.

The Institute of Medicine has indicated [2] that the flexibility of computer-based patient records is primarily due to their adoption of a data dictionary that can be expanded to accommodate new elements. In addition, the IOM has identified [2] the following as crucial to the evolution of content and standard formats in computer-based patient record systems:

- The content of CPRs must be defined and contain a uniform core set of data elements.
- Data elements must be named consistently via the enforcement of some form of vocabulary control.
- Format standards for data exchange must be developed and used.

In addition, the IOM's study committee identified the ability for CPRs to be linked with other clinical records as a critical attribute of a comprehensive computer-based patient record. The combination of these observations is a strong indication that in the future, clinical data management systems will be built on information management systems that adopt semantic web technologies in order to better meet the growing needs of the management of clinical research data.

Finally, a new generation of technologies for building declarative web applications will lower the technological barrier associated with the kind of user interfaces necessary for the adoption of electronic data capture methods at health care institutions. In particular, an XML-based technology known as *XForms* is well positioned to have a significant impact on the front end of the clinical data pipeline (data collection).

XForm applications are web form-based, independent of the device on which they are deployed and use XML as the data model of the underlying content. This approach has strong correspondence with the current direction of clinical data exchange standards with the adoption of XML as the format for communication between health care systems.

In the near future, lightweight devices (such as Tablet PCs) will connect to remote, distributed computer-based patient record systems over a secure web-based network protocol. Electronic data capture will be implemented by XForm applications that run in a browser and compose XML documents that represent sections of a computer-based patient record. These documents will adhere to a standard document format for the exchange of medical records such as the HL7 Clinical Document Architecture (*CDA*). The HL7 CDA is an XML-based document markup standard that specifies the structure and semantics of clinical documents for the purpose of exchange.

These documents will be securely transmitted directly into a primary computer-based patient record which employs XML as its core data model and uses GRDDL to also store an RDF representation of the document that conforms to a formal, standard ontology (expressed in OWL) that describes the meaning of the terms. This ontology provides a certain degree of logical consistency that facilitates ad hoc analysis through the use of logical inference.

Patients that meet the criteria for a particular research protocol will be identified by a SPARQL query that is dispatched against the patient record system, which uses terminology easily understood by the investigators themselves (rather than an intermediary database administrator). These patient records will then be transmitted directly into a clinical data management system (or patient registry) that will include the facilities for managing the workflow associated with the relevant research protocol. These facilities will be implemented as web applications built on the same underlying information management systems as those used by the primary computer-based patient records.

Clinical Data and Information Models

Chintan Patel, Chunhua Weng
Columbia University, New York, NY, USA

Definition

A formal representation of the clinical data using entities, types, relationships and attributes. The abstraction of clinical data into an information model enables reusability and extensibility of the database to satisfy different application needs and accommodate changes in the underlying data.

Key Points

The clinical domain is a data rich environment with multitude of different data entities ranging from several thousands of laboratory tests, procedures or medications that change often with new ones getting added almost every day. Furthermore these data are generated from different information systems or devices (often from different vendors) in the hospital. Integrating such wide variety of data streams into a common information model is a challenging task.

Most healthcare databases use generic information models [3,4] such as event-component models with an Entity-Attribute-Value [5] (EAV) schema to represent the data (see Fig. 1). The advantage of using a generic information model is to accommodate the data heterogeneity and extensibility. Generally, an external terminology or vocabulary is used in conjunction with a generic information model to represent the clinical domain (laboratory tests, medications and so on) and the healthcare activities, for example, LOINC is a

```
Event (Chest X-Ray*)  -> Attribute1 = Value1 (on-date* = mm/dd/yyyy)
                      -> Attribute2 = Value2 (finding-site* = breast*)
                      -> Attribute3 = Value3 (has-morphology* = neoplasm*)
                                 ...
*coded using an external terminology
```

Clinical Data and Information Models. Figure 1. The event component information model.

standard vocabulary for representing laboratory data or SNOMED CT for healthcare activities.

Various information models have been proposed towards standardizing the representation of clinical data. The goal of standardizing the information model is to facilitate exchange, sharing and reuse of clinical data by different systems locally as well as nationally. Following are some current standardized models:

HL7 Reference Information Model: The HL7 standards organization [2] has developed a Reference Information Model (RIM) to share consistent meaning of healthcare data beyond local context. The RIM specifies a set of abstract bases classes Entity, Role, Participation and Act, which contain specific classes/attributes such as Person, Organization, Patient, Provider, Intent, Observation and so on. This model is used to create concrete concepts by combining the RIM types, for example, *elevated blood pressure* would be represented in RIM as class = Observation with code = Finding of increased blood pressure (SNOMED#241842005), mood = Event, interpretation code = abnormal (HL7#A), target site = heart (LOINC#LP7289). Note that standardized terminology codes (SNOMED CT and LOINC) are used to represent specific findings and modifiers. An implementation of HL7 RIM based model over a relational database schema is described here [1].

openEHR Reference Model: The openEHR specification [6] (developed largely by the institutions in EU and Australia) provides information models for the electronic health record (EHR), demographics, data structures, integration and so on. The openEHR EHR model represents various facets of EHR such as clinician/patient interaction, audit-trailing, technology/data format independence and supporting secondary uses. The openEHR project uses the notion of archetypes that enable domain experts to formally model a domain concept (or an aggregation of concepts), corresponding constraints and other compositions, for example, an archetype on *blood pressure measurement* consists of systolic, diastolic measurements and units with other clinically relevant information such as history.

Clinical Data Management Systems

► Clinical Data Acquisition, Storage and Management

Clinical Data Quality and Validation

Chintan Patel, Chunhua Weng
Columbia University, New York, NY, USA

Definition

Clinical data quality is defined as the accuracy and completeness of the clinical data for the purposes of clinical care, health services and other secondary uses such as decision support and clinical research. The quality of clinical data can be achieved by the standardization, inspection and evaluation of the data generating processes and tools [2].

Key Points

The term data quality can potentially have different meanings or interpretation based on the domain or the application using the data [1]. Even within the context of clinical databases, there exists a multitude of different data types (administrative data, procedure data, laboratory data and so on) that may be used for several different applications such as clinical report generation, billing or research. The major components of clinical data quality can be broadly characterized as follows:

Accuracy

Clinical data are often generated by automated systems (such as lab equipment) or manually entered by clinicians (notes). These data generating processes are prone to errors that result in incorrect data being stored in the database. The severity of errors can vary significantly, for example, a minor misspelling in patient history note versus a prescription error in drug dosage order can lead to drastically different outcomes in terms of patient care. The accuracy of clinical data is defined as the proportion of correct data (truly representing the actual patient condition or measurement) in the clinical database. The accuracy of clinical data depends on the enforcement of well-defined data entry standards and protocols.

Completeness

It is defined as the availability of data elements in a clinical database that are necessary to accomplish a given task, for example, a clinical trial recruitment application with detailed eligibility criteria would require information from the clinical notes in addition to coded problem list data. The completeness of a patient record is critical for a clinician to choose a most appropriate treatment plan for the patient. The availability of complete patient information is critical during an emergency condition. In the case of unavailability of data elements, some applications tend to substitute data sources, which can lead to sub-optimal results. Consider for example, a clinical decision support application reusing coarse ICD (International Classification of Disease) classification to generate decisions.

Reliability

The notion of "repeatability" – to determine whether the clinical data generation processes produce consistent data at different times or settings. Hospitals are a chaotic environment with multiple care providers taking care of a single patient. It becomes critical to develop data entry protocols to ensure consistent representation of patient information in the clinical database. Often to eliminate the variations across different users the data entry software systems such as the EMR (electronic medical record) contain various checks to ensure the correctness and completeness of the data elements [3]. The coding of clinical data using terminologies such as ICD has to be done in a consistent fashion to facilitate applications that require data integration or comparative analysis.

Maintaining quality in clinical databases is a continuous process requiring strong commitment from different stakeholders involved. The amount of electronic biomedical data generated is growing at an exponential rate. Developing high quality clinical databases can have significant implications for the applications reusing the data.

Clinical Decision Support

Adam Wright
Partners HealthCare, Boston, MA, USA

Synonyms

CDS; Decision support

Definition

Clinical Decision Support systems are computer systems which assist humans in making optimal clinical decisions. While clinical decision support systems are most often designed for clinicians, they can also be developed to assist patients or caregivers. Common examples of clinical decision support systems include drug-drug interaction checks, dose range checking for medication and preventive care reminders.

Historical Background

The first clinical decision support system was described in 1959 by Robert Ledley and Lee Lusted [6] in their paper "Reasoning foundations of medical diagnosis; symbolic logic, probability, and value theory aid our understanding of how physicians reason." Ledley and Lusted described an analog computer used to sort cards containing a diagnosis and a series of punches which represented symptoms. By selecting the cards which matched the symptoms present in a given case a clinician could develop a possible set of diagnosis.

In 1961, Homer Warner [15] described a clinical decision support system for diagnosing congenital heart defects. The system was developed around a contingency table that mapped clinical symptoms to forms of congenital heart disease. A physician would input the patient's symptoms and findings from the clinical exam and other studies into the system, which would then proceed to suggest the most probable diagnoses based on the contingency table.

In the 1970s, Edward Shortliffe developed the well-known MYCIN system for antibiotic therapy. MYCIN was an expert system with a large knowledge base of clinical rules [12]. Users of MYCIN would input known facts about their patient, and MYCIN would apply them to the rule base using backward chaining to yield a probable causative agent for infections as well as suggestions for antibiotic therapy.

While the systems described so far all focused on a specific area of medicine, the INTERNIST-I system, developed by Randy Miller, Harry Pople and Jack Myers [8] targeted the broad domain of diagnosis in internal medicine. The INTERNIST-I knowledge base consisted of a large set of mappings between symptoms and diagnoses. These links were scored along three axes: evoking strength (the likelihood that a patient has a diagnosis given a particular symptom), frequency (how often a symptom is present given a particular diagnosis) and import (how critical it is that a particular diagnosis be considered given that it is possible or probable based on a set of symptoms). Octo Barnett's DXplain system for diagnostic decision support was developed around the same time as INTERNIST-I.

The earliest decision support systems were standalone, but the second wave in clinical decision support, beginning in the 1970s, was the integration of decision support systems into broader clinical information systems. The first two examples of this integration were the Health Evaluation through Logical Processing (HELP) system at the University of Utah and LDS Hospital, and the Regenstrief Medical Records System (RMRS) developed at the Regenstrief Institute in Indianapolis. The HELP system, which was used for many facets of patient care, had support for the development of a variety of kinds of decision support, and was especially well known for its Bayesian reasoning modules. The RMRS was developed, from the ground up, with a large knowledge base of clinical care rules. Both HELP and RMRS are in active use today.

Most current commercially available clinical information systems have some support for clinical decision support, and efforts to standardize representation and enable the sharing of decision support content are ongoing.

Foundations

Development of clinical decision support systems entails a variety of issues. The first step in developing any clinical information system is to identify an important clinical target, and then consider interventions. The most critical database systems related issues are knowledge representation, storage and standards.

Issues of Knowledge Representation

Once a desired clinical decision support target has been identified and relevant medical knowledge has been collected, the knowledge must somehow be represented. Knowledge in clinical decision support systems has been represented in a variety of ways, the most common being if-then rules, expert systems, probabilistic and Bayesian systems and reference content.

Perhaps the simplest form of knowledge is if-then rules. Much of clinical decision support content can be represented this way (for example "if the acetaminophen dose is 10 g per day, alert the user that this is too high" or "if the patient is over 50 years of age and has not had a sigmoidoscopy, recommend one"). These rules are frequently designed to be chained together, although generally in a fixed and predetermined pattern.

More complex than simple if-then rules are expert systems. These systems are composed of large knowledge bases which contain many intermediate states and assertions. Like if-then rules, these rules are composed of an antecedent, a consequent and an implication. However, expert systems are generally designed to elicit emergent behavior from extensive chaining including, in many cases, goal-directed backward chaining.

Probabilistic and Bayesian systems share much in common with if-then rules. However, instead of modeling knowledge and clinical states as deterministic values, they use probabilities. By combining these probabilities with knowledge provided by the user, these systems can estimate the likelihood of various diagnostic possibilities, or the relative utility of different therapeutic modalities. It is important to note that many expert systems employ probabilistic or Bayesian reasoning.

A simpler form of knowledge representation is reference knowledge designed to be read by a human. This form of decision support provides information to the user but expects him or her to formulate a plan of action on his or her own. In many cases knowledge, such as clinical guidelines, can be equivalently modeled as rules or as reference content. Reference content is simpler to construct, but it sometimes can not be as proactive as rule-based content.

Storage of Clinical Knowledge in Database Systems

A key challenge for developers of database systems for clinical decision support is selecting the optimal strategy for storing clinical knowledge in a database. This selection has many tradeoffs among performance, space, maintainability and human readability.

Rule based decision support content is often stored as compiled or interpreted code and, when properly integrated into clinical information support systems, can be very efficient. However, many systems instead choose to store rules in some intermediate form, often indexed according to their trigger (a clinical event, such as a new prescription, which causes decision support rules to fire). A chained hash table with these triggers as its keys and decision support rules to invoke as values can be a particularly efficient representation.

In cases of particularly high transaction volume, where performance is important and the number of rules to evaluate is large, more sophisticated storage and processing mechanisms can be used. One of the most effective in terms of performance (although not necessarily in terms of space) is Charles Fogarty's Rete algorithm. The Rete algorithm is an efficient network-based method for pattern matching in rule-based systems.

Because it is not rule based, reference knowledge requires a different set of storage and retrieval strategies, based largely on the principles of information retrieval. In general, these strategies employ one or some combination of full-text search and metadata queries.

Standards for Sharing Clinical Decision Support Content between Database Systems

In addition to the aforementioned issues of internal representation of clinical knowledge, there are also issues relating to the sharing of clinical decision support content between systems. Several standards for sharing such content have been proposed, beginning with Arden Syntax, a standard for event-driven rule-based decision support content. Other standards, such as Guideline Interchange Format (GLIF) and the related expression language GELLO exist to represent more complex forms of clinical knowledge. While construction of standards for representing clinical knowledge may seem straightforward, issues relating to terminology and a reference model for patient information have proven formidable.

An alternate approach to strict structured knowledge representation formalisms for sharing clinical decision support content is the use of services. Several recent efforts, including SEBASTIAN and SANDS have defined a set of interfaces and, in the case of SANDS, patient data models to help overcome prior difficulties in sharing decision support content.

Key Applications

Applications of clinical decision support can be categorized along a variety of axes, including intervention type (alert, reminder, reference information, etc.), clinical purpose (diagnosis, therapy, prevention), disease target (diabetes, hypertension, cancer, etc.) and user (physician, nurse, patient, etc.).

Several clinical decision support systems have been described in the historical background section. Additional significant systems include:

- Morris Collen's system for "Automated Multiphasic Screening And Diagnosis."
- Howard Bleich's system for diagnosis and treatment of acid-base disorders.
- A system for the diagnosis and management of abdominal complaints developed by F.T. de Dombal.
- The ATTENDING system developed by Perry Miller and designed to critique and suggest improvements to anesthesia plans.
- A system for ventilator management by Dean Sittig.

- A blood product ordering critiquing system by Reed Gardner.
- An antibiotic advising system by Scott Evans.

Experimental Results

There is a long experimental tradition in the field of clinical decision support, and many systems have shown strong results, even for the earliest systems. Warner's system for congenital heart defects was compared favorably to experienced cardiologists, MYCIN proposed clinically appropriate antibiotic therapy 75% of the time (and got better as more rules were added) and INTERNIST performed about as well as average doctors at diagnosis.

Just as significant is the effect that such systems have on physician practice. In a landmark paper, Clem McDonald described the results of an experimental trial performed within the RMRS system. In the trial, half of the physician users of RMRS received patient care suggestions based on the knowledge base of rules, while half did not. Physicians who received the suggestions carried them out 51% of the time, while physicians who did not receive suggestions performed the actions that would have been suggested only 22% of the time. When the reminder system was turned off, physician performance returned almost immediately to baseline.

There have been several significant systematic reviews of clinical decision support systems. A 2005 review by Amit Garg [2] found that decision support systems were associated with improved provider performance in 64% of the controlled trials reviewed. Another systematic review by Ken Kawamoto found that decision support systems improved performance in 68% of trials, and that systems designed to the highest criteria improved performance in 94% of trials.

Clinical Document Architecture

Amnon Shabo (Shvo)
IBM Research Lab-Haifa, Haifa, Israel

Synonyms

CDA; CDA R1; CDA R2

Definition

The Clinical Document Architecture (CDA) is a document markup standard that specifies the structure and semantics of clinical documents for the purpose of exchange and share of patient data. The standard is developed by Health Level Seven (HL7) – a Standards Development Organization [2] focused on the area of healthcare. At the time of writing this entry, two releases of CDA were approved: CDA R1 was approved in 2000 and CDA R2 in 2005. Both releases are part of the HL7 new generation of standards (V3), all derived from a core reference information model (RIM) that assures semantic consistency across the various standards such as laboratory, medications, care provision and so forth. The RIM is based on common data types and vocabularies, and together these components constitute the HL7 V3 Foundation that is an inherent part of the CDA standard specification.

Key Points

Clinical documents such as discharge summaries, operative notes and referral letters are ubiquitous in healthcare and currently exist mostly in paper. The computerized clinical document is similar in purpose to its paper counterpart and the clinician's narratives are a key component of both versions. Narratives are compositions based on the natural language of the writer, while computerized structuring of a document is limited to some computer language. The design of the CDA standard strives to bridge the gap between these "languages" especially when it comes to the mixture of structured and unstructured data intertwined to describe the same phenomena, while addressing two important goals: human readability and machine-processability. The drive to structure medical narratives is also challenging the thin line between art and craftsmanship in the medical practice [3].

The basic structure of a CDA document consists of a header and a body. The header represents an extensive set of metadata about the document such as time stamps, the type of document, encounter details and of course the identification of the patient and those who participated in the documented encounter or service. While the header is a structured part of the document and is similar in the two releases of CDA, the body consists of clinical data organized in sections and only in CDA R2 it enables the formal representation of structured data along with narratives [1]. Data is structured in clinical statements based on entries such as observations, medication administrations, or adverse events where several entries are associated into a compound clinical statement. Nevertheless, only the narrative parts of the CDA body are mandatory, which makes CDA easy to adopt if structured data is not yet available. It is even possible to simply wrap a non-XML document with the CDA header or create a document with a structured header and sections containing only narrative content. The purpose of this design is to encourage widespread adoption, while providing an information infrastructure to incrementally move toward structured documents, serving the goal of semantic interoperability between disparate health information systems.

Beside text, CDA can also accommodate images, sounds, and other multimedia content. It can be transferred within a message and can be understood independently, outside the relaying message and its sending and receiving systems. CDA documents are encoded in Extensible Markup Language (XML), and they derive their machine processable meaning from the RIM, coupled with specific vocabularies.

A CDA document is a collection of information that is intended to be legally authenticated and has to be maintained by an organization entrusted with its care (stewardship). Inherent in the HL7 CDA standard are mechanisms for dealing with the authentication and versioning of documents so that it can be used in medical records enterprise repositories as well as in cross-institutional sharing of personal health information to facilitate continuity of care.

Clinical Event

Dan Russler
Oracle Health Sciences, Redwood Shores, CA, USA

Definition

Vernacular Definition

1. In event planning circles, a "clinical event" is an event, e.g., meeting or party, attended by clinicians as opposed to administrative or financial personnel.

Technical Definitions

1. A state transition, normally a "create" or "update" state transition, targeting a record in an electronic medical record system or one of the systems associated with an electronic medical record system.
2. A report generated within a clinical trial that is subsequently evaluated for the presence of an adverse event by a clinical trial Clinical Event Committee.

Words often confused by use of the term "Clinical Event" include: Clinical Event (multiple definitions); Adverse Event; Clinical Act; Patient Event, Information Event.

The primary technical definition of "clinical event" includes the kind of "events" that are monitored by a "clinical event monitor"[1–3] used in synchronous or asynchronous decision support functions. Examples of these events include clinical orders, electronic medical record entries, admission, transfer and discharge notifications, lab results, and patient safety reports. These events trigger state transitions in an electronic medical record system or related system.

Typically, once the clinical event monitoring system, such as an HL7 Arden Syntax-based system, discovers a state transition, in the electronic medical record system, a decision support rule is applied to the clinical event and related data in order to determine whether a notification of a person or another system is required.

Key Points

"Event" or "Action" analysis traces its roots to the work of Aristotle on propositions. Propositions usually follow the form of Subject-Predicate and, upon analysis, may be found to be "true" or "false." The classic example of a proposition is "Socrates is a man." "Socrates" is the "Subject" and "is a man" is the "Predicate." An analogous proposition in healthcare is "Peter has a potassium level of 5.5 mg/dl." Clinical Events are propositions in healthcare that may be evaluated themselves by clinicians as "true" or "false" or may be applied in rules that evaluate to true or false.

For example, the creation of a record asserting that "Peter has a potassium level of 5.5 mg/dl" might trigger a clinical event monitoring system to implement the rule: "If potassium level record created, then evaluate if ("record value" >5.0); if "true," then notify Dr. X."

"Event-driven programming" as opposed to "procedural programming" utilizes the same kinds of predicate logic in evaluating state transitions or triggers to state transitions in a modern computer-programming environment. Consequently, Clinical Events drive programming logic in many modern systems.

The HL7 Reference Information Model (RIM) describes clinical events; the term "Act" in the RIM identifies objects that are instantiated in XML communications between systems or in records within the electronic healthcare systems themselves. These "Acts" correspond to "clinical events" used for monitoring systems in healthcare. However, in the RIM, "Event" is defined narrowly as an instance of an Act that has been completed or is in the process of being completed. Clinical event monitoring systems may also evaluate HL7 "Orders or Requests" or other kinds of "Act" instances as events of interest (www.hl7.org).

Definition

A clinical knowledge repository (CKR) is a multipurpose storehouse for clinical knowledge assets. "Clinical knowledge asset" is a generic term that describes any type of human or machine-readable electronic content used for computerized clinical decision support. A CKR is normally implemented as an enterprise resource that centralizes a large quantity and wide variety of clinical knowledge assets. A CKR provides integrated support to all asset lifecycle phases such as authoring, review, activation, revision, and eventual inactivation. A CKR routinely provides services to search, retrieve, transform, merge, upload, and download clinical knowledge assets. From a content curation perspective, a CKR has to ensure proper asset provenance, integrity, and versioning, along with effective access and utilization constraints compatible with collaborative development and deployment activities. A CKR can be considered a specialized content management system, designed specifically to support clinical information systems. Within the context of clinical decision support systems, a CKR can be considered a special kind of knowledge base – one specially designed to manage multiple types of human and machine-readable clinical knowledge assets.

Key Points

In recent years, multiple initiatives have attempted to better organize, filter, and apply the ever-growing biomedical knowledge. Among these initiatives, one of the most promising is the utilization of computerized clinical decision support systems. Computerized clinical decision support can be defined as computer systems that provide the correct amount of relevant knowledge at the appropriate time and context, contributing to improved clinical care and outcomes. A wide variety of knowledge-driven tools and methods have resulted in multiple modalities of clinical decision support, including information selection and retrieval, information aggregation and presentation, data entry assistance, event monitors, care workflow assistance, and descriptive or predictive modeling. A CKR provides an integrated storage platform that enables the creation and maintenance of multiple types of knowledge assets. A CKR ensures that different modalities of decision support can be combined to properly support the activities of clinical workers. Core requirements guiding the implementation of a CKR include clinical knowledge asset provenance (metadata), versioning, and integrity. Other essential requirements include the proper representation of access and utilization constraints, taking into account the collaborative nature of asset development processes and deployment environments. Another fundamental requirement is to aptly represent multiple types of knowledge assets, where each type might require specialized storage and handling. The CKR core requirements are generally similar to those specified for other types of repositories used for storage and management of machine-readable assets.

Historical Background

Biomedical knowledge has always been in constant expansion, but unprecedented growth is being observed during the last decade. Over 30% of the 16.8 million citations accumulated by MEDLINE until December of 2007 were created in the last 10 years, with an average of over 525,000 new citations per year [5]. The number of articles published each year is commonly used as an indicator of how much new knowledge the scientific community is creating. However, from a clinical perspective, particularly for those involved with direct patient care, the vast amount of new knowledge represents an ever-growing gap between what is known and what is routinely practiced. Multiple initiatives in recent years have attempted to better organize, filter, and apply the knowledge being generated. Among these various initiatives, one of the most promising is the utilization of computerized clinical decision support systems [6]. In fact, some authors avow that clinical care currently mandates a degree of individualization that is inconceivable without computerized decision support [1].

Computerized clinical decision support can be defined as computer systems that provide the correct amount of relevant knowledge at the appropriate time and context, ultimately contributing to improved clinical care and outcomes [3]. Computerized clinical decision support has been an active area of informatics research and development for the last three decades [2]. A wide variety of knowledge-driven tools and methods have resulted in multiple modalities of clinical decision support, including information selection and retrieval (e.g., infobuttons, crawlers), information aggregation and presentation (e.g., summaries, reports, dashboards), data entry assistance (e.g., forcing functions, calculations, evidence-based templates for ordering and documentation), event monitors (e.g., alerts, reminders, alarms), care workflow assistance (e.g., protocols, care pathways, practice guidelines), and descriptive or predictive modeling (e.g., diagnosis, prognosis, treatment planning, treatment outcomes). Each modality requires specific types of knowledge assets, ranging from production rules to mathematical formulas, and from automated workflows to machine learning models. A CKR provides an integrated storage platform that enables the creation and maintenance of multiple types of assets using knowledge management best practices [4].

The systematic application of knowledge management processes and best practices to the biomedical domain is a relatively recent endeavor [2]. Consequently, a CKR should be seen as a new and evolving concept that is only now being recognized as a fundamental component for the acquisition, storage, and maintenance of clinical knowledge assets. Most clinical decision support systems currently in use still rely on traditional knowledge bases that handle a single type of knowledge asset and do not provide direct support for a complete lifecycle management process. Another relatively recent principle is the recognition that different modalities of decision support have to be combined and subsequently integrated with information systems to properly support the activities of clinical workers. The premise of integrating multiple modalities of clinical decision support reinforces the need for knowledge management processes supported by a CKR.

Foundations

Core requirements guiding the implementation of a CKR include clinical knowledge asset provenance (metadata), versioning, and integrity. Requirements associated with proper access and utilization constraints are also essential, particularly considering the collaborative nature of most asset development processes and deployment environments. Another fundamental requirement is to aptly represent multiple types of knowledge assets, where each type might require specialized storage and handling. The CKR core requirements are generally similar to those specified for other types of repositories used for storage and management of machine-readable assets (e.g., "ebXML Registry" (http://www.oasis-open.org/committees/tc_home.php?wg_abbrev = regrep)).

Requirements associated with asset provenance can be implemented using a rich set of metadata properties that describe the origin, purpose, evolution, and status of each clinical knowledge asset. The metadata properties should reflect the information that needs to be captured during each phase of the knowledge asset lifecycle process, taking into account multiple iterative authoring and review cycles, followed by a possibly long period of clinical use that might require multiple periodic revisions (updates). Despite the diversity of asset types, each with a potentially distinct lifecycle process, a portion of the metadata properties should be consistently implemented, enabling basic searching and retrieval services across asset types. Ideally, the shared metadata should be based on metadata standards (e.g., "Dublin Core Metadata Element Set" (http://dublincore.org/documents/dces/)). The adoption of standard metadata properties also simplifies the integration of external collections of clinical knowledge assets in a CKR. In addition to a shared set of properties, a CKR should also accommodate extended sets of properties specific for each clinical knowledge asset type and its respective lifecycle process. Discrete namespaces are commonly used to represent type-specific extended metadata properties.

Asset version and status, along with detailed change tracking, are vital requirements for a CKR. Different versioning strategies can be used, but as a general rule there should be only one clinically active version of any given knowledge asset. This general rule is easily observed if the type and purpose of the clinical knowledge asset remains the same throughout its lifecycle. However, a competing goal is created with the very desirable evolution of human-readable assets to become machine-readable. Such evolution invariably requires the creation of new knowledge assets of different types and potentially narrower purposes. In order to support this "natural" evolution, a CKR should implement the concept of asset generations, while preserving the change history that links one generation to the next. Also within a clinical setting, it is not uncommon to have to ensure that knowledge assets comply with, or directly implement, different norms and regulations. As a result, the change history of a clinical knowledge asset should identify the standardization and compliance aspects considered, enabling subsequent auditing and/or eventual certification.

Ensuring the integrity of clinical knowledge assets is yet another vital requirement for a CKR. Proper integrity guarantees that each asset is unique within a specific type and purpose, and that all its required properties are accurately defined. Integrity requirements also take into account the definition and preservation of dependencies between clinical knowledge assets. These dependencies can be manifested as simple hyperlinks, or as integral content defined as another independent asset. Creating clinical knowledge assets from separate components or modules (i.e., modularity) is a very desirable feature in a CKR – one that ultimately contributes to the overall maintainability of the various asset collections. However, modularity introduces important integrity challenges, particularly when a new knowledge asset is being activated for clinical use. Activation for clinical use requires a close examination of all separate components, sometimes triggering unplanned revisions of components already in routine use. Another important integrity requirement is the ability to validate the structure and the content of a clinical knowledge asset against predefined templates (schemas) and dictionaries (ontologies). Asset content validation is essential for optimal integration with clinical information systems. Ideally, within a given healthcare organization all clinical information systems and the CKR should utilize the same standardized ontologies.

Contextual characteristics of the care delivery process establish the requirements associated with proper access, utilization, and presentation of the clinical knowledge assets. The care delivery context is a multidimensional constraint that includes characteristics of the patient (e.g., gender, age group, language, clinical condition), the clinical worker (e.g., discipline, specialty, role), the clinical setting (e.g., inpatient, outpatient, ICU, Emergency Department), and the information system being used (e.g., order entry, documentation, monitoring), among others. The care delivery context normally applies to the entire clinical knowledge asset, directly influencing search, retrieval, and presentation services. The care delivery context can also be used to constrain specific portions of a knowledge asset, including links to other embedded assets, making them accessible only if the constraints are satisfied. An important integrity challenge created by the systematic use of the care delivery context is the need for reconciling conflicts caused by incompatible asset constraints, particularly when different teams maintain the assets being combined. In this scenario, competing requirements are frequently present, namely the intention to maximize modularity and reusability versus the need to maximize clinical specificity and ease or use.

The accurate selection, retrieval, and presentation of unstructured assets is generally perceived as a simple but very useful modality of clinical decision support, particularly if the information presented to the clinical worker is concise and appropriate to the care being delivered. However, the appropriateness of the information is largely defined by the constraints imposed by the aforementioned care delivery context. Moreover, the extent of indexing ("retrievability") of most collections of unstructured clinical knowledge assets is not sufficient to fully recognize detailed care delivery context expressions. Ultimately, the care delivery context provides an extensible mechanism for defining the appropriateness of a given clinical knowledge asset in response to a wide variety of CKR service requests.

The requirements just described are totally or partially implemented as part of general-purpose (enterprise) content management systems. However, content management systems have been traditionally constructed for managing primarily human-readable electronic content. Human-readable content, more properly characterized as unstructured knowledge assets, include narrative text, diagrams, and multimedia objects. When combined, these unstructured assets likely represent the largest portion of the inventory of clinical knowledge assets of any healthcare institution. As a result, in recent years different healthcare organizations have deployed CKRs using enterprise content management systems, despite their inability to manage machine-readable content.

Key Applications

Computerized Clinical Decision Support, Clinical Knowledge Engineering, Clinical Information Systems.

Clinical Nomenclatures

▶ Clinical Ontologies

Clinical Observation

Dan Russler
Oracle Health Sciences, Redwood Shores, CA, USA

Synonyms

Clinical result; Clinical judgment; Clinical test; Finding of observation

Definition

1. The act of measuring, questioning, evaluating, or otherwise observing a patient or a specimen from a patient in healthcare; the act of making a clinical judgment.
2. The result, answer, judgment, or knowledge gained from the act of observing a patient or a specimen from a patient in healthcare.

These two definitions of "observation" have caused confusion in clinical communications, especially when applying the term to the rigor of standardized terminologies. When developing a list of observations, the terminologists have differed on whether the list of terms should refer to the "act of observing" or the "result of the observation."

Logical Observation Identifiers Names and Codes (LOINC) (www.loinc.org) focus on observation as the "act of observing." Systematized Nomenclature of Medicine (SNOMED) (www.ihtsdo.org) asserts that "General finding of observation of patient" is a synonym for "General observation of patient." Of note is the analysis in HL7 that identifies many shared attributes between descriptions of the act of observing and the result obtained. As a consequence, in HL7 Reference Information Model (RIM), both the act of observing and the result of the observation are contained in the same Observation Class (www.hl7.org).

Key Points

The topic of clinical observation has been central to the study of medicine since medicine began. Early physicians focused on the use of all five senses in order to make judgments about the current condition of the patient, i.e., diagnosis, or to make judgments about the future of patients, i.e., prognosis. Physical exam included sight, touch, listening, and smell. Physicians diagnosed diabetes by tasting the urine for sweetness.

As more tests on bodily fluids and tissues were discovered and used, the opportunity for better diagnosis and prognosis increased. Philosophy of science through the centuries often included the study of clinical observation in addition to the study of other observations in nature.

During the last century, the study of rigorous testing techniques that improve the reproducibility and interpretation of results has included the development of extensive nomenclatures for naming the acts of observation and observation results, e.g., LOINC and SNOMED. These terminologies were developed in part to support the safe application of expert system rules to information recorded in the electronic health care record.

The development of the HL7 Reference Information Model (RIM) was based on analysis of the "act of observing" and the "result of the act of observing" [1]. Today, new Entity attributes proposed for the HL7 RIM are evaluated for inclusion based partly on whether the information is best communicated in a new attribute for an HL7 Entity or best communicated in an HL7 Observation Act.

Improved standardization of clinical observation techniques, both in the practice of bedside care and the recording of clinical observations in electronic healthcare systems is thought to be essential to the continuing improvement of healthcare and patient safety.

Clinical Ontologies

Yves A. Lussier, James L. Chen
University of Chicago, Chicago, IL, USA

Synonyms

Clinical terminologies; Clinical nomenclatures; Clinical classifications

Definition

An ontology is a formal representation of a set of heterogeneous concepts. However, in the life sciences, the term clinical ontology has also been more broadly defined as also comprising all forms of classified terminologies, including classifications and nomenclatures. Clinical ontologies provide not only a controlled vocabulary but also relationships among concepts allowing computer reasoning such that different parties, like physicians and insurers, can efficiently answer complex queries.

Historical Background

As the life sciences integrates increasingly sophisticated systems of patient management, different means of data representation have had to keep pace to support user systems. Simultaneously, the explosion of genetic information from breakthroughs from the Human Genome Project and gene chip technology have further expedited the need for robust, scalable platforms for handling heterogeneous data. Multiple solutions have been developed by the scientific community to answer these challenges at all different levels of biology.

This growing field of "systems medicine" starts humbly at the question – how can one best capture and represent complex data in a means that can be understood globally without ambiguity? In other words, does the data captured have the same semantic validity after retrieval as it did prior? These knowledgebases are in of themselves organic. They need to be able to expand, shrink, and rearrange themselves based on user or system needs. This entry will touch upon existing clinical ontologies used in a variety of applications.

Foundations

The complexity of biological data cannot be understated. Issues generally fall into challenges with (i) definition, (ii) context, (iii) composition, and (iv) scale. One cannot even take for granted that the term "genome" is well-understood. Mahner found five different characterizations for the term "genome" [8]. Ontologies then provide a means of providing representational consistency through their structure and equally important provide the ability to connect these terms together in a semantically informative and computationally elegant manner [9]. This has led to their ubiquity in the life sciences. Formal ontologies are designated using frames or description logics [5]. However, few life science knowledgebases are represented completely in this manner due to difficulties with achieving consensus on definitions regarding the terms and the effort required to give context to the terms. Thus, this article defines well-organized nomenclatures and terminologies as clinical ontologies – regardless if their terms adhere to strict formalism.

Looking at elevations in gene expression, it matters what organism and under what experimental conditions the experiment was conducted. Clinical context changes the meaning of terms. The term "cortex" can either indicate a part of the kidney or that of the brain. Generalized or "essential hypertension" can be what is known colloquially as "high blood pressure" or localized to the lungs as "pulmonary hypertension." One can have pulmonary hypertension but not essential hypertension. This leads to the next representational challenge – that of composition. Should hypertension be represented implicitly as "essential hypertension" and as "pulmonary hypertension"? Or should it be stored explicitly as "hypertension" with a location attribute? These representational decisions are driven by the queries that may be asked. The difficulty arises in anticipating the queries and in post-processing of the query to split the terminological components of the overall concept. Finally, the knowledge model needs to be able to scale upward. The same decision logic that was relevant when the knowledgebase contained 100 concepts needs to still be relevant at 1,000,000 concepts.

Properties of Clinical Ontologies

Ontologies vary widely in their degree of formalism and design. With this comes differing computability. In 1998, Cimino proposed desirable properties for purposes of clinical computation [3,4]. Table 1 summarizes the overall properties of the commonly used clinical ontologies.

1. Concept-oriented: a single concept is the preferred unit
2. Formal semantic definition: well-defined terms
3. Nonredundancy: each concept needs to be unique
4. Nonambiguity: different concepts should not overlap or be conflated
5. Relationships: the structure of connections between concepts differentiate ontologies:

- Monohierarchy (tree): each concept only has one parent concept
- Polyhierarchy: each concept may multiply inherit from multiple parents
- Directed Acycle Graph (DAG): there are no cycles in the graph – in other words, children concepts may not point to parent terms

Key Applications

This section reviews different, well-used life science ontologies used to annotate datasets. First, this discussion summarizes a select number of archetypal clinical

Clinical Ontologies. Table 1. Properties of clinical ontologies

	Architecture					
Ontology	Concept oriented	Formal semantic definition	Concept permanence	Nonredundancy	Uniqueness	Relationship
ICD-9	+		±	+	+	M
LOINC	±		+	+		P
CPT	±		±			M
SNOMED	+	+	+	+	+	DAG
UMLS	+		+	+	+	CG

M = Monohierarchy/tree, P = Polyhierarchy, DAG = Directed Acyclic Graph, CG = cyclic graph

Clinical Ontologies. Table 2. Coverage of classification, nomenclatures and ontologies

Ontology	Content						Number of concepts (order of magnitude)
	Diseases	Anatomy	Morphology	Labs	Procedures	Drugs	
ICD-9	X						10^4

ontologies that comprise one or several types of clinical entities such as diseases, clinical findings, procedures, laboratory measurements, and medications. Table 2 below summarizes the content coverage of each of archetypal health ontologies.

Prototypical Clinical Ontologies

a. The Systematized Nomenclature of Medicine (SNOMED CT) SNOMED CT is the most extensive set of publically available collection of clinical concepts. It is organized as a directed acyclic graph (DAG) and contains class/subclass relationships and partonomy relationships. It is maintained by the College of American Pathologists and is available in the United States through a license from the National Library of Medicine in perpetuity. SNOMED CT is one of the designated data standards for use in U.S. Federal Government systems for the electronic exchange of clinical health information. SNOMED CT is now owned by the International Healthcare Terminology Standards Development Organization [6].

b. International Statistical Classification of Diseases (ICD-9, ICD-10, ICD-CM) ICD-9 and ICD 10 are detailed ontologies of disease and symptomatology used ubiquitously for reimbursement systems (i.e., Medicare/Medicaid) and automated decision support in medicine. ICD-10 is used worldwide for morbidity and mortality statistics. Owned by the World Health Organization (WHO), licenses are available generally free for research. ICD-9 CM is a subtype of ICD-9 with clinical modifiers for billing purposes [11].

c. Medical Subject Headings (MeSH) MeSH grew out of an effort by the NLM for indexing life science journal articles and books. {Nelson S.J., 2001 #6}. The extensive controlled vocabulary MeSH serves as the backbone of the MEDLINE/PubMed article database. MeSH can be browsed and downloaded free of charge on the Internet [10].

d. International Classification of Primary Care (ICPC-2, ICPC-2-E) ICPC is a primary care encounter classification system [12]. It has a biaxial structure of 17 clinical systems and 7 types of data. It allows for the classification of the patient's reason for encounter (RFE), the problems/diagnosis managed, primary care interventions, and the ordering of the data. of the primary care session in an episode of care structure. ICPC-2-E refers to a revised electronic version.

e. Diagnostic and Statistical Manual of Mental Disorders (DSM-IV, DSM-V) The DSM is edited and published by the American Psychiatric Association provides categories of and diagnosis criteria for mental disorders [2]. It is used extensively by clinicians, policy makers and insurers. The original version of the DSM was published in 1962. DSM-V is due for publication in May 2012. The diagnosis codes are developed to be compatible with ICD-9.

f. Logical Observation Identifiers Names and Codes (LOINC) LOINC is a database protocol aimed at standardizing laboratory and clinical codes. The Regenstrief Institute, Inc, maintains the LOINC database and supporting documentation. LOINC is endorsed by the American Clinical Laboratory Association and College of American Pathologist and is one of the accepted standards by the US Federal Government for information exchange [7].

g. Current Procedural Terminology (CPT) The CPT code set is owned and maintained by the American Medical Association through the CPT Editorial Panel [1]. The CPT code set is used extensively to communicate medical and diagnostic services that were rendered among physicians and payers. The current version is the CPT 2008.

Clinical Order

Dan Russler
Oracle Health Sciences, Redwood Shores, CA, USA

Synonyms

Order item; Service order; Service request; Service item; Procedure order; Procedure request

Definition

The act of requesting that a service be performed for a patient.

Clinical orders in healthcare share many characteristics with purchase orders in other industries. Both clinical orders and purchase orders establish a customer-provider relationship between the person placing the request for a service to be provided and the person or organization filling the request. In both cases, the clinical order and purchase order are followed by either a promise or intent to fill the request, a decline to fill the request, or a counter-proposal to provide an alternate service. In both scenarios, an authorization step such as an insurance company authorization or a credit company authorization may be required. Therefore, the dynamic flow of communications between a placer and filler in a clinical order management system and a purchase order management system are very similar.

Both clinical order and purchase order management systems maintain a catalog of items that may be requested. These items in both kinds of systems may represent physical items from supply or services from a service provider. Each of these items in both kinds of systems is associated with an internally unique identifier, a text description, and often a code. Dates, status codes, delivery locations, and other attributes of a clinical order and purchase order are also similar. Therefore, in addition to similarities in the dynamic flow of order communications, the structure of the content in clinical orders and purchase orders is similar.

Logical Observation Identifiers Names and Codes (LOINC) (www.loinc.org) describe many of the requested services in healthcare, especially in laboratory systems. Other procedural terminologies exist for healthcare, either independently in terminologies like LOINC or included in more comprehensive terminologies such as Systematized Nomenclature of Medicine (SNOMED) (www.ihtsdo.org).

Key Points

Clinical orders exist in the context of a larger clinical management, process. The order management business process of an organization, that includes defining a catalog of services to be provided and then allowing people to select from the catalog of services, is common in many industries. However, the decision support opportunities for helping providers select the optimum set of services for a patient are often more complex in healthcare than occurs in other industries. The outcomes of this selection process are studied in clinical research, clinical trials on medications and devices, and in organizational quality improvement initiatives. Finally, the outcomes of the service selection process are used to improve the clinical decision support processes utilized by providers selecting services for patients. This business process in healthcare as well as in many other industries describes a circular feedback loop defined by the offering of services, the selection of services, the delivery of services, the outcome of services, and finally, the modification of service selection opportunities and decision support.

In the HL7 Reference Information Model (RIM), "ACT" classes sub-typed with the moodCode attribute support the healthcare improvement process (www.hl7.org). These objects with process "moods" support the sequence of objects created during the execution of a process defined in Business Process Execution Language (BPEL) in a service oriented architecture that begins with an "order", evolves into an "appointment", which then is completed as an "event". The reason the term "mood" is used is that the values of the moodcode attribute are analogous to the models of verbs in many languages, e.g., the "Definition mood" used to define service catalogs corresponds to the "infinitive" verbal mood, i.e., a possible action; the "Request or Order mood" corresponds to the "imperative" verbal mood; the "Event mood" corresponds to the "indicative" verbal mood; and the "Goal mood," which describes the desired outcome of the selected service, corresponds to the "subjunctive" verbal mood.

Closed Itemset Mining and Non-redundant Association Rule Mining

Mohammed J. Zaki
Rensselaer Polytechnic Institute, Troy, NY, USA

Synonyms

Frequent concepts; Rule bases

Definition

Let I be a set of binary-valued attributes, called *items*. A set $X \subseteq I$ is called an *itemset*. A transaction database D is a multiset of itemsets, where each itemset, called a transaction, has a unique identifier, called a tid. The *support* of an itemset X in a dataset D, denoted $sup(X)$, is the fraction of transactions in D where X appears as a subset. X is said to be a *frequent* itemset in D if $sup(X) \geq minsup$, where $minsup$ is a user defined minimum support threshold. An (frequent) itemset is called *closed* if it has no (frequent) superset having the same support.

An *association rule* is an expression $A \Rightarrow B$, where A and B are itemsets, and $A \cap B = \emptyset$. The *support* of the rule is the joint probability of a transaction containing both A and B, given as $sup(A \Rightarrow B) = P(A \wedge B) = sup(A \cup B)$. The *confidence* of a rule is the conditional probability that a transaction contains B, given that it contains A, given as: $conf(A \Rightarrow B) = P(B|A) = \frac{P(A \wedge B)}{P(A)} = \frac{sup(A \cup B)}{sup(A)}$. A rule is frequent if the itemset $A \cup B$ is frequent. A rule is confident if $conf \geq minconf$, where $minconf$ is a user-specified minimum threshold. The aim of non-redundant association rule mining is to generate a *rule basis*, a small, non-redundant set of rules, from which all other association rules can be derived.

Historical Background

The notion of closed itemsets has its origins in the elegant mathematical framework of Formal Concept Analysis (FCA) [3], where they are called *concepts*. The task of mining frequent closed itemsets was independently proposed in [7,11]. Approaches for non-redundant association rule mining were also independently proposed in [1,9]. These approaches rely heavily on the seminal work on rule bases in [5,6]. Efficient algorithms for mining frequent closed itemsets include CHARM [10], CLOSET [8] and several new approaches described in the Frequent Itemset Mining Implementations workshops [4].

Foundations

Let $I = \{i_1, i_2, \ldots, i_m\}$ be the set of items, and let $T = \{t_1, t_2, \ldots, t_n\}$ be the set of tids, the transaction identifiers. Just as a subset of items is called an itemset, a subset of tids is called a tidset. Let $\mathbf{t} : 2^I \rightarrow 2^T$ be a function, defined as follows:

$$\mathbf{t}(X) = \{t \in T \mid X \subseteq \mathbf{i}(t)\}$$

That is, $\mathbf{t}(X)$ is the set of transactions that contain *all* the items in the itemset X. Let $\mathbf{i} : 2^T \rightarrow 2^I$ be a function, defined as follows:

$$\mathbf{i}(Y) = \{i \in I \mid \forall t \in Y,\ t \text{ contains x}\}$$

That is, $\mathbf{i}(T)$ is the set of items that are contained in *all* the tids in the tidset Y. Formally, an itemset X is closed if $\mathbf{i} \circ \mathbf{t}(X) = X$, i.e., if X is a fixed-point of the closure operator $\mathbf{c} = \mathbf{i} \circ \mathbf{t}$. From the properties of the closure operator, one can derive that X is the maximal itemset that is contained in all the transactions $\mathbf{t}(X)$, which gives the simple definition of a closed itemset, namely, a closed itemset is one that has no superset that has the same support.

Based on the discussion above, three main families of itemsets can be distinguished. Let $\mathcal{F}$ denote the set of all frequent itemsets, given as

$$\mathcal{F} = \{X \mid X \subseteq I \text{ and } sup(\mathrm{X}) \geq minsup\}$$

Let $\mathcal{C}$ denote the set of all closed frequent itemsets, given as

$$\mathcal{C} = \{X|X \in \mathcal{F} \text{ and } \nexists \mathrm{Y} \supset \mathrm{X} \text{ with } sup(\mathrm{X}) = sup(\mathrm{Y})\}$$

Finally, let $\mathcal{M}$ denote the set of all *maximal* frequent itemsets, given as

$$\mathcal{M} = \{X|X \in \mathcal{F} \text{ and } \nexists \mathrm{Y} \supset \mathrm{X}, \text{ such that } \mathrm{Y} \in \mathcal{F}\}$$

The following relationship holds between these sets: $\mathcal{M} \subseteq \mathcal{C} \subseteq \mathcal{F}$, which is illustrated in Fig. 1, based on the example dataset shown in Table 1 and using minimum support $minsup = 3$. The *equivalence classes* of itemsets that have the same tidsets have been shown clearly; the largest itemset in each equivalence class is a closed itemset. The figure also shows that the maximal itemsets are a subset of the closed itemsets.

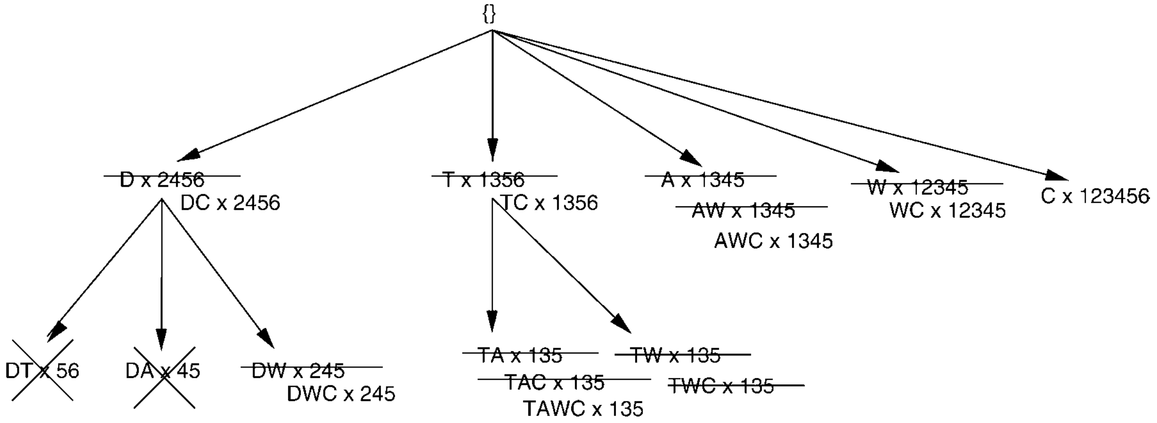
Mining Closed Frequent Itemsets

CHARM [8] is an efficient algorithm for mining closed itemsets. Define two itemsets X, Y of length k as belonging to the same *prefix equivalence class*, $[P]$, if they share the $k - 1$ length prefix P, i.e., $X = Px$ and $Y = Py$, where $x,y \in I$. More formally, $[P] = \{Px_i \mid x_i \in I\}$, is the class of all itemsets sharing P as a common prefix. In CHARM there is no distinct candidate generation and support counting phase. Rather, counting is simultaneous with candidate generation. For a given prefix class, one performs intersections of the tidsets ofall pairs of itemsets in the class, and checks if the resulting tidsets have cardinality at least *minsup*. Each resulting frequent itemset generates a new class which will be expanded in the next step. That is, for a given class of itemsets with prefix P, $[P] = \{Px_1, Px_2, ..., Px_n\}$, one performs the intersection of Px_i with all Px_j with $j > i$ to obtain a new class $[Px_i] = [P']$ with elements $P'x_j$ provided the itemset Px_ix_j is frequent. The computation progresses recursively until no more frequent itemsets are produced. The initial invocation is with the class of frequent single items (the class $[\emptyset]$). All tidset intersections for pairs of class elements are computed. However in addition to checking for frequency, CHARM eliminates branches that cannot lead to closed sets, and grows closed itemsets using subset relationships among tidsets. There are four cases: if $\mathbf{t}(X_i) \subset \mathbf{t}(X_j)$ or if $\mathbf{t}(X_i) = \mathbf{t}(X_j)$, then replace every occurrence of X_i with $X_i \cup X_j$, since whenever X_i occurs X_j also occurs, which implies that $\mathbf{c}(X_i) \subseteq \mathbf{c}(X_i \cup X_j)$. If $\mathbf{t}(X_i) \supset \mathbf{t}(X_j)$ then replace X_j for the same reason. Finally, further recursion is required if $\mathbf{t}(X_i) \neq \mathbf{t}(X_j)$. These four properties allow CHARM to efficiently prune the search tree (for additional details see [10]).

Figure 2 shows how CHARM works on the example database shown in Table 1. First, CHARM sorts the items in increasing order of support, and initializes the root class as $[\emptyset] = \{D \times 2456,\ T \times 1356,\ A \times 1345,\ W \times 12345,\ C \times 123456\}$. The notation $D \times 2456$ stands for the itemset D and its tidset $\mathbf{t}(D) = \{2,4,5,6\}$. CHARM first processes the node $D \times 2456$; it will be combined with the sibling elements. DT and DA are not frequent and are thus pruned. Looking at W, since $\mathbf{t}(D) \neq \mathbf{t}(W)$, W is inserted in the new equivalence class $[D]$. For C, since $\mathbf{t}(D) \subset \mathbf{t}(C)$, all occurrences of D are replaced with DC, which means that $[D]$ is also changed to $[DC]$, and the element DW to DWC. A recursive call with class $[DC]$ is then made and since



Closed Itemset Mining and Non-redundant Association Rule Mining. Figure 2. CHARM: mining closed frequent itemsets.

there is only a single itemset *DWC*, it is added to the set of closed itemsets $\mathcal{C}$. When the call returns to *D* (i.e., *DC*) all elements in the class have been processed, so *DC* itself is added to $\mathcal{C}$.

When processing *T*, $\mathbf{t}(T) \neq \mathbf{t}(A)$, and thus CHARM inserts *A* in the new class $[T]$. Next it finds that $\mathbf{t}(T) \neq \mathbf{t}(W)$ and updates $[T] = \{A,W\}$. When it finds $\mathbf{t}(T) \subset \mathbf{t}(C)$ it updates all occurrences of *T*with *TC*. The class $[T]$ becomes $[TC] = \{A,W\}$. CHARM then makes a recursive call to process $[TC]$. When combining *TAC* with *TWC* it finds $\mathbf{t}(TAC) = \mathbf{t}(TWC)$, and thus replaces *TAC* with *TACW*, deleting *TWC* at the same time. Since *TACW* cannot be extended further, it is inserted in $\mathcal{C}$. Finally, when it is done processing the branch *TC*, it too is added to $\mathcal{C}$. Since $\mathbf{t}(A) \subset \mathbf{t}(W) \subset \mathbf{t}(C)$ no new recursion is made; the final set of closed itemsets $\mathcal{C}$ consists of the uncrossed itemsets shown in Fig. 2.

Non-redundant Association Rules

Given the set of closed frequent itemsets $\mathcal{C}$, one can generate all non-redundant association rules. There are two main classes of rules: (i) those that have 100% confidence, and (ii) those that have less than 100% confidence [9]. Let X_1 and X_2 be closed frequent itemsets. The 100% confidence rules are equivalent to those directed from X_1 to X_2, where $X_2 \subseteq X_1$, i.e., from a superset to a subset (not necessarily proper subset). For example, the rule $C \Rightarrow W$ is equivalent to the rule between the closed itemsets $\mathbf{c}(W) \Rightarrow \mathbf{c}(C) \equiv CW \Rightarrow C$. Its support is $sup(CW) = 5/6$, and its confidence is $\frac{sup(CW)}{sup(W)} = 5/5 = 1$, i.e., 100%. The less than 100% confidence rules are equivalent to those from X_1 to X_2 where $X_1 \subset X_2$, i.e., from a subset to a proper superset. For example, the rule $W \Rightarrow T$ is equivalent to the rule $\mathbf{c}(W) \Rightarrow \mathbf{c}(W \cup T) \equiv CW \Rightarrow ACTW$. Its support is $sup(TW) = 3/6 = 0.5$, and its confidence is $\frac{sup(TW)}{sup(W)} = 3/5 = 0.6$ or 60%. More details on how to generate these non-redundant rules appears in [9].

Key Applications

Closed itemsets provide a loss-less representation of the set of all frequent itemsets; they allow one to determine not only the frequent sets but also their exact support. At the same time they can be orders of magnitude fewer. Likewise, the non-redundant rules provide a much smaller, and manageable, set of rules, from which all other rules can be derived. There are numerous applications of these methods, such as market basket analysis, web usage mining, gene expression pattern mining, and so on.

Future Directions

Closed itemset mining has inspired a lot of subsequent research in mining compressed representations or summaries of the set of frequent patterns; see [2] for a survey of these approaches. Mining compressed pattern bases remains an active area of study.

Experimental Results

A number of algorithms have been proposed to mine frequent closed itemsets, and to extract non-redundant rule bases. The Frequent Itemset Mining Implementations (FIMI) Repository contains links to many of the latest implementations for mining closed itemsets. A report on the comparison of these methods also appears in [4]. Other implementations can be obtained from individual author's websites.

Data Sets

The FIMI repository has a number of real and synthetic datasets used in various studies on closed itemset mining.

Url to Code

The main FIMI website is at http://fimi.cs.helsinki.fi/, which is also mirrored at: http://www.cs.rpi.edu/~zaki/FIMI/

Closest Pairs

▶ Closest-Pair Query

Closest-Pair Query

Antonio Corral[1], Michael Vassilakopoulos[2]
[1]University of Almeria, Almeria, Spain
[2]University of Central Greece, Lamia, Greece

Synonyms

Closest pairs; k-Closest pair query; k-Distance join; Incremental k-distance join; k-Closest pair join

Definition

Given two sets P and Q of objects, a closest pair (CP) query discovers the pair of objects (p, q) with a distance that is the smallest among all object pairs in the Cartesian product P×Q. Similarly, a k closest pair query (k-CPQ) retrieves k pairs of objects from P and Q with the minimum distances among all the object pairs. In spatial databases, the distance is usually defined according to the Euclidean metric, and the set of objects P and Q are disk-resident. Query algorithms aim at minimizing the processing cost and the number of I/O operations, by using several optimization techniques for pruning the search space.

Historical Background

The closest pair query, has been widely studied in computational geometry. More recently, this problem has been approached in the context of spatial databases [4,8,12,14]. In spatial databases, existing algorithms assume that P and Q are indexed by a spatial access method (usually an R-tree [1]) and utilize some pruning bounds and heuristics to restrict the search space.

[8] was the first to address this issue, and proposed the following distance-based algorithms: incremental distance join, k distance join and k distance semijoin between two R-tree indices. The incremental processing reports one-by-one the desired elements of the result in ascending order of distance (k is unknown in advance and the user can stop when he/she is satisfied by the result). The algorithms follow the Best-First (BF) traversal policy, which keeps a heap with the entries of the nodes visited so far (it maintains a priority queue which contains pairs of index entries

and objects, and pop out the closest pair and process it). BF is near-optimal for CP queries; i.e., it only visits the pairs of nodes necessary for obtaining the result with a high probability. In [12] several modifications to the algorithms of [8] had been proposed in order to improve performance. Mainly, a method was proposed for selecting the sweep axis and direction for the plane sweep technique in bidirectional node expansion which minimizes the computational overhead of [8].

Later, an improved version of BF and several algorithms that follow Depth-First (DF) traversal ordering from the non-incremental point of view (which assumes that k is known in advance and reports the k elements of the result all together at the end of the algorithm) was proposed in [4]. In general, a DF algorithm visit the roots of the two R-trees and recursively follows the pair of entries $< E_P, E_Q >$, $E_P \in R_P$ and $E_Q \in R_Q$, whose MINMINDIST is the minimum distance among all pairs. At the opposite of BF, DF is sub-optimal, i.e., it accesses more nodes than necessary. The main disadvantage of BF with respect to DF is that it may suffer from buffer thrashing if the available memory is not enough for the heap (it is space-consuming), when a great quantity of elements of the result is required. In this case, part of the heap must be migrated to disk, incurring frequent I/O accesses. The implementation of DF is by recursion, which is available in most of the programming languages, and linear-space consuming with respect to the height of the R-trees. Moreover, BF is not favored by page replacement policies (e.g., LRU), as it does not exhibit locality between I/O accesses.

Another interesting contribution to the CP query was proposed by [14], in which a new structure called the b-Rdnn tree was presented, along with a better solution to the k-CP query when there is high overlap between the two datasets. The main idea is to find k objects from each dataset which are the closest to the other dataset.

There are a lot of papers related to k-CP query, like buffer query [3], iceberg distance join query [13], multi-way distance join query [6], k-nearest neighbor join [2], closest pair query with spatial constraints [11], etc. For example, a buffer query [3] involves two spatial datasets and a distance threshold ρ; the answer to this query is a set of pairs of spatial objects, one from each input dataset, that are within distance ρ of each other.

Foundations

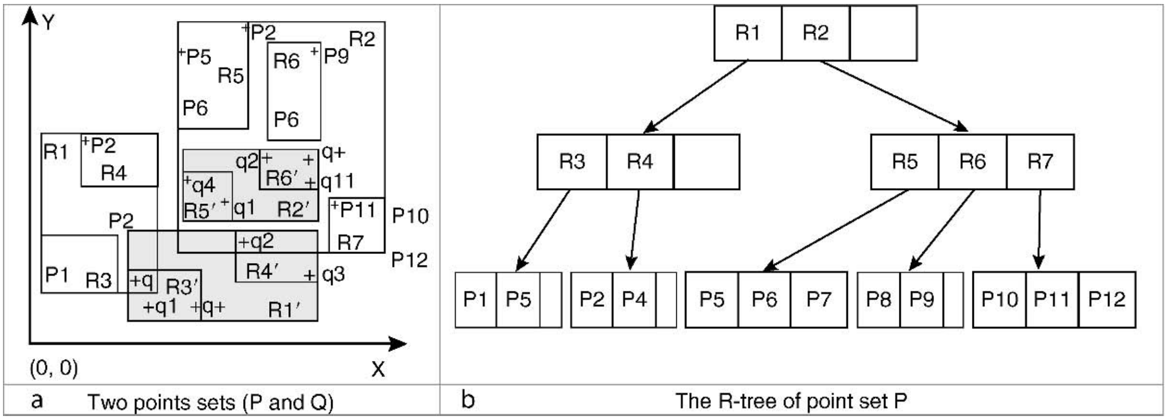
In spatial databases, existing algorithms assume that sets of spatial objects are indexed by a spatial access method (usually an R-tree [1]) and utilize some pruning bounds to restrict the search space. An R-tree is a hierarchical, height balanced multidimensional data structure, designed to be used in secondary storage based on B-trees. The R-trees are considered as excellent choices for indexing various kinds of spatial data (points, rectangles, line-segments, polygons, etc.). They are used for the dynamic organization of a set of spatial objects approximated by their Minimum Bounding Rectangles (MBRs). These MBRs are characterized by *min* and *max* points of rectangles with faces parallel to the coordinate axis. Using the MBR instead of the exact geometrical representation of the object, its representational complexity is reduced to two points where the most important features of the spatial object (position and extension) are maintained. The R-trees belong to the category of data-driven access methods, since their structure adapts itself to the MBRs distribution in the space (i.e., the partitioning adapts to the object distribution in the embedding space). Figure 1a shows two points sets P and Q (and the node extents), where the closest pair is (p_8, q_8), and Fig. 1b is the R-tree for the point set $P = \{p_1, p_2, \ldots, p_{12}\}$ with a capacity of three entries per node (branching factor or fan-out).

Assuming that the spatial datasets are indexed on any spatial tree-like structure belonging to the R-tree family, then the main objective while answering these types of spatial queries is to reduce the search space. In [5], three MBR-based distance functions to be used in algorithms for CP queries were formally defined, as an extension of the work presented in [4]. These metrics are MINMINDIST, MINMAXDIST and MAXMAXDIST. MINMINDIST (M_1, M_2) between two MBRs is the minimum possible distance between any point in the first MBR and any point in the second MBR. Maxmaxdist between two MBRs (M_1, M_2) is the maximum possible distance between any point in the first MBR and any point in the second MBR. Finally, MINMAXDIST between two MBRs (M_1, M_2) is the minimum of the maximum distance values of all the pairs of orthogonal faces to each dimension. Formally, they are defined as follows:

Given two MBRs $M_1 = (a, b)$ and $M_2 = (c, d)$, in the d-dimensional Euclidean space,

$M_1 = (a, b)$, where $a = (a_1, a_2, \ldots, a_d)$ and $b = (b_1, b_2, \ldots, b_d)$ such that $a_i \leq b_i$ $1 \leq i \leq d$

$M_2 = (c, d)$, where $c = (c_1, c_2, \ldots, c_d)$ and $d = (d_1, d_2, \ldots, d_d)$ such that $a_i \leq b_i$ $1 \leq i \leq d$



a Two points sets (P and Q)

b The R-tree of point set P

Closest-Pair Query. Figure 1. Example of an R-tree and a point CP query.

the MBR-based distance functions are defined as follows:

$$MINMINDIST(M_1, M_2) = \sqrt{\sum_{i=1}^{d} \begin{cases} (c_i - b_i)^2, & c_i > b_i \\ (a_i - d_i)^2, & a_i > d_i \\ 0, & otherwise \end{cases}}$$

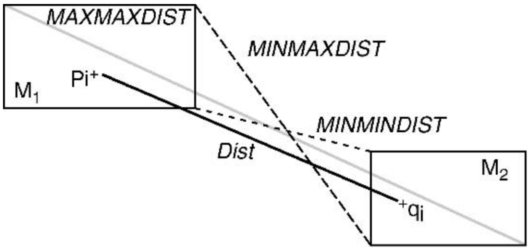
$$MAXMAXDIST(M_1, M_2) = \sqrt{\sum_{i=1}^{d} \begin{cases} (d_i - a_i)^2, & c_i > b_i \\ (b_i - c_i)^2, & a_i > d_i \\ \max\{(d_i - a_i)^2, (b_i - c_i)^2\}, & otherwise \end{cases}} .$$

$$MINMAXDIST(M_1, M_2) = \sqrt{\min_{1 \le j \le d} \left\{ x_j^2 + \sum_{i=1, i \ne j}^{d} y_i^2 \right\}}$$

where

$$x_j = \min\{|a_j - c_j|, |a_j - d_j|, |b_j - c_j|, |b_j - d_j|\} \text{and}$$
$$y_i = \max\{|a_i - d_i|, |b_i - c_i|\}$$

To illustrate the distance functions MINMINDIST, MINMAXDIST and MAXMAXDIST which are the basis of query algorithms for CPQ, in Fig. 2, two MBRs and their MBR-based distance functions and their relation with the distance (dist) between two points (p_i, q_j) are depicted in 2-dimensional Euclidean space.



Closest-Pair Query. Figure 2. MBR-based distance functions in 2-dimensional Euclidean space.

According to [5], MINMINDIST(M_1,M_2) is monotonically non-decreasing with the R-tree heights. MINMINDIST(M_1,M_2) and MAXMAXDIST(M_1, M_2) serve respectively as lower and upper bounding functions of the Euclidean distance from the k closest pairs of spatial objects within the MBRs M_1, and M_2. In the same sense, MINMAXDIST(M_1, M_2) serves as an upper bounding function of the Euclidean distance from the closest pair of spatial objects enclosed by the MBRs M_1 and M_2. As long as the distance functions are consistent, the branch-bound algorithms based on them will work correctly [5].

Moreover, the general pruning mechanism for k-CP queries over R-tree nodes using branch-and-bound algorithms is the following: *if MINMINDIST (M_1, M_2) > z, then the pair of MBRs (M_1, M_2) will be discarded*, where *z* is the distance value of the k-th closest pair that has been found so far (during the processing of the algorithm), or the distance value of the k-th largest MAXMAXDIST found so far (*z* is also called as the pruning distance).

Branch-and-bound algorithms can be designed following DF or BF traversal ordering (Breadth-First traversal order (level-by-level) can also be implemented, but the processing of each level must follow a BF order) to report k closest pairs in non-incremental way (for incremental processing the ordering of traversal must be BF [8]).

As an example, Fig. 3 shows the BF k-CPQ algorithm for two R-trees, for the non-incremental processing version. This algorithm needs to keep a minimum binary heap (H) with the references to pairs of internal nodes (characterized by their MBRs) accessed so far from the two different R-trees and their minimum distance (<MINMINDIST, $\mathrm{Addr}_{\mathrm{MPi}}$, $\mathrm{Addr}_{\mathrm{MQj}}$>). It visits the pair of MBRs (nodes) with the minimum MINMINDIST in H, until it becomes empty or the MINMINDIST value of the pair of MBRs located in the root of H is larger than the distance value of the k-th closest pair that has been found so far (z). To keep track of z, an additional data structure that stores the k closest pairs discovered during the processing of the algorithm is needed. This data structure is organized as a maximum binary heap (k-heap) and holds pairs of objects according to their minimum distance (the pair with the largest distance resides in the root). In the implementation of k-CPQ algorithm, the following cases must be considered: (i) initially the k-heap is empty (z is initialized to ∞), (ii) the pairs of objects reached at the leaf level are inserted in the k-heap until it gets full (z keeps the value of ∞), (iii) if the distance of a new pair of objects discovered at the leaf level is smaller than the distance of the pair residing in the k-heap root, then the root is extracted and the new pair is inserted in the k-heap, updating this data structure and z (distance of the pair of objects residing in the k-heap root).

Several optimizations had been proposed in order to improve performance, mainly with respect to the CPU cost. For instance, a method for selecting the sweep axis and direction for the plane sweep technique has been proposed [12]. But the most important optimization is the use of the plane-sweep technique for k-CPQ [5,12], which is a common technique for computing intersections. The basic idea is to move a sweep-line perpendicular to one of the dimensions, so-called the sweeping dimension, from left to right. This technique is applied for restricting all possible combinations of pairs of MBRs from two R-tree nodes from R_P

```
Create and initialize H, k-heap, z = ∞;
for each pair of MBRs <$M_{Pi}$, $M_{Qj}$> in <$root_{RP}$, $root_{RQ}$> do
      H.insert(MINMINDIST($M_{Pi}$, $M_{Qj}$), $Addr_{MPi}$, $Addr_{MQj}$);
enddo
While (not H.isEmpty()) and (H.MinimumDistance() ≤ z) do
      minimum = H.deleteMinimum();
      $node_{RP}$ = RP.readNode(minimum.$Addr_{MP}$);
      $node_{RQ}$ = RQ.readNode(minimum.$Addr_{MQ}$);
      if ($node_{RP}$ and $node_{RQ}$ are internal nodes) then
           for each pair of MBRs <$M_{Pi}$, $M_{Qj}$> in < $node_{RP}$, $node_{RQ}$> do
                if (MINMINDIST($M_{Pi}$, $M_{Qj}$) ≤ z) then
                  H.insert(MINMINDIST($M_{Pi}$, $M_{Qj}$), $Addr_{MPi}$, $Addr_{MQj}$);
                endif
           enddo
      else
         for each pair of points <$p_i$, $q_j$> in <$node_{RP}$, $node_{RQ}$> do
           distance = dist($p_i$, $q_j$);
           if (k-heap.isFull()) then
              if (distance ≤ z) then
                 k-heap.delete Maximum();
                 k-heap.insert(distance, $p_i$, $q_j$);
                 z = k-heap.get Maximum();
              endif
           else
              k-heap.insert(distance, $p_i$, $q_j$);
           endif
         enddo
      endif
endod
Destroy H;
```

Closest-Pair Query. Figure 3. Best-First k-CPQ Algorithm using R–trees.

and R_Q. If this technique is not used, then a set with all possible combinations of pairs of MBRs from two R-tree nodes must be created. In general, the technique consists in sorting the MBRs of the two current R-tree nodes, based on the coordinates of one of the lower left corners of the MBRs in increasing order. Each MBR encountered during a plane sweep is selected as a pivot, and it is paired up with the non-processed MBRs in the other R-tree node from left to right. The pairs of MBRs with MINMINDIST on the sweeping dimension that are less than or equal to z (pruning distance) are selected for processing. After all possible pairs of MBRs that contain the pivot have been found, the pivot is updated with the MBR of the next smallest value of a lower left corner of MBRs on the sweeping dimension, and the process is repeated. In summary, the application of this technique can be viewed as a *sliding window* on the sweeping dimension with a width of z starting in the lower end of the pivot MBR, where all possible pairs of MBRs that can be formed using the MBR of the pivot and the other MBRs from the remainder entries of the other R-tree node that fall into the current sliding window are chosen. For example, in Fig. 4, a set of MBRs from two R-tree nodes ({M_{P1}, M_{P2}, M_{P3}, M_{P4}, M_{P5}, M_{P6}} and {M_{Q1}, M_{Q2}, M_{Q3}, M_{Q4}, M_{Q5}, M_{Q6}, M_{Q7}}) is shown. Without plane-sweep, 6*7 = 42 pairs of MBRs must be generated. If the plane-sweep technique is applied over the X axis (sweeping dimension) and taking into account the distance value of z (pruning distance), this number of possible pairs will reduced considerably (the number of selected pairs of MBRs using the plane sweep technique is only 29).

Key Applications

Geographical Information Systems

Closest pair is a common distance-based query in the spatial database context, and it has only recently received special attention. Efficient algorithms are important for dealing with the large amount of spatial data in several GIS applications. For example, k-CPQ can discover the K closest pairs of cities and cultural landmarks providing an increase order based on its distances.

Data Analysis

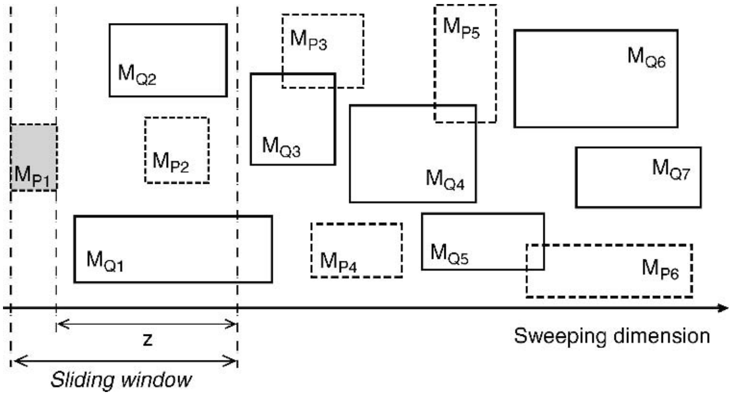
Closest pair queries have been considered as a core module of clustering. For example, a proposed clustering algorithm [10] owes its efficiency to the use of closest pair query, as opposed to previous quadratic-cost approaches.

Decision Making

A number of decision support tasks can be modeled as closest pairs query. For instance, find the top k factory-house pairs ordered by the closeness to one another. This gives us a measure of the effect of individual factory on individual household, and can give workers a priority to which factory to address first.

Future Directions

k-closest pair query is a useful type of query in many practical applications involving spatial data, and the traditional technique to handle this spatial query generally assumes that the objects are static. Objects represented as a function of time have been studied in other domains, as in spatial semijoin [9]. For this reason,



Closest-Pair Query. Figure 4. Using plane-sweep technique over MBRs from two R-tree nodes.

closest pair query in spatio-temporal databases could be an interesting line of research.

Another interesting problem to study is the monitoring of k-closest pairs over moving objects. It aims at maintaining closest pairs results while the underlying objects change the positions [15]. For example, return k pairs of taxi stands and taxies that have the smallest distances.

Other interesting topics to consider (from the static point of view) are to study k-CPQ between different spatial data structures (Linear Region Quadtrees for raster and R-trees for vector data), and to investigate k-CPQ in non-Euclidean spaces (e.g., road networks).

Experimental Results

In general, for every presented method, there is an accompanying experimental evaluation in the corresponding reference. [4,5,8] compare BF and DF traversal order for conventional k-CPQ (from the incremental and non-incremental point of view). In [7], a cost model for k-CPQ using R-trees was proposed, evaluating their accuracy. Moreover, experimental results on k-closest pair queries to support the fact that b-Rdnn tree is a better alternative with respect to the R*-trees, when there is high overlap between the two datasets, were presented in [14].

Data Sets

A large collection of real datasets, commonly used for experiments, can be found at: http://www.rtreeportal.org/

URL to Code

R-tree portal (see above) contains the code for most common spatial access methods (mainly R-tree and variations), as well as data generators and several useful links for researchers and practitioners in spatial databases.

Clustering

Clustering is the assignment of objects to groups of similar objects (clusters). The objects are typically described as vectors of features (also called attributes). So if one has *n* attributes, object **x** is described as a vector $(x_1,..,x_n)$. Attributes can be numerical (scalar) or categorical. The assignment can be hard, where each object belongs to one cluster, or fuzzy, where an object can belong to several clusters with a probability. The clusters can be overlapping, though typically they are disjoint. Fundamental in the clustering process is the use of a distance measure.

Distance Measure

In the clustering setting, a distance (or equivalently a similarity) measure is a function that quantifies the similarity between two objects.

Key Points

The choice of a distance measure depends on the nature of the data, and the expected outcome of the clustering process. The most important consideration is the type of the features of the objects. One first focuses on distance measures when the features are all numerical. This includes features with continuous values (real numbers) or discrete values (integers). In this case, typical choices include:

1. The L_p norm. It is defined as $D(\mathbf{x},\mathbf{y}) = \left(\sum_{1\leq i\leq n}(X_1 - Y_1)^p\right)^{1/p}$. Typically p is 2 (the intuitive and therefore widely used Euclidean distance), or 1 (the Manhattan or city block distance), or infinity (the Maximum distance).
2. The Mahalanobis distance. It is defined as $D(\mathbf{x},\mathbf{y}) = (\mathbf{x}-\mathbf{y})\sum^{-1}(\mathbf{x}-\mathbf{y})^T$which generalizes the Euclidean and allows the assignment of different weights to different features.
3. The angle between two vectors, computed using the inner product of two vectors $\mathbf{x}\cdot\mathbf{y}$.
4. The Hamming distance, which measures the number of disagreements between two binary vectors.

In different settings different distance measures can be used. The edit, or Levenshtein, distance, is an extension of the Hamming distance, and is typically used for measuring the distance between two strings of characters. The edit distance is defined as the minimum number of insertions, deletions or substitutions that it takes to transform one sting to another.

When two time series are compared, the Dynamic Time Warping distance measure is often used to quantify their distance. The length of the Longest Common Subsequence (LCSS) of two time series is also frequently used to provide a similarity measure between the time series. LCSS is a similarity measure because the longest common subsequence becomes longer when two time series are more similar. To create a distance measure, LCSS is typically normalized by dividing by the length of the longest of the two sequences, and then subtracting the ratio from one.

Finally, when sets of objects are compared, the Jaccard coefficient is typically used to compute their distance. The Jaccard coefficient of sets A and B is defined as $J(A,B) = |A \cap B| / |A \cup B|$, that is, the fraction of the common elements over the union of the two sets.

The majority of the distance measures used in practice, and indeed most of the ones described above are metrics. Formally, a distance measure D is a metric if it obeys the following properties:

For objects A, B, (i) D(A,B)\geq 0, (ii) D(A,B) = 0 if and only if A = B, and (iii) D(A,B) = D(B,A), and (iv) for any objects A,B,C, D(A,B) + D(B,C)\geq D(A,C) (triangle inequality).

Most distance measures can be trivially shown to observe the first three properties, but do not necessarily observe the triangle inequality. For example, the constrained Dynamic Time Warping distance, a typically used measure to compute the similarity between time series which does not allow arbitrary stretching of a time series, is not a metric because it does not satisfy the triangle inequality. Experimental results have shown that the constrained Dynamic Time Warping distance performs at least as good as the unconstrained one and it is also faster to compute, thus justifying its use although it is not a metric. Note however that, if it is so required, any distance measure can be converted into a metric by taking the shortest path between objects A and B in the complete graph where each object is a node and each edge is weighted by the distance between the two nodes.

Document clustering

Definition

Clustering is a technique that allows similar objects to be grouped together based on common attributes. It has been used in information retrieval for different retrieval process tasks and objects of interest (e.g., documents, authors, index terms). Attributes used for clustering may include assigned terms within documents and their co-occurrences, the documents themselves if the focus is on index terms, or linkages (e.g., hypertext links of Web documents, citations or co-citations within documents, documents accessed). Clustering in IR facilitates browsing and assessment of retrieved documents for relevance and may reveal unexpected relationships among the clustered objects.

Historical Background

A fundamental challenge of information retrieval (IR) that continues today is how to best match user queries with documents in a queried collection. Many mathematical models have been developed over the years to facilitate the matching process. The details of the matching process are usually hidden from the user, who is only presented with an outcome. Once a set of candidate documents has been identified, they are presented to the user for perusal. Traditional approaches have relied on ordered linear lists of documents based on calculated relevance or another sequencing criterion (e.g., date, alphabetical by title or author). The resulting linear list addresses the assessed relationship of documents to queries, but not the relationships of the documents themselves. Clustering techniques can reduce this limitation by creating groups of documents (or other objects of interest) to facilitate more efficient retrieval or perusal and evaluation of retrieved sets.

The application of clustering techniques to IR extends back to some of the earliest experimental IR systems including Gerard Salton's SMART system, which relied on document cluster identification within a vector space as a means of quickly identifying sets of relevant documents. The rationale for applying clustering was formalized as the “cluster hypothesis,” proposed by Jardine and van Rijsbergen [6]. This hypothesis proposes that documents that are relevant to a query are more similar to each other than to documents that are not relevant to the query. The manifestation of this relationship can be represented in different ways by grouping like documents or, more recently, visualizing the relationships and resulting proximities in a multidimensional space.

Early applications of clustering emphasized its use to more efficiently identify groups of related, relevant documents and to improve search techniques. The computational burden associated with real-time cluster identification during searches on increasingly larger data corpora and the resulting lackluster performance improvements have caused clustering to lose favor as a primary mechanism for retrieval. However, clustering methods continue to be studied and used today (see, for example, [7]). Much of the recent research into clustering for information retrieval has focused on other areas that support the retrieval process. For instance, clustering has been used to assist in query expansion, where additional terms for retrieval may be identified. Clustering of similar terms can be used to construct thesauri, which can be used to index documents [3].

Recent research on clustering has highlighted its benefits for post hoc retrieval tasks, in particular for the presentation of search results to better model user and usage behavior. The focus of applications presented here is on these post hoc IR tasks, dealing with effective representation of groups of objects once identified to support exploratory browsing and to provide a greater understanding of users and system usage for future IR system development.

Foundations

Methods used to identify clusters are based on cluster analysis, a multivariate exploratory statistical technique. Cluster analysis relies on similarities or differences in object attributes and their values. The granularity of the analysis and the validity of the resulting groups are dependent on the range of attributes and values associated with objects of interest. For IR applications, clusters are based on common occurrences and weights of assigned terms for documents, the use of query terms, or linkages between objects of interest represented as hypertext linkages or citations/co-citations.

Clustering techniques can be divided into hierarchical and non-hierarchical approaches. Non-hierarchical clustering methods require that a priori assumptions be made about the nature and number of clusters, but can be useful if specific cluster parameters are sought. Hierarchical clustering, which is more commonly used, begins with many small groups of objects that serve as initial clusters. Existing groups are clustered into larger groups until only one cluster remains. Visually, the structure and relationship of clusters may be represented as a dendrogram, with different cluster agglomerations at different levels on the dendrogram representing the strength of relationship between clusters. Other visualization techniques may be applied and are covered elsewhere. In hierarchical methods, the shorter the agglomerative distance, the closer the relationship and the more similar the clusters are. As an exploratory technique, there is no universally accepted algorithm to conduct the analysis, but the general steps for conducting the analysis are similar. First, a similarity measure is applied to the object attributes, which serves as the basis for pairwise comparisons. Standard similarity or distance measures applied in IR research such as the Euclidean distance, cosine measure, Jaccard coefficient, and Dice coefficient can be used. Next, a method for cluster determination is selected. Common methods include: single complete linkage, average linkage, nearest neighbor, furthest neighbor, centroid clustering (representing the average characteristics of objects within a cluster), and Ward’s method. Each method uses a different algorithm to assess cluster membership and may be found to be more appropriate in given circumstances. Outcomes can vary significantly depending on the method used. This flexibility underscores one of the challenges for effectively implementing cluster analysis. With no one correct or accepted way to conduct the analysis, outcomes are open to interpretation, but may be viewed as equally valid. For example, single linkage clustering, which links pairs of objects that most closely resemble one another, is comparatively simple to implement and has been widely used, but can result in lengthy linear chains of clusters. Parameters may need to be specified that dictate the minimum size of clusters to avoid situations where there are large orders of difference in cluster membership. Another challenge inherent in clustering is that different clustering algorithms can produce similar numbers of clusters, but if some clusters contain few members, this does little to disambiguate the members within large clusters. The number of clusters that partition the object set can be variable in hierarchical clustering. More clusters result in fewer objects per cluster with greater inter-object similarity, but with potentially more groups to assess. It is possible to test for an optimal number of clusters using various measures that calculate how differing numbers of clusters affect cluster cohesiveness.

Clustering may be implemented in dynamic environments by referencing routines based on specific clustering algorithms developed by researchers or through specialty clustering packages. Details on clustering algorithms for information retrieval can be found in Rasmussen [8]. Standard statistical and mathematical software packages such as SAS and SPSS also support a range of clustering algorithms. Special algorithms may need to be applied to very large datasets to reduce computational overhead, which can be substantial for some algorithms.

Key Applications

In addition to early applications of clustering for improving retrieval efficiency, clustering techniques in IR have included retrieval results presentation, and modeling of IR user and usage characteristics based on transactions logs. Although largely a topic of research interest, some applications have found their way into commercial systems. Clustering of search results has been applied by several Web-based search services since the late 1990s, some of which are no longer available. Most notable of the current generation is Clusty (clusty.com), which organizes retrieval results from several search services around topical themes.

The application of clustering to support interactive browsing has been an active area of investigation in recent years. Among the earliest demonstrations for this purpose was the Scatter/Gather method outlined by Cutting et al. [4], in which the authors demonstrated how clustering of retrieved items can facilitate browsing for vaguely defined information needs. This approach was developed to serve as a complement to more focused techniques for retrieval assessment. In application, the method presents users with a set of clusters that serves as the starting point for browsing. The user selects the clusters of greatest interest. The contents of those clusters are then gathered into a single cluster, which now serves as the corpus for a new round of clustering, into which the new smaller corpus of items is scattered. The process continues until the user's information need is met or the user abandons the search. To support real time clustering of datasets, the authors developed an efficient clustering algorithm, called buckshot, plus a more accurate algorithm, called fractionation, to permit more detailed clustering in offline environments where a timely response is less critical. Another algorithm, called cluster digest, was used to encapsulate the topicality of a given cluster based on the highest weighted terms within the cluster. Hearst and Pedersen [5] evaluated the efficacy of Scatter/Gather on the top-ranked retrieval outcomes of a large dataset, and tested the validity of the cluster hypothesis. The authors compared the number of known relevant items to those appearing in the generated clusters. A user study was also conducted, which demonstrated that participants were able to effectively navigate and interact with the system incorporating Scatter/Gather.

Increasingly, IR systems provide access to heterogeneous collections of documents. The question arises whether the cluster hypothesis, and the benefits of capitalizing on its attributes, extends to the distributed IR environment, where additional challenges include the merger of different representations of documents and identification of multiple occurrences of documents across the federated datasets. Crestani and Wu [2] conducted an experimental study to determine whether the cluster hypothesis holds in a distributed environment. They simulated a distributed environment by using different combinations of retrieval environments and document representation heterogeneity, with the most sophisticated implementation representing three different IR environments with three different collections. Results of the different collections and systems were clustered and compared. The authors concluded that the cluster hypothesis largely holds true in distributed environments, but fails when brief surrogates of full text documents are used.

With the growing availability of large IR system transaction logs, clustering methods have been used to identify user and usage patterns. By better understanding patterns in usage behavior, IR systems may be able to identify types of behaviors and accommodate those behaviors through context-sensitive assistance or through integration of system features that accommodate identified behaviors. Chen and Cooper [1] relied on a rich dataset of user sessions collected from the University of California MELVYL online public access catalog system. Based on 47 variables associated with each user session (e.g., session length in seconds, average number of items retrieved, average number of search modifications), their analysis identified six clusters representing different types of user behaviors during search sessions. These included help-intensive searching, knowledgeable usage, and known-item searching. Similarly, Wen et al. [9] focused on clustering of user queries in an online encyclopedia environment to determine whether queries could be effectively clustered to direct users to appropriate frequently asked questions topics. IR environments that cater to a broad range of users are well-known for short query submissions by users, which make clustering applications based solely on query term co-occurrence unreliable. In addition to the query content, the authors based their analysis on common retrieved documents viewed by users. By combining query content with common document selections, a link was established between queries that might not share search terms. The authors demonstrated how the application of their clustering method, which was reportedly adopted by the encyclopedia studied, could effectively guide users to appropriate frequently asked questions.

The previous examples represent only a sample of clustering applications in an IR context. Additional recent research developments and applications using clustering may be found in Wu et al. [10].

Clustering on Streams

Suresh Venkatasubramanian
University of Utah, Salt Lake City, UT, USA

Definition

An instance of a clustering problem (see clustering) consists of a collection of points in a distance space, a measure of the *cost* of a clustering, and a measure of the *size* of a clustering. The goal is to compute a partitioning of the points into clusters such that the cost of this clustering is minimized, while the size is kept under some predefined threshold. Less commonly, a threshold for the cost is specified, while the goal is to minimize the size of the clustering.

A data stream (see data streams) is a sequence of data presented to an algorithm one item at a time. A stream algorithm, upon reading an item, must perform some action based on this item and the contents of its working space, which is sublinear in the size of the data sequence. After this action is performed (which might include copying the item to its working space), the item is discarded.

Clustering on streams refers to the problem of clustering a data set presented as a data stream.

Historical Background

Clustering (see clustering) algorithms typically require access to the entire data to produce an effective clustering. This is a problem for large data sets, where random access to the data, or repeated access to the entire data set, is a costly operation. For example, the well-known k-means heuristic is an iterative procedure that in each iteration must read the entire data set twice. One set of approaches to performing clustering on large data involves sampling: a small subset of data is extracted from the input and clustered, and then this clustering is extrapolated to the entire data set.

The *data stream* paradigm [14] came about in two ways: first, as a way to model access to large streaming sources (network traffic, satellite imagery) that by virtue of their sheer volume, cannot be archived for offline processing and need to be aggregated, summarized and then discarded in real time. Second, the streaming paradigm has shown itself to be the most effective way of accessing large databases: Google's Map Reduce [9] computational framework is one example of the efficacy of stream processing.

Designing clustering algorithms for stream data requires different algorithmic ideas than those useful for traditional clustering algorithms. The online computational paradigm [4] is a potential solution: in this paradigm, an algorithm is presented with items one by one, and using only information learned up to the current time, must make a prediction or estimate on the new item being presented. Although the online computing paradigm captures the sequential aspect of stream processing, it does not capture the additional constraint that only a small portion of the history may be stored. In fact, an online algorithm is permitted to use the entirety of the history of the stream, and is usually not limited computationally in any way. Thus, new ideas are needed to perform clustering in a stream setting.

Foundations

Preliminaries

Let X be a domain and d be a distance function defined between pairs of elements in X. Typically, it is assumed that d is a metric (i.e., it satisfies the triangle inequality $d(x, y) + d(y, z) \geq d(x, z) \forall x,y,z \in X$). One of the more common measures of the cost of a cluster is the so-called *median cost*: the cost of a cluster $C \subseteq X$ is the function

$$\mathrm{cost}(C) = \sum_{x \in C} d(x, c^*)$$

where $c^* \in X$, the *cluster center*, is the point that minimizes cost(C). The *k-median problem* is to find a collection of k disjoint clusters, the sum of whose costs is minimized.

An equally important cost function is the *mean cost*: the cost of a cluster $C \subseteq X$ is the function

$$\mathrm{cost}(C) = \sum_{x \in C} d^2(x, c^*)$$

where c^* is defined as before. The *k-means problem* is to find a collection of clusters whose total *mean cost* is minimized. It is useful to note that the median cost is more robust to outliers in the data; however, the mean cost function, especially for points in Euclidean spaces, yields a very simple definition for c^*: it is merely the centroid of the set of points in the cluster. Other measures that are often considered are the k-center cost, where the goal is to minimize the maximum radius of a cluster, and the diameter cost, where the goal is to minimize the maximum diameter of a cluster (note that the diameter measure does not require one to define a cluster center).

A data stream problem consists of a sequence of items $x_1, x_2,\ldots,x_n$, and a function $f(x_1,\ldots,x_n)$ that one wishes to compute. The limitation here is that the algorithm is only permitted to store a *sublinear* number of items in memory, because n is typically too large for all the items to fit in memory. Further, even random access to the data is prohibitive, and so the algorithm is limited to accessing the data in sequential order.

Since most standard clustering problems (including the ones described above) are NP-hard in general, one cannot expect solutions that minimize the cost of a clustering. However, one can often show that an algorithm comes close to being optimal: formally, one can show that the cost achieved by an algorithm is within some multiplicative factor c of the optimal solution. Such an algorithm is said to be a c-approximation algorithm. Many of the methods presented here will provide such guarantees on the quality of their output. As usual, one should keep in mind that these guarantees are *worst-case*, and thus apply to any possible input the algorithm may encounter. In practice, these algorithms will often perform far better than promised.

General Principles

Stream clustering is a relatively new topic within the larger area of stream algorithms and data analysis. However, there are some general techniques that have proven their usefulness both theoretically as well as practically, and are good starting points for the design and analysis of stream clustering methods. This section reviews these ideas, as well as pointing to examples of how they have been used in various settings.

Incremental Clustering The simplest way to think about a clustering algorithm on stream data is to imagine the stream data arriving in chunks of elements. Prior to the arrival of the current chunk, the clustering algorithm has computed a set of clusters for all the data seen so far. Upon encountering the new chunk, the algorithm must update the clusters, possibly expanding some and contracting others, merging some clusters and splitting others. It then requests the next chunk, discarding the current one. Thus, a core component of any stream clustering algorithm is a routine to incrementally update a clustering when new data arrives. Such an approach was developed by Charikar et al. [6] for maintaining clusterings of data in a metric space using a diameter cost function. Although their scheme was phrased in terms of incremental clusterings, rather than stream clusterings, their approach generalizes well to streams. They show that their scheme yields a provable approximation to the optimal diameter of a k-clustering.

Representations One of the problems with clustering data streams is choosing a representation for a cluster. At the very least, any stream clustering algorithm stores the location of a cluster center, and possibly the number of items currently associated with this cluster. This representation can be viewed as a *weighted point*, and can be treated as a single point in further iterations of the clustering process. However, this representation loses information about the geometric size and distribution of a cluster. Thus, another standard representation of a cluster consists of the center and the number of points augmented with the sum of squared distances from the points in the cluster to the center. This last term informally measures the variation of points within a cluster, and when viewed in the context of density estimation via Gaussians, is in fact the sample variance of the cluster.

Clusters reduced in this way can be treated as weighted points (or weighted balls), and clustering algorithms should be able to handle such generalized points. One notable example of the use of such a representation is the one-pass clustering algorithm of Bradley et al. [5], which was simplified and improved by Farnstrom et al. [11]. Built around the well known k-means algorithm (that iteratively seeks to minimize the k-means measure described above), this technique proceeds as follows.

Algorithm 1: Clustering with representations

```
Initialize cluster centers randomly
**While** chunk of data remains to be read **do**
    Read a chunk of data (as much as will fit in memory),
    and cluster it using the k-means algorithm.
    For each cluster, divide the points contained within it
    into the core (points that are very close to the center
    under various measures), and the periphery.
    Replace the set of points in the core by a summary as
    described above. Discard all remaining points.
    Use the current cluster list as the set of centers for the
    next chunk.
```

It is important that representations be *linear*. Specifically, given two chunks of data c,c', and their representations r,r', it should be the case that the representation of $c \cup c'$ be formed from a linear combination of r and r'. This relates to the idea of *sketching* in stream algorithms, and is important because it allows the clustering algorithm to work in the (reduced) space of representations, rather than in the original space of data. Representations like the one described above are linear, and this is a crucial factor in the effectiveness of these algorithms.

Hierarchical Clustering Viewing a cluster as a weighted point in a new clustering problem quickly leads to the idea of *hierarchical clustering*: by thinking of a point as a single-element cluster, and connecting a cluster and its elements in a parent-child relationship, a clustering algorithm can represent multiple levels of merges as a tree of clusters, with the root node being a single cluster containing all the data, and each leaf being a single item. Such a tree is called a Hierarchical Agglomerative Clustering (HAC), since it can be viewed bottom-up as a series of agglomerations. Building such a hierarchy yields more general information about the relationship between clusters, and the ability to make better judgments about how to merge clusters.

The well-known clustering algorithm BIRCH [15] makes use of a hierarchy of cluster representations to cluster a large database in a few passes. In a first pass, a tree called the CF-tree is constructed, where each internal node represents a cluster of clusters, and each leaf represents a cluster of items. This tree is controlled by two parameters: B, the branching factor, and T, a diameter threshold that limits the size of leaf clusters.

In further passes, more analysis is performed on the CF-tree to compress clusters further. The tree is built much in the way a B+-tree is built: new items are inserted in the deepest cluster possible, and if the threshold constraint is violated, the cluster is split, and updates are propagated up the tree.

BIRCH is one of the best-known large-data clustering algorithms, and is generally viewed as a benchmark to compare other clustering algorithms against. However, BIRCH does not provide formal guarantees on the quality of the clusterings thus produced. The first algorithm that computes a hierarchical clustering on a stream while providing formal performance guarantees is a method for solving the k-median problem developed by Guha et al. [12,13]. This algorithm is best described by first presenting it in a non-streaming context:

Algorithm 2: Small space

```
Divide the input into $l$ disjoint parts.
Cluster each part into $O(k)$ clusters. Assign each point to its nearest cluster center.
cluster the $O(lk)$ cluster centers, where each center is weighted by the number of points assigned to it.
```

Note that the total space required by this algorithm is $O(\ell k + n/\ell)$. The value of this algorithm is that it propagates good clusterings: specifically, if the intermediate clusterings are computed by algorithms that yield constant-factor approximations to the best clustering (under the k-median cost measure), then the final output will also be a (larger) constant factor approximation to the best clustering. Also note that the final clustering step may itself be replaced by a recursive call to the algorithm, yielding a hierarchical scheme.

Converting this to a stream algorithm is not too difficult. Consider each chunk of data as one of the disjoint parts the input is broken into. Suppose each part is of size m, and there exists a clustering procedure that can cluster these points into $2k$ centers with reasonable accuracy. The algorithm reads enough data to obtain m centers ($m^2/2k$ points). These m "points" can be viewed as the input to a second level streaming process, which performs the same operations. In general, the ith-level stream process takes $m^2/2k$ points from the $(i-1)$th-level stream process and clusters them into m points, which are appended to the stream for the next level.

The guarantees provided by the method rely on having accurate clustering algorithms for the intermediate steps. However, the general paradigm itself is useful as a heuristic: the authors show that using the k-means algorithm as the intermediate clustering step yields reasonable clustering results in practice, even though the method comes with no formal guarantees.

On Relaxing the Number of Clusters If one wishes to obtain guarantees on the quality of a clustering, using at least k clusters is critical; it is easy to design examples where the cost of a $(k-1)$-clustering is much larger than the cost of a k-clustering. One interesting aspect of the above scheme is how it uses weaker clustering algorithms (that output $O(k)$ rather than k clusters) as intermediate steps on the way to computing a k-clustering. In fact, this idea has been shown to be useful in a formal sense: subsequent work by Charikar et al. [7] showed that if one were to use an extremely weak clustering algorithm (in fact, one that produces $O(k \log n)$ clusters), then this output can be fed into a clustering algorithm that produces k clusters, while maintaining overall quality bounds that are better than those described above. This idea is useful especially if one has a fast algorithm that produces a larger number of clusters, and a more expensive algorithm that produces k clusters: the expensive algorithm can be run on the (small) output of the fast algorithm to produce the desired answer.

Clustering Evolving Data

Stream data is often temporal. Typical data analysis questions are therefore often limited to ranges of time ("in the last three days," "over the past week," "for the period between Jan 1 and Feb 1," and so on). All of the above methods for clustering streams assume that the goal is to cluster the entire data stream, and the only constraint is the space needed to store the data. Although they are almost always incremental, in that the stream can be stopped at any time and the resulting clustering will be accurate *for all data seen upto that point*, they cannot correctly output clusterings on *windows* of data, or allow the influence of past data to gradually wane over time. Even with non-temporal data, it may be important to allow the data analysis to operate on a subset of the data to capture the notion of *concept drift* [10], a term that is used to describe a scenario when natural data characteristics change as the stream evolves.

Sliding Windows A popular model of stream analysis is the *sliding window* model, which introduces a new parameter W. The goal of the stream analysis is to produce summary statistics (a clustering, variance estimates or other statistics), on the *most recent W items only*, while using space that is sublinear in W. This model can be thought of as represented by a *sliding window* of length W with one end (the sliding end) anchored to the current element being read. The challenge of dealing with sliding windows is the problem of deletion. Although not as general as a fully dynamic data model where arbitrary elements can be inserted and deleted, the sliding window model introduces with the problem of updating a cluster representation under deletions, and requires new ideas.

One such idea is the *exponential histogram*, first introduced by Datar et al. [8] to estimate certain statistical properties of sliding windows on streams, and used by Babcock et al. [3] to compute an approximate k-median clustering in the sliding window model. The idea here is to maintain a set of buckets that together partition all data in the current window. For each bucket, relevant summary statistics are maintained. Intuitively, the smaller the number of items assigned to a bucket, the more accurate the summary statistics (in the limit, the trivial histogram has one bucket for each of the W items in the window). The larger this number, the fewer the number of buckets needed. Balancing these two conflicting requirements yields a scheme where each bucket stores the items between two timestamps, and the bucket sizes increase exponentially as they store items further in the past. It requires more detailed analysis to demonstrate that such a scheme will provide accurate answers to queries over windows, but the use of such exponentially increasing bucket sizes allows the algorithm to use a few buckets, while still maintaining a reasonable approximation to the desired estimate.

Hierarchies of Windows The sliding window model introduces an extra parameter W whose value must be justified by external considerations. One way of getting around this problem is to maintain statistics for multiple values of W (typically an exponentially increasing family). Another approach, used by Aggarwal et al. [1] is to maintain *snapshots* (summary representations of the clusterings) at time steps at different levels of resolution. For example, a simple two level snapshot scheme might store the cluster representations computed after times t, $t + 1$,...$t + W$, as well as t, $t + 2$, $t + 4$,...$t + 2W$ (eliminating duplicate summaries as necessary). Using the linear structure of representations will allow the algorithm to extract summaries for time intervals: they show that such a scheme uses space efficiently while still being able to detect evolution in data streams at different scales.

Decaying Data For scenarios where such a justification might be elusive, another model of evolving data is the *decay model*, in which one can think of a data item's influence waning (typically exponentially) with time. In other words, the value of the ith item, instead of being fixed at x_i, is a function of time $x_i(t) = x_i(0)\exp(-c(t - i))$. This reduces the problem to the standard setting of computing statistics over the entire stream, while using the decay function to decide which items to remove from the limited local storage when computing statistics. The use of exponentially decaying data is quite common in temporal data analysis: one specific example of its application in the clustering of data streams is the work on HPStream by Aggarwal et al. [2].

Key Applications

Systems that manage large data sets and perform data analysis will require stream clustering methods. Many modern *data cleaning systems* require such tools, as well as large scientific databases. Another application of stream clustering is for network traffic analysis: such algorithms might be situated at routers, operating on packet streams.

Experimental Results

Most of the papers cited above are accompanied by experimental evaluations and comparisons to prior work. BIRCH, as mentioned before, is a common benchmarking tool.

Definition

Clustering is the assignment of objects to groups of similar objects (clusters). The objects are typically described as vectors of features (also called attributes). Attributes can be numerical (scalar) or categorical. The assignment can be hard, where each object belongs to one cluster, or fuzzy, where an object can belong to several clusters with a probability. The clusters can be overlapping, though typically they are disjoint. A distance measure is a function that quantifies the similarity of two objects.

Historical Background

Clustering is one of the most useful tasks in data analysis. The goal of clustering is to discover groups of similar objects and to identify interesting patterns in the data. Typically, the clustering problem is about partitioning a given data set into groups (clusters) such that the data points in a cluster are more similar to each other than points in different clusters [4,8]. For example, consider a retail database where each record contains items purchased at the same time by a customer. A clustering procedure could group the customers in such a way that customers with similar buying patterns are in the same cluster. Thus, the main concern in the clustering process is to reveal the organization of patterns into "sensible" groups, which allow one to discover similarities and differences, as well as to derive useful conclusions about them. This idea is applicable to many fields, such as life sciences, medical sciences and engineering. Clustering may be found under different names in different contexts, such as unsupervised learning (in pattern recognition), numerical taxonomy (in biology, ecology), typology (in social sciences) and partition (in graph theory) [13].

The clustering problem comes up in so many domains due to the prevalence of large datasets for which labels are not available. In one or two dimensions, humans can perform clustering very effectively visually, however in higher dimensions automated procedures are necessary. The lack of training examples makes it very difficult to evaluate the results of the clustering process. In fact, the clustering process may result in different partitioning of a data set, depending on the specific algorithm, criterion, or choice of parameters used for clustering.

Foundations

The Clustering Process

In the clustering process, there are no predefined classes and no examples that would show what kind of desirable relations should be valid among the data. That is the main difference from the task of classification: Classification is the procedure of assigning an object to a predefined set of categories [FSSU96]. Clustering produces initial categories in which values of a data set are classified during the classification process. For this reason, clustering is described as "unsupervised learning"; in contrast to classification, which is considered as "supervised learning." Typically, the clustering process will include at least the following steps:

1. Feature selection: Typically, the objects or observations to be clustered are described using a set of features. The goal is to appropriately select the features on which clustering is to be performed so as to encode as much information as possible concerning the task of interest. Thus, a pre-processing step may be necessary before using the data.
2. Choice of the clustering algorithm. In this step the user chooses the algorithm that is more appropriate for the data at hand, and therefore is more likely to result to a good clustering scheme. In addition, a similarity (or distance) measure and a clustering criterion are selected in tandem
   – The distance measure is a function that quantifies how "similar" two objects are. In most of the cases, one has to ensure that all selected features contribute equally to the computation of the proximity measure and there are no features that dominate others.
   – The clustering criterion is typically a cost function that the clustering algorithm has to optimize. The choice of clustering criterion has to take into account the type of clusters that are expected to occur.
3. Validation and interpretation of the results. The correctness of the results of the clustering algorithm is verified using appropriate criteria and techniques. Since clustering algorithms define clusters that are not known a priori, irrespective of the clustering methods, the final partition of the data typically requires some kind of evaluation. In many cases, the experts in the application area have to integrate the clustering results with other experimental evidence and analysis in order to draw the right conclusion.

After the third phase the user may elect to use the clustering results obtained, or may start the process from the beginning, perhaps using different clustering algorithms or parameters.

Clustering Algorithms Taxonomy

With clustering being a useful tool in diverse research communities, a multitude of clustering methods has been proposed in the literature. Occasionally similar techniques have been proposed and used in different communities. Clustering algorithms can be classified according to:

1. The type of data input to the algorithm (for example, objects described with numerical features or categorical features) and the choice of similarity function between two objects.
2. The clustering criterion optimized by the algorithm.
3. The theory and fundamental concepts on which clustering analysis techniques are based (e.g., fuzzy theory, statistics).

A broad classification of clustering algorithms is the following [8,14]:

1. *Partitional clustering algorithms*: here the algorithm attempts to directly decompose the data set into a set of (typically) disjoint clusters. More specifically, the algorithm attempts to determine an integer number of partitions that optimize a certain criterion function.
2. *Hierarchical clustering algorithms*: here the algorithm proceeds successively by either merging smaller clusters into larger ones, or by splitting larger clusters. The result of the algorithm is a tree of clusters, called dendrogram, which shows how the clusters are related. By cutting the dendrogram at a desired level, a clustering of the data items into disjoint groups is obtained.
3. *Density-based clustering*: The key idea of this type of clustering is to group neighbouring objects of a data set into clusters based on density conditions. This includes grid-based algorithms that quantise the space into a finite number of cells and then do operations in the quantised space.

For each of above categories there is a wealth of subtypes and different algorithms for finding the clusters. Thus, according to the type of variables allowed in the data set additional categorizations include [14]: (i) Statistical algorithms, which are based on statistical analysis concepts and use similarity measures to partition objects and they are limited to numeric data.

(ii) Conceptual algorithms that are used to cluster categorical data. (iii) Fuzzy clustering algorithms, which use fuzzy techniques to cluster data and allow objects to be classified into more than one clusters. Such algorithms lead to clustering schemes that are compatible with everyday life experience as they handle the uncertainty of real data. (iv) Crisp clustering techniques, that consider non-overlapping partitions so that a data point either belongs to a class or not. Most of the clustering algorithms result in crisp clusters, and thus can be categorized in crisp clustering. (v) Kohonen net clustering, which is based on the concepts of neural networks.

In the remaining discussion, partitional clustering algorithms will be described in more detail; other techniques will be dealt with separately.

Partitional Algorithms

In general terms, the clustering algorithms are based on a criterion for assessing the quality of a given partitioning. More specifically, they take as input some parameters (e.g., number of clusters, density of clusters) and attempt to define the best partitioning of a data set for the given parameters. Thus, they define a partitioning of a data set based on certain assumptions and not necessarily the "best" one that fits the data set.

In this category, K-Means is a commonly used algorithm [10]. The aim of K-Means clustering is the optimisation of an objective function that is described by the equation:

$$E = \sum_{i=1}^{c} \sum_{x \in C_i} d(x, m_i)$$

In the above equation, m_i is the center of cluster C_i, while $d(x, m_i)$ is the Euclidean distance between a point x and m_i. Thus, the criterion function E attempts to minimize the distance of every point from the center of the cluster to which the point belongs.

It should be noted that optimizing E is a combinatorial problem that is NP-Complete and thus any practical algorithm to optimize it cannot guarantee optimality. The K-means algorithm is the first practical and effective heuristic that was suggested to optimize this criterion, and owes its popularity to its good performance in practice. The K-means algorithm begins by initialising a set of c cluster centers. Then, it assigns each object of the dataset to the cluster whose center is the nearest, and re-computes the centers. The process continues until the centers of the clusters stop changing.

Another algorithm of this category is PAM (Partitioning Around Medoids). The objective of PAM is to determine a representative object (medoid) for each cluster, that is, to find the most centrally located objects within the clusters. The algorithm begins by selecting an object as medoid for each of c clusters. Then, each of the non-selected objects is grouped with the medoid to which it is the most similar. PAM swaps medoids with other non-selected objects until all objects qualify as medoid. It is clear that PAM is an expensive algorithm with respect to finding the medoids, as it compares an object with the entire dataset [12].

CLARA (Clustering Large Applications), is an implementation of PAM in a subset of the dataset. It draws multiple samples of the dataset, applies PAM on samples, and then outputs the best clustering out of these samples [12]. CLARANS (Clustering Large Applications based on Randomized Search), combines the sampling techniques with PAM. The clustering process can be presented as searching a graph where every node is a potential solution, that is, a set of k medoids. The clustering obtained after replacing a medoid is called the neighbour of the current clustering. CLARANS selects a node and compares it to a user-defined number of their neighbours searching for a local minimum. If a better neighbor is found (i.e., having lower-square error), CLARANS moves to the neighbour's node and the process starts again; otherwise the current clustering is a local optimum. If the local optimum is found, CLARANS starts with a new randomly selected node in search for a new local optimum.

The algorithms described above result in crisp clusters, meaning that a data point either belongs to a cluster or not. The clusters are non-overlapping and this kind of partitioning is further called crisp clustering. The issue of uncertainty support in the clustering task leads to the introduction of algorithms that use fuzzy logic concepts in their procedure. A common fuzzy clustering algorithm is the Fuzzy C-Means (FCM), an extension of classical C-Means algorithm for fuzzy applications [2]. FCM attempts to find the most characteristic point in each cluster, which can be considered as the "center" of the cluster and, then, the grade of membership for each object in the clusters.

Another approach proposed in the literature to solve the problems of crisp clustering is based on probabilistic models. The basis of this type of clustering algorithms is the EM algorithm, which provides a quite general approach to learning in presence of unobservable variables [11]. A common algorithm is the probabilistic variant of K-Means, which is based on the mixture of Gaussian distributions. This approach of K-Means uses probability density rather than distance to associate records with clusters. More specifically, it regards the centers of clusters as means of Gaussian distributions. Then, it estimates the probability that a data point is generated by the jth Gaussian (i.e., belongs to jth cluster). This approach is based on Gaussian model to extract clusters and assigns the data points to clusters assuming that they are generated by normal distribution. Also, this approach is implemented only in the case of algorithms based on the EM (Expectation Maximization) algorithm.

Another type of clustering algorithms combine graph partitioning and hierarchical clustering algorithms characteristics. Such algorithms include CHAMELEON [9], which measures the similarity among clusters based on a dynamic model contrary to the clustering algorithms discussed above. Moreover in the clustering process both the inter-connectivity and closeness between two clusters are taken into account to decide how to merge the clusters. The merge process based on the dynamic model facilitates the discovery of natural and homogeneous clusters. Also it is applicable to all types of data as long as a similarity function is specified. Finally, BIRCH [ZRL99] uses a data structure called CF-Tree for partitioning the incoming data points in an incremental and dynamic way, thus providing an effective way to cluster very large datasets.

Partitional algorithms are applicable mainly to numerical data sets. However, there are some variants of K-Means such as K-prototypes, and K-mode [7] that are based on the K-Means algorithm, but they aim at clustering categorical data. K-mode discovers clusters while it adopts new concepts in order to handle categorical data. Thus, the cluster centers are replaced with "modes," a new dissimilarity measure used to deal with categorical objects.

The K-means algorithm and related techniques tend to produce spherical clusters due to the use of a symmetric objective function. They require the user to set only one parameter, the desirable number of clusters K. However, since the objective function gets smaller monotonically as K increases, it is not clear how to define what is the best number of clusters for a given dataset. Although several approaches have been proposed to address this shortcoming [14], this is one of the main disadvantages of partitional algorithms. Another characteristic of the partitional algorithms is that they are unable to handle noise and outliers and they are not suitable to discover clusters with non-convex shapes. Another characteristic of K-means is that the algorithm does not display a monotone behavior with respect to K. For example, if a dataset is clustered into M and 2M clusters, it is intuitive to expect that the smaller clusters in the second clustering will be subsets of the larger clusters in the first; however this is typically not the case.

Key Applications

Cluster analysis is very useful task in exploratory data analysis and a major tool in a very wide spectrum of applications in many fields of business and science. Clustering applications include:

1. *Data reduction.* Cluster analysis can contribute to the compression of the information included in the data. In several cases, the amount of the available data is very large and its processing becomes very demanding. Clustering can be used to partition the data set into a number of "interesting" clusters. Then, instead of processing the data set as an entity, the representatives of the defined clusters are adopted in the process. Thus, data compression is achieved.
2. *Hypothesis generation.* Cluster analysis is used here in order to infer some hypotheses concerning the data. For instance, one may find in a retail database that there are two significant groups of customers based on their age and the time of purchases. Then, one may infer some hypotheses for the data, that it, "young people go shopping in the evening," "old people go shopping in the morning."
3. *Hypothesis testing.* In this case, the cluster analysis is used for the verification of the validity of a specific hypothesis. For example, consider the following hypothesis: "Young people go shopping in the evening." One way to verify whether this is true is to apply cluster analysis to a representative set of stores. Suppose that each store is represented by its customer's details (age, job, etc.) and the time of transactions. If, after applying cluster analysis, a cluster that corresponds to "young people buy in the evening" is formed, then the hypothesis is supported by cluster analysis.
4. *Prediction based on groups.* Cluster analysis is applied to the data set and the resulting clusters are characterized by the features of the patterns that

belong to these clusters. Then, unknown patterns can be classified into specified clusters based on their similarity to the clusters' features. In such cases, useful knowledge related to this data can be extracted. Assume, for example, that the cluster analysis is applied to a data set concerning patients infected by the same disease. The result is a number of clusters of patients, according to their reaction to specific drugs. Then, for a new patient, one identifies the cluster in which he/she can be classified and based on this decision his/her medication can be made.

5. *Business Applications and Market Research.* In business, clustering may help marketers discover significant groups in their customers' database and characterize them based on purchasing patterns.
6. *Biology and Bioinformatics.* In biology, it can be used to define taxonomies, categorize genes with similar functionality and gain insights into structures inherent in populations.
7. *Spatial data analysis.* Due to the huge amounts of spatial data that may be obtained from satellite images, medical equipment, Geographical Information Systems (GIS), image database exploration etc., it is expensive and difficult for the users to examine spatial data in detail. Clustering may help to automate the process of analysing and understanding spatial data. It is used to identify and extract interesting characteristics and patterns that may exist in large spatial databases.
8. *Web mining.* Clustering is used to discover significant groups of documents on the Web huge collection of semi-structured documents. This classification of Web documents assists in information discovery. Another application of clustering is discovering groups in social networks.

In addition, clustering can be used as a pre-processing step for other algorithms, such as classification, which would then operate on the detected clusters.

Synonyms

Cluster validation; Cluster stability; Quality assessment; Stability-based validation of clustering

Definition

A problem one faces in clustering is to decide the optimal partitioning of the data into clusters. In this context visualization of the data set is a crucial verification of the clustering results. In the case of large multidimensional data sets (e.g., more than three dimensions) effective visualization of the data set is cumbersome. Moreover the perception of clusters using available visualization tools is a difficult task for humans that are not accustomed to higher dimensional spaces. The procedure of evaluating the results of a clustering algorithm is known under the term *cluster validity*. Cluster validity consists of a set of techniques for finding a set of clusters that best fits natural partitions (of given datasets) without any a priori class information. The outcome of the clustering process is validated by a cluster validity index.

Historical Background

Clustering is a major task in the data mining process for discovering groups and identifying interesting distributions and patterns in the underlying data. In the literature a wide variety of algorithms for different applications and sizes of data sets. The application of an algorithm to a data set, assuming that the data set offers a clustering tendency, aims at discovering its inherent partitions. However, the clustering process is an unsupervised process, since there are no predefined classes or examples. Then, the various clustering algorithms are based on some assumptions in order to define a partitioning of a data set. As a consequence, they may behave in a different way depending on: i. the features of the data set (geometry and density distribution of clusters) and ii. the input parameter values.

One of the most important issues in cluster analysis is the evaluation of clustering results to find the partitioning that best fits the underlying data. This is the main subject of cluster validity. If clustering algorithm parameters are assigned an improper value, the clustering method results in a partitioning scheme that is not optimal for the specific data set leading to wrong decisions. The problems of deciding the number of clusters better fitting a data set as well as the evaluation of the clustering results has been subject of several research efforts. The procedure of evaluating the results of a clustering algorithm is known under the term cluster validity. In general terms, there are three approaches to investigate cluster validity. The first is based on *external criteria*. This implies that the results of a clustering algorithm are evaluated based on a prespecified structure, which is imposed on a data set and reflects one's intuition about the clustering structure of the data set. The second approach is based on *internal criteria*. The results of a clustering algorithm may be evaluated in terms of quantities that involve the vectors of the data set themselves (e.g., proximity matrix). The third approach of clustering validity is based on *relative criteria*. Here the basic idea is the evaluation of a clustering structure by comparing it to other clustering schemes, resulting by the same algorithm but with different parameter values. There are two criteria proposed for clustering evaluation and selection of an optimal clustering scheme: (i) Compactness, the members of each cluster should be as close to each other as possible. A common measure of compactness is the variance, which should be minimized. (ii) Separation, the clusters themselves should be widely spaced.

Foundations

This section discusses methods suitable for the quantitative evaluation of the clustering results, known as cluster validity methods. However, these methods give an indication of the quality of the resulting partitioning and thus they can only be considered as a tool at the disposal of the experts in order to evaluate the clustering results. The cluster validity approaches based on external and internal criteria rely on statistical hypothesis testing. In the following section, an introduction to the fundamental concepts of hypothesis testing in cluster validity is presented.

In cluster validity the basic idea is to test whether the points of a data set are randomly structured or not. This analysis is based on the *Null Hypothesis*, denoted as *Ho*, expressed as a statement of random structure of a data set X. To test this hypothesis, statistical tests are used, which lead to a computationally complex procedure.

Monte Carlo techniques are used as a solution to this problem.

External Criteria

Based on external criteria, one can work in two different ways. First, one can evaluate the resulting clustering structure **C**, by comparing it to an independent partition of the data ***P*** built according to one's intuition about the clustering structure of the data set. Second, one can compare the proximity matrix P to the partition ***P***.

Comparison of C with Partition P (Non-hierarchical Clustering) Let ***C*** = {C_1...C_m} be a clustering structure of a data set X and ***P*** = {P_1...P_s} be a defined partition of the data. Refer to a pair of points ($\mathbf{x_v}$, $\mathbf{x_u}$) from the data set using the following terms:

- ***SS***: if both points belong to the same cluster of the clustering structure **C** and to the same group of partition ***P***.
- ***SD***: if points belong to the same cluster of **C** and to different groups of ***P***.
- ***DS***: if points belong to different clusters of **C** and to the same group of ***P***.
- ***DD***: if both points belong to different clusters of **C** and to different groups of ***P***.

Assuming now that **a**, **b**, **c** and **d** are the number of SS, SD, DS and DD pairs respectively, then $a+b+c+d=\mathbf{M}$ which is the maximum number of all pairs in the data set (meaning, M = N(N−1)/2 where N is the total number of points in the data set).

Now define the following indices to measure the degree of similarity between ***C*** and ***P***:

1. *Rand Statistic*: R = (a + d)/M
2. *Jaccard Coefficient*: J = a/(a + b + c)
   The above two indices range between 0 and 1, and are maximized when m=s. Another known index is the:
3. *Folkes and Mallows index*:

$$FM = a/\sqrt{m_1 m_2} = \sqrt{\frac{a}{a+b}\cdot\frac{a}{a+c}} \qquad [1]$$

   where m_1 = (a + b), m_2= (a + c).
   For the previous three indices it has been proven that the higher the values of these indices are the more similar ***C*** and ***P*** are. Other indices are:
4. *Huberts Γ statistic*:

$$\Gamma = (1/M)\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} X(i,j)Y(i,j) \qquad [2]$$

   High values of this index indicate a strong similarity between the matrices X and Y.
5. *Normalized Γ statistic*:

$$\hat{\Gamma} = \frac{\left[(1/M)\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}(X(i,j)-\mu_X)(Y(i,j)-\mu_Y)\right]}{\sigma_X\sigma_Y} \qquad [3]$$

   where X(i, j) and Y(i, j) are the (i, j) element of the matrices X, Y respectively that one wants to compare. Also μ_x, μ_y, σ_x, σ_y are the respective means and variances of X, Y matrices. This index takes values between –1 and 1.

All these statistics have right-tailed probability density functions, under the random hypothesis. In order to use these indices in statistical tests, one must know their respective probability density function under the Null Hypothesis, *Ho*, which is the hypothesis of random structure of the data set. Thus, if one accepts the Null Hypothesis, the data are randomly distributed. However, the computation of the probability density function of these indices is computationally expensive. A solution to this problem is to use Monte Carlo techniques.

After having plotted the approximation of the probability density function of the defined statistic index, its value, denoted by q, is compared to the q(C_i) values, further referred to as q_i. The indices R, J, FM, Γdefined previously are used as the q index mentioned in the above procedure.

Internal Criteria

Using this approach of cluster validity the goal is to evaluate the clustering result of an algorithm using only quantities and features inherited from the data set. There are two cases in which one applies internal criteria of cluster validity depending on the clustering structure: (i) hierarchy of clustering schemes, and (ii) single clustering scheme.

Validating Hierarchy of Clustering Schemes A matrix called cophenetic matrix, P_c, can represent the hierarchy diagram that is produced by a hierarchical algorithm. The element $P_c(i, j)$ of cophenetic matrix represents the proximity level at which the two vectors x_i and x_j are found in the same cluster for the first time. A statistical index can be defined to measure the degree of similarity between P_c and P (proximity matrix) matrices. This index is called *Cophenetic Correlation Coefficient* and defined as:

$$\mathrm{CPCC} = \frac{(1/M)\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} d_{ij}c_{ij} - \mu_P\mu_C}{\sqrt{\left[(1/M)\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} d_{ij}^2 - \mu_P^2\right]\left[(1/M)\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} c_{ij}^2 - \mu_C^2\right]}}, \quad [4]$$

where $M = N\times(N-1)/2$ and N is the number of points in a data set. Also, μ_p and μ_c are the means of matrices P and P_c respectively, and are defined in the (Eq. 5):

$$\mu_P = (1/M)\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} P(i,j), \quad [5]$$
$$\mu_C = (1/M)\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} P_c(i,j)$$

Moreover, d_{ij}, c_{ij} are the (i, j) elements of P and P_c matrices respectively. The CPCC values range in [–1, 1]. A value of the index close to 1 is an indication of a significant similarity between the two matrices.

Validating a Single Clustering Scheme The goal here is to find the degree of match between a given clustering scheme C, consisting of n_c clusters, and the proximity matrix P. The defined index for this approach is Hubert's Γstatistic (or normalized Γstatistic). An additional matrix for the computation of the index is used, that is

$$Y(i,j) = \begin{cases} 1, \text{ if } x_i \text{ and } x_j \text{ belong to different clusters} \\ 0, \text{ otherwise } \textit{array}. \text{ where } i,j = 1, 1/4, N. \end{cases}$$

The application of Monte Carlo techniques is also a means to test the random hypothesis in a given data set.

Relative Criteria

The major drawback of techniques based on internal or external criteria is their high computational complexity. A different validation approach is discussed in this section. The fundamental idea of the relative criteria is to choose the best clustering scheme of a set of defined schemes according to a pre-specified criterion. More specifically, the problem can be stated as follows:

Let P_{alg} be the set of parameters associated with a specific clustering algorithm (e.g., the number of clusters n_c). Among the clustering schemes C_i, i = 1,...,n_c, is defined by a specific algorithm. For different values of the parameters in P_{alg}, choose the one that best fits the data set.

Then, consider the following cases of the problem:

1. *P_{alg} does not contain the number of clusters, n_c, as a parameter.* In this case, the choice of the optimal parameter values are described as follows: The algorithm runs for a wide range of its parameters' values and the largest range for which n_c remains constant is selected (usually $n_c << N$ (number of tuples)). Then the values that correspond to the middle of this range are chosen as appropriate values of the P_{alg} parameters. Also, this procedure identifies the number of clusters that underlie the data set.
2. *P_{alg} contains n_c as a parameter.* The procedure of identifying the best clustering scheme is based on a validity index. Selecting a suitable performance index, q, one proceeds with the following steps:
   - clustering runs for all values of n_c between n_{cmin} and n_{cmax} defined a priori by the user.
   - For each of n_c values, the algorithm runs r times, using different sets of values for the other parameters of the algorithm (e.g., different initial conditions).
   - The best values of the index q obtained by each n_c are plotted as the function of n_c.

Based on this plot, the best clustering schemes are identified. There are two approaches for defining the best clustering depending on the behavior of q with respect to n_c. Thus, if the validity index does not exhibit an increasing or decreasing trend as n_c increases, one seeks the max (min) of the plot. On the other hand, for indices that increase (decrease) as the number of clusters increase, one searches for the values of n_c at which a significant local change in value of the index occurs. This change appears as a "knee" in the plot and it is an indication of the number of clusters underlying the data set. The absence of a knee is an indication that the data set possesses no clustering structure. Below, some representative relative validity indices are presented.

The Modified Hubert Γ Statistic

The definition of the modified Hubert Γstatistic is given by the equation

$$\Gamma = (1/\mathrm{M}) \sum_{\mathrm{i}=1}^{\mathrm{N}-1} \sum_{\mathrm{j}=\mathrm{i}+1}^{\mathrm{N}} \mathrm{P}(\mathrm{i},\mathrm{j}) \cdot \mathrm{Q}(\mathrm{i},\mathrm{j}) \qquad [6]$$

where N is the number of objects in a data set, M = N (N−1)/2, P is the proximity matrix of the data set and Q is an N × N matrix whose (i, j) element is equal to the distance between the representative points (v_{ci}, v_{cj}) of the clusters where the objects x_i and x_j belong.

Similarly, one can define the normalized Hubert Γstatistic, given by equation

$$\hat{\Gamma} = \frac{\left[(1/\mathrm{M}) \sum_{\mathrm{i}=1}^{\mathrm{N}-1} \sum_{\mathrm{j}=\mathrm{i}+1}^{\mathrm{N}} (\mathrm{P}(\mathrm{i},\mathrm{j}) - \mu_{\mathrm{P}})(\mathrm{Q}(\mathrm{i},\mathrm{j}) - \mu_{\mathrm{Q}})\right]}{\sigma_{\mathrm{P}}\sigma_{\mathrm{Q}}}. \qquad [7]$$

where μ_P, μ_Q, $\sigma_{P,}$ σ_Q are the respective means and variances of P, Q matrices.

If the d(v_{ci}, v_{cj}) is close to d(x_i, x_j) for i, j =1, 2,...,N, P and Q will be in close agreement and the valuesof Γ and $\hat{\Gamma}$(normalized Γ) will be high. Conversely, a high value of Γ ($\hat{\Gamma}$) indicates the existence of compact clusters. Thus, in the plot of normalized Γ versus n_c, one seeks a significant knee that corresponds to a significant increase of normalized Γ. The number of clusters at which the knee occurs is an indication of the number of clusters that occurs in the data. Note that for $n_c = 1$ and $n_c = N$, the index is not defined.

Dunn Family of Indices

A cluster validity index for crisp clustering proposed by Dunn (1974), aims at the identification of "compact and well separated clusters". The index is defined in the following equation for a specific number of clusters

$$D_{n_c} = \min_{i=1,\ldots,n_c} \left\{ \min_{j=i+1,\ldots,n_c} \left(\frac{d(c_i, c_j)}{\max_{k=1,\ldots,n_c} (\mathrm{diam}(\mathrm{c_k}))} \right) \right\} \qquad [8]$$

where d(c_i, c_j) is the dissimilarity function between two clusters c_i and c_j defined as $d(c_i, c_j) = \min_{x \in C_i, y \in C_j} d(x, y)$, and diam(c) is the diameter of a cluster, which may be considered as a measure of clusters' dispersion. The diameter of a cluster *C* can be defined as follows:

$$\mathrm{diam(C)} = \max_{\mathrm{x,y} \in \mathrm{C}} \{\mathrm{d(x, y)}\} \qquad [9]$$

If the data set contains compact and well-separated clusters, the distance between the clusters is expected large and the diameter of the clusters is expected small. Based on the Dunn's index definition, one concludes that large values of the index indicate the presence of compact and well-separated clusters.

The problems of the Dunn index are: (i) its considerable time complexity, and (ii) its sensitivity to the presence of noise in data sets, since these are likely to increase the values of the diameter.

RMSSDT, SPR, RS, CD

This family of validity indices is applicable in the cases that hierarchical algorithms are used to cluster the data sets. Hereafter the discussion refers to the definitions of four validity indices, which have to be used simultaneously to determine the number of clusters existing in the data set. These four indices are applied to each step of a *hierarchical* clustering algorithm and they are known as:

- *Root-mean-square standard deviation (RMSSTD) of the new cluster,*
- *Semi-partial R-squared (SPR),*
- *R-squared (RS),*
- *Distance between two clusters (CD).*

Getting into a more detailed description of them, one can say that:

RMSSTD of a new clustering scheme defined at a level of a clustering hierarchy is the square root of the variance of all the variables (attributes used in the clustering process). This index measures the homogeneity of the formed clusters at each step of the hierarchical algorithm. Since the objective of cluster analysis is to form homogeneous groups the RMSSTD of a cluster should be as small as possible. Where the values of RMSSTD are higher than the ones of the previous step, one has an indication that the new clustering scheme is worse.

In the following definitions, the term SS is used, which means *Sum of Squares* and refers to the equation:

$$\mathrm{SS} = \sum_{i=1}^{n} (X_i - \overline{X})^2 \qquad [10]$$

Along with this, additional terms will be used, such as:

1. SS_w referring to the sum of squares within group,
2. SS_b referring to the sum of squares between groups,
3. SS_t referring to the total sum of squares, of the whole data set.

In the case cluster join to form a new one, *SPR*- for the new cluster – is defined as the difference between SS_w of the new cluster and the sum of the SS_w's values of clusters joined to obtain the new cluster (*loss of homogeneity*), divided by the SS_t for the whole data set. This index measures the loss of homogeneity after merging the two clusters of a single algorithm step. If the index value is zero then the new cluster is obtained by merging two perfectly homogeneous clusters. If its value is high then the new cluster is obtained by merging two heterogeneous clusters.

RS of the new cluster is the ratio of SS_b over SS_t. SS_b is a measure of difference between groups. Since $SS_t = SS_b + SS_{w,}$ the greater the SS_b the smaller the SS_w and vice versa. As a result, the greater the differences between groups, the more homogenous each group is and vice versa. Thus, RS may be considered as a measure of dissimilarity between clusters. Furthermore, it measures the degree of homogeneity between groups. The values of RS range between 0 and 1. Where the value of RS is zero, there is an indication that no difference exists among groups. On the other hand, when RS equals 1 there is an indication of significant difference among groups.

Key Applications

There is a certain cross disciplinary interest for clustering validity method and indices. A prominent area where cluster validity measures apply is the area of biological data [2,6]. Patterns hidden in gene expression data offer a tremendous opportunity for an enhanced understanding of functional genomics. However, the large number of genes and the complexity of biological networks greatly increase the challenges of comprehending and interpreting the resulting mass of data, which often consists of millions of measurements. The data mining process aims to reveal natural structures and identify interesting patterns in the underlying data. Clustering techniques constitute a first essential step toward addressing this challenge. Moreover recent research effort papers in the area of image segmentation [13,3].

The area is fertile as the clustering issue is a fundamental problem and the application domains are still widening. Challenging relevant research directions [9] follow:

- Is there a principled way to measure the quality of a clustering on particular data set?
- Can every clustering task be expressed as an optimization of some explicit, readily computable, objective cost function?
- Can stability be considered a first principle for meaningful clustering?
- How should the similarity between different clusterings be measured?
- Can one distinguish clusterable data from structureless data?
- What are the tools that should be imported from other relevant areas of research?

Clustering with Constraints

Ian Davidson
University of California-Davis, Davis, CA, USA

Synonyms

Semi-supervised clustering

Definition

The area of clustering with constraints makes use of hints or advice in the form of constraints to aid or bias the clustering process. The most prevalent form of advice are conjunctions of pair-wise instance level constraints of the form must-link (ML) and cannot-link (CL) which state that pairs of instances should be in the same or different clusters respectively. Given a set of points P to cluster and a set of constraints C, the aim of clustering with constraints is to use the constraints to improve the clustering results. Constraints have so far being used in two main ways: (i) Writing algorithms that use a standard distance metric but attempt to satisfy all or as many constraints as possible and (ii) Using the constraints to learn a distance function that is then used in the clustering algorithm.

Historical Background

The idea of using constraints to guide clustering was first introduced by Wagstaff and Cardie in their seminal paper ICML 2000 [13] with a modified COBWEB-style algorithm that attempts to satisfy all constraints. Later [14] they introduced constraints to the *k*-means algorithms. Their algorithms (as most algorithms now do) look at satisfying a conjunction of must-link and cannot-link constraints. Independently, Cohn, Caruana and McCallum [3,4] introduced constraints as a user feedback mechanism to guide the clustering algorithm to a more useful result.

In 2002 Xing and collaborators [15] (NIPS 2002) and Klein and collaborators (ICML 2002) [12] explored making use of constraints by learning a distance function for non-hierarchical clustering and a distance matrix for hierarchical clustering respectively.

Basu and collaborators more recently have looked at key issues such as which are the most informative sets of constraints [2] and seeding algorithms using constraints [1]. Gondek has explored using constraints to find orthogonal/alternative clusterings of data [3,11]. Davidson and Ravi explored the intractability issues of clustering under constraints for non-hierarchical clustering [6], hierarchical clustering [5] and non-hierarchical clustering with feedback [9].

Foundations

Clustering has many successful applications in a variety of domains where the objective function of the clustering algorithm finds a novel and useful clustering. However, in some application domains the typical objective functions may lead to well-known or non-actionable clusterings of the data. This could be overcome by an ad hoc approach such as manipulating the data. The introduction of constraints into clustering allows a principled approach to incorporate user preferences or domain expertise into the clustering process so as to guide the algorithm to a desirable solution or away from an undesirable solution. The typical semi-supervised learning situations involves having a label associated with a subset of the available instances. However in many domains, knowledge of the relevant categories is incomplete and it is easier to obtain pairwise constraints either automatically or from domain experts.

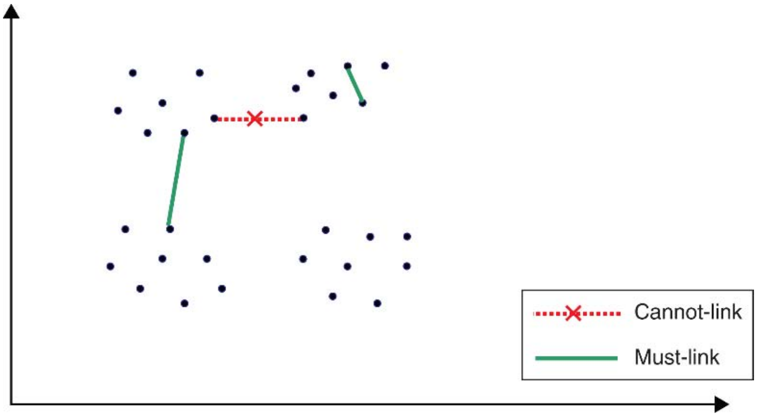
Types of Constraints. Must-link and cannot-link constraints are typically used since they can be easily generated from small amounts of labeled data (generate a must-link between two instances if the labels agree, cannot-link if they disagree) or from domain experts. They can be used to represent geometric properties [6,14] by noting that for instance, making the maximum cluster diameter be α is equivalent to enforcing a conjunction of cannot-link constraints between all points whose distance is greater than α. Similarly, clusters can be separated by distance at at least δ by enforcing a conjunction of must-link constraints between all points whose distance is less than δ. Both types of instance-level constraints have interesting properties that can be used to effectively generate many additional constraints. Must-link constraints are transitive: $ML(x,y)$, $ML(y,z) \rightarrow ML(x,z)$ and cannot link constraints have an entailment property: $ML(a,b)$, $ML(x,y)$, $CL(a,x) \rightarrow CL(a,y)$, $CL(b,x)$, $CL(b,y)$.

How Constraints Are Used. Constraints have typically been used in clustering algorithms in two ways. Constraints can be used to modify the cluster assignment stage of the cluster algorithm [4,14], to enforce satisfaction of the constraints or as many as possible [2,6]. These approaches typically use a standard distance or likelihood function. Alternatively, the distance function of the clustering algorithm can also be trained either before or after the clustering actually occurs using the constraints [12,15]. The former are called constraint-based approaches and the later distance based approaches.

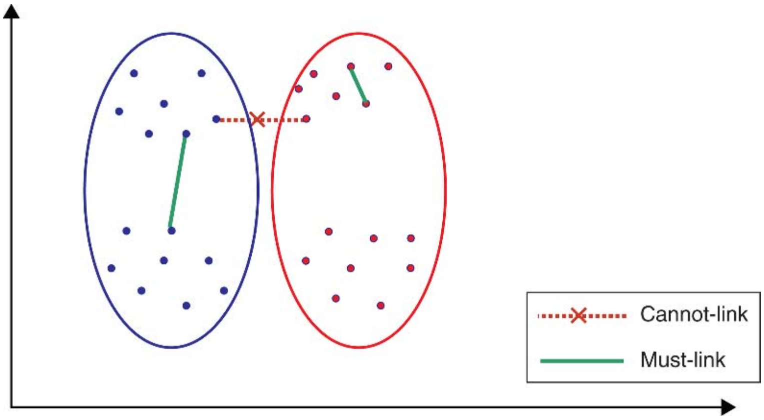
Constraint-Based Methods. In constraint-based approaches, the clustering algorithm itself (typically the assignment step) is modified so that the available constraints are used to bias the search for an appropriate clustering of the data. Fig. 2 shows how though two clusterings exist (a horizontal and vertical clustering) just three constraints can rule out the former.

Constraint-based clustering is typically achieved using one of the following approaches:

1. Enforcing constraints to be satisfied during the cluster assignment in the clustering algorithm [5,13].



Clustering with Constraints. Figure 1. Input instances and constraints.



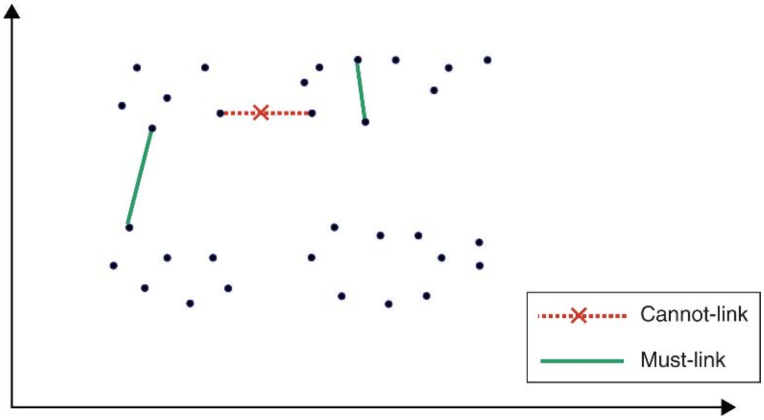
Clustering with Constraints. Figure 2. A clustering that satisfies all constraints.

2. Modifying the clustering objective function so that it includes a term for satisfying specified constraints. Penalties for violating constraints have been explored in the maximum likelihood framework [2] and distance framework [6].
3. Initializing clusters and inferring clustering constraints based on neighborhoods derived from labeled examples [1].

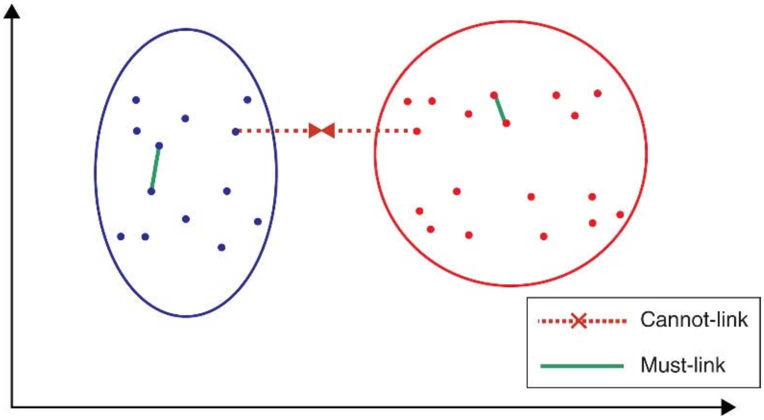
Each of the above approaches provides a simple method of modifying existing partitional and agglomerative style hierarchical algorithms to incorporate constraints. For more recent advances in algorithm design such as the use of variational techniques for constrained clustering see [3].

Distance-Based Methods. In distance-based approaches, an existing clustering algorithm that uses a distance measure is employed. However, rather than use the Euclidean distance metric, the distance measure is first trained to "satisfy" the given constraints. The approach of Xing and collaborators [15] casts the problem of learning a distance *metric* from the constraints so that the points (and surrounding points) that are part of the must-link (cannot-link) constraints are close together (far apart). They consider two formulations: firstly learning a generalized Mahanabolis distance metric which essentially stretches or compresses each axis as appropriate. Figure 4 gives an example where the constraints can be satisfied by stretching the *x*-axis and compressing the *y*-axis and then applying a clustering algorithm to the new data space. The second formulation allows a more complex transformation on the space of points.

Klein and collaborators [12] explore learning a distance *matrix* from constraints for agglomerative clustering. Only points that are directly involved in the constraints are brought closer together or far apart



Clustering with Constraints. Figure 3. Input instances and constraints.



Clustering with Constraints. Figure 4. A learnt distance space respective of the constraints.

using a multi-step approach of making must-linked points have a distance of 0 and cannot-linked points having the greatest distance.

There have been some algorithms that try to both enforce constraints and learn distance functions from constraints [2].

Key Applications

Key application areas include images, video, biology, text, web pages, audio (speaker identification) [3] and GPS trace information [14].

Column Segmentation

Sunita Sarawagi
IIT Bombay, Mumbai, India

Synonyms

Text segmentation; Record extraction; Information extraction

Definition

The term column segmentation refers to the segmentation of an unstructured text string into segments such that each segment is a column of a structured record.

As an example, consider a text string S=``18100 New Hampshire Ave. Silver Spring, MD 20861'' representing an unstructured form of an Address record. Let the columns of this record be House number, Street name, City name, State, Zip and Country. In column segmentation, the goal is to segment S and assign a column label to each segment so as to get an output of the form:

```
House Number   :  18100
Street Name    :  New Hampshire Ave.
City           :  Silver Spring
State          :  MD
Zip            :  20861
Country        :  --
```

Historical Background

The column segmentation problem is a special case of a more general problem of Information Extraction (IE) that refers to the extraction of structure from unstructured text. Column segmentation is typically performed on short text strings where most of the tokens belong to one of a fixed set of columns. In the more general IE problem, the unstructured text could be an arbitrary paragraph or an HTML document where the structured entities of interest form a small part of the entire string.

There is a long history of work on information extraction [5]. Most of the early work in the area was in the context of natural language processing, for example for extracting named entities like people names, organization names, and location names from news articles. The early systems were based on hand-coded set of rules and relied heavily on dictionaries of known records. Later systems were based on statistical methods like maximum entropy taggers [9], Hidden Markov Models [11] and Conditional Random Fields (CRFs) [7].

In the database research community, interest in column segmentation arose in the late nineties as a step in the process of cleaning text data for data warehousing. Many commercial tools were developed purely for the purposes of cleaning names and addresses. These were based on hand-coded, rule-based, database driven methods that work only for the region that they are developed for and do not extend to other domains. Much manual work has to be done to rewrite these rules when shifting the domain from one locality to another. This led to the adoption of statistical techniques [1,3] which proved to be more robust to noisy inputs.

Foundations

A formal definition of column segmentation follows. Let $Y = \{y_1,\ldots,y_m\}$ denote the set of column types of the structured record. Given any unstructured text string $\mathbf{x}$, column segmentation finds segments of $\mathbf{x}$ and labels each with one of the columns in Y. The input $\mathbf{x}$ is typically treated as a sequence of tokens obtained by splitting $\mathbf{x}$ along a set of delimiters. Let $x_1,\ldots,x_n$ denote such a sequence of tokens. A segmentation of $\mathbf{x}$ is a sequence of segments $s_1\ldots s_p$. Each segment s_j consists of a *start position* t_j, an *end position* u_j, and a *label* $y_j \in Y \cup \{\text{“Other”}\}$. The special label “Other” is used to label tokens not belonging to any of the columns. The segments are assumed to be contiguous, that is, segment s_{j+1} begins right after segment s_j ends. Also, the last segment ends at n and the first segment starts at 1.

As a second example consider a citation String T=P.P.Wangikar, T.P. Graycar, D.A. Estell, D.S. Clark, J.S. Dordick (1993) Protein and Solvent Engineering of Subtilising BPN' in Nearly Anhydrous Organic Media J.Amer. Chem. Soc. 115, 12231-12237. and a set of columns: Author names, title, year, publication venue, volume, number. A segmentation of this string is:

```
Title     :  Protein and Solvent Engineering
             of Subtilising BPN
Authors   :  P.P.Wangikar, T.P.Graycar,
             D.A. Estell, D.S. Clark, J.S. Dordick
Year      :  1993
Venue     :  Nearly Anhydrous Organic Media
             J.Amer. Chem. Soc.
Volume    :  115
Number    :  --
Pages     :  12231-12237
```

In this example, the tokens "in", "(" and ")" of the input have been assigned label "Other".

Challenges

The problem of column segmentation is challenging because of the presence of various kinds of noise in the unstructured string.

- The same column might be represented in many different forms, for example "Street" might be abbreviated as "St." or "st".
- The order in which columns appear might be different in different strings: for example, in some citations authors could be before title, and after title in others.
- Columns might be missing: some addresses might contain a country name, others may not.
- Strings from different sources might be formatted differently: for example, some citations might use a comma to separate fields whereas others might have no regular delimiter between fields.

Main Techniques

A column segmentation technique needs to combine information from multiple different sources of evidence to be able to correctly recognize segmentations in noisy strings. One source is the characteristic words in each elements, for example the word "street" appears in road-names. A second source is the limited partial ordering between its element. Often the first element is a house number, then a possible building name and so on and the last few elements are zipcode and state-name. A third source is the typical number of words in each element. For example, state names usually have one or two words whereas road names are longer. Even within a field, some words are more likely to appear in the beginning of the field rather than towards its end. Often, there is a pre-existing database of known values of columns. Match of a substring of the text to an existing database column, can be a valuable clue for segmentation. The format of the entry, presence of certain regular expression, capitalization, and punctuation patterns can be useful when word-level matches are absent. A good column segmentation technique would combine evidence from all of these clues in performing the final segmentation.

The three main types of column segmentation techniques are:

Rule-Based Systems

A rule-based technique, as the name suggests, encodes one or more of the above clues as rules. These are applied in a specified order and when more than two rules conflict, another set of rule resolution mechanisms are used to decide which one wins.

Here are some examples of rules that can be used to extract columns from citation records:

Punctuation CapsWord{2–10} Dot → Title
CapsWord Comma Initial Dot Initial Dot → Author name
Initial Dot CapsWord Comma → Author name
AllCaps Words{1–2} Journal → Journal

For example, the first rule marks as title any substring of two to ten capitalized words appearing between a punctuation and a full-stop. The second rule marks as an author name any substring consisting of a capitalized word followed by comma and two initials. This would identify strings of the form "Gandhi, M. K." as author names. Whereas the third rule would mark strings like "V. Ganti," as author names. The fourth rule would mark string like "ACM computing Journal" as journal names.

Such rules could be either hand-coded or learnt from example datasets [2,6]. Existing rule-based techniques are able to concentrate only on a subset of the above mentioned clues to limit the complexity of the learnt rules. They provide high precision segmentation in uniform settings where the amount of noise is limited. When the input becomes noisy, rule-based systems tend to lose on recall.

Hidden Markov Models

Hidden Markov Models (HMMs) provide an intuitive statistical method for combining many of the above clues in a unified model. A HMM is a probabilistic finite state automata where the states represent the fields to be extracted, directed edges between edges are attached with probability values indicating probability of transitioning from one state to another, and states are attached with a distribution over the words that can be generated from the state. A segmentation of a string *S* is achieved by finding the sequence of states for which the product of the probability of generating the words in *S* and following the transitions in state sequences is maximized. Such a path can be found efficiently using a dynamic programming algorithm. The parameters controlling the transition and word distributions of states are learnt using examples of correctly segmented strings.

An example, of a Hidden Markov Model trained to recognize Indian addresses appears in Fig. 1. The number of states is 10 and the edge labels depict the state transition probabilities. For example, the probability of an address beginning with House Number is 0.92 and that of seeing a City after Road is 0.22. The dictionary and the emission probabilities are not shown for compactness.

For more details on the use of HMMs in column segmentation see [1,3,11].

Conditional Models

A limitation of HMMs is that the distribution that controls the generation of words within a state is generative, and can therefore capture only a limited set of properties of the words it can generate. For example, it is complicated to account for various orthographic properties of words, like its capitalization pattern, or the delimiter following that word. These limitations are removed by recently proposed formalisms like Conditional Random Fields (CRFs) that capture the conditional distribution of column sequence *given* the sequence of words in a string *S*. This enables the incorporation of any arbitrary set of clues derived from a word and the words in its neighborhood. Also it becomes easy to incorporate clues derived from the degree of match of a proposed column with pre-existing values in the database.

A CRF models the conditional probability distribution over segmentations **s** for a given input sequence **x** as follows:

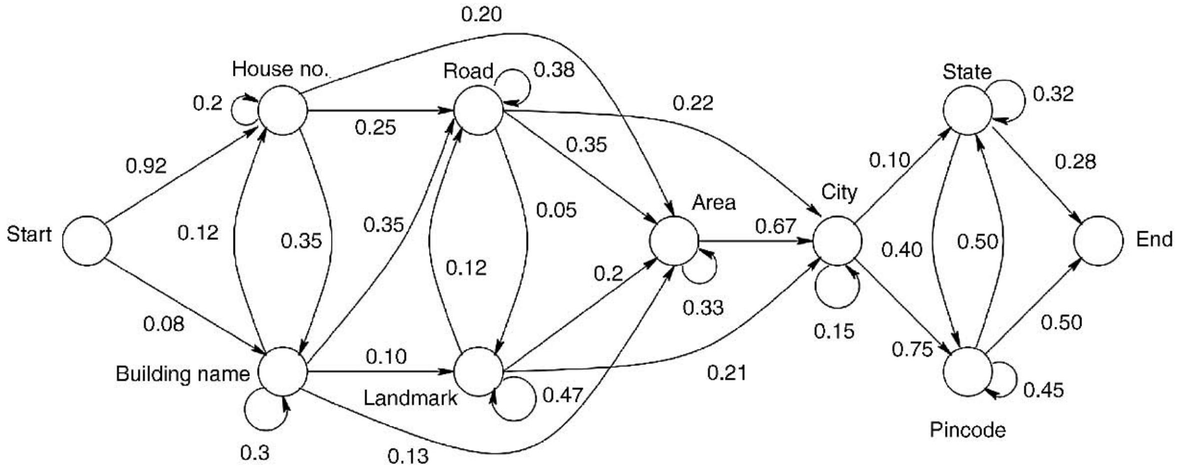
$$\Pr(\mathbf{s}|\mathbf{x},\mathbf{W}) = \frac{1}{Z(\mathrm{x})}\exp\left(\mathbf{W}.\sum_{\mathrm{j}}\mathbf{f}(j,\mathbf{x},\mathbf{s})\right) \qquad (1)$$

where $\mathbf{f}(j,\mathbf{x},\mathbf{s})$ is a vector of local feature functions $f_1 \ldots f_N$ of **s** at the jth segment and $\mathbf{W} = (W_1, W_2, \ldots, W_N)$ is a weight vector that encodes the importance of each feature function in **f**. $Z(\mathbf{x}) = \sum_{\mathbf{s}'} \mathbf{exp}(\mathbf{W} \cdot \sum_{\mathrm{j}} \mathbf{f}(j, \mathbf{x},\mathbf{s}'))$ is a normalization factor. The label of a segment depends on the label of the previous segment and the properties of the tokens comprising this segment and the neighboring tokens. Thus a feature for segment $s_j = (t_j, u_j, y_j)$ is a function of the form $f(y_j, y_{j-1}, \mathbf{x}, t_j, u_j)$ that returns a numeric value. Example of such features are:

$$f_8(y_i, y_{i-1}, \mathbf{x}, 3, 5) = [\![x_3x_4x_5 \text{ appears in a journal list}]\!].[\![y_i = \text{journal}]\!]$$

$$f_{12}(y_i, y_{i-1}, \mathbf{x}, 19, 19) = [\![x_{19} \text{ is an integer}]\!].[\![y_i = \text{year}]\!].[\![y_{i-1} = \text{month}]\!]$$

The weight vector **W** is learnt during training via a variety of methods, such as likelihood maximization [7]. During *segmentation*, the goal is to find a



Column Segmentation. Figure 1. An example of trained HMM for segmenting addresses.

$\mathbf{s} = s_1 \ldots s_p$ for the input sequence $\mathbf{x} = x_1 \ldots x_n$ such that $\Pr(\mathbf{s}|\mathbf{x}, \mathbf{W})$ (as defined by (1) is maximized.

$$\arg\max_{s} \Pr(\mathbf{s}|\mathbf{x}, \mathbf{W}) = \arg\max_{\mathbf{s}} \mathbf{W}. \sum_j \mathbf{f}(y_i, y_{j-1}, \mathbf{x}, t_j, u_j)$$

The right hand side can be efficiently computed using dynamic programming. Let L be an upper bound on segment length. Let $\mathbf{s}_{i:y}$ denote set of all partial segmentation starting from 1 (the first index of the sequence) to i, such that the last segment has the label y and ending position i. Let $V(i, y)$ denote the largest value of $\mathbf{W} \cdot \sum_j \mathbf{f}(j, \mathbf{x}, \mathbf{s}')$ for any $\mathbf{s}' \in \mathbf{s}_{i:y}$. The following recursive calculation finds the best segmentation:

$$V(i,y) = \begin{cases} \max_{y', i'=i-L \ldots i-1} V(i', y') \\ \qquad + \mathbf{W} \cdot \mathbf{f}(y, y', \mathbf{x}, i'+1, i) & \text{if } i > 0 \\ 0 & \text{if } i = 0 \\ -\infty & \text{if } i < 0 \end{cases}$$

The best segmentation then corresponds to the path traced by $\max_y V(|\mathbf{x}|, y)$.

More details on CRFs can be found in [7] and the extension of CRFs for segmentation can be found in [10]. [8] reports an empirical evaluation of CRFs with HMMs for segmenting paper citations. [4] shows how to perform efficient segmentation using CRFs in the presence of a large pre-existing database of known values.

Key Applications

Column segmentation has many applications, including,

Cleaning of text fields during warehouse construction: In operational datasets, text fields like addresses are often recorded as single strings. When warehousing such datasets for decision support, it is often useful to identify structured elements of the address. This not only allows for richer structured queries, it also serves as a useful pre-processing step for duplicate elimination.

Creation of citation databases: A key step in the creation of citation databases like Citeseer and Google Scholar, is to resolve for each citation, which paper it refers to in the database. Citations as extracted from papers are unstructured text strings. These have to be segmented into component author names, titles, years, and publication venue before they can be correctly resolved to a paper entry in the database.

Extraction of product information from product descriptions: Comparison shopping websites often need to parse structured fields representing various attributes of product from unstructured HTML sources.

URL to Code

Java packages for column segmentation using conditional random fields are available via Source Forge at http://crf.sf.net and as part of the Mallet package at http://mallet.cs.umass.edu

Common Warehouse Metamodel

Liam Peyton
University of Ottawa, Ottawa, ON, Canada

Synonyms

Common Warehouse Metadata Interchange (CWMI); CWM

Definition

The Common Warehouse Metamodel (CWM™) is an adopted specification from the OMG (Object Management Group) standards body. It defines standard interfaces that can be used to enable easy interchange of data warehouse and business intelligence metadata between data warehouse tools, data warehouse platforms and data warehouse metadata repositories in distributed heterogeneous environments. It supports relational, non-relational, multi-dimensional, and most other objects found in a data warehousing environment. It leverages three other standards from OMG:

- UML – Unified Modeling Language
- MOF – Meta Object Facility
- XMI – XML Metadata Interchange

The Object Management Group has been an international, open membership, not-for-profit computer industry consortium since 1989 with over 700 member organizations.

Historical Background

An initial Request For Proposal (RFP) for a common warehouse metadata interchange (CWMI) was issued by the OMG (Object Management Group) in 1998. A joint submission was received by the OMG in 1999 from Dimension EDI, Genesis Development Corporation, Hyperion Solutions, International Business Machines, NCR, Oracle, UBS AG, and Unisys.

At the time, there was a competing initiative from the Meta Data Coalition (MDC) which was supported by Microsoft and others. In 2000, however the two initiatives merged when the MDC joined OMG [5]. In 2001, version 1.0 of the specification was adopted with the name: Common Warehouse Metamodel (CWM™). The currently adopted version is 1.1 [1] (March, 2003).

The purpose of the Common Warehouse Metamodel specification was to make it possible for large organizations to have a metadata repository with a single metamodel. In practice this was not possible to achieve, since every data management and analysis tool requires different metadata and different metadata models [3]. Instead, the CWM specification defines interfaces that facilitate the interchange of data warehouse metadata between tools. In particular, the OMG Meta-Object Facility (MOF™) bridges the gap between dissimilar meta-models by providing a common basis for meta-models. If two different meta-models are both MOF-conformant, then models based on them can reside in the same repository.

However, compliance with the CWM specification does not guarantee tools from different vendors will integrate well, even when they are "CWM-compliant." The OMG addressed some of these issues by releasing patterns and best practices to correct these problems in a supplementary specification, the Common Warehouse Metamodel (CWM™)) Metadata Interchange Patterns (MIP) Specification. Version 1.0 [2] was released in March 2004.

Foundations

The Common Warehouse Metamodel enables organizations and tool vendors to define and represent their metadata, metadata models and the processes which manipulate them in a common format so that the information can be streamed between tools and accessed programmatically [4].

The basic architecture and key technologies supporting the Common Warehouse Metamodel are shown in Fig. 1, on the next page. Metadata in a variety of formats, and from a variety of sources (Tools, Repositories, Databases, Files, etc.) is defined and represented in UML notation, based on the objects and classes that are defined in the Common Warehouse Metamodel. That representation is persisted in an XML notation that can be streamed to other tools, repositories, databases or files based on the XMI protocol. Finally, MOF is used to provide a broker facility that supports the ability to define and manipulate metamodels programmatically using fine grained CORBA interfaces. Using this architecture, organizations can create a single common repository which stores all the CWM-modeled descriptions of metadata and metamodels.

An example of a CWM description of a table from a relational database is shown below, along with the metadata description of the type of one of its columns (type="22");

```
<CWMRDB:Table xmi.id="_15" name="MyTableName">
 <CWM:Classifier.feature>
  <CWMRDB:Column xmi.id="_16" name="myPrimaryKeyID" precision="4" type="_17"/>
  <CWMRDB:Column xmi.id="_18" name="myForeignKey1ID" precision="4" type="_17"/>
  <CWMRDB:Column xmi.id="_19" name="myForeignKey2ID" precision="4" type="_17"/>
 <CWMRDB:Column xmi.id="_20" name=" myForeignKey3ID" precision="4" type="_17"/>
 <CWMRDB:Column xmi.id="_21" name="description" length="200" type="_22" />
 </CWM:Classifier.feature>
 <CWM:Namespace.ownedElement>
  <CWMRDB:ForeignKey xmi.id="_23" name="unnamed_23" namespace="_15" feature="_19" uniqueKey="_24"/>
 </CWM:Namespace.ownedElement>
</CWMRDB:Table>
<CWMRDB:SQLSimpleType
  xmi.id="_22"
  name="VARCHAR2"
  visibility="public"characterMaximumLength="200"
  characterOctetLength="1" type
  Number="12"/>
```

The CWM specifications consists of a collection of metamodels (defined in UML) that capture all the elements of metadata, metamodels, and their processing that can be expressed when exchanging information between tools. These are what is identified in Fig. 1 as the Common Warehouse Metamodel. It is organized into five layers of abstraction.

Object Model

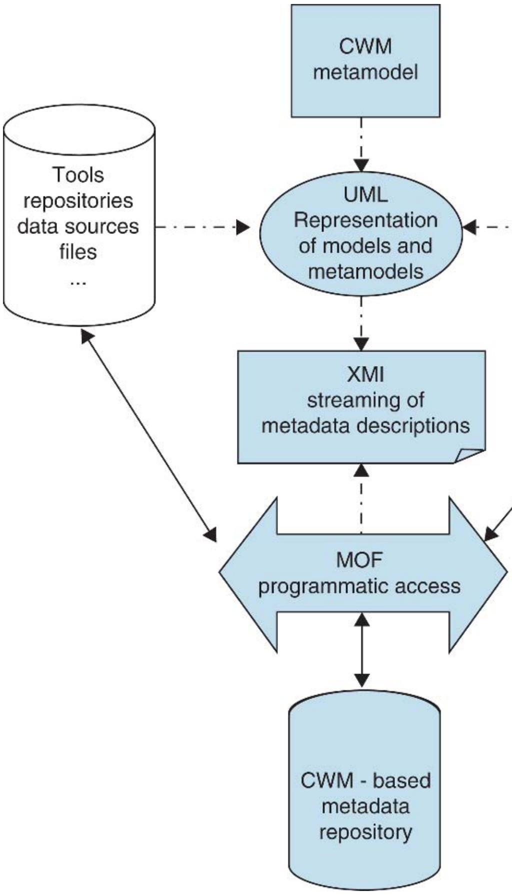
The Object Model layer is the base layer of the Common Warehouse Metamodel. The metamodels in the Object Model layer define the subset of UML that is used for creating and describing the CWM. They are the building blocks used by all the metamodels in the upper layers. This enables CWM to leverage UML's concepts without requiring implementations to support all full of UML's capabilities.

- Core
  The Core metamodel contains basic classes and associations used by all other CWM metamodels like Namespace, Constraint, Attribute, ModeledElement etc.
- Behavioral
  The Behavioral metamodel describe the behavior of CWM types and how that behavior is invoked with classes like Event, Parameter, CallAction etc.
- Relationships
  The Relationships metamodel describes two types of relationships between object within a CWM information store: generalizations (for parent-child relationships) and associations (for links between objects).
- Instance
  The Instance metamodel contains classes to support the inclusion of data instances with the metadata.

Foundation

The metamodels in the Foundation layer contain general model elements that represent concepts and structures shared by other CWM packages. Metamodels in this layer are not necessarily complete, but serve as a common basis that can be shared with other metamodels.

- Data Types
  The DataTypes metamodel supports definition of metamodel constructs that modelers can use to create the specific data types they need with classes like Enumeration, Union, EnumerationLiteral, UnionMember, etc.
- Expression
  The Expressions metamodel supports the definition of expression trees.
- Keys and Indexes
  This metamodel defines the basic concepts of Index, IndexedFeature, UniqueKey, and KeyRelationship.



CWM metamodel
Tools repositories data sources files ...
UML Representation of models and metamodels
Tools repositories data sources files ...
XMI streaming of metadata descriptions
MOF programmatic access
CWM - based metadata repository

Common Warehouse Metamodel. Figure 1. Common warehouse metamodel architecture.

- Type Mapping
  This metamodel is used to support the mapping of types between different tools or data sources.
- Business Information
  The Business Information metamodel supports business-oriented information about model elements with classes like ResponsibleParty, Contact, ResourceLocater etc.
- Software Deployment
  The Software Deployment metamodel contains classes like SoftwareSystem, Component, Site to record how the software in a data warehouse is used.

Resource

The metamodels in the resource layer define the type of data sources and formats that are supported.

- Relational
  The Relational metamodel describes relational data this is accessed through an interface like ODBC, JDBC or the native interface of a relational database.
- Record
  The Record metamodel describes the concept of a record and its structure that can be applied to data records stored in files and databases, or to programming language structured data types.
- Multi-Dimensional
  The Multi-Dimensional metamodel describes a generic representation of a multidimensional database using classes like Schema, Dimension, Member etc.
- XML
  The XML metamodel describes the metadata of XML data with classes like ElementType, Attribute etc.

Analysis

The metamodels in the analysis layer define the types of interaction with metadata that are supported.

- Transformation
  The Transformation metamodel contains classes to describe common transformation metadata used

in Extract, Transform, Load (ETL) tools and processes.

- OLAP
  The OLAP metamodel contains classes to describe common analysis metadata using in OLAP processing with classes like MemberSelection and CubeDeployment.
- Data Mining
  The Data Mining metamodel provide the necessary abstractions to model generic representations of both data mining tasks and models (i.e., mathematical models produced or generated by the execution of data mining algorithms).
- Information Visualization
  The Information Visualization metamodel contains classes like Rendering, RenderedObject, to describe metadata associated with the display of data.
- Business Nomenclature
  The Business Nomenclature metamodel supports the definition of terms used in capturing business requirements with classes like Nomenclature, BusinesDomain, Taxonomy, Glossary, Term, Concept, etc.

Management

The metamodels in the management layer define two aspects of warehouse management.

- Warehouse Process
  The Warehouse Process metamodel supports the documentation of process flows used to execute transformations. A process flow can associate a transformation with a set of events, which will be used to trigger the execution of the transformation.
- Warehouse Operation
  The Warehouse Operation metamodel contains classes for the day-to-day operation and maintenance of the warehouse including scheduled activities, measurements, and change requests.

Key Applications

Vendors of data warehouse tools, conform to the CWM specification to ensure that the metadata in their tools is open and accessible to any CWM compliant tool.

Large organizations leverage the specification in order to be able to manage and maintain there data warehouses in a common metadata repository. By using the CWM specification IT administrators and system integrators can extract and link metadata from different vendors tools.

Oracle, IBM, SA, Informatica, Meta Integration Technology Incorporated are among several industry leaders who have data warehouse tools that are CWM compliant to facilitate interoperability.

Synonyms

Comparative analysis

Definition

Comparative visualization refers to

1. Methods that support the process of understanding in what way different datasets are similar or different.
2. Methods that allow comparing different characteristics of a given dataset.
3. Methods that allow a comparison of different types of (linked) data graphics.

Key Points

Comparisons of datasets may occur in different ways. Data value to data value: entries of different datasets are compared to one another based on their values; derived quantity to derived quantity: these could be statistical moments of data fields or topological characteristics; methodology to methodology: comparisons of methodologies involve quantifying differences in experiment or simulation parameters; and, if the data are visualized, image to image: such comparisons quantify the differences in the visualizations produced by a given graphical method.

Comparative visualization methods have been developed as an enabling technology for computational and experimental scientists whose ability to collect and generate data far outpaces their ability to analyze and understand such data. The Visualization and Analysis Center for Enabling Technologies (http://www.vacet.org), for example, provides (publicly available) comparative data visualization software [1] for the scientists at the various research labs associated with the US Department of Energy.

Graphical displays that readily allow simultaneous comparisons of several characteristics of multivariate datasets – the parallel coordinate display for example – are sometimes referred to as "comparative graphs."

There is evidence that visual explorations into a dataset's structure are particularly effective when the data can be compared by simultaneously observing different visualizations of the same data. Today's data visualization packages routinely include several different graphic methods to allow such comparisons. To be truly effective, the different graphics should be operationally linked. See [2] and [3] for two examples among others.

Compensating Transactions

Greg Speegle
Baylor University, Waco, TX, USA

Definition

Given a transaction *T*, and its compensating transaction *C*, then for any set of transactions *H* executing concurrently with *T*, the database state *D* resulting from executing *THC* is equivalent to the database state D' resulting from executing *H* alone. Typically, equivalent means both *D* and D' satisfy all database consistency constraints, but *D* and D' do not have to be identical.

A compensating transaction is defined in terms of its corresponding failed transaction, and once started, must be completed. This may involve re-executing the compensating transaction multiple times. The result of compensation is application dependent.

Key Points

A *compensating transaction* is a set of database operations that perform a logical undo of a failed transaction. The goal of the compensating transaction is to restore any database consistency constraints violated by the failed transaction without adversely affecting other concurrent transactions (e.g., *cascading aborts*). However, it does not require the database to be in the exact same state as if the transaction had never executed as with traditional *ACID* properties. A compensating transaction also removes the externalized affects of a failed transaction [2].

Compensating transactions can best be understood by comparing them to traditional atomicity requirements. Under traditional atomicity, either all effects of a transaction are present in the database, or none of them are. Thus, if a transaction T_1 updates a data item and transactions T_2 reads that update, in order to remove all of the effects of T_1, T_2 must also be removed. With compensating transactions, the abort of T_2 is not be required.

Consider an example application of a company manufacturing widgets. The transaction for buying widgets consists of two subtransactions, one to order the widgets and another to pay for them. Since this business is very efficient, as soon as the widgets are ordered, another transaction starts executing the desired widgets. It is possible to compensate for the ordered widgets by simply removing the order from the system. The extra widgets would be produced, but they will be consumed by later orders. Under traditional atomicity requirements, the production transaction would have to be aborted if the buying transaction failed after the order was placed (for example, if the customer could not pay for the widgets).

Compensating transactions are used in long duration transactions called *Sagas* [1], and other applications that require *semantic atomicity*. Unfortunately, compensation is not universally possible – the common example of an externalized event that cannot be undone is the launching of a missile – or may be very complex. Thus, compensating transactions are used when the benefits of avoiding cascading aborts and early externalization of results outweigh the difficulty in determining the compensation.

Computationally Complete Relational Query Languages

Victor Vianu[1], Dirk Van Gucht[2]
[1]University of California-San Diego, La Jolla, CA, USA
[2]Indiana University, Bloomington, IN, USA

Synonyms

Complete query languages; Chandra and Harel complete query languages

Definition

A *relational query language* (or query language) is a set of expressions (or programs). The semantics of a query language defines for each of these expressions a corresponding query which is a generic, computable function from finite relation instances to finite relation instances over fixed schemas. A query language is *computationally complete* (or complete) if it defines all queries.

The genericity condition is a consistency criterion requiring that a query commute with isomorphisms of the database domain. Thus, when applied to isomorphic input relation instances, a query returns isomorphic output relation instances. The concept of genericity is based on the well-accepted idea that the result of a query should be independent of the representation of data in a database, and should treat the elements of the database as uninterpreted objects [4]. The computability condition requires that the query can be effectively computed, in other words it must be *implementable* by a program of a Turing-complete programming language under some suitable encoding of relation instances into objects of that language.

Historical Background

The search for an appropriate notion of "complete" query language began soon after the introduction of the relational model by Codd, with its accompanying query languages relational algebra (RA) and relational calculus (RC) [9]. Initially, RA was proposed as a yardstick for query expressiveness. A language was called by Codd "relationally complete" if it was able to simulate RA [10]. Bancilhon and Paredaens independently proposed the notion of BP-completeness of a language, using an instance-based approach: a language is BP-complete if for every pair of input and output instances satisfying a consistency criterion (The criterion requires that every automorphism of the input be also an automorphism of the output) there exists a query in the language mapping the input instance to the output instance [5,13]. The notion of genericity was first articulated in the database context by Aho and Ullman [4], although its roots can already be found in the consistency criterion used in the definition of BP-completeness, and an idea similar to genericity underlies Tarski's concept of "logical notion," introduced in a series of lectures in the mid 1960s [15]. The modern notion of computationally complete query language is due to Chandra and Harel, who also defined the first such language, QL [7].

Foundations

Codd introduced the relational model and its query languages, relational algebra (RA) and relational calculus (RC). These query languages are equivalent, i.e., they define the same set of queries. For example, assuming that **R** and **S** are relation schemas both of arity 2, then the RA-expression $\pi_{1,4}(\sigma_{2=3}(\mathbf{R} \times \mathbf{S})) \cup (\mathbf{R} - \mathbf{S})$, and the RC-expression $\{(x, y) \mid \exists z : (\mathbf{R}(x, z) \wedge \mathbf{S}(z, y)) \vee (\mathbf{R}(x, y) \wedge \neg \mathbf{S}(x, y))\}$ define the same computable query Q which maps each relation instance R over **R** and each relation instance S over **S** to their join unioned with their set difference. Notice that Q is also generic: consider, for example, the input relation instances

$$R_1 = \boxed{\begin{array}{cc} a & b \\ a & c \end{array}} \quad S_1 = \boxed{\begin{array}{cc} a & b \\ b & d \end{array}}$$

and the isomorphic input relation instances

$$R_2 = \boxed{\begin{array}{cc} e & f \\ e & g \end{array}} \quad S_2 = \boxed{\begin{array}{cc} e & f \\ f & h \end{array}}$$

then $Q(R_1, S_1)$ and $Q(R_2, S_2)$ are the isomorphic output relation instances $\boxed{a \quad c}$ and $\boxed{e \quad g}$, respectively. (As a caveat to genericity, consider the query C defined by the RA-expression $\sigma_{1=\mathbf{a}}(\mathbf{R})$, where **a** is some *constant* interpreted as a. Then, $C(R_1) = R_1$, but $C(R_2) = \emptyset$. The difficulty is that, though R_1 and R_2 are isomorphic, they are not isomorphic by an isomorphism that *fixes* a. If however, the value of e in R_2 is replaced by a, then $C(R_2^{e \leftarrow a}) = R_2^{e \leftarrow a}$. This suggests that when constants are involved, genericity should be modified to isomorphisms that fix these constants. In the literature, this is referred to as **C**-genericity.)

The development of the relational model led to the introduction of the query language SQL which has, at its logical core, a sub-language pure-SQL, that is equivalent with RA and RC. For example, in pure-SQL, the query Q can be defined by the expression (Here A, B, C, and D are attribute names referring to the first and second columns of **R**, and the first and second columns of **S**, respectively.)

```
(SELECT R.A, S.D AS B FROM R, S WHERE R.B = S.C)
  UNION
  (
  (SELECT R.A, R.B FROM R)
  EXCEPT
  (SELECT S.C AS A, S.D AS B FROM S)
  );
```

A natural question is now "Are RA, RC, and pure-SQL complete query languages?" The answer is no. To this end, consider the following three queries, which are easily seen to be generic and computable:

1. TC maps each binary relation instance R to its transitive closure R^*.
2. EVEN maps each unary relation instance R to $\{()\}$ (true) if $|R|$ is even, and to $\emptyset$ (false), otherwise.
3. EVEN$^<$ maps each pair of a unary relation instance R and a binary relation instance O to EVEN(R) if O defines an ordering on $dom(R)$, and is undefined otherwise. (Here, $dom(R)$ denotes the set of values that occur in the tuples of R.)

It turns out that none of the above queries is expressible in RA (or RC, or pure-SQL). Consider (1). Fagin showed in [11] that the TC query cannot be defined by any RC expression (the result was later re-proven for RA by Aho and Ullman [4]). Intuitively, the difficulty in computing TC is the following. For each $i \geq 0$, there exists an RA-expression $\mathbf{E}^i$ that defines the pairs of elements in R at distance i in the directed graph represented by R. However, there does not exist a *single* RA-expression that defines the union of all these pairs, as needed for computing TC. A solution to this problem is to augment RA with an *iteration* construct. This led Chandra and Harel to define the language While (initially introduced as RQ in [8] and LE in [6]). The language uses, in addition to database relations, typed relational variables (of fixed arity) initialized to ∅, to which RA expressions can be assigned. Iteration is provided by a construct "while change to **R** do ⟨program⟩ od" whose semantics is to iterate ⟨*program*⟩ as long as the value of the relational variable **R** changes. For example, the following While program defines TC:

```
$\mathbf{TC} := \mathbf{R}$;
while change to $\mathbf{TC}$
    do $\mathbf{TC} := \mathbf{TC} \cup \pi_{1,4}(\sigma_{3=4}(\mathbf{TC} \times \mathbf{R}))$ od.
```

Here **TC** is a binary relation variable (initialized to ∅). The program first assigns R to **TC**, then loops as long as **TC** changes. Upon termination, this value is R^*. One might hope that While is a complete query language. However, this is not the case. Indeed, even though it is easy to write a While program that defines the $\text{EVEN}^<$ query, Chandra showed that no such program can define the simple linear-time computable EVEN query [6]. Thus, While is not computationally complete. Intuitively, While programs do not have the ability to compute with natural numbers, unless such computations can be simulated by utilizing an ordering on the elements of its input. With such orderings available, While can define precisely the PSPACE-computable queries [17]. The PSPACE upper bound (that holds with or without order) is a consequence of the fact that a program's finite set of variables are of fixed arity and can only hold relation instances built from the elements of its inputs.

To overcome these problems, it appears natural to embed RA into a language that can perform arbitrarily powerful computations. This is in the spirit of "embedded SQL" languages, in which a computationally complete programming language such as C or Java accesses the database using SQL queries. A language called LC (for *Looping+Counters*), abstracting the "embedded SQL" paradigm, was introduced by Chandra [6] (with a variant called WhileN later defined in [1]). The language LC extends While by allowing integer variables (initialized to zero) that can be incremented or decremented. Iteration for computation on integers is provided by an additional while loop of the form "while i > 0 do ⟨program⟩ od" which causes ⟨program⟩ to iterate as long as the value of the integer variable i is positive. For example, consider the following program in an LC-like syntax: (The "if-else" statement is a macro that can be easily written using just the "while-change" construct.)

```
$\mathbf{TC} := \mathbf{R}$;
$n := 0$;
while change to $\mathbf{TC}$
    do
      $n := n + 1$;
      $\mathbf{TC} := \mathbf{TC} \cup \pi_{1,4}(\sigma_{2=3}(\mathbf{TC} \times \mathbf{R}))$
    od;
if $n \leq 1$ return $\{()\}$ else return $\emptyset$
```

At the end of the computation, n contains the number of times the body of the *while* loop was executed. Thus, if R is non-empty, the final value of n is the diameter of the directed graph represented by R (here the diameter means the maximum finite distance between two nodes). The program returns {()} (true) if n ≤ 1 and ∅ (false) otherwise. Note that, since LC is computationally complete on the integers, the condition "n ≤ 1" could be replaced by *any* computable property of n. Thus, LC can test any computable property of the diameter of R. Clearly, LC can define strictly more queries than While, since all computable functions on natural numbers can be defined and used. This leads to the next question: "Is LC a complete query language?" Again, the answer is no. Indeed, Chandra showed that the EVEN query can still not be defined in this language. This time, the difficulty stems from the fact that, even though the values of the relation and natural number variables can depend on each other, LC programs lack the ability to *explicitly coerce* (encode) these values into each other. However, when input relation instances are accompanied by an ordering of the domain, such coercions can be simulated, and Abiteboul and Vianu showed that then LC *is* complete [1].

To obtain a complete language without order, several solutions are possible. A brute force approach to the coercion problem is to augment LC with an encoding function *enc* mapping relations to integers, and a decoding function *dec* returning query answers from their encodings and the original input database. Since LC is computationally complete on integers, it can compute the integer encoding of the answer from that of the input. Although this theoretically produces a complete language, manipulating integer encodings of databases is not a satisfying solution, so further discussion of this approach is omitted. Instead, two more appealing alternatives are described, that both go back to While as a starting point and extend it in different ways. Recall that While is limited to PSPACE computations, as a consequence of two facts: (i) only relations of fixed arity are used, and (ii) the relations can be populated by tuples using only elements occurring in the input. The first approach, proposed by Chandra and Harel, breaks the PSPACE space barrier by relaxing (i) it allows untyped relational variables, whose arity can grow arbitrarily. The other approach, introduced by Abiteboul and Vianu, relaxes (ii) it keeps typed relational variables but allows the introduction of new domain values in the course of the computation. These languages are described next.

The complete language proposed by Chandra and Harel was called QL [6]. Up to minor syntactic differences, QL is very similar to While, only with untyped relation variables. Consider the following QL program (For simplicity, the syntax used here differs slightly from the original QL syntax.) which is strikingly similar to the LC program shown above:

```
$\mathbf{TC} := \mathbf{R}$;
$\mathbf{ONE} := \pi_1(\mathbf{R}) \cup \pi_2(\mathbf{R})$;
$\mathbf{N} := \{()\}$;
while change to $\mathbf{TC}$
    do
      $\mathbf{N} := \mathbf{N} \times \mathbf{ONE}$;
      $\mathbf{TC} := \mathbf{TC} \cup \pi_{1,4}(\sigma_{2=3}(\mathbf{TC} \times \mathbf{R}))$
    od;
if $(\mathbf{N} = \{()\})$ or $(\mathbf{N} = \mathbf{ONE})$ then return $\{()\}$ else
return $\emptyset$.
```

In this program, **R** is a binary relation input variable, and **TC**, **ONE**, and **N** are relation variables. Note that the arities of **TC** and **ONE** remain fixed throughout the execution of the program, while the arity of **N** changes. Integers can be easily simulated using the arity of relations. Thus, starting with relation instance R, the variable **ONE** is initialized to dom(R), which plays the role of the natural number 1. The variable **N** plays the role of a natural number variable n. The statement **N** :=$\{()\}$ corresponds the statement n = 0, and the statement **N** := **N** ×**ONE** serves to increment n by 1; notice that the × operator plays the role of the addition operator + over natural numbers, and the decrement operator can be simulated by projection. Similarly to the earlier LC program, the final arity of **N** is the diameter of the directed graph represented by **R**. The final "if" statement compares **N** to $\{()\}$ or **ONE**, and the program returns $\{()\}$ (true) if the diameter of **R** is at most 1, and $\emptyset$ (false) otherwise. Observe therefore that this QL program defines the same query as its corresponding LC program.

The above example illustrates how arithmetic on natural numbers can be simulated in QL. So far, this allows simulating LC. Recall that LC is not complete, but becomes so if an ordering of the domain is provided. QL is however complete even if an ordering is not provided, because it can construct its own orderings! Indeed, such orderings of the domain can simply be constructed in QL by building one relation whose arity equals the size of the input domain. In such a relation, any tuple that does not contain repeated elements provides a successor relation on the domain, which in turns induces an ordering. The completeness of QL now follows from the completeness of LC on ordered domains. Thus, QL can express all computable queries. But is everything it expresses a query? It is easy to see that all mappings defined by QL programs are computable and generic. The difficulty is to guarantee that a QL program always produces answers of the desired arity. In fact, this property is undecidable for QL programs. Fortunately, there is an effective syntactic restriction guaranteeing that QL programs are "well behaved," i.e., always produce answers of fixed arity. Moreover, all computable queries can be expressed by QL programs satisfying the syntactic restriction.

The language WhileNew, introduced by Abiteboul and Vianu in [3], extends While by allowing the creation of new values throughout the computation. This is achieved by an instruction of the form **S** := new(**R**), where **R** and **S** are relational variables and arity(**S**) = *arity*(**R**) + 1. The semantics is the following. Given a relation instance R over **R**, the relation instance S over **S** is obtained by extending each tuple of R by one distinct new value not occurring in the input, the current state, or in the program. For example, if R is the relation instance in Fig. 1 then S is of the form shown in the same figure. The values α,β,γ are distinct new values. Note that the new construct is, strictly speaking, nondeterministic. Indeed, the new values are arbitrary, so several outcomes are possible depending on the choice of values. However, the different outcomes differ *only* in the choice of new values.

The ability to successively introduce new values throughout the computation easily allows simulating integers and arithmetic, yielding the power of LC. Moreover, orderings of the input domain can also be constructed and marked by distinct new values. Since LC is complete on ordered domains, this shows that

WhileNew can express all computable queries. As in the case of QL, one must ask whether *all* mappings expressed by WhileNew are in fact queries according to the definition. The difficulty arises from the presence of new values. Indeed, if new values may appear in the outputs of a WhileNew program, the mapping it defines is non-deterministic. Moreover, it is undecidable whether a WhileNew program never contains new values in its output. The solution to this problem is similar to the one for QL: one can impose a syntactic restriction on WhileNew programs guaranteeing that no new value appears in their answers. All generic computable queries can be expressed by WhileNew programs satisfying the syntactic restriction.

As an aside, suppose the definition of query is extended by allowing new values in query answers. This arises naturally in some contexts such as object-oriented databases, where outputs to queries may contain new objects with their own fresh identifiers. One might hope that WhileNew remains complete for this extension. Surprisingly, it was shown by Abiteboul and Kanellakis that the answer is negative [2]. Indeed, WhileNew cannot express the query containing the input/output pair shown in Fig. 2, where $\psi_0,\ldots,\psi_3$ are new values. As shown by Abiteboul and Kanellakis, completeness with new values can be achieved by adding to WhileNew a construct called *duplicate elimination*. This is however a rather complex construct, that encapsulates a test for isomorphism of relations. The search for a language using more natural primitives and complete for queries with new values in the answer remains open.

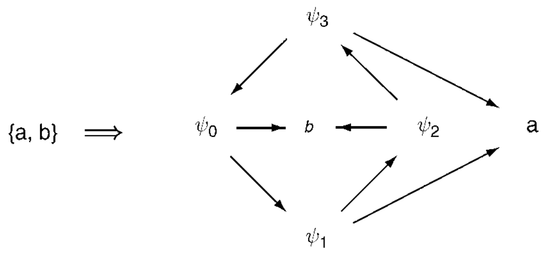
Computationally Complete Relational Query Languages. Figure 1. An application of new. Here, $S = \text{new}(R)$.



Computationally Complete Relational Query Languages. Figure 2. A query with new values not expressible in WhileNew.

The relational model, though very simple, is not always the most natural model for databases in certain application domains. In the late 1980s and early 1990s database researchers considered object-oriented databases as an alternative to the relational model, and a significant amount of theory was developed around the model and its query languages, including the completeness of object-oriented query languages (see [1,16]). Finally, consistency notions other than genericity can be considered for specialized application domains. This was done, for example, in the context of spatial databases [12,14].

Key Applications

The theoretical query languages discussed here are closely related to various practical languages. Thus, RA and RC correspond to pure-SQL. The language While corresponds to wrapping programming constructs such as loops around SQL, as done in PL/SQL (Oracle); assignment statements can be implemented using SQL insert and delete operations.

The language LC (or WhileN) can again be simulated in PL/SQL augmented with natural number variables (with no coercion allowed). Another approach is to embed SQL in a programming language such as C or Java. In such languages, relational variables must be statically defined and so have fixed arity. One significant feature of the embedded SQL languages that sets them apart from LC is that they allow accessing tuples in relations one at a time, using looping over cursors. In particular, this allows coercing the entire database into a native data structure, and yields computational completeness. However, there is a catch: programs using cursors are generally non-deterministic, in the sense that running the same program on the same database content may yield different results. Unfortunately, it is undecidable whether a given embedded SQL program is deterministic, and no natural syntactic restriction is known that ensures determinism while preserving completeness. Thus, completeness is achieved at the cost of losing the guarantee of determinism.

The computationally complete language QL can be simulated in Dynamic SQL. In this language one can dynamically create relation variables whose schemas depend on the data in the database. This can be used to support untyped relational variables. The language WhileNew allowing the introduction of new domain values is akin to object-oriented languages that allow the creation of new object identifiers.

Future Directions

The database area is undergoing tremendous expansion and diversification under the impetus of the Web and a host of specialized applications. Consequently, new structures and objects have to be modeled and manipulated. For example, in biological and scientific applications, sequences and matrices occur prominently; in XML databases, text and tree-structured documents are the main objects. This has led to new database models and query languages. Their formal foundations are fast developing, but are not yet as mature as for the relational data model. Notions of computationally complete languages for the new models are still emerging, and are likely to build upon the theory developed for relational databases.

Complex Event

Opher Etzion
IBM Research Lab in Haifa, Haifa, Israel

Synonyms

Composite event; Derived event

Definition

A complex event is an event derived from a collection of events by either aggregation or derivation function [3].

Key Points

A complex event [2], [1] is a derived event; it can be derived by various means:

1. Explicit concatenation of a collection of events,
   - Example: Create an event that contains all the events that are related to the 2008 USA presidential elections.

2. Derivation of an aggregated value from a collection of events from the same type.
   - Example: Create an event that contains the average, maximal and minimal value of a certain stock during a single trade day.
3. Derivation [4] of an event as a function of other events that is a result of event pattern detection.
   - Example: Whenever a sequence of three complain-events from the same customer occurs within a single week, create an event "angry customer" with the customer-id.

     Note that this event may or may not contain the raw complain events.

IBM Research Lab in Haifa, Haifa, Israel

Synonyms

Event processing; Event stream processing

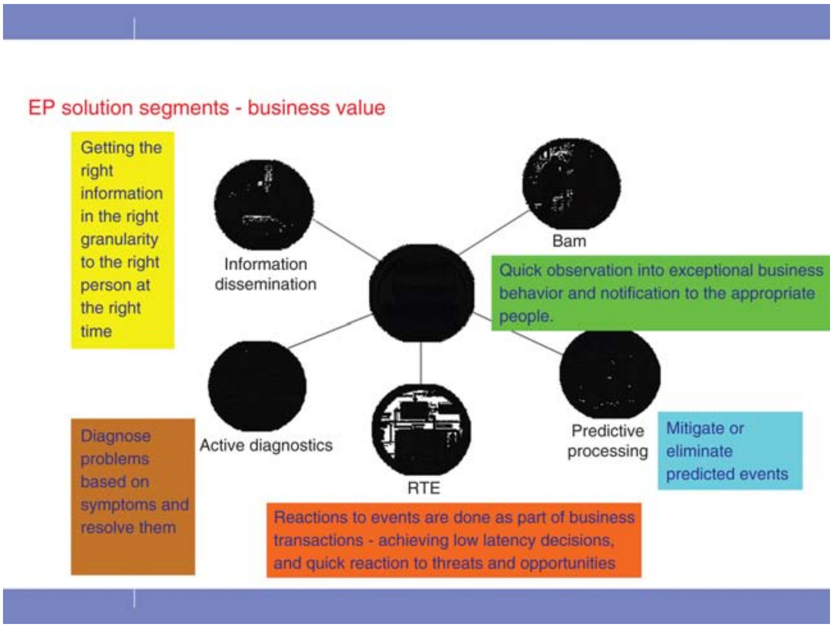
Definition

Complex event processing deals with various types of processing complex events.

Key Points

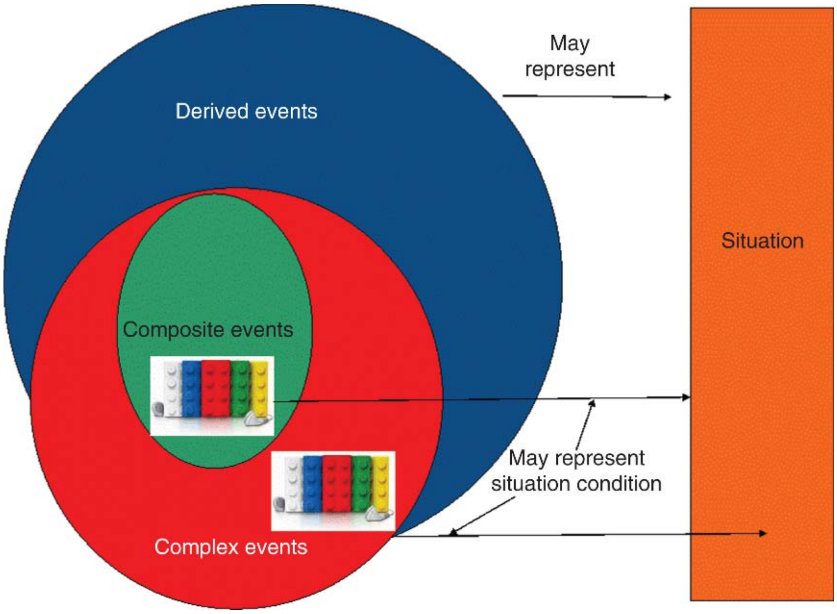
Figure 1 shows that the different applications of the CEP technology are not monolithic, and can be classified into five different solution segments, which differ in their motivation, from the user's perspective, they are:

- *RTE (Real-Time Enterprise)*: The processing should affect business processes while they are still running. For example, stop an instance of a workflow that deals with trading a certain stock, if the trade request has been withdrawn.
- *Active Diagnostics*: Finding the root-cause of a problem based on events that are symptoms.
- *Information Dissemination*: A personalized subscription that enables subscriptions in lower granularity, where the subscription does not match the published



EP solution segments - business value
Getting the right information in the right granularity to the right person at the right time
Information dissemination
Bam
Quick observation into exceptional business behavior and notification to the appropriate people.
Active diagnostics
RTE
Predictive processing
Mitigate or eliminate predicted events
Diagnose problems based on symptoms and resolve them
Reactions to events are done as part of business transactions - achieving low latency decisions, and quick reaction to threats and opportunities

Complex Event Processing. Figure 1. Various CEP solution semgents.



Complex Event Processing. Figure 2. Relationships among major complex event processing terms.

event, but a combination of event. For example, notify me when IBM stock has gone up 2% within 1 hour.

- *BAM (Business Activity Management)*: Monitor for exceptional behavior, by defining KPI (Key Performance indicators) and other exceptional behavioral constraints. For example, the delivery has not been shipped by the deadline.
- *Prediction*: Mitigate or eliminate future predicted events.

Figure 2 shows the relations among the different terms around complex event processing. Complex event may be a derived event, but the overlapping among them is partial, the complex event processing is materialized by detecting patterns which may correspond to situations (cases that require action). The exact definitions of terms can be found in the EPTS glossary.

Composed Services and WS-BPEL

Francisco Curbera

Service orchestration; Service choreography; WS-BPEL; Web services business process execution language

Definition

Service oriented architectures (SOAs) are models of distributed software components where business or scientific functions are delivered by a network of distributed services. Services can be classified into atomic services and composed services, based on how they are created and run. Atomic services are those that do not depend on other services for their operation, and are typically built on technologies native to a specific platform, such as COBOL or Enterprise Java Beans. Composed services are created by composing the function provided by one or more external services into a new service. There is no restriction implied as to the programming model used to create composed services; platform specific programming models such as Enterprise Java Beans or C# have been extended to support the creation of composed services. In addition to that approach, service centric programming models have been defined to support the development of composed services. Foremost among those is the Web Services Execution Language for Web Services (WS-BPEL or BPEL), a service composition language based on the workflow programming model.

Historical Background

The service oriented architecture model [1] evolved early on to include aspects of a component oriented architecture, based on the similarity between the reuse of services and of traditional software components. Component oriented software development has been a constant reference point in the development of SOA. Service composition also draws from the experience of workflow programming and business process reengineering [5] as it developed throughout the 1990s. The workflow programming model relies on a two level programming paradigm in which applications are combined to accomplish a business goal by means of a graph oriented programming approach. The term "two level programming" derives from the differentiation between the programming task whose goal is to create the individual applications and the creation of the workflow control and data graphs whose goal is the use of those applications to achieve a particular business goal. Because of the close alignment between two level programming and SOA service reuse through composition, workflow programming became a second reference point in the early development of the SOA model, leading to process oriented service composition models and eventually the WS-BPEL language [10].

Foundations

Services and Components

The component oriented software development model (COSD) assumes that software applications and systems can be more efficiently developed and managed when created through the aggregation (composition) of a set of software building blocks (components) independently produced by third parties. Szyperski [8] restricts components to binary code and associated resources, to differentiate components from other software abstractions. More importantly, components are units of deployment (can be independently deployed) and composition (can be independently integrated in composed applications). Components are endowed with well defined interfaces through which they interact with other components.

Service oriented architectures build on this same paradigm. Services in SOA are nothing but the interfaces of SOA components. SOAs add an important new perspective to the usual COSD approach. Components in SOAs are not only units of independent deployment, but also units of independent ownership and management by third parties. The implication is that when creating a composite application two related perspectives are possible. In a traditional COSD approach ("component composition"), a single party deploys and maintains control and management rights over all components. The subjects of the composition task are individual software (binary) components. At runtime they are managed as parts of the composed application to which they belong. By contrast, in a service oriented approach, the subjects of the composition are the services exposed by software components, which are in principle deployed and managed independently of the composite application itself. The term "service composition" is used to refer to a new SOA application created by composing services. The services exposed by a service composition are called "composite services."

The traditional COSD approach is followed by the Service Component Architecture (SCA, see [2]), which defines a straightforward model for the deployment and composition of service oriented components. In SCA, components are "wired" to each other by connecting their interfaces, to create new SCA applications or "composites." SCA composites are component compositions, and they can provide services by exposing one or more service interfaces. Composites are deployed by deploying and configuring their constituent component's binary implementations. SCA composites are potentially components themselves, thus supporting a recursive composition model.

Service Composition Models

Focusing on both the development time and runtime natures of a service composition, it is possible to distinguish two types of service composition strategies.

"Localized" compositions specify the composite's application internal operation and its dependencies on a set of external services, including in particular the expected behavior of those services. Localized compositions are concerned with applications executing in a single logical location of control. The composition relies on a single logical node where the application logic is executed and from which the interactions with the composed services are controlled. The services used by the composite are naturally executed in separate nodes, but their operation is not the concern of the composition except for its externally visible behavior. The term "service orchestration" is sometimes used to refer to localized service compositions. WS-BPEL is the model for this type of service composition.

"Distributed" service compositions specify the behavior of a set of independent SOA applications interacting through service interfaces as part of a distributed composite application. In its purest form, a distributed composition doesn't specify the internal behavior of any of the participating applications, but only the interactions between the participating services. The execution of the composite is assumed to be distributed among a set of independent nodes, which coordinate their operation according to the composition's specification. The Web Services Choreography Description Language [7] is the prime example of this type of composition. It is also important to mention in this category of service composition the use of SCA as a service wiring specification, in particular in the context of Enterprise Service Bus runtimes; this usage of SCA is discussed later in this entry, under "Key Applications."

In spite of the difference in approach, all service composition models share a set of common characteristics. Both types of service composition require the specification of the expected behavior from the composed services. Expected behavior refers here to the message exchange sequence between the services, which is frequently referred to as a "service conversation." A service conversation is the realization of a business protocol between two parties, over a SOA infrastructure, and is the basis for business level interoperability between services.

Together with a particular service conversation, the relationship between two services is characterized by a particular interaction pattern. Several of these patterns are possible. In a hierarchical organization, the lifecycle of one service is subordinated to another's, such that the later is responsible for the creation and termination of runtime instances of the former. This is the relationship between a process and a sub-process. In a peer-to-peer interaction, both services maintain independent lifecycles and interact as peers. Again, both relationships are possible in both localized and distributed compositions.

It is clear that maintaining the appropriate level of distributed coordination between participating services at runtime is a non-trivial problem. Hierarchical lifecycle dependencies as well as distributed transactional behavior must rely on coordination middleware to ensure agreement on the outcome and synchronization of the interaction. These "coordinated behaviors" of distributed systems are supported in the Web services specification stack by the Web Services Coordination specification, which defines a framework for the creation of distributed protocols [11].

Finally, "recursive composition" is a common characteristic of all service composition models, and the basis for the creation of composite services through composition. In a recursive model, the service composition becomes a service itself, available for further invocation and composition. WS-BPEL, SCA and WS-CDL all allow the creation of new services through composition. A survey of different methodologies for development of service compositions can be found in [4].

Workflow Oriented Composition in WS-BPEL

WS-BPEL is the model and industry standard for localized service composition. WS-BPEL is also the prototype for workflow (or process) oriented composition, a form of service composition that follows the workflow programming model. The WS-BPEL specification adapts the workflow two level programming model to a service centric environment.

The WS-BPEL language consists of two main parts, one dealing with the representation of service interaction requirements and a second one dealing with the specification of the control and data logic of the workflow.

Service Interaction in Processes A WS-BPEL composition is called a "process model." Service interaction requirements are defined in terms of "abstract" Web services interfaces, that is, XML interface definitions containing no references to service access details such as interaction protocol or endpoint address. Abstract interfaces are defined using the Web Services Description Language (WSDL, see [11]); abstract interfaces are called portTypes in WSDL 1.1. The interaction between the process model and each of the composed services requires in the general case two such abstract interfaces, one used by the process to call the service and one for the service to call back on the process. This pair of interfaces characterizes the interaction and is called a "partner link" in WS-BPEL. The actual ways in which these interfaces are exercised is defined by the business logic of the process definition, which is described later in this section.

WS-BPEL service composition takes place at the interface type level ("service types composition") instead at the instance level ("service instance composition"): abstract service interfaces are referenced by the process, instead of actually deployed services. The goal of this approach to composition is to expand the reusability of WS-BPEL processes, since it allows the same process composition to be used with different services and using different access protocols, as long as the correct portTypes are supported. One particular consequence of this approach is the absence of quality of service specifications in WS-BPEL processes.

A second aspect of the interaction between services is the identification of dynamic correlation data fields for process instance identification and message routing. A WS-BPEL process specifies a model for the execution of individual "process instances." A new process instance is started any time a "start" message (as defined by the process model business logic) is received by the process engine. At any point in time, many instances of the each process model are executing the same process engine. In traditional workflow infrastructures, each instance is identified by a unique identifier, which is carried by all messages sent to the process instance. By carrying this identifier, messages can be routed to the correct instance.

WS-BPEL takes a different approach to the routing problem. The correlation between messages and process instances is done using business information fields, grouped in data sets that the WS-BPEL specification calls "correlation sets." A correlation set is a group of message fields that collectively identify the executing process instance. Correlation fields are identified using XPath expressions to point to individual data fields within the messages received by the process, allowing content based message routing to instances. Correlation information is also specified in outgoing messages, when the values of these fields need to be communicated to an external service. The main benefit of the WS-BPEL correlation approach is to replace the use of platform specific artifacts by business meaningful information for the purpose of interoperable message routing and transaction identification. Correlation values are a key element of any message oriented business protocol.

Specification of Business Logic in Process Compositions Business logic (the control and data graphs of a workflow) is specified in WS-BPEL by means of a set of "atomic" and "structured activities." Atomic activities represent individual steps in the computation of the process graph, and they stand for external service interaction steps (calling or being called by a service), or data manipulation primitives (assignment of data fields). Atomic activities are combined according to a particular sequence of execution using structured activities. WS-BPEL provides structured activities for sequential, parallel as well as conditional and iterative execution. These activities allow the creation of "structured" process graphs, those in which the programming style is similar to that of structured programming languages (albeit with intrinsic parallel capabilities).

WS-BPEL also supports a graph oriented process modeling approach, where atomic activities are combined as nodes of an explicit graph. Edges of the graph are called "control links," and represent explicit transfer of control between a source and a target activity (as opposed to the implicit dependency defined by a sequence activity for example). The execution of the control link graph follows the "dead path elimination" operational semantics where those graph branches not followed in the execution of a process instance (typically because of conditional statements are not satisfied) are transitively eliminated to ensure that every activity in the graph is eventually executed or marked as part of an eliminated "dead path." Dead path elimination and the rule that prevents cyclic control graphs ensure the termination of every valid WS-BPEL graph's execution. The graph and structured styles are however not strictly separated and can be combined in a rich but at times challenging authoring style. Dead path elimination semantics are embedded in the structured execution model through exception handling, see [3].

Data flow in WS-BPEL is not explicitly modeled, but implied by the use of a set of process variables as inputs and outputs of atomic activities. Data variables in WS-BPEL contain XML data, which is typed according to the XML Schema language.

WS-BPEL contains error handling and recovery primitives to support business interaction in loosely coupled environment. Error handling is supported through the introduction of "fault handlers" which are charged with recovering from errors generated in the course of process execution: faults generated in the course of a service call, errors explicitly raised by the process when certain business conditions are detected, and system generated faults raised when the underlying execution runtime cannot comply with the requirements of process logic (such as errors accessing message data and other error conditions).

Fault handlers are associated with sections of the process called "scopes," the complete process being the outermost scope. Faults originated within a scope are handled by the fault handlers attached to the scope. In the course of recovering from a fault, it may be determined that a particular action already competed must be "undone." A "compensation handler" may be associated with that action (atomic activity) or with a collection of actions (a scope) to indicate the steps required to "undo" that activity or scope, and would then be executed by the fault handler. A compensation handler defines a set of business level actions that provide a logical reversal (backward execution path) of the action in question. Compensation recovery represents an alternative to automatic rollback, and is necessary in service oriented scenarios where loosely coupled services cannot participate in transactions with atomic semantics and automatic rollback recovery. Business transaction in SOA environments require looser transactional semantics (see [7] for details) where recovery is typically specified at the application level.

Key Applications

Current practice of service composition is closely tied to two types of SOA runtimes available in the industry: SOA-enabled business process management (BPM) platforms and enterprise service bus (ESB) infrastructures.

WS-BPEL service composition on BPM platforms represents is by far the most extensive application of the service composition model in enterprise computing. Its success is due to two factors: the increased focus of enterprises on end-to-end business automation, and the fact that service composition builds on the well known business process integration paradigm.

There are important differences between platforms for process oriented service composition and traditional BPM, appearing in two main areas: the reach of the process integration capabilities and the approach to process management. Service oriented process composition adds a new perspective typically absent from traditional BPM platforms, namely, a uniform model for representing internal and external business function based on the service paradigm. The result is the ability to seamlessly incorporate cross departmental and cross organizational services to capture and automate end-to-end business requirements. End-to-end business automation is the main driver of SOA adoption by businesses today.

The management capabilities of the BPM platform are also significantly affected by the service oriented model. Full management is now limited to the process itself and any services deployed locally within the BPM platform. Unlike in traditional BPM, the ability to manage other services is limited (or missing altogether) because they are typically run and managed by different parties (other departmental organizations or different enterprises). BPM platforms supporting service composition must rely on service management standards (such as the Web Services Distributed Management specification [7]) and service level agreements (such as the Web Services Agreement specification, [7]) to provide visibility and limited control over the execution of remote services.

The enterprise service bus architecture (ESB, see [7]) is quickly gaining widespread adoption because it enables simplified service access and reuse across the enterprise. Services are plugged to the ESB to make them available for access by other enterprise applications. ESBs are usually built as service extensions to traditional messaging backbones ("messaging clouds"). Services and applications are connected across the ESB by creating "wires" that declaratively create a logical communication channel between the two. The SCA component and wiring model is used in this context both to drive deployment of SOA components and also to wire existing services, thus exposing its ability to function as both a component and a service composition model.

Scientific computing middleware software has, independently of its commercial counterpart, identified the need for an architectural model in which computing resources are consumed following the service model. The Open Grid Services Architecture (see [6,7]) shows how the Grid application model is supported by SOA. In this context, scientific workflows have been characterized as compositions of scientific services and specialized languages have been developed to enable the composition of complex scientific computing experiments as process oriented service compositions [9]. The Grid Process Execution Language (GPEL) in particular adapts WS-BPEL to deal with scientific and Grid computing requirements such as processing extremely large data sets, allocating dynamic resources from a Grid infrastructure, and supporting the integration with legacy scientific code among several others (see Chapter 15 in [9]).

Composite Event

ANNMARIE ERICSSON, MIKAEL BERNDTSSON,
JONAS MELLIN
University of Skövde, Skövde, Sweden

Definition

A composite event is a set of events matching an event specification.

Key Points

Pioneering work on composite events was done in the HiPAC project [3] and the ideas were extended and refined in most proposals for active object-oriented databases during the early 1990s.

A composite event is composed according to an event specification (in an event algebra), where the composition is performed using a set of event operators such as disjunction, conjunction and sequence. More advanced event operators have been suggested in literature, e.g., [2,4,5].

The *initiator* of a composite event is the event initiating the composite event occurrence and the *terminator* is the event terminating the composite event occurrence.

Events contributing to composite events may carry parameters (e.g., temporal) in which the event is said to occur. Events contributing to composite events are also referred to as constituent events.

Composite events need to be composed according to some event context that define which event that can participate in the detection of a composite event. The event context is an interpretation of the streams of contributing events. The seminal work by Chakravarthy et al. [1,2], defines four different event contexts (or consumption policies): recent, chronicle, continuous, and cumulative.

In the recent event context, only the most recent constituent events will be used to form composite events. The recent event context is, for example, useful if calculations must be performed on combinations of the last measured values of temperature and pressure in a tank [1,2].

In the chronicle event context, events are consumed in chronicle order. The earliest unused initiator/terminator pair are used to form the composite event. The chronicle event context is, for example, useful if sensors are placed along a conveyor-belt monitoring objects traveling along the belt and combinations of sensor events triggered by the same object is needed. In that case events must be combined in occurrence order since the first event from the first sensor and the first event from the second sensor are likely triggered by the same object [1,2].

In the continuous event context, each initiator starts the detection of a new composite event and a terminator may terminate one or more composite event occurrences. The difference between continuous and chronicle event contexts is that in the continuous event context, one terminator can detect more than one occurrence of the composite event.

In the cumulative event context, all events contributing to a composite event are accumulated until the composite event is detected. When the composite event is detected, all contributing events are consumed [1,2].

Synonyms

Service composition; Process composition

Definition

In computer science, *composition* is the act or mechanism to combine simple components to build more complicated ones. Composition exists at different levels. For example, one can think of the usual composition of functions in mathematics, i.e., the result of the composed function is passed to the composing one via a parameter. If one has to functions f and g, these can be combined into a new function $h = f.g$, i.e., $h(x) = f(g(x))$. Another level of abstraction is the level of activities. Here all kinds of process modeling languages can be used to compose activities into processes (e.g., Petri nets, BPMN, etc.). Typical composition operators are sequential composition, parallel composition, etc. Process composition is related to business process management, workflow management, etc. Yet another level of abstraction is provided by services, i.e., more complex services can be composed from simpler ones even when they do not reside in the same organization. Service composition is sometimes also referred to as orchestration and a typical language used for this purpose is BPEL.

Key Points

The composition of more complex components from simpler components has been common practice in computer science right from the start. It is clear that composition is needed to allow for "divide and conquer" strategies and reuse. One of the most complex issues is the composition of processes. There are basically two types of composition approaches: graphs-based languages and process algebras. Examples of graph-based languages are Petri nets, state charts, BPMN, EPCs, etc. In these languages activities and subprocesses are connected to impose some ordering relations. For example two transitions in a Petri net can be connected by a place such that the first one triggers the second one [3]. Process algebras enforce a more structured way of modeling processes. Typical operations are sequential composition ($x.y$, i.e., x is followed by y), alternative composition ($x + y$, i.e., there is a choice between x and y), and parallel composition ($x||y$, i.e., x and y are executed in parallel) [1,2]. Languages like BPEL provide a mixture of both styles, e.g., operators such as `sequence`, `switch`, `while` and `pick` correspond to the typical process-algebraic operators while the `flow` construct defines in essence an acyclic graph.

The principle of compositionality states that the meaning of a composite is determined by the meanings of its constituent parts and the rules used to combine them. For example, if a process is composed of parts that have certain properties, then these properties should be preserved by the composition and should not depend on lower-level interactions. Such properties can be obtained by simplifying the language used or restricting the compositions allowed.

Calculus expression; List comprehension; Set abstraction; ZF-expression

Definition

The comprehension comes from ideas of mathematical set theory. It originated as a way of defining sets of values so as to avoid the famous paradoxes of early set theory, by starting from other well-defined sets and using some carefully chosen constructors and filters. The values in the sets could be tuples of basic values, which suits the *relational model*, or they could be object identifiers, which fits with *ODMG object data models* [2], or they could be tagged variant records which fit well with *semi-structured data*. They could even be sets, lists or bags defined by other comprehensions.

The abstract structure of a comprehension precisely describes almost all the computations done in functional query languages, despite their very different surface syntax. Better still, it allows many optimizations to be expressed as well defined mathematical transformations.

Key Points

Consider an example, using SQL syntax, to find the set of surnames of persons whose forename is "Jim":

```
SELECT surname FROM person WHERE forename = "Jim"
```

Using a list comprehension this can be written as:

```
[surname(p) | p <- person; f <- forename
(p); f = "Jim"]
```

This denotes the list of values of the expression to the left of the vertical bar. This expression usually includes variables such as p which are instantiated by generators to the right of the bar. It can be transliterated as:

The set of values of the surname of p *such that* p *is in the set* person *and* f *is in the set* of forenames of p *and* f is equal to "Jim". Here *forename(p)* could alternatively be written *p.forename* or *(forename p)*.

Thus, the vertical bar can be read as *such that* and the semicolons as conjunctions (*and*). The arrows act as *generators*, supplying alternative possible values, subject to restrictions by predicate terms to the right, acting as *filters*. Thus p is generated from the set of persons but is only chosen where the forename of p satisfies the test of equalling "Jim".

In the above syntax the arrow operator is overloaded , so that if a function such as `forename` delivers a single value instead of a set then the arrow just assigns that single value to the variable on its left. Strictly, one should make a singleton set containing this value, and then extract it:

```
[surname(p) | p <- person; f <- [fore-
name(p)]; f = "Jim"]
```

This wasteful operation would be compiled away to give this equivalent form:

```
[surname(p) | p <- person; forename
(p) = "Jim"]
```

The term "list comprehension" is commonly used, but one should really distinguish between lists, sets and bags [1]. Thus comprehensions are usually represented internally as lists, but often the order is ignored, as in sets, and sometimes it is necessary to keep duplicates and form a bag, especially when totaling up the contents! Particular classes of operator used in comprehensions give rise to *monad comprehensions* and *monoid comprehensions* with valuable mathematical properties.

Spatio-temporal data reduction

Definition

In moving objects databases (MOD) [8], the data pertaining to the whereabouts-in-time of a given mobile object is commonly represented as a sequence of *(location, time)* points, ordered by the temporal dimension. Depending on the application's settings, such points may be obtained by different means, e.g., an on-board GPS-based system, RFID sensors, road-network sensors, base stations in a cellular architecture, etc. The main motivation for compressing the location data of the moving objects is twofold: (i) Reducing the storage requirements: for example, maintaining the information about the daily routes of a few million vehicles, even if the GPS samples are taken once every 30 s, can still generate Terra-Bytes (TB) of data. In addition, with the increase in the number of cellular phones and personal digital assistants that are location aware, the volume of the data corresponding all the mobile entities in a given region will even further increase. However, if a given point, say, (x, y, t) can be eliminated from the representation of the particular trajectory without prohibitively sacrificing the accuracy of its representation, then the space required for that point's storage can be saved; (ii) If a particular point along a given trajectory can be eliminated as soon as it is "generated" (i.e., when the *location* value is obtained by the on-board GPS at a given *time*), yet another type of savings can be achieved – that object need not transmit the *(location, time)* value to a given server, thus reducing the bandwidth consumption. This entry explains the basic problems involved in compressing spatio-temporal data corresponding to trajectories of mobile objects, and outlines the foundations of the approaches that have addressed some of those problems.

Historical Background

The field of *data compression* originated in the works of Shannon, Fano, and Huffman in the 1940s [11], and its main goal is to represent information in as compact form as possible. Some popular forms of data compression have, historically, been around even earlier, for instance, the Morse code has been used in telegraphy since the mid-nineteenth century. Based on the observation that some letters occur more frequently than others, the code assigns shorter sequences of (combinations of) "·" and "−" to such letters. Thus, for example, "*e*" → " · ", "*a*" → " ·−". On the other hand, the letters which occur less frequently, are assigned longer sequences like, for example, "*q*" → "−−·−". In this setting, the frequency of the occurrence of single letters provided statistical structure that was exploited to *reduce the average time* to transmit a particular message since, in practice, the duration of the symbol " − " is (approximately) three times longer than the duration of the "·" symbol. A natural extension is to use frequency of the *words* over a given alphabet, in order to further compress the encoding of a given text, which is used in the Grad-2 Braille coding. When the probability model of the source is known, the popular approach for encoding a collection of *letters* of a given *alphabet* is the Huffman coding [11]. Contrary to the ASCII/EBDCIC which are *fixed-length* codes, in the sense that every symbol is assigned same number of bits, Huffman code is a *variable-length* one, which assigns shorter codewords to symbols occurring less frequently, in an optimal manner with respect to the entropy of the source. When dealing with texts, some statistical correlations can be detected in terms of the occurrences of *words*. Taking this into consideration the, so called, *dictionary techniques* for data compression have been obtained, an example of which is the UNIX `compress` command. In computer science, the need for compression techniques was mainly motivated by the reduction of the size of the data for storage and transmission purposes.

Different kind of data may exhibit different kinds of structures that can be exploited for compression, provided a proper model is developed. For example, given the sequence of numbers {9,11,11,11,14,13, 15,17,16,17,20,21}, let x_n denote its nth element. If one transmits the binary representation of each x_i ($i \in \{1,2,...,12\}$), 5 bits-per-sample are needed, for a total of 60 bits transmitted. However, if one provides a model represented by the equation $\overline{x}_n = n + 8$, then the difference-sequence (i.e., the residual) of the initial sequence, represented as $e_n = x_n - \overline{x}_n$ becomes: {0, 1, 0, −1, 1, −1, 0, 1, −1, −1, 1, 1}. This sequence consists of only three different numbers {− 1, 0, 1} Using the mapping " − 1" → "00"; "0" → " − 1"; "1" → "10", each e_i can be encoded with only 2 bits. Hence, the sequence can be transmitted with a total of 24 bits, achieving 60% compression ratio and, consequently, savings in the transmission. Such intrinsic properties of the underlying domain have been heavily exploited in the areas of speech compression, image compression, etc. [11].

There are several classification of compression techniques. One example, as mentioned above, is *fixed* vs. *variable* length, however, one may also need to distinguish between *static* (the codewords are fixed, say, before the transmission) and *dynamic/adaptive*. The classification that is most relevant for this article is *lossless* vs. *lossy* compression. With lossless compression, the original data can be *exactly* recovered from the compressed one, which it is not the case for the lossy compression.

There are several different measures regarding the quality of a given compression method: (i) the complexity of the algorithms; (ii) the memory footprint required; (iii) the amount of compression; (iv) the quality of the data (in lossy compression). The main goal of the methods for compressing *spatio-temporal* data is to strike a good balance between the complexity of the algorithm and the error-bound on the compressed data with respect to the original one.

There are two research fields that have addressed problems similar in spirit to the ones of compressing mobile location data:

1. *Cartography*. The goal of the *map generalization* in cartography is to reduce the size/complexity of a given map for the purpose of simplified representation of the details appropriate to a given scale [16].
2. *Computational geometry* (CG). In particular, the problem of *polyline* (which is, a sequence of nodes specifying a chain of line segments) simplification [3], that can be described as follows. Given a polyline PL_1 with vertices $\{v_1,v_2,...,v_n\}$ in a respective k-dimensional Euclidean space, and a tolerance ε, construct another polyline PL_1' with vertices $\{v_1',v_2',...,v_m'\}$ in the same space, such that $m \leq n$ and for every point $P \in PL_1$ its distance from PL_1' is smaller than a given threshold: $dist(P, PL_1') \leq \varepsilon$. In case $\{v_1',v_2',...,v_m'\} \subseteq \{v_1, v_2,...,v_n\}$, PL_1' is a *strong* simplification of PL_1; otherwise PL_1' is called a *weak* simplification. There are two distinct facets of the minimal line simplification problem: (i) Given PL and ε, minimize the number of points m in PL' (known as min-# problem) [5], and (ii) Given PL and the "budget" m of the vertices in PL', minimize the error ε (known as min-ε problem).

A popular heuristic for polyline simplification in the context of map generalization was proposed by Douglas and Peucker in [6]. Essentially, it recursively approximates a given polyline in a "divide and conquer" manner, where the farthest vertex, according to the distance used, is selected as the "divide" point. Given a *begin_vertex* p_i and an *end_vertex* p_j, if the greatest distance from some vertex p_k to the straight line segment $\overline{p_ip_j}$ is greater than the tolerance ε, then the trajectory is broken into two parts at p_k and the procedure is recursively called on each of the sub-polylines $\{p_i,...,p_k\}$ and $\{p_k,...,p_j\}$; Otherwise, the vertices between p_i and p_j are removed from trajectory and this segment is simplified as a straight line $\overline{p_ip_j}$. An illustration of the DP heuristic is given in Fig. 1. Although the original version of the algorithm, as presented in [6], has a running time $O(n^2)$, an $O(n \log n)$ algorithm was presented in [9]. However, none of these algorithms can ensure an optimality, in terms of the size of the compression (alternatively, in terms of a minimal ε-error for a fixed reduction factor). An optimal algorithm was presented in [5], with a complexity of $O(n^2)$, subsequently extended for 3D and higher dimensions in [3].

Foundations

Assuming that the objects are moving in a 2D space with respect to a given coordinate system, a *trajectory*, which is often used in the MOD literature [8,13,15] to describe the motion of the moving objects, is defined as a function $F_t : T \rightarrow \mathcal{R}^2$ which maps a given (temporal) interval $[t_b, t_e]$ into a one-dimensional subset of $\mathcal{R}^2$. It is represented as a sequence of 3D points (2D geography + time) (x_1,y_1,t_1), (x_2,y_2,t_2),...,(x_n,y_n,t_n), where $t_b = t_1$ and $t_e = t_n$ and $t_1 \leq t_2 \leq ... \leq t_n$. Each point (x_i,y_i,t_i) in the sequence represents the 2D location (x_i,y_i) of the object, at the time t_i. For every $t \in (t_i,t_{i+1})$, the *location* of the object is obtained by a *linear interpolation* between (x_i,y_i) and (x_{i+1},y_{i+1}) with the ratio $(t - t_i)/(t_{i+1} - t_i)$, which is, in between two points the object is assumed to move along a straight line-segment and with a constant speed. The 2D

projection of the trajectory is a polygonal chain with vertices (x_1, y_1), (x_2, y_2)...(x_n, y_n), called a *route*.

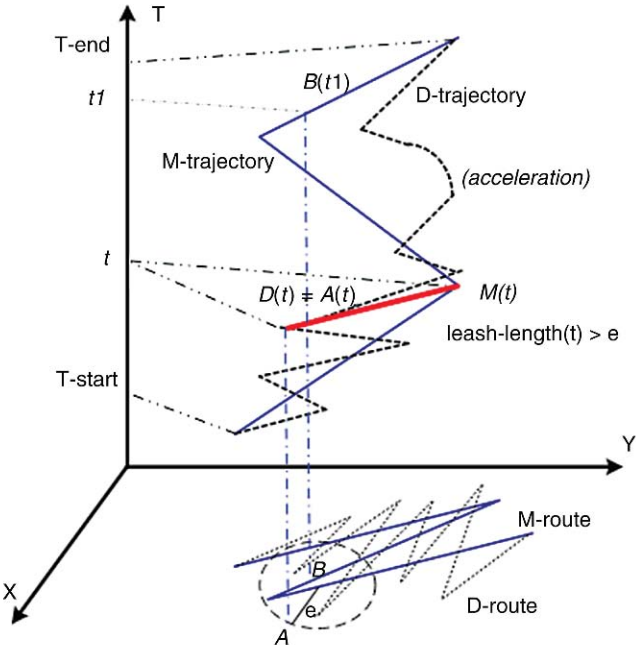
Observe that a trajectory may represent both the *past* and the *future* motion, i.e., the *motion plan* of a given object (c.f. [8]). Typically, for future trajectories, the user provides the starting location, starting time and the destination (plus, possibly, a set of to-be-visited) points, and the MOD server uses these, along with the distribution of the speed-patterns on the road segments as inputs to a dynamic extension of the Dijkstra's algorithm [13], to generate the shortest travel-time trajectory.

One may be tempted to straightforwardly apply the existing results on polyline simplification from the CG literature (e.g., the DP [6,9] or the optimal algorithm [3,5]), in order to compress a given trajectory. However, as pointed out in [4], the semantics of the spatial + temporal domain combined, raises two major concerns:

1. What is the *function* used to measure the *distance between points* along trajectories?
2. How does the choice of that function affect the *error* that the compressed trajectory introduces in the answers of the popular spatio-temporal queries? In the sequel, each of these questions is addressed in a greater detail.

Distance Function

A popular distance function between two curves, often used in CG applications is the, so called, Hausdorff distance [1]. Essentially, two curves C_1 and C_2, their Hausdorff distance simply looks for the smallest ε such that C_1 is completely contained in the ε-neighborhood of C_2 (i.e., C_1 is completely contained in the Minkowski Sum of C_2 and a disk with radius ε) and vice versa. Although it is arguably a very natural distance measure between curves and/or compact sets, the Hausdorff distance is too "static", in the sense that it neither considers any direction nor any dynamics of the motion along the curves. A classical example of the inadequacy of the Hausdorff distance, often used in the CG literature [1,2] is the *"man walking the dog"*. Figure 2 illustrates the corresponding routes of the man *(M-route)* and the dog *(D-route)*, as well as their trajectories *M-trajectory* and *D-trajectory*. Observe that, ignoring the temporal aspect of their motions, the D-route and the M-route are within Hausdorff distance of *e*, as exemplified by the points *A* and *B* in the *XY* plane. However, their actual *temporally aware* distance corresponds to the minimal length of the leash that the man needs to hold. The 3D part of Fig. 2 illustrates the discrepancy between the distances among the points along the *routes*, and their corresponding counterparts along *trajectories*: when the dog is at the point



Compression of Mobile Location Data. Figure 2. Hausdorff vs. Fréchet distance.

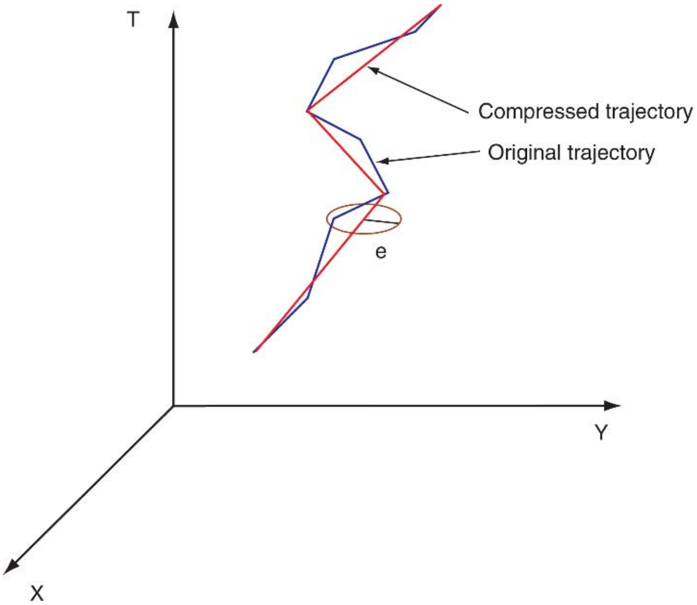
A, which is at time *t*, the man is actually at *M*(*t*), and their distance is much greater then *e* (the man is at the geo-location *B* at the time $t_1 > t$). The Fréchet distance [2] is more general than the Hausdorff one, in the sense that it allows for a variety of possible motion-patterns along the given route-segments. As an illustration, observe that on the portion of the *D-trajectory*, the dog may be moving non-uniformly (i.e., accelerating) along a route segment.

The discussion above illustrates two extreme points along the spectrum of distance functions for moving objects. Although the Fréchet distance is the most general one, regarding the possible dynamics of motions, it is unnecessarily complex for the common trajectory model in MOD settings. The inadequacy of the L_2 norm as a distance function for spatio-temporal trajectories was pointed out in [4] where, in order to properly capture the semantics of the problem domain, alternative distance functions were introduced. Given a spatio-temporal point $p_m = (x_m, y_m, t_m)$ and a trajectory segment $\overline{p_i, p_j}$ between the vertices $p_i = (x_i, y_i, t_i)$ and $p_j = (x_j, y_j, t_j)$, [4] proposed the E_u and E_t distance functions between the p_m and $\overline{p_i, p_j}$, which are explained next

1. E_u – The three dimensional time_uniform distance, which is defined when $t_m \in [t_i, t_j]$, as follows: $E_u(p_m, \overline{p_i p_j}) = \sqrt{(x_m - x_c)^2 + (y_m - y_c)^2}$ where $p_c = (x_c, y_c, t_c)$ is the unique point on $\overline{p_i p_j}$ which has the same *time* value as p_m (i.e., $t_c = t_m$). An illustration of using the E_u distance function for reducing the size of a given trajectory is presented in Fig. 3. Intuitivelly, the distance is measured at equal *horizontal* planes, for the respective values of the temporal dimension. One can "visually" think of the relationship between the original trajectory and the compressed trajectory as follows: the original trajectory is contained inside the sheared cylinder obtained by sweeping (the center of) a horizontal disk with radius ε along the compressed trajectory.
2. E_t – The time distance is defined as: $E_t(p_m, \overline{p_i p_j}) = |t_m - t_c|$, where t_c is the time of the point on the *XY* projection $\overline{p'_i p'_j}$ of $\overline{p_i p_j}$, which is closest (in terms of the 2D Euclidean distance) to the *XY* projection p'_m of p_m. Intuitively, to find the time distance between p_m and $\overline{p_i p_j}$, one needs to:

   1. Project each of them on the *XY* plane;
   2. Find the point $p'_c \in \overline{p'_i, p'_j}$ that is closest to p'_m;
   3. Find the difference between the corresponding times of p_c and p_m.

An important observation regarding the *computation* of the compressed version of a given original trajectory as an input, is that both the DP [6] and the



Compression of Mobile Location Data. Figure 3. E_u distance function for trajectory compression.

optimal algorithm [5] can be used, provided they are appropriately modified to reflect the distance function used. Experimental results in [4] demonstrated that the DP heuristics yields a compression factor that is very comparable to the one obtained by the optimal algorithm, however, its execution is much faster.

Spatio-Temporal Queries and Trajectory Compression

The most popular categories of spatio-temporal queries, whose efficient processing has been investigated by many MOD researchers [8] are:

1. *where_at*(T,t) – returns the expected location at time t.
2. *when_at*(T,x,y) – returns the time t at which a moving object on trajectory T is expected to be at location (x,y).
3. *intersect*(T,P,t_1,t_2) – is *true* if the trajectory T intersects the polygon P between the times t_1 and t_2. This is an instance of the, so called, spatio-temporal range query).
4. *nearest_neighbor*(T,O,t) – The operator is defined for an arbitrary set of trajectories O, and it returns a trajectory T' of O. The object moving according to T', at time t, is closest than any other object of O to the object moving according to T.
5. *join*(O, Θ) – O is a set of trajectories and the operator returns the pairs (T_1,T_2) such that their distance, according to the distance function used, is less than a given threshold Θ.

An important practical consideration for compressing trajectory data is how the (im)precision generated by the compression, affects the answers of the spatio-temporal queries. As it turns out, the distance function used in the compression process plays an important role and, towards this, the concept of *soundness* [4] of a distance function with respect to a particular query was introduced in [4]. A pair *(distance_function, query)* is called *sound* if the error of the *query*-answer, when processed over the compressed trajectory is bounded. In case the error is *unbounded*, which is, although the compression itself guarantees a distance-error of ε between the points on the compressed trajectory with respect to the original one, the error of the answer to the query can grow arbitrarily large, the pair is called *unsound*. Table 1 below (adapted from [4]) summarizes the soundness properties of three distance functions with respect to five categories of spatio-temporal queries.

Compression of Mobile Location Data. Table 1. Distance soundness and error-bound on spatio-temporal query answers

	Where_at	*When_at*	*Intersect*	*Nearest neighbor*
E_2 (L_2*over routes)*	Unsound	Unsound	Unsound	Unsound
E_u	Sound (ε)	Unsound	Sound (ε)	Sound (2ε)
E_t	Unsound	Sound (ε)	Unsound	Unsound

As one can see, there is no single distance function that is sound for all the possible spatio-temporal queries.

The compression techniques for spatio-temporal data presented thus far, implicitly assumed that the trajectories are available in their entirety, i.e., they are past-motion trajectories. However, in practice, it is often the case that the *(location, time)* data is generated on-board mobile units, and is transmitted to the MOD server in real time [7,17]. *Dead-reckoning* is a policy which essentially represents an agreement between a given moving object and the MOD server regarding the updates transmitted by that particular object. The main idea is that the *communication* between them can be reduced (consequently, network bandwidth can be spared) at the expense of the *imprecision* of the data in the MOD representing the object's motion. In order to avoid an unbounded error of the object's location data, the agreement specifies a threshold δ that is a parameter of the policy, which can be explained as follows:

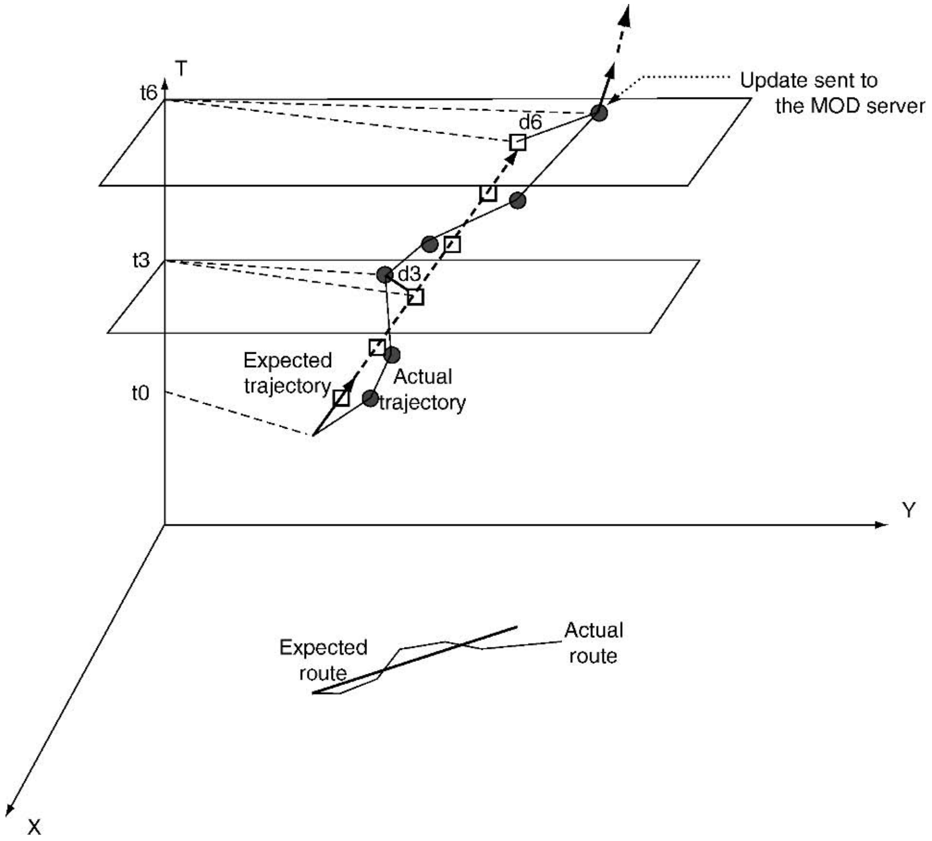
1. The object sends its *location* and the *expected velocity* to the MOD server and, as far as the MOD server is concerned, the future trajectory of that object is an infinite ray originating at the update point and obtained by extrapolation, using the velocity vector.
2. The information that the MOD server has is the *expected trajectory* of the moving object. However, each moving object is aware of its *actual location*, by periodically sampling it, e.g., using an on-board GPS.
3. For as long as its actual location at a given time t_i does not deviate by more than δ from the location that the MOD estimates at t_i using the information previously transmitted, the object does not

transmit any new updates. When the actual distance deviates by more then δ from its location on the expected trajectory, the object will send another *(location, time, velocity)* update.

The policy described above is commonly known as a *distance-based* dead reckoning, and an illustration is given in Fig. 4. At time t_0 the object sent its location and the predicted velocity (arrowed line) to the MOD server. The dashed line extending the vector indicate the expected trajectory of the moving object and the squares along it indicate the object's positions at six time instances, as estimated by the MOD, while the shaded circles indicate the actual positions of the object. Typically, the actual trajectory is obtained by connecting the GPS points with straight line-segments, assuming that in-between two updates, the object was moving with a constant speed. As illustrated, at t_6 the distance between the actual position and the MOD-estimated one exceeds the threshold agreed upon ($d_6 > \delta$) and the object sends a new update, at which point the MOD changes the expected trajectory, based on that update. Thus, at t_6, the MOD server actually performs two tasks:

1. Corrects its own "knowledge" about the recent past and approximates the actual trajectory between t_0 and t_6 with a straight line-segment, which defines the *actual simplification* of the near-past trajectory;
2. generates another infinite ray corresponding to the future-expected trajectory, starting at the last update-point, and using the newly received velocity vector for extrapolation.

Various trade-offs between the update costs and the (impacts on the) imprecision of the MOD data for several different variants of dead reckoning are investigated in [17]. The dead-reckoning, in a sense, achieves in real-time both of the goals of compression: – reduces the communication, and enables the MOD server to store only a subset of the actual trajectory. Assuming that a dead-reckoning policy with threshold δ was used in real-time, clearly, the MOD has obtained a compressed past-trajectory, say $Tr_m{}^c$, of a given mobile



Compression of Mobile Location Data. Figure 4. Distance-based dead-reckoning policy.

object o_m. If o_m was to transmit every single GPS-based update, i.e., no dead-reckoning applied, the MOD would have an uncompressed trajectory Tr_m available. The results in [14] have established that ${Tr_m}^c$ is a strong simplification of Tr_m, with an error-bound 2δ.

Key Applications

The compression of moving objects trajectories data is of interest in several scientific and application domains.

Wireless Sensor Networks (WSN)

Wireless sensor networks consist of a large number of *sensors* – devices that are capable of measuring various phenomena; performing elementary calculations; and communicating with each other, organizing themselves in an ad hoc network [19]. A particularly critical aspect of the WSN is the efficient management of the energy-reserves, given that the communication between two nodes drains a lot more battery-power than the operations of sensing and (local) computing. Consequently, in many tracking applications that can tolerate delays and imprecision in the *(location, time)* data, performing local compression of the trajectory data, before it is sent to a particular sink, can yield substantial increase in the networks' lifetime. Different policies for such compressions are presented in [18].

Location-Based Services (LBS)

A variety of applications in LBS depend on the data for mobile objects with different mobility properties (e.g., pedestrians, private vehicles, taxis, public transportation, etc.). Typically, LBS are concerned with a context-aware delivery of the data which matches the preferences of users based on their locations [12]. In order to provide faster response time, and more relevant information, the LBS should be able to predict, based on the motion patterns, what kind of data will be relevant/requested in a near future by given users. This, in turn, implies some accumulated knowledge about the mobility patterns of the users in the (near) past. However, keeping such data in its entirety can impose prohibitively high storage requirements.

Geographic Information Systems (GIS)

Recently, a plethora of services and devices has emerged for providing path planning and navigation for the mobile users: from MapQuest and Google-maps, through Garmin and iPaq Travel Companion. Each of these services relies on some traffic-based information in order generate the optimal (in distance or travel-time) path for their users. However, as the traffic conditions fluctuate, the future-portions of the routes may need to be recalculated. In order to better estimate the impact of the traffic fluctuations, some knowledge from the past is needed which, ultimately means storing some past information about trajectories. However, as observed in the literature [4], storing the uncompressed trajectory data corresponding to daily driving activities of few millions of users, could require TBs of data.

Spatio-Temporal Data Mining

Clustering is a process of grouping a set of (physical or abstract) objects into classes of similar objects, and its purpose is to facilitate faster data analysis in a given domain of interest. With the recent advances in miniaturization of computing devices and communications technologies, the sheer volume makes it very costly to apply clustering to the original trajectories' data. Compressing such data, especially if one can guarantee a bounded error for the queries of interest, can significantly improve the processing time for many algorithms for trajectories clustering [10].

Future Directions

Any problem-domain that depends on storing large volumes of trajectories' data, in one way and level or another, needs some sort of data compression in order to reduce the storage requirements and to speed up processing of spatio-temporal queries of interest. Clearly, a desirable property of the compression techniques is to ensure a bound on the errors of the answers to the queries.

There are several directions of interest for the future research on mobile data compression. In applications like GIS and LBS, it is a paramount to add some context-awareness to the compression techniques. For example, combining the mobile location data compression with the particular tourists attractions and the season/time, could provide a speed-up in algorithms which are used for generating real-time advertisements, while ensuring that the error (in terms of users that received particular ad) is bounded. An interesting aspect that has been presented in [4] is the, so-called, *aging* of the trajectories: a trajectory that is 1-week old could have higher impact on the traffic-impact analysis, than a trajectory that was recorded

5weeks ago. Consequently, one may reduce the older trajectory with a higher error-bound, thus further reducing the storage requirements. Automatizing this process in a manner that reflects the specifics of a given problem-domain (e.g., context-aware information delivery) is an open question. Despite the large body of works on OLAP and warehousing of traditional data, very little has been done on spatio-temporal OLAP. It is likely that the process of mobile data compression will play an important role in these directions.

Computational Media Aesthetics

Chitra Dorai

Synonyms

CMA; Media semantics; Production-based approach to media analysis

Definition

Computational media aesthetics is defined as the algorithmic study of a variety of image and aural elements in media founded on their patterns of use in film grammar, and the computational analysis of the principles that have emerged underlying their manipulation, individually or jointly, in the creative art of clarifying, intensifying, and interpreting some event for the audience [3]. It is a computational framework to establish semantic relationships between the various elements of sight, sound, and motion in the depicted content of a video and to enable deriving reliable, high-level concept-oriented content annotations as opposed to verbose low-level features computed today in video processing for search and retrieval, and nonlinear browsing of video. This media production knowledge-guided semantic analysis has led to a shift away from a focus on low level features that cannot answer high level queries for all types of users, to applying the principled approach of computational media aesthetics to analyzing and interpreting diverse video domains such as movies, instructional media, broadcast video, etc.

Historical Background

With the explosive growth of media available on the Web, especially on hugely popular video sharing websites such as YouTube, managing the digital media collections effectively and leveraging the media content in the archives in new and profitable ways continues to be a challenge to enterprises, big and small. Multimedia content management refers to everything from ingesting, archival and storage of media to indexing, annotation and tagging of content for easy access, search and retrieval, and browsing of images, video and audio. One of the fundamental research problems in multimedia content management is the semantic gap – that renders all automatic content annotation systems of today brittle and ineffective – between the shallowness of features in their descriptive power that can be currently computed automatically and the richness of meaning and interpretation that users desire search algorithms to associate with their queries for easy searching and browsing of media. Smeulders et al. [8] describe that while "the user seeks semantic similarity, the database can only provide similarity on data processing." This semantic gap is a crucial obstacle that content management systems have to overcome in order to provide reliable media descriptions to drive search, retrieval, and browsing services that can gain widespread user acceptance and adoption. There is a lack of framework to establish semantic relationships between the various elements in the content since current features are frame/shot-representational and far too simple in their expressive power.

Addressing the semantic gap problem in video processing will enable innovative media management, annotation, delivery and navigational services for enrichment of online shopping, help desk services, and anytime-anywhere training over wireless devices. Creating technologies to annotate content with deep semantics results in an ability to establish semantic relationships between the form and the function in the media, thus for the first time enabling user access to stored media not only in predicted manner but also in unforeseeable ways of navigating and accessing media elements. Semantics-based media annotations will break the traditional linear manner of accessing and browsing media, and support vignette-oriented viewing of audio and video as intended by the content creators. This can lead to new offerings of customized media management utilities for various market segments such as education and training video archives, advertisement houses, news networks, broadcasting studios, etc.

Foundations

Computational Media Aesthetics advocates an approach that markedly departs from existing methods for deriving video content descriptions by analyzing audio and visual features (for a survey of representative work, see [8]). It proposes that to go beyond describing just what is seen in a video, the visual and emotional impact of how the content is depicted needs to be understood. Both media compositional and aesthetic principles need to guide media analysis for richer, more expressive descriptions of the content depicted and seen.

What are the methodologies for analyzing and interpreting media? Structuralism, in film studies for example, proposes film segmentation followed by an analysis of the parts or sections. Structural elements or portions of a video, when separated from cultural and social connotations can be treated as plain data and therefore, can be studied using statistical and computational tools. Another rich source is production knowledge or film grammar. Directors regularly use accepted rules and techniques to solve problems presented by the task of transforming a story from a written script to a captivating visual and aural narration [2]. These rules encompass a wide spectrum of cinematic aspects ranging from shot arrangements, editing patterns and the triangular camera placement principle to norms for camera motion and action scenes. Codes and conventions used in narrating a story with a certain organization of a series of images have become so standardized and pervasive over time that they appear natural to modern day film production and viewing. However, video production mores are found more in history of use, than in an abstract predefined set of regulations, are descriptive rather than prescriptive, and elucidate on ways in which basic visual and aural elements can be synthesized into larger structures and on the relationships that exist between the many cinematic techniques employed worldwide and their intended meaning to a movie audience.

Media aesthetics is both a process of examination of media elements such as lighting, picture composition, and sound by themselves, and a study of their role in manipulating the viewer's perceptual reactions, in communicating messages artistically, and in synthesizing effective media productions [10]. Inspired by it, Dorai and Venkatesh defined Computational media aesthetics [3] as the algorithmic study of a variety of image and aural elements in media guided by the patterns of their use, and the computational analysis of the principles for manipulating these elements to facilitate high-level content annotations.

Computational media aesthetics provides a handle on interpreting and evaluating relative communication effectiveness of media elements in productions through knowledge of film codes that mediate perception of the content shown in the video. It exposes the semantic and semiotic information embedded in the media production by focusing not merely on the representation of perceived content in digital video, but on the semantic connections between the elements and the emotional, visual appeal of the content seen and remembered. It advocates a study of mappings between specific cinematic elements and narrative forms, and their intended visual and emotional import.

In multimedia processing, many research efforts have sought to model and describe specific events occurring in a particular video domain in detail for providing high-level descriptions; computational media aesthetics, on the other hand enables development of video analysis techniques founded upon production knowledge for film/video understanding, for the extraction of high-level semantics associated with the expressive elements and narrative forms synthesized from the cinematic elements, and for the detection of high-level mappings through the use of software models. It highlights the systematic use of film grammar, as motivation and also as foundation in the automated process of analyzing, characterizing, and structuring of produced videos for media search, segment location, and navigational functions.

Computational media aesthetics provides a framework to computationally determine elements of form and narrative structure in videos from the basic units of film grammar namely, the shot, the motion, the recording distances, and from the practices of combination that are commonly followed during the audiovisual narration of a story. At first, primitive computable aspects of cinematographic techniques are extracted. New expressive elements (higher order semantic entities) can then be defined and constructed from these primitive aspects. Both the definition and extraction of these semantic entities are based on film grammar, and these entities are formulated only if directors purposefully design them and manipulate them. The primitive features and the higher order semantic notions thus form the vocabulary of content description language for media.

Key Applications

In seeking to create tools for the automatic understanding of media, computational media aesthetics states the problem as one of faithfully reflecting the forces at play in media production, and interpreting the data with its maker's eye. Several studies have explored the workings of Computational Media Aesthetics when applied to extraction of meaning using many of the aesthetic elements introduced by Zettl [10]: Time, sound and color. Adams et al. [1] took an example of carrying one aspect of film grammar all the way from literature to computable entity, namely tempo and pace for higher level analysis of movies. Adams et al. [1] showed that although descriptive and sometimes fuzzy in scope, film grammar provides rich insights into the perception of subjective time as tempo and pace and its manipulation by the makers of film for drama. Further research [9,6,5,7,4] has applied this approach pervasively from extracting mood in music, emotion in movies, to adding musical accompaniment to videos and extracting semantic metadata for mobile images at the time of image capture.

Film is not the only domain with a grammar to leverage in analysis. News, sitcoms, educational video, etc., all have more or less complex grammars that may be used to capture their crafted structure and to derive semantic descriptions with automated techniques following the framework of computational media aesthetics.

Computerized Physician Order Entry

Michael Weiner
Indiana University School of Medicine, Indianapolis, IN, USA

Synonyms

Computer-based physician order entry; Computer-based provider order entry; Computerized provider order entry; Computerized order entry (COE); Physician order entry

Definition

In daily medical practice, physicians routinely create plans of diagnosis and treatment for their patients. These plans typically contain specific, formal orders – directives – that are expected to be implemented by other medical professionals, such as nurses or personnel at laboratories or pharmacies. When such personnel are expected to implement part of a physician's diagnosis or treatment plan, corresponding orders must be created and documented in the patient's medical record. Physicians have traditionally used paper-based charting systems to record medical orders.

Computerized physician order entry (CPOE) is a process by which physicians directly enter medical orders into a computer. CPOE is typically done when the computer is being used to access an electronic health record (EHR), and the physician is creating a treatment plan for a specific patient in a clinical setting.

In many medical institutions, non-physicians such as nurses, dieticians, social workers, pharmacists, therapists, or advanced nurse practitioners can also enter certain types of orders, hence the broader, useful term "*computerized provider order entry*."

Historical Background

CPOE was first implemented and described in the latter half of the twentieth century. In the US, early reports came from several institutions, including Harvard Medical School and Brigham and Women's Hospital, the US Veterans Health Administration [16,20], Vanderbilt University [8], University of Virginia [12], Indiana University, and Regenstrief Institute for Health Care [14].

In 1994, Sittig and Stead published "Computer-based physician order entry: the state of the art" [17], summarizing many of the early results. Many difficulties were reported regarding leadership, delays, cultural resistance, high costs, technical support, workflow, and other operational difficulties for end users.

By the end of 2006, CPOE was on the rise, though adoption rates – often correlated with adoption of EHRs – varied widely throughout the world. Most modern EHR systems, whether developed by public, private, or academic institutions, would be expected to include at least some form of CPOE. In the US, only 10% of hospitals had complete availability of CPOE in 2002 [2]. In the United Kingdom, Australia, and New Zealand [21], the fraction is much higher, since use of EHRs exceeds 80% and is approaching 99% among general practitioners in ambulatory practice.

Foundations

CPOE can be used to order a variety of medical services. In some medical institutions with EHRs, CPOE can be used to order any type of medical service and may be required to generate any order. When not required, providers may have the opportunity to select between writing orders in a paper-based chart or an EHR, or clerks or other professionals may perform CPOE on a provider's behalf or direction.

CPOE is performed via a user interface of some kind, though this may occur on a desktop computer, terminal or thin client, personal digital assistant, other portable computer, or other form of computer. A user would typically authenticate himself or herself, identify a patient, and proceed to enter orders, often by navigating through a series of forms, each of which might facilitate a certain type of order, such as for radiology, laboratory, pharmacy, nursing, or referral (see Fig. 1). The layout or interface seen by the user is highly variable and may depend on the developer, personal preferences, underlying database structures, or medical or administrative processes generated in response to specific orders.

Many EHRs allow providers to generate orders and non-order documentation in a single computer session. Non-order documentation may include clinical details such as historical information, measurements, other observations, patient's preferences or directives, or narrative notes or reports. The workflow imposed by a CPOE system should be considered carefully in conjunction with the user's baseline workflow. Greatest success with implementation can often be found when the system does not disrupt the user's own pattern of work.

Computerized Physician Order Entry. Figure 1. A user interface for computerized physician order entry. A user would typically authenticate himself or herself, identify a patient, and proceed to enter orders, often by navigating through a series of forms, each of which might facilitate a certain type of order. This screenshot shows form fields that allow entry of orders for drugs, diagnostic tests, and other types of orders (e.g., nursing). The visual separation of types of orders into categories is done primarily for the user's convenience and organization; it may or may not reflect underlying data models.

Once a session is completed, the orders generated lead to action. This may occur via simple printing of the orders or through electronic delivery to remote locations, such as a radiology department, consultant's office, laboratory, or pharmacy. Some orders, such as for prescriptions for drugs or lifestyle changes, may be provided to patients for direct implementation or delivery elsewhere. A session's orders are then typically archived in the EHR. Consistent with traditional medical documentation, orders from CPOE are generated once and cannot be modified or deleted once finalized, though what is being ordered can often later be modified or discontinued with a subsequent order.

CPOE has been developed and implemented for a variety of reasons. Many advantages have been postulated, including rectification of substantial legibility problems with handwritten orders. CPOE systems have the potential to refer to all of a patient's medical history as well as all available medical knowledge, to improve the quality of medical care in real time, at the point of care. One of the most important potentials of CPOE is inclusion of *clinical decision support*, by which the computer can be programmed to suggest tailored orders *de novo* (e.g., for a vaccination recommended by clinical guidelines) or respond to specific orders, such as in the event of a possible drug reaction [11] or contraindication to a procedure (see Fig. 2). CPOE can reduce the rate of certain medication errors by more than half [4]. Removing the healthcare provider from electronic order entry, or moving CPOE outside the point of care, could negate these large potential benefits.

Some institutions are starting with, focus, or limit their computer-based development to electronic prescribing, or "e-prescribing." This is a form of CPOE. E-prescribing is targeted especially because prescribing is frequent, can be targeted by CPOE algorithms, and represents a most common form of medical error [13,18]. In the US, the Institute of Medicine has recommended e-prescribing of drugs, in conjunction with clinical decision support [9].

Medical orders symbolize but also allow and direct the operations behind medical care. By encoding and electronically documenting orders, CPOE improves capabilities to assess and improve quality of care and to conduct clinical research related to diagnosis and treatment. Medical practices, governments, and other authorities can gather and study data from CPOE systems to improve knowledge about how medical

Computerized Physician Order Entry. Figure 2. Example of clinical decision support. In this instance, the user has prescribed benazepril. The software responds, as shown, by prompting the user to decide about ordering blood tests, to monitor for possible side effects from the drug. To enable this capability, the application has been programmed with clinical rules that combine guidelines or medical knowledge with this patient's medical history, evaluation, or treatment.

care is formulated and delivered. CPOE can also facilitate billing processes that depend on orders, such as for certain procedures or drugs. Query languages or systems must be designed to accommodate data models used for CPOE.

Customization of CPOE systems may allow individual providers or groups of providers to create templates or order sets, which are groups of orders often used or often used together. This could save time, improve standardization, and improve care.

CPOE does have costs, risks, and unintended consequences [5]. A CPOE system must be developed thoughtfully and be maintained frequently and regularly, to ensure that it accommodates the latest tests, treatments, and guidelines, both locally and more broadly. If an institution does not stock a particular drug, the system might not allow that drug to be ordered or might at least alert the provider about the issue. Institutional changes and policies that can affect CPOE are frequent and so must lead to corresponding modifications to the CPOE system.

CPOE can increase the time required to generate a medical order [3,15]. Studies of this have reported mixed findings, with increases in some and decreases in others. Increased time for initial learning and ongoing use can cause dissatisfaction among providers and even complete failures of systems. Increasing time to generate or implement orders can have adverse clinical effects. Adverse effects might be expected especially in emergencies or acute care, when life-saving drugs may be needed rapidly. Errors in processing electronic orders could also be expected to lead to adverse effects in at least some cases. In 2005, Koppel et al. reported that one CPOE system design often facilitated medication-related errors, such as by providing inadequate views of medications and increasing inappropriate dosing and incompatible orders [10].

If not implemented effectively, increased use of computers in healthcare might distract providers, causing them to spend less time with patients or decrease patient's satisfaction [7,19]. This could have an adverse effect on patient-provider relationship or patient's health. Provider-to-provider communication might also suffer if appropriate internal communications systems are not used.

Clinical decision support, a key feature of CPOE systems, can backfire by presenting too many or inappropriate alerts. Effective solutions to "alert overload" are not yet well developed or widespread, though some solutions have been discussed [18]. Several recent studies of interventions in decision support have had negative results and require further investigation.

Financial costs of implementing CPOE can be high, especially initially. Developing cost-effectiveness analyses of EHRs and CPOE systems are thus complex, because benefits or harms can occur much later than implementation of a system and later than the time of initial care or clinical presentation.

Moving orders from paper to computers has created situations that require new handling. Computer programs, for example, must know the authority of the authenticated user and whether the user has permission to generate the requested orders. This need also exists with paper systems but is handled in those environments by people, rather than computers. In addition, the use of templates or order sets has not been heavily studied. Templates may in some cases decrease quality of care if they are adopted hastily or used in the wrong setting. In ultimately pooling or sharing data across institutions, it will be important to use standards and customary terminologies to represent orders.

Technical Issues

"Prescription" is another term for medical order, though the term is used conventionally to refer to providing instructions to patients. The structure of a traditional drug prescription provides a useful framework for understanding the primary components of medical orders. Drug orders have a superscription (including timestamp and patient's identifier), inscription (name and amount or strength of ingredient), subscription (formulation or method to prepare), and *signa* ("sig," or directions including route and frequency). Orders of any other type have analogous components, though some may have additional or somewhat different components. CPOE systems should handle components of orders with agility. Below are discussed a few key technical issues that present themselves in the design, study, and implementation of CPOE systems.

Data Models for CPOE. One must consider what data model would best support CPOE. For example, should orders be categorized and, if so, how? Many institutions have found that categories of orders, such as laboratory, consultative, pharmacy, nursing, and radiological, are clinically and informationally logical but may also be necessary from the standpoint of linking disparate data systems. A key goal in the design is the ability to accommodate future expansion of order types and categories even before those types are developed or identified. This can prompt a somewhat "flat" model, in which the nature, type, or category of an order is a value of a database field, rather than a field or variable itself. Other important aspects of orders that may have implications for the data model are the indication for the order, urgency (i.e., when it should be implemented), and who is expected to implement it.

Standardization of text in an order can be helpful for both accuracy of implementation and research. For example, an order that can have multiple forms, such as "take two 40-mg tablets by mouth twice daily" and "take one 80-mg tablet by mouth every 12 hours" can complicate both clinical care and research. Allowing providers to add narratives or free text is essential for tailoring to patient's needs, but this demands effective handling in data storage and clinical decision support. A system that can standardize the order accurately without hindering the user's experience is desirable but challenging to create. Standardization of terminology used in orders should accommodate query systems. One difficulty is that each type of order – such as for a drug, diet, radiological procedure, or laboratory test – may have unique "domains" or components. For example, only drugs have a dose, yet the dose may need to be a discrete, searchable component of a query. Therefore, an ideal data model can handle all types of orders, as well as new types, but it can also identify and distinguish between various values of key components of orders, regardless of how widespread those components are across various types of orders.

Order sets can often translate directly into a group of individual orders, but users often desire the ability to customize order sets. This may mean maintaining a base of order sets but also the customizations that are unique to each provider or role. Order sets also need to be integrated with any available decision support systems, and many providers seek to share customized order sets with each other. There are thus aspects of order sets that pertain to the system itself and to particular patients, groups of providers, and individual providers. Associated with each order set is also generally information about conditions under which the order set applies, such as a diagnosis, age group, or other criteria found in a clinical guideline – hence the possible need for order sets to be linked to ontologies or terminology systems that in turn link to such guidelines.

Specific types of orders often require further processing or delivery to specific clinical departments. Therefore, the processing needed must be encoded into the system, though it might be a part of the main data engine more than a core part of the data model or record. In any case, if laboratory orders, for example, need to be delivered to the laboratory, then the data system must support this well enough so that all laboratory orders – and only laboratory orders – are processed in this way. Similarly, systems that notify particular professionals or departments should be modular enough that those systems can be updated readily as personnel or even departments change.

An audit trail is important for documentation, accreditation, and quality and safety of care. Included in the data system should be a method to indicate formally not just who created a record and when, but what happened to the record: where it was sent and who accessed it later. Whether this is part of CPOE or the larger records system may depend on the circumstances and design of a system. Many alert systems that stem from orders do not currently provide effective prioritization, so this is an area of important research.

Key Applications

CPOE continues to undergo development and will for the foreseeable future. Due to the difficulty and time required to generate electronic orders, various forms of data entry are being explored. These include transcription with or without voice recognition and input using portable devices, digital pens, or tablets. Due to capability for electronic communication of orders, development is also occurring in remote areas or environments with limited access to healthcare, such as for rural or homebound patients.

CPOE is undergoing significant development especially in the US, the United Kingdom and other parts of Europe, Asia, Australia, and New Zealand. It can be expected to grow throughout the world, even as developing countries create EHR systems.

Future Directions

The largest looming issues for CPOE are how to maximize efficiency of data entry and effectiveness of decision support in the complex environment. There are also unmet needs for CPOE to be linked to access to general medical knowledge. Health policy, attention to quality, patient safety, and reimbursement will likely gain importance in driving uses of CPOE, especially in areas where its use is currently low. The precise roles, usefulness, impact, and specifications of incentives for healthcare providers to adopt health information technologies such as CPOE are not yet clear.

Conceptual Schema Design

Alexander Borgida[1], John Mylopoulos[2]
[1]Rutgers University, New Brunswick, NJ, USA
[2]University of Trento, Trento, Italy

Definition

Conceptual schema design is the process of generating a description of the contents of a database in high-level terms that are natural and direct for users of the database. The process takes as input information requirements for the applications that will use the database, and produces a schema expressed in a conceptual modeling notation, such as the Extended Entity-Relationship (EER) Data Model or UML class diagrams. The challenges in designing a conceptual schema include: (i) turning informal information requirements into a *cognitive model* that describes unambiguously and completely the contents of the database-to-be; and (ii) using the constructs of a data modeling language appropriately to generate from the cognitive model a conceptual schema that reflects it as accurately as possible.

Historical Background

The history of conceptual schema design is intimately intertwined with that of conceptual data models (aka semantic data models). In fact, for many years researchers focused on the design of suitable *languages* for conceptual schemas, paying little attention to the design process itself. Jean-Raymond Abrial proposed the *binary semantic model* in 1974 [1], shortly followed by Peter Chen's *entity-relationship model* (ER for short) [4]. Both were intended as advances over logical data models proposed only a few years earlier, and both emphasized the need to model more naturally the contents of a database. The ER model and its extensions were relatively easy to map to logical schemas for relational databases, making EER [9] the first conceptual modeling notation to be used widely by practitioners. On the other hand, Abrial's semantic model was more akin to object-oriented data models that became popular more than a decade later.

The advent of object-oriented software analysis techniques in the late 1980s revived interest in object-oriented data modeling and led to a number of proposals. Some of these, notably OMT [7] adopted many ideas from the EER model. These ideas were consolidated into the *Unified Modeling Language* (UML), specifically UML class diagrams.

The process of designing conceptual schemas by using such modeling languages was not studied until the late 1970s, see for instance [8]. In the early 1980s, the DATAID project proposed a state-of-the-art design process for databases, including conceptual schema design [2].

Throughout this history, research on knowledge representation in Artificial Intelligence (AI) has advanced a set of concepts that overlaps with those of conceptual data models. Notably, semantic networks, first proposed in the 1960s, were founded on the notions of *concept*, *link* and *isA* hierarchy (analogously to *entity*, *relationship* and *generalization* for the EER model). The formal treatment of these notations has led to modern modeling languages such as Description Logics, including OWL, for capturing the semantics of web data. In fact, Description Logics have been shown to be able to capture the precise semantics of conceptual modeling notations such as EER diagrams and UML class diagrams.

Another important recent development has been the rise of *ontological analysis*. An ontology is a specification of a conceptualization of a domain. As such, an ontology offers a set of concepts for modeling an application, and foundational ontologies strive to uncover appropriate cognitive primitives with which to describe and critique conceptual modeling notations [5]. Foundational ontologies have been used to analyze the appropriate use of EER constructs [10] and UML [6]. Based on this work, a two-phase perspective is adopted here by distinguishing between the design of a *cognitive model* based on cognitive primitives, and the design of a corresponding *conceptual schema* that is based on the constructs of a conceptual model such as the EER or UML class diagrams.

Foundations

Building a cognitive model. Information requirements for a database-to-be are generally expressed informally, based on multiple sources (e.g., applications/queries that need to be supported, existing paper and computerized systems). Information requirements describe some part of the world, hereafter the *application domain* (or *universe of discourse*). A *cognitive model* is a human conceptualization of this domain, described in terms of cognitive primitives that underlie human cognition. The following are some of the most important among these primitives.

An *object* is anything one may want to talk about, and often represents an *individual* ("my dog," "math422"). Usually, individual objects persist over many states of the application domain. Moreover, they have *qualities* (such as size, weight), and can be related to other individuals by *relations* (e.g., "friendOf," "part of," "between"). Individuals may be concrete (such as "Janet," or "that tree"), abstract (e.g., "the number 12," "cs422"), or even hypothetical (e.g., "Santa," "the king of the USA"). Individuals have a notion of *identity*, allowing them, for example, to be distinguished and counted. For some individuals such as "Janet," identity is an intrinsic notion that distinguishes her from all other objects. *Values* are special individuals whose identity is determined by their structure and properties (e.g., numbers, sets, lists and tuples). The number "7," for example, is the unique number that comes after "6," while "{a, b, c}" is the unique set with elements "a," "b" and "c."

Individuals can be grouped into *categories* (also called *concepts*, *types*), where each category (e.g., "Book") captures common properties of all its instances (e.g., "my DB textbook," "Ivanhoe"). Categories themselves are usefully structured into taxonomies according to their generality/specificity. For instance, "Book" is a specialization of "LibraryMaterial," along with "Journal" and "DVD." Moreover, "Book" has its own specializations, such as "Hardback," "Paperback."

Many categories (e.g., "Person") are *primitive*, in the sense that they don't have a definition. By implication, there is no algorithm to determine whether a given individual object is an instance of such a category – one must be told explicitly such facts. Other categories are *defined*, in the sense that instances can be recognized based on some rule. For example, an instance of "Teenager" can be recognized given an instance of "Person" and its age.

Relations relate two or more objects, for example "book45 is on loan to Lynn," or "Trento is between Bolzano and Verona" and can represent among others a dependence of some sort between these objects. Each relation is characterized by a positive integer n–its *arity*–representing the number of objects being related. In the example above, "onLoanTo" is binary, while "between" is ternary. Predicate logic notation is used to express specific relations between individuals, e.g., "between(Trento,Bolazano,Verona)." Like their individual counterparts, relations can be grouped into relation categories. In turn, relation categories can be organized into subcategory hierarchies: "brotherOf" and "sisterOf" are subcategories of "siblingOf," which in turn is a subcategory of "relativeOf." A binary relation category has a *domain* and a *range*. A cognitive model can specify arbitrary constraints between relations and categories, which describe the valid states ("semantics") of the application domain. Cardinality constraints, for instance, specify upper/lower bounds on how many instances of the range of a relation can be associated to an instance of the domain, and vice versa.

A subtle complexity arises when one wants to describe information *about* a relation, for example when did it become or ceased to be true. In such cases the modeler can resort to *reification*. For example, the reification of "Trento is between Bolzano and Verona" consists of creating a new individual, "btw73" which is an instance of the category "Between" and is related to its three arguments via three functional relations: "refersTo (btw73,Trento)," "source(btw73,Bolzano)," "destination (btw73,Verona)." Note that this representation allows another instance of "Between," say "btw22," with functions to the same three individuals. To avoid this redundancy, one needs suitable constraints on "Between." One can now model other information about such reified relations, e.g., "believes(yannis,btw73)."

There are several categories of relations that deserve special consideration.

PartOf (with inverse *hasPart*) represents the part-whole relation that allows composite conceptualizations consisting of simpler parts. PartOf actually represents several distinct relations with different formal properties [5]. Most prominent among them are the relations *componentOf* (e.g., cover is a component of book) and *memberOf* (e.g., player member of a team). PartOf is frequently confused with other relations, such as *containment, connectedness, hasLocation.* A useful diagnostic test for this confusion is to check that if A is part of B, and B is damaged, then A is also considered damaged. Note how "love-note placed inside book" fails this test.

The relation between an object and a category is often called *instanceOf*, and the set of all instances of a category are called its *extension*. The *isA* (*subcategory*) relation represents a taxonomic ordering between categories, e.g., "isA(HardcoverBook,Book)." The isA relation is transitive and anti-symmetric and interacts with instanceOf in an important way: if "isA(A, B)" and "instanceOf(x,A)" then "instanceOf(x,B)." Any general statements one associates with a category, apply to all its specializations. For example, "every book has a title" will automatically apply to subcategories ("every HardcoverBook has a title"); this is called *inheritance* of constraints. In many cases, a group of subcategories are mutually *disjoint* (e.g., "Hardcover," "Paperback," are disjoint subcategories of the category "Book"). Sometimes, a set of subcategories *covers* their common parent category in the sense that every instance of the latter is also an instance of at least one subcategory (for example, "Male," "Female" cover "Person"). When a collection of subcategories partitions a parent category, it is often because some relation (e.g., "gender") takes on a single value from an enumerated set (e.g., {"M," "F"}).

When building an isA hierarchy, it is useful to start by building a backbone consisting of primitive, disjoint concepts that describe the basic categories of individuals in the application domain. Some categories can be distinguished from others by their *rigidity* property: an instance of the category remains an instance throughout its lifetime. For example, "Person" is such a category (in the sense of "once a person, always a person"), but "Student" is not. Once a backbone taxonomy has been constructed, other categories, such as role categories, can be added to the hierarchy as specializations of the categories. Welty and Guarino [11] present a principled approach to the construction of taxonomies. A useful rule for building meaningful isA hierarchies is to ensure that the children of any category are all at the same level of granularity. A leaf category in an isA hierarchy should be further refined if it has instances that can be usefully grouped into sub-categories, which participate in new relations or which are subject to new constraints.

Categories may also be seen as objects, and can then be grouped into meta-categories that capture common meta-properties of their instances. For example, the meta-category "LibraryMaterialType" has instances such as "Book," "Hardback" and "DVD," and may have an integer-valued meta-property such as "number-on-order."

In most worlds there are not just enduring objects but also occurrences of events, activities, processes, etc., such as borrowing, renewing or returning a book. These phenomena are called *events*. An event can be described from a number of perspectives: First, there are the *participants* in an event: the material borrowed, the patron who did the borrowing, the library from which the material was borrowed, the date when the material is required to be returned, etc. Often these participants are given names describing the *role* they play in the event: "borrower," "lender," "due date." Second, every event takes place in time, so its temporal aspects can be represented: starting and possibly ending time if it is of a long duration, cyclic nature, etc. Third, events may also have parts – the sub-events that need to take place (e.g., taking the book to the counter, proffering the library card,...). There may also be special relations, such as causality or temporal precedence that hold among events.

In database modeling, one often ignores events because they are transient, while the database is supposed to capture persistence. However, events are in fact present in the background: relations between objects other than "partOf" are usually established or terminated by events. The "onLoan" relation, for example, is created by a "borrow" event and terminated by a "return" event. And values for many qualities (e.g., the size or weight of an object) are established through events representing acts of observation. As a result, relations often carry information about the events. Thus information about the "borrow" activity's participants is present in the arguments of the "onLoan" relation. And since "renew" shares the main participants of "borrow," its traces can also be attached to "onLoan," through an additional temporal argument, such as "lastRenewedOn."

Note that it is application requirements that determine the level of detail to be maintained in a cognitive model. For example, whether or not one records the time when the borrowing and renewal occurred, or whether it is sufficient to have a "dueDate" attribute on the "onLoan" relation. In addition, the details of the subparts of "borrow" will very likely be suppressed. On the other hand, semantic relations between events, such as the fact that a book renewal can only occur after the book has been borrowed, do need to be captured.

Because databases often have multiple sets of users, there may be several conflicting interpretations of terms and information needs. The important process of reconciling such conflicts, known in part as "view integration" is not addressed in this entry.

From a cognitive model to a conceptual schema. The above account has focused on the construction of a model that captures information requirements in terms of cognitive primitives, with constraints expressed in a possibly very rich language. Every effort was made to keep the modeling and methodology independent of a particular modeling language. Next, one must tackle the problem of producing a conceptual schema expressed in some particular formal notation, in this case the EER. Comparable discussions apply if the target was UML class diagrams, or even OWL ontologies.

The basic mapping is quite straightforward: *categories of individuals* in the conceptual model are mapped to ER *entity sets*; relation categories in the conceptual model are modeled directly as relationship sets, with the participating entities playing (potentially named) roles in the relationship set. Qualities and values related to individuals by binary relations, or appearing as arguments of relations become *attributes.* Cardinality constraints of the cognitive model are mapped directly to the conceptual schema.

One complex aspect of EER schema development is the definition of *keys* consisting of one or more attributes that uniquely distinguish each individual instance of an entity set. Moreover, the values of these attributes must be stable/unchanging over time. For example, "isbnNr" or "callNumber" would be a natural key attributes for "Book." Globally unique identifiers are actually relatively rare. Instead, entities are often identified with the help of intermediate relationships (and attributes). For example, "BookCopy," has attribute "copyNr," which surely does not identify a particular book copy; but if "BookCopy" is represented as a *weak entity*, related to "Book" via the "copyOf" identifying relationship then "BookCopy" will have a composite identifier. In other situations where one would need a large set of attributes to identify an entity, and especially if these attributes are not under the control of database administrators, the designer may introduce a *new* surrogate entity attribute specifically for identification purposes (e.g., "studentId" for the entity set "Student").

Sub-categories, with possible disjoint and coverage constraints, are represented in a direct manner in EER since it supports these notions. Significantly, in most version of EER key attribute(s) can only be specified for the top-most entity in a hierarchy, and must then be inherited by all sub-entities. Therefore one cannot have "Employee" with key "ssn," while sub-class "TeachingAssistant" has key "studentId." The reason for this is to avoid multiple ways of referring to what would otherwise be the same individual.

Since the EER model supports n-ary relationships, reified relationships are normally only required in case the model needs to make "meta" statements about relationships, e.g., recording that a particular loan was verified by a clerk. In variants of the EER that allow aggregate relationships, this is modeled by relating entity "Clerk" via relationship "hasVerified" to the aggregate representing the "lentTo" relationship. In impoverished variants of EER that do not support aggregates, this can be encoded using weak entities that reify the relationship.

The EER notation (in constrast to UML, say), does not provide support for distinguishing *partOf* relationships, nor for relationship hierarchies. However, the designer may encode these using reified relationships.

Conceptual Schema Design in Practice

There is a plethora of commercial tools for conceptual schema design based on the EER model or UML class diagrams. These support the drawing, documenting and layout of conceptual schemas, and even the automatic generation of standard logical (relational) schemas to support database design.

More advanced tools, such as icom (http://www.inf.unibz.it/~franconi/icom/), allow not just the drawing of conceptual schemas, but their translation to formal logic. Advantages of such tools include (i) precise, formal semantics for all the constructs of the conceptual model; (ii) the ability to check the conceptual schema for consistency–an issue which is particularly interesting in the case of *finite models*; (iii) the ability to augment a conceptual schema with constraints expressed in the underlying logic.

Key Applications

Conceptual schema design is the first–and for many the most important–step in the design of any database.

Future Directions

One of the major research challenges of the new century is data integration, and the semantics of data captured in conceptual models has been shown to form a useful foundation for merging multiple information sources. In this context, one can imagine using a conceptual schema as the mediating schema to access different database sources.

The advent of the Web has made databases a public resource that can be shared world-wide. In such a setting, where the user may know nothing about a database she is accessing, the issues that dominate are (i) encapsulating the semantics of data along with the data, so that the user can interpret the data; (ii) ensuring data quality, so that the user can determine whether the data are suitable for her purposes; (iii) ensuring compliance with privacy, security and governance regulations. In turn, these new requirements are going to redefine the scope of database design in general and conceptual schema design in particular.

Specifically, extended conceptual modeling languages and conceptual schema design techniques are envisioned where quality, privacy, security and governance policies can be expressed explicitly and can be accommodated during the design process to produce conceptual schemas that are well-suited to address such concerns. We also envision extensions to conceptual modeling languages that introduce primitive concepts for modeling dynamic, intentional and social aspects of an application domain. These aspects constitute an important component of the semantics of any database and a prerequisite for dealing with data quality and regulation compliance.

Concurrency Control – Traditional Approaches

Gottfried Vossen
University of Münster, Münster, Germany

Synonyms

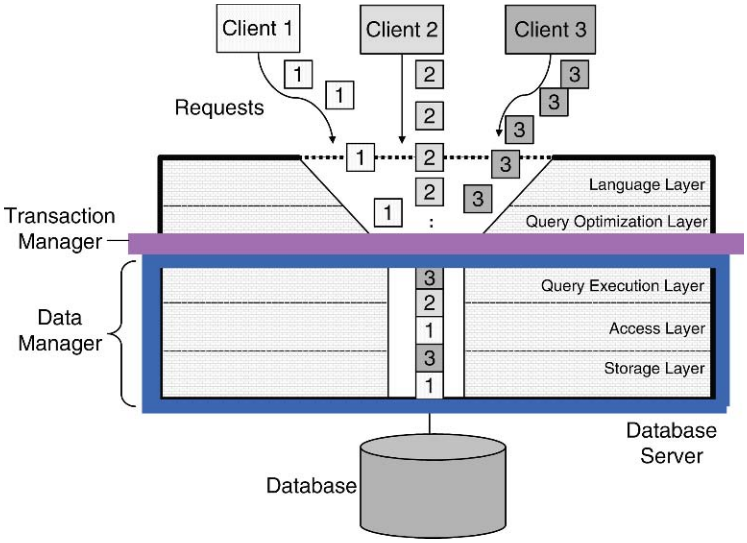
Concurrency control; Transaction execution; Scheduling; Page locking; Two-phase-locking

Definition

The core requirement on a transactional server is to provide the ACID properties for transactions, which requires that the server includes a *concurrency control* component as well as a *recovery component*. Concurrency control essentially guarantees the isolation properties of transactions, by giving each transaction the impression that it operates alone on the underlying database and, more technically, by providing serializable executions. To achieve serializability, a number of algorithms have been proposed. Traditional approaches focus on the read-write model of transactions and devise numerous ways for correctly scheduling read-write transactions. Most practical solutions employ a variant of the two-phase locking protocol.

Key Points

Concurrency control for transactions is done by the *transaction manager* of a database system and within that component by a *scheduler*. The scheduler implements an algorithm that takes operations from active transactions and places them in an interleaving or *schedule* that must obey the correctness criterion of serializability. As illustrated in Fig. 1, which indicates the "positioning" of a transaction manager within the multi-layer architecture of a database system, the scheduler receives steps from multiple transactions, one after the other, and tries to attach them to the schedule already output. This is possible if the new schedule is still serializable; otherwise, the scheduler can block or even reject a step (thereby causing the respective transaction to abort) [1,5,6]. The algorithm a scheduler follows must be such that serializability can be tested



Concurrency Control – Traditional Approaches. Figure 1. Illustration of a transaction scheduler.

on the fly; moreover, it must be very efficient so that high throughput rates (typically measured in [committed] transactions per minute) can not only be achieved, but even be guaranteed.

Classification of Approaches

Scheduling algorithms for database transactions can be classified as "traditional" if they concentrate on scheduling read-write transactions; non-traditional schedulers takes semantic information into account which is not available at the syntactic layer of read and write page operations. Traditional schedulers generally fall into two categories: A scheduler is *optimistic* or aggressive if it mostly lets steps pass and rarely blocks; clearly, this bears the danger of "getting stuck" eventually when the serializability of the output can no longer be guaranteed. An optimistic scheduler is based on the assumption that conflicts between concurrent transactions are rare; it will only test from time to time whether the schedule produced so far is still serializable, and it takes appropriate measures if the schedule is not.

On the other hand, a scheduler is *pessimistic* or conservative if it mostly blocks (upon recognizing conflicts); in the extreme yet unlikely case that all transactions but one have been blocked, the output would become a serial schedule. This type of scheduler is based on the assumption that conflicts between transactions are frequent and therefore need to be constantly observed. Pessimistic schedulers can be *locking* or *non-locking* schedulers, where the idea of the former is to synchronize read or write access to shared data by using locks which can be set on and removed from data items on behalf of transactions. The intuitive meaning is that if a transaction holds a lock on a data object, the object is not available to transactions that execute concurrently. Non-locking schedulers replace locks, for example, by timestamps that are attached to transactions. Among locking schedulers, the most prominent protocol is based on a *two-phase* approach (and hence abbreviated two-phase locking or 2PL) in which, for each transaction, a first phase during which locks are obtained is strictly separated from a second phase where locks can only be released. Non-two-phase schedulers replace the two-phase property, for example, by an order in which transactions may access data objects. Figure 2 summarizes the major classes of concurrency control protocols. Beyond the approaches shown in Fig. 2, the concurrency control problem can even be broken into two subproblems, which could then be solved individually by possibly distinct protocols: (i) read operations are synchronized against write operations or vice versa; (ii) write operations are synchronized against other write operations, but not against reads. If these synchronization tasks are distinguished, a scheduler can be thought of as consisting of two components, one for each of the respective synchronization tasks. Since the two components need proper integration, such a scheduler is called a hybrid scheduler. From an application point of view, most classes of protocols surveyed above, including the hybrid ones, have not achieved great relevance in practice. Indeed, 2PL is by far the most important concurrency control protocol, since it can be implemented with low overhead, it can be extended to abstraction levels beyond pure page operations, and it has always outperformed any competing approaches [2–4].

Concurrency Control and Recovery

► Transaction Management

Concurrency Control Manager

Andreas Reuter[1,2]
[1]EML Research GmbH Villa Bosch, Heidelberg, Germany
[2]Technical University Kaiserslautern, Kaiserslautern, Germany

Synonyms

Concurrency control manager; Lock manager; Synchronization component

Definition

The concurrency control manager (CCM) synchronizes the concurrent access of database transactions to shared objects in the database. It is responsible for maintaining the guarantees regarding the effects of concurrent access to the shared database, i.e., it will protect each transaction from anomalies that can result from the fact that other transactions are accessing the same data at the same time. Ideally, it will make sure that the result of transactions running in parallel is identical to the result of some serial execution of the same transactions. In real applications, however, some transactions may opt for lower levels of synchronization, thus trading protection from side effects of other transactions for performance. The CCM is responsible for orchestrating all access requests issued by the transactions such that each transaction receives the level of protection it has asked for. The CCM essentially implements one of a number of different synchronization protocols, each of which ensures the correct execution of parallel transactions, while making different assumptions regarding prevalent access patterns, frequency of conflicts among concurrent transactions, percentage of aborts, etc. The protocol that most CCMs are based on is using locks for protecting database objects against (inconsistent) parallel accesses; for that reason, the CCM is often referred to as the "lock manager." Some CCMs distinguish between multiple versions of a data object (e.g., current version, previous version) in order to increase the level of parallelism [2].

Key Points

The CCM monitors all access requests issued by higher-level components, be it to the primary data (tuples, records), or to access paths, directory data, etc. on behalf of the database transactions. This information (transaction **X** accesses object **O** in order to perform action **A** at time **T**) is employed in different ways, depending on the synchronization protocol used. In case of locking protocols, each access request has to be explicitly granted by the CCM. If no conflict will arise by performing action A on object O, the access request is granted. If, however, a conflict is detected (e.g., A is an update request, and some other transaction Y is already updating object O), the request is not granted, and the CCM will record the fact that X has to wait for the completion of transaction Y. In case of optimistic protocols, the requests are granted right away, but when X wants to commit, all its accesses are checked for conflicts with accesses performed by other transactions that are either still running or have committed while X was active. In those situations the time T of the access request is relevant. So the basic data structure maintained by the CCM is a table of accesses/access requests. For locking protocols, the CCM will also maintain a list of which transaction waits for the completion of which other transaction(s). That list is tested by the CCM for deadlocks. If a deadlock or, in case of optimistic protocols, a conflict is detected, the CCM decides which transaction will be aborted. It then informs the transaction manager, who will initiate the abort; rollback of the operations is performed by the recovery manager [1].

Conditional Tables

Gösta Grahne
Concordia University, Montreal, QC, Canada

Synonyms

C-tables; Extended relations

Definition

A conditional table [4] generalizes relations in two ways. First, in the entries in the columns, variables, representing unknown values, are allowed in addition to the usual constants. The second generalization is that each tuple is associated with a condition, which is a Boolean combination of atoms of the form $x = y$, $x = a$, $a = b$, for x, y null values (variables), and a, b constants. A conditional table essentially represents an existentially quantified function free first order theory.

Formally, let *con* be a countably infinite set of constants, and *var* be a countably infinite set of variables, disjoint from *con*. Let U be a finite set of attributes, and $R \subseteq U$ a relational schema. A tuple in a c-table over R is a mapping from R, and a special attribute, denoted φ, to $con \cup var \cup \beta$, where β is the set of all Boolean combinations of equality atoms, as above. Every attribute in R maps to a variable or a constant, and φ maps to β. In a multirelational database schema, there are multi-tables, meaning in effect that variables can be shared between tables (just as constants are). An example of a 2-multitable is shown below. The conditions φ are all *true*, and it so happens that the two tables do not share any variables.

T_1	A	B	C	φ
	a	*b*	*x*	*true*
	e	*f*	*g*	*true*

T_2	B	C	D	φ
	y	*c*	*d*	*true*

Key Points

It is now possible to extend the complete set of regular relational operators $\{\pi,\sigma,\bowtie,\cup,-,\rho\}$ to work on c-tables. To distinguish the operators that apply to tables from the regular ones, the extended operators are accented by a dot. For instance, c-table join is denoted $\dot{\bowtie}$. The extended operators work as follows: projection $\dot{\pi}$ is the same as relational projection, except that the condition column φ can never be projected out. Selection $\dot{\sigma}_{A=a}(T)$ retains all tuples t in table T, and conjugates the condition $t(A) = a$ to $t(\varphi)$. A join $T \dot{\bowtie} T'$ is obtained by composing each tuple $t \in T$ with each tuple $t' \in T'$. The new tuple $t \cdot t'$ has condition $t(\varphi) \wedge t'(\varphi) \wedge \delta(t,t')$, where condition $\delta(t,t')$ states that the two tuples agree on the values of the join attributes. The example below serves as an illustration of this definition. The union $\dot{\cup}$ is the same as relational union, and so is renaming $\dot{\rho}$, except that the φ-column cannot be renamed. Finally, the set difference, say $T \dot{-} T'$ is obtained by retaining all tuples $t \in T$ and conjugating to them the condition stating that the tuple t differs from each tuple t' in T'. A tuple t differs from a tuple t', if it differs from t' in at least one column.

Let T_1 and T_2 be as in the figure above. The three c-tables in the figure below, illustrate the result of evaluating $\dot{\sigma}_{C=g}(T_1)$, $T_1 \dot{\bowtie} T_2$, and $\dot{\pi}_{BC}(T_2) \dot{-} \dot{\pi}_{BC}(T_1)$, respectively.

A	B	C	φ
a	b	x	$x = g$
e	f	g	$g = g$

A	B	C	D	φ
a	y	x	d	$b = y \wedge x = c$
e	y	g	d	$f = y \wedge g = c$

B	C	φ
y	c	$(y \neq b \vee c \neq x) \wedge (y \neq f \vee c \neq g)$

Note that the second tuple in the first c-table has a tautological condition. Likewise, since any two constants differ, the condition of the second tuple in the middle c-table is contradictory.

So far, nothing has been said about what the c-tables mean. In the *possible worlds* interpretation, an incomplete database is a usually infinite *set* of ordinary databases, one of which corresponds to the actual (unknown) database. Considering c-tables, they serve as finite representations of sets of possible databases. One (arbitrary) such database is obtained by instantiating the variables in the c-table to constants. Each occurrence of a particular variable is instantiated to the same constant. Formally, the instantiation is a valuation $v : con \cup var \rightarrow con$, that is identity on the constants. Valuations are extended to tuples and conditions tables in the obvious way, with the caveat that given a particular valuation v, only those tuples t for which $v(t(\varphi)) \equiv true$, are retained in $v(T)$. Consider for instance the first table above. For those valuations v, for which $v(x) = g$, there will be two tuples in $v(T)$, namely (a,b,g) and (e,f,g). For valuations v', for which $v(x) \neq g$, there will only be the tuple (e,f,g) in $v'(T)$.

The remarkable property of c-tables is that for all c-tables T and relational expressions E, it holds that $v(\dot{E}(T)) = E(v(T))$ for all valuations v. In other words, the extended algebra is a Codd sound and complete inference mechanism for c-tables. Furthermore, c-tables are closed under relational algebra, meaning that the result of applying any relational expression on any (schema-wise appropriate) c-table can be represented as another c-table. The extended algebra actually computes this representation, as was seen in the example above.

Needless to say, all of this comes with a price. Testing whether a c-table is satisfiable, that is, whether there exists at least one valuation v, such that $v(T) \neq \emptyset$ is an NP-complete problem [2]. Furthermore, even if one starts with a simple c-table where all variables are distinct, and all conditions are *true*, applying even a monotone relational expression to such a c-table can result in quite a complex table, so here again [2] satisfiability of the resulting table is NP-complete [2]. To make matters even worse, testing containment of c-tables is Π_2^p-complete. A c-table T is contained in a c-table T', if every for every valuation v of T, there exists a valuation v' of T', such that $v(T) = v(T')$. Nonetheless, c-tables possess a natural robustness. For instance, it has been shown [1,3] that the set of of possible databases defined by a set of materialized views, can be represented as a c-table.

Conjunctive Query

Val Tannen
University of Pennsylvania, Philadelphia, PA, USA

Synonyms

SPC query; Horn clause query

Definition

Conjunctive queries are first-order queries that both practically expressive and algorithmically relatively tractable. They were studied first in [2] and they have played an important role in database systems since then.

As a subset of the relational calculus, conjunctive queries are defined by formulae that make only use of atoms, conjunction, and existential quantification. As such they are closely related to Horn clauses and hence to logic programming. A single Datalog rule can be seen as a conjunctive query [1].

Optimization and reformulation for various purposes is quite feasible for conjunctive queries, as opposed to general relational calculus/algebra queries. The equivalence (and indeed the *containment*) of conjunctive queries is decidable, albeit NP-complete [1].

Key Points

This entry uses terminology defined in the entry Relational Calculus.

Conjunctive queries are first-order queries of a particular form: $\{\langle e_1,\ldots,e_n\rangle \mid \exists x_1\ldots x_m \psi\}$ where ψ is an (equality-free) conjunction of relational atoms, i.e., atoms of the form $R(d_1,\ldots,d_k)$ (where $d_1,\ldots,d_k$ are variables of constants). In addition, it is required that any variable among $e_1,\ldots,e_n$ must also occur in one of the relational atoms of ψ. This last condition, called *range restriction* [3] is necessary for *domain independence*, e.g., consider $\{(x, y) | R(x)\}$, and, in fact, it is also sufficient.

The semantics of a conjunctive query in an instance $\mathcal{I}$, as a particular case of first-order queries, involves assignments μ defined on the variables among $e_1,\ldots,e_n$ such that $\mathcal{I}, \mu \models \exists\, x_1..x_m\psi$. Note however that this is the same as extending μ to a *valuation* ν defined in addition on $x_1\ldots x_m$ and such that $\mathcal{I}, \nu \models \psi$. Since ψ is a conjunction of relational atoms, this amounts to ν being a *homomorphism* from ψ seen as a relational instance (the *canonical instance* associated to the query) into $\mathcal{I}$. This simple observation has many useful consequences, including some that lead to the decidability of equivalence (containment). It also leads to an alternative way of looking at conjunctive queries, related to logic programming. Here is an example of a conjunctive query in both relational calculus form and in a Prolog-like, or "rule-based," formalism, also known as a *Datalog rule* [1,3]:

$$\{(x, c, x) \mid \exists y\ R(c, y) \wedge S(c, x, y)\}\mathit{ans}(x, c, x) :$$
$$- R(c, y), S(c, x, y)$$

In the spirit of rule-based/logic programming, the output tuple of a conjunctive query is sometimes called the "head" of the query and the atom conjunction part the "body" of the query. So far, this discussion has considered only the class CQ of conjunctive without equality in the body. The class $\mathrm{CQ}^=$ which allows equalities in the body defines essentially the same queries but there are a couple of technical complications. First, the range restriction condition must be strengthened since, for example, $\{(x, y)|\exists z\ R(x)\ \wedge\ y = z\}$ is domain dependent. Therefore, for $\mathrm{CQ}^=$ it is required that any variable among $e_1,\ldots,e_n$ must equal, as a consequence of the atomic equalities in ψ, some constant, or some variable that occurs in one of the relational atoms of ψ.

$\mathrm{CQ}^=$ has the additional pleasant property (shared, in fact, with the full relational calculus) that query heads can be restricted to consist of just distinct variables.

Clearly $\mathrm{CQ} \subseteq \mathrm{CQ}^=$. The converse is "almost true." It is possible to get rid of equality atoms in a conjunctive query iff the query is *satisfiable* i.e., there exists some instance on which the query returns a nonempty answer. All the queries in CQ are satisfiable (take the canonical instance). Queries in $\mathrm{CQ}^=$ are satisfiable iff the equalities in their body do not imply the equality of distinct constants. Thus, for conjunctive queries (of both kinds) satisfiability is decidable, as opposed to general first-order queries. Now, any satisfiable query in $\mathrm{CQ}^=$ can be effectively translated into an equivalent query in CQ.

The conjunctive queries correspond to a specific fragment of the relational algebra, namely the fragment that uses only the selection, projection, and cartesian product operations. This fragment is called the *SPC algebra*. There is an effective translation that takes every conjunctive query into an equivalent SPC algebra expression. There is also an effective translation that takes every SPC algebra expression into an equivalent conjunctive query.

Via the translation to the SPC algebra it can be seen that conjunctive queries correspond closely to certain SQL programs. For example, the CQ$^{=}$ query $ans(x, y) : -R(x, z), x = c, S(x, y, z)$ corresponds to

```
select r.1, s.2
from R r, S s
where r.1=c and s.1=r.1 and r.3=s.2
```

Such SQL programs, in which the "where" clause is a conjunction of equalities arise often in practice. So, although restricted, conjunctive queries are important.

Connection

Sameh Elnikety
Microsoft Research, Cambridge, UK

Synonyms

Database socket

Definition

A connection is a mechanism that allows a client to issue SQL commands to a database server. In a typical usage, the client software opens a connection to the database server, and then sends SQL commands and receives responses from the server.

To open a connection, the client specifies the database server, database name, as well as the client's credentials. Opening the connection includes a handshake between the client software and the database server. The client sends its credentials, for example in the simplest form a user name and password. The server examines the credentials to authorize the connection. Further information may also be negotiated such as the specific protocol and data encoding.

Key Points

Handling and servicing connections is an important part of database servers because connections are the main source of concurrency.

Database servers limit the number of connections they can accept and may provide differentiated service to connections from high priority clients (e.g., from database administrators).

Connections are implemented using inter-process (e.g. pipes) or remote (e.g., TPC sockets) communication mechanisms. Database vendors and third-party providers supply libraries that client programs use to open connections to database servers. Several standards have emerged such as ODBC (Open Database Connectivity) [2], JDBC (Java Database Connectivity) [3], and ADO.NET (data access classes in Microsoft.NET platform) [1].

When client software uses a database system extensively, it employs a connection pool to reuse a group of open connections, allowing multiple concurrent SQL commands. Using a connection pool avoids closing and reopening connections, as well as opening too many connections that tie up resources at both ends of the connection.

Consistency Models For Replicated Data

Alan Fekete
University of Sydney, Sydney, NSW, Australia

Synonyms

Replica consistency; Memory consistency

Definition

When a distributed database system keeps several copies or replicas for a data item, at different sites, then the system may ensure that the copies are always consistent (that is, they have the same value), or the system may allow temporary discrepancy between the copies. Even if the copies are not the same, the algorithms that manage the data may be able to hide the discrepancies from clients. A consistency model defines the extent to which discrepancies can exist or be observed, between the copies. If the system offers a strong consistency model, then clients will not be aware of the fact that the system has replicated data, while a weak consistency model requires more careful programming of the clients, so they can cope with the discrepancies they observe.

Historical Background

Most replication research in the 1970s aimed to provide the illusion of an unreplicated database offering serializability. In the early 1980s, Bernstein and colleagues formalized this notion as a strong consistency model [2].

The late 1980s and early 1990s focused on systems that offered weak consistency in various definitions. Eventual consistency was introduced in the work of Demers et al. [3], while consistency models in which reads might see stale values were also explored by several groups [1,5].

Since 2000, a new strong consistency model, one-copy SI, was introduced [4], and it has attracted much attention.

Foundations

There are many different system architectures that can be used for a distributed database with replicated data. For example, clients may submit operations directly to the different databases, or instead requests may all go through a middleware layer; the local databases may communicate directly with one another, or only with the clients or middleware; the requests that arrive at a local database may be a read or write on the local replica of an item, or they may be a SQL statement (which might involve many reads and/or writes), or indeed a whole transaction may form a single request; a read may be performed on one replica and writes on all replicas (read-one-write-all), or else a complex quorum rule may determine where reads and writes are performed; and each site may perform the operations once only, or else there may be possibilities for operations to be done tentatively, then (after conflicting information is received) the system might be able to roll back some operations and then replay them in a different order. Sometimes several system designs offer clients the same functionality, so the choice would be based only on performance, or the validity of assumptions in the design (such as the ability to know in advance which transactions access which items). If the client cannot learn, by the values returned or the operations which are allowed, which system design is used, then one can say that the different designs offer the same consistency model. However, sometimes a difference in design does change the functionality of the whole system, in ways that clients can detect. If one abstracts away the details of the system design, and instead focuses on what the essential features are that distinguish between the properties, then one is describing the consistency model offered by the system. For example, some system designs allow clients to learn about the existence of several copies. Perhaps one client might read the same item several times and see different values in each read. These values may have been taken from different older transactions. This can't happen in a system where all the data is at one site, with one copy for each item. Thus this system provides a consistency model which reveals the existence of copies to the client.

A system provides a strong consistency model if it provides clients with the illusion that there is a single copy of each piece of data, hiding all evidence of the replication. There are in fact several variants among strong models, because there are several different isolation models used by different DBMS platforms, and because the formal definition of isolation doesn't always capture exactly the properties of an implementation. For example, one-copy serializability (q.v.) was defined in [2] as a consistency model in which clients have the illusion of working with a single-site unreplicated database which uses a concurrency control algorithm that offer serializability (q.v.) as the isolation level. In contrast, one-copy SI [4] is a different strong consistency model, where clients see the same behaviors as in an unreplicated system where concurrency control is done by Snapshot Isolation (q.v.).

In contrast to strong consistency models which maintain an illusion of a single-site system, in weaker models the clients are able to see that the system has replicas. Different models are characterized by the ways in which the divergence between replicas is revealed. The best-known weak consistency model is eventual consistency (q.v.) which is suitable for replicated databases where an updating transaction can operate at any replica, and the changes are then propagated lazily to other replicas through an epidemic mechanism. Eventually, each replica learns about the updates, and this consistency model ensures that a reconciliation mechanism resolves conflicting information, so that when the system quiesces, the values in all the replicas of a logical item eventually converge to the same value. In a system providing eventual consistency, there is not much that can be said about the value seen by a read, before convergence has been reached.

A different weak consistency model is common in systems where there is a single master copy for each item, and all updates are done first at the master, before being propagated in order, to the replicas. In this model, writes happen in a well-defined order, and each read sees a value from some prefix of this order; however, a read can see a value that is stale, that is, it does not include the most recent updates to the item.

Key Applications

The commercial DBMS vendors all offer replication mechanisms with their products. The performance impact of strong consistency models is usually seen as high, and these are typically provided only within a single cluster. For replication across dispersed machines, most platforms offer some form of weak consistency. There are also a range of research prototypes which give the user a choice between several consistency models; in general the user sees a tradeoff, where improved performance comes from accepting weaker consistency models.

Future Directions

Effective database replication is not yet a solved problem; the existing proposals compromise somehow among many desired properties, such as scalability for read-heavy workloads, scalability for update-heavy workloads, availability in face of failures or partitions, generality of the clients supported, ease of system programming, capacity to use varied local databases as black boxes, and the consistency provided. Thus the design space of possible systems is still being actively explored, and sometimes a new design achieves a consistency model different from those previously seen. One topic for ongoing research is how users can express their requirements for performance and for different levels of consistency, and how a system can then choose the appropriate replica control mechanism to provide the user with what they need. Research is also likely in consistency models that deal, to some extent, with malicious (often called "Byzantine") sites.

Consistent Query Answering

LEOPOLDO BERTOSSI
Carleton University, Ottawa, ON, Canada

Definition

Consistent query answering (CQA) is the problem of querying a database that is inconsistent, i.e., that fails to satisfy certain integrity constraints, in such a way that the answers returned by the database are consistent with those integrity constraints. This problem involves a characterization of the semantically correct or consistent answers to queries in an inconsistent database.

Key Points

Databases may be inconsistent in the sense that certain desirable integrity constraints (ICs) are not satisfied. However, it may be necessary to still use the database, because it contains useful information, and, most likely, most of the data is still consistent, in some sense. CQA, as introduced in [1], deals with two problems. First, with the logical characterization of the portions of data that are consistent in the inconsistent database. Secondly, with developing computational mechanisms for retrieving the consistent data. In particular, when queries are posed to the database, one would expect to obtain as answers only those answers that are semantically correct, i.e., that are consistent with the ICs that are violated by the database as a whole.

The consistent data in the database is characterized [1] as the data that is invariant under all the database instances that can be obtained after making minimal changes in the original instance with the purpose of restoring consistency. These instances are the so-called (minimal) *repairs*. In consequence, what is consistently true in the database is what is *certain*, i.e., true in the collection of possible worlds formed by the repairs. Depending on the queries and ICs, there are different algorithms for computing consistent answers. Usually, the original query is transformed into a new query, possibly written in a different language, to be posed to the database at hand, in such a way that the usual answers to the latter are the consistent answers to the former [1]. For surveys of CQA and specific references, c.f. [2,3].

Constraint Databases

FLORIS GEERTS
University of Edinburgh, Edinburgh, UK

Definition

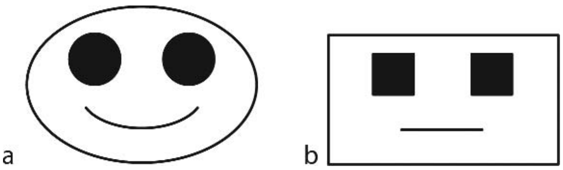
Constraint databases are a generalization of relational databases aimed to store possibly infinite-sized sets of data by means of a finite representation (*constraints*) of that data. In general, constraints are expressed by *quantifier-free first-order formulas* over some fixed vocabulary Ω and are interpreted in some Ω-structure $\mathcal{M} = \langle \mathbb{U}, \Omega \rangle$. By varying Ω and $\mathcal{M}$, constraint databases can model a variety of data models found in practice including traditional relational databases, spatial and spatio-temporal databases, and databases with text fields (strings). More formally, let Ω be a fixed vocabulary consisting of function, predicate and constant symbols, and let $\mathcal{R} = \{R_1,\ldots,R_\ell.\}$ be a relational schema, where each relation name R_i is of arity

$n_i > 0$. An Ω*-constraint database* $\mathbf{D}$ with schema $\mathcal{R}$ maps each relation $R_i \in \mathcal{R}$ to a quantifier-free formula $\varphi^{\mathbf{D}}_{R_i}(x_1,\ldots,x_{n_i})$ (with n_i free variables $x_1,\ldots,x_{n_i}$) in *first-order logic* over Ω. When interpreted over an Ω-structure $\mathcal{M} = \langle\mathbb{U},\Omega\rangle$, an Ω-constraint database $\mathbf{D}$ with schema $\mathcal{R}$ corresponds to the collection of the $\mathcal{M}$*-definable sets* $[\![R_i]\!]^{\mathbf{D}}_{\mathcal{M}} = \{(a_1,\ldots,a_{n_i}) \in \mathbb{U}^{n_i} \mid \mathcal{M} \models \varphi^{\mathbf{D}}_{R_i}(a_1,\ldots,a_{n_i})\}$, for $R_i \in \mathcal{R}$. Constraint query languages have been devised to manipulate and query constraint databases.

Key Points

The primary motivation for constraint databases comes from the field of spatial and spatio-temporal databases where one wants to store an infinite set of points in the real Euclidean space and query it as if all (infinitely) many points are present [3,4,5]. In the spatial context, the constraints used to finitely represent data are *Boolean combinations of polynomial inequalities.* For instance, the infinite set of points in the real plane $\mathbb{R}^2$ depicted in Fig. 1(a) can be described by means of a disjunction of polynomial inequalities with integer coefficients as follows: $\varphi(x, y) = (x^2/25 + y^2/16 = 1) \vee (x^2 + 4x + y^2 - 2y \leq 4) \vee (x^2 - 4x + y^2 - 2y \leq -4) \vee (x^2 + y^2 - 2y = 8 \wedge y < -1)$. In the language of constraint databases, $\varphi(x, y)$ is a quantifier-free first-order formula over $\Omega = (+,\cdot,0,1,<)$ and Fig. 1(a) represents the $\mathcal{M}$-definable set in $\mathbb{R}^2$ corresponding to the formula φ for the Ω-structure $\mathcal{M} = \langle\mathbb{R},\Omega\rangle$. If $\mathcal{R}$ is a relational schema consisting of a binary relation R, then the Ω-constraint database $\mathbf{D}$ with schema $\mathcal{R}$ defined by $R \mapsto \varphi(x, y)$ "stores" the set in Fig. 1(a). In this case, the $\mathcal{M}$-definable sets are also known as semi-algebraic sets [2].

When *Boolean combination of linear inequalities* suffice, such as in geographical information systems (GIS), one considers constraint databases over $\Omega = (+,0,1,<)$ and $\mathcal{M} = \langle\mathbb{R},\Omega\rangle$. Fig. 1(b) shows an example of a set defined by means of a first-order formula over $\Omega = (+,0,1,<)$. The advantage of the constraint approach to represent spatial data is the uniform representation of the various spatial entities. Whereas in GIS one normally defines a special data-type for each spatial object such as line, poly-line, circle,..., each of those are now represented by constraints in the same constraint language.



Constraint Databases. Figure 1. Example of set definable by (a) polynomial constraints and (b) linear constraints.

Other common scenarios of constraint databases include: *dense order constraints over the rationals*, where $\Omega = (<,(c)_{c\in\mathbb{Q}})$ and $\mathcal{M} = \langle\mathbb{Q},\Omega\rangle$. That is, rational numbers with order and constants for every $c \in \mathbb{Q}$; and *constraints over strings*, where $\Omega = ((f_a)_{a\in\Sigma},\prec,\text{el})$ and $\mathcal{M} = \langle\Sigma^*,\Omega\rangle$ [1]. Here, Σ is a finite alphabet, f_a is a function that adds a at the end of its argument, $\prec$ is the prefix relation and $\text{el}(x, y)$ is a binary predicate that holds if $|x| = |y|$, where $|\cdot|$ stands for the length of a finite string. In the latter case, the $\mathcal{M}$-definable sets are precisely the regular languages over Σ.

Finally, standard relational databases with schema $\mathcal{R}$ can be considered as constraint databases over *equality constraints over an arbitrary infinite domain* $\mathbb{U}$, where $\Omega = ((c)_{c\in\mathbb{U}})$ and $\mathcal{M} = \langle\mathbb{U},\Omega\rangle$. Indeed, consider a tuple $t = (a_1,\ldots,a_n)$ consisting of some constants $a_i \in \mathbb{U}$, for $i \in [1,n]$. The tuple t can be expressed by the formula $\varphi_t(x_1,\ldots,x_n) = (x_1 = a_1) \wedge\ldots\wedge (x_n = a_n)$ over the signature $\Omega = ((c)_{c\in\mathbb{U}})$. More generally, an instance $I = \{t_1,\ldots,t_N\}$ over $R \in \mathcal{R}$ corresponds to $\varphi_I = \bigvee_{i=1}^{N} \varphi_{t_i}$. Therefore, a relational instance $(I_1,\ldots,I_\ell)$ over $\mathcal{R}$ can be represented as the constraint database $\mathbf{D}$ defined by $R_i \mapsto \varphi_{I_i}(x_1,\ldots,x_{n_i})$, for $i \in [1,\ell]$. This shows that constraint databases indeed generalize standard relational databases.

Constraint Query Languages

FLORIS GEERTS
University of Edinburgh, Edinburgh, UK

Definition

A constraint query language is a query language for constraint databases.

Historical Background

The field of constraint databases was initiated in 1990 in a paper by Kanellakis, Kuper and Revesz [9]. The goal was to obtain a database-style, optimizable version of constraint logic programming. It grew out of the research on DATALOG and constraint logic programming. The key idea was that the notion of tuple in a relational database could be replaced by a conjunction of constraints from an appropriate language, and that many of the features of the relational model could then be extended in an appropriate way. In particular, standard query languages such as those based on first-order logic and DATALOG could be extended to such a model.

It soon became clear, however, that recursive constraint query languages led to non-effective languages. The focus therefore shifted to non-recursive constraint query languages. The standard query language is the constraint relational calculus (or equivalently, the constraint relational algebra). The study of this query language turned out to lead to many interesting research problems. During the period from 1990 to 2000, the constraint setting has been studied in great generality which led to deep connections between constraint databases and embedded finite model theory. Also, the potential application of constraint databases in the spatial context led to numerous theoretical results and concrete implementations such as the DEDALE and the DISCO systems. The connection with so-called o-minimal geometry underlies many of the results in the spatial setting. The success of this research led to the publication of a comprehensive survey of the area in 2000 [11] and a textbook in 2002 [13].

In recent years, constraint query languages have been studied in new application domains such a strings, spatio-temporal and moving objects.

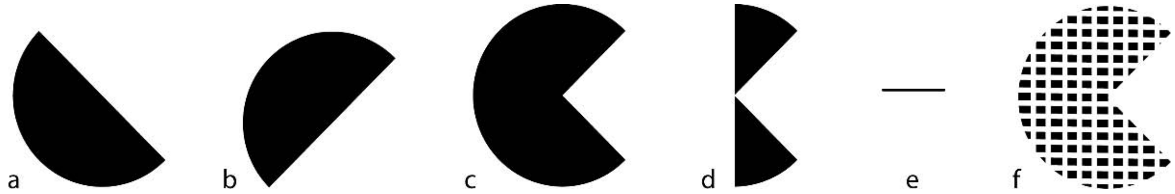
Foundations

In the constraint model, a database is viewed as a collection of constraints specified by quantifier-free first-order logic formulas over some fixed vocabulary $\mathbf{\Omega}$. When interpreted over an $\mathbf{\Omega}$-structure $\mathcal{M} = \langle \mathbb{U}, \mathbf{\Omega} \rangle$, each constraint corresponds to an $\mathcal{M}$-definable set. Consequently, when interpreted over $\mathcal{M}$, an $\mathbf{\Omega}$-constraint database corresponds to a collection of $\mathcal{M}$-definable sets. For instance, consider the vocabulary $\mathbf{\Omega} = (+, \cdot, 0, 1, <)$ and $\mathcal{M} = \langle \mathbb{R}, \mathbf{\Omega} \rangle$. Constraints in first-order logic over $\mathbf{\Omega}$, denoted by FO($\mathbf{\Omega}$), correspond to Boolean combinations of polynomial inequalities with integer coefficients. The corresponding $\mathcal{M}$-definable sets are better known as semi-algebraic sets. Let $\mathcal{R} = \{R, S\}$ be a relational schema consisting of two binary relations R and S and let $\mathbf{D}$ be the constraint database that maps $R \mapsto \varphi_R(x, y) = (x^2 + y^2 \leq 1) \wedge (y - x \geq 0)$ and $S \mapsto \varphi_S(x, y) = (x^2 + y^2 \leq 1) \wedge (-y - x \geq 0)$. The two $\mathcal{M}$-definable sets in $\mathbb{R}^2$ corresponding to φ_R and φ_S are shown in Figs. 1(a) and (b) respectively.

A constraint database can therefore be viewed from two different perspectives: First, one can simply look at the finite representations (constraints) stored in them; Second, one can regard them as a set of definable sets. Whereas in traditional relational databases, a query is simply a mapping that associates with each database an answer relation, in the constraint setting the two different perspectives give rise to two different notions of queries.

Indeed, for a fixed vocabulary $\mathbf{\Omega}$, relational schema $\mathcal{R}$ consisting of relation names $R_1,\ldots,R_\ell$, where each relation R_i is of arity $n_i > 0$, and natural number k, a *k-ary constraint query* with schema $\mathcal{R}$ over $\mathbf{\Omega}$, is a (partial) function Q that maps each $\mathbf{\Omega}$-constraint databases $\mathbf{D}$ with schema $\mathcal{R}$ to a k-ary $\mathbf{\Omega}$-constraint relation $Q(\mathbf{D})$. That is, a constraint query works entirely on the representational (constraint) level. On the other hand, given an additional $\mathbf{\Omega}$-structure $\mathcal{M} = \langle \mathbb{U}, \mathbf{\Omega} \rangle$, a *k-ary unrestricted query* with schema $\mathcal{R}$ over $\mathcal{M}$ is a (partial) function Q that maps each collection $\mathbf{D}$ of sets in $\mathbb{U}^{n_i}$, for $i \in [1, \ell]$, to a set $Q(\mathbf{D})$ in $\mathbb{U}^k$. Such a collection of sets $\mathbb{U}^{n_i}$, for $i \in [1, \ell]$, is called an *unrestricted database* with schema $\mathcal{R}$ over $\mathcal{M}$.

For instance, consider again $\mathbf{\Omega} = (+, \cdot, 0, 1, <)$ and $\mathcal{R} = \{R, S\}$. The mapping Q_1 that associates each $\mathbf{\Omega}$-constraint database $\mathbf{D}$ over $\mathcal{R}$ with the binary $\mathbf{\Omega}$-constraint relation defined by taking the disjunction of the constraints in R and S, is an example of a 2-ary constraint query over $\mathbf{\Omega}$. When applied on the database $\mathbf{D}$ given above, $Q_1(\mathbf{D})$ is mapped to $\varphi_R(x, y) \vee \varphi_S(x, y)$. Similarly, the mapping Q_2 that maps $\mathbf{D}$ to the



Constraint Query Languages. Figure 1. Sets in $\mathbb{R}^2$ defined by $\varphi_R(x, y)$ (a); by $\varphi_S(x, y)$ (b); by $\varphi_R(x, y) \vee \varphi_S(x, y)$ (c); and by $\varphi_1(x, y)$ (d). The set in $\mathbb{R}$ defined by $\varphi_2(x)$ (e). An example of a non-definable set in $\mathbb{R}^2$ (f).

constraint in R or S that contains the polynomial with the largest coefficient (if there is no such unique constraint then Q_2 is undefined) is also a constraint query. It will be undefined on the example database $\mathbf{D}$ since both R and S consist of a polynomial with coefficient one.

So far, only constraint queries have been considered. To relate constraint and unrestricted queries requires some care. Clearly, a constraint query only makes sense if it corresponds to an unrestricted query. In this case, a constraint query is called *consistent*. More formally, a constraint query Q is called consistent if there exists an unrestricted query Q_0 such that for any constraint database $\mathbf{D}$ and any unrestricted database $\mathbf{D}_0$, if $\mathbf{D}$ represents $\mathbf{D}_0$, then $Q(\mathbf{D})$ is defined if and only if $Q_0(\mathbf{D}_0)$ is defined and furthermore, $Q(\mathbf{D})$ represent $Q_0(\mathbf{D}_0)$. One also says that Q *represents* Q_0.

For instance, consider again $\Omega = (+, \cdot, 0, 1, <)$, $\mathcal{M} = \langle \mathbb{R}, \Omega \rangle$ and $\mathcal{R} = \{R, S\}$. The mapping $\tilde{Q}_1$ that assigns to any two sets $A \subseteq \mathbb{R}^2$ and $B \subseteq \mathbb{R}^2$, corresponding to R and S, respectively, their union $A \cup B \subseteq \mathbb{R}^2$ is an unrestricted query. It is clear that Q_1 and $\tilde{Q}_1$ satisfy the condition of consistency and therefore Q_1 is consistent. Fig. 1(c) shows $\tilde{Q}_1(\mathbf{D}_0)$ for the unrestricted database $\mathbf{D}_0$ shown in Fig. 1(a) and (b). This set is indeed represented by the constraint relation $Q_1(\mathbf{D}) \mapsto \varphi_R(x, y) \vee \varphi_S(x, y)$. On the other hand, it is easily verified that Q_2 is not consistent. Indeed, it suffices to consider the behavior of Q_2 on $\mathbf{D}$ defined above and $\mathbf{D}'$ defined by $R \mapsto \varphi'_R(x, y) = (x^2 + y^2 \leq 1) \wedge (6(y - x) \geq 0)$ and $S \mapsto \varphi'_S(x, y) = (x^2 + y^2 \leq 1) \wedge (-y - x \geq 0)$. While both $\mathbf{D}$ and $\mathbf{D}'$ represent the same unrestricted database, note that $Q_2(\mathbf{D})$ is undefined while $Q_2(\mathbf{D}') \mapsto \varphi_R$. Hence, no unrestricted query that is consistent with Q_2 can exist.

Finally, unrestricted queries are defined without any reference to the class of $\mathcal{M}$-definable sets. A desirable property, however, is that when an unrestricted query Q is defined on an unrestricted database $\mathbf{D}$ that consists of $\mathcal{M}$-definable sets, then also $Q(\mathbf{D})$ is an $\mathcal{M}$-definable set. Such unrestricted queries are called *closed*. Note that an unrestricted query that is represented by a consistent constraint query is uniquely defined and moreover is trivially closed. An example of an unrestricted query for $\Omega = (+, \cdot, 0, 1, <)$ and $\mathcal{M} = \langle \mathbb{R}, \Omega \rangle$ that is not closed is the query Q that maps any $\mathcal{M}$-definable set A in $\mathbb{R}^2$ to its intersection $A \cap \mathbb{Q}^2$. Fig. 1(f) shows (approximately) the result of this query on $\tilde{Q}_1(\mathbf{D}_0)$ (i.e., Fig. 1(c)). Since this is not a semi-algebraic set in $\mathbb{R}^2$, it cannot be defined by means of a quantifier-free FO(Ω)-formula. As a consequence, Q is not closed.

Now that the notion of query is defined in the setting of constraint databases, the basic *constraint query language* is introduced. This language, in the same spirit as the relational calculus for traditional relational databases, is the *relational calculus* or first-order logic of the given class of constraints. More specifically, given a vocabulary Ω and relational schema $\mathcal{R}$, a *relational calculus formula* over Ω is a first-order logic formula over the expanded vocabulary $(\Omega, \mathcal{R})$ obtained by expanding Ω with the relation names (viewed as predicate symbols) of the schema $\mathcal{R}$. This class of queries is denoted by FO($\Omega, \mathcal{R}$), or simply FO(Ω) when $\mathcal{R}$ is understood from the context.

For instance, for $\Omega = (+, \cdot, 0, 1, <)$ and $\mathcal{R} = \{R, S\}$, the expressions $\varphi_1(x, y) = (R(x, y) \vee S(x, y)) \wedge x > 0$ and $\varphi_2(x) = \exists y \varphi_1(x, y)$ are formulas in FO($+, \cdot, 0, 1, <, R, S$).

Given an Ω-structure $\mathcal{M} = \langle \mathbb{U}, \Omega \rangle$, formulas in FO($\Omega, \mathcal{R}$) express (everywhere defined) unrestricted queries with schema $\mathcal{R}$ over $\mathcal{M}$. Indeed, a formula $\varphi(x_1, \ldots, x_k) \in$ FO($\Omega, \mathcal{R}$) defines the k-ary unrestricted query Q over $\mathcal{M}$ as follows: consider the expansion of $\mathcal{M}$ to a structure $\langle \mathcal{M}, \mathbf{D} \rangle = \langle \mathbb{U}, \Omega, \mathbf{D} \rangle$ over the expanded vocabulary $(\Omega, \mathcal{R})$ by adding the sets in the unrestricted database $\mathbf{D}$ to $\mathcal{M}$ for each $R_i \in \mathcal{R}$. Then, $Q(\mathbf{D}) = \{(a_1, \ldots, a_k) \in \mathbb{U}^k \mid 0\langle \mathcal{M}, \mathbf{D} \rangle \models \varphi(a_1, \ldots, a_k)\}$.

For instance, for $\Omega = (+, \cdot, 0, 1, <)$ and $\mathcal{M} = \langle \mathbb{R}, \Omega \rangle$, the formula $\varphi_1(x, y)$ defined above corresponds to the unrestricted query Q_1 that takes the union of the two sets in $\mathbb{R}^2$ corresponding to R and S, respectively, restricted to those points in $\mathbb{R}^2$ with strictly positive x-coordinate. Similarly for φ_2, but with an additional projection on the x-axis. The results of these two unrestricted queries have been shown in Figs. 1(d), (e), respectively.

The previous example raises the following two questions: (i) are the unrestricted queries expressed by formulas in first-order logic closed, and (ii) if so, can one find a corresponding constraint query that is effectively computable? The fundamental mechanism underlying the use of first-order logic as a constraint query language is the following observation that provides an answer to both questions:

- Every relational calculus formula φ expresses a consistent, effectively computable, total constraint query that represents the unrestricted query expressed by φ, if and only if $\mathcal{M}$ admits *effective quantifier elimination*.

Here, an Ω-structure $\mathcal{M}$ admits effective quantifier elimination if there exists an effective algorithm that transforms any first-order formula in FO(Ω) to an equivalent (in the structure $\mathcal{M}$) *quantifier-free* first-order formula in FO(Ω).

Consider the two FO($+,\cdot,0,1,<, R, S$)-formulas φ_1 and φ_2 given above. It is known that the structure $\langle\mathbb{R}, +, \cdot, 0, 1, <\rangle$ admits effective quantifier-elimination. In case of φ_1 it is easy to see that the result of corresponding constraint query is obtained by "plugging" in the constraints for R (resp. S) as given by the constraint database into the expression for φ_1. That is, on the example database **D**, φ_1 corresponds to the constraint query that maps **D** to $(\varphi_R(x, y) \vee \varphi_S(x, y)) \wedge (x > 0)$, which is a 2-ary Ω-constraint relation. In case of φ_2, however, first plug in the descriptions of the constraints as before, resulting in $\exists y\, (\varphi_R(x, y) \vee \varphi_S(x, y)) \wedge (x > 0)$. In order to obtain an Ω-constraint relation, one needs perform quantifier-elimination. It is easily verified that in this example, a corresponding constraint query is one that maps **D** to $(0 < x) \wedge (x \leq 1)$ which is consistent with Fig. 1(e).

For Ω-structures $\mathcal{M}$ that admit effective quantifier-elimination, this suggests the following effective evaluation mechanism for constraint relational calculus queries φ on a constraint database **D**: (i) plug in the contents of **D** in the appropriate slots (relations). Denote the resulting formula by plug(φ, **D**); and (ii) eliminate the quantifiers in plug(φ, **D**). Since **D** consists of quantifier-free formulas, the number of quantifiers that need to be eliminated is the same as in φ and is therefore independent of **D**. For many structures $\mathcal{M}$ this implies that the evaluation of constraint queries can be done in polynomial data complexity, which is a desirable property for any query language.

It is important to point out that the classical equivalence between the relational calculus and the relational algebra can be easily extended to the constraint setting. That is, for a fixed Ω and schema $\mathcal{R}$, one can define a *constraint relational algebra* and show that every constraint relational calculus formula can be effectively converted to an equivalent constraint relational algebra expression, and vice versa. This equivalence is useful for concrete implementations of constraint database systems.

The study of expressivity of FO($\Omega, \mathcal{R}$) for various Ω-structures $\mathcal{M}$ has led to many interesting results. In particular, the impact of the presence of the "extra" structure on the domain elements in $\mathbb{U}$ has been addressed when **D** consists of an ordinary finite relational database that takes values from $\mathbb{U}$ [3]. In particular, the correspondence between natural and active-domain semantics has been revisited. That is, conditions are identified for $\mathcal{M} = \langle\mathbb{U}, \Omega\rangle$ such that the language FO($\Omega, \mathcal{R}$) is equal to $\text{FO}_{\text{act}}(\Omega, \mathcal{R})$, the query language obtained by interpreting $\forall x$ and $\exists x$ over the active domain of **D** instead of over $\mathbb{U}$. Such structures are said to admit the *natural-active collapse*. Similarly, ordered structures $\mathcal{M}$ are identified that admit the *active-generic collapse*. That is, $\text{FO}_{\text{act}}(\Omega, \mathcal{R})$ is equal to $\text{FO}_{\text{act}}(<, \mathcal{R})$ with respect to the class of generic queries. In other words, every generic query definable under active domain semantics with Ω-constraints is already definable with just order constraints. Finally, structures $\mathcal{M}$ are considered that allow the *natural-generic collapse*. This is the same as the active-generic collapse but with natural domain semantics instead of active domain semantics. The study of these collapse properties for various structures not only sheds light on the interaction of the structure on $\mathbb{U}$ and the query language, it is also helpful to understand the expressiveness of constraint query languages [3,11].

Indeed, let $\Omega = (+, \times, 0, 1, <)$ and $\mathcal{M} = \langle\mathbb{R}, \Omega\rangle$. It can be shown that $\mathcal{M}$ admits all three collapses because it is a so-called o-minimal structure. As a consequence, the query EVEN that returns **yes** if the cardinality of **D** is even and **no** otherwise, is not expressible in $\mathrm{FO}(\Omega, \mathcal{R})$. Indeed, if it would be expressible by a query φ in $\mathrm{FO}(\Omega, \mathcal{R})$ it would already have been expressible by a query in $\mathrm{FO}_{\mathrm{act}}(<, \mathcal{R})$, which is known not to be true in the traditional database setting.

The expressivity of $\mathrm{FO}(\Omega, \mathcal{R})$ has been studied extensively as well when **D** corresponds to sets of infinite size. In particular, expressiveness questions have been addressed in the spatial setting where $\Omega = (+, \cdot, 0, 1, <)$ and $\mathcal{M} = \langle \mathbb{R}, \Omega \rangle$ (polynomial constraints); and $\Omega' = (+, 0, 1, <)$ and $\mathcal{M} = \langle \mathbb{R}, \Omega' \rangle$ (linear constraints). In this setting, many reductions are presented in [7] to expressiveness questions in the finite case. Combined with the collapse results mentioned above, these reductions were used to show that, for example, topological connectivity of Ω- (resp. Ω'-) constraint databases is not expressible in first-order logic. Indeed, a proof of this results relies on the fact that the EVEN-query is not expressible in $\mathrm{FO}(\Omega, \mathcal{R})$ (resp. $\mathrm{FO}(\Omega', \mathcal{R})$) [7].

An interesting line of work in the spatial context concerns the expressive power of $\mathrm{FO}(\Omega, \mathcal{R})$ with respect to queries that preserve certain geometrical properties. More formally, let $\mathcal{G}$ be a group of transformations of $\mathbb{R}^k$. A query Q is called $\mathcal{G}$-generic if, for every transformation $g \in \mathcal{G}$, and for any two databases **D** and **D**′, $g(\mathbf{D}) = \mathbf{D}'$ implies $g(Q(\mathbf{D})) = Q(\mathbf{D}')$. Transformation groups and properties of the corresponding generic queries have been studied for the group of homeomorphisms, affinities, similarities, isometries, among others [8]. Especially the study of the topologically queries (those that are generic under homeomorphisms) has received considerable attention [10,2].

To conclude, both for the historical reasons mentioned above and in view of the limited expressive power of $\mathrm{FO}(\Omega, \mathcal{R})$, various recursive extensions of $\mathrm{FO}(\Omega, \mathcal{R})$ have been proposed such as: constraint transitive-closure logic [5], constraint DATALOG [9], and $\mathrm{FO}(\Omega, \mathcal{R})$ extended with a WHILE-loop [8]. The interaction of recursion with the structure on $\mathbb{U}$ imposed by Ω leads in most cases to computationally complete query languages. Worse still, queries defined in these languages may not be closed or even terminate. To remedy this, special-purpose extensions of $\mathrm{FO}(\Omega, \mathcal{R})$ have been proposed that guarantee both termination and closure. Characteristic examples include $\mathrm{FO}(\Omega, \mathcal{R}) + \mathrm{AVG}$ and $\mathrm{FO}(\Omega, \mathcal{R}) + \mathrm{SUM}$ in the context of aggregation [4]. In the spatial setting, extensions of $\mathrm{FO}(\Omega, \mathcal{R})$ with various connectivity operators have been proposed [1].

Results concerning constraint query languages have been both extended to great generality and applied to concrete settings. Refer to [14] for a gentle introduction and to [11] for a more detailed survey of this research area up to 2000. Some more recent results are included in Chapter 5 of [12] for the general constraint setting and Chapter 12 in [6] for the spatial setting.

Key Applications

Manipulation and querying of constraint databases, querying of spatial data.

Constraint-Driven Database Repair

Synonyms

Data reconciliation; Minimal-change integrity maintenance; Data standardization

Definition

Given a set Σ of integrity constraints and a database instance D of a schema R, the problem of *constraint-driven database repair* is to find an instance D' of the same schema R such that (i) D' is *consistent*, i.e., D' satisfies Σ, and moreover, (ii) D' *minimally differs* from the original database D, i.e., it takes a minimal number of repair operations or incurs minimal cost to obtain D' by updating D.

Historical Background

Real life data is often dirty, i.e., inconsistent, inaccurate, stale or deliberately falsified. While the prevalent use of the Web has made it possible, on an unprecedented scale, to extract and integrate data from diverse sources, it has also increased the risks of creating and propagating dirty data. Dirty data routinely leads to misleading or biased analytical results and decisions, and incurs loss of revenue, credibility and customers. With this comes the need for finding repairs of dirty data, and editing the data to make it consistent. This is the data cleaning approach that US national statistical agencies, among others, has been practicing for decades [10].

The notion of constraint-based database repairs is introduced in [1], highlighting the use of integrity constraints for characterizing the consistency of the data. In other words, constraints are used as data quality rules, which detect inconsistencies as violations of the constraints. Prior work on constraint-based database repairs has mostly focused on the following issues. (i) Integrity constraints used for repair. Earlier work considers traditional functional dependencies, inclusion dependencies and denial constraints [1,2,4,6,12]. Extensions of functional and inclusion dependencies, referred to as conditional functional and inclusion dependencies, are recently proposed in [3,9] for data cleaning. (ii) Repair semantics. Tuple deletion is the only repair operation used in [6], for databases in which the information is complete but not necessarily consistent. Tuple deletion and insertion are considered in [1,4] for databases in which the information may be neither consistent nor complete. Updates, i.e., attribute-value modification are proposed as repair operations in [12]. Cost models for repairs are studied in [2,8]. (iii) Algorithms. The first algorithms for finding repairs are developed in [2], based on traditional functional and inclusion dependencies. Algorithms for repairing and incrementally repairing databases are studied in [8], using conditional functional dependencies. The repair model adopted by these algorithms supports updates as repair operations. (iv) Fundamental issues associated with constraint-based repairs. One issue concerns the complexity bounds on the database repair problem [2,6]. Another issue concerns the static analysis of constraint consistency [3,9] for determining whether a given set of integrity constraints is dirty or not itself.

Constraint-based database repairs are one of the two topics studied for constraint-based data cleaning. The other topic, also introduced in [1], is *consistent query answers*. Given a query Q posed on an inconsistent database D, it is to find tuples that are in the answer of Q over every repair of D. There has been a host of work on consistent query answers [1,4,6,11,12] (see [5,7] for comprehensive surveys).

Foundations

The complexity of the constraint-based database repair problem is highly dependent upon what integrity constraints and repair model are considered.

Integrity Constraints for Characterizing Data Consistency

A central technical issue for data cleaning concerns how to tell whether the data is dirty or clean. Constraint-based database repair characterizes inconsistencies in terms of violations of integrity constraints. Constraints employed for data cleaning include functional dependencies, inclusion dependencies, denial constraints, conditional functional dependencies and conditional inclusion dependencies. To illustrate these constraints, consider the following relational schema R, which consists of three relation schemas:

customer(name, country-code, area-code, phone, city, street, zip)
order(name, country-code, area-code, phone, item-id, title, price, item-type)
book(isbn, title, price, format)

Traditional functional dependencies and inclusion dependencies defined on the schema R include:

FD: customer(country-code, area-code, phone → city, street, zip)
IND: order(name, country-code, area-code, phone) $\subseteq$ customer(name, country-code, area-code, phone)

The functional dependency FD asserts that the phone number (country-code, area-code and phone) of a customer uniquely determines her address (state, city, street, zip). That is, for any two customer tuples, if they have the same country-code, area-code and phone number, then they must have the same state, city, street, zip code. The inclusion dependency IND asserts that for any order tuple t, there must exist a customer tuple t' such that t and t' match on their name, country-code, area-code and phone attributes. In other words, an item cannot be ordered by a customer who does not exist.

Consider a set Σ consisting of FD and IND . One may want to use Σ to specify the consistency of database instances of R. An example instance D of R is shown in Fig. 1. This database is inconsistent, because tuples t_3 and t_4 in D violate the functional dependency FD . Indeed, while t_3 and t_4 have the same country-code, area-code and phone number, they differ in their street attributes. In other words, t_3, t_4 or both of them may be dirty.

One may also want to add a denial constraint to the set Σ:

DC : $\forall$nm, cc, ac, ph, id, tl, tp, pr$\neg$ (order(nm, cc, ac, ph, id, tl, pr, tp) $\wedge$pr $>$ 100)

Here nm, cc, ac, ph, id, tl, tp, pr stand for name, country-code, area-code, phone number, item-id, title, item type and price, respectively. This constraint says that no items in the order table may have a price higher than 100. In the database D of Fig. 1, tuple t_6 violates the constraint DD : the price of the CD is too high to be true. In general denial constraints can be expressed as universally quantified first-order logic sentences of the form:

$$\forall \bar{x}_1,\ldots,\bar{x}_m \neg(R_1(\bar{x}_1) \wedge \ldots \wedge R_m(\bar{x}_m) \wedge \varphi(\bar{x}_1,\ldots,\bar{x}_m)),$$

where R_i is a relation symbol for $i \in [1,m]$, and φ is a conjunction of built-in predicates.

Now consider an instance D' of D by removing t_3 from D and changing t_6[pr] to, e.g., 7.99. Then the database D' satisfies Σ. However, D' is not quite clean: it violates each of the following constraints. In other

	Name	Country-code	Area-code	Phone	City	Street	Zip
t_1:	M. Smith	44	131	1233444	NYC	Mayfield	EH8 8LE
t_2:	L. Webber	44	131	2344455	NYC	Crichton	EH8 8LE
t_3:	M. Hull	01	908	3456788	NYC	Mountain Ave	07974
t_4:	R. Xiong	01	908	3456788	NYC	Main St	07974

a Example customer data

	Name	Country-code	Area-code	Phone	Item-id	Title	Price	Item-type
t_5:	M.Smith	44	131	1233444	b23	H. Porter	17.99	book
t_6:	M.Hull	01	908	3456788	c68	John Denver	2000	CD

b Example order data

	isbn	Title	Price	Format
t_7:	b23	Harry porter	17.99	hard-cover
t_8:	b88	Snow white	7.94	audio

c Example book data

Constraint-Driven Database Repair. Figure 1. Example database instance.

words, if one further extends Σ by including the following constraints, then D' no longer satisfies Σ.

CFD1 : customer(country-code = 44, zip → street)
CFD2 : customer(country-code = 44, area-code = 131, phone → city = EDI, street, zip)
CFD3 : customer(country-code = 01, area-code = 908, phone → city = MH, street, zip)
CIND1 : order(id, title, price; item-type = book) ⊆ book(isbn, title, price)

Here CFD1, CFD2 and CFD3 are conditional functional dependencies defined on the customer relation. The constraint CFD1 asserts that for each customer in the UK, i.e., when the country code is 44, her zip code uniquely determines her street. In contrast to traditional functional dependencies, CFD1 does not hold on the entire customer relation. Indeed, it does not hold on customer tuples with, e.g., country-code = 01. Instead, it is applicable only to the set of customer tuples with country-code = 44. Constraints CFD2 and CFD3 refine the traditional functional dependency FD given earlier: CFD2 requires that when the country-code is 44 and area-code is 131, the city must be Edinburgh (EDI); similarly for CFD3. None of these can be expressed as traditional functional dependencies.

The constraint CIND1 is a conditional inclusion dependency, asserting that when the type of an item t in the order table is book, there must exist a corresponding tuple t' in the book table such that t and t' match on their id, title and price. Again this is a constraint that only holds conditionally. Indeed, without the condition item-type = book, a traditional inclusion dependency order(id, title, price) ⊆ book (isbn, title, price) does not make sense since, among other things, it is unreasonable to require each CD item in the order table to match a tuple in the book table.

These conditional dependencies tell us that the database D' is not clean after all. Indeed, tuples t_1,t_2 in the customer table violate CFD1: while they both represent customers in the UK and have the same zip code, they differ in their street attributes. Furthermore, each of t_1 and t_2 violates CFD2: while its area-code is 131, its city is NYC instead of EDI. Similarly, t_4 violates CFD3. From these one can see that while it takes two tuples to violate a traditional functional dependency, a single tuple may violate a conditional functional dependency. The inconsistencies in D' are not limited to the customer table: while tuple t_5 in the order table has item-type = book, there exists no tuple t' in the book table such that t_5 and t' match on their id, title and price attributes. Thus either t_5 in the order table is not error-free, or the book table is incomplete or inconsistent.

Conditional functional and inclusion dependencies are extensions of traditional functional and inclusion dependencies, respectively. In their general form each conditional functional (resp. inclusion) dependency is a pair comprising of (i) a traditional functional (resp. inclusion) dependency and (ii) a pattern tableau consisting of tuples that enforce binding of semantically related data values. Traditional functional (resp. inclusion) dependencies are a special case of conditional functional (resp. inclusion) dependencies, in which the tableaux do not include tuples with patterns of data values. As opposed to traditional functional and inclusion dependencies that were developed mainly for schema design, conditional functional and inclusion dependencies aim to capture the consistency of the data, for data cleaning. As shown by the example above, conditional dependencies are capable of detecting more errors and inconsistencies than what their traditional counterparts can find.

In summary, integrity constraints specify a fundamental part of the semantics of the data. Indeed, errors and inconsistencies in real-world data often emerge as violations of integrity constraints. The more expressive the constraints are, the more errors and inconsistencies can be caught. On the other hand, as will be seen shortly, the expressive power of the constraints often comes with the price of extra complexity for finding database repairs.

Repair Models

Consider functional dependencies, inclusion dependencies, denial constraints, conditional functional dependencies and inclusion dependencies. Given a database instance D of a schema R, if D violates a set Σ consisting of these constraints, one can always edit D to obtain a consistent instance D' of R, such that D' satisfies Σ. An extreme case is to delete all tuples from D and thus get an empty D'. Such a fix is obviously impractical: it removes inconsistencies as well as correct information. Apparently database repairs should not be conducted with the price of losing information of the original data. This motivates the criterion for database repairs to minimally differ from the original data.

Several repair models have been proposed [1,6]. One model allows tuple deletions only, assuming that the information in the database D is inconsistent but is complete. In this model, a repair D' is a maximal subset of D that satisfies Σ. For example, consider Σ consisting of FD given above, and the database D shown in Fig. 1. Then a repair of D can be obtained by removing either t_3 or t_4 from the customer table.

Another model allows both tuple deletions and insertions. In this model, a repair D' is an instance of R such that (i) D' satisfies Σ, and (ii) the difference between D and D', i.e., $(D \setminus D') \cup (D' \setminus D)$, is minimal when D' ranges over all instances of R that satisfy Σ. As an example, let Σ consist of FD and CIND given above, and D be the database of Fig. 1. Then one can obtain a repair of D either by removing both t_3 and t_5, or by removing t_3 but inserting a tuple t' to the book table such that t_5 and t' agree on their id, title and price attributes.

A more practical model is based on updates, i.e., attribute-value modifications. To illustrate this, let us consider Σ consisting of all the constraints that have been encountered, i.e., FD, IND, DD, CFD1, CFD2, CFD3 and CIND given above, and the database D of Fig. 1. Observe that every tuple in the customer relation violates at least one of the (conditional) functional dependencies in Σ. In the two models mentioned above, the only way to find a repair is by removing all tuples from the customer table. However, it is possible that only some fields in a customer tuple are not correct, and thus it is an overkill to remove the entire tuple. A more reasonable fix is to update the tuples by, e.g., changing t_1[city] and t_2[city] to EDI (for CFD2), t_1[street] to Crichton (forCFD1), t_3[city] and t_4[city] to MH (for CFD3), t_3[street] to Mountain Ave (for FD), t_6[price] to 7.99 (for DD), and t_5[title] to Harry Porter (for CIND). This yields a repair in the update model.

An immediate question about the update model concerns what values should be changed and what values should be chosen to replace the old values. One should make the decisions based on both the accuracy of the attribute values to be modified, and the "closeness" of the new value to the original value. Following the practice of US national statistical agencies [10], one can define a cost metric as follows [2,8]. Assuming that a *weight* in the range [0,1] is associated with each attribute A of each tuple t in D, denoted by $w(t,A)$ (if $w(t,A)$ is not available, a default weight can be used instead). The weight reflects the confidence of the *accuracy* placed by the user in the attribute $t[A]$, and can be propagated via data provenance analysis in data transformations. For two values v,v' in the same domain, assume that a *distance function* $\text{dis}(v,v')$ is in place, with lower values indicating greater similarity. The cost of changing the value of an attribute $t[A]$ from v to v' can be defined to be:

$$\text{cost }(v, v') = w(t, A) \cdot \text{dis }(v, v')/\max\ (|v|, |v'|),$$

Intuitively, the more accurate the original $t[A]$ value v is and more distant the new value v' is from v, the higher the cost of this change. The similarity of v and v' is measured by $\text{dis}(v,v')/\max(|v|,|v'|)$, where $|v|$ is the length of v, such that longer strings with 1-character difference are closer than shorter strings with 1-character difference. The cost of changing the value of a tuple t to t' is the sum of $\text{cost}(t[A],t'[A])$ when A ranges over all attributes in t for which the value of $t[A]$ is modified. The cost of changing D to D', denoted by $\text{cost}(D',D)$, is the sum of the costs of modifying tuples in D. A repair of D in the update model is an instance D' of R such that (i) D' satisfies Σ, and (ii) $\text{cost}(D',D)$ is minimal when D' ranges over all instances of R that satisfy Σ.

The accuracy of a repair can be measured by precision and recall metrics, which are the ratio of the number of errors correctly fixed to the total number of changes made, and the ratio of the number of errors correctly fixed to the total number of errors in the database, respectively.

Methods for Finding Database Repairs

It is prohibitively expensive to find a repair of a dirty database D by manual effort. The objective of constraint-based database repair is to automatically find candidate repairs of D. These candidate repairs are subject to inspection and change by human experts. There have only been preliminary results on methods for finding quality candidate repairs, as outlined below.

Given a set Σ of integrity constraints, either defined on a schema R or discovered from sample instances of R, one first wants to determine whether or not Σ is dirty itself. That is, before Σ is used to find repairs of D, one has to check, at compile time, whether or not Σ is consistent or makes sense, i.e., whether or not there exists a nonempty database instance of R that satisfies Σ. For traditional functional and inclusion dependencies, this is not an issue: one can specify arbitrary functional and inclusion dependencies without worrying about their consistency. While conditional inclusion dependencies alone retain this nice property, it is no longer the case when it comes to conditional functional dependencies. For example, consider the following conditional functional dependencies: $\psi_1 = R(A = \text{true} \rightarrow B = b_1)$, $\psi_2 = R(A = \text{false} \rightarrow B = b_2)$, $\psi_3 = R(B = b_1 \rightarrow A = \text{false})$, and $\psi_4 = R(B = b_2 \rightarrow A = \text{true})$, where the domain of attribute A is Boolean. While each of these constraints can be separately satisfied by a nonempty database instance, there exists no nonempty instance that satisfies all of these constraints. Indeed, for any tuple t in an instance, no matter what Boolean value $t[A]$ has, these constraints force $t[A]$ to take the other value from the Boolean domain.

The consistency problem is already NP-complete for conditional functional dependencies alone [9], and it becomes undecidable for conditional functional and inclusion dependencies taken together [3]. In light of the complexity, the consistency analysis is necessarily conducted by effective heuristic methods, ideally with performance guarantee. There has been approximate algorithms developed for checking the consistency of conditional functional dependencies, and heuristic algorithms for conditional functional and inclusion dependencies taken together.

After Σ is confirmed consistent, one needs to detect the inconsistencies in the database D, i.e., to find all tuples in D that violate one or more constraints in Σ. It has been shown that it is possible to automatically generate a fixed number of SQL queries from Σ, such that these queries can find all violations in D. This strategy works when Σ consists of functional dependencies, inclusion dependencies, conditional functional and inclusion dependencies [9]. Better yet, the size of the queries is dependent upon neither the number of constraints in Σ nor the pattern tableaux in the conditional dependencies in Σ.

After all violations are identified, the next step is to find an accurate repair of D by fixing these violations. This is challenging: in the repair model based on attribute-value updates, the problem of finding a database repair is already NP-complete even when the database schema is fixed and only a fixed number of traditional functional (or inclusion) dependencies are considered [2].

To cope with the tractability of the problem, several heuristic algorithms have been developed, based on the cost model given above. A central idea of these algorithms is to separate the decision of which attribute values should be equal from the decision of what value should be assigned to these attributes. Delaying value assignment allows a poor local decision to be improved in a later stage of the repairing process, and also allows a user to inspect and modify a repair. To this end an equivalence class eq(t,A) can be associated with each tuple t in the dirty database D and each attribute A in t. The repairing is conducted by merging and modifying the equivalence classes of attributes in D. For example, if tuples t_1,t_2 in D violate a functional dependency $R(X \rightarrow A)$, one may want to fix the inconsistency by merging eq(t_1,A) and eq(t_2,A) into one, i.e., by forcing t_1 and t_2 to match on their A attributes. If a tuple t_1 violates an inclusion dependency $R_1[X] \subseteq R_2[Y]$, one may want to resolve the conflict by finding an existing tuple t_2 in the R_2 relation or inserting a new tuple t_2 into the R_2 table, such that for each corresponding attribute pair (A,B) in $[X]$ and $[Y]$, $t_1[A] = t_2[B]$ by merging eq(t_1,A) and eq(t_2,B) into one. A target value is assigned to each equivalence class when no more merging is possible.

Based on this idea, effective heuristic algorithms have been developed for repairing databases using traditional functional and inclusion dependencies (e.g., [8]). The algorithms modify tuple attributes in the right-hand side of a functional or inclusion dependency in the presence of a violation. This strategy, however, no longer works for conditional functional dependencies: the process may not even terminate if only tuple attributes in the right-hand side of a conditional functional dependency can be modified. Heuristic algorithms for repairing conditional functional dependencies have been developed [8], which are also based on the idea of equivalence classes but may modify tuple attributes in either the left-hand side or right-hand side of a conditional functional dependency in the presence of a violation.

Key Applications

Constraint-based database repairs have a wide range of applications in, e.g., data standardization, data quality tools, data integration systems, master data management, and credit-card fraud detection.

Future Directions

The study of constraint-based database repair is still in its infancy. There is naturally much more to be done. One topic for future research is to identify new integrity constraints that are capable of detecting inconsistencies and errors commonly found in practice, without incurring extra complexity. The second topic is to develop more accurate and practical repair models. The third topic is to find heuristic methods, with performance guarantees, for reasoning about integrity constraints used for data cleaning, such as their consistency and implication analyses. The fourth yet the most challenging topic is to develop scalable algorithms for finding database repairs with performance guarantee, such as to guarantee that the precision and recall of the repairs found are above a predefined bound with a high confidence.

Content-and-Structure Query

Thijs Westerveld[1,2]
[1]Teezir Search Solutions, Ede, Netherlands
[2]CWI, Amsterdam, Netherlands

Synonyms

CAS query; CO+S query

Definition

A content-and-structure query is a formulation of an information need in XML retrieval or, more generally, in semi-structured text retrieval that includes explicit information about the structure of the desired result.

Key Points

Content-and-structure query is a term from semi-structured text retrieval, used predominantly for XML retrieval. The term refers to a specific way of querying a structured document collection. In addition to describing the (topical) content of the desired result, content-and-structure queries include explicit hints about the structure of the desired result or the structure of the context it appears in. Content-and-structure queries are useful for users who have knowledge about the collection structure and want to express the precise structure of the information they are after. For example, they can express the granularity of the desired results, e.g., return *sections* about architecture, or they can express the structural context of the information they are looking for, e.g., return *sections* about architecture within documents about *Berlin*. It is up to the retrieval system to decide how to use the structural hints in locating the most relevant information. In INEX, the Initiative for the Evaluation of XML Retrieval [1], content-and-structure queries are known as *CAS* queries or CO+S queries (*Content-Only queries* with structural hints) and expressed in the NEXI language [2]. More information on query languages, including content-only and content-and-structured queries in the field of XML search can be found in [1].

Content-Based Publish/Subscribe

Hans-Arno Jacobsen
University of Toronto, Toronto, ON, Canada

Definition

Content-based publish/subscribe is a communication abstraction that supports selective message dissemination among many sources and many sinks. The publication message content is used to make notification decisions. Subscribers express interest in receiving messages based on specified filter criteria that are evaluated against publication messages. Content-based publish/subscribe is an instance of the publish/subscribe concept.

Key Points

Content-based publish/subscribe is an instance of the publish/subscribe concept. In the content-based model clients interact by publishing messages and subscribing to messages through the publish/subscribe system. The key difference between the content-based and other publish/subscribe models is that the content of publication messages is used as the basis for disseminating publications to subscribers. Subscriptions consist of filters that specify subscriber interests making reference to publication message content. The publish/subscribe system matches publications against subscriptions by evaluating the publication message content against the filters expressed in subscriptions. The kind of content to subscribe to that exists in content-based publish/subscribe systems is either out-of-band information and must be know to clients, or is dynamically discoverable by clients based on additional support provided by the system.

A publication message published to the content-based publish/subscribe system is delivered to all subscribers with matching subscriptions. A subscription is a Boolean function over predicates. A publication matches a subscription, if the Boolean function representing it evaluates to true, otherwise the publication does not match the subscription.

As in the other publish/subscribe models, the content-based publish/subscribe model decouples the interaction among publishing data sources and subscribing data sinks. The same decoupling characteristics as discussed under the general publish/subscribe concept apply here as well. Specific realizations of this model found in practice vary in the exact decoupling offered. To properly qualify as publish/subscribe, at least the anonymous communication style must exist. That is publishing clients must not be aware of who the subscribing clients are and how many subscribing clients exist, and vice versa. Thus, content-based publish/subscribe enables the decoupled interaction of n sources with m sinks for $n, m \geq 1$.

In content-based publish/subscribe, the publication data model is defined by the data model underlying the definition of publication messages. The publication data model defines the structure and the type of publication messages processed by the system. In many approaches, a publication is a set of attribute-value pairs, where values are explicitly or implicitly typed. In explicit typing, each attribute-value pair has an additional type component specifying the type of the value. In implicit typing, no type is specified, and the type interpretation for matching is conveyed by the operator specified in the subscription referencing the attribute. The type-based publish/subscribe concept is a refinement of this based on programming language type theory.

Some content-based publish/subscribe approaches exist that define multi-valued attributes, where an attribute may have more than one value. Also, publication schemas and patterns have been introduced that specify certain attributes as required, while others are optional. Besides representing publications as attribute-value pairs, many other representations of publications have been introduced in the literature, such as XML, RDF, and strings.

The subscription language model is closely tied to the publication data model and defines the subscriptions the publish/subscribe system processes. The subscription language model that corresponds to the above described attribute-value pair-based publication data model, represents subscriptions as Boolean functions over predicates. Most content-based publish/subscribe systems process conjunctions of predicates only. In these systems, more general subscriptions must be represented as separate conjunctive subscriptions. A predicate is an attribute- operator-value triple that evaluates to true or false. Besides representing subscriptions as Boolean functions over predicates, many other representations of publications have been introduced in the literature, such as XPath, RQL, regular expressions, and keywords.

Subscription language and publication data model define subscriptions and publications processed by the publish/subscribe system. The matching semantic defines when a publication matches a subscription. Commonly the matching semantic is crisp; that is a publication matches a subscription or it does not. However, other semantics have been explored, such as an approximate match, a similarity-based match, or even a probabilistic match.

The publish/subscribe matching problem is stated as follows: Given a set of subscriptions and a publication, determine the subscriptions that match for the given publication. The publish/subscribe system can be interpreted as a filter that based on the subscriptions it stores, publications that do not match are filtered out, while those that match are forwarded to subscribers that have expressed interest in receiving information by registering subscriptions. The challenge is to efficiently solve this problem without computing a separate match between all subscriptions and the given publication. This is possible since in many applications, subscriptions share predicates, subsumption relationships exist among different subscriptions, and the evaluation of one predicate may allow to determine the result of other predicates without requiring explicit computation.

Content-based publish/subscribe systems differ in the publication data model, the subscription language model, the matching semantic, and the system architecture. In a system based on a centralized architecture, all publishers and subscribers connect to one and the same publish/subscribe system. In a system based on a distributed architecture, publishers and subscribers connect to one of many publish/subscribe systems that are interconnected in a federation. The federated publish/subscribe system offers the same functionality and solves the same matching problem as the centralized one.

Content-based publish/subscribe differs from topic-based publish/subscribe in that the entire message content is used for matching, while in a topic-based approach only the topic associated with a message is used.

Content-based publish/subscribe differs from database stream processing in that the publish/subscribe system processes publications of widely varying schemas. In the extreme case, every publication processed by the system could be based on a different schema. In stream processing, each data stream follows one and the same schema, which is an important assumption in the design of the stream query engine.

Content-based publish/subscribe has been an active area of research, since at least the late 1990s. The early work in the area was influenced from approaches in active databases, network management, and distributed systems. Many academic and industry research projects have developed content-based publish/subscribe systems. Various standards exhibit elements of the above described content-based publish/subscribe model. These standards are the CORBA Notification Service [3], the OMG Data Dissemination Service [4], the OGF's Info-D specification [2], and the Advanced Message Queuing Protocol [1].

Content-based publish/subscribe intends to support applications that need to highly selectively disseminate messages from one or more data sources to several data sinks. The mapping of sources to sinks can change dynamically with every message published and is fully determined by the publication content and the at publication time existing subscriptions. Given no change in the subscription set, one and the same message published twice, is sent to the same recipient set. Applications that require fine-grained filtering capabilities are ideally suited for realization with content-based publish/subscribe. Most existing publish/subscribe systems allow the application to dynamically change subscriptions at run-time. There are many applications that follow these characteristics. Examples include selective information dissemination, information filtering, database trigger processing, application-level firewalls, intrusion detection systems, and notification and altering services. Furthermore, recently it was demonstrated how higher-level applications can be build effectively with content-based publish/subscribe. Scenarios in this category are business activity monitoring, business process execution, monitoring and control of service level agreements, and automatic service discovery.

In the literature, the term content-based publish/subscribe refers to the above-described model and encompasses the centralized as well as the distributed realization of the publish/subscribe concept. In this context the terms matching and filtering are used interchangeably. The term content-based routing is reserved for the distributed realization of the model, where the publish/subscribe system is also referred to as a router, a broker, or a publish/subscribe message broker. In information retrieval, the publish/subscribe matching problem is referred to as information filtering. Subscriptions are then referred to as profiles or filters.

Content-Based Video Retrieval

Cathal Gurrin
Dublin City University, Dublin, Ireland

Synonyms

Digital video search; Digital video retrieval

Definition

Content-based Video Retrieval refers to the provision of search facilities over archives of digital video content, where these search facilities are based on the outcome of an analysis of digital video content to extract indexable data for the search process.

Historical Background

As the volume of digital video data in existence constantly increases, the resulting vast archives of professional video content and UCC (User Created Content) are presenting an opportunity for the development of content-based video retrieval systems. Content-based video retrieval system development was initially lead by academic research such as the Informedia Digital Video Library [3] from CMU and the Físchlár Digital Video Suite [6] from DCU (Dublin City University). Both of these systems operated over thousands of hours of content, however digital video search has now become an everyday WWW phenomenon, with millions of items of digital video being indexed by the major WWW search engines and video upload sites. The early research focused content-based digital video systems, such as the offerings from CMU and DCU, exploited aspects of text search and content-based image search in order to provide intelligent indexing, retrieval, summarization and visualization of digital video content. In recent years, the emerging WWW search engines have focused on the textual indexing of large quantities of digital video, at the expense of performing complex and time-consuming visual content analysis.

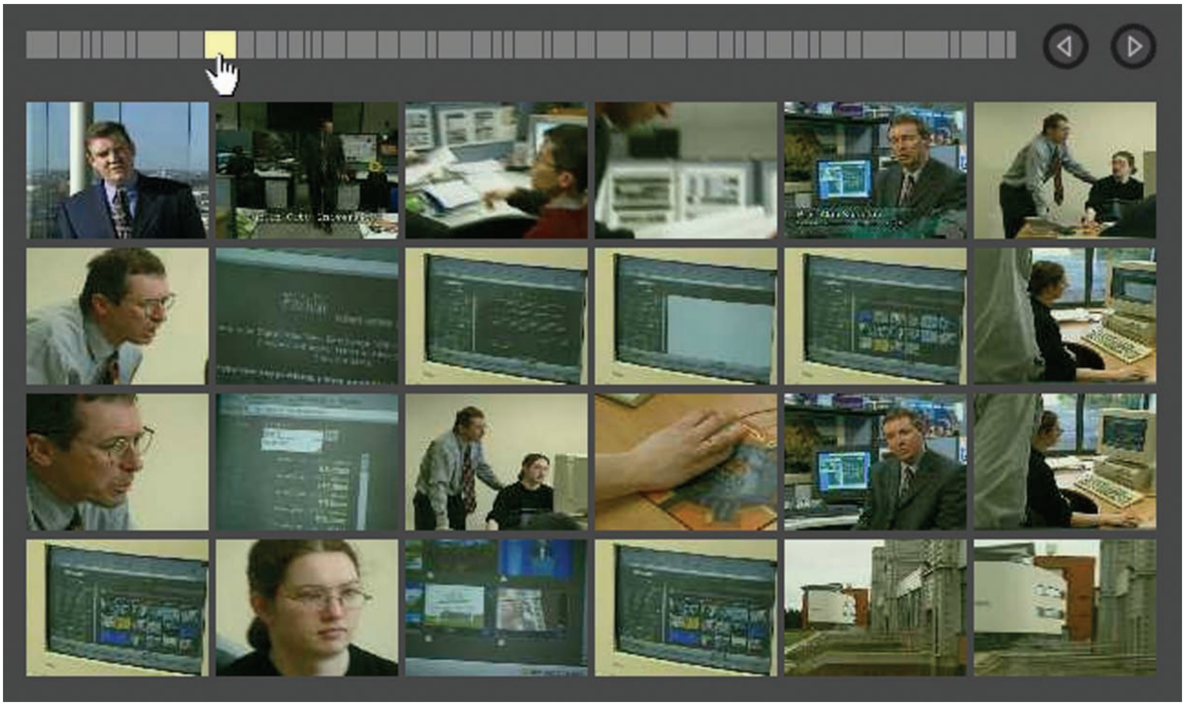
Foundations

The aim of a content-based video search system is to answer user queries with a (ranked) list of appropriate video content. Many different sources of video content exist and each needs to be treated differently. Firstly there is professional created content such as TV news content, documentaries, TV programmes, sports video and many others. Professional content is directed and polished content with many visual effects, such as a movie, music video or TV programme. Secondly there is the increasing quantities of UCC (User Created Content), such as home movie content or amateur/semi-professional content and finally there is security video content, which is increasingly being captured as the number of surveillance cameras in use increases. In addition to the type of content, another factor of key importance for content-based video search is the unit of retrieval.

Unit of Retrieval

Different content types will require different units of retrieval. In most WWW video search systems such as YouTube or Google Video, the unit of retrieval is the entire video content, which is sensible because most of the video content is short UCC or UUC (User Uploaded Content) clips. Retrieval of entire video units is not ideal for other types of content, for example TV news video, where the logical unit of retrieval would be a news story. There are a number of units of retrieval that are typically employed in addition to the entire video unit.

A *shot* in digital video is a sequence of continuous images (frames) from a single camera. A shot boundary is crossed when a recording instance ends and a new one begins. In many content-based video search systems the (automatically segmented) shot is the preferred unit of retrieval due to the fact that it is relatively easy to split a video file into its constituent shot in an automatic process called shot boundary detection [1]. Once a video stream has been segmented into shots, it can be browsed or indexed for subsequent search and retrieval, as shown in Fig. 1. A *scene* in digital video is a logical combination of video shots that together comprise some meaningful semantic unit. A *news story* is a special type of scene that is found in the context of news video. News stories can be automatically segmented from news video in a process called story-segmentation. This, like scene segmentation, is not a simple process, though reasonable accuracy can be achieved by replying on a number of individual cues from the video content and can be improved by exploiting the unique video production techniques of a particular broadcaster. For some video content, generating a *summary* or a *video skim* is a logical unit of retrieval. These summaries can be independent of any user need (context or query) or can be generated in response to a user need. Summaries have been successfully employed in the domain of field



Content-Based Video Retrieval. Figure 1. StoryBoard Interface from the Físchlár Video Retrieval System [2].

sports [4] or news summaries of reoccurring news topics [2]. Finally, as mentioned earlier, the entire video content may be returned in response to a user query, as is the case on many WWW video search engines in 2008.

Representing Video Content Visually on Screen

The quality of the interface to a content-based video retrieval system has a great effect on the usefulness of the system. In order to represent digital video visually, one or more keyframes (usually JPEG images) are usually extracted from the video to represent the content. These keyframes can then be employed for visual analysis of the video content by representing a video clip (typically a shot) by its keyframe and applying visual analysis techniques to the keyframe. In addition, these keyframes may be employed for visual presentation of video contents to support a degree of random access into the content. By processing video into a sequence of shots/scenes, and representing each shot/scene with one or more keyframes allows for the display of an entire video as a sequence of keyframes in what is called a StoryBoard interface, as shown in Fig. 1. Clicking on any keyframe would typically begin video playback from that point.

However, relying on simply presenting keyframes in screen can still require browsing through a very large information entity for long videos, maybe having over a hundred keyframes (shots) per hour. Therefore the ability to search within video content to locate a desired section of the video is desirable.

Searching Archives of Digital Video

The goals of supporting search through digital video archives are to (i) understand video content and (ii) understand how relevant content is likely to be to a user's query and to (iii) present the most highest ranked content for user consideration. We try to achieve these goals by indexing video content utilizing a number of sources (textual, audio and visual), either alone or in any combination. The unit of retrieval can be shots, scenes, stories, entire video units or any other unit of retrieval required.

Content-Based Retrieval using Text Sources The most common searching technology used for video retrieval in the WWW is content searching using proven text search techniques. This implies that it is possible to generate textual content (often referred to as a text surrogate) for the video. There are a number of sources of text content that can be employed to generate these textual surrogates, for example sources based on analyzing the digital video or the broadcast video stream:

- *Spoken words*, generated by utilizing a speech-to-text tool. The spoken words will provide an indication of the content of the video.
- *Written words*, extracted using a process of OCR (OCR – Optical Character Recognition) from the actual visual content of the video frames.
- *Professional closed caption annotation,* which are the closed caption (teletext) transcripts of video that accompanies much broadcast video content.

In addition there are many sources of textual evidence that can be employed that do not directly rely on the content of the digital video stream, and typically, these would be available for publicly available WWW digital video content:

- *Professionally annotated metadata* from the content provider which, if available, provides a valuable source of content for the textual surrogate.
- *Community annotated metadata* from general users of the content. On WWW video sharing sites users are encouraged to annotate comments about the video content and these annotations can be a valuable source of indexable content.

All of these sources of textual data can be employed alone, or in any combination to generate textual surrogates for video content (shots, scenes, stories or entire videos). Users can query such systems with conventional text queries and this is the way that most WWW video search engines operate. Text search through video archives is a very effective way to support search and retrieval and relies on well-known and proven text search techniques.

Content-Based Retrieval using Visual Sources

Digital Video, being a visual medium, can also be analyzed using visual analysis tools, which typically operate over individual keyframes to visually index each clip (typically a shot or scene). The visual content analysis tools are often borrowed from the domain of visual image analysis. The first generation of video analysis systems relied on modeling video with easily extractable low-level visual features such as color, texture and edge detection. However a significant 'semantic gap' exists between these low-level visual features and the semantic meaning of the video content, which is how a typical user would like to query a video search system. To help bridge this semantic gap, video content in the current generation of video search systems is processed to seek more complex semantic (higher-level or derived) visual concepts, such as people (faces, newsreaders), location (indoor/outdoor, cityscape/landscape), objects (buildings, cars, airplanes), events (explosions, violence) and production techniques such as camera motion. The output of these higher-level concept detectors can, with sufficient development and training, be successfully integrated (mainly as filters) into content-based video retrieval systems. However, the development of these concept detectors can be a difficult process and it is not reasonable to assume the development of tens of thousands of concept detectors to cover all concepts for the video archive. Research carried out by the Informedia team at CMU suggest that "concept-based" video retrieval with fewer than 5,000 concepts, detected with minimal accuracy of 10% mean average precision is likely to provide high accuracy results, comparable to text retrieval on the web, for a typical broadcast news video archive. Extending into other domains besides broadcast news may require some additional concepts. A review of image analysis techniques will provide more details of these semantic visual concept detectors and how they can be developed.

The output of easily extracted low-level feature analysis can be also employed in a content-based video retrieval system to support linking between visually similar content, though it is unlikely to be used to support direct user querying. Semantic features can form part of a user query, whereby a user, knowing the semantic factures extracted from a video archive, can specify semantic features that are required/not required in the result of a video search. For example, a user may request video content concerning forest fires, that also contains the feature 'fire'.

Content-Based Retrieval using Audio Sources

Apart from the speech-to-text there are other uses of audio sources for content-based video retrieval. For example, security video to identify non-standard audio events, such as a window breaking to provide a special access point to security video at this point. Key events in sports video can be identified using visual analysis (e.g., goal-mouth detection, or onscreen scoreboard changing) but also using audio analysis, for example crowd noise level or commentator excitement level.

Effective Retrieval

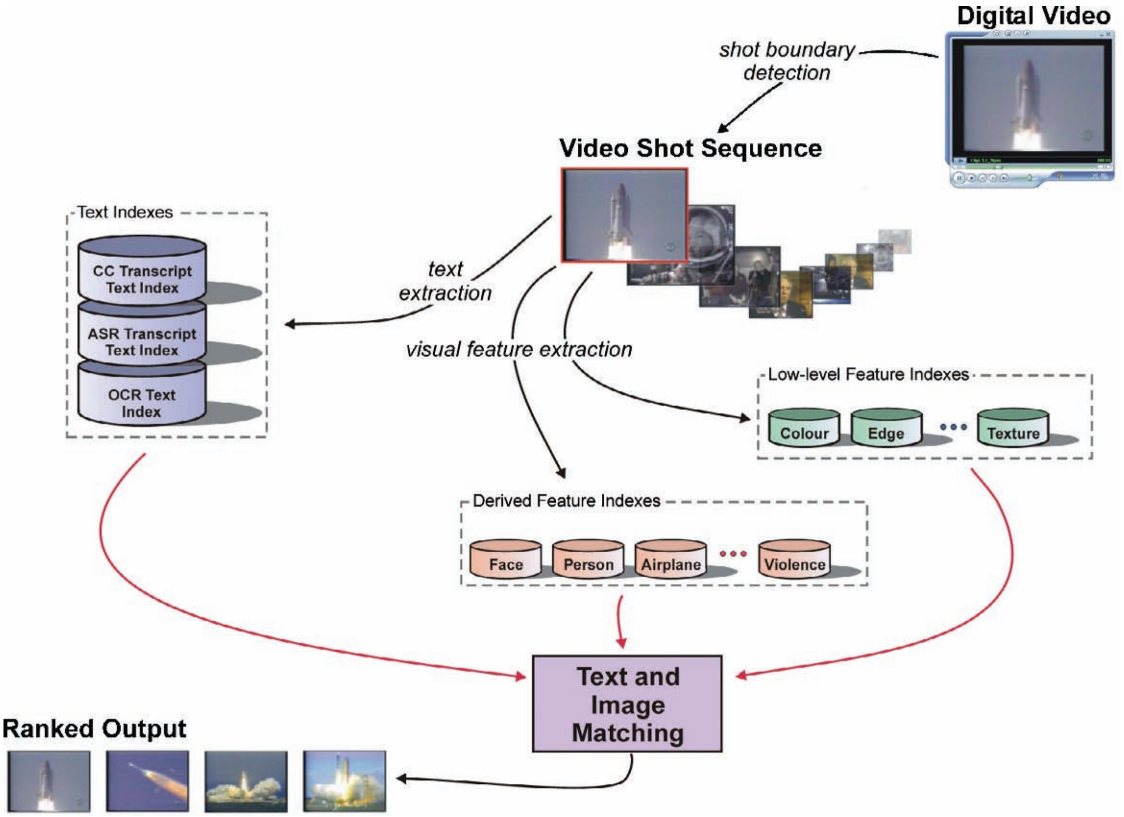
As can be seen from the current generation of WWW video search engines, most content-based video retrieval relies on user text queries to operate over text surrogates of video content. In typical situations the use of visual sources does not achieve any noticeable improvement in performance over using textual sources (such as CC text or ASR text). However, combining both sources of evidence can lead to higher performance than using either source alone. Figure 2 summarizes a typical shot-level content-based indexing process for digital video and illustrates some of the indexing options available.

Often successful academic video search systems allow the user to search to find the location in a piece of video which is likely to be of interest, with the user being encouraged to browse this area of the video by presenting keyframes from shots in the general video area (before and after).

Key Applications

The key application areas can be broadly divided into two categories; domain dependent video retrieval and generic (non-domain) video retrieval. In *domain dependent video retrieval*, the domain of the search system is limited, thereby allowing the search tool to exploit any domain dependent knowledge to develop a tailored and more effective content-based video retrieval system. Typical domains include news video where the unit of retrieval would a news story. Domain dependent additions for news video retrieval include anchor person detection to aid in the identification of news story bounds, inter-story linkage, story trails and timeline story progression. An example of a typical news story retrieval system is the Físchlár-News Digital Video Library that was operational from 2001 to 2004 at Dublin City University, and shown in Fig. 3.

Another example domain dependent application area is sports video, where research has been progressing on generating automatic summaries of field sports events and a third example is security video where research is ongoing into the automatic analysis of security footage to identify events of interest or even to identify and track individuals and objects in the video streams from many cameras in a given location.



Content-Based Video Retrieval. Figure 2. The content-based indexing process for digital video (from Físchlár system at TRECVid in 2004) showing some text extraction, some low-level features and some higher level (derived) features (concepts).

Domain independent video retrieval attempts to index all types of content, such as general TV programmes or generic UCC. Given that there are no domain specific clues to exploit, retrieval is usually on textual indexing of a textual surrogate or extracted visual concepts, such as objects [5], locations, people, etc. The unit of retrieval would typically be a shot or an entire video clip, but could also be a non-shot unit that matches the user request. Domain independent video retrieval is most commonly seen in WWW video search engines, which index content based on text surrogates and returns entire videos in the result set.

Future Directions Future applications of, and research into content-based video search will likely focus on developing techniques for providing access to large archives of digital video content as broadcasters continue the process of digitizing their huge archives of programmes and the raw video content (rushes) that is used in the making of TV programmes. For rushes content especially, one will not be able to rely on text transcripts for indexing purposes. In addition, the ever increasing volume of UCC requires content-based retrieval techniques to be developed that will provide an improved semantic search facility over this content. Finally, the third point of research into the future will likely be in migrating content-based retrieval tools onto consumer devices (PVRs for example), which themselves are becoming capable of storing hundreds of hours of recorded video and UCC.

Experimental Results In the field of content-based video retrieval there exists an annual, worldwide forum for the evaluation of techniques for video search, called TRECVid [7] which began in 2001. The TRECVid workshop is (2007) part of the TREC [8] conference series is sponsored by the National Institute of Standards and Technology (NIST). In 2007, 54 teams from Europe, the Americas, Asia, and Australia participated in TRECVid. Over the course of the TRECVid evaluations, data employed has been either TV news, documentaries, educational video and rushes
