The problem of the measurement of system functions of time-variant channels differs from that of the time-invariant case. Even in the absence of noise the system function of a time-variant channel may be unmeasurable. The condition on the measurability of a linear time-varying WSSUS channel was first presented by Kailath and later extended by Bello [10]. It turns out that the channel measurability depends on the value of the area spread factor, which in effect is the area of region where the scattering function is effectively nonzero. If the area spread factor is less than or equal to a threshold, the channel impulse response could be measured unambiguously [10]. The value of the threshold is of the order of unity. The channels for which the area spread factor fulfills the criterion mentioned above are called *underspread*; otherwise they are called *overspread*. If the channel is overspread, it is not possible to measure the instantaneous values of the impulse response, even in the absence of the noise. Fortunately, most physical channels are underspread. The average parameters can be determined either from the instantaneous values of the channel impulse response or by cross-correlation methods. Since the statistical averages contain much less information than the instantaneous values, the channel need not always be underspread before the average parameters could be measured.

Various channel measurement techniques have been proposed [11]. However, two practical methods of measuring the impulse response of the underspread cellular channel can be identified. One method is to transmit a very short impulselike pulse to the channel and observe the multiple pulses received. In order to follow the time variation of the channel, the pulses need to be transmitted periodically. The short pulses result in a high ratio of peak to average transmission power, which could be undesirable. Another, more efficient, method to measure the impulse

response is the use of direct sequence spread-spectrum signals [6]. A pseudonoise (PN) sequence is used to modulate the carrier. Maximal-length sequences (m sequences) are widely used because of their excellent periodic autocorrelation properties. The receiver is based on a correlation principle. It can be implemented by a matched filter or a sliding correlator [5]. Nowadays, high-speed digital signal processing techniques can be employed to implement real-time matched filter channel sounders. In a WSSUS channel, time averaging can be used to obtain the autocorrelation function of the measured impulse response. An estimate of the scattering function can then be calculated by the Fourier transform [12,13]. Angle-of-arrival measurements can be conducted by using directional or array antennas at the receiver [4]. To some extent, angle of arrival can be deduced from the measured scattering function [12].

One of the earliest measurement results of the impulse response of the cellular channel in urban and suburban areas by using short pulses was reported by Turin in 1972 [3]. The delay, amplitude, and phase of multipath components were measured at three different frequencies simultaneously. It was found that spatial correlation distances of these variables at neighboring geographic points vary considerably. They ranged from less than a wavelength for the phases, through tens of wavelengths for the amplitudes and delays, to hundreds of wavelengths for the means and variances, or powers, of the amplitudes.

More recent measurement studies have used almost exclusively the direct-sequence spread-spectrum signals with m sequences to measure the channel. Wideband macrocell measurements conducted at 1 GHz show that in typical urban areas the delay spread from 1 to 2 μs is characteristic. In suburban areas delay spreads from 10 to 20 μs are typical. The longest delay spreads occur in mountainous environments, where delay spreads from 100 to 150 μs have been encountered. In open areas the delay spread is practically nonexistent and the received signal consists of the directly propagated component only [12]. Wideband measurements in urban microcell environments at 2 GHz have been reported [13]. The delay power spectrum, average normalized correlation functions, and scattering functions have been calculated from the measured impulse response. Under LOS conditions, the direct component with unresolvable specular reflections dominated the propagation. Some resolvable specular reflections existed at delays of up to 1.5 μs. In non-LOS situations, the powers of the strongest received signals were more than 15 dB below the LOS components that resulted in nearby locations. The propagation process was found to be dominated by multiple reflections and scattering along the streets, and not by diffraction (13).

Relatively few results on spatial channel measurements have been published. Ertel et al. have summarized some of the results [4]. Measurements conducted at 2 GHz with a 10-MHz bandwidth, by using a rotating azimuth beam directional antenna at the receiver, have shown that delay and angle-of-arrival spreads are small in rural, suburban, and even many urban environments. Measurements in urban areas have shown that most of the major features of the delay angle of arrival spectra can be accounted for by considering the large buildings in the environment. Finally, variations in the spatial characteristics with both time and frequency have been measured. The results indicate that the uplink spatial characteristics cannot be directly applied for downlink beamforming in most of the present cellular and personal communication systems that have 45-MHz and 80-MHz separations between the uplink and downlink frequencies, respectively [4].

4. SIMULATION MODELS

The evolution of channel simulation models has been parallel to that of cellular systems. The early models considered only the signal amplitude-level distributions and Doppler spreads of the received signals. A delay spread information was later added to the channel models. In addition to those, modern channel models also include such concepts as angle-of-arrival and adaptive array antenna geometries. The signal parameters that need to be simulated in these models for each multipath component are the amplitude, carrier phase shift, time delay, angle of arrival, and Doppler shift. All of these parameters are in general time-varying, causing Doppler spread in addition to delay spread [4].

The channel simulators can be categorized into three classes according to the way the channel impulse response is modeled: stored channel impulse response, ray tracing models, and stochastic parametric models for the channel impulse response. The stored channel impulse responses are based on selected measurements, which are then stored for later use. Although this method provides actual information from the channel, the proper selection criterion for the measurements may be difficult to identify. Also, the large amount of data needed to store the measurement results could be difficult to handle. However, some models have been proposed [4,14]. The ray tracing models are deterministic. They are based on geometric propagation theory and reflection, diffraction, and scattering models. Accurate channel models are possible using this method. However, the high computational burden and lack of detailed terrain and building databases make these models difficult to use [4]. By far the most popular channel simulation models are stochastic parametric models. In this approach, the channel impulse response is characterized by a set of deterministic and random parameters. The values of the parameters and the probability distributions governing their behavior are selected according to measurements. The remaining challenge is to develop models, that exhaustively reproduce the propagation scenarios accounted in reality [14]. A recommended summary of stochastic channel models can be found in Ref. 14. Spatial, or 2D, stochastic channel models are summarized in Ref. 4.

Usually, discrete-time channel impulse responses in the form of transversal filters are used in the stochastic channel simulators. The transversal filter model allows the simulators to be implemented either by software or hardware. The time-varying complex coefficients and delays of the transversal filter are generated according to the statistics associated with the different parameters. The amplitudes are usually assumed to be Rayleigh or Rice distributed as a result of multipath fading. A uniform and

Poisson distribution is usually assumed for the phases and delays, respectively. However, in a Rice fading channel the phase is concentrated around the phase of the strong component unless there is a Doppler shift in it. As mentioned earlier, the delay power spectrum is typically approximated by an exponential function. There are several methods to simulate the angles of arrival. For example, in Ref. 15 they are modeled as normally distributed random variables. Other methods have been summarized in Ref. 4. Rayleigh and Rice processes needed to simulate the amplitudes can be generated by using colored Gaussian noise processes. A well-known method to produce colored Gaussian noise processes is to filter WGN with a filter having a transfer function of the square root of the Doppler power spectrum. Typically, the Doppler power spectrum by Clarke is used. Another method is based on Rice's sum of sinusoids. In this case, a colored Gaussian noise process is approximated by a finite sum of weighted and properly designed sinusoids [16]. The long-term variations in the channel impulse response can be modeled by making the delays drift with time and by using an attenuation filter to model the lognormal fading caused by shadowing or transitions between different environments [14]. An exponential function is used to approximate the autocorrelation of the shadowing as a function of distance. A correlation distance of 20 m is typically used for urban environments. For suburban environments, much larger correlation distances should be used. In a hardware implementation, digitally controllable attenuators can be used to simulate the attenuation caused by the shadowing [15].

Different standardization organizations are actively defining channel models as a part of specification of new mobile cellular systems. Their motivation is to specify the operational environment of the system and to provide test parameters for manufacturers. The channel models for second-generation digital advanced mobile phone system (DAMPS) and global system for mobile communications (GSM) mobile cellular systems were specified by the Telecommunications Industry Association (TIA) in the United States and the European Telecommunications Standards Institute (ETSI) in Europe. For the third-generation cellular systems a global standard has been defined as the International Mobile Telecommunications (IMT-2000) proposal by the International Telecommunication Union (ITU). For a more thorough discussion, see Ref. 6. The standardization work of third-generation systems has now shifted to the international 3rd Generation Partnership Project (3GPP).

The channel models have also been developed by different research consortia in international research programs. In Europe, particularly Cooperation in the Field of Scientific and Technical Research (COST) projects have been extremely influential when GSM and digital communication system at 1800 MHz (DCS 1800) systems were developed. The achievements in COST partly stimulated the Universal Mobile Telecommunications System (UMTS) Code-Division Testbed (CODIT) project within the Research and Development in Advanced Communication Technologies in Europe (RACE-II) program. The CODIT 2D channel models seem to be state-of-the-art. A summary of European research programs can be found in Ref. 14.

5. MORE RECENT TRENDS

Channel modeling for cellular communications is a rapidly changing area, and the models are becoming increasingly accurate. Some of the more recent trends are summarized here. Higher frequencies of up to ~60 GHz will be used in the future. The cell size is made smaller since the channel attenuation is larger at higher frequencies. Frequencies above ~10 GHz are also affected more by air molecules and rain. Consequently, the highest frequencies can be used only in indoor environments. Also, with the increasing data rates, the bandwidths are becoming larger, approaching 10–100 MHz. 3D models are important in macrocells, for example, in urban and mountainous areas where the base station antenna is much higher than the mobile station antenna. The 3D models take into account the elevation angle of the arriving waves, in addition to the azimuthal angle and the delay. Various nonstationary models are often used. In addition to the lognormal distribution, shadowing effects are modeled with birth–death processes, where some delays suddenly appear and disappear, simulating rapid changes as in street corners and tunnels. In some models the delays are time-variant to test the delay tracking ability of the receiver. Furthermore, the models are becoming more comprehensive in the sense that they will have multiple inputs and outputs. In this way the models can be used to simulate diversity systems with many users. Even handoffs between base stations should be simulated. Correlation and crosstalk between the multiple channels are important effects in such systems. An example of crosstalk is the cochannel and adjacent-channel interference between the various users of the same frequency band in the same geographic region.

BIOGRAPHIES

Aarne Mämmelä was born in Vihanti, Finland, in 1957. He received the degrees of M.Sc. (Eng), Lic.Tech., and Ph.D. (all with distinction) from the Department of Electrical Engineering, University of Oulu, Finland, in 1983, 1988, and 1996, respectively. His doctoral thesis was on diversity receivers in fast fading multipath channels. From 1982 to 1993 he was with the Telecommunication Laboratory at the University of Oulu and researched adaptive algorithms in spread-spectrum systems. In 1990–1991 he visited the University of Kaiserslautern, Germany. In 1993 he joined VTT, Computer Technology Laboratory, which was merged to VTT Electronics in 1994. In 1996–1997 he was on leave as a postdoctoral fellow at the University of Canterbury, Christchurch, New Zealand. Since 1996 he has been a research professor of digital signal processing at VTT Electronics. His research area is the design of digital transmitter-receivers in wireless communications. In addition, since 2000 he has been a docent or adjunct professor of receiver signal processing at the Helsinki University of Technology, Espoo, Finland. He

is especially interested in synchronization and estimation problems in wireless digital communications, both in single- and multi-carrier systems.

Pertti Järvensivu was born in Laukaa, Finland, in 1966. He received a M.Sc. degree in electrical engineering from the University of Oulu, Finland, in 1992. From June 1988 to December 1999 he was in various teaching and research positions at the University of Oulu. Since January 2000 he has been with VTT Electronics as research scientist in digital signal processing. His current research interests are channel estimation and wireless adaptive radio systems.

CHANNEL MODELING AND ESTIMATION

1. INTRODUCTION

One of the objectives of receiver design for digital communications is to minimize the probability of detection error. In general, the design of the optimal detector requires certain prior knowledge of the channel characteristics, which are usually estimated through the use of pilot symbols. A typical example is the voiceband modem where, on establishing the initial connection, a signal known to the receiver is transmitted through the telephone channel. The receiver is then tuned to compensate for the distortions caused by the channel. The process of using pilot symbols to estimate the channel, or directly, the receiver coefficients is referred to as *training*.

If there is a sufficient amount of training time, and the channel does not vary significantly, the problem of channel estimation can be formulated either as the classical point estimation or as the Bayesian estimation. Techniques such as maximum-likelihood estimation and methods of least squares are readily applicable, and they generally offer good performance. For these applications, the choice of algorithm is often determined by the complexity of implementation.

The explosive growth in wireless communications and the increasing emphasis on packet-switched transmissions present a new set of challenges in channel estimation and receiver design. Although critical to reliable communications, channel acquisition and tracking are difficult because of the rapid variations caused by multipath fading and the mobility of users. The use of training is no longer straightforward, as the receiver must be trained repeatedly for time-varying channels. Since the time used for training is the time lost for transmitting information, there is a tradeoff between the quality of channel estimation and the efficiency of channel utilization.

This article presents an overview of the modeling and estimation of channels for digital transmission of single carrier linearly modulated signals. In Section 2, we present the complex baseband representation of intersymbol interference channels. A discrete-time linear model is obtained that relates the received data samples with the channel coefficients and the transmitted pilot and data symbols. Within the framework of parametric estimation, we present techniques and performance analysis of various channel estimation problems in Sections 3 and 4. A brief bibliography note is provided at the end of this article.

2. THE BASEBAND MODEL OF BAND-LIMITED CHANNELS

In this section, we consider the baseband model, in both continuous and discrete time, for linearly modulated signals transmitted over band-limited passband channels.

2.1. The Continuous-Time Model

Figure 1 illustrates the passband transmission of linearly modulated baseband signals. To transmit a sequence of

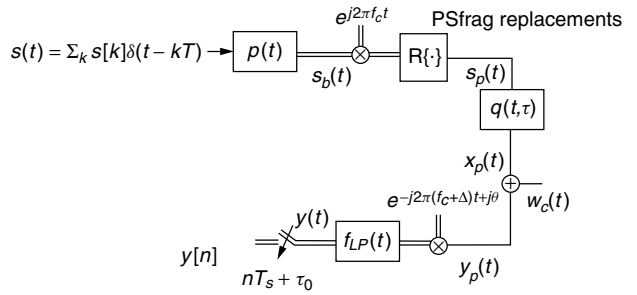

Figure 1. The transmission of linearly modulated baseband signal through a band-limited passband channel. Double lines are paths for complex signals and single lines for real signals. The operator $\Re\{\cdot\}$ takes the real part of its argument. The filter $f_{LP}(t)$ is the impulse response of an ideal lowpass filter.

information-carrying symbols $\{s[k]\}$, the baseband signal $s_b(t)$ is formed as

$$s_b(t) = \sum_k s[k]p(t - kT) \tag{1}$$

where $p(t)$ is the baseband pulse, T the symbol interval, and $1/T$ the symbol rate. For passband transmissions, where the transmitted signals do not contain any DC component, the symbol sequence $\{s[k]\}$ may be complex in general. If the transmission is at the baseband, then $s[k]$ is real. In this article, we will assume that $\{s[k]\}$ is a complex sequence and the results are also valid when $\{s[k]\}$ is a real.

If $s_b(t)$ is transmitted over a band-limited channel, the Nyquist criterion for choosing $p(t)$ needs to be satisfied. In particular, $p(t)$ should be such that

$$\frac{1}{T}\sum_{i=-\infty}^{\infty}\left|P\left(f + \frac{i}{T}\right)\right|^2 = 1 \tag{2}$$

where $P(f)$ is the Fourier transform of $p(t)$. A usual choice is from the class of square-root raised-cosine pulses. The minimum bandwidth pulse is the ideal lowpass filter with bandwidth $1/2T$. In practical implementations, the actual bandwidth is between $1/2T$ and $1/T$ for narrowband transmissions and much greater than $1/T$ for spread spectrum transmissions.

To transmit $s_b(t)$ through a particular frequency band, the baseband signal is converted to the passband signal $s_p(t)$ by (quadrature) amplitude modulation. Hence, the transmitted signal is represented as

$$\begin{aligned} s_p(t) = \Re\{s_b(t)e^{j2\pi f_c t}\} &= \Re\{s_b(t)\}\cos(2\pi f_c t) \\ &\quad - \Im\{s_b(t)\}\sin(2\pi f_c t), \end{aligned} \tag{3}$$

where the operator $\Re\{\cdot\}$ takes the real part of its argument and $\Im\{\cdot\}$ the complex part of its argument. The (real) passband signal is transmitted through a linear, possibly time-varying, propagation channel $q(t, \tau)$ whose output $x_p(t)$ is given by

$$\begin{aligned} x_p(t) &= \int q(t,\tau)s_p(t-\tau)\,d\tau \\ &= \Re\left\{e^{j2\pi f_c t}\int q(t,\tau)e^{-j2\pi f_c \tau}s_b(t-\tau)\,d\tau\right\} \\ &= \Re\left\{e^{j2\pi f_c t}\int q_b(t,\tau)s_b(t-\tau)\,d\tau\right\} \end{aligned} \tag{4}$$

where we note that the passband propagation channel $q(t, \tau)$ is always real and denote the baseband propagation channel as

$$q_b(t,\tau) \triangleq q(t,\tau)e^{-j2\pi f_c \tau} \tag{5}$$

The received *passband* signal $y_p(t)$ is corrupted by noise $w_c(t)$ assumed to be zero mean, white, and Gaussian. The passband signal is then converted back to the baseband signal by frequency downshifting and lowpass filtering:

$$\begin{aligned} y(t) &= f_{LP}(t) * [y_p(t)e^{-j2\pi(f_c+\Delta)t+j\theta}] \\ &= e^{j(2\pi\Delta t+\theta)}\int q_b(t,\tau)s_b(t-\tau)d_\tau + w(t) \end{aligned} \tag{6}$$

where Δ is the frequency offset and θ the phase offset, and $w(t)$ is zero mean complex Gaussian with constant power spectrum density within the spectral range of the signal. Substituting (1) into Eq. (6), we obtain

$$y(t) = e^{j2\pi\Delta t}\sum_k h_k(t)s[k] + w(t) \tag{7}$$

where

$$h_k(t) = e^{j\theta}\int q_b(t,\tau)p(t - kT - \tau)d\tau \tag{8}$$

Note that the transmitted signal is distorted by two major factors: the propagation channel $q_b(t, \tau)$ and carrier-phase synchronization errors Δ and θ. Typically, carrier synchronization is performed separately from channel estimation. Assuming that the frequency offset Δ has been corrected before channel estimation, we can let $\Delta = 0$ and combine the phase error θ with baseband channel $h_k(t)$.

The problem of channel estimation can then be formulated as estimating $h_k(t)$, which combines the propagation channel $q(t, \tau)$, the signal waveform $p(t)$, and the phase error θ. Notice that $p(t)$ is known in general, and that it can be exploited to improve channel estimation.

If the channel can be modeled as time-invariant within the interval that channel estimation is performed, we then have $q_b(t, \tau) = q_b(\tau)$, and

$$y(t) = \sum_k s[k]h(t - kT) \tag{9}$$

where

$$h(t) = e^{j\theta}\int q_b(\tau)p(t-\tau)d_\tau \tag{10}$$

is called the *composite baseband channel*, which is, in general, complex.

2.2. The Discrete-Time Model

For band-limited transmissions, the baseband signal $y(t)$ can be sampled without loss of information if the sampling rate $f_s = 1/T_s$ exceeds the Nyquist rate. This implies that the sampling rate should be at least the symbol rate. If the transmitted pulse $p(t)$ has the bandwidth that exceeds the minimum bandwidth of $1/2T$, the sampling rate should be higher than the symbol rate. We will assume that the received signal is "over" sampled at a rate G times the symbol rate, namely, $T = GT_s$. For narrowband

transmissions, $G = 2$ satisfies the Nyquist rate, whereas, for spread-spectrum communications, G should be greater than or equal to the spreading gain of the system.

Denote the sampled discrete-time baseband signals as

$$y[n] \triangleq y(nT_s + \tau_0), \quad w[n] \triangleq w(nT_s + \tau_0) \tag{11}$$

where τ_0 is the sampling phase. For time-invariant channels with synchronized carrier as defined in (9), the received data samples satisfy

$$y[n] = \sum_k h(nT_s - kGT_s + \tau_0)s[k] + w[n] \tag{12}$$

$$= \sum_k h[n - kG]s[k] + w[n], \quad h[n] \triangleq h(nT_s + \tau_0) \tag{13}$$

Note that, when the input sequence $s[n]$ is stationary, $y[n]$ is not stationary unless $G = 1$. In general, the oversampled signal $y[n]$ is cyclostationary.

2.2.1. The SIMO Model. A convenient model for the oversampled discrete-time channel is the vectorized single-input multioutput (SIMO) model shown in Fig. 2. This model is obtained by noting that, if the received signal is sampled G times faster than the symbol rate $1/T$, there are G samples per symbol period, and $y[n]$ can be split into G subsequences. Specifically, for $i = 1, \ldots, G$, denote

$$y_i[n] \triangleq y[nG + i - 1], \mathbf{y}[n] = [y_1[n], \ldots, y_G[n]]^T \tag{14}$$

$$w_i[n] \triangleq w[nG + i - 1], \mathbf{w}[n] = [w_1[n], \ldots, w_G[n]]^T \tag{15}$$

$$h_i[n] \triangleq h[nG + i - 1], \mathbf{h}[n] = [h_1[n], \ldots, h_G[n]]^T \tag{16}$$

We then have the SIMO model given by

$$\mathbf{y}[n] = \sum_{k=0}^{L} \mathbf{h}[k]s[n - k] + \mathbf{w}[n], \tag{17}$$

where L, referred to as the channel order, is such that $k > L$ and $k < 0$. We assume that L is finite.[1]

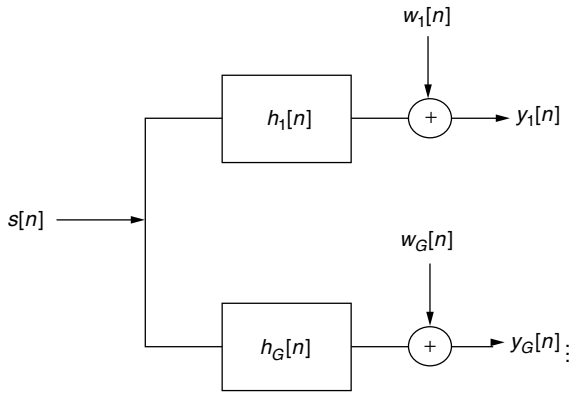

Figure 2. The SIMO vector channel model.

[1] For strictly band-limited signals, $L = \infty$. On the other hand, for strictly time-limited signals, L is always finite but, unfortunately, the Nyquist sampling frequency is ∞. In practice, L can be chosen large enough so that the model is sufficiently accurate.

If we collect all the transmitted symbols in a vector $\mathbf{s}$, all the received data samples in $\mathbf{y}$, and all channel parameters in $\mathbf{h}$

$$\mathbf{y} \triangleq \begin{pmatrix} \mathbf{y}[N-1] \\ \vdots \\ \mathbf{y}[0] \end{pmatrix}, \mathbf{h} \triangleq \begin{pmatrix} \mathbf{h}[0] \\ \vdots \\ \mathbf{h}[L] \end{pmatrix}, \mathbf{s} \triangleq \begin{pmatrix} s[N-1] \\ \vdots \\ s[-L] \end{pmatrix}$$

with noise vector $\mathbf{w}$ similarly defined, we have the following model equations:

$$\mathbf{y} = \mathcal{H}(\mathbf{h})\mathbf{s} + \mathbf{w} = \mathcal{F}(\mathbf{s})\mathbf{h} + \mathbf{w} \tag{18}$$

where $\mathcal{H}(\mathbf{h})$ is a block Toeplitz matrix generated from the channel $\mathbf{h}$ and $\mathcal{F}(\mathbf{s})$ a block Hankel matrix generated from the input $\mathbf{s}$ with dimensions matched to those of $\mathbf{y}$ and $\mathbf{s}$

$$\mathcal{H}(\mathbf{h}) = \begin{pmatrix} \mathbf{h}[0] & \cdots & \mathbf{h}[L] & & \\ & \ddots & & \ddots & \\ & & \mathbf{h}[0] & \cdots & \mathbf{h}[L] \end{pmatrix} \tag{19}$$

$$\mathcal{F}(\mathbf{s}) = \begin{pmatrix} s[N-1]\mathbf{I}_G & \cdots & s[N-L-1]\mathbf{I}_G \\ \vdots & \text{Block Hankel} & \vdots \\ s[0]\mathbf{I}_G & \cdots & s[-L]\mathbf{I}_G \end{pmatrix} \tag{20}$$

$$= \begin{pmatrix} s[N-1] & \cdots & s[N-L-1] \\ \vdots & \text{Hankel} & \vdots \\ s[0] & \cdots & s[-L] \end{pmatrix} \otimes \mathbf{I}_G, \tag{21}$$

where the operator $\otimes$ is the Kronecker product and $\mathbf{I}_G$ is the $G \times G$ identity matrix.

2.2.2. The MIMO Model. The SIMO model can be easily extended to incorporate systems that involve multiple users and multiple transmitting and receiving antennas. A general schematic is shown in Fig. 3, where there are K users, each transmitting a sequence of symbols $s_i[n]$ using a particular waveform. The signals $\{y_i(t)\}$ received by M receivers are distorted by noise, their corresponding propagation channels, and cross-interference. Let $\mathbf{y}_j[k]$ and $\mathbf{w}_j[n]$ be the received signal vector and the additive noise at the jth antenna, respectively, and $\mathbf{h}_{ji}[k]$ be the channel

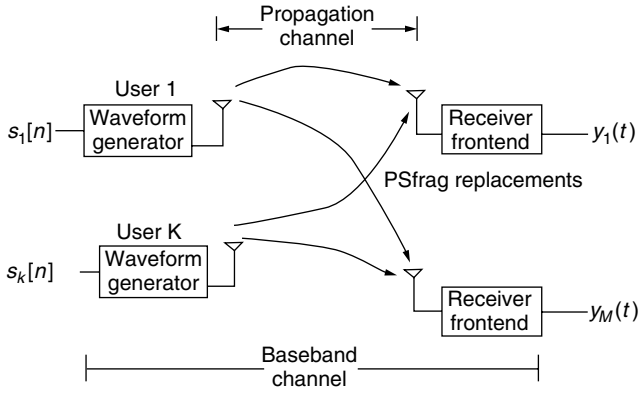

Figure 3. A general multiuser communication system.

between the ith user and the jth antenna. We then have the multiinput multioutput (MIMO) channel model

$$\mathbf{y}_j[n] = \sum_{i=1}^{K} \sum_{k} s_i[k]\mathbf{h}_{ij}[n-k] + \mathbf{w}_j[n], \quad j = 1, \ldots, M$$

Stacking data from all antennas as

$$\mathbf{y}[k] \triangleq \begin{pmatrix} \mathbf{y}_1[k] \\ \vdots \\ \mathbf{y}_M[k] \end{pmatrix}, \mathbf{h}_j[k] \triangleq \begin{pmatrix} \mathbf{h}_{1j}[k] \\ \vdots \\ \mathbf{h}_{Mj}[k] \end{pmatrix}, \quad j = 1, \ldots, M$$

one obtains the MIMO model

$$\mathbf{y}[k] = \sum_{i=1}^{M} \sum_{k} s_i[k]\mathbf{h}_i[n-k] + \mathbf{w}[n]$$

where $\mathbf{w}[n]$ is the noise vector similarly defined, and $\mathbf{h}_j[k]$ is the (vector) channel impulse response from the jth user to all receiving antennas. Again collecting all received data in a single vector $\mathbf{y}$ and transmitted symbols in $\mathbf{s} = [\mathbf{s}_1^T, \ldots, \mathbf{s}_K^T]^T$, we obtain the (batch) MIMO equation

$$\mathbf{y} = [\mathcal{H}(\mathbf{h}_1), \ldots, \mathcal{H}(\mathbf{h}_K)]\mathbf{s} + \mathbf{w} = [\mathcal{F}(\mathbf{s}_1), \ldots, \mathcal{F}(\mathbf{s}_K)]\mathbf{h} + \mathbf{w} \tag{22}$$

While we shall restrict our discussion to the single-user case multiple-antenna systems, many results apply directly to the estimation of MIMO channels described in Eq. (22).

3. CHANNEL ESTIMATION: GENERAL CONCEPTS

The objective of channel estimation is to infer channel parameters from the received signal. The function that maps the received signal and prior knowledge about the channel and pilot symbols is called the *estimator*. In this section, we discuss the formulation of the estimation problem. The development of specific estimators will be considered in Section 4.

3.1. Channel Estimation Techniques

3.1.1. Transmissions with Embedded Pilot Symbols. The development of channel estimation algorithms depends on the format of the transmitted symbols. Traditionally, the transmission is divided into two phases: the training phase and the transmission phase. In the training phase, pilot symbols known to the receiver are transmitted so that channel parameters can be estimated. The estimated channel is then used in the design of the receiver. When a feedback channel is available, the estimated channel can also be utilized to design an optimal transmitter.

For packet transmissions, especially in a wireless environment, it may be necessary that the channel be estimated separately for each packet. For example, the base station in a cellular system receives packets from different users, each with a different propagation channel. Therefore, pilot symbols need to be inserted into every data packet. The presence (or the absence) of pilot symbols, the number of pilot symbols, and the placement of pilot symbols all affect the parametric model from which channel estimators are derived. Figure 4 shows a typical packet format for the transmitted symbol $s[n]$ and its corresponding received signal $\mathbf{y}[n]$. The shaded area in the transmitted data frame is where pilot symbols are located. In general, there may be multiple pilot clusters $\{\mathbf{s}_{pi}\}$ whose location and values are known to the receiver.

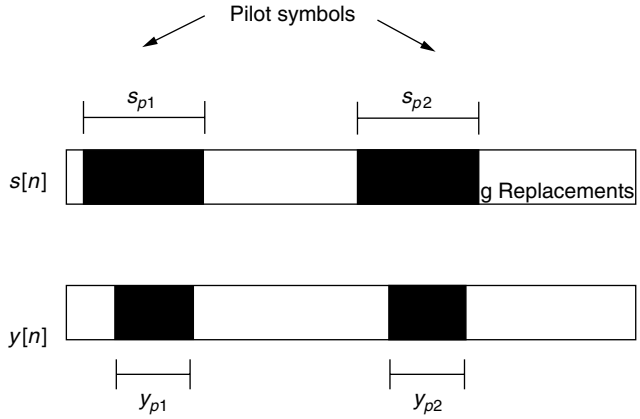

Figure 4. Signal frame structure. The shaded areas in the transmitted data frame are where pilot symbols are located. The shaded areas in the received signal frame are where samples corresponding to only pilot symbols are located.

3.1.2. Training-Based, Semiblind, and Blind Estimators. If the channel is memoryless, that is, if $L = 0$ in (17), then any received sample, say, $y[k]$, is a function of either a data symbol or a pilot symbol. However, if the channel has memory, $L > 0$, a received sample $\mathbf{y}[k]$ may be a function of (1) the (unknown) data symbols only, (2) the pilot symbols only, or (3) both data and pilot symbols. As illustrated by the shaded parts in Fig. 4, let $\mathbf{y}_{pi}$ be the cluster of received samples corresponding only to pilot cluster $\mathbf{s}_{pi}$. In other words, every sample in $\mathbf{y}_{pi}$ is a function of the pilot symbols in $\mathbf{s}_{pi}$ only. With this in mind, we consider three types of channel estimators, depending on the information that is used by the estimator.

- *Training-Based Channel Estimators*. A training-based channel estimator only uses data that correspond to the pilot symbols. In the case illustrated in Fig. 4, the estimator takes $\{\mathbf{y}_{p1}, \mathbf{s}_{p1}\}$ and $\{\mathbf{y}_{p2}, \mathbf{s}_{p2}\}$ as its input and produces an estimate of the channel. If $\mathbf{h}$ is the vector containing all channel parameters, $\mathbf{s}_p$ the vector containing all pilot clusters, and $\mathbf{y}_p$ the vector containing all received data corresponding to $\mathbf{s}_p$, a training-based channel estimator can be written as

$$\hat{\mathbf{h}} = G_T(\mathbf{s}_p, \mathbf{y}_p). \tag{23}$$

  Notice that although other received data also contain information about the channel, they are not utilized by the estimator. Training-based channel estimators are commonly used in practice. These estimators are easy to derive and analyze because the unknown data are not part of the observation. On the other hand, there needs to be a sufficient number of pilot

symbols present for good performance, and there are restrictions on how they should be placed in the data packet. For example, the size of pilot clusters must be at least $L+1$ in order to have one received data sample that is related to pilot symbols only.

- *Blind Channel Estimator*. When there are no pilot symbols available, the channel estimator is called "blind." In this case, the channel estimator uses the received signal $\mathbf{y}$ to estimate the channel

$$\hat{\mathbf{h}} = G_B(\mathbf{y}) \tag{24}$$

where the estimator $G_B(\cdot)$ is derived on the basis of certain qualitative information about the model. For example, although the input data are not known to the receiver, their statistical properties may be known. Other techniques include the exploitation of the finite-alphabet property of the source and certain parametric models of the channel. It is not obvious that blind channel estimation is even possible as neither the input nor the channel is known to the receiver. Indeed, such estimation is possible only under certain identifiability conditions, and the identification can be achieved only up to a scaling factor. In some applications such as terrestrial broadcasting of high-definition television (HDTV) where the requirement of efficient bandwidth utilization is stringent, pilot symbols may be so scarce that the receiver must acquire the channel without training. In such cases, blind channel estimation is necessary.

- *Semiblind Channel Estimator*. Between training-based and blind estimators is the class of semiblind channel estimators that utilize not only that part of signal corresponding to the training symbols but also the part corresponding to data symbols. In particular, a semiblind channel estimator takes $\{\mathbf{s}_{p1}, \mathbf{s}_{p2}, \mathbf{y}\}$ to generate a channel estimate. A semiblind channel estimator can be expressed as

$$\hat{\mathbf{h}} = G_{SB}(\mathbf{s}_p, \mathbf{y}) \tag{25}$$

By fully exploiting the information about the channel contained in the entire data record, semiblind channel estimation may provide considerable gain over training-based algorithms as shown in Section 4.2.

3.2. Performance Measure and Performance Bound

In estimating the channel, we can model $\mathbf{h}$ as a deterministic vector or a random vector with a certain probability distribution. If $\mathbf{h}$ is deterministic, we have the problem of point estimation whereas, when $\mathbf{h}$ is random, the estimation problem is Bayesian. In the following discussion, we will restrict ourselves to the case when $\mathbf{h}$ is deterministic but unknown.

The problem of channel estimation is to find an estimator $\hat{\mathbf{h}}$ that is close to the true channel under a certain performance measure. Typically, we will be concerned about the bias and covariance of the estimator defined by

$$\mathcal{B}(\hat{\mathbf{h}}) \triangleq E\{\hat{\mathbf{h}} - \mathbf{h}\}, \mathcal{V}(\hat{\mathbf{h}}) \triangleq E\{[\hat{\mathbf{h}} - E(\hat{\mathbf{h}})][\hat{\mathbf{h}} - E(\hat{\mathbf{h}})]^H\} \tag{26}$$

where both, in general, are functions of $\mathbf{h}$. If $\mathcal{B}(\mathbf{h}) = 0$ for all possible $\mathbf{h}$, then the estimator is unbiased. The performance of an estimator can also be measured by the covariance matrix of the estimation error

$$\mathcal{M}(\hat{\mathbf{h}}) \triangleq E(\hat{\mathbf{h}} - \mathbf{h})(\hat{\mathbf{h}} - \mathbf{h})^H \tag{27}$$

from which we obtain the *mean-square error*

$$E(\|\hat{\mathbf{h}} - \mathbf{h}\|^2) = tr\{\mathcal{M}(\hat{\mathbf{h}})\} \tag{28}$$

These definitions also apply to random channels.

In assessing the performance of the estimator, it is often useful to compare the covariance of the estimation error with the *Cramér–Rao bound* (CRB), which is a lower bound on the MSE of any unbiased estimator. Given a deterministic channel $\mathbf{h}$, assume that we have a well-defined probability density function $\mathbf{f}(\mathbf{y}; \mathbf{h})$. Viewed as a function of $\mathbf{h}$, $\boldsymbol{f}(\mathbf{y}; \mathbf{h})$ is the likelihood function of the channel parameter $\mathbf{h}$. The complex Fisher information matrix (FIM) $\boldsymbol{I}(\mathbf{h})$ is defined by

$$\mathbf{I}(\mathbf{h}) \triangleq E\{[\nabla_{\mathbf{h}^*} \ln f(\mathbf{y}; \mathbf{h})][\nabla_{\mathbf{h}^*}^H \ln f(\mathbf{y}; \mathbf{h})]\} \tag{29}$$

where the complex gradient operator applied to a real function $g(\mathbf{x})$ with complex argument $\mathbf{x} \in C^K$ is defined by

$$\nabla_{\mathbf{x}^*} g(\mathbf{y}) \triangleq \frac{1}{2}\begin{pmatrix} \dfrac{\partial g(\mathbf{x})}{\partial \Re\{x_1\}} \\ \vdots \\ \dfrac{\partial g(\mathbf{x})}{\partial \Re\{x_K\}} \end{pmatrix} + \frac{j}{2}\begin{pmatrix} \dfrac{\partial g(\mathbf{x})}{\partial \Im\{x_1\}} \\ \vdots \\ \dfrac{\partial g(\mathbf{x})}{\partial \Im\{x_K\}} \end{pmatrix} \tag{30}$$

Under regularity conditions [19,34], the MSE of any unbiased estimator $\hat{\mathbf{h}}$ is lower-bounded by $\mathbf{I}^{-1}$ $(\mathbf{h})$ and MSE by $tr\{\mathbf{I}^{-1}(\mathbf{h})\}$:

$$E(\hat{\mathbf{h}} - \mathbf{h})(\hat{\mathbf{h}} - \mathbf{h})^H \geq \mathbf{I}^{-1}(\mathbf{h}), \tag{31}$$

$$E(\|\hat{\mathbf{h}} - \mathbf{h}\|^2) \geq tr\{\mathbf{I}^{-1}(\mathbf{h})\} \tag{32}$$

An unbiased estimator that achieves the CRB is called *efficient*. The same expression also holds when $\mathbf{h}$ is random except that the expectation in (29) is taken over $\mathbf{y}$ and the channel vector $\mathbf{h}$.

3.3. Estimation Techniques

3.3.1. The Maximum-Likelihood Methods. One of the most popular parameter estimation algorithms is the maximum-likelihood (ML) method. The ML estimator can usually be derived in a systematic way by maximizing the likelihood function

$$\hat{\mathbf{h}}_{ML} = \arg\max_{\mathbf{h}\in\Theta} \boldsymbol{f}(\mathbf{y}; \mathbf{h}) \tag{33}$$

where Θ is the set of channels that satisfy certain constraints.

The ML estimator has a number of attractive properties. If an efficient estimator exists, it must be an ML estimator; it can be shown that the class of maximum-likelihood estimators are asymptotically efficient [23],

although examples exist that the ML estimator may perform poorly when the data size is small.

While the ML estimator is conceptually simple, the implementation of the ML estimator is sometimes computationally intensive. Furthermore, the optimization of the likelihood function in (33) is often hampered by the existence of local maxima. Therefore, it is desirable that effective initialization techniques are used in conjunction with ML estimation.

3.3.2. The Moment Methods. For some applications, the knowledge of the model is incomplete and the likelihood function cannot be specified explicitly. In such cases, the method of moments may be applied. Suppose that we know the explicit form that the ith moments $\mathbf{M}_i(\mathbf{h})$ of $\mathbf{y}$ relate to the channel parameter. The moment estimator is then given by matching the moment functions $\mathbf{M}_i(\mathbf{h})$ with moments estimated from the data. Often, simple estimators can be obtained from solving for $\hat{\mathbf{h}}$ directly from

$$\mathbf{M}_i(\mathbf{h}) = \hat{\mathbf{M}}_i \tag{34}$$

The matching of moments can also be done using least-squares techniques.

4. ESTIMATION OF SIMO CHANNELS

We now apply the performance bound and general estimation techniques to the estimation of the SIMO channel model (17) developed in Section 2. Training-based estimation is presented first followed by blind and semiblind estimation.

4.1. Training-Based Channel Estimation Algorithms

Training-based estimators use only those parts of the received signal corresponding to pilot symbols. If there is a single cluster of training symbols, we can use the model given in (18) assuming that all symbols $s[n]$ are known to the receiver, and

$$\mathbf{y} = \mathcal{F}(\mathbf{s})\mathbf{h} + \mathbf{w},\ \mathcal{F}(\mathbf{s}) = \mathcal{F}_1(\mathbf{s}) \otimes \mathbf{I}_G \tag{35}$$

where the noise vector $\mathbf{w}$ is zero mean, Gaussian with covariance $\sigma^2\mathbf{I}$, and

$$\mathcal{F}_1(\mathbf{s}) \triangleq \begin{pmatrix} s[N-1] & \cdots & s[N-L-1] \\ \vdots & \text{Hankel} & \vdots \\ s[0] & \cdots & s[-L] \end{pmatrix}$$

If there are multiple clusters, the preceding equations remain valid with $\mathcal{F}(\mathbf{s})$ replaced by a stack of $\mathcal{F}(\mathbf{S}_{pi})$, each corresponding to one cluster of pilot symbols.

4.1.1. Performance Bound and Identifiability. The likelihood function $f(\mathbf{y}, \theta)$ for the parameter $\boldsymbol{\theta} = \begin{pmatrix} \mathbf{h} \\ \sigma^2 \end{pmatrix}$ is given by

$$f(\mathbf{y};\theta) = \frac{1}{(\pi\sigma^2)^N} \exp\left\{-\frac{1}{\sigma^2}\|\mathbf{y} - \mathcal{F}(\mathbf{s})\mathbf{h}\|^2\right\} \tag{36}$$

The (complex) Fisher information matrix is given by

$$I(\boldsymbol{\theta}) = \frac{1}{\sigma^2}\begin{pmatrix} \mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s}) & \mathbf{0} \\ \mathbf{0} & \dfrac{N}{\sigma^2} \end{pmatrix} \tag{37}$$

and the CRB for the training-based channel estimators is

$$CRB_T(\mathbf{h}) = \sigma^2[\mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s})]^{-1} \tag{38}$$

assuming the inverse exists.

The assumption that $\mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s})$ is invertible is significant. If this condition is not satisfied, the channel is not identifiable. Specifically, if $\mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s})$ is not invertible, columns of $\mathcal{F}(\mathbf{s})$ are linearly dependent. Hence, there exists a vector $\Delta\mathbf{h}$ such that

$$\mathcal{F}(\mathbf{s})\Delta\mathbf{h} = \mathbf{0}$$

which implies that

$$\mathbf{y} = \mathcal{F}(\mathbf{s})(\mathbf{h} + \gamma\,\Delta\mathbf{h}) + \mathbf{w}$$

for any γ. In other words, the estimation error can be arbitrarily large.

4.1.2. Design of Pilot Sequence. The condition of identifiability imposes certain constraints on the training sequence. To ensure that $\mathcal{F}(\mathbf{s})$ has full column rank, it is necessary and sufficient that $\mathcal{F}_1(\mathbf{s})$ have full column rank. An equivalent condition is that the *linear complexity*[2] [5] of the pilot sequence $s[n]$ should be greater than L. This implies that, to estimate a set of parallel channels of order L, the minimum number of training symbols must be greater than $2L$.

Note that the CRB in (38) is not a function of the channel parameter. It is, however, a function of the transmitted (pilot) symbol vector $\mathbf{s}$. Since the CRB can be achieved by the ML estimator described below, the training sequence should be designed to minimize the CRB. Specifically, we may choose the training sequence with constant amplitude σ_s according to the following optimization:

$$\min_{\mathbf{s}} tr\{(\mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s}))^{-1}\}$$

It can be shown that among all possible transmitted symbols with constant amplitude σ_s, the one that minimizes the CRB satisfies the orthogonality condition

$$\mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s}) = N\sigma_s^2\mathbf{I}$$

The sequence that gives the minimum CRB can be chosen from points on the circle with radius σ_s in the complex plane [6].

[2] The linear complexity of a sequence $s[n]$ is defined as the smallest number c such that there exist α_i such that $s[n] = \sum_{i=1}^{c} \alpha_i s[n-i]$ for all $n \geq c$.

4.1.3. THE ML ESTIMATOR

The maximum-likelihood (ML) estimator of the channel is given by

$$\mathbf{h}_{ML} = \arg\min_{\mathbf{h}} \|\mathbf{y} - \mathcal{F}(\mathbf{s})\mathbf{h}\|^2 \tag{39}$$

$$= [\mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s})]^{-1}\mathcal{F}^H(\mathbf{s})\mathbf{y}$$

$$= (\{[\mathcal{F}_1^H(\mathbf{s})\mathcal{F}_1(\mathbf{s})]^{-1}\mathcal{F}_1^H(\mathbf{s})\} \otimes \mathbf{I}_G)\mathbf{y} \tag{40}$$

assuming again the inverse exists. It is easily verified that

$$E(\hat{\mathbf{h}}_{ML}) = \mathbf{h},\ \mathcal{V}(\hat{\mathbf{h}}_{ML}) = \sigma^2(\mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s}))^{-1} \tag{41}$$

In other words, the ML channel estimator is efficient. When the optimal training sequence is used, from (41), we obtain

$$\mathcal{V}(\hat{\mathbf{h}}_{ML}) = \frac{1}{N} \xrightarrow{N\to\infty} 0 \tag{42}$$

Hence, the estimator is consistent and the estimation error decreases to zero at the rate of $1/N$.

The implementation of the ML estimator can be simplified by treating the G subchannels in Fig. 2 separately. Let $\mathbf{h}^{(i)}$ be the channel vector containing the impulse response of the ith subchannel, and $\mathbf{y}^{(i)}$ be the observation corresponding to the ith subchannel. Because the assumption that the noise samples in $\mathbf{w}$ are independent, we have

$$\hat{\mathbf{h}}^{(i)} = [\mathcal{F}_1^H(\mathbf{s})\mathcal{F}_1(\mathbf{s})]^{-1}\mathcal{F}_1^H(\mathbf{s})\mathbf{y}^{(i)} \tag{43}$$

which involves the inversion of a $(L_i+1)\times(L_i+1)$ Hermitian matrix where L_i is the order of the ith channel. In contrast, the inversion of a $G(L+1)\times G(L+1)$ matrix is involved in (40).

4.1.4. Recursive Least Squares. The ML channel estimator, under the assumption that $\mathbf{w} \sim \mathcal{N}(\mathbf{0}, \sigma^2\mathbf{I})$ is zero mean, Gaussian with covariance $\sigma^2\mathbf{I}$, is also the least-squares estimator defined by (40). In addition to reducing computation complexity by avoiding direct matrix inverse, the recursive least-squares (RLS) algorithm computes the channel estimate recursively, allowing updates as more data become available.

Since all sub-channels can be estimated independently, without loss of generality, we assume that $G = 1$. Suppose that we have already obtained the LS estimate $\hat{\mathbf{h}}_n$ using all observation $\mathbf{y}_n$ up to time n and their corresponding input symbols $\mathbf{s}_n$ defined by

$$\mathbf{y}_n = \begin{pmatrix} y[n] \\ \vdots \\ y[0] \end{pmatrix},\ \mathbf{s}_n = \begin{pmatrix} s[n] \\ \vdots \\ s[-L] \end{pmatrix} \tag{44}$$

From (40), we have

$$\hat{\mathbf{h}}_n \triangleq \underbrace{[\mathcal{F}^H(\mathbf{s}_n)\mathcal{F}(\mathbf{s}_n)]}_{\mathbf{R}_n}{}^{-1}\ \underbrace{\mathcal{F}^H(\mathbf{s}_n)\mathbf{y}_n}_{\mathbf{r}_n}$$

$$= \mathbf{R}_n^{-1}\mathbf{r}_n = \mathbf{P}_n\mathbf{r}_n \tag{45}$$

where $\mathbf{P}_n \triangleq \mathbf{R}_n^{-1}$. Letting $\mathbf{s}_{L+1}[n] \triangleq [s[n], \ldots, s[n-L]]^T$, we note that $\mathbf{R}_n$ can be computed recursively

$$\mathbf{R}_n = \mathbf{R}_{n-1} + \mathbf{s}_{L+1}^*[n]\mathbf{s}_{L+1}^T[n]$$

Recursive relations also hold for $\mathbf{P}_n$ and $\mathbf{r}_n$

$$\mathbf{P}_n \triangleq \mathbf{R}_n^{-1} = \mathbf{P}_{n-1} - \frac{\mathbf{P}_{n-1}\mathbf{s}_{L+1}^*[n]\mathbf{s}_{L+1}^T[n]\mathbf{P}_{n-1}^H}{1 + \mathbf{s}_{L+1}^T[n]\mathbf{P}_{n-1}\mathbf{s}_{L+1}^*[n]} \tag{46}$$

$$\mathbf{r}_n \triangleq \mathcal{F}^H(\mathbf{s}_n)\mathbf{y}_n = \mathbf{r}[n-1] + y[n]\mathbf{s}_{L+1}^*[n] \tag{47}$$

Suppose now that we are made available the next pilot $s[n+1]$ and the corresponding observation $y[n+1]$. Then, the ML estimator using data up to time $n+1$ can be updated from the previous estimate by

$$\hat{\mathbf{h}}_{n+1} \triangleq \hat{\mathbf{h}}_n + \mathbf{g}_{n+1}\varepsilon[n+1] \tag{48}$$

where $\varepsilon[n+1]$ is the error of the predicted observation using $\hat{\mathbf{h}}[n]$

$$\varepsilon[n+1] = y[n+1] - \mathbf{s}_{L+1}^T[n+1]\hat{\mathbf{h}}_n, \tag{49}$$

and $\mathbf{g}_{n+1}$ is the gain vector

$$\mathbf{g}_{n+1} = \frac{\mathbf{P}_n\mathbf{s}_{L+1}^*[n+1]}{1 + \mathbf{s}_{L+1}^T[n+1]\mathbf{P}_n\mathbf{s}_{L+1}^*[n+1]} \tag{50}$$

It is interesting to note that the amount of update in the channel estimate depends on the prediction error by the channel estimate. The RLS algorithm reduces the computation of the batch ML estimation to $\mathcal{O}((L+1)^2)$.

4.1.5. The LMS Algorithm. For its simplicity, the LMS algorithm, originally proposed by Widrow and Hoff [36], is perhaps the most widely used adaptive estimation algorithm. It resembles the RLS update and may be expressed as follows

$$\hat{\mathbf{h}}_{n+1} \triangleq \hat{\mathbf{h}}_n + \mu\mathbf{s}_{L+1}^*[n+1]\varepsilon[n+1] \tag{51}$$

where the computationally more expensive gain vector $\mathbf{g}_{n+1}$ in RLS is replaced by the readily available input vector and a constant-step-size μ for the update. The derivation of the LMS algorithm does not have a direct connection to the ML estimation. Under the assumption that the input sequence $s[n]$ is random, the LMS can be viewed as the stochastic gradient implementation of the minimization of the average prediction error

$$\min_{\mathbf{h}} E\left\{|y[n] - \sum_i h[i]s[n-i]|^2\right\} \tag{52}$$

where the expectation is taken over the noise and the input process.

4.2. Blind and Semiblind Channel Estimation Algorithms

We now consider the semiblind and blind channel estimation problem where the channel estimator uses the entire data record.

The input sequence can be partitioned into two parts: the pilot symbols $\mathbf{s}_p$ and data symbols $\mathbf{s}_d$. With the corresponding partition in the channel matrix, we have

$$\mathbf{y} = \mathcal{H}_p(\mathbf{h})\mathbf{s}_p + \mathcal{H}_d(\mathbf{h})\mathbf{s}_d + \mathbf{w} \tag{53}$$

where $\mathbf{w} \sim \mathcal{N}(0, \sigma^2\mathbf{I})$ is again assumed to be zero mean Gaussian with covariance $\sigma^2\mathbf{I}$. The estimation problem can now be formulated on the basis of two models of the input data vector $\mathbf{s}_d$. The *deterministic model* assumes that $\mathbf{s}_d$ is a deterministic, unknown nuisance parameter in the channel estimation. The *stochastic model*, on the other hand, assumes that $\mathbf{s}_d$ is random with certain distribution. These two models lead to different likelihood functions and therefore, different performance bounds and estimation algorithms. The choice of modeling depends naturally on the application. Typically, if the channel is to be estimated using a small number of samples, the deterministic model is more effective.

4.2.1. The Performance Bound. Under the deterministic model, the likelihood function of the unknown parameter $\boldsymbol{\theta} = [\mathbf{h}^T \mathbf{s}_d^T \sigma^2]^T$ is given by

$$f(\mathbf{y}; \boldsymbol{\theta}) = \frac{1}{\pi^N \sigma^{2N}} \exp\left\{-\frac{1}{\sigma^2}\|\mathbf{y} - \mathcal{H}_p(\mathbf{h})\mathbf{s}_p - \mathcal{H}_d(\mathbf{h})\mathbf{s}_d\|^2\right\} \tag{54}$$

The complex Fisher information matrix is given by

$$I(\boldsymbol{\theta}) = \frac{1}{\sigma^2}\begin{pmatrix} \mathcal{F}^H(\mathbf{s})\mathcal{F}(\mathbf{s}) & \mathcal{F}^H(\mathbf{s})\mathcal{H}_d(\mathbf{h}) & \mathbf{0} \\ \mathcal{H}_d^H(\mathbf{h})\mathcal{F}(\mathbf{s}) & \mathcal{H}_d^H(\mathbf{h})\mathcal{H}_d(\mathbf{h}) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \dfrac{N}{\sigma^2} \end{pmatrix} \tag{55}$$

Using the block matrix inversion formula, we obtain the CRB for any unbiased semiblind channel estimator $\hat{\mathbf{h}}$

$$\mathrm{CRB}_{SB}(\mathbf{h}) = \sigma^2[\mathcal{F}^H(\mathbf{s})\mathcal{P}^{\perp}_{\mathcal{H}_d(\mathbf{h})}\mathcal{F}(\mathbf{s})]^{-1} \tag{56}$$

where

$$\mathcal{P}^{\perp}_{\mathcal{H}_d(\mathbf{h})} \triangleq \mathbf{I} - \mathcal{H}_d(\mathbf{h})[\mathcal{H}_d^H(\mathbf{h})\mathcal{H}_d(\mathbf{h})]^{-1}\mathcal{H}_d(\mathbf{h}) \tag{57}$$

is the projection matrix onto the null space of $\mathcal{H}_d(\mathbf{h})$. It is clear from the above expressions and (38) that

$$\mathrm{CRB}_{SB}(\mathbf{h}) \le \mathrm{CRB}_T(\mathbf{h})$$

with equality when all symbols are known.

The derivation for the CRB under the stochastic model is more complicated unless one assumes that the input sequence is Gaussian. Details can be found in Ref. 7.

4.2.2. The Design of Pilot Symbols and Their Placement. The design of training for semiblind channel estimation involves the joint design of the number of pilot symbols, the pilot symbols, and their placements. The CRB can be used as the performance measure for this design.

It is natural to expect that more pilot symbols lead to better performance. On the other hand, increasing the number of pilot symbols reduces the number of data symbols transmitted in a packet. The gain in performance can be evaluated against the percentage of known symbols in a packet using (56). Figure 5 shows an example of the relation between the MSE and the percentage η of known symbols in the data packet for a multipath channel of order $L = 5$ at 10 dB SNR. Notice that $\eta = 100\%$ corresponds to the performance of the training-based ML algorithm. It can be seen that the gain of using all pilot symbols ($\eta = 100\%$) over that of using 1% pilot symbols is about 45 dB, and about 40 dB of gain can already be achieved at $\eta = 20\%$.

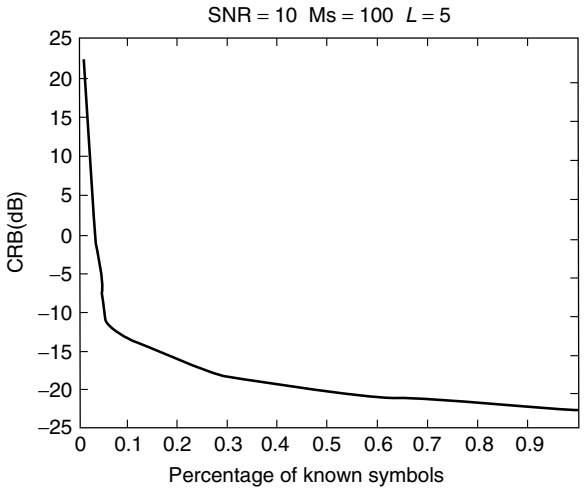

Figure 5. CRB for a multipath channel with $L = 5$; SNR = 10 dB.

Given the percentage of pilot symbols in a data packet, the problem of pilot design can be formulated as minimizing $tr\{\mathrm{CRB}_{SB}(\mathbf{h})\}$ among choices of pilot symbols and their placement. This optimization, unfortunately, depends on the channel coefficients. For random channels, however, the minimization of CRB does lead to the optimal design of pilot symbols and their placement, which are independent of the channel [9].

4.2.3. The ML Estimation. When some or all of the input symbols are unknown, the likelihood function of the channel parameters and the unknown symbols depends on the model assumed for the unknown symbols. We then have the so-called deterministic maximum likelihood (DML) where the unknown input symbols are deterministic, and the stochastic maximum likelihood (SML), where the unknown symbols are assumed to be random with some known distribution.

4.2.3.1. The SML Estimation. While the input vector $\mathbf{s}$ is unknown, it may be modeled as a random vector with known distribution. In such a case, the likelihood function of the channel parameter $\mathbf{h}$ can be obtained by

$$f(\mathbf{y}; \mathbf{h}) = \int f(\mathbf{y}|\mathbf{s}_d; \mathbf{h}) f(\mathbf{s}_d) d\mathbf{s}_d \tag{58}$$

where $f(\mathbf{s}_d)$ is the marginal pdf of the unknown data vector and $f(\mathbf{y}|\mathbf{s}_d; \mathbf{h})$ is the likelihood function of $\mathbf{h}$ for a particular choice of $\mathbf{s}_d$. If the input symbols $\{s[k]\}$ take, with equal probability, a finite number of values, the data vector $\mathbf{s}_d$ also takes values from the signal set $\{\mathbf{v}_1, \ldots, \mathbf{v}_Q\}$ with equal probability.

The likelihood function of the channel parameter is then given by

$$f(\mathbf{y};\mathbf{h}) = \sum_{i=1}^{Q} f(\mathbf{y}|\mathbf{s}_d = \mathbf{v}_i;\mathbf{h})\Pr(\mathbf{s}_d = \mathbf{v}_i)$$
$$= C\sum_{i=1}^{Q} \exp\left\{-\frac{\|\mathbf{y} - \mathcal{F}(\mathbf{v}_i)\mathbf{h} - \mathcal{F}(\mathbf{s}_p)\mathbf{h}\|^2}{\sigma^2}\right\} \quad (59)$$

where C is a constant. The stochastic maximum-likelihood estimator is given by

$$\hat{\mathbf{h}} = \arg\min_{\mathbf{h}} \sum_{i=1}^{Q} \exp\left\{-\frac{\|\mathbf{y} - \mathcal{F}(\mathbf{v}_i)\mathbf{h} - \mathcal{F}(\mathbf{s}_p)\|^2}{\sigma^2}\right\} \quad (60)$$

The maximization of the likelihood function defined in (58) is in general difficult. The expectation–maximization (EM) algorithm [2,8] can be applied to transform the complicated optimization to a sequence of quadratic optimizations. Kaleh and Vallet [18] first applied the EM algorithm to the equalization of communication channels with the input sequence having the finite-alphabet property. By using a *hidden Markov model* (HMM), the authors of Ref. 18 developed a batch (offline) procedure that includes the so-called forward and backward recursions [27]. Unfortunately, the complexity of this algorithm increases exponentially with the channel memory. To relax the memory requirements and facilitate channel tracking, "online" sequential approaches have been proposed [30,31,35] for a general input, and for an input with finite alphabet properties under a HMM formulation [21]. Given the appropriate regularity conditions [30] and a good initialization, it can be shown that these algorithms converge (almost surely and in the mean square sense) to the true channel value.

4.2.3.2. DML Estimation. When the noise is zero-mean Gaussian with covariance $\sigma^2 I$, the DML estimator can be obtained by the nonlinear least-squares optimization

$$\{\hat{\mathbf{h}}, \hat{\mathbf{s}}_d\} = \arg\min_{\mathbf{h},\mathbf{s}_d} \|\mathbf{y} - \mathcal{H}_p(\mathbf{h})\mathbf{s}_p - \mathcal{H}_d(\mathbf{h})\mathbf{s}_d\|^2 \quad (61)$$

The joint minimization of the likelihood function with respect to both $\mathbf{h}$ and $\mathbf{s}_d$ is also difficult in general. However, for the general estimation model (18) considered here, the observation vector $\mathbf{y}$ is linear in both the channel and the input parameters individually. We therefore have a separable nonlinear least-squares problem that can be solved sequentially:

$$\{\hat{\mathbf{h}}, \hat{\mathbf{s}}_d\} = \arg\min_{\mathbf{s}_d}\{\min_{\mathbf{h}} \|\mathbf{y} - \mathcal{F}(\mathbf{s})\mathbf{h}\|^2\} \quad (62)$$
$$= \arg\min_{\mathbf{h}}\{\min_{\mathbf{s}_d} \|\mathbf{y} - \mathcal{H}(\mathbf{h})\mathbf{s}\|^2\} \quad (63)$$

If we are interested only in estimating the channel, the preceding minimization can be rewritten as

$$\hat{\mathbf{h}} = \arg\min_{\mathbf{h}} \| \underbrace{(\mathbf{I} - \mathcal{H}(\mathbf{h})\mathcal{H}^{\dagger}(\mathbf{h}))}_{\mathcal{P}(\mathbf{h})} \mathbf{y}\|^2 = \arg\min_{\mathbf{h}} \|\mathcal{P}(\mathbf{h})\mathbf{y}\|^2 \quad (64)$$

where $\mathcal{P}(\mathbf{h})$ is a projection transform of $\mathbf{y}$ into the orthogonal complement of the range space of $\mathcal{H}(\mathbf{h})$, or the noise subspace of the observation. Discussions of algorithms of this type can be found in an earlier study [32].

Similar to the hidden Markov model (HMM) for the statistical maximum-likelihood approach, the finite-alphabet properties of the input sequence can also be incorporated into the deterministic maximum-likelihood methods. These algorithms, first proposed by Seshadri [28] and Ghosh and Weber [12], iterate between estimates of the channel and the input. At iteration k, with an initial guess of the channel $\mathbf{h}^{(k)}$, the algorithm estimates the input sequence $\mathbf{s}_d^{(k)}$ and the channel $\mathbf{h}^{(k+1)}$ for the next iteration by

$$\mathbf{s}_d^{(k)} = \arg\min_{\mathbf{s}_d \in S} \|\mathbf{y} - \mathcal{H}(\mathbf{h}^{(k)})\mathbf{s}\|^2 \quad (65)$$

$$\mathbf{h}^{(k+1)} = \arg\min_{\mathbf{h}} \|\mathbf{y} - \mathcal{H}(\mathbf{s}^{(k)})\mathbf{h}\|^2 \quad (66)$$

where $\mathcal{S}$ is the (discrete) domain of $\mathbf{s}_d$. The optimization in (66) is a linear least-squares problem whereas the optimization in (65) can be achieved by using the Viterbi algorithm [10]. The convergence of such approaches is not guaranteed in general.

Although the ML channel estimator usually provides better performance, the computation complexity and the existence of local optima are the two major impediments. Next we present two classes of suboptimal techniques that avoid the problem of local optima with significantly reduced computation complexity.

4.2.4. Moment Techniques: The Subspace Algorithms. Subspace techniques convert the problem of blind or semiblind channel estimation to the identification of a one-dimensional subspace that contains the channel vector. By exploiting the multichannel aspects of the channel, many of these techniques lead to a constrained quadratic optimization

$$\hat{\mathbf{h}} = \arg\min_{\|\mathbf{h}\|=1} \mathbf{h}^H Q(\mathbf{y}, \mathbf{s}_p)\mathbf{h} \quad (67)$$

where $Q(\mathbf{y}, \mathbf{s}_p)$ is a positive-definite matrix constructed from the observation and pilot symbols. The solution to the preceding optimization is then given by the eigenvector of $Q(\mathbf{y}, \mathbf{s}_p)$ associated with the minimum eigenvalue.

A simple yet informative approach [37] illustrates the basic idea in a noiseless two-channel scenario. From Fig. 2, if there is no noise, the received signals from the two channels satisfy the relation

$$y_1[n] = h_1[n] * s[n], y_2[n] = h_2[n] * s[n] \quad (68)$$

where $*$ is the linear convolution. Consequently, we have

$$y_1[n] * h_2[n] = y_2[n] * h_1[n] \quad (69)$$

Since the convolution operation is linear with respect to the channel and $y_i[n]$ is available, the above equation is equivalent to solving a homogeneous linear equation

$$\mathbf{Rh} = \mathbf{0} \quad (70)$$

where $\mathbf{R}$ is a matrix made of observations from the two channels. It can be shown that under certain identifiability conditions [32], the null space of $\mathbf{R}$ has dimension 1, which means that the channel can be identified up to a constant. When there is noise, the channel estimator can be obtained from a constrained quadratic optimization

$$\hat{\mathbf{h}} = \arg \min_{\|\mathbf{h}\|=1} \mathbf{h}^H \mathbf{R}^H \mathbf{R} \mathbf{h}, \tag{71}$$

which implies that $\hat{\mathbf{h}}$ is the eigenvector corresponds to the smallest eigenvalue of $\mathbf{Q} = \mathbf{R}^t \mathbf{R}$.

Some insight into the identifiability condition can be gained in the frequency domain. Equation (68) implies that

$$\frac{y_1(z)}{y_2(z)} = \frac{h_1(z)}{h_2(z)}$$

It is clear that if the two subchannels have common zeros, it is not possible to obtain all the zeros from the observation $\{y_1(z), y_2(z)\}$.

4.2.5. Projection Algorithms. The subspace algorithms are batch algorithms, and they are not easily amenable to adaptive forms. The projection based techniques [1,11,29,33,39], on the other hand, convert the problem of channel estimation to the classic problem of linear prediction or smoothing. As a result, these estimators can be implemented adaptively in time and recursively with respect to the delay spread of the channel. The first projection-based algorithm was proposed by Slock [29], where linear prediction is used to obtain the subspace of the channel matrix. Subsequent development [1,11] based on linear predictions assumed that the input sequence is a white sequence. Under the deterministic model, a least-squares smoothing (LSS) technique was developed [33,39] that offers finite sample convergence property in the absence of noise. It also allows a lattice filter implementation that is recursive both in time and the delay spread of the channel. In fact, both the channel and the input sequence can be obtained simultaneously by using oblique projections [38].

1.5. BIBLIOGRAPHY NOTES

The modeling of linearly modulated signals can be found in standard textbooks [22,26]. For fading dispersive channels encountered in wireless communications, earlier treatments can be found in Refs. 3, 16, and 20 and more recent developments in Ref. 4. The general theory of parameter estimation, including the Cramér-Rao bound, the maximum-likelihood estimation, and the moment methods, are presented in many books. See, for example, Lehmann [23] for the mathematical treatment of the subject and Refs. 19, 24, 25, and 34 from engineering application perspectives. The estimation of complex parameters is discussed by Kay [19].

The training-based channel estimation under additive white Gaussian noise is a form of a linear least-squares problem, which is discussed extensively in Ref. 17. See also Ref. 15 for various adaptive implementations. A survey of blind channel estimation algorithms can be found in Ref. 32. The problem of semiblind channel estimation is discussed in detail in Ref. 7. Articles about more recent trends in channel estimation and equalization can be found in Refs. 13 and 14.

BIOGRAPHY

Lang Tong received his B.E. degree from Tsinghua University, Beijing, China, in 1985, and M.S. and Ph.D. degrees in electrical engineering in 1987 and 1990, respectively, from the University of Notre Dame, Indiana. He was a postdoctoral research affiliate at the Information Systems Laboratory, Stanford University, in 1991. Currently, he is an associate professor in the School of Electrical and Computer Engineering, Cornell University, Ithaca, New York.

Dr. Tong received Young Investigator Award from the Office of Naval Research in 1996, and the Outstanding Young Author Award from the IEEE Circuits and Systems Society. His areas of interest include statistical signal processing, adaptive receiver design for communication systems, signal processing for communication networks, and information theory.

CHANNEL TRACKING IN WIRELESS COMMUNICATION SYSTEMS

GREGORY E. BOTTOMLEY
HÜSEYIN ARSLAN
Ericsson Inc.
Research Triangle Park, North Carolina

1. INTRODUCTION

In digital wireless communication systems, information is transmitted to a receiver, as illustrated in Fig. 1. The transmitted information reaches the receiver after passing through a radio channel, which can be represented as an unknown, time-varying filter. For conventional, coherent receivers, the effect of the channel on the transmitted signal must be estimated to recover the transmitted information. For example, with binary phase shift keying (BPSK), binary information is represented as $+1$ and -1 symbol values. The radio channel can apply a phase shift to the transmitted symbols, possibly inverting the symbol values. As long as the receiver estimates what the channel did to the transmitted signal, it can accurately recover the information sent.

Channel estimation is a challenging problem in wireless communications. Transmitted signals are typically reflected and scattered, arriving at the receiver along multiple paths. How these signals interact depends on

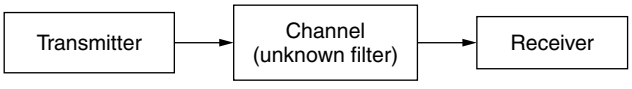

Figure 1. A wireless communication system.

their relative delays. When the relative delays are small compared to the transmitted symbol period, then different "images" of the *same* symbol arrive at the same time, adding either constructively or destructively. The overall effect is a random, fading channel response. When the relative path delays are on the order of a symbol period or more, then images of *different symbols* arrive at the same time. For example, when a particular symbol arrives at the receiver along one path, the previous symbol is arriving along another, delayed path. This is analogous to an acoustic echo and results in a more complicated channel response. Finally, because of the mobility of the transmitter, the receiver, or the scattering objects, the channel response can change rapidly with time.

This article provides an overview of channel tracking approaches commonly applied to digital cellular communication systems. Related work can be found in the study of system identification [1] and in high-frequency (HF) modem design [2].

As shown in Fig. 1, the channel impulse response is modeled as an unknown filter. Specifically, a finite-impulse-response (FIR) filter with discrete filter delays and coefficients is used. We focus on estimation of the channel coefficients, given a set of delays. Also, we focus on conventional demodulation approaches and single-antenna receivers.

In typical digital cellular systems, some part of the transmitted signal is known. In one approach, the transmitter periodically provides known *pilot symbols*, as illustrated in Fig. 2a, which can be used for channel estimation [3,4]. This approach is used in one of the downlink slot structures of the Telecommunications Industry Association/Electronics Industry Association/Interim Standard 136 (TIA/EIA/IS-136 or simply IS-136) system. In this time-division multiple-access (TDMA) system, information is transmitted in time slots. Within each time slot, clusters of known pilot symbols are provided to assist in channel estimation.

The pilot symbol approach has also been used in direct-sequence code-division multiple-access (DS-CDMA) systems. With these systems, each information symbol is represented by a sequence of "chip" symbols. This results in a spreading of the bandwidth (spread-spectrum), allowing multiple information signals to be transmitted in parallel at the same time. For convenience, we will refer to DS-CDMA systems as *wideband* systems and TDMA systems as *narrowband* systems. Pilot symbols are available in the following DS-CDMA systems: the IS-2000 system (uplink, mobile to base station) and the wideband CDMA (WCDMA) system (uplink and downlink).

In a second approach, a *pilot channel* is provided for channel estimation [5], as illustrated in Fig. 2b. This approach is related to the pilot tone approach, developed for narrowband systems [6]. The pilot channel approach is used for the downlink in the IS-95, IS-2000, and WCDMA systems. Usually the pilot channel is shared by many users and is stronger in power than an information channel.

A third approach is to provide a *training sequence* during part of the transmission, which can be used to provide an initial channel estimate. In this case, the channel must be tracked over the data portion of the signal using this signal in some way. This approach, illustrated in Fig. 2c, is used in one of the slot formats of the IS-136 system.

A training sequence is also used in the global system for mobile communications (GSM). This is a TDMA system with time slots that have short duration relative to the maximum rate of channel variation. As a result, the initial channel estimate obtained from the training sequence can be used to demodulate the data in the slot, without having to track the channel. Approaches for channel estimation in this situation are given in a separate article in this encyclopedia and elsewhere [7].

The article is organized as follows. In Section 2, a baseband-equivalent system model is given, including a model for the time-varying channel. Approximate channel models commonly used to develop tracking approaches are given in Section 3. In Section 4, filtering approaches to channel tracking are presented, based on either periodic pilot symbols or a pilot channel. Recursive approaches are presented in Section 5. Data-directed channel tracking is considered in Sections 6 and 7. Section 8 concludes the article.

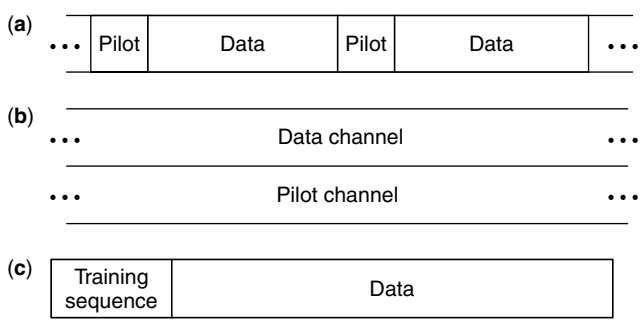

Figure 2. Systems with pilot information: (**a**) pilot symbols, (**b**) pilot channel, and (**c**) training sequence.

2. SYSTEM MODEL

A narrowband system model is presented and then extended to a wideband system model.

2.1. Narrowband System

A complex, baseband-equivalent system model is given in Fig. 3. The complex values correspond to in-phase (cosine) and quadrature (sine) components of the radio signal. At the transmitter, a sequence of digital symbols are transmitted using pulse shaping, giving

$$x(t) = \sum_k b_k f(t - kT) \tag{1}$$

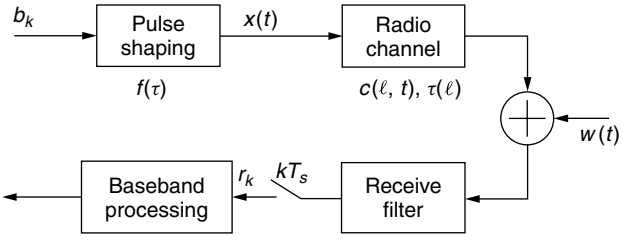

Figure 3. System model.

where b_k corresponds to the sequence of symbols, $f(\tau)$ is the pulse shape as a function of delay τ, and T is the symbol period. We assume either BPSK or quadrature phase shift keying (QPSK) modulation, so that all possible symbol values have the same amplitude ($|b_k|^2 = 1$).

The transmitted signal passes through a radio channel that can be modeled as a linear FIR filter. The resulting signal is received in the presence of noise, giving

$$y(t) = \sum_{\ell=0}^{L-1} c(\ell, t)x(t - \tau(\ell)) + w(t) \tag{2}$$

where $c(\ell, t)$ and $\tau(\ell)$ are the ℓth complex, time-varying channel coefficient and ℓth delay, respectively, and L is the number of channel taps. The noise term $w(t)$ is assumed to be white, complex (circular) Gaussian noise.

The delays are often assumed to be equally spaced; specifically, $\tau(\ell) = \ell T/M$, where M is an integer, and the spacing (T/M) for accurate modeling depends on the bandwidth of the system [8]. Typically M is 1 (symbol-spaced channel modeling) or 2 (fractionally-spaced channel modeling). For simplicity, symbol-spaced channel modeling is assumed, although extension to fractionally-spaced channel modeling is possible.

The coefficients represent the result of different multipath signal images adding together, constructively or destructively. They are well modeled as random variables. Specifically, they are modeled as uncorrelated, zero-mean complex Gaussian random variables [9]. This corresponds to "Rayleigh" fading, in that channel tap magnitudes (amplitudes) are Rayleigh-distributed. Also, the phases of the channel taps are uniformly distributed.

As the mobile transmitter or receiver moves, the phases of all multipath signal images change. This changes how the multipath images add together, so that the channel coefficient varies with time. This time variation is characterized by an autocorrelation function. The Jakes model [10], which is commonly used, assumes that the Gaussian channel coefficients have the following autocorrelation function:

$$R_\ell(\tau) = \mathrm{E}\{c^*(\ell, t)c(\ell, t + \tau)\} = \sigma_\ell^2 J_0(2\pi f_D \tau) \tag{3}$$

where the asterisk superscript denotes complex conjugation, index ℓ denotes the ℓth channel coefficient, τ is the autocorrelation delay, σ_ℓ^2 is the mean-square value of the channel coefficient, f_D is the Doppler spread, and $J_0(\cdot)$ is the zeroth-order Bessel function of the first kind. The corresponding power spectrum of the fading process is shown in Fig. 4. This spectrum shows that the fading process has different frequency components, corresponding to different rates of change. Most of the energy is near the maximum frequency component, the Doppler spread (f_D).

The Doppler spread is proportional to the radio carrier frequency and the speed of the transmitter or receiver. For the examples given, the carrier frequency is either ~900 MHz or ~2 GHz. At a high vehicle speed of 100 km/h, these carrier frequencies correspond to Doppler spread values of 83 and 185 Hz, respectively. The ability to track channel variation depends on how rapidly the channel changes from symbol to symbol. In all the examples given, the symbol rate is much higher than the Doppler spread, so that the channel coefficient value is highly correlated

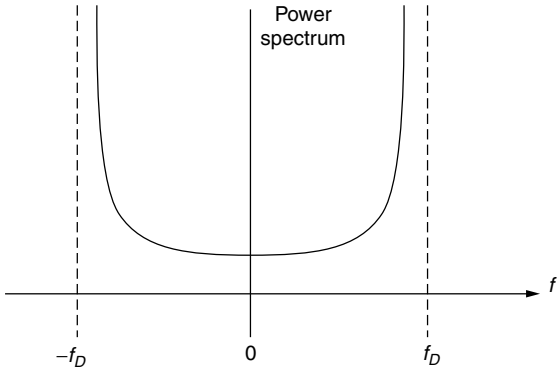

Figure 4. Spectrum of fading process.

from symbol to symbol, making channel tracking possible. Also, the Doppler spread is considered constant, because the speed of the transmitter or receiver changes slowly relative to the transmission rate. However, it is possible to model the time variation of the Doppler spread [11].

At the receiver, $y(t)$ is passed through a filter matched to the pulse shape and sampled, giving received samples

$$r_k = \int f^*(\tau)y(\tau + kT_s)\, d\tau, \quad k = 0, 1, \ldots \tag{4}$$

where $T_s = T/M = T$ is the sampling period. Because the fading varies slowly from symbol to symbol, it can be approximated as constant over the pulse shape. With this approximation, substituting (2) into (4) gives

$$\boxed{r_k = \sum_{j=0}^{J-1} h_k(j)b_{k-j} + z_k} \tag{5}$$

where $h_k(j)$ is the jth composite channel coefficient, reflecting the influence of the transmit filter, the radio channel, and the receive filter

$$h_k(j) = \sum_{\ell=0}^{L-1} c(\ell, kT)R_{ff}(jT - \ell T) \tag{6}$$

where $R_{ff}(\tau)$ is the pulse shape autocorrelation function. Note that z_k corresponds to a sequence of complex Gaussian noise samples, which may be correlated depending on the pulse shape autocorrelation function. Observe that at the receiver, there is intersymbol interference (ISI), as the received samples contain the current symbol b_k as well as interference from previous symbols. The number (J) of composite coefficients needed to accurately model r_k depends on L and on the shape of $R_{ff}(\tau)$. For the special case of root-Nyquist pulse shaping, $J = L$, $h_k(j) = c(j, kT)$, and the noise samples z_k are uncorrelated.

When developing certain channel tracking approaches, it is convenient to formulate the tracker in terms of the conjugate of $h_k(j)$, i.e., $g_k(j) = h_k^*(j)$. This gives the alternative formulation

$$\boxed{r_k = \mathbf{g}_k^H \mathbf{b}_k + z_k} \tag{7}$$

where superscript H denotes Hermitian (conjugate) transpose, $\mathbf{g}_k = [g_k(0)\ g_k(1)\ \cdots\ g_k(J-1)]^T$ is a vector of channel coefficients, $\mathbf{b}_k = [b_k, \ldots, b_{k-J+1}]^T$ is a vector of symbols, and superscript T denotes transpose.

2.2. Simple Narrowband Demodulator Example

Here, a simple coherent receiver for the case of a one-tap channel is given. Using the formulation in (5), we obtain

$$r_k = h_k(0)b_k + z_k \tag{8}$$

Assuming that the information symbol b_k is either $+1$ or -1 (BPSK), we can recover the information using

$$\hat{b}_k = \text{sign}(\text{Re}\{\hat{h}_k^*(0)r_k\}) \tag{9}$$

where $\hat{h}_k(0)$ is an estimate of the channel coefficient and $\text{Re}\{\cdot\}$ denotes the real part of a complex number. When quadrature phase shift keying (QPSK) is used, each symbol represents two bit values. One of the bit values is recovered using (9), and the other bit value is recovered using a similar expression in which the imaginary part is taken instead of the real part.

Multiplying the received value by the conjugate of the channel coefficient estimate removes the phase rotation introduced by the channel and weights the value proportional to how strong the channel coefficient is, which is important when soft information [sign operation omitted in (9)] is used in subsequent forward error correction (FEC) decoding.

2.3. Wideband System

A similar system model can be used for DS-CDMA systems. For these systems, the pulse shape $f(\tau)$ is replaced with the convolution of the chip sequence and a chip pulse shape. Basically, each symbol is represented by a sequence of N_c chips, so that $T = N_c T_c$, where T_c is the chip period. We refer to N_c as the *spreading factor*, which is typically a large integer (e.g., 64, 128) for speech applications. In the DS-CDMA examples given, the chip sequence changes each symbol period, so that the overall symbol pulse shape is time-dependent [$f(\tau)$ is replaced by $f_k(\tau)$]. Also, channel tap delays are typically modeled on the order of the chip period T_c, not the symbol period T. Thus, $\tau(\ell) = \ell T_c/M$. As in the narrowband case, we assume $M = 1$.

As in the narrowband case, the receiver correlates to the symbol pulse shape. For each symbol period k, it produces a "despread" value for each of the L channel taps:

$$r_{k,\ell} = \int f_k^*(\tau)y(\tau + \tau(\ell))\,d\tau \quad \ell = 1, \ldots, L \tag{10}$$

In practice, this involves filtering matched to the chip pulse shape followed by correlation (despreading) using the chip sequence for symbol k. Assuming the spreading factor is large enough, the contribution from adjacent symbols (ISI) can be ignored. Thus, for symbol period k, the despread value for the ℓth channel tap can be modeled as

$$r_{k,\ell} \approx b_k \sum_{\ell=0}^{L-1} c(\ell, kT)R_{f_k f_k}(kT_c - \ell T_c) + z_{k,\ell} \tag{11}$$

Typically $R_{f_k f_k}(iT_c) \approx \delta(i)$ (e.g., when N_c is large), so that

$$r_{k,\ell} \approx c(\ell, kT)b_k + z_{k,\ell} = h_k(\ell)b_k + z_{k,\ell} \tag{12}$$

Comparing (12) to (5), we see that the DS-CDMA case can be treated as L separate, one-tap channels.

The RAKE receiver [9] combines signal energy from each signal image to form a decision variable. For BPSK modulation, this gives the detected bit value

$$\hat{b}_k = \text{sign}\left(\text{Re}\left\{\sum_{\ell=1}^{L} \hat{h}_k^*(\ell, kT)r_{k,\ell}\right\}\right) \tag{13}$$

Observe that the despread values are weighted by the conjugates of the channel coefficient estimates, then added together. Thus, channel estimates are needed to combine the signal images properly.

3. MODELS FOR CHANNEL TRACKING

Channel tracking approaches are often developed from a model of the channel, such as the Rayleigh fading model described in Section 2. However, to obtain reasonable complexity, the model used can be an approximate, simpler model. In this section, such models are described.

There are basically two types of models used to develop channel trackers. The type that is used most often is a *stochastic model*, in which the channel coefficient is modeled as a random process. The Jakes model is an example of a stochastic model. These models are fairly robust, as they allow for random fluctuations in the channel coefficient.

The second type of model is a *deterministic model*, in which the channel coefficient variation in time is represented by a function with parameters. This model is useful when representing the channel variation over a limited period of time, for which the channel variation fits well to a particular functional form. It is particularly useful in predicting future coefficient values when the channel is varying rapidly but the model parameters are varying slowly.

3.1. Stochastic Models

With stochastic models, the channel coefficients are modeled as stochastic random processes. The most commonly used models can be described using the Kalman state-space model [12] given in Fig. 5. This model is fairly general and can well approximate the Jakes model given in Section 2.

With the Kalman model, the $N_s \times 1$ state vector $\mathbf{s}_k$ includes the channel coefficients. The updated state value $\mathbf{s}_{k+1}$ depends on the previous value $\mathbf{s}_k$ through a state transition matrix $\mathbf{F}$ as well as the plant noise $\mathbf{u}_k$ through a gain matrix $\mathbf{G}$. The plant noise is assumed to be a zero-mean, complex white Gaussian process with covariance $\mathbf{I}$ (the identity matrix). This leads to Gaussian channel coefficients, which is consistent with the Rayleigh fading assumption.

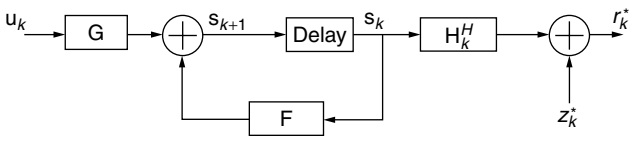

Figure 5. Kalman signal model.

The state is mapped to the output (observation) through a measurement matrix $\mathbf{H}_k$, which includes the symbol values. The output is observed in the presence of zero-mean, complex white Gaussian measurement noise z_k with mean-square value σ_z^2. The observation is defined as the conjugate of the received samples (r_k^*) so that standard expressions can be used. Mathematically, the system is described by the following *process* and *measurement* equations:

$$\mathbf{s}_{k+1} = \mathbf{F}\mathbf{s}_k + \mathbf{G}\mathbf{u}_k \quad \text{(process)} \tag{14}$$

$$r_k^* = \mathbf{H}_k^H \mathbf{s}_k + z_k^* \quad \text{(measurement)} \tag{15}$$

In general, these equations can model an autoregressive moving-average (ARMA) process [13].

One of the simplest channel models is the random-walk model [12]. With this model, the state vector is the conjugate channel coefficient vector ($\mathbf{s}_k = \mathbf{g}_k$), the measurement matrix is the symbol vector ($\mathbf{H}_k = \mathbf{b}_k$), $\mathbf{F} = \mathbf{I}$, and $\mathbf{G} = \sigma_g \mathbf{I}$, so that

$$\mathbf{g}_{k+1} = \mathbf{g}_k + \mathbf{u}_k \tag{16}$$

$$r_k^* = \mathbf{b}_k^H \mathbf{g}_k + z_k^* \tag{17}$$

Note that σ_g is a parameter related to tap strength.

A slightly more general channel model is a first-order autoregressive (AR) process (AR1) [14,15]. This process is similar to the random-walk process, except that $\mathbf{F} = \beta \mathbf{I}$, where β is a parameter between 0 and 1. The choice of β can be related to Doppler spread [14,16]. The *process* equation becomes

$$\mathbf{g}_{k+1} = \beta \mathbf{g}_k + \mathbf{u}_k \tag{18}$$

The random-walk and AR1 models are fairly simple, first-order models that are useful when the channel variation is relatively slow. Note that with these models, as with many other models, the channel coefficients corresponding to different taps are assumed to be uncorrelated (the off-diagonal elements of $\mathbf{F}$ and $\mathbf{G}$ are zero).

When channel variation is relatively fast, a second-order model is used, such as the second-order autoregressive (AR2) channel model [17,18]. Intuitively, such an approach can more accurately model the two spectral peaks that occur at plus and minus the Doppler spread (see Fig. 4). For the simple case of a one-tap channel model ($J = 1$), the model quantities become [17]

$$\mathbf{s}_k = \begin{pmatrix} g_k \\ -a_2 g_{k-1} \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} -a_1 & 1 \\ -a_2 & 0 \end{pmatrix},$$
$$\mathbf{G} = \begin{pmatrix} G_1 \\ 0 \end{pmatrix}, \quad \mathbf{H} = \begin{pmatrix} b_k \\ 0 \end{pmatrix} \tag{19}$$

where G_1 is a model parameter related to tap strength. In Refs. 19 and 20, higher-order AR modeling is used, including adaptive estimation of the AR parameters.

Higher-order modeling can also be obtained by tracking different order derivatives of the channel coefficients. For example, the channel tap and its derivative are tracked in the second-order integrated random-walk (IRW) channel model [17,21]. For the simple case of a one-tap channel model ($J = 1$), the model quantities become [17]

$$\mathbf{s}_k = \begin{pmatrix} g_k \\ \dot{g}_k \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{G} = \begin{pmatrix} 0 \\ G_2 \end{pmatrix}, \quad \mathbf{H} = \begin{pmatrix} b_k \\ 0 \end{pmatrix} \tag{20}$$

where $\dot{g}_k$ denotes the time derivative of g_k and G_2 is a model parameter. This approach can be generalized to include higher-order derivatives [22].

3.2. Deterministic Models

The time evolution of channel coefficients can also be expressed as a deterministic function of time with parameters. Once the function's parameters have been estimated, the channel coefficient as a function of time is determined. The parameters are assumed to vary more slowly than the channel coefficients, which is helpful when the channel varies rapidly.

One model is a polynomial function of time [23,24]. For example, quadratic variation of the channel can be represented as

$$g_k = d_0 + d_1 k + d_2 k^2 \tag{21}$$

The model parameters can be estimated and tracked using a least-squares approach. Model order can be determined by the fading rate, signal-to-noise ratio (SNR), and the duration of the received data. Linear and quadratic functions are most commonly used.

Another deterministic model is the complex sinusoidal model [25]. With this model, a tap is modeled as

$$g_k = \sum_{n=1}^{N_e} A_n e^{j(2\pi f_n k T_s + \phi_n)} \tag{22}$$

where A_n, f_n, and ϕ_n are the amplitude, frequency, and phase of the nth exponential, respectively, and N_e is the number of exponentials (typically <9).

4. FILTERING APPROACHES FOR CHANNEL TRACKING

When there is a sufficiently strong pilot channel or sufficient pilot symbols, the channel can be tracked by filtering channel measurements obtained from the pilot information. The filter smooths the noisy measurements over time and works best when the channel estimate is based on future as well as past channel measurements. Specifically, for a given filter, channel estimation performance depends on the pilot information, fading channel characteristics, and noise level. Pilot information, in terms of how much energy and how often it is available, is a tradeoff between minimizing overhead and optimizing channel estimation performance. For example, with pilot symbols, how often symbols must be sent depends on how rapidly the channel is changing.

In this section, we first examine filtering approaches based on continuous measurements of the channel, which can be obtained from a pilot channel. The simple moving-average filter is examined, as well as the more advanced Wiener filter. Learning the filter weights adaptively,

using adaptive filter techniques, is also discussed. We then examine filtering approaches based on discontinuous measurements of the channel, which can be obtained from pilot symbols. Simple linear interpolation is discussed, as well as Wiener interpolation. To simplify the discussion, the example of a one-tap channel model ($J = 1$) is used throughout this section.

4.1. Estimation Using a Pilot Channel

When a continuous pilot channel is available, a sequence of *channel measurements* can be obtained, as illustrated in Fig. 6. From (8) or (12), measurements of $h_k(0)$ can be obtained by multiplying r_k by b_k^* (assuming $|b_k|^2 = 1$). To estimate the conjugate of $h_k(0)$, which is $g_k(0)$ or simply g_k, we use $r_k^* b_k$ for the channel measurements. These measurements are filtered, giving

$$\hat{g}_k = \sum_{n=N_1}^{N_2} w_{n,k}^* [r^*(k-n)b(k-n)] = \mathbf{w}_k^H \tilde{\mathbf{g}} \tag{23}$$

where $\hat{g}_k$ is the channel estimate at the kth sample position, $\mathbf{w}_k$ represents the vector filter weights as a function of time k, and $\tilde{\mathbf{g}}$ is a vector of measurements. Typically the filter "slides" across the measurements, providing a continuous sequence of channel estimates. The filter weights change slowly in time (k), due to changes in the radio environment.

The parameters N_1 and N_2 are integers ($N_2 \geq N_1$). If only the past samples are used for estimation ($N_1 > 0$), then this operation is called "prediction." Often one-step prediction is used ($N_1 = 1$). If future samples are used ($N_1 < 0$), then this is called "smoothing." In the subsequent subsections, different choices for the filter weights are given.

4.1.1. Moving-Average Filter. The moving-average or sliding-rectangular-window approach is commonly used [26–28]. The channel estimate at time k is obtained by averaging measurements from time $N_1 = k - N$ through $N_2 = k + N$ [i.e., $w_{k,n} = 1/(2N+1)$ in (23)]. The sliding-window approach implies a channel model in which the channel is constant over the averaging window period. The choice of window size is a tradeoff between tracking ability and noise suppression [26]. Thus, it depends on Doppler spread and signal-to-noise ratio (SNR) [28].

4.1.2. Wiener Filtering. With Wiener filtering, the filter weights are designed to minimize the mean-square error (MSE) between the channel estimate and the true channel coefficient [29,30]. The vector of filter weights is given by solving the Wiener–Hopf equation [12]

$$\mathbf{w}_k = \mathbf{R}_{\tilde{g}}^{-1} \mathbf{p} \tag{24}$$

where $\mathbf{R}_{\tilde{g}}$ is the correlation matrix of the measurement vector ($\mathbf{R}_{\tilde{g}} = \mathrm{E}\{\tilde{\mathbf{g}}\tilde{\mathbf{g}}^H\}$) and $\mathbf{p}$ is the correlation vector between the measurement vector and the true channel coefficient ($\mathbf{p} = \mathrm{E}\{\tilde{\mathbf{g}} g_k^*\}$). These quantities typically change slowly in time.

The expressions for $\mathbf{R}_{\tilde{g}}$ and $\mathbf{p}$ depend on the model for the channel coefficient and which channel measurements are used. Consider a simple example, in which the channel is to be estimated at time kT using measurements at times $(k-1)T$, kT, and $(k+1)T$. Also, assume that the channel follows the model given in (3) and has a mean-square value of 1. Then, the Wiener filter quantities are given by

$$\mathbf{R}_{\tilde{g}} = \begin{bmatrix} 1+\sigma_z^2 & J_0(2\pi f_D T) & J_0(2\pi f_D 2T) \\ J_0(2\pi f_D T) & 1+\sigma_z^2 & J_0(2\pi f_D T) \\ J_0(2\pi f_D 2T) & J_0(2\pi f_D T) & 1+\sigma_z^2 \end{bmatrix},$$

$$\mathbf{p} = \begin{bmatrix} J_0(2\pi f_D T) \\ 1 \\ J_0(2\pi f_D T) \end{bmatrix} \tag{25}$$

where σ_z^2 is the noise power. In this example, the Wiener filter design requires knowledge of Doppler spread (f_D) and noise power (σ_z^2). The filter design can be obtained on the basis of the worst-case expected Doppler spread value [31]. Alternatively, the Wiener quantities $\mathbf{R}_{\tilde{g}}$ and $\mathbf{p}$ can be estimated [29].

Approximations to the Wiener filter can be used. A simple approximation is to use a lowpass filter with a cutoff frequency greater than or equal to the maximum expected Doppler frequency [30,32]. In Ref. 33, the channel is approximately modeled as having constant amplitude and linearly varying phase, and other approximations are also made.

4.1.3. Adaptive Filter. Adaptive filtering approaches can be used to "learn" the filter weights [34,35]. The filter output for time k is compared to the channel measurement at time k to generate an error signal, which is used to update the filter weights. Updating approaches are given in Section 5. This approach is often used for prediction.

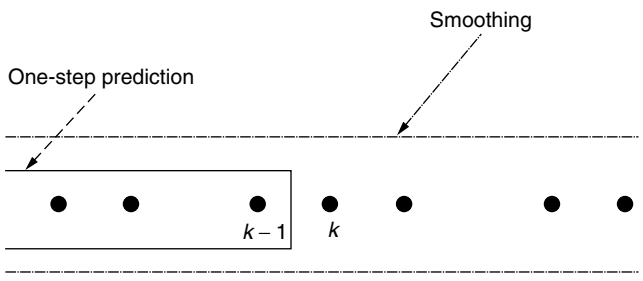

Figure 6. Prediction and smoothing of channel measurements.

4.2. Estimation Using Pilot Symbol Clusters

The channel can be estimated by periodically inserting one or more pilot symbols into the stream of data. Like the pilot channel case, channel measurements can be obtained at the pilot symbol locations. When there is a cluster of pilot symbols, it is often assumed that the channel is approximately constant over the cluster, so that these measurements can be added to give one measurement. In the case of very long pilot clusters, the cluster can be divided into smaller segments [36].

For the case of a multitap channel model, a time-invariant approach [7] can be used to obtain a channel measurement using a cluster of pilot symbols [37]. Another

approach is to run a recursive channel tracker over the pilot cluster [38].

4.2.1. Linear Interpolation. One of the simplest forms of channel estimation using pilot symbols is linear interpolation [4]. With linear interpolation, the channel estimate at a certain time period is a linear combination of the two "nearest" channel measurements. For example, suppose that there are measurements from pilot symbols at times $k = 0$ and $k = M$, denoted $\tilde{g}_0$ and $\tilde{g}_M$, respectively. Then, the channel estimate at time k, $0 < k < M$, is given by

$$\hat{g}_k = w_{0,k}\tilde{g}_0 + w_{M,k}\tilde{g}_M \tag{26}$$

where $w_{0,k}$ and $w_{M,k}$ are given as

$$w_{0,k} = \frac{M-k}{M}, \quad w_{M,k} = \frac{k}{M} \tag{27}$$

Linear interpolation can be viewed as applying a filter with symbol-spaced taps to the channel measurements, which contain zeros at the unknown data symbol points, as illustrated in Fig. 7.

Other simple interpolation filters include lowpass filters [3,38], Gaussian filters [4], and truncated Nyquist interpolation [37], as well as other filter forms [39]. Sometimes there is a tradeoff between using a simpler filter but requiring more closely spaced pilot symbols [4].

4.2.2. Wiener Interpolation. The Wiener filter described previously can also be applied to discontinuous channel measurements [36,40–42]. Continuing with the example given previously, suppose that the channel is to be estimated at time kT using pilot symbol measurements at times $(k-2)T$ and $(k+5)T$. Then, the Wiener filter quantities would be given by

$$\mathbf{R}_{\tilde{g}} = \begin{bmatrix} 1+\sigma_z^2 & J_0(2\pi f_D 7T) \\ J_0(2\pi f_D 7T) & 1+\sigma_z^2 \end{bmatrix}, \quad \mathbf{p} = \begin{bmatrix} J_0(2\pi f_D 2T) \\ J_0(2\pi f_D 5T) \end{bmatrix} \tag{28}$$

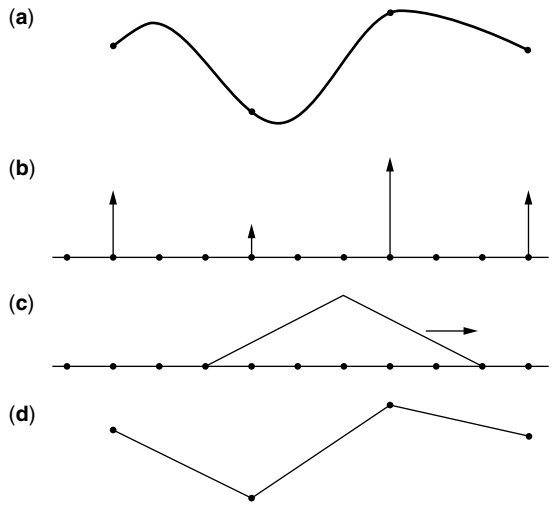

Figure 7. Linear interpolation filtering using pilot symbols: (**a**) fading channel, (**b**) measurements at pilot locations, (**c**) interpolation filter, (**d**) estimated channel.

Observe that the Wiener filter quantities will be different for time $(k+1)T$, requiring the filter weights to change. In general, Wiener interpolation is more complex than the previously described filtering approaches, but its performance is usually better, depending on the accuracy of the Wiener filter quantities.

4.3. Summary

Filtering approaches track the channel by filtering (smoothing) measurements of the channel. Simple filters, with fixed filter coefficients, work well when the channel variation is slow. When the channel variation is rapid, Wiener filtering works better. However, Wiener filtering requires knowledge of the statistics of the fading process and the statistics of the measurement noise process. The fading process statistics can be related to parameters of a channel model, such as Doppler spread and average channel coefficient power. The measurement noise process statistics are usually represented as a noise power or signal-to-noise ratio (SNR). When such information is unavailable, it is possible to "learn" good filter weights using adaptive filter techniques.

5. RECURSIVE APPROACHES FOR CHANNEL TRACKING

With recursive approaches, channel measurements are used one at a time to update channel estimates. For example, recursive approaches are often used in conjunction with data-directed tracking, in which channel estimates are used to detect a data symbol. The detected symbol value is then used to form a channel measurement for updating the channel estimates before detecting the next symbol. Data-directed tracking will be discussed in detail in Sections 6 and 7. Recursive approaches can also be used with pilot channel measurements as an alternative to filtering approaches.

To get started, an initial channel estimate value is needed. The simplest method is to set the initial value to zero, which means that there is a delay before the channel estimate becomes reliable. Another common method is to initially estimate the channel from a training sequence.

In this section, recursive channel tracking approaches are developed assuming a continuous sequence of known symbols (e.g., pilot channel). We start with two simple, related approaches, the least-mean-square (LMS) algorithm and the exponential filter. We then continue with more complex approaches, the recursive-least-squares (RLS) and Kalman filtering approaches. An approximation to the Kalman filter, the Kalman LMS approach, is then discussed.

5.1. Least-Mean-Square (LMS) Algorithm

The least-mean-square (LMS) algorithm [12,43] is one of the simplest approaches to channel tracking. LMS channel tracking is performed according to

$$\hat{\mathbf{g}}_{k+1} = \hat{\mathbf{g}}_k + \mu \mathbf{b}_k e_k^* \tag{29}$$

$$e_k = r_k - \hat{\mathbf{g}}_k^H \mathbf{b}_k \tag{30}$$

In essence, at symbol period k, an error e_k between what is received and what is modeled is formed. This error is used to update the channel coefficient estimate for the next symbol period. The step size μ is a parameter.

For a time-invariant channel, LMS channel tracking can be interpreted as an iterative, stochastic gradient approach for finding the channel coefficients that minimize the mean-square error (MSE) between the *received samples* and the model of the received samples [43]. For two noncomplex (real) channel coefficients, the MSE as a function for the two channel coefficients has a bowl shape [43]. At symbol period k, the LMS algorithm forms a noisy estimate of the slope or gradient at the place on the bowl corresponding to the current channel coefficient estimates. It then updates the taps in the direction of the negative gradient, so as to find the bottom of the bowl. Selection of the step size μ is a tradeoff between rate of convergence and how noisy the model is at convergence (misadjustment noise). For a time-varying channel, the step size μ trades tracking ability for misadjustment noise.

The LMS algorithm is a popular approach for channel tracking [44–46]. It can be derived from the Kalman filter (see Section 5.4), assuming a random-walk model for the channel coefficients [1]. The "leaky" LMS algorithm [12] [obtained by multiplying the first term on the right-hand side of (29) by leakage factor β] can be derived from the Kalman filter assuming an AR1 model [16]. The LMS structure has been further generalized [47], introducing additional parameters whose values are based on first-order or higher-order models of the channel coefficients. Conventional LMS and leaky LMS are special cases of this general, "Wiener LMS" approach.

Different step sizes can be used for different taps depending on the average tap power [16,48], which can also be derived from a Kalman filter formulation [16]. Note that the step size can be adaptive in time [49,50].

5.2. Exponential Filtering (Alpha Tracker)

Exponential filtering, also referred to as an *alpha tracker*, is commonly used with one-tap channels [51,52]. The channel estimate is updated using

$$\hat{g}_{k+1} = \alpha \hat{g}_k + (1-\alpha)\left\{r_k^* b_k\right\} \tag{31}$$

This approach can be derived from the LMS tracker by assuming that the symbols have constant magnitude ($|b_k| = 1$) [51]. It can also be interpreted as a filtering approach employing a first-order infinite-impulse-response (IIR) filter.

5.3. Recursive Least-Squares (RLS)

Recursive least-squares (RLS) [12,43] has also been applied to channel tracking, due to its rapid convergence properties. Conventional RLS channel tracking is performed according to

$$\hat{\mathbf{g}}_{k+1} = \hat{\mathbf{g}}_k + \left(\frac{\mathbf{A}_k}{\lambda + \mathbf{b}_k^H \mathbf{A}_k \mathbf{b}_k}\right) \mathbf{b}_k e_k^* \tag{32}$$

$$\mathbf{A}_{k+1} = \frac{1}{\lambda}\left(\mathbf{A}_k - \frac{\mathbf{A}_k \mathbf{b}_k \mathbf{b}_k^H \mathbf{A}_k}{\lambda + \mathbf{b}_k^H \mathbf{A}_k \mathbf{b}_k}\right) \tag{33}$$

where e_k is given in (30). Compared to LMS, RLS updates a second quantity, the matrix $\mathbf{A}_k$. This quantity is typically initialized to a diagonal matrix with large diagonal entries. The term λ is the "forgetting factor" and, like the LMS step size, determines convergence/tracking rate and misadjustment noise properties. Typically, λ is chosen to be slightly less than 1.

RLS channel tracking can be viewed as finding the set of channel coefficients that minimizes a deterministic weighted squared error between the received samples and the modeled samples [43]:

$$E = |r_k - \mathbf{g}_{k+1}^H \mathbf{b}_k|^2 + \lambda |r_{k-1} - \mathbf{g}_{k+1}^H \mathbf{b}_{k-1}|^2 + \lambda^2 |r_{k-2} - \mathbf{g}_{k+1}^H \mathbf{b}_{k-2}|^2 + \cdots \tag{34}$$

As errors in modeling past received samples are weighted less, the RLS approach tracks the channel by trying to accurately model the most recent data. Because of the exponential weighting, this form of RLS algorithm is also referred to as *exponentially windowed RLS* (EW-RLS) [53,54]. Conventional EW-RLS has been used to track wireless channels [55,56]. It has also been extended to track the channel tap and its derivative [57,58]. Alternatively, a sliding-window RLS (SW-RLS) approach can be used [54], in which the window can be tapered based on statistical knowledge of the fading channel and SNR.

RLS channel tracking can be related to Kalman filtering, based on a first-order AR process with zero plant noise [12,59]. Improved tracking approaches have been developed by considering nonzero plant noise and a time-varying state transition matrix [60].

5.4. Kalman Filtering

Kalman filtering [12,13] provides a recursive form of MMSE filtering. For the Kalman signal model given previously, the corresponding one-step prediction Kalman filter is given by

$$\hat{\mathbf{s}}_{k+1} = \mathbf{F}\hat{\mathbf{s}}_k + \mathbf{K}_k e_k^* \tag{35}$$

$$\mathbf{P}_{k+1} = \mathbf{F}\left(\mathbf{P}_k - \frac{\mathbf{P}_k \mathbf{H}_k \mathbf{H}_k^H \mathbf{P}_k}{\mathbf{H}_k^H \mathbf{P}_k \mathbf{H}_k + \sigma_z^2}\right)\mathbf{F}^H + \mathbf{G}\mathbf{G}^H \tag{36}$$

where

$$\mathbf{K}_k = \frac{\mathbf{F}\mathbf{P}_k \mathbf{H}_k}{\mathbf{H}_k^H \mathbf{P}_k \mathbf{H}_k + \sigma_z^2} \tag{37}$$

and e_k is given by (30). Note that $\mathbf{K}_k$ is a $N_s \times 1$ vector and $\mathbf{P}_k$ is a $N_s \times N_s$ matrix. Also, the Kalman filter requires knowledge of $\mathbf{F}$, $\mathbf{G}$, and $\mathbf{H}_k$.

Kalman filtering has been applied to channel tracking using a variety of channel models, such as the random-walk model [1,61]. Using the random-walk expressions (16) and (17), Eqs. (35) through (37) simplify to

$$\hat{\mathbf{g}}_{k+1} = \hat{\mathbf{g}}_k + \mathbf{K}_k \mathbf{e}_k^* \tag{38}$$

$$\mathbf{P}_{k+1} = \left(\mathbf{P}_k - \frac{\mathbf{P}_k \mathbf{b}_k \mathbf{b}_k^H \mathbf{P}_k}{\mathbf{b}_k^H \mathbf{P}_k \mathbf{b}_k + \sigma_z^2}\right) + \sigma_g^2 \mathbf{I} \tag{39}$$

$$\mathbf{K}_k = \frac{\mathbf{P}_k \mathbf{b}_k}{\mathbf{b}_k^H \mathbf{P}_k \mathbf{b}_k + \sigma_z^2}. \tag{40}$$

Kalman filtering has been used with the AR1 model [14], higher-order AR models [19], and ARMA models [62]. When model parameters are unknown, extended Kalman filtering can be used to estimate the channel and the unknown parameters [11,63].

To reduce complexity, an approximate form of the Kalman filter can be used, which decouples the tracking of the different channel taps [15]. Another form of approximation is given in Section 5.5, as follows.

5.5. Kalman LMS

In Ref. 17, a series of approximations are applied to the Kalman filter to obtain a lower complexity tracking approach similar to LMS. The key approximation is to average out the effect of the time-varying symbol vector $\mathbf{b}_k$ (part of $\mathbf{H}_k$), which causes the Kalman gain $\mathbf{K}_k$ to vary with time. The resulting "Kalman LMS" (KLMS) approach was applied to two second order models: the IRW model and the AR2 model.

For a single channel tap, the KLMS tracking expressions for these two models are given by

$$\hat{\mathbf{s}}_{k+1} = \mathbf{F}\hat{\mathbf{s}}_k + \boldsymbol{\mu} b_k e_k^* \tag{41}$$

where $\boldsymbol{\mu}$ is a 2×1 vector of step sizes, and $\hat{\mathbf{s}}_k$ and $\mathbf{F}$ are defined earlier for the two models. The two elements in $\boldsymbol{\mu}$ are related by design formulas [17]. The KLMS AR2 form is particularly useful for rapid fading channels [18].

The IRW Kalman LMS form, which tracks the channel coefficient and its derivative, can alternatively be developed from a form of least-squares prediction [22]. This approach was extended to track acceleration (second derivative) as well.

5.6. Summary

When the channel varies slowly, simple approaches such as the LMS algorithm and the exponential filter work well. If rapid convergence at initialization is a concern, the RLS approach can be used. However, these three approaches are based on a first-order model of the channel coefficient. For rapid fading, a higher-order model is needed. In this case, the Kalman filter can be used, as it allows for higher-order models. To reduce complexity, the Kalman LMS approach is useful.

6. DATA-DIRECTED TRACKING, SEPARATE TRACKING

Data-directed tracking is used when there is insufficient pilot information. For systems with only an initial training sequence, the channel may vary significantly over the data portion of the received signal. For other systems, which employ a pilot channel or pilot symbols, data-directed tracking may be beneficial when the power allocated to the pilot information is low, so the channel estimates are very noisy.

In this section, we consider examples in which each channel coefficient is tracked separately. This includes narrowband systems in which there is only one channel tap as well as wideband systems. Joint tracking of multiple coefficients is addressed in Section 7.

6.1. Decision Feedback

With decision feedback, previously detected symbols are used to update the channel estimate before detecting the next symbol [51,52,64]. The detected symbol values fed back can be tentative decisions, with final decisions made using the updated channel estimates [11,22]. Decision feedback has been used with exponential filtering [52], polynomial modeling [65], linear prediction [33,66], and Kalman-based prediction [11].

Before making final symbol decisions, the channel can be estimated again, so that both channel estimation and symbol detection end up being performed twice [66,67]. In the first stage, conventional decision feedback is applied, in which channel estimates are based only on past decisions. In the second stage, channel estimates are based on first-stage decisions of future symbols as well as second-stage decisions of past symbols. The two-stage approach can be extended to multiple stages, further refining the channel estimate and data decisions [67,68]. Depending on the modulation, the first stage may not require channel estimation, as symbols can be detected noncoherently [68].

One problem with decision feedback is that decisions errors can cause the channel estimate to be phase-rotated from the true channel. For example, with BPSK modulation, decision errors correspond to a 180° rotation in the symbol values. To compensate for this, the channel estimates become rotated 180° with respect to the true channel coefficients. This is because the received signal can be equally modeled by an inverted symbol sequence and rotated channel coefficients, sometimes referred to as the *phase ambiguity problem*. Differential modulation can be used to mitigate this problem [51].

6.2. Per-Survivor Processing

Decision errors can also be mitigated by keeping multiple channel estimates. Ideally, a channel estimate should be formed for each possible sequence of symbols [64]. In practice, multiple channel estimates can be formed, corresponding to all possible values for the previous K symbols [29,69–71]. A cost function can be used to decide which channel estimate to keep. This approach can be interpreted as a form of per-survivor processing (PSP), which will be discussed in Section 7.

6.3. Data-Directed Tracking with Pilot Information

When the pilot information is weak, a combination of reference-assisted and data-directed channel tracking can be used. Similar to the case without pilot information, a multistage approach can be used [72,73]. In the first stage, a channel estimate is obtained from the pilot information and used to make tentative symbol decisions. In the second stage, these tentative decisions provide more channel measurements, which are used with the pilot information to produce a refined channel estimate and new symbol values. Note that in the first stage, it is possible to use a mixture of pilot information and decision feedback [34] or a PSP-based approach [29].

A PSP-based approach can be used with pilot information in a single-stage approach as well. Channel measurements from a weak pilot channel can be combined with

PSP-based data-directed channel measurements to form improved channel estimates for demodulation [70,71]. Alternatively, periodic pilot symbols can be used to simply constrain the symbol hypotheses of the PSP process [29,69]. This helps resolve phase ambiguity problem [69] as well as prevent the channel estimator from breaking down because of a high level of decision errors [29].

7. DATA-DIRECTED TRACKING, JOINT TRACKING

Data-directed tracking can also be used when multiple channel coefficients must be estimated together. In this situation, data symbols interfere with one another (ISI) and must be detected together using some form of equalization. Here we consider only equalization approaches that rely on channel estimates, focusing mostly on decision feedback equalization (DFE) and maximum-likelihood sequence estimation (MLSE). There is also the situation in which there may be only one channel coefficient, but the transmitter causes ISI due to the modulation (e.g., partial response pulse shaping).

First, the basic principles for DFE and MLSE are reviewed. Initial channel estimation using a training sequence is then discussed. Various data-directed tracking approaches are presented, showing the tradeoffs between tracking delay, symbol value accuracy, and complexity.

7.1. Equalization

Adaptive equalization has an extensive history [74,75]. In narrowband wireless communication systems, DFE and MLSE are two commonly used forms of equalization. To understand the basic principles of these approaches, consider the simple case of BPSK symbols ($b_k = \pm 1$) and a two-tap channel model, so that

$$r_k = g_k^*(0)b_k + g_k^*(1)b_{k-1} + z_k \tag{42}$$

The DFE, shown in Fig. 8, consists of a feedforward filter, a feedback filter, and a decision device [9]. Conceptually, the feedforward filter tries to collect all signal energy for b_k (which appears in both r_k and r_{k+1}) while suppressing intersymbol interference (ISI) from subsequent symbols (e.g., b_{k+1}). The feedback filter removes ISI from previous symbols (e.g., b_{k-1}). Notice that the feedforward filter introduces delay between when the first image of a symbol arrives and when that symbol is decided.

With MLSE, the likelihood of the received data samples, conditioned on the symbol values, is maximized [9]. The conditional loglikelihood of the kth data sample, assuming that z_k is Gaussian and uncorrelated in time, is related to the following metric or cost function:

$$M(\hat{b}_k, \hat{b}_{k-1}) = |r_k - (g_k^*(0)\hat{b}_k + g_k^*(1)\hat{b}_{k-1})|^2 \tag{43}$$

For different symbol sequence hypotheses ("paths"), this metric is accumulated, generating a path metric. Once all the data samples have been processed, the sequence corresponding to the smallest path metric determines the detected sequence. Intuitively, the metric indicates how well the model of the received data fits the actual received data.

A brute-force search of all possible sequences would require high computational complexity. However, it is possible to determine the smallest metric sequence through a process of path pruning known as the Viterbi algorithm [76]. This involves defining a set of "states" corresponding to a set of paths. Tentative decisions can be made after some delay D. The path "history" (sequence of symbol values) corresponding to the state with the best path metric after processing the kth sample can be used to determine the $(k - D)$th symbol value.

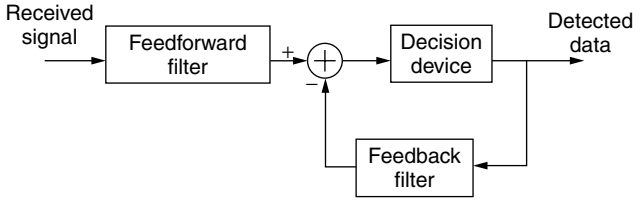

Figure 8. DFE receiver.

7.2. Initialization

A time-invariant approach [7] can be used to initially estimate the channel with a training sequence [77]. Recursive channel tracking can also be used to obtain an initial estimate [78] or to refine an estimate obtained by a time-invariant approach [18].

7.3. Decision Feedback

As in Section 6, decision feedback can be used with MLSE [44]. To obtain reliable tentative symbol decisions, a certain delay (D) is needed. To compensate for this delay, D-step channel prediction can be used, such as linear prediction [78] or a Kalman-based approach [18]. However, channel prediction becomes less reliable with larger D values. Thus, there is still a tradeoff between accuracy of symbol values and tracking delay.

There are several other issues related to decision feedback tracking and MLSE:

1. The "best" path can suddenly change, so that the detected symbol sequence does not correspond to any one path history. Regularization can be used to improve channel tracking in this situation [79].
2. As discussed in Section 6, the channel estimate can be phase rotated [80]. Bidirectional channel tracking can be used to resolve this problem [81].
3. Overmodeling the finite-impulse-response (FIR) channel can cause equalizer timing divergence after fading dips in fast-fading channels [18]. Figure 9 shows an example where a two-tap model is used when only one tap is needed. During recovery from a deep fade, the position of the nonzero tap might change (false lock or time slip). When this happens, the channel is, in fact, being tracked, but with the wrong delay. This problem can be mitigated by using

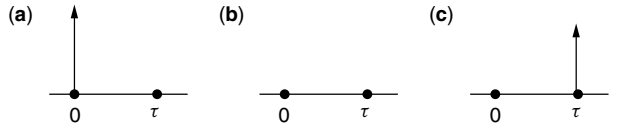

Figure 9. Time-slip problem, channel estimates (**a**) before, (**b**) during, and (**c**) after fade.

different recursive tracking step sizes for different taps [18] or by employing bidirectional tracking [82].

4. Finally, as in Section 6, a multistage approach can be used [29,83].

Decision feedback for channel estimation can also be used with DFE [14,45,48]. Similar to MLSE, delay can be addressed with prediction [14,48]. Decision feedback has also been applied to a form of linear equalization that employs channel estimates [84].

7.4. Per-Survivor Processing

For MLSE, tracking delay can be eliminated by keeping a different channel model for each state [85,86]. In the pruning process, the path that is kept also determines which channel model is updated for the new state. Such an approach is a form of *per-survivor processing* (PSP) [86]. While the channel estimate is usually updated after pruning, it is possible to update the channel estimate before pruning [87].

To reduce complexity, the number of channel models can be less than the number of states [88,89]. Conversely, to improve performance, the size of the state space can be increased [90] to create more channel models.

When the channel is estimated, Viterbi pruning does not necessarily lead to the smallest metric sequence [91]. This leads to keeping channel models for each sequence hypothesis (path) [90]. The M-algorithm [92] can be used to prune paths, keeping the M best paths [93].

8. CONCLUSION

Channel tracking is an important part of receiver design in digital wireless communication systems. Tracking approaches are based on a model of how the channel changes in time. First-order models are often used for slowly varying channels, whereas higher-order models are used for rapidly varying channels.

Reference-assisted channel estimation, using either pilot symbols or a pilot channel, is commonly used to estimate the time-varying channel impulse response. When reference information is unavailable or insufficient, data-directed tracking can be used. Obtaining reliable symbol decisions and reducing tracking delay are the main challenges. The tracking delay can be minimized by keeping multiple channel models, corresponding to different hypotheses of the data symbol values.

Currently, third-generation digital wireless communication systems are being deployed. As modulation formats for these systems require coherent reception, channel estimation will continue to be a key element in receiver design.

Acknowledgment

The authors would like to thank A. Khayrallah, K. Molnar, J. G. Proakis, and Y.-P. E. Wang for reviewing a draft of this article. The authors gratefully acknowledge the help of others in identifying references. Finally, the authors wish to thank their colleagues for many helpful discussions on channel estimation.

BIOGRAPHIES

Gregory E. Bottomley received his B.S. and his M.S. degrees from Virginia Polytechnic Institute and State University, Blacksburg, Virginia, in 1983 and 1985, respectively, and his Ph.D. degree from North Carolina State University, Raleigh, in 1989, all in electrical engineering.

From 1985 to 1987 he was with AT&T Bell Laboratories, Whippany, NJ, working in the area of sonar signal processing. In 1990, he was a visiting lecturer at North Carolina State University, Raleigh. Since 1991, he has been with Ericsson Inc., Research Triangle Park, NC, where he is currently a member of the Advanced Development and Research Department. He is listed as an inventor on over 30 patents in wireless communications and was a recipient of Ericsson's Inventor of the Year Award in 1997.

Dr. Bottomley is an associate member of Sigma Xi and a senior member of The Institute of Electrical and Electronics Engineers, Inc. (IEEE). In 1998, he was a recipient of the IEEE Eastern North Carolina Section Outstanding Engineer Award. He served as associate editor (1997–2000) and currently serves as editor for the *IEEE Transactions on Vehicular Technology*. His research interests are in baseband signal processing for wireless communications, including equalization, RAKE reception, and interference suppression.

Huseyin Arslan (eushura@rtp.ericsson.se) was born in Nazilli, Turkey, in 1968. He received a B.S. degree from Middle East Technical University, Ankara, Turkey, and M.S. and Ph.D. degrees from Southern Methodist University, Dallas, Texas, in 1992, 1994, and 1998, respectively, all in electrical engineering. Since January 1998, he has been at Ericsson research at RTP, North Carolina. His research interests are in baseband signal processing for mobile communications, including interference cancellation, channel estimation, modulation, demodulation, and equalization.

CHAOS IN COMMUNICATIONS

KUNG YAO
CHI-CHUNG CHEN
University of California
Los Angeles, California

1. INTRODUCTION

In 1963, Lorenz used a digital computer to study the numerical solutions of nonlinear dynamical systems modeling convection in the atmosphere. He found that even a very small difference in the initial conditions can lead to solutions that can grow rapidly apart with time [1]. The deterministic but unpredictable behaviors of certain classes of nonlinear dynamical systems have been called *chaos*. Later, Lorenz presented a talk with the title "Predictability: Does the flap of a butterfly's wings in Brazil set off a tornado in Texas?" Thus, the essence of the sensitivity of initial conditions to the long-term solutions of these chaotic systems has been colorfully called the "butterfly effect." Since that time, chaos has become a well-developed branch of mathematics, with applications to physics, biology, medicine, engineering, economics, and other fields. Chaos was also shown to be related to the work of fractal by Mandelbrot [2]. Researchers in nonlinear circuits and systems have found large numbers of fairly simple nonlinearities that can induce quite complicated chaotic solutions [3]. Since the early 1960s, thousands of papers and hundreds of books have been written on various aspects of chaos. Since then, a small-scale intellectual industry has been formed in exploiting chaos. Gleick's book, *Chaos: The Amazing Science of the Unpredictable,* which introduced chaos to the general public, is extremely readable, and was a bestseller when it was published [4]. Quoting Gleick's book (pp. 5–6), "The most passionate advocates of this new science go so far as to say that twentieth-century science will be remembered for just three things: relativity, quantum mechanics, and chaos." Chaos, they contend, has become the century's third great revolution in the physical sciences. Like the first two revolutions, chaos cuts away at the tenets of Newton's physics. As one physicist put it: "Relativity eliminated the Newtonian illusion of absolute space and time; quantum mechanics eliminated the Newtonian dread of a controllable measurement process; and chaos eliminates the Laplacian fantasy of "deterministic predictability." Of the three, the revolution in chaos applies to the universe as we see and touch, to objects at human scale. It remains to be seen whether the long-range impacts of chaos both to theory and applications are as profound as some advocates have claimed. In any case, for communication engineers not familiar with chaos, some useful books include: a very readable account of basic chaotic concepts by Williams [5], a medium-level graduate text on chaos by Hilborn [6], and an advanced treatise on stochastic aspects of dynamics and chaos by Lasota and Mackey [7]. Various introductory surveys, overviews, and special issue papers on chaotic communications have appeared elsewhere in the literature [3,8–14].

In the early 1990s, Pecora and Carroll [15] showed that despite the broadband nature of the spectrum, noiselike

behavior, and sensitivity to initial conditions inherented in chaotic systems, two chaotic systems can be synchronized. This rather remarkable discovery has caused much interest and created the research field of "chaotic communication." Many papers motivated by this work have been published since the early 1990s. The drive–response synchronization configuration that Pecora and Carroll proposed is shown in Fig. 1. We will use the Lorenz system example unless mentioned otherwise. If a chaotic system can be decomposed into two subsystems, a drive system x and a conditionally stable response system $\{y, z\}$ as shown in this example, then the identical chaotic system at the receiver can be synchronized when driven with a common signal. The reason for this is simple. In the absence of noise, the output signals y_r and z_r will follow the signals y and z since it is a stable subsystem. For more discussion on chaotic synchronization, see the paper by Pecora et al. [16].

On the basis of the self-synchronization properties of chaotic systems, various chaotic communication systems using chaos as carrier have been proposed. We summarize many of these systems in Section 2. Specifically, in Section 2.1, we deal with the chaotic masking modulation/demodulation scheme of Cuomo et al. [17], which was one of the earliest proposed methods to perform chaotic communication. In order to circumvent an inadequacy of chaotic masking modulation/demodulation due to the small amplitude of the information signal, the dynamical feedback modulation (DFM) scheme of Milanovic and Zaghloul [18] was proposed and treated in Section 2.2. In Section 2.3, we consider the chaotic switching modulation (CSM) scheme of Kocarev et al. [19]. In all three of these schemes, since the communication system performances strongly depend on the synchronization capability of the chaotic systems, the robustness ability of self-synchronization to the white noise needs to be explored [17,20]. However, it is generally difficult to obtain the analytic solutions to the nonlinear stochastic systems, in particular, the chaotic systems. The use of Monte Carlo (MC) simulation is a standard method for the evaluation of complicated communication systems over noisy channels. However, because of the nonlinear stochastic dynamical system modeling of these chaotic communication systems, standard deterministic MC simulation method turns out to be inadequate. In Section 2.4, we show the need to use Ito–Stratonovich stochastic integrations for the performance evaluation of continuous-time chaotic communication systems. Specifically, we show that the use of conventional Runge–Kutta numerical integration method can yield incorrect results. Furthermore, the precise evaluation of the performance of many of these chaotic communication systems showed the required SNRs (signal-to-noise ratios) to achieve nominal acceptable error probabilities are significantly higher than those conventional (nonchaotic) communication systems.

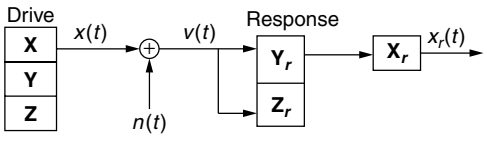

Figure 1. Drive–response self-synchronization scheme.

In order to mitigate the poor system performance of the chaotic modulation schemes due to the ill effect of the self-synchronizing aspects of these schemes, Dedieu et al. [21] first proposed the chaos shift-keyed modulation(CSK), then Kennedy and Kolumban [22–24] proposed the differential shift-keyed modulation (DCSK), and later the frequency modulation DCSK (FM-DCSK) schemes [25,26]. In Section 2.5, we discuss these different forms of CSK schemes and show in particular the FM-DCSK scheme to be competitive to conventional digital modulation schemes in performance. This is to be contrasted to earlier chaotic modulation schemes, which are intellectually interesting but not practical for implementation on a real communication system.

The symbolic dynamic model is one tool that can be used to analyze a complex chaotic dynamical system. Based on the symbolic dynamics of a chaotic system and using chaos control technique, Hayes et al. [27,28] proposed that the information message can be embedded into the chaotic dynamics for transmission to the receiver. This approach is considered in Section 3. Since it is usually difficult to estimate a chaotic signal, Papadopoulos and Wornell [29] developed a maximum-likelihood estimator for the tent map. By setting the information data into the initial condition, the information data can be encoded using a chaotic dynamical system, and can be retrieved by estimating the initial condition by Chen and Wornell [30]. These issues are considered in Section 4.

Instead of transmitting the chaotic waveform, a chaotic pulse position modulation (CPPM) scheme was proposed [31]. This proposed system is similar to an ultra-wide-bandwidth impulse radio [32] that offers a very promising communication platform, especially in a severe multipath environment. A pulse position method is used to modulate the binary information onto the carrier. The separation between the adjacent pulses is chaotic because of the dynamical system with irregular behavior. These methods are discussed in Section 5.

Since the 1960s, first for military, then later for commercial applications, code-division multiple access (CDMA) communication techniques have been used extensively. Early special issues on CDMA appeared [33,34], but extensive paper publications and books appeared later. More recently, the use of CDMA for cellular telephone communication has provided explosive worldwide interests in CDMA systems. System performance of a direct-sequence CDMA (DSCDMA) system critically depends on the auto- and cross-correlation properties of the *spreading sequences*. The chaotic signals have low non-zero-shift autocorrelation and all cross-correlation properties due to the intrinsic broad spectrum and sensitivity to initial conditions. The sequences generated by a logistic map can also be used for a DSCDMA communication system as first proposed [49]. The use of the correlation function characteristics of some specific chaotic sequences and its comparison to m sequences/Gold sequences have been discussed [50,51,53,54,56,57,59–61]. Such optimum sequences derived and generated on chaos-based concepts can support about 15% more users than previously known sequences generated by deterministic methods. These issues are discussed in Section 6. Finally, two

distinct applications of chaos-related stochastic processes to optical communication based on chaos in semiconductor lasers [65] and modeling of radar and radio propagation effects [66,74] are considered in Section 7.

2. COMMUNICATIONS USING CHAOS AS CARRIER

The use of modulating an aperiodic chaotic waveform, instead of a periodic sinusoidal signal, for carrying information messages has been proposed, in particular, chaotic masking, dynamical feedback, chaotic switching, chaos shift keying, and inverse approach modulations [10,17–19,21,22,35,36]. In this section, we summarize several of these chaotic modulation schemes and the impact of self-synchronization in the demodulation process.

2.1. Chaotic Masking Modulation

The basic idea of a chaotic masking modulation (CMM) scheme is based on chaotic signal masking and recovery. As shown in Fig. 2, we add a noiselike chaotic signal to the information signal at the transmitter, and at the receiver the masking signal is removed. The received signal, consisting of masking and information signals, is used to regenerate the masking signal at the receiver. The masking signal is then subtracted from the received signal to retrieve the information signal. The regeneration of the masking signal can be done by synchronizing the receiver chaotic system with the transmitter chaotic system. This communication system could be used for analog and digital information data. Cuomo et al. [17] have built a Lorenz system circuit and demonstrated the performance of a CMM system with a segment of speech from the sentence "He has the bluest eyes." The communication system performance truly relies on the synchronization ability of chaotic system. The masking properties of this scheme work only when the amplitudes of the information signals are much smaller than the masking chaotic signals.

2.2. Dynamical Feedback Modulation

To avoid the small-amplitude restriction of the information signal, another modulation scheme, called *dynamical feedback modulation* (DFM), has been proposed by Milanovic and Zaghloul [18] and is shown in Fig. 3. The basic idea is to feed back the information signal into the chaotic transmitter in order to ensure the identical input signal for the chaotic transmitter and the receiver. Specifically, the transmitted signal $v(t) = x(t) + m(t)$, consisting of the information signal $m(t)$ and the chaotic signal $x(t)$, is communicated to the receiver which is identical to the chaotic

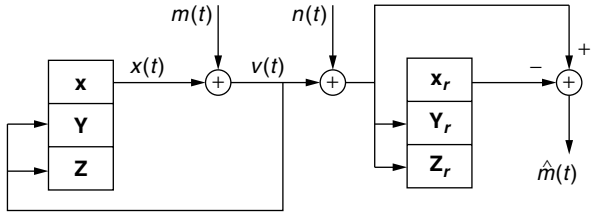

Figure 3. Dynamical feedback modulation.

transmitter. Since the reconstructed signal $x_r(t)$ will be identical to $x(t)$ in the absence of noise $n(t)$, the information signal $m(t)$ can be decoded from the received signal by using $\hat{m}(t) = x(t) + m(t) - x_r(t)$.

This *analog* communication technique can be also applied to binary data communication by setting $m(t) = A$ if binary information data are one, and $m(t) = -A$ if binary data are zero. The sufficient statistic η_d of detection is the average of the error signal at the receiver after discarding a transient period before synchronization, and is given by

$$\eta_d = \frac{1}{T}\int_{t_0}^{t_0+T} e_d(t)\,dt \tag{1}$$

where the error signal $e_d(t)$ is defined by

$$e_d(t) = v(t) + n(t) - x_r(t) \tag{2}$$

Since the feedback information will affect the chaotic property, the information level A should be scaled carefully to make the transmitter still chaotic to maintain the desired communication security.

2.3. Chaotic Switching Modulation

In contrast to DFM, the chaotic switching modulation (CSM) communication system, as illustrated in Fig. 4, does not suffer the above scaling problem as discussed by Kocarev et al. [19]. The basic idea is to encode the binary data $m(t)$ with different chaotic attractors by modulating the transmitter parameters and then transmitting the chaotic drive signal $x_m(t)$. At the receiver, the parameter modulation will produce a synchronization error between the received drive signal and the regenerated drive signal with an error amplitude that depends on the modulation. Using the synchronization error, the binary data can be detected.

In Fig. 4, the parameter b of the transmitter is modulated by the binary data $m(t)$. Assume that the communication link is an AWGN channel; the synchronization

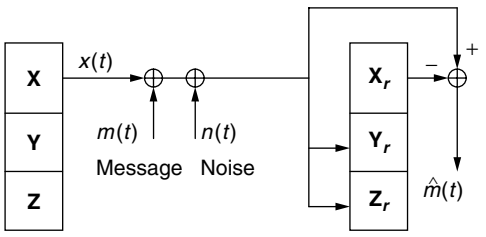

Figure 2. Chaotic masking modulation.

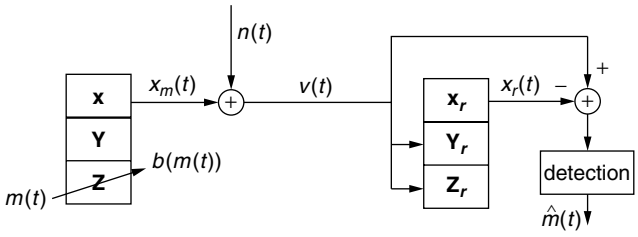

Figure 4. Chaotic switching modulation.

error $e_s(t)$ is defined in Eq. (3) as the difference between the noisy received signal $r(t) = x_m(t) + n(t)$ and the regenerated signal $x_r(t)$ at the receiver, and is given by

$$e_s(t) = r(t) - x_r(t) \tag{3}$$

For this binary hypothesis problem, the sufficient statistic η_s is the squared mean of the synchronization error after discarding some transient data and is defined by

$$\eta_s = \frac{1}{T}\int_{t_0}^{t_0+T} e_s^2(t)\,dt \tag{4}$$

Synchronization of the chaos signal is a common feature of the above three chaotic modulation–demodulation schemes, and system performance depends crucially on this synchronization capability. When the channel condition is so poor that it is impossible to achieve chaotic synchronization, different chaotic modulation techniques for digital communication, based on variations of chaos shift keying modulation (CSK) (see Fig. 5, have been introduced. The details of this approach will be discussed in Section 2.5.

2.4. Numerical Algorithm and Performance Evaluation of Chaotic Communications Based on Stochastic Calculus

Because of inherent nonlinearity of chaotic systems, the analytic performance evaluation of a chaotic communication system using chaos as a carrier is in general very difficult, and thus a numerical simulation approach is needed as shown by Chen and Yao [20]. It is known that commercial numerical computational packages using the standard Euler or Runge–Kutta (RK) algorithm designed for a deterministic differential equation to approximate the solution of a nonlinear stochastic differential equation (SDE) will incur significant errors [38]. This is particularly true for a nonlinear chaotic dynamical system modeling the transmitter inputting into an AWGN channel and followed by another nonlinear chaotic dynamical system.

We use the stochastic calculus approach to perform the integration algorithm for the sample functions of nonlinear dynamic systems excited by the stochastic white noise. Depending on the precise interpretation of the white noise, there are two different solutions to the SDE based on the Stratonovich or Ito integral [40–42]. Using the conversion between them, a correct numerical integration algorithm in the Ito sense is introduced. With this algorithm, the correct error probability of the robust self-synchronization

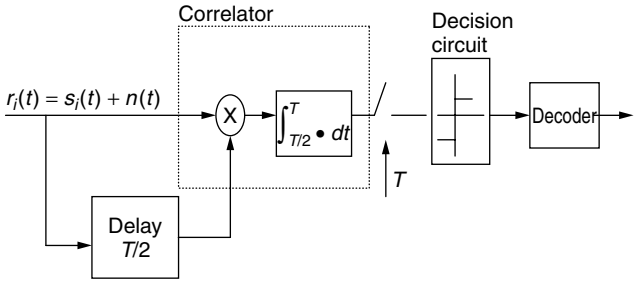

Figure 5. Differential chaos shift keying receiver.

Lorenz communication system with AWGN perturbation can be evaluated numerically. In the following, we present the numerical problem when evaluating the synchronization ability of the Lorenz system. Details regarding the error probabilities of CSM and DFM systems are given in Ref. 20.

2.4.1. Problem Description. A modified Lorenz system [17] is given by

$$\begin{aligned}\frac{dx}{d\tau} &= \sigma(y(t) - x(t))\\ \frac{dy}{d\tau} &= rx(t) - y(t) - 20x(t)z(t)\\ \frac{dz}{d\tau} &= 5x(t)y(t) - bz(t)\end{aligned} \tag{5}$$

where σ, r, and b are system parameters, and $\tau = t/K$, in which K is a timescaling factor. To characterize the robust ability of synchronization to white noise, the modified Lorenz system can be interpreted as the drive system, the signal $v(t)$ is the received waveform at the response system as defined by

$$\begin{aligned}\frac{dx_r}{d\tau} &= \sigma(y_r(t) - x_r(t))\\ \frac{dy_r}{d\tau} &= rv(t) - y_r(t) - 20v(t)z_r(t)\\ \frac{dz_r}{d\tau} &= 5v(t)y_r(t) - bz_r(t)\end{aligned} \tag{6}$$

where $v(t) = x(t) + n(t)$, and $n(t)$ is white Gaussian noise with zero mean and power spectrum density σ_n^2. The chosen coefficients are $\sigma = 16$, $r = 45.6$, and $b = 4$.

We define the vector $\mathbf{X} = [x, y, z, x_r, y_r, z_r]^T$. The entire system composed of the drive subsystem and the response subsystem can be viewed as a nonlinear system with an external white-noise input, and has the following standard form

$$\dot{\mathbf{X}}_i = f_i(\mathbf{X}) + g_i(\mathbf{X})n(t),\ i = 1, 2, \ldots, 6 \tag{7}$$

where f_1, f_2, f_3 are the modified Lorenz system equations, and

$$\begin{aligned}g_1 &= g_2 = g_3 = g_4 = 0\\ f_4 &= \sigma(y_r - x_r)\\ g_5 &= r - 20z_r\\ f_5 &= rx - y_r - 20xz_r\\ g_6 &= 5y_r\\ f_6 &= 5xy_r - bz_r\end{aligned} \tag{8}$$

and $n(t)$ is the WGN with zero mean and unity variance. The evolution of (7) is then given by

$$\mathbf{X}_i(t_0 + h) = \mathbf{X}_i(t_0) + \int_{t_0}^{t_0+h} f_i(\mathbf{X})\,dt + \int_{t_0}^{t_0+h} g_i(\mathbf{X})n(t)\,dt \tag{9}$$

A commonly made mistake is to treat the third term of (9) using the deterministic ordinary calculus method and apply the standard Euler or RK integration algorithm. Thus, assuming $g_i(\mathbf{X})$ is a smooth function, the integration result can be approximated by

$$\int_{t_0}^{t_0+h} g_i(\mathbf{X})n(t)\,dt \approx g_i(\mathbf{X}(t_0))Y_1 h \tag{10}$$

where Y_1 is a Gaussian random variable with zero mean and unity variance.

In order to illustrate this issue clearly, we use the preceding algorithm to characterize the robust self-synchronization ability of a Lorenz system by numerical computation as considered in Ref. 17. The simulation results are shown in Fig. 6 with the middle dashed curve, which is consistent with that in Ref. 17. The definitions of the input SNR and output SNR quantities in Fig. 6 are defined by input $\text{SNR} = 10\log_{10}(\sigma_x^2/\sigma_n^2)$, and output $\text{SNR} = 10\log_{10}(\sigma_x^2/\sigma_e^2)$, where σ_x^2 is the power of transmitted signal $x(t)$, and σ_e^2 is the power of the synchronization error $e(t) = x(t) - x_r(t)$. Clearly, we note the output SNR varies with the integration step size using the standard Euler/RK integration algorithm. Furthermore, the output SNR decreases by 3 dB as the step size is doubled. This is not a reasonable consequence for a given system which is excited by a stationary external white noise.

2.4.2. Numerical Algorithm for SDE. For the above-described chaotic system, the corresponding SDE in the sense of Ito is

$$dX_i = f_i(\mathbf{X})\,dt + g_i(\mathbf{X})\,dw(t), \mathbf{X}(t_0) = \mathbf{X}_0 \tag{11}$$

where $w(t)$ is the one-dimensional Wiener process or Brownian motion, and $\mathbf{X}_0$ is the initial conditions.

Mannella and Palleschi [39] have derived an accurate integration algorithm in the sense of Stratonovich [40], which treats the white noise as the limiting behavior of band-limited white noise, and the approximate results are summarized by the following algorithm

$$X_i(h) - X_i(0) = \delta X_i^{1/2} + \delta X_i^1 + \delta X_i^{3/2} + \delta X_i^2 + \cdots \tag{12}$$

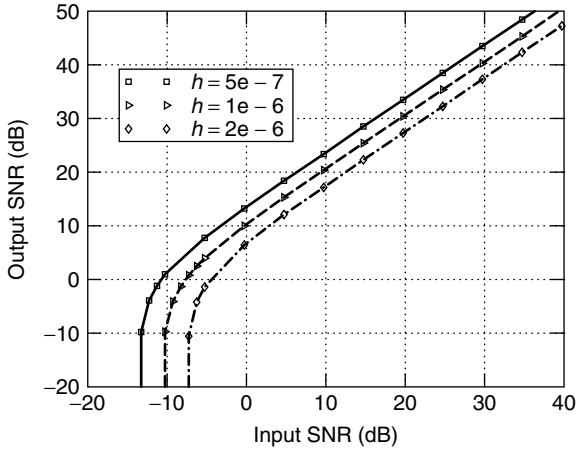

Figure 6. Robust ability for incorrect algorithm simulation with $K = 2505$.

where h is the integration step size, and $\delta X_i^{1/2} = g_i \int_0^h dw(t) = \sqrt{h} g_i Y_1$, where Y_1 is a Gaussian random variable with zero mean and unity variance, while the remaining terms are given in Eq. (6) of Ref. 39.

According to Stratonovich [40–42], the integral in the sense of Stratonovich can be converted into an Ito integral by adding one correction term. That is, if the SDE is modified and is given in the sense of Stratonovich as

$$dX_i = \left[f_i(\mathbf{X}) - \frac{1}{2}\sum_J \frac{\partial g_i(\mathbf{X})}{\partial \mathbf{X}_J} g_J(\mathbf{X}) \right] dt + g_i(\mathbf{X})\,dw(t) \tag{13}$$

the system evolution of (13) by using the above numerical algorithm is statistically equivalent to the evolution of (11) in the sense of Ito [41,42], which is desired here because the stochastic term $n(t)$ is modeled as a true white noise. We use this algorithm to resimulate the robust self-synchronization ability for white noise, and the simulation results are shown Fig. 7. Now, simulation results are consistent using different integration step sizes, which is necessary for a valid system modeling. [20] also provided the error probabilities of CSM and DFM communication systems using the appropriate stochastic integration algorithm as described above (see Fig. 8).

2.5. CSK, DCSK, and FM-DCSK

As seen in Fig. 8, the extremely poor performances of antipodal DFM and CSM systems motivate a fundamental consideration of the use of chaotic waveforms for digital communications. Since the chaotic waveform used in a coherent receiver, obtained by self-synchronization, is known to be extremely sensitive to channel noise, one approach to improve the system performance is to consider the use of different versions of CSK modulations. For an antipodal CSK transmitter, let $x(t)$ be a chaotic waveform and the modulated bits 0 and 1 be given by $s_0(t) = x(t),\ 0 \le t \le T$, and $s_1(t) = -x(t),\ 0 \le t \le T$, respectively. Of course, at the receiver, in order to perform coherent correlation operation, the chaotic waveform $x(t)$ is not available if the self-synchronization property of the chaotic waveform is

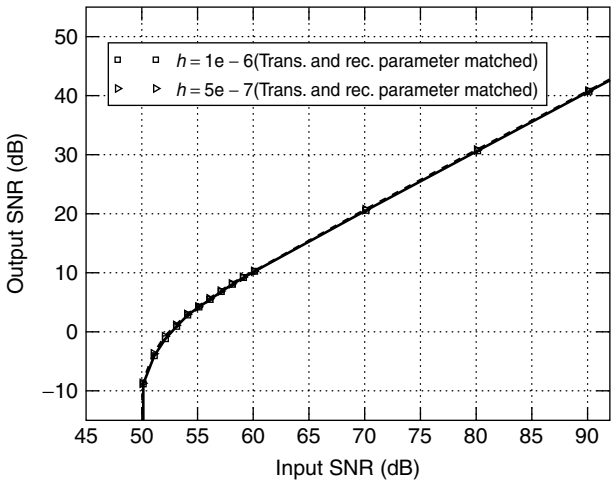

Figure 7. Robust ability for Mannella algorithm simulation with $K = 2505$.

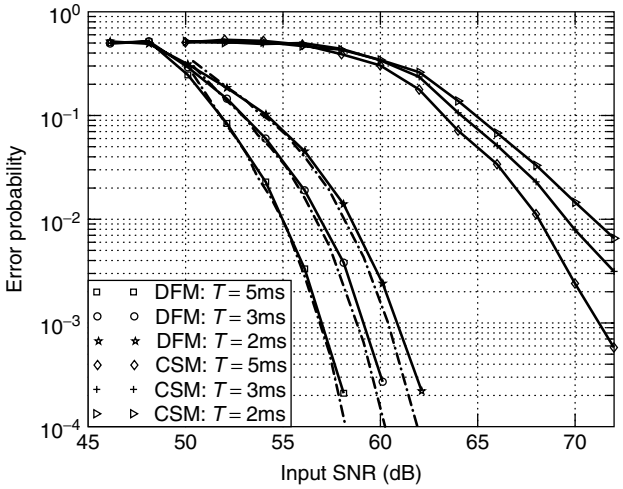

Figure 8. Comparison of BER versus input SNR for DFM and CSM systems.

not used. One way to circumvent this problem is to use the differential CSK (DCSK) modulation scheme as advocated by Kolumban [22]. For an antipodal DCSK transmitter, the two waveforms are given by

$$s_0(t) = \begin{cases} x(t), 0 \le t \le \dfrac{T}{2}, \\ x\left(t - \dfrac{T}{2}\right), \dfrac{T}{2} \le t \le T \end{cases}$$

$$s_1(t) = \begin{cases} x(t), 0 \le t \le \dfrac{T}{2} \\ -x\left(t - \dfrac{T}{2}\right), \dfrac{T}{2} \le t \le T \end{cases} \tag{14}$$

Then the received waveform is given by

$$r(t) = s_i(t) + n(t) = \begin{cases} x(t) + n(t), 0 \le t \le \dfrac{T}{2}; x\left(t - \dfrac{T}{2}\right) \\ \qquad +n(t), \dfrac{T}{2} \le t \le T, H_0 \\ x(t) + n(t), 0 \le t \le \dfrac{T}{2}; -x\left(t - \dfrac{T}{2}\right) \\ \qquad +n(t), \dfrac{T}{2} \le t \le T, H_1 \end{cases} \tag{15}$$

where $n(t)$ is the AWGN channel noise. For a differential coherent detection scheme, the first portion of the received chaotic waveform is used as a reference to perform coherent integration of the second portion of the received waveform. Then the output of the integrator is given by

$$\eta = \int_0^{T/2} r(t) r\left(t + \frac{T}{2}\right) dt = \pm \int_0^{T/2} x^2(t)\, dt \pm \int_0^{T/2} x\left(t + \frac{T}{2}\right) n(t)\, dt + \int_0^{T/2} x(t) n\left(t + \frac{T}{2}\right) dt + \int_0^{T/2} x\left(t + \frac{T}{2}\right) n(t)\, dt \tag{16}$$

In a conventional differential coherent BPSK system, the output of the integrator has the same form as that given in (16) except for the first term on the right-hand side (RHS). In a conventional system, $x(t)$ is a known deterministic waveform, and thus the first term is a known constant. However, for a chaotic $x(t)$ waveform that first term is not a constant, but only the expectation of that term (i.e., $E\{\int_0^{T/2} x^2(t)\, dt\}$) is a constant [22]. The nonconstancy of this term causes an additional system performance degradation of the DCSK system relative to the differential coherent BPSK system. We also note that, in the DCSK scheme, since the first portion of the waveform over a duration of $T/2$ seconds carries no information, the transmission rate of the system is one-half that of a nondifferential CSK system.

One possible remedy to eliminate the nonconstancy problem is to frequency-modulate the chaotic $x(t)$ waveform, which results in still another chaotic waveform but has constant energy. This leads to the FM-DCSK modulation scheme [24,25]. The demodulation of the FM-DCSK waveforms is performed in the same manner as that of the DCSK system, except now FM chaotic waveforms are used. Performances of non-band-limited BPSK, FSK, noncoherent FSK, and FM-DCSK are compared in Fig. 9. Some advantages of the FM-DCSK system [25] include the following:

1. There is no need to use the self-synchronization property of the chaotic waveform, which yields low performance in the presence of noise; it is relatively insensitive to channel distortions, and thus nonlinear amplifier can be used.
2. Since the FM-DCSK waveforms are wideband, they are relatively immune to frequency-selective fading in multipath scenarios.
3. Unlike the case in conventional DS-CDMA systems, since chaotic waveforms are used here, no distinct spectral lines are present; multiuser capability also exists.

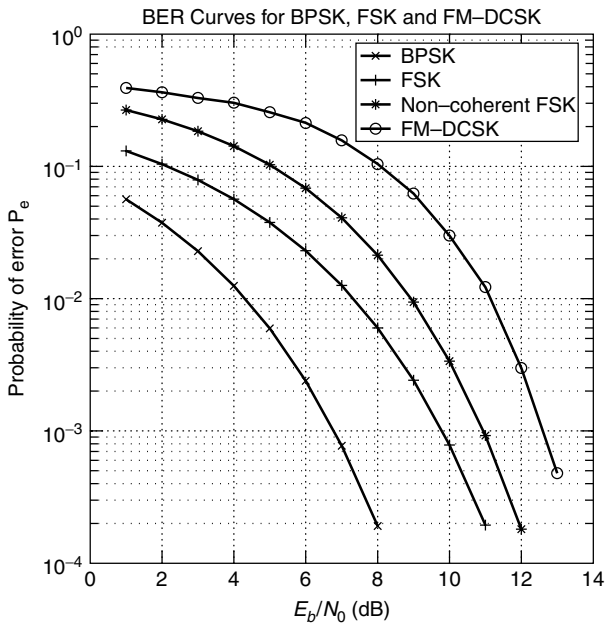

Figure 9. Comparison of BER versus E_b/N_0 of BPSK, FSK, noncoherent FSK, and FM-DCSK systems.

FM-DCSK is probably one of the more practical communication systems using chaos-based carrier modulations.

Besides frequency modulation, the basic DCSK scheme can be extended in various directions. Just as QPSK and QAM are extensions of BPSK in order to transmit more information data per baud, multilevel quadrature CSK scheme has also been proposed by Galias and Maggio [37].

3. SYMBOLIC DYNAMICS

A quite different chaotic communication technique using symbolic dynamics was originally proposed by Hayes et al. [27]. This approach attempts to provide a bridge between the theory of the chaotic system and information theory to design a communication system using chaotic dynamics. From the formalism of *symbolic dynamics* [63], Hayes et al. considered a chaotic system to be a natural digital information source with some constraint, denoted as the *grammar*. They showed that the symbolic dynamics of a chaotic oscillator can be made to follow a desired symbol sequence by using small perturbations. The mechanism behind the chaos control can be explained in an abstract but simple way [28]. Consider the Bernoulli map given by $x_{n+1} = 2x_n \bmod 1$. If x is represented by a binary fraction with finite precision, say, $x_n = .10101010$, then either $x_{n+1} = .01010101$ or $x_{n+1} = .01010100$ can be obtained by changing the eighth significant bit, representing a change of about 0.004 in base 10. By repeatedly changing the eighth bit, the change will show up in the most significant bit, which determines whether $x \geq \frac{1}{2}$ or $x < \frac{1}{2}$, a large-scale and easily observable signal attribute. Therefore, any message that can be encoded in a sequence of bits can be transmitted by controlling the symbolic dynamics of the chaotic system. The receiver is a simple level threshold detector.

For the continuous-time and continuous-state system, which is described by a set of ordinary differential equations, the symbolic dynamics of the system can be constructed using the Poincaré section concept by running the system without control [27]. Then we associate each binary sequence generated when the corresponding trajectory, starting from the initial condition, crosses the Poincaré surface with a real number, denoted by the *coding function*. The information message can be embedded into the chaotic dynamics by applying control pulses according to the coding function. The receiver observes the transmitted chaotic waveform and make a decision by observing the points on the Poincaré surface to see which side of the surface the crossing point lies in.

As stated earlier, in a DCSK system, the first portion of the chaotic waveform is used for reference purpose, carries no information, and yields an inefficient use of the channel bandwidth. Maggio and Galias [43] encoded some information onto the first portion of the chaotic waveform through the use of symbolic dynamics and increased the effective throughput of the system. Ciftci and Williams [44] proposed the use of optimum Viterbi estimation and channel equalization algorithms to estimate sequences encoded using symbolic dynamics over a channel with distortion. Other advanced symbolic dynamics and related analytic tools relevant to chaotic communications include those described in Refs. 45–47.

4. ANALOG CHANNEL ENCODING AND ESTIMATION

The use of chaotic dynamics as a channel encoder was proposed by Chen and Wornell [30]. A novel analog code based on the tent map dynamics and having a fast decoding algorithm was proposed for use on unknown, multiple, and time-varying channels with different SNRs. These practical chaotic codes having recursive receiver structures and important performance advantages over conventional codes were demonstrated. A convolutional encoder and multiresolution codes using chaotic systems are also developed in this article.

The basic idea of this chaotic encoder is to encode the analog message into the initial condition of the chaotic system, and an estimation technique was used to retrieve the message. Optimal state estimation for chaotic sequences is in general a difficult problem. Papadopoulos and Wornell [29] derived the maximum-likelihood (ML) estimator for the tent map sequences in stationary AWGN and showed that it can be implemented by a forward recursive filter followed by a backward recursive smoother. The forward recursive filter developed by Papadopoulos and Wornell [29] is identical to the Kalman filter.

5. CHAOTIC PULSE POSITION MODULATION

Instead of transmitting the chaos waveform, a chaotic pulse position modulation (CPPM) scheme was proposed Sushchik et al. [31]. This proposed system is similar to an ultra-wide-bandwidth impulse radio system of Win [32] that offers a promising communication method, especially in a severe multipath environment. A pulse position method is used to modulate binary information onto the carrier. The separation between the adjacent pulses is chaotic, arising from a dynamical system with irregular behavior.

The communication scheme is built around a chaotic pulse regenerator (CPRG), as shown in Fig. 10. With a pulse train of interpulse intervals T_i as its input to the CPRG, the nth incoming pulse is produced after a delay time given by $\Delta T_n = F(T_{n-1}, \ldots, T_{n-k})$ where $F(.)$ is a chaotic map. Thus, the system is expected to generate a pulsetrain with chaotic interpulse intervals. The binary information message is modulated at the output of the CPRG by delaying the pulse of a fixed time if binary 1

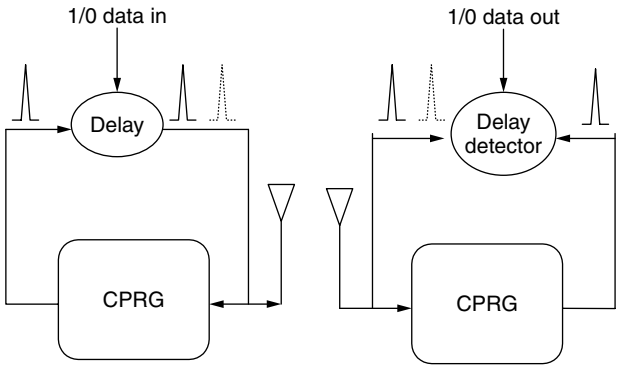

Figure 10. Chaotic pulse position modulation.

is being transmitted, or leaving unchanged if binary 0 is being transmitted. The received signal is fed into the identical CPRG at the receiver. Since the inputs to both CPRGs at the transmitter and receiver are identical, the outputs of CPRGs are expected to be identical. By computing the timing difference between the received signal and the output signal of the CPRG at the receiver, the embedded message can be retrieved.

This communication system may have a lower probability of intercept due to the aperiodicity of the chaos signal. This system performs well compared to other chaos-based convert communication schemes. Rulkov et al. have further analyzed the CPPM system with application to multiuser communication [64].

6. CHAOTIC SPREAD-SPECTRUM SEQUENCES

There has been an increasing interest in spread-spectrum communications, particularly in code-division multiple-access (CDMA) format. Some of the operations, concepts, and advantages of direct-sequence CDMA (DSCDMA) have been described [48]. System performance of DSCDMA critically depends on the auto- and cross-correlation properties of the *spreading sequences*. The use of chaotic sequence/waveform as spread sequences for DSCDMA communication systems has been proposed [49–51,53–58]. The chaotic signals have low nonzero shift autocorrelation and all cross-correlation properties due to the intrinsic broad nature of the spectrum and sensitivity to initial conditions. The use of the correlation function characteristics of some specific chaotic sequences and its comparison to *m* sequences/Gold sequences has been studied.

The chaotic sequence, generated by a logistic map, was first proposed for DSCDMA in 1992 [49]. The correlation properties of these logistic sequences are similar to random white noise. By simulations, the performance of chaotic sequences in the DSCDMA system is shown to be similar to that of PN sequences. Furthermore, due to their real values instead of binary values, chaotic sequences outperform PN sequences in low probability of intercept (LPI). Umeno et al. [51] used Chebyshev sequences for a synchronous CDMA system and analyzed the system performance using ergodic theory [7,52].

The statistical properties of binary sequences generated by a class of ergodic maps with some symmetric properties have been discussed [53]. Simple methods were used to generate a sequence of i.i.d. binary random sequence. The correlation functions of various types of chaotic binary sequences have been evaluated exactly by ensemble-averaging technique based on the Perron–Frobenius operator theory [7]. They also obtained a sufficient condition for a binary function to produce a sequence of i.i.d. binary random variables.

Mazzini et al. [54,55] proposed chaotic complex spreading sequences for asynchronous DSCDMA. They provided rigorous analysis of DSCDMA system performance bounds using chaotic complex spreading sequences. The simulation results in these papers show that systems based on chaotic spreading sequences perform generally better than the *Gold sequences*. Moreover, by treating the spreading sequences as random processes, Mazzini et al. [57] have shown the optimal *ensemble-averaged* autocorrelation of spreading sequences with minimum achievable interference variance decays nearly exponentially. They also proposed a chaotic map to generate the sequences with nearly exponential autocorrelation function. Without the assumption of independence and stationarity of the spreading sequences required by Mazzini et al. [57], Chen and Yao [60] provided a methodology to derive the general results on the partial autocorrelation function of the spreading sequences to minimize interference variance as well as a real-valued spreading sequence implementation that is at the same time optimal and practical by using the ergodic theory. For an asynchronous DSCDMA system, results in Refs. 57 and 60 show that these sequences generated based on chaos and ergodic theory concepts, can support approximately 15% more users for a fixed amount of interferences compared to Gold codes. Equivalently, for a fixed number of users, these sequences produce ~15% fewer interferences. In Fig. 11, there are nine BER curves for sequences of length 64 in AWGN. But there are essentially only three sets of curves, with each set having about the same performance. The lowest set of curves include the two optimal sequences for asynchronous CDMA operation (induced from optimal filtering of either a second- or third-order Chebyshev sequence); the middle set of curves include the Gold code and the original unfiltered second- or third-order Chebyshev sequence in asynchronous CDMA operation; and the upper set of curves represent operations under the chip-synchronized CDMA operations. There is an approximate 15% improvement in the lower set of curves compared to the middle set of curves. Various other related issues on sequences generated based on chaos theory and their implementations have also appeared in the literature [59,61,62].

7. CHAOS IN LASER COMMUNICATION AND MODELING OF RADAR AND RADIO PROPAGATION EFFECTS

There are many applications of chaotic nonlinear dynamics to various system problems. We consider only two such

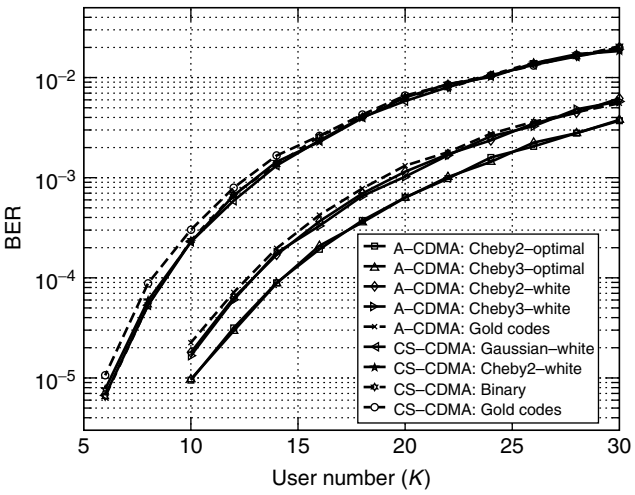

Figure 11. BER versus user number for nine chaotic spreading sequence asynchronous DSCDMA scenarios.

applications in communications. Semiconductor lasers are the most important light sources for optical communications. Unlike the previously considered electronic chaotic communication systems, where the nonlinearities are often introduced intentionally to create chaos, single-mode semiconductor lasers operate with various complex intrinsic nonlinearities due to the physical behaviors of the devices. Thus, chaos may or may not be avoidable in such devices. Many papers have dealt with the chaotic behaviors of lasers. The paper by Liu et al. [65] exploits the chaotic behaviors of the lasers and deals with the dynamics, synchronization, and message encoding and decoding of two optical laser communication systems. One system uses optical injection and the other uses delayed optoelectronic feedback. From these numerical simulation and experimental measurement works, the basic concept of using chaotic optical communication to transmit and receive hundreds of gigabit rate data has been demonstrated as feasible and practical.

Radar and radiofrequency propagation effects due to scattering, reflection, and shadowing are known in various scenarios to severely limit the performance of these systems. The modeling and understanding of these propagation effects are of great theoretical and practical interest. In this section we consider two physical problems. The first problem considers sea clutter as the backscattered returns from a patch of the sea surface illuminated by a transmitted radar pulse. Sea clutter waveforms are quite complicated. Traditionally, they have been modeled by statistical means such as through the marginal densities of the amplitude of the waveform. Often there is little insight or justification for these statistical characterizations such as lognormal, or k distribution. Since the sea clutter waveforms are functions of sometimes turbulent wave motions on the sea surface, it is not unreasonable to conjecture that perhaps nonlinear dynamics may be in operation. Perhaps the apparent seemingly randomness of the sea clutter may be modeled by deterministic chaos. Haykin and colleagues [66,67] have collected considerable amount of sea clutter data and used the method of Grassberger and Procaccia [68] and found nonintegral fractal dimensions and positive Lyapunov exponents from these data. Thus, they conjectured that under certain conditions, sea clutter may be modeled as deterministic chaos. But it is also known that a nonintegral fractal dimension together with a positive largest Lyapunov exponent obtained by computational means is not a sufficient condition. Specifically, the $1/f$ fractal random process (which is not a deterministic chaos) may have a nonintegral fractional dimension and also a positive Lyapunov exponent. Gao and Zheng [69,70] provided a more stringent test for chaos by showing that for a chaotic sequence, a plot of the time-dependent exponent $\Lambda(k)$–time index k forms a common envelope over different shells. The slope of these envelope is the largest Lyapunov exponent. This common envelope property is shown in Fig. 12 for the well-known chaotic Lorenz sequence. On the other hand, for a nonchaotic sequence, such as that for a white sequence (Fig. 13), the common envelope property does not hold. For the 130 s of sea clutter, Haykin et al. [71] obtained the results shown in Fig. 14, which does not manifest the common

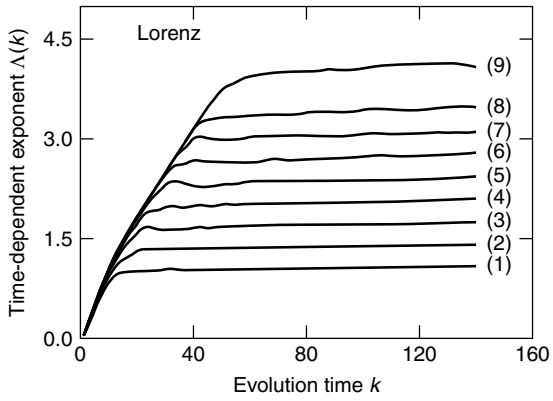

Figure 12. Exponent versus evolution time for different shells of a chaotic Lorenz sequence.

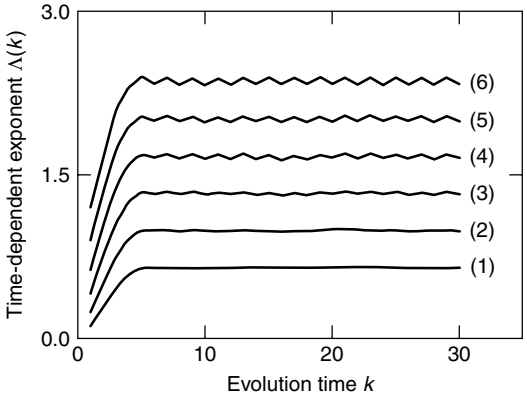

Figure 13. Exponent versus evolution time for different shells of a white-noise sequence.

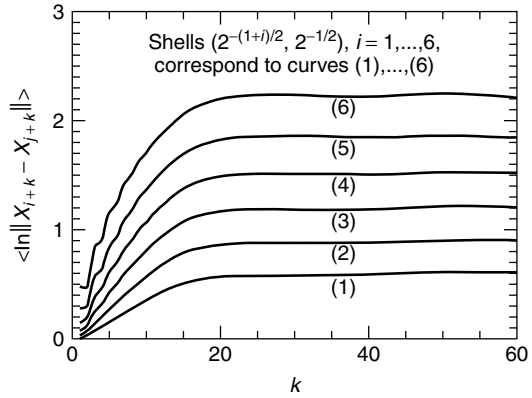

Figure 14. Exponent versus evolution time for different shells of a sea clutter sequence.

envelope property. This would seem to indicate that sea clutter data are not deterministic chaos. To obtain deeper insight from these sea clutter data, a multifractal analysis was performed [71]. Without going into detail, random multiplicative multifractal theory [76,77] shows that if a sequence of data has infinitely many power-law scaling relationships, then plots of $\log_2 M_q(\varepsilon)$ versus $-\log_2 \varepsilon$ for different values of q should form a straight line and the amplitudes must be lognormally distributed. Here the

moment $M_q(\varepsilon) = \sum_i w_i^q$, $\varepsilon = 2^{-N}$ at stage N, where q is a real number, and the weights $w_i, i = 1, \ldots$ are obtained directly from the measured data. For this set of sea clutter data, Fig. 15 shows the amplitude and particularly the envelopes form essentially sets of straight lines. Furthermore, Fig. 16 shows the amplitude and particularly the envelope indeed satisfies the lognormal distribution. Indeed, lognormal distribution for radar clutter amplitude has been known for many years, although no known justification has been given until now. It is also interesting that some work by Cowper and Mulgrew [72] and even Haykin et al. [73] shows reservations about the proper modeling of sea clutter as deterministic chaos. Clearly, more data should be collected and analysis performed in order to construct a valid propagation model for radar clutter returns.

The second problem considered in this section deals with the modeling of the fading radio propagation phenomena in wireless communication. There have been many propagation measurements in different frequency bands, and various statistical models have been proposed. Tannous et al. [74] applied the method of Grassberger and Procaccia [68] to some indoor 0.915-GHz radio propagation data, and found nonintegral fractal dimensions together with positive largest Lyapunov exponents and concluded that the propagation channel may be modeled by chaos. However, due to the limited data length and highly nonstationary character of their measured data, it is not obvious that a deterministic chaos conclusion can be made from these data. Gao et al. [75] reported on short timescaled analysis of some indoor 1-GHz propagation data using the method due to Gao and Zheng [69,70]. Figure 17 shows a

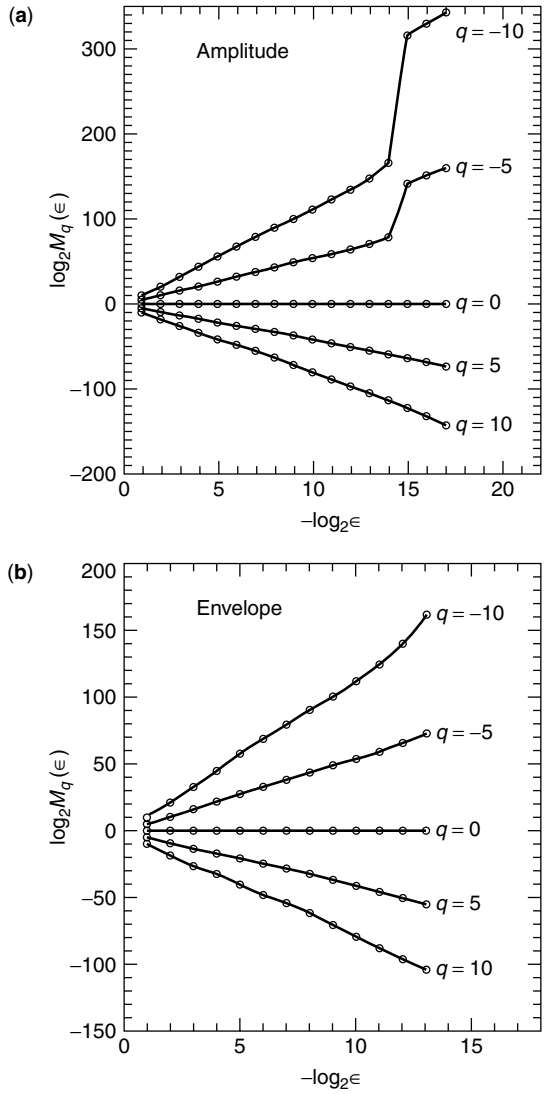

Figure 15. Multifractal scaling law for amplitude and envelope of a sea clutter sequence.

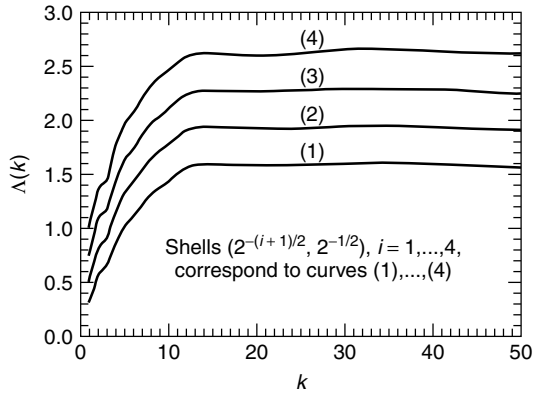

Figure 17. Exponent versus evolution time for different shells of a measured radio propagation data.

typical plot of the time-dependent exponent $\Lambda(k)$ versus time index k and reveals no common envelope property. From the earlier comments made with regard to Figs. 12 and 13, we may conclude that at least for these measurements, deterministic chaos were not present. Further analysis based on fractional Brownian motion process (FBMP) [78] were reported [75]. A FBMP is a Gaussian process with zero-mean and stationary increments. Its variance has the form of t^{2H}, and its power spectral density has the form of $f^{-(2H+1)}$, where H is the Hurst parameter. For $0.5 < H < 1$, the process has long-range dependence. For $H = 0.5$, the process becomes the standard BMP (whose formal derivative is the standard white Gaussian noise used in communication system analysis). For $0 < H < 0.5$, the adjacent values of the process have highly negative correlations and the process fluctuates widely. Details are omitted here, but if the data are from an FBMP, then the set of variance–time $\log_2 F_q(m)/\log_2 m$ curves in Fig. 18 should form straight lines. For two sets of measured data, the estimated Hurst parameters have almost constant values of about 0.4 and 0.45. For these limited number of measurements, the data may suggest a fractal FBM-like process modeling. However, since the RF band around 1 GHz is crowded with various radio transmitters and microwave ovens, drawing definitive conclusion about the true nature of the observed data is delicate. It is interesting that researchers in electromagnetics [79] have also proposed the modeling of RF scattering based on fractal theory. Clearly, more careful data collection and advanced tools for analyzing these data must be performed before valid models can be established and these results can be applied to practical wireless communication applications.

8. CONCLUSIONS

In this article, we have summarized various aspects of deterministic chaos to the analysis, design, and modeling of communication systems and channels. We first provided some background on the history of chaos. Then early chaotic modulation techniques utilizing self-synchronization of the chaotic waveform were discussed. Evaluation of the error probability of these systems cannot be performed analytically or even by conventional numerical simulation. A numerical simulation method for a nonlinear stochastic system is discussed, and an accurate stochastic integration algorithm is provided. Because of the sensitivity of the self-synchronization process to channel distortion and noise, the performances of these early chaotic communication systems were poor. The FM-DCSK modulation scheme was proposed and shown to be practical for implementation. It is competitive to conventional communication system performance and may possess certain additional desirable properties. Chaotic pulse position modulation particularly with application to UWB systems may also be practical and useful. More recently, various chaotic nonlinear dynamics and ergodic theory concepts have been proposed to create CDMA sequences that can perform better than known sequences in the asynchronous CDMA mode. Preliminary investigations show these results are practical for implementation.

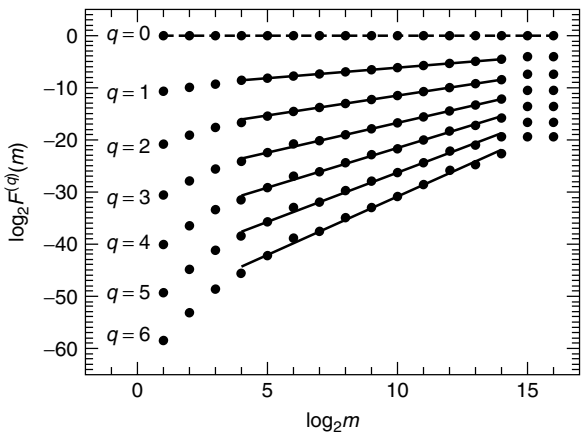

Figure 18. Power versus time for different scalings for a measured radio propagation data.

It is quite clear that many of the researchers in "chaotic communications" are more interested in exploiting various complex and often interesting properties of chaotic nonlinear dynamics rather than using them for explicit communication purpose. Ultimately, "chaotic communication" schemes must be compared to comparable conventional communication schemes with respect to bandwidth, data rate, energy per bit, error probability, and complexity of the transmitter and receiver. It remains a challenge to exploit the complexity and richness of chaos and related analytic tools to understand, analyze, design, and model communication systems and channels.

BIOGRAPHIES

Kung Yao received the B.S.E. (Highest Honors), M.A., and Ph.D. degrees in electrical engineering, all from Princeton University, Princeton, New Jersey. He was a NAS-NRC Post-Doctoral Research Fellow at the University of California, Berkeley. Presently, he is a Professor in the Electrical Engineering Department at UCLA. In 1969, he was a Visiting Assistant Professor at the Massachusetts Institute of Technology. In 1985–1988, he served as an Assistant Dean of the School of Engineering and Applied Science at UCLA. His research and professional interests include sensor array systems, digital communication theory and systems, smart antenna and wireless radio systems, chaos communications and system theory, digital and array signal and array processing, systolic and VLSI algorithms, architectures and systems, radar systems, and simulation. He has published over 250 journal and conference papers. Dr. Yao received the IEEE Signal Processing Society's 1993 Senior Award in VLSI Signal Processing. He was the co-editor of a two-volume series of an IEEE reprint book entitled *High Performance VLSI Signal Processing*, IEEE Press, 1997. He was a Guest Associate Editor of a Special Issue on "Applications of Chaos in Modern Communication Systems" of the *IEEE Transactions on Circuits and Systems* — Part I, December 2001. He is a Fellow of IEEE.

Chi-Chung Chen was born in Taiwan in 1970. He received the B.S. and M.S. degrees in control engineering from National Chiao Tung University, Taiwan, in 1993 and 1995, respectively, and the Ph.D. degree in electrical engineering from the University of California at Los Angeles in 2000. He was employed as an Associate Researcher on the design of controller in MIRL, ITR1, Taiwan from 1995 through 1996. From 1997 to 2000, he was a Research Assistant at UCLA. His current research interests include chaotic communications, spread-spectrum COMA systems, pseudorandom sequences, adaptive systems, and wireless communication systems. Dr. Chen is a member of the Phi Tau Phi Scholastic Honor Society. Since 2001, he has been with Accton Technology Corporation in Tainan, Taiwan.

CHARACTERIZATION OF OPTICAL FIBERS

GILBERTO M. CAMILO
OmniGuide Communications
Cambridge, Massachusetts

1. INTRODUCTION

At present there are many practical applications of optical fibers of different technologies. Optical fibers are used primarily (90% of total applications) in telecommunications because optical signals can be transmitted over long distances at high speed in optical fibers. Other applications are also important, such as military, medical, and industrial. The economic advantage of the optical fiber technology and its exploding implementation has pushed the manufacturing process from 60 m/min in 1978 to 1800 m/min in 2002.

Different glasses and coating materials have been developed since the early 1980s, but most of the optical fibers installed in the field are silica glass optical fibers protected by a polymeric coating. The coating is applied during the manufacturing process and is used to protect the surface of the glass from defects caused by abrasion, thus avoiding premature breaks. The high purity of the silica glass being used can guarantee very low attenuation of the light radiation being transmitted and also good mechanical qualities.

Other optical fiber technologies not based in silica glass are under study or already in use as all-plastic optical fibers [1], used in illumination systems and short-distance data communication; and infrared optical fibers [2,3], manufactured using chalcogenide glasses, or crystal glasses, which are used in sensor systems and telecommunication systems.

The optical and mechanical characterization methods used in optical fiber qualification are in general the same for all optical fiber types. Depending on which optical fibers are being tested, the appropriate light wavelength is used during the measurement process. Optical fibers can operate from the visible range (600 nm) to the infrared range (10,000 nm).

Measurement methods for silica glass optical fibers, coated by a primary and a secondary polymeric material, with operating range 1300–1550 nm, are considered here. Multimode silica optical fibers will be discussed briefly.

A silica glass optical fiber has an overall polymeric coating diameter of 250 μm and a centered glass with diameter around 125 μm. The glass part is composed of a core and a cladding, one glass cylinder inside another with a slight difference in refraction index. In the lightpulse that travels through the single-mode optical fiber, the core guides only the fundamental mode. The diameter of the core in these optical fibers is around 9 μm. In multimode optical fibers, hundreds of modes propagate at the same time in the lightpulse, and the optical fiber core is around 50 μm in diameter.

Presently the most widely used coating polymers are ultraviolet-cured acrylates. For mechanical and optical reasons, two polymer layers with distinct mechanical properties are applied to the glass surface. The soft inner polymer is in direct contact with the glass and absorbs small mechanical stresses. The harder external polymer has much higher elastic modulus compared to the internal polymer and is intended to resist the environment and abrasion.

2. CHARACTERIZATION METHODS

The National Standard Committees formed by industries, universities, and government standard institutions propose and discuss various characterization methods. These methods are used to specify and qualify optical fiber systems, including optical fibers as a telecommunication product. Fiberoptic test procedures (FOTPs) are developed to provide a uniform plan of action during the tests of optical fiber system components. The Telecommunications Industry Association and the Electronic Industries Alliance (TIA/EIA) specify the optical fiber and optical fiber cable standards in the United States. Many other countries use these standards as well. In Europe, Japan, and other foreign markets the International Electrotechnical Commission (IEC) determine alternative telecommunication standards studies.

Among these organizations, in the United States and Europe, a homogenization process of procedures and specifications for optical fibers and optical fiber cables is currently under way.

The characterization methods and techniques discussed here are in accordance with national and international standard procedures. The optical fiber characterization can be divided in three different aspects:

- Geometric characterization
- Transmission characterization
- Mechanical characterization

2.1. Geometric Characterization

An optical fiber is an electromagnetic waveguide operating at a very short wavelength, around 1300–1550 nm. The micrometer optical fiber geometric characteristics are essential to maintain the integrity of the optical signal, which carries the information. According to the standard specifications, many parameters need to be checked and must be maintained inside narrow ranges; these include:

- Diameters of the core and of the cladding
- Core–cladding concentricity

- Ellipticity of the core and of the cladding
- Length of the optical fiber
- Numerical aperture
- Primary and secondary coating diameters

Numerical aperture is the cone angle light acceptance in front of the optical fiber. If the incident light radiation is inside this cone angle, and this light consists of a wavelength compatible with the geometric guidance characteristics of the optical fiber, this radiation will be coupled in the core and transmitted through the length of the fiber. If it is outside the cone angle, the radiation will be reflected by the glass in the extremity of the optical fiber or refracted and spread in the cladding, and from the cladding to the outside of the optical fiber.

Different techniques can be used to measure these optical fiber geometric parameters. The most common are

- Refracted near-field method
- Transmitted near-field method
- Transmitted far-field method
- Microscopy method

These techniques use the radiation pattern that is refracted or transmitted at a very short distance in the extremity of the optical fiber in order to measure the geometric parameters. In the refracted near-field method [4], a laser coupled to a very precise stepper motor is used to focus a lightbeam at different angles in the core of the optical fiber. By analyzing the cladding refracted light, it is possible to measure precisely the dimensions of the core–cladding and cladding–coating interfaces.

In the *transmitted field method*, after the light is transmitted by a small piece of optical fiber, very sensitive optical detectors, or charge-coupled device (CCD) cameras, measure its dimensions.

In the microscopic method, a microscope with a photographic machine, or a videocamera, inspects directly the transmitted radiation in the extremity of a small piece of optical fiber and performs the geometric measurement.

To measure the length of the optical fiber, it is most common to use optical time-domain reflectometry (OTDR) [5]. This technique was developed as a modification of a similar technique that was used during decades in metallic telecommunication cables. The great advantage of this technique is that it is necessary to have access to only one extremity of the optical fiber. In this method, modulated laser light is injected in the core of the optical fiber and during its propagation through the optical fiber length part of the radiation is reflected and spread by defects in the glass structure. A small backscattered portion of the reflected radiation returns to the extremity and brings back the information necessary to localize precisely (to within a few centimeters), those defects. By capturing the light that reflects in the other extremity it is possible to determine the length of the optical fiber.

In an OTDR, which is the equipment that uses such a technique in optical fibers, a small percentage of the incident radiation returns to the detector and defines the maximum length range to be analyzed. This technique can still be used to measure the attenuation of the optical signal after it has been transmitted through the optical fiber length. Actually, a commercial OTDR can measure the optical attenuation, the length, and localize defects to within a range of a few meters over 200 km of an optical fiber length.

It must be pointed out that some of these methods are still being refined, and the commercial apparatus that use them have significantly improved since the early 1980s.

2.2. Transmission Characterization

The transmission characteristics are related to capacity of the optical fiber and its ability to maintain the optical signal integrity after being conducted through the length of the fiber. Different characteristics of the optical fiber can affect its capacity to perform well at long distances. The most important factors that cause power depletion can be subsumed in what is called the attenuation of the optical fiber.

The optical fiber materials absorb part of the light radiation when the lightpulse travels through the glass and a part is spread in glass imperfections, causing attenuation. Most of the spread light goes from the core into the cladding, and from there it is lost. Absorption and spreading are caused by several different phenomena, including nonuniformity of the glass composition, particles and gas bubbles trapped in the glass structure, cracks and other mechanical defects in the glass, nonuniformity of the glass geometry, and defective coatings. The majority of these imperfections originate during the optical fiber manufacturing process and others result from installation and use of the optical fiber cables.

The methods most commonly used to measure the attenuation of the optical fiber consist of measuring the power loss, using power detectors. Another important technique is based on optical time-domain reflectometry (OTDR). OTDR measuring apparatus are compact and versatile devices, easily transported to the field, and have the capability to measure very long lengths of optical fiber. Attenuation can be measured for a specific operating wavelength of the optical fiber, as in OTDRs, or in a broader wavelength range, called *spectral attenuation*.

Figure 1 shows the schematics of an apparatus to measure the optical fiber spectral attenuation by power

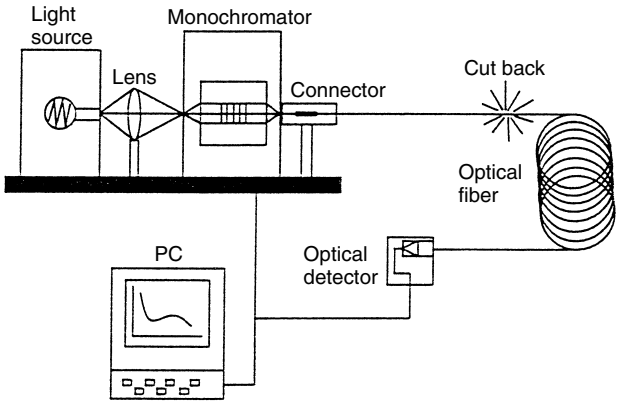

Figure 1. Spectral attenuation apparatus schematics.

measurement. In this test the wavelength is selected using a computer-controlled monochromator, and the light source consists of a white-colored, powerful device. After the monochromator the monochromatic selected light is injected into the optical fiber extremity. This extremity of the optical fiber must be cleaned and cut carefully in order to guarantee that the maximum light is injected in the optical fiber core. The other extremity of the optical fiber, clean and with a good quality cut, is in contact with the power detector. For silica glass optical fibers, the first power measurement series is done with the monochromator scanning at each few nanometers in the range 600–1600 nm. After the first power scanning, the optical fiber is cut at approximately 2 m from the launching extremity and inserted again in the power detector. Another power measurement is performed as described above, and the attenuation at each wavelength is the quotient between the second power measurement and the first power measurement divided by the length of the optical fiber. It is convenient to use the common logarithm of the power quotient to express the attenuation in decibels per kilometer (dB/km).

Because the cut is made close to the power source, this technique is also known as the *cutback method*. This method is precise and reliable and is used as a reference for other attenuation measurements methods.

In single-mode optical fibers the loss of light radiation that affects the intensity and spreading of the lightpulse can be caused by other phenomena. Light sources, such as lasers and light-emitting diodes (LEDs), are designed to emit a specific wavelength, but they really emit light in a wavelength range. A lightpulse generated by those sources has many components with different wavelengths. In the core of the optical fiber different wavelengths travel at different velocities causing a time spreading of the pulse. The phenomenon in which the velocity of propagation of an electromagnetic wave is wavelength-dependent is called *dispersion*, in which different wavelengths are connected with different colors. This phenomenon is thus called *chromatic dispersion*.

At least two methods are used to measure chromatic dispersion: the spectral group delay method and the phase-shift method [6,7]. These methods measure the time dispersion of the lightpulse that occurs after the pulse has traveled the length of the optical fiber.

The optical fiber core does not have a perfectly symmetric cylindrical shape; the purpose of this design is to avoid *polarization mode dispersion* (PMD). In practice, the core diameter and shape vary slightly in a random fashion during the optical fiber manufacturing process. In PMD, internal stresses induced by thermal expansion and external forces induced by the environment through handling and cabling adds more stress fields inside the optical fiber core. Those perturbations induce the two orthogonally polarized modes that travel at different group velocities in a single-mode optical fiber, and the lightpulse is broadened and distorted. At frequency transmissions above 10 gigabits per second (Gb/ps), PMD is a limiting factor for lightwave transmission in optical fiber systems.

Nowadays systems operating at very high transmission rates are commonly installed in practice. The PMD limitation has motivated many efforts to understand and quantify the phenomenon. Since the early 1990s, at least six methods have been proposed to measure PMD; they are divided in two groups: (1) methods that involve performing measurements in the time domain and (2) methods involving measurements in the frequency domain. In the time domain, three methods are used: the modulation phase-shift method, the pulse delay method, and the interferometric method. In the frequency domain the methods are the fixed analyzer method; the Poincare arc method, which is also called the *Muller matrix* method, and the Jones matrix method.

The fixed analyzer method is the most commonly used method [8] (Fig. 2). In this method polarized light is injected into an optical fiber and then the optical power transmitted through the optical fiber and then through a polarizer, as a function of the wavelength, is measured. As the wavelength is changed, the power transmitted through the polarizer goes up and down. By counting the number of maximums and minimums or counting the number of zero crossings it is possible to determine the average PMD. When these zero crossings are counted, the test actually consists in measuring the rate at which the output state of polarization changes with the wavelength.

It is possible to use an OTDR to measure the PMD in optical fibers by interferometric methods [9].

In multimode optical fibers a wide range of wavelengths constitutes the lightpulse and hundreds of modes travel together. The electromagnetic interference of those mode components reduces the power intensity being transmitted and, because the modes all travel at different velocities, the pulse spreads in time. If the transmission rate of pulses being transmitted increases, the pulse spreading causes adjacent pulses to overlap in time, resulting in interpulse interference and errors in signal detection. The maximum frequency at which it is still possible to recover the information is called the *bandwidth* of the multimode optical fiber. Measurement of this parameter is done in two domains; (1) the time domain, where the pulse spreading time is measured; and (2) the frequency domain, where the maximum frequency is measured according to the power loss in system detection [10].

2.3. Mechanical Characterization

Ensuring adequate integrity of optical fibers is complex because of the wide range conditions of temperature, humidity, and mechanical stresses that are present in

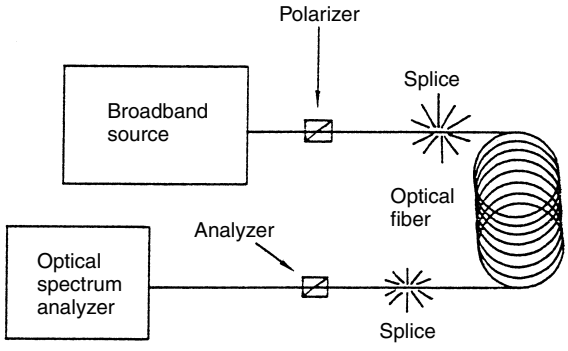

Figure 2. PMD measurement using the fixed analyzer method.

the manufacturing and in the optical fiber field. It is safe to state that the only way to determine the effectiveness of the optical fiber mechanical quality and how long it survives in the presence of moisture in the field is to wait until it breaks. But the lifetime can be very long, and predictability is needed. A short-term mechanical characterization can be useful to qualify the optical fiber, and a strength degradation model is necessary in order to predict failures.

After the manufacturing process it is necessary to embed the optical fibers in stronger structures in order to be installed and reliably operated during a minimum calculated period of time. These structures are called *optical fiber cables*.

Currently hundreds of optical fiber cable structures have been proposed for a large variety of applications, including submarine transoceanic cables, aerial cables, and underground cables. A common optical fiber cable design consists of a few basic elements. A strong tensile member of stranded steel wires, which are used to pull the cable during the installation process; a multilayer polymeric and metallic cover used to protect the optical fiber from contamination due to chemicals from the surrounding environment; and polymeric tubes with optical fibers inside it.

The silica glass chemically reacts with water, causing mechanical degradation of the glass optical fiber in a well-known phenomenon studied since the 1950s [11]. In the presence of stress and humidity a glass surface flaw can accelerate its growth and subsequently cause a fracture. Mechanical laboratory tests have shown that in a free water environment, as in tests performed with the sample immersed in liquid nitrogen, the strength of the optical fiber is at least 3 times higher compared with tests in a humid environment. Some authors found that this water glass corrosion is still possible in a stress-free situation for optical fibers coated with different polymeric materials [12,13].

Flaws in the surface of the glass are classified in two groups. The first group, *extrinsic defects*, represents a serious danger to the optical fiber. These flaws are many micrometers in length and in general originated during the manufacturing process, or were introduced in the glass surface by mechanical abrasion and handling. These defects can usually be identified after the optical fiber breaks, using microscopic techniques to analyze the broken surface [14]. The second group of flaws, called *intrinsic defects*, whose lengths are of the order of the silica glass structure (a few nanometers), cannot be observed using conventional microscopes, but studies using atomic force microscopy have revealed how they can affect the strength degradation process [15].

To mechanically qualify the optical fiber immediately after the manufacturing process, it is possible to do an optical fiber length tensile test in a proof testing machine [16]. The objective of this test is to eliminate large flaws that cause breaks during the optical cable manufacturing process, or in the cable lifetime. The test consists in applying a controlled tensile stress to the entire length of the optical fiber, which is done by using a system with pulleys and belts driven by electric motors (Fig. 3). In this test, when a large flaw is present in the length of the optical fiber that passes through the tensile proof test region, the applied stress activates the crack growth, causing a break in the fiber. The minimum stress level guaranteed for the survival of the optical fiber pieces after this destructive test is a function of the constant stress used in the tensile region, of the crack growth during the unloading time, and of the functional characteristics of the machine, such as the velocity of the fiber passing through the system.

The complete analysis of the proof testing must take into account the additional crack growth during the applied proof stress. Some of these flaws can be taken to their critical fracture size during the test causing breaks, and others can be very close to the critical size after the test. The proof test must be performed at the highest velocity of the fiber passing through the machine, in order to minimize the mechanical strength degradation.

After the proof stress area, the optical fiber is unloaded in the last pulley and an additional crack growth occurs, and this additional flaw growth during the unloading time

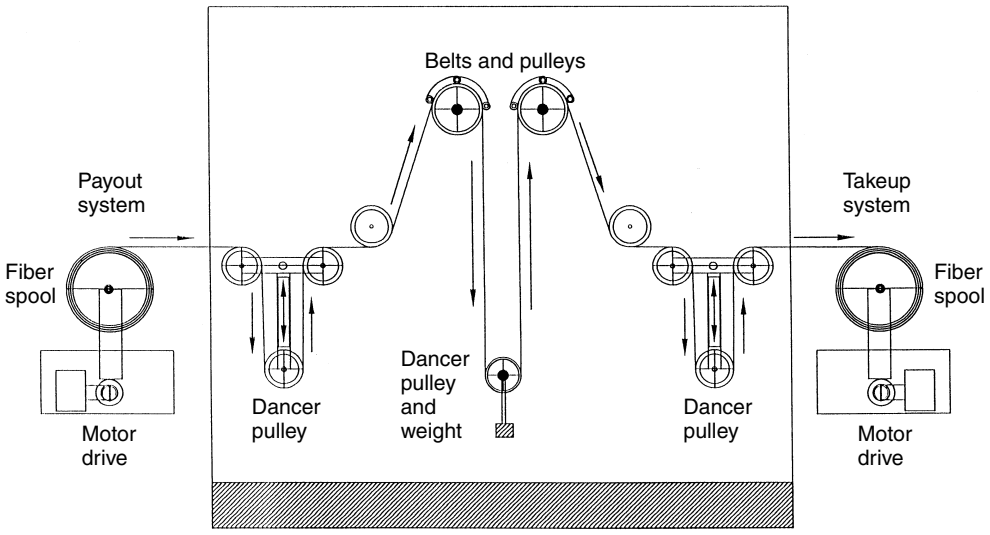

Figure 3. Optical fiber proof test machine.

reduces the guaranteed minimum strength to a level that is under the stress level applied to the tensile region. It is possible to calculate the minimum guaranteed strength by using the crack growth theory, the proof test specifications, and the velocity of the optical fiber passing through the system. The minimum strength after the proof test is a very useful parameter in order to guarantee a reliable cable manufacturing process, the optical fiber integrity during the installation of the cable, and the use of the cable.

After the proof test, additional mechanical characterization consists of measuring the strength of the optical fibers under tensile or bending stresses and their susceptibility to environmental changes. These tests, applied to a few samples removed from one extremity of the optical fiber, consist of applying a crescent force until the break. By assuming that the maximum force is connected with the geometric and physical parameters of the optical fiber, such as its diameter and length, and the elastic modulus of the silica glass, it is possible to calculate the maximum stress in the moment of the fracture. This is called the *strength* of the optical fiber. The results for these few samples removed from one extremity of the fiber are extrapolated to the entire length, assuming that the optical fiber presents the same mechanical characteristics in its entire length. The flaws distributed in the glass surface length can be compared to weak links in a chain, and a specific fracture probability distribution can be developed to describe the fracture event. This distribution is called the *Weibull fracture probability distribution* [17]. The Weibull model is applied to the strength of the tested samples from which the mean strength and the variability of the strength, referred as the m Weibull parameter, are calculated. These parameters are very useful for comparison of distinct optical fiber mechanical qualities.

In the past, mechanical apparatus used to test metal wires and pieces of plastics were adapted to test the tensile strength of pieces of optical fibers. Currently, mechanical apparatus have been developed specifically to test multiple and longer samples simultaneously. Laboratory tensile apparatus normally use a few meters of optical fibers, around 24 samples of 0.5 m each, tested one by one, to characterize many kilometers of an optical fiber (Fig. 4). Once the extremities of the optical fiber sample are securely held, a crescent force is applied until it breaks; this is known as the *dynamic fatigue test*. It is necessary to apply a high intensity force to hold the extremities of an optical fiber sample until it breaks. To avoid fractures to the extremities held by grip devices, it is common to wrap two or three turns around cylindrical pieces of metal, called *mandrels*. The force is applied by pulling the mandrels mechanically attached to the tensile machine. To guarantee no slippage of the optical fiber sample in the mandrel surface, it is necessary to use a double-face tape in the surface of the mandrel. Today this is the most commonly used method.

The problem with this approach is that it is not possible to know exactly what length of fiber is being tested, and part of the force is absorbed by the piece of optical fiber glued to the mandrel surface. In order to do fracture probability extrapolation to the untested piece of optical fiber using the Weibull model, it is essential to know the tested

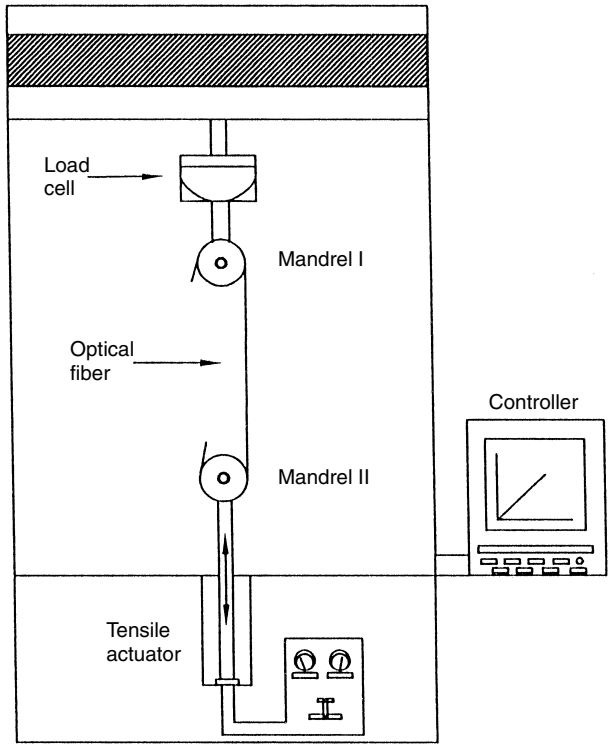

Figure 4. Optical fiber tensile tester.

length. To minimize this problem, one possibility is to test long-length samples of ($\geq$10 m). Another advantage with long length tests is that it gives more knowledge about the extrinsic defects present in the optical fiber [18].

Bending tests are performed in very small pieces of optical fiber samples, around 5 cm in length. In this test an optical fiber sample is introduced between two grooved steel plates. When one plate is pushed against the other, the curvature radius decreases until the optical fiber breaks. This is called the *bending dynamic fatigue test* (Fig. 5). By measuring the optical fiber curvature radius in the moment of the fracture, it is possible to know the maximum bending stress at the fracture (bending strength). This test can be performed on one by one sample or in multigrooved plates, up to 24 samples. Acoustic detectors can be used to precisely measure the distance

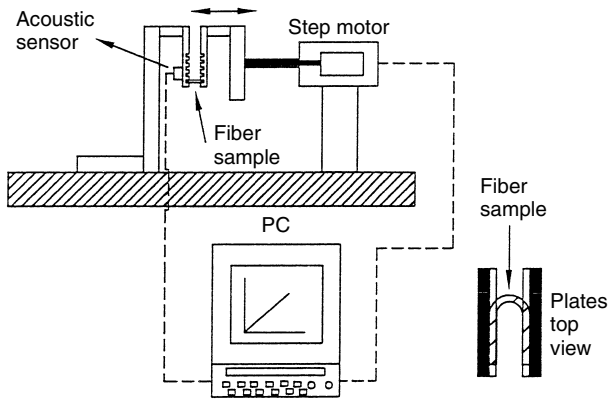

Figure 5. Two-point bending tester with acoustic detector.

of the plates that is connected with the curvature radius during the breaks [19].

The maximum bending stress is applied to a few square micrometers of the glass surface. The probability of finding an extrinsic defect in such areas is small, assuming that the optical fiber is of reasonable quality. This test is intended to measure the intrinsic strength of the glass surface. The test can be used to check how much the coating covers the glass, or the glass corrosion when the optical fiber is under chemical attack in harsh environments.

Another test in bending consists of holding the steel plates at a calculated distance, maintaining the bending stress constant, until the samples break. This is called a *static fatigue in bending*. In such a case, the survival time of the optical fiber under bending stress is measured. This bending test can be easily performed in harsh environments but cannot be done so easily under tension. In order to perform the static fatigue test for tensile, strength it is necessary to have a lot of space in order to accommodate the samples and the expensive equipment that is required to maintain constant environmental conditions in the area of the test.

The dimensions of the optical fiber core and its cladding refractive-index contrast confine the light being transmitted, but slight perturbations in geometry can cause a loss of power. Small mechanical forces acting on the surface of the optical fiber coating can be mechanically transmitted to the core, causing small perturbations in diameter. These perturbations are of the order of the fiber core diameter or less. Pressing a piece of fiber in a rough surface can be sufficient to change the optical fiber attenuation. This phenomenon is called *microbending sensitivity*. In cable design, this parameter must be minimized, taking in to account the maximum and minimum temperature fluctuations that can affect the format of the fiber inside the cable, the number of optical fibers in contact with each other, and the compatibility of the optical fiber with other cable structures. In order to measure the microbending sensitivity, attenuation measurements are used during susceptibility tests, such as temperature fluctuations and mechanical tests, with optical fiber cables.

It is still possible to measure the microbending sensitivity of a piece of optical fiber by monitoring the attenuation in a test where the optical fiber is compressed at known loads between two rough sandpaper sheets. This it can be done for a specific light wavelength using a power detector or for a broader wavelength range, using a spectral attenuation apparatus. Actually there does not exists standard procedure for this test.

When a piece of optical fiber is bent in a radius larger than that of the fiber, a small part of the light radiation can propagate through the core and leak to the cladding, causing the light to be lost. This phenomenon is called *macrobending attenuation*. Using metallic mandrels at different diameters and wrapping the same length of fiber around them, it is possible to measure relatively accurately the relationship between the fiber bent diameter and the optical attenuation. This measurement can be done for a specific wavelength or for a wide wavelength range, using a spectral attenuation apparatus. This is useful information in cable design and installation of optical fiber systems.

Silica glass is susceptible to environmental humidity, and polymer-coated optical fibers reach equilibrium with the environment in less than an hour. The plastic polymer coating works as a net on the surface of the glass, as it is permeable to the water molecules. Environmental humidity fluctuations, around 10% relative humidity (RH), can affect the optical fiber mechanical tests. Other liquids and gases can affect the strength performance of the fiber. Basic substances are more supportive of glass corrosion. All mechanical tests must be performed in a humidity-controlled environment, after the optical fiber is in equilibrium with the environment. Environmental recommendations are present in all standardized mechanical tests.

The glass susceptibility to the environment can be measured by performing strength tests at different stress rates. Stress rates are related to the force variation in time applied to a sample. Using different stress rates, it is possible to isolate the strength degradation caused by the presence of humidity from the strength degradation caused by the stress alone. The parameter that describes how rapidly the strength degradation occurs in the presence of humidity is called *optical fiber fatigue n* [20]. This parameter is obtained using at least four groups of samples tested at four different stress rates. In terms of fiber reliability, this is the most important parameter. The n number is the power that will be used to calculate the optical fiber lifetime.

An important aspect of the optical fiber mechanical degradation is related to the survival time of the optical fiber in the field. This is called the *optical fiber reliability* [21]. For this calculation it is necessary to know well the *fiber stress history* (FSH), which *FSH* is the accumulation of all the stresses applied to the optical fiber during the different transmission system construction and use: optical fiber manufacturing, proof testing, cabling, installation, and application. The FSH parameters using time fracture probability to estimate the fiber lifetime after installation are the minimum guaranteed strength after the proof test, as described above; the optical fiber fatigue parameter n; and the low−stress break flaw distribution, measured using the tensile test For long lengths of the proof tested optical fibers. To complete the necessary calculations, it is necessary to use a crack growth model when the optical fiber is under low stress in the presence of humidity. Normally, a *power-law crack growth model* is used, which assumes a power relation between the crack growth velocity, the parameters of the material, and the applied stress. The fatigue parameter n is the power variable in this model. Other crack growth models were proposed in the last decade but the power law is the most reliable and treatable model. The power-law model is used in national and international standards.

To complete the mechanical characterization, it is necessary to measure the qualities of the optical fiber coatings. The most important characteristics of the fiber coatings are (1) the primary coating must have a good chemical reactivity with the glass surface, to protect the glass from moisture; (2) the primary polymer coating must have lower elastic modulus, to absorb external small stress that causes attenuation by microbending sensitivity; and

(3) the secondary polymer coating must have a higher elasticity modulus to improve the resistance to the abrasion.

It is possible to join the extremities of optical fibers by keeping the attenuation and the mechanical qualities under control. This operation is called *optical fiber splice*. Splices are common in optical fiber cable installation and in optical fiber cable repairs. An important step in the splice procedure consists in removing the coating of the fiber extremities. The glass must be completely clean and well cleaved to perform the thermal fusion of the extremities. If the primary coating is overconnected with the glass, the operation will be difficult and can affect the splice quality. If the primary polymer coating is loose on the surface of the fiber, or not completely cured, it does not promote the necessary protection [22].

Standard procedures to measure coating quality and how it affects splice performance are under study by standards committees and include methods to measure the simplicity of removing the coating of the optical fiber, strip-force and pullout force techniques, and methods to measure the elasticity modulus of the primary coating.

BIOGRAPHY

Gilberto Camilo received his D.Sc. degree from Campinas University, Sao Paulo, Brazil, in 1991. He was employed by PIRELLI Optical Fibers, Sao Paulo, Brazil, between 1987 and 1991. He taught physics and mechanical engineering at Goias and CEFET-Parana Federal University, Brazil, during 1991–1998. He was a Post-Doctoral Fellow at Rutgers University, and worked on the Ceramic and Materials Engineering — Optical Fibers Project during 1994–1995. He was with Furukawa Optical Fiber Cables, Parana State, Brazil, during 1997–1998 and with Alcatel, in charge of Optical Fibers Mechanical Reliability at Claremont, North Carolina, during 1998–2001. Since 2001 he has been with OmniGuide Communications, at Cambridge, Massachusetts, as Optical Fiber Reliability Specialist. He has been active in the TIA/EIA Optical Fibers Standard Committees since 1998. He is a member of the OSA, IEEE, and SPIE. Dr. Camilo has published over 50 papers in the area of optical fiber mechanical Characterization. His main interest areas are optical and mechanical characterization and reliability of optical fibers and optical cables.

CHIRP MODULATION

DIRK DAHLHAUS
Communication Technology Laboratory
Zurich, Switzerland

1. INTRODUCTION

Chirp modulation (CM) represents a special type of spread-spectrum signaling where a carrier signal is modulated in two ways. The primary modulation is carried

out in the complex baseband and constitutes the usual formats such as phase shift keying (PSK), pulse position modulation (PPM), or binary orthogonal keying (BOK). The primary modulation is combined with a secondary modulation for spectrum spreading. For a data rate T^{-1} with T denoting the symbol duration, the occupied Fourier bandwidth B exceeds T^{-1} considerably; that is, in general, the time-bandwidth product $TB \gg 1$. The spreading is advantageous in frequency-selective fading channels often encountered in wireless or mobile radio systems. If the occupied spectrum is larger than the coherence bandwidth of the channel, the transmission is more robust against the fading because of the resulting frequency diversity. In addition, as shown by Berni and Gregg [1], CM is resistant to the Doppler effect arising in time-variant scenarios typically encountered in mobile radio applications. CM signals have been first proposed by Winkler [2] for their high robustness against distortions and different types of interference.

In most cases, "chirp modulation" refers to a sinusoidal signal of duration T whose instantaneous frequency changes linearly in time t between the lower frequency $f_1 = f_0 - B/2$ and the upper frequency $f_2 = f_0 + B/2$, where f_0 denotes the carrier frequency of the signal. In its simplest form, CM is used in combination with binary signaling as primary modulation. To transmit a logical 0 using a binary CM signal, an "upchirp" is used, which corresponds to a linear frequency sweep from f_1 to f_2. A logical 1 is transmitted correspondingly as a "downchirp," a linear frequency sweep from f_2 to f_1. For sufficiently large values of the time-bandwidth product, the upchirp and downchirp signals transmitted in a common band constitute the aforementioned BOK. The name *chirp* has been given to such signals by Bell Telephone Laboratories because of the resemblance to a sound heard in nature [2]. CM signals have their roots in radar applications where one of the most important observations states that range resolution and accuracy are functions of the signal bandwidth, and not of the transmitted pulsewidth [3].

In Section 2, important properties of CM signals are discussed including the form of linear frequency-modulated (FM) signals, the signal spectrum, the matched-filter (MF) characteristics, measures for sidelobe reduction, and modulation schemes. In Section 3, the performance of the different schemes is analyzed. Section 4 describes different ways to implement CM systems including surface acoustic wave (SAW) devices as well as digital baseband techniques. Other aspects related to CM in communication systems are discussed in Section 5.

2. PROPERTIES OF CM SIGNALS

2.1. Time and Frequency Representation

The general form of FM bandpass signals to be considered is given by

$$s(t) = a(t)\cos(\omega_0 t + \theta(t)), \qquad -\frac{T}{2} < t < \frac{T}{2} \tag{1}$$

where $f_0 = \omega_0/2\pi$ and $\theta(t)$ denote the carrier frequency and the signal phase, respectively. The envelope $a(t)$ can be used as a weighting function to improve the autocorrelation properties of $s(t)$ as discussed in Section 2.3. Here, it is first assumed a rectangular function over the interval $[-T/2, T/2]$. The instantaneous frequency is defined by

$$f(t) = \frac{1}{2\pi}\left(\frac{\omega_0 + d\theta}{dt}\right) \tag{2}$$

For linear FM signals, we obtain

$$f(t) = f_0 + \mu t, \qquad -\frac{T}{2} < t < \frac{T}{2} \tag{3}$$

with $\mu \in \mathcal{R}$ denoting the dispersive slope or rate of the chirp signal. From (3), $f(t)$ varies between the lower (resp. upper) frequencies

$$f_1 = f_0 - |\mu|\frac{T}{2}$$

$$f_2 = f_0 + |\mu|\frac{T}{2}$$

over a range $B = |\mu|T$[1], where $\mu > 0$ and $\mu < 0$ denote an upchirp and (resp. downchirp) signal, as shown in Fig. 1. The signal phase results in

$$\theta(t) = \pi\mu t^2 + \theta_0, \qquad -\frac{T}{2} < t < \frac{T}{2} \tag{4}$$

with a suitable initial phase value θ_0. For the usually valid narrowband assumption $f_0 \gg |\mu|T$ [3] and $\theta_0 = 0$, the spectrum of an upchirp $S(\omega) = \int_{\mathcal{R}} s(t)\exp[-\jmath\omega t]\,d\omega$ of $s(t)$ is given by [3]

$$S(\omega) = \frac{1}{2\sqrt{2\mu}}\exp\left[-\jmath\frac{(\omega-\omega_0)^2}{4\pi\mu}\right] \times \left[\mathcal{C}(X_+) + \jmath\mathcal{S}(X_+) + \mathcal{C}(X_-) + \jmath\mathcal{S}(X_-)\right]$$

where

$$\mathcal{C}(X) = \int_0^X \cos\left(\frac{\pi y^2}{2}\right)dy, \qquad \mathcal{S}(X) = \int_0^X \sin\left(\frac{\pi y^2}{2}\right)dy$$

are Fresnel integrals and the integral limits are given by

$$X_\pm = \frac{\pi\mu T \pm (\omega - \omega_0)}{\pi\sqrt{2\mu}}$$

On substituting

$$\mu = \frac{B}{T}, \qquad \omega - \omega_0 = n\pi B$$

with the normalized frequency n, we obtain

$$X_\pm = \frac{1 \pm n}{\sqrt{2}}\sqrt{TB}$$

[1] The bandwidth occupied by $s(t)$ is larger than B, but approaches B for $TB \to \infty$.

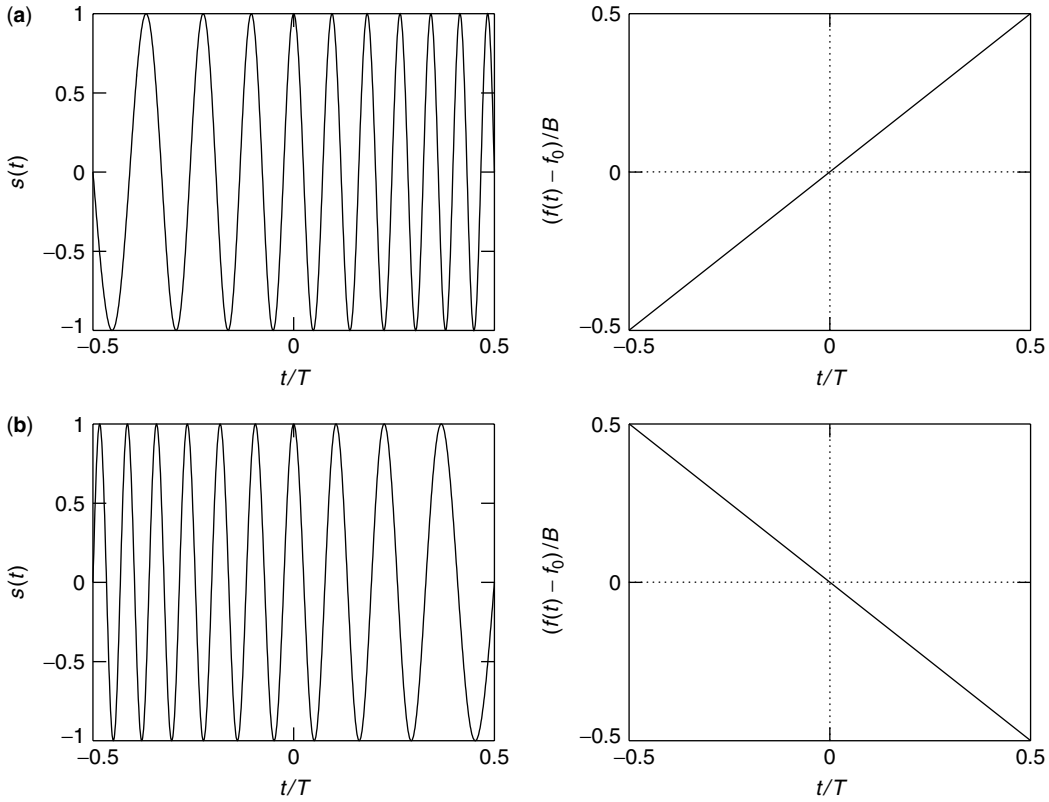

Figure 1. Chirp signals and corresponding instantaneous frequencies: (**a**) upchirp; (**b**) downchirp.

specifically, the amplitude spectrum of $s(t)$

$$|S(\omega)| = \frac{1}{2\sqrt{2\mu}}\sqrt{\left[\mathcal{C}(X_+) + \mathcal{C}(X_-)\right]^2 + \left[\mathcal{S}(X_+) + \mathcal{S}(X_-)\right]^2} \tag{5}$$

in Fig. 2 depends solely on the time–bandwidth product TB. The spectrum characteristics in the band center are mainly determined by the so-called Fresnel ripples arising from the Fresnel integrals. The height of the ripples increase for decreasing TB while the spectrum is asymptotically rectangular for $TB \to \infty$. It can be shown that the amplitude spectrum in (5) is valid also for a downchirp if μ is replaced by $|\mu|$ in all terms containing the dispersive slope variable. More information on the phase spectrum for upchirp and downchirp signals can be found in the treatise by Cook and Bernfeld [3]. For $TB \gg 1$, the described binary modulation is sometimes termed BOK since the normalized cross-correlation of upchirp and downchirp signals is almost zero. The correlation properties of the chirp signals are considered in the next section.

2.2. Matched Filtering

The MF providing a sufficient statistic for symbol detection in additive white Gaussian noise (AWGN) and maximizing the signal-to-noise ratio (SNR) for a perfectly synchronized receiver is termed a *compression filter* in linear FM systems. For an upchirp signal in (1), the impulse response of the MF is a downchirp given by

$$h(t) = ks(-t) = k\cos\left(\omega_0 t - \pi\mu t^2\right), \qquad -\frac{T}{2} < t < \frac{T}{2}$$

where $k = 2\sqrt{\mu}$ is chosen for a unity gain of the MF at $f = f_0$. Here, the MF output is considered for a channel with a Doppler shift f_D. This situation studied extensively in radar applications [3] arises in mobile communications, such as in time-varying line-of-sight channels. The MF output signal in the absence of thermal receiver noise is given by

$$\begin{aligned} g(t, f_D) &= \int_{\mathcal{R}} s(\tau)\, h(t-\tau)\, d\tau \\ &= 2\sqrt{\mu}\int_a^b \cos\left[(\omega_0 + 2\pi f_D)\,\tau + \pi\mu\tau^2\right] \\ &\quad \times \cos\left[\omega_0(t-\tau) - \pi\mu(t-\tau)^2\right] d\tau \\ &= \begin{cases} \dfrac{\sqrt{\mu}}{\pi}\,\dfrac{\sin\left(\pi\left(f_D + \mu t\right)\left(T - |t|\right)\right)}{f_D + \mu t} \\ \quad \times \cos\left(2\pi\left(\dfrac{f_0 + f_D}{2}\right)t\right), & -T < t < T \\ 0 & |t| \geq T \end{cases} \end{aligned} \tag{6}$$

with

$$a = -\frac{T}{2} + t, \quad b = \frac{T}{2} \qquad \text{for } t \geq 0$$

$$a = -\frac{T}{2}, \qquad b = \frac{T}{2} + t \quad \text{for } t < 0$$

The frequency shift of $f_D/2$ in (6) can be easily understood from considering the spectra of the input and MF signals [3]. Figure 3 shows the envelope of $g(t) =$

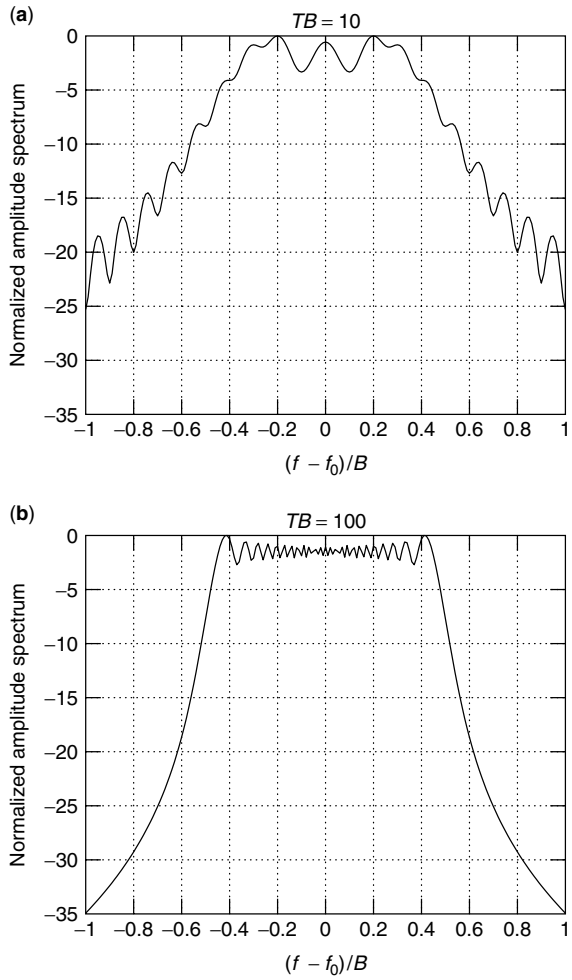

Figure 2. Amplitude spectra for different time–bandwidth product values: (**a**) $TB = 10$; (**b**) $TB = 100$.

$g(t, f_D = 0)$ for different values of TB. As can be concluded from (6), the height of the correlation peak is $T\sqrt{\mu} = \sqrt{TB}$. Thus, the *compression gain*, defined as the ratio of the peak value to the chirp amplitude, is $G = 10\log(TB)$ dB. For $TB \gg 1$, it can be shown that the width of the mainlobe is $2/B$ while the minimum sidelobe suppression, expressed by the ratio G_{SL} of the mainlobe and the first sidelobe values, is approximately 13.3 dB. This ratio essentially determines the system robustness against intersymbol interference (ISI) in frequency-selective fading channels arising from multipath propagation of the transmitted signal. Measures for reducing the sidelobes are discussed in the next section. Figure 4 shows the shape of $g(t, f_D)$ for different values f_D/B. Obviously, the correlation peak is shifted, attenuated, and spread as compared to Fig. 3. Proceeding as in (6), it is readily shown that the cross-correlation for $f_D = 0$ and $t = 0$ between upchirp and downchirp equals $(C\sqrt{TB})$, which approaches $\frac{1}{2}$ for large TB. In this case, the ratio of the cross-correlation and autocorrelation equals $1/(2\sqrt{TB})$ which justifies the assumption of BOK for large TB.

2.3. Sidelobe Reduction

One way to increase the dynamic range of the pulse compression is to modify the signal spectrum of $g(t)$

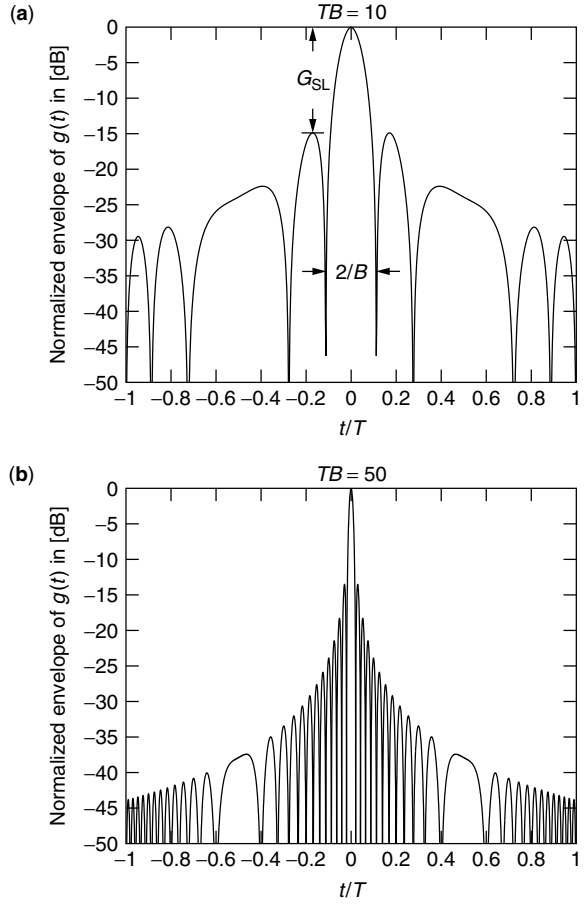

Figure 3. Normalized envelope of the MF output signal $g(t)$ for different time–bandwidth product values: (**a**) $TB = 10$ (**b**) $TB = 50$.

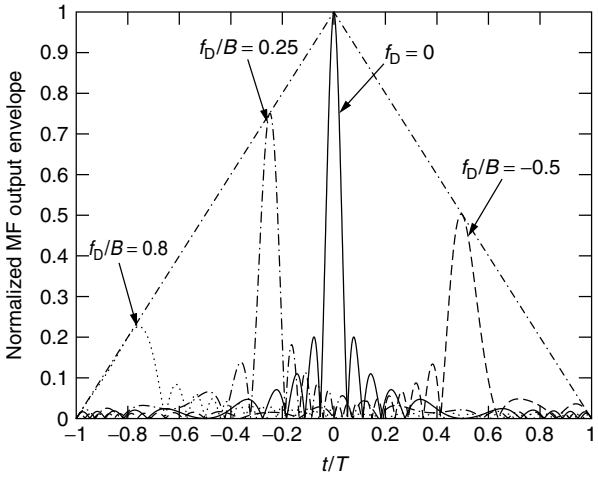

Figure 4. MF output signal $g(t, f_D)$ for different values f_D/B and $TB = 20$.

for decreasing the sidelobe levels. The corresponding weighting can be implemented in the frequency or time domain. The optimum distribution function can be derived from an analogous problem in antenna theory treated by Dolph [4] and Van der Mass [5] that targets the narrowest beamwidth of a broadside antenna array for a desired

sidelobe level. However, the resulting Dolph–Chebyshev weighting function has infinite power and is thus physically not realizable. Approximations to the optimum solution are provided by the Taylor functions and modified Taylor functions [3]. The latter contain the so-called Hamming function

$$W_H(f) = 0.08 + 0.92\cos^2\left(\pi\frac{f-f_0}{B}\right), \qquad |f-f_0| \le \frac{B}{2}$$

as a special case. It can be shown that this weighting results in a sidelobe suppression of −42.8 dB, a spreading of the mainlobe by a factor of 1.47 and a loss in compression gain of 1.34 dB. The influence of the Fresnel ripples on Hamming weighted chirp compression is treated by Kowatsch and others [6,7] who considered both time and frequency weighting as well as Doppler shifts. A considerable reduction of the Fresnel ripples can be achieved by using a Tukey window, where the undesirable mainlobe width increase is only moderate [6].

2.4. Modulation Schemes

Although the spectrum spreading in CM can in principle be combined with any baseband signaling, the choice of the primary modulation in a practical system is restricted by, For example, performance requirements, an efficient implementation, and component imperfections. Here, some modulation schemes are described that can be used in CM and are discussed in Section 3 in terms of the achievable bit error rate (BER). As in Proakis' text [8], linear modulation is distinguished from nonlinear modulation with memory.

2.4.1. Linear Modulation. The chirp pulse in (1) can be implemented efficiently by a SAW device (see Section 4). The properties of this technology rule out certain modulation schemes, such as amplitude shift keying (ASK). The problem with the latter scheme is the high dependence of the output power on the rising time of the broadband pulse exciting the filter. This problem is usually circumvented if PSK, BOK, or PPM is employed [9,10]. El-Khamy and Shaaban [11], match μ to the dispersion parameters of the communication channel. They show that for a channel with a second-order polynomial phase spectrum and a partially coherent detection, μ should be chosen according to $TB = 2.65$, which minimizes the BER. The aforementioned BOK requires upchirp and downchirp filters at both the transmitter and the receiver. Clearly, the bit error performance depends critically on the sidelobe level and the cross-correlation properties of the employed chirp signals as well as the delay dispersion of the channel. Some of the problems can be solved if PPM signals are employed using only one chirp signal type (e.g., an upchirp). In PPM [9], the binary signals are orthogonal, the cross-correlation problem does not arise, and only one chirp filter has to be implemented in the transmitter and the receiver. In case of a logical 1, the chirp is sent Δt before the reference clock, while for a logical 0, the chirp is delayed by Δt. The system performance is determined by the value Δt and the channel delay dispersion. Another standard modulation method is differentially encoded quaternary PSK (DQPSK), which allows for a differential demodulation without carrier phase estimation. Usually, $\pi/4$ DQPSK offering reduced envelope fluctuations as compared to ordinary DQPSK is employed. Again, the performance limiting factors are the sidelobe levels and the channel delay dispersion. In general, the data rate can be increased by applying overlapping signal pulses that can be resolved at the receiver for sufficient sidelobe reduction capabilities of the employed MF output signals.

2.4.2. Nonlinear Modulation with Memory. CM for binary signaling Hirt and Pasupathy combined with full-response (FR) continuous phase modulation and termed FR *continuous-phase chirp modulation* (FR-CPCM). The idea of FR-CPCM is the improvement of the independent bit-by-bit detection in conventional CM systems by observing the phase-constrained received signal over two or more bit intervals prior to bit detection. In CPCM, instead of (4), the transmitted signal phase for $t \ge 0$ is given by

$$\theta_k(t) = a_k\psi(t-kT) + \pi q\sum_{r=0}^{k-1} a_r + \theta_{-1}, \quad kT \le t \le (k+1)T \tag{7}$$

where $a_i = \pm 1$ denotes the binary data, $k = 0, 1, \ldots$ and the phase function is defined as

$$\psi(t) = \begin{cases} 0, & t \le 0, t > T \\ \pi\left(h\dfrac{t}{T} - w\left(\dfrac{t}{T}\right)^2\right), & 0 \le t \le T \\ \pi q = \pi(h-w), & t = T \end{cases}$$

where h and w represent the normalized initial peak-to-peak frequency deviation and the frequency sweep width, respectively. For the case of coherent detection, it has been shown [12] that a receiver with an observation of 2 bits provides a good compromise between signal-to-noise ratio (SNR) gain and system complexity.

As conjectured by Hirt and Pasupathy [12], the system performance can be further improved by considering multimode continuous phase systems. Raveendra [13] investigated the approach of varying the modulation of a continuous-phase FSK. Here, the phase in (7) is replaced by

$$\theta(t) = \sum_{i=1}^{n} a_i\psi_i(t-(i-1)T), \qquad 0 \le t \le nT \tag{8}$$

where the phase functions in (8) depend now on the symbol interval i according to

$$\psi_i(t) = \begin{cases} 0, & t \le 0 \\ \pi\left(h_i\dfrac{t}{T} - w_i\left(\dfrac{t}{T}\right)^2\right), & 0 \le t \le T \\ \pi q_i = \pi(h_i - w_i), & t \ge T \end{cases}$$

While in conventional monomode continuous-phase chirp transmission $q_i = q$ and $w_i = w$ for $i = 1, 2, \ldots$, the (q_i, w_i) now form a sequence of sets with period K, specifically, $(q_i, w_i) = (q_{i+K}, w_{i+K})$.

Fonseka [14] employed partial-response CPCM (PR-CPCM) signals in an attempt to increase the minimum distance $d_{\min}$ of the signals that determines the system performance. At the same time, the spectrum is to be kept flat so that the system is robust against jammers in the transmission band. The increase in the number of states in PR-CPCM as compared to FR-CPCM is an important issue. If in the latter $(h - w)$ is expressed as the ratio of two relatively prime integers as $h - w = \ell/m$, the m possible states during any interval can be represented by m evenly spaced phase states. In PR-CPCM with LT denoting the support of the baseband frequency pulse, the number of phase states depends on the individual values of h and w. When h and w are expressed as ratios of integers $h/L = \ell_1/m$ and $w/L^2 = \ell_2/m$ with the smallest common denominator m, the number of phase states during any interval is m. In view of the symbol states arising from the $(L - 1)$ previous symbols, the total number of states in PR-CPCM is $m2^{(L-1)}$.

2.4.3. Multiple Access. The aforementioned modulation schemes are designed for the case where receiver thermal noise (and possibly some narrowband interfering signals) represent the only disturbances in the bandwidth occupied by the signal. If the spectrum is shared among M simultaneously transmitting users, the resulting multiple-access interference (MAI) among the users increases the BER as compared to the single-user system. To avoid complex signal processing schemes for interference mitigation at the receiver, the signal formats have to be chosen carefully in order to limit the MAI. Different approaches based on CM have been proposed and are discussed below.

Takeuchi and Yamanouchi [15] assigned consecutive bits transmitted by CM with DPSK to different users; thus, time-division multiple access (TDMA) is applied here. The sidelobe level suppression and processing gain are 30 and 19 dB, respectively, and the system is implemented using SAW devices. Nonlinear CM is applied in order to obtain a flat amplitude spectrum within B.

A more sophisticated approach [16] for multiple access assigns $2M$ different instantaneous frequency functions $f(t)$ [cf. Eq. (2)] to M users employing binary signaling. The chirp duration T is split into two intervals of length $T/2$, and each of the proposed multiuser chirp signals of duration T is characterized by two different slopes in the two intervals. This approach is a straightforward extension of the chirp signals used in BOK to a M-user system where all signals occupy a common bandwidth B. Since the detection of the M symbols requires $2M$ different chirp matched filters, however, the complexity of the receiver is relatively high as compared to that reported by Takeuchi and Yamanochi [15].

Frequency-hopped code-division multiple access (FH-CDMA) is employed in another study [17]. Using basically the multiuser chirp signals of Ref. 16 in each time–frequency (TF) hop, the collision of different FH-CDMA user signals containing binary frequency-shift keying (FSK) symbols in the same TF hop can be resolved. Still, however, $2M$ different chirp matched filters are required and all chirp filters have to be changed after a new user has entered the system.

Improved flexibility and a simple receiver design are the main objectives of the multiple-access scheme in another paper [18], where transmission from a base station to multiple users over a multipath channel is considered. Here, the advantages of synchronous binary direct-sequence (DS) CDMA are combined with chirp signaling. The positive and negative chip pulses $\pm c(t)$ normally used in DS-CDMA for spreading the signal spectrum are replaced by the upchirp and downchirp signals in Section 2.1. It is shown that the quasiorthogonality of these signals allows for a noncoherent detection followed by a postdetection integrator (PDI) whose output is sampled to provide estimates of the superimposed code sequences of the different users. Finally, the information bit of a certain user is estimated from the correlation of the sample sequence with the user code. Only two different chirp filters are required, and the multiple access can be fully controlled by assigning codes in the digital domain.

3. PERFORMANCE ANALYSIS

For the case of linear modulation, the BER of a BOK system has been evaluated [10] for nonoverlapping chirp signals with $T = 2\,\mu\text{s}$, $B = 80\,\text{MHz}$, and a sidelobe suppression of $G_{SL} = 42\,\text{dB}$, resulting in a bit rate of 500 kbps (kilobits per second). To increase the data rate to 2 Mbps, the chirp pulses are allowed to overlap. Figure 5 shows the resulting BER as a function of the SNR $\gamma = E_b/N_0$ in an AWGN channel where E_b and N_0 denote the bit energy and the noise power spectral density, respectively. It has been pointed out [10] that multipath propagation limits the BER performance where sequences of consecutive upchirp or downchirp signals are to be avoided. BER results corresponding to Fig. 5 for $\pi/4$-DQPSK can be found in Gugler's thesis [9].

Hirt and Pasupathy [12] investigated the BER performance of FR-CPCM for coherent detection. It has been shown that a receiver with an observation of 2 bits provides a good compromise between SNR gain and system complexity. In this case, the optimum choice $(q, w) = (0.28, 1.85)$ gives an SNR gain of 1.75 dB over the optimum coherent 1-bit chirp receiver with $(q, w) = (0.35, 1.55)$.

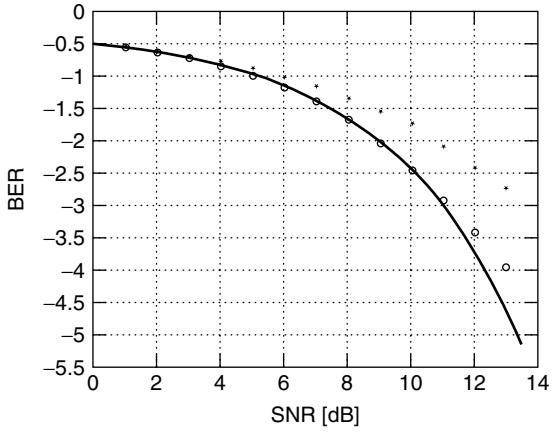

Figure 5. BER for BOK and different data rates: lower bound for orthogonal signals [8] (−), nonoverlapping 2-μs-long chirp signals (○), and overlapping 2-μs-long chirp signals with a data rate of 2 Mbps (∗) (figure taken from Ref. 10).

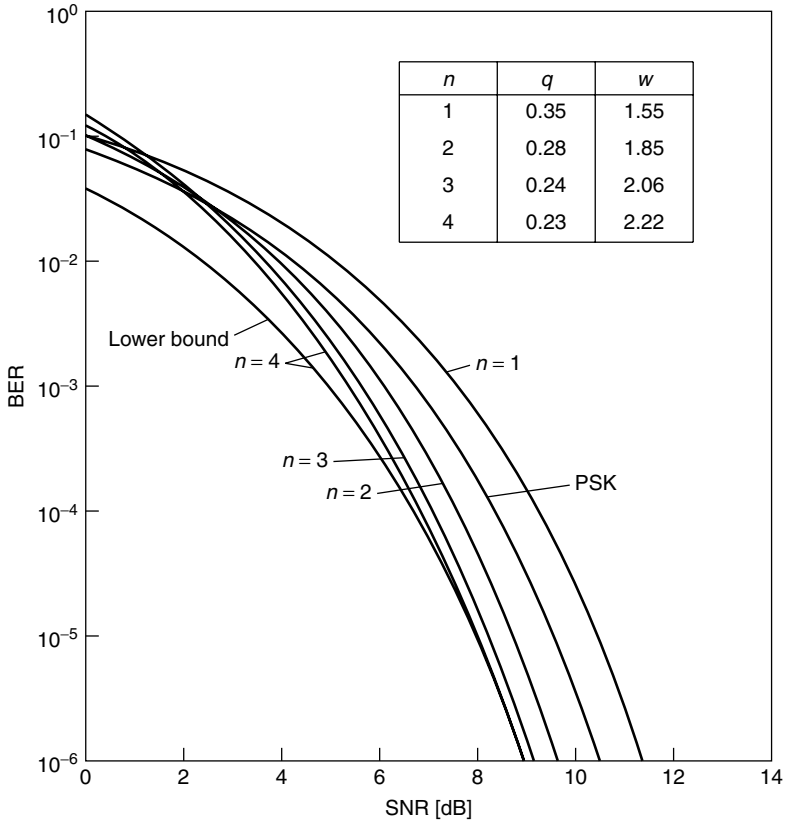

Figure 6. BER bounds for a coherent FR-CPCM receiver (figure taken from Ref. 12).

Upper BER bounds for different values of the observation length n together with the optimal values for q and w are shown in Fig. 6. The lower bound for $n = 4$ indicates the tightness of the bounds for increasing SNR values. In the context of a possible implementation, a simple suboptimum average matched filter (AMF) is shown to provide binary PSK performance for an optimum 2-bit observation. In another study, Hirt and Pasupathy [19] investigated the noncoherent detection case for FR-CPCM and showed the 3-bit noncoherent AMF receiver is to yield a 3-dB SNR gain over a wide range of signal parameters.

An investigation of multimode transmission performance [13] reveals that for an observation interval with $n = 5$, the optimum dual-mode chirp system, namely, $K = 2$, with $(q_1, w_1) = (0.3, 1.68)$ and $(q_2, w_2) = (0.5, 1.68)$ outperforms the optimum coherent 1-bit chirp receiver with $(q, w) = (0.35, 1.55)$ by 3.4 dB.

For Fonseka's [14] PR-CPCM with $L = 4$ and 24 states, the value of $d^2_{\min}$ can be increased by a factor of 2.15 as compared to the case $L = 1$ [14]. Furthermore, the PR-CPCM signals, are shown to have better spectral variations than conventional CM signals which indeed leads to the required robustness against jamming.

A CM TDMA scheme with DPSK [15] shows a BER that increases is only marginally for an increasing number of simultaneous users M. It is shown in simulations that the SNR loss for $M = 9$ as compared to $M = 1$ is only about 1 dB, where the latter case is about 2 dB worse than the lower BER bound for DPSK transmission.

The CM multiple-access scheme with the $2M$ different instantaneous frequency functions has been analyzed [16] for an AWGN channel using upper BER bounds for different values of M. As in the case of the CM TDMA scheme with DPSK, the bounds are relatively robust against different values of M. For $TB = 500$, the SNR loss of $M = 16$ as compared to $M = 1$ is only about 1 dB, and the BER decreases for increasing values of TB.

In another study [17], FH-CDMA with multirate chirp rate (MRC) signals is compared with a FH-CDMA scheme with FSK for an AWGN channel. It is observed that MRC-FH-CDMA is at least 2 dB better than the FSK-FH-CDMA scheme. For a BER of 10^{-1}, an increase of M to $M + 5$ results in a loss of 0.6 dB for MRC-FH-CDMA and 1.5 dB for FSK-FH-CDMA, respectively.

Kocian and Dahlhaus [18] observed bounds on the BER performance of the CDMA scheme described at the end of Section 2.4.3 with PDI and derived a square-law envelope detector in a non-frequency-selective channel (NFSC). The BER in a frequency-selective channel (FSC) with Rayleigh fading and an exponential power delay profile is depicted in Fig. 7 for $M = 1$ and $M = 16$ users, respectively, for a CDMA codelength of $N_c = 16$. For comparison, the BER of the optimum noncoherent detector (ND) has been included in Fig. 7. If the data rate is increased, the decision variable is corrupted by ISI and MAI, and the BER starts to saturate for increasing γ.

The preceding analysis has assumed a perfect channel state information at the receiver. Partially coherent detection of CPCM signals is considered in another study [20], while parameter estimation of chirp signals has been treated by Kay and others [21,22].

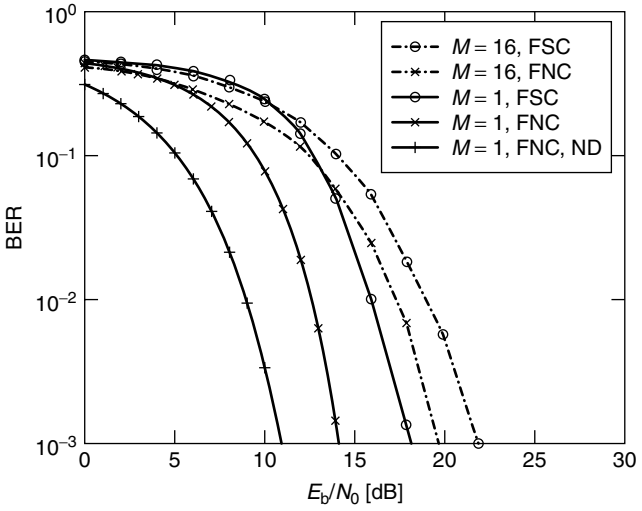

Figure 7. Mean BER for $N_c = 16$ in a multipath fading channels for different numbers M of users (figure taken from Ref. 18).

4. IMPLEMENTATION ISSUES

There are different ways to implement communication systems using CM. The two most prominent ones, namely SAW filters and direct digital frequency synthesizers (DDFS), are outlined below. Approaches based on voltage-controlled oscillators with appropriate function generators as well as excitation of a conjugate MF network with an impulse are described in another treatise [3].

In SAW filters there is no need for complex digital baseband signal processing. SAW filters are well suited for today's wireless communications because of their high performance, small size, and low cost [23]. On the other hand, since the CM parameters specify the form of the filter, SAW devices are not flexible and cannot be applied in systems where the parameters are subject to changes. SAW filters operate at an intermediate frequency (IF), and a mixer is used to upconvert the signal to the radiofrequency (RF). For the system reported by Koller et al. [23], IF = 348.8 MHz, RF = 2.45 GHz, $B = 80$ MHz, and $T = 0.5\,\mu$s. For the $\pi/4$-DQPSK modulation described by Gugler [9], a suitable pulse for exciting the filter is located at the IF center frequency and has a rectangular shape, the length of which equals four periods of the IF. Unlike in conventional systems where the IF is modulated by a $\pi/4$-DQPSK signal, the IF pulse exciting the SAW filter is modulated. Because of the sensitivity of the output power on the rising time of the broadband pulse exciting the filter, ASK is not suited for CM with SAW filters. Other examples of CM systems based on SAW filters can be found in the literature [15,24,25].

Unlike SAW filters, DDFS are highly flexible since the parameters of the CM signal can be set by a digital controller. Salous et al. [26] have presented a digital chirp sounder for mobile radio applications. In particular, the time and frequency resolutions are fully programmable. This is important for the different multiple-access schemes in Section 2.4.3, where the CM signal format depends on the number of simultaneous users. Clearly, the computational effort is large, but it is expected for decreasing costs of digital components such as digital–analog converters and dedicated signal processors that the DDFS will be preferred to the SAW approach in the future. A commercially available digital channel sounder with CM is described in Ref. 27 and a digital local oscillator for CM generation, in Ref. 28. Allen et al. [29] have direct digital synthesis of CM signals for a light detection and ranging application.

5. OTHER ASPECTS RELATED TO CM IN COMMUNICATION SYSTEMS

CM has been described in Section 2.4 as a means of transmitting information in form of a spread-spectrum signal over a linear channel. In semiconductor lasers (SCL), frequency chirping arises as an undesired effect in fiberoptic transmission using current modulation. As pointed out in another study [30], when the device current is modulated at frequencies approaching a few gigahertz, the dynamic response of SCL leads to an increased linewidth of an individual longitudinal mode where the line broadening is proportional to the linewidth enhancement factor (also termed the *antiguiding parameter*) β_c. The resulting chirp has its origin in the carrier-induced refractive-index change that accompanies any gain change in SCL. Agrawal and Dutta [30] described several measures that lead to light emission of SCL predominantly in a single longitudinal mode even under high-speed modulation.

Concerning the use of CM in communication systems, there are presently only very few applications. One example is the Consumer Electronic Bus (CEBus) EIA/IS60 powerline communications standard where CM can be used with a data rate of 10 kbps in an unlicensed frequency band, 100–450 kHz, for home networking. Although proposals have been made to use CM in wireless communication systems, especially in wireless local-area networks, standardization bodies have preferred other types of modulation to CM. With the advent of more advanced CM systems based on DDFS in combination with software defined radio concepts, however, CM might be an interesting alternative modulation format for future communication systems operating in frequency-selective channel environments.

BIOGRAPHY

Dirk Dahlhaus received the Dipl.-Ing. degree in electrical engineering from Ruhr-Universität Bochum, Germany, in 1992, and the Ph.D. degree from Swiss Federal Institute of Technology (ETH) Zurich, Switzerland, in 1998. Since April 1999, he has been assistant professor for mobile radio systems at the Communication Technology Laboratory of ETH Zurich. He was president of the 2002 International Zurich Seminar on Broadband Communications. His main research interests include radio channel modelling, digital signal processing and link adaptation in multiuser wireless and mobile radio communication systems.

COCHANNEL INTERFERENCE IN DIGITAL CELLULAR TDMA NETWORKS

Savo G. Glisic
Pekka Pirinen
University of Oulu
Oulu, Finland

1. INTRODUCTION

In cellular TDMA networks cochannel interference is generated in surrounding cells using the same carrier frequency. For this reason a careful planning of sectors and surrounding layers allowed to reuse the same frequency is required. In addition to sectorization (three sectors per cell), narrower antenna lobes can be used to further reduce the angular sectors of the receiving antennas so that the interference can be spatially filtered.

Usually none of these measures are efficient enough to warrant additional action to deal with the interference by using different cancellation techniques in either time,

frequency, or spatial domain. Having this in mind, we can represent the residual interference signal power as

$$I_r(r,\theta,f,t) = (1-C_f)(1-C_p)(1-C_\theta)(1-C_t)I(r,\theta,f,t)$$
$$= (1-C_r)(1-C_\theta)(1-C_t)I(r,\theta,f,t) \quad (1)$$

where C_f, C_p, C_θ, and C_t are frequency, propagation (distance + shadowing + fading), angle (space), and time isolation coefficients, respectively. $I(r,\theta,f,t)$ is the interference signal power without any suppression techniques. For perfect isolation, at least one of these coefficients is equal to one and the interference has no influence on the received signal. In practice, it is rather difficult and economically impractical to reach the point where $C_i = 1$. Instead, the product $(1-C_r)(1-C_\theta)(1-C_t)$ depending on these coefficients should be kept as low as possible with an affordable effort measured by cost, power consumption, and physical size of the hardware required for the solution.

Coefficient C_f is related to frequency assignment in the cellular network, while coefficient C_p is related to the propagation conditions. $C_f = 1$ if the interfering signal frequency is different from the frequency of the useful signal. $C_p = 1$ if, as a result of propagation losses, the interfering signal cannot reach the site of the useful reference signal. In general, the same frequency can be used in two cells only if the propagation losses between the two cells are high enough that the interfering signals are attenuated to the acceptable level. This will be characterized by the frequency reuse coefficient C_r defined as $(1-C_r) = (1-C_f)(1-C_p)$ and will be discussed in Section 2. Coefficient C_θ is related to antenna beamforming, and possibilities of reducing the interference level by spatial filtering are discussed in Section 3. Finally, interference cancellation and equalization in time domain, which is included in coefficient C_t, will be discussed in Section 4.

2. NETWORK PLANNING AND FREQUENCY REUSE

Depending on the cell size, three different categories of cellular networks can be distinguished. *Macrocells* are the largest, with a cell radius of 1 km up to 35 km or more. Base station antennas are located well above the rooftop level. The commonly used macrocellular modeling structure assumes a uniform grid of hexagonal cells [1]. Part of the hexagonal cellular layout is illustrated in Fig. 1. In Fig. 1a frequencies are reused in each cluster of seven cells and in Fig. 1b the cluster size is 3.

The hexagonal grid is optimal in the sense that there is no overlap between cells. In addition, hexagons closely approximate circles. This kind of modeling is highly theoretical since effective cell coverage areas vary considerably depending on factors such as terrain, buildings, weather, and time. Cellular models can be further classified according to base station antenna directivity. In the case of omnidirectional antennas, base stations can be located in the cell centers as illustrated in Fig. 2a. When directional antennas are used, cells can be divided into widebeam sectors as shown in Fig. 2b. Directional antenna patterns can also be modeled by corner-illuminated base stations with three narrow antenna lobes per base station. One advantage of this approach is lower cost. Fewer base stations are required over a certain geographical area than with direct sectorization. Corner-illuminated cells or the so-called "three leaf clover" structure is illustrated in Fig. 2c.

Microcells are smaller than macrocells with a typical cell radius of 20–300 m. In this scenario base station antennas are usually below the mean rooftop level. In urban areas microcells are often characterized as having a Manhattan type of grid, where the base stations are in the crossings of linear streets as shown in Fig. 1c. *Picocells* or indoor cells usually cover indoor areas (rooms, halls) with typical cell radius of 5–30 m. These scenarios are not covered in this article.

Frequency reuse is an essential element in cellular networks. It means that the same frequencies are reused in the system within a certain distance depending on the reuse factor. This reuse factor can be represented as a cluster size, which includes the group of cells where all different available channels are used. Regular cluster sizes K [1] can be calculated according to

$$K = i^2 + ij + j^2 \quad (2)$$

where i and j are nonnegative integers. Equation (2) leads to balanced cluster sizes $K = 1, 3, 4, 7, 9, 12, \ldots$. If D is defined as the distance between the closest cochannel centers and R is the cell radius (see Fig. 1a), the frequency reuse factor D/R and the cluster size K are related as [1]

$$\frac{D}{R} = (3K)^{1/2} \quad (3)$$

In order to increase network capacity, cluster size must be reduced. The more aggressive reuse (smaller the cluster size), the higher the level of cochannel interference that will be generated and vice versa. For these reasons frequency reuse has been studied extensively in the literature [1–4]. The problem becomes even more challenging if macrocells and microcells are overlaid [5].

2.1. Cochannel Interference Distributions

From the previous discussion one can see that no matter what cluster size is chosen, a certain level of cochannel interference (CCI) can not be avoided. For the analysis of cochannel interference statistics, the CCI distribution function is required. Cochannel interference can be seen as a superposition of distance-dependent attenuation (path loss), short-term fluctuations, and long-term variations. The long-term or large-scale signal variation (shadowing, slow fading) can be characterized by the lognormal distribution. The short-term signal variation (fast fading), on the other hand, may fit to some other distributions such as Rayleigh, Rice, or Nakagami. An overview of fading distributions related to CCI can be found in the paper by Yacoub [6]. In the sequel, the lognormal shadowing is assumed.

The total interference power is often accumulated from several cochannel signals. Unfortunately, there is no known closed-form expression for the distribution of

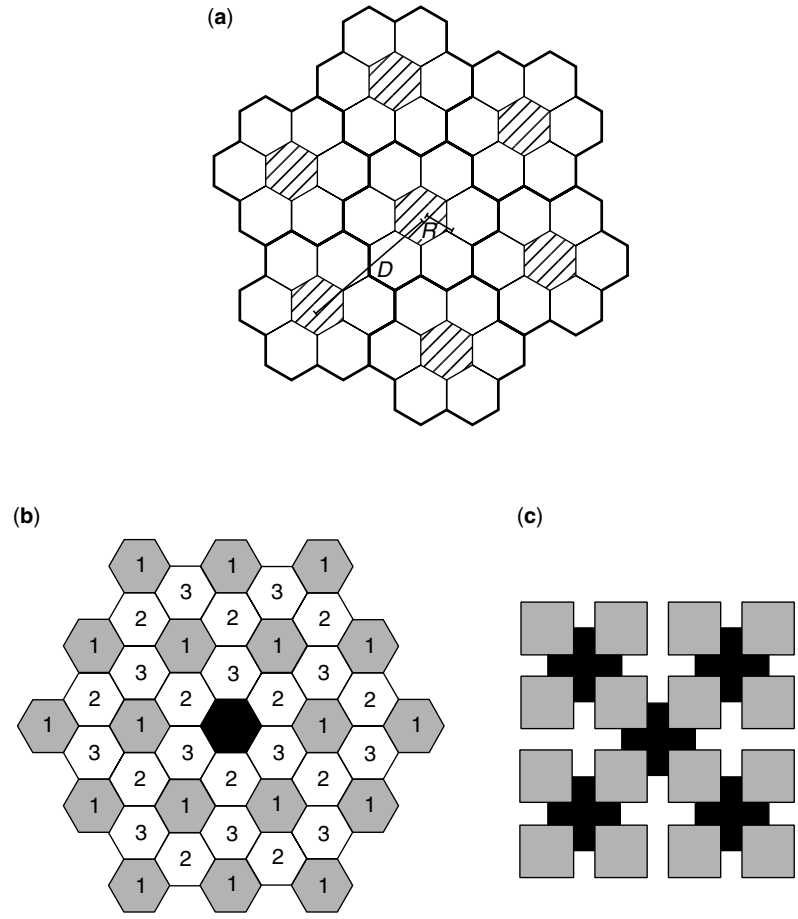

Figure 1. Cellular layouts: (**a**) uniform hexagonal cellular layout with reuse 7; (**b**) macrocell layout with reuse 3; (**c**) street microcell layout with reuse 2.

the sum of lognormally distributed random variables. However, several approximations have been derived. A common feature for all these approximations is that they estimate the sum of lognormal random variables by another lognormally distributed random variable [7]. This can be represented as

$$L = \sum_{i=1}^{n} e^{y_i} = \sum L_i \cong e^z \tag{4}$$

where y_i represents Gaussian random variables. In the Fenton–Wilkinson (FW) approximation [7–10], the mean m_z and the standard deviation σ_z of z are derived by matching the first two moments of the both sides of Eq. (4). If the first moment of $(L_1 + L_2 + \cdots + L_n)$ is denoted by u_1 and the second by u_2, the following expression is obtained after moment matching [9]

$$m_z = 2 \ln u_1 - \tfrac{1}{2} \ln u_2 \tag{5}$$

$$\sigma_z^2 = \ln u_2 - 2 \ln u_1. \tag{6}$$

The Fenton–Wilkinson approach is applicable when the standard deviations of the lognormal components are lower than 4 dB for uncorrelated signal components [11]. For higher deviation values, this approximation tends to underestimate the mean and overestimate the variance of the sum distribution. When there is correlation between the components, the FW approximation is quite accurate for higher deviation values ($\leq$12 dB), too [9].

The Schwartz–Yeh (SY) method [7,9–11] is also based on the assumption that the power sum is lognormally

distributed. The SY approximation is different in the use of the exact expressions for the first two moments of the sum of two lognormal random variables. Nesting and recursion techniques are then used to extend the approach to a larger number of cumulative random variables. Originally, the SY method was developed for the sum of independent lognormal random variables. However, it has been extended to the case of correlated lognormal random variables with some modifications [9].

The Schwartz–Yeh approximation can be best applied when the range of the standard deviation is $4 \leq \sigma \leq 12$ dB. If all components in the summation are identically distributed, this approximation tends to underestimate the variance in the resulting signal distribution. The error increases as a function of the number of added components.

In addition to the Fenton–Wilkinson and Schwartz–Yeh approaches, there are some other approximations for the sum of lognormal components. For example, Farley's approximation is a strict lower bound for the cumulative distribution function (CDF) of a sum of independent lognormal random variables [7]. For further studies on lognormal sum approximations the reader is referred to the additional reading listed at the end of this article.

2.2. Cochannel Interference and Outage Probabilities

Following Refs. 10 and 12, cochannel interference probability is defined as

$$P(I_c) = \sum_n P(I_c|n)P_n(n) \tag{7}$$

where $P_n(n)$ is the probability of n cochannel interferers being active and $P(I_c|n)$ is the corresponding conditional CCI probability.

The conditional CCI probability can be defined as

$$P(I_c|n) = P\left(\frac{C}{I} < \alpha\right) \tag{8}$$

where C is the instantaneous power of the desired signal (carrier), I is the joint interference power from n active cochannel users, and α is the specified cochannel interference protection ratio.

$P_n(n)$ can be represented by the binomial distribution in terms of carried traffic per channel

$$P_n(n) = \binom{N}{n} a_c^n (1 - a_c)^{N-n} \tag{9}$$

where N is the number of effective cochannel interferers ($N = 6$ if only the closest ring cochannel interferers are taken into account) and $a_c = m_1/m_t$ is carried traffic per channel (erlangs per channel). Parameters m_1 and m_t are discussed in more detail in the next Section 2.3. It is assumed that the number of traffic channels is equal for all cells.

The outage probability P_{out} for the desired user can be defined as the probability of failing to achieve a bit error probability P_e lower than a fixed threshold P_{e0}, namely

$$P_{\text{out}} = P(P_e > P_{e0}) \tag{10}$$

If only the effects of cochannel interference are taken into account, the received carrier-to-interference ratio C/I is the key parameter. If the minimum required carrier-to-interference ratio is α and it corresponds to the bit error probability $P_e = P_{e0}$, the outage probability is the same as the conditional CCI probability defined by (8).

Following the procedure in [9], the outage probability of the lognormally distributed signals can be represented in the form

$$P_{\text{out}} = P(I_c|n) = 1 - Q\left(\frac{\ln\alpha - \ln\xi_d + m_{z_n}}{(\sigma_d^2 + \sigma_{z_n}^2 - 2r_{yz}\sigma_d\sigma_{z_n})^{1/2}}\right) \tag{11}$$

where ξ_d is the area mean desired signal power, m_{z_n} is the area mean joint interference power of n interferers, σ_d is the standard deviation of the desired signal, σ_{z_n} is the standard deviation of the joint interference from n interferers, and r_{yz} is the correlation coefficient of the desired signal and joint interference. The initial mean single interferer power in the worst geometric case can be approximated by

$$m_{z_{1w}} = \ln[((3K)^{1/2} - 1)^{-\beta}] \tag{12}$$

In the average geometric case, the exact interferer power is of the form

$$m_{z_{1a}} = \ln[(3K)^{-\beta/2}] \tag{13}$$

The desired signal area mean power ξ_d can be represented as

$$\xi_d = \left(\frac{r}{R}\right)^{-\beta} \tag{14}$$

In Eqs. (12)–(14), β denotes the path loss exponent, K is the cluster size, and $r/R \in (0, 1]$ is the normalized distance between the desired mobile station and the base station.

The combined effect of frequency allocation and propagation conditions, characterized implicitly by the parameter $(1 - C_r)$, is illustrated in Fig. 3. The figure shows the outage probability defined by (11) with the maximum number of first-tier interferers as a function of cluster size (worst and average case geometries) with variable path loss exponents β. The standard deviation of each lognormal component is 6 dB. All signals are uncorrelated. The Fenton–Wilkinson method has been used for the mean and variance approximations.

It can be noted that in free-space propagation conditions ($\beta = 2$), cochannel interference can be very severe even for large cluster sizes. On the other hand, in dense urban areas, where the path loss attenuation slope is steep, small cluster sizes can be supported. That allows larger system capacity for highly populated cities where it is the most desirable. The outage probability is very sensitive to the changes in the propagation environment.

Figure 4 shows the strong impact of normalized mobile distance (14) on conditioned full load CCI probability (outage probability) in the presence of lognormal shadowing ($\sigma = 6$ dB, FW approximation). It can be seen that without power control, outage events are more likely near the cell edges. Larger cluster sizes guarantee lower outage probabilities. The gap between worst and average

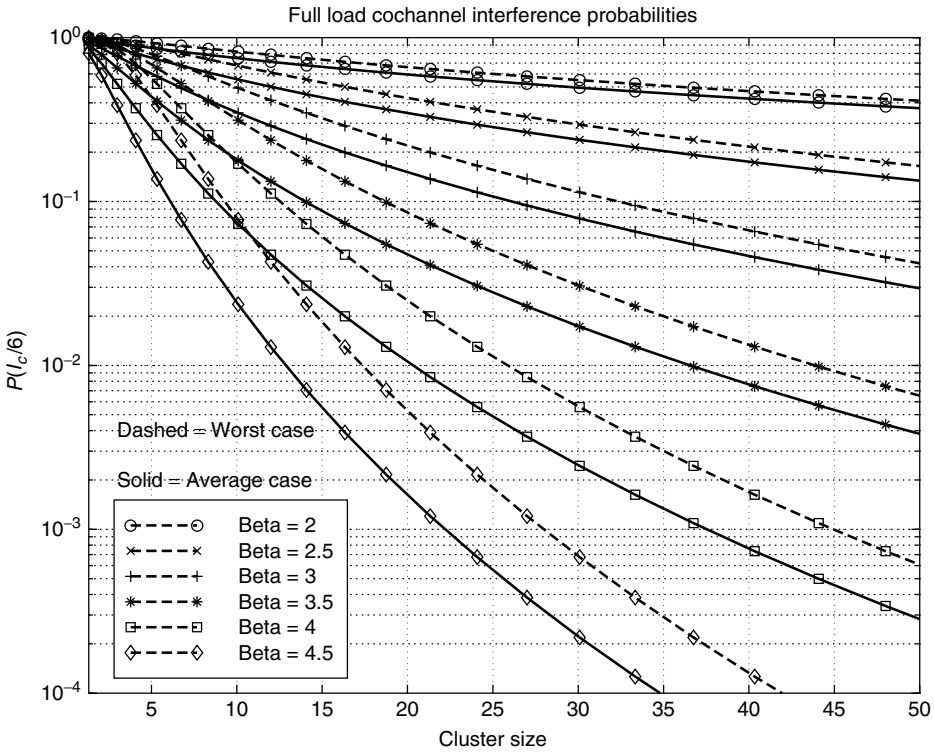

Figure 3. Effect of path loss exponent variation to the outage probability.

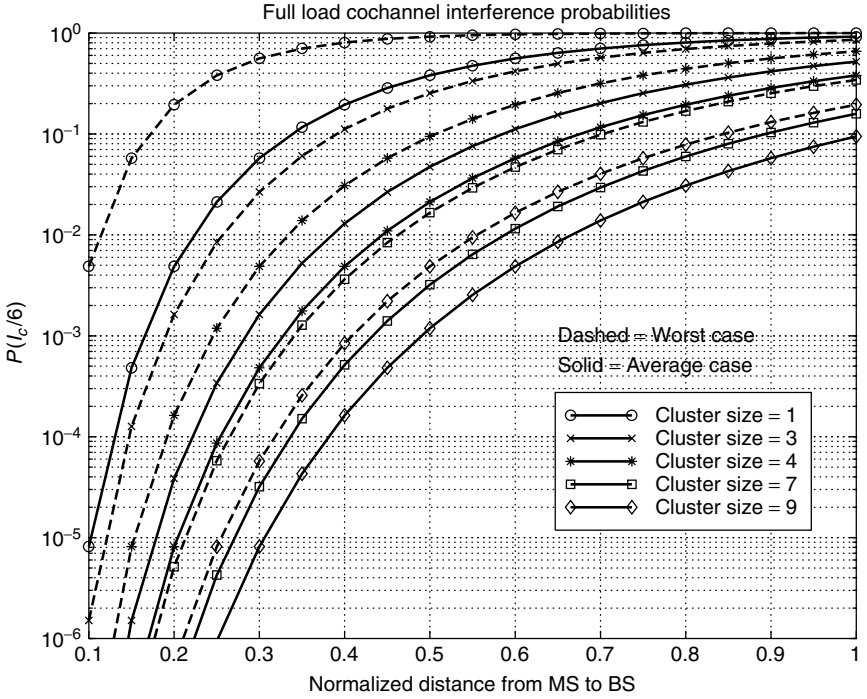

Figure 4. Full-load outage probabilities at variable cluster sizes.

case interference geometries diminishes as the cluster size increases.

2.3. Spectrum Efficiency

Spectrum efficiency describes how effectively a system can utilize limited frequency resources. In general, spectrum efficiency can be seen as a ratio between benefit (number of traffic channels, data rate) and cost (bandwidth) [13]. Spectrum efficiency is usually measured in units related to system capacity. Problems may arise if system capacities of different systems have been calculated with different assumptions or if they are represented in different units. A fair comparison of different systems is often cumbersome. Falciasecca et al. [13] discuss the effect of some working assumptions on spectrum efficiency, and ways to allow a fair comparison.

The system capacity of a voice-oriented network is related to the grade of service by the Erlang-B formula

$$P_B = \frac{{m_1}^{m_t}/m_t!}{\sum_{n=0}^{m_t} {m_1}^{m_t}/n!} = \Im(m_t, m_1) \tag{15}$$

where P_B is blocking probability, m_1 is the offered traffic (capacity) (in erlangs), and m_t is the total number of traffic channels. The blocking probability P_B refers to the probability that a new call attempt will not find an available channel in a trunk of channels and is dropped. Thus, there is no queueing in the system. The Erlang formula was originally developed for wired telephone traffic. It is not strictly applicable to cellular systems, because it does not take into account the handover traffic. An additional assumption of this model is that the total offered traffic is constant, which is not valid in the cell where the traffic is time-varying as a result of moving subscribers. Despite the limitations of the Erlang formula, it can be used for relative comparison purposes; however, one must be careful in interpreting the absolute values.

The spectrum efficiency and capacity evaluation are based on the radio capacity m_t introduced by Lee [14]. The radio capacity of the omnicellular TDMA system is defined as

$$m_t = \frac{N_s B_t}{B_c \left(\frac{2}{3}\left(\frac{C}{I}\right)_s\right)^{1/2}} = \frac{M_t}{\left(\frac{2}{3}\left(\frac{C}{I}\right)_s\right)^{1/2}} = \frac{M_t}{K} \quad \text{(frequency channels/cell)} \tag{16}$$

where B_t is the total allocated spectrum for the system, B_c is the channel bandwidth, $(C/I)_s$ is the minimum required carrier-to-interference ratio, M_t is the total number of frequency channels multiplied by the number of TDMA slots N_s, and K is the cluster size.

Radio capacity can be represented in different units as presented in Lee's paper [14]. These new measures can be derived from the general radio capacity definition and depend on issues such as service area, call duration, number of calls, and total bandwidth. Other commonly used units for spectrum efficiency are erlangs per MHz/km^2 and erlangs per cell/MHz.

For the system with parameters given in Table 1, maximum capacity obtained from Eq. (15) is presented in Table 2. By using (15) and (16), Fig. 5 illustrates real Erlang capacities for TDMA omnicellular uplink with

Table 1. Essential Parameters for the Capacity Evaluation of TDMA System

B_t (MHz)	R_C (kHz)	B_c (kHz)	α	$M = B_t/B_c$	M_t
10	270.8	200	9 dB	50	400

Table 2. Maximum Radio Capacities of Compared Cluster Sizes ($P_B = 0.02$)

TDMA (K)	m_t (Traffic Channels)	m_1 (erlangs/cell)	$a_c = m_1/m_t$
TDMA(7)	57	46.8	0.821
TDMA(9)	44	34.7	0.789
TDMA(12)	33	24.6	0.745
TDMA(21)	19	12.3	0.679

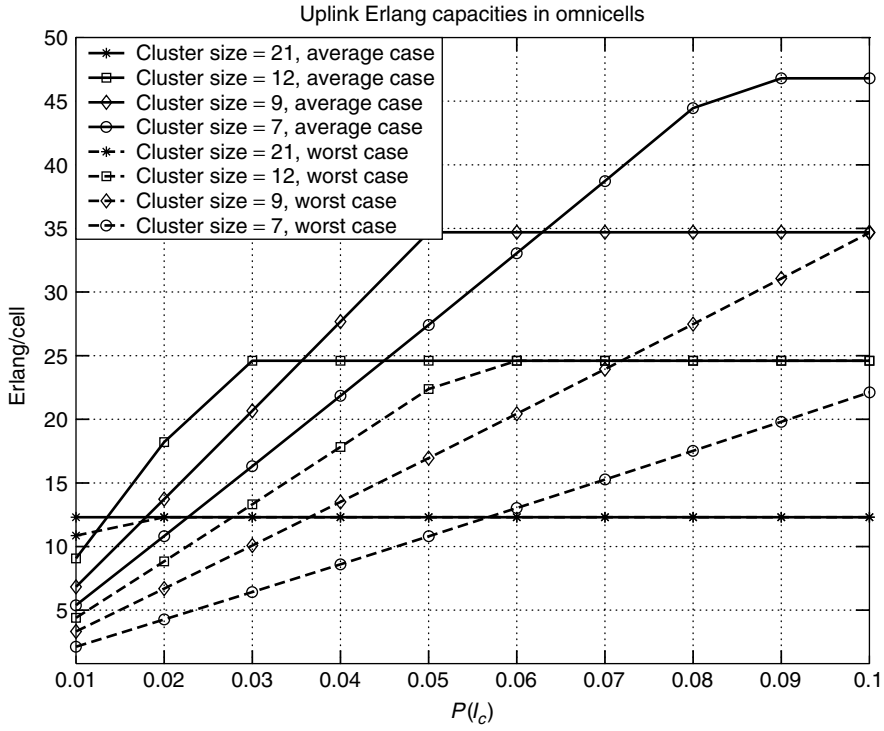

Figure 5. Uplink Erlang capacities in omnicells (Rayleigh fading only).

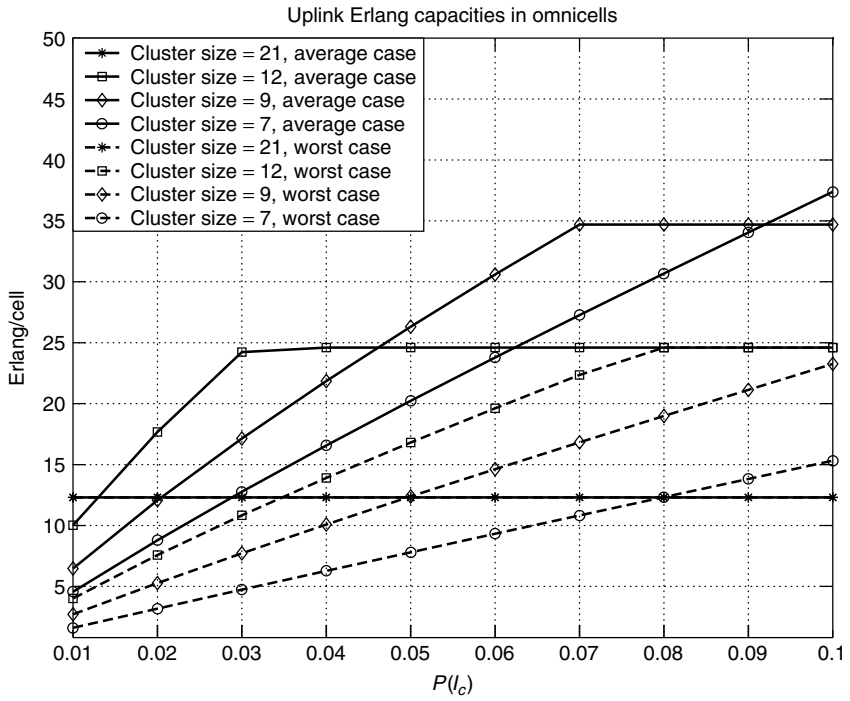

Figure 6. Uplink Erlang capacities in omnicells (lognormal shadowing only, $\sigma = 6$ dB).

several cluster sizes in a Rayleigh fading environment. Figure 6 presents uplink Erlang capacities when both the desired signal and cochannel interferers are lognormally shadowed with standard deviation $\sigma = 6$ dB.

Curves in Fig. 6 show that the performance is very close to the purely Rayleigh case. For larger cluster sizes, lognormal shadowing only ($\sigma = 6$ dB) will give more optimistic results than the purely Rayleigh case. Horizontal parts of the curves indicate that the maximum capacity limit m_1, for the particular cluster size, has been reached (hard capacity limit). Elsewhere, the Erlang capacity is softly limited by the highest tolerated CCI probability.

Alouini and Goldsmith consider a slightly different definition of spectrum efficiency, the area spectral efficiency (ASE) [15]. It is better suited for variable rate data transmissions, where the total throughput is of interest. The measure for average area spectral efficiency is the sum of the maximum average data rates divided by the bandwidth and the unit area for the system: bandwidth per second per Hz/m^2. The analytical framework provides theoretical limits for area spectral efficiency versus reuse distance for adaptive data rate cellular systems, where the rate adaptation depends on fading and interference conditions. Users' random locations, impact of propagation parameters, cell size, carrier frequency, and sectorization in both macrocells and microcells are taken into account. Furthermore, the loading in the cells is varied. Best and worst case analytical results are verified via average case Monte Carlo simulations.

Results based on the worst-case interference geometry show that the optimal reuse distance is close to 4. The area efficiency decreases as an exponential of a fourth-order polynomial relative to the cell size. Shadowing and fading reduce the absolute ASE, but do not affect the relative behavior as the function of reuse distance. Moreover, it is noted that the fading parameters of the desired user have stronger contribution on the ASE than do the fading parameters of the interferers [15].

3. SPATIAL FILTERING

Spatial domain processing included in the term $(1 - C_\theta)$ can be used to combat cochannel interference. At least at the base station there is a possibility to steer radiation/reception to the desired directions: (1) spatially directed transmission can enhance signal coverage and quality and (2) interference coming outside from the antenna main lobe is suppressed significantly in the reception.

3.1. Sectorization

One conventional way to improve cellular system capacity is cell splitting, that is, subdividing the coverage area of one base station to be covered by several base stations (smaller cells) [1]. Another simple and widely applied technique to reduce interference spatially is to divide cells into sectors, for example, three 120° sectors. These sectors are covered by one or several directional antenna elements. Effects of sectorization to spectrum efficiency have been studied [16]. Chan [16] concluded that sectorization reduces cochannel interference and improves signal-to-noise ratio of the desired link at the given cluster size. However, at the same time the trunking efficiency is decreased. Because of the improved link quality, a tighter frequency reuse satisfies the performance criterion in comparison to the omnicellular case. Therefore, the net effect of sectorization is positive at least for large cells and high traffic densities.

3.2. Adaptive Antennas

By using M-element antenna arrays at the base station the spatial filtering effect can be further improved.

The multiple beam adaptive array would not reduce the network trunking efficiency unlike sectorization and cell splitting [17]. These adaptive or "smart" antenna techniques can be divided into switched-beam, phased-array, and purely adaptive antenna systems. Advanced adaptive systems are also called *spatial division multiple access* (SDMA) systems. Advanced SDMA systems maximize the gain toward the desired mobile user and minimize the gain toward interfering signals in real time.

According to Winters [18], by applying a four-element adaptive array at the TDMA uplink, frequencies can be reused in every cell (three-sector system) and sevenfold capacity increase is achieved. Correspondingly, a four-beam antenna leads to reuse of 3 or 4 and doubled capacity at small angular spread.

Some practical examples of the impact of the use of advanced antenna techniques on the existing cellular standards have been described [19,20]. Petrus et al. [19] use the AMPS reference system and Mogensen et al. [20] use GSM. The Petrus et al. analysis [19] uses ideal and flat-top beamformers. The mainlobe of the ideal beamformer is flat and there are no sidelobes whereas the flat-top beamformer has a fixed sidelobe level. The ideal beamformer can be seen as a realization of the underloaded system; that is, there are less interferers than there are elements in the array. The overloaded case is better modeled by the flat-top beamformer because all interferers cannot be nulled and sidelobe level is increased. Performance results show that a reuse factor of 1 is not feasible in AMPS, but reuse factors of 4 and 3 can be achieved with uniform linear arrays (ULA) with five and eight elements, respectively.

Mogensen et al. [20] concentrate on the design and performance of the frequency-hopping GSM network using conventional beamforming. Most of the results are based on simulated and measured data of eight-element ULA. The simulated C/I improvement follows closely the theoretical gain at low azimuth spreads. In urban macrocells the C/I gain is reduced from the theoretical value 9 dB down to approximately 5.5–7.5 dB. The designed direction of arrival (DoA) algorithm is shown to be very robust to cochannel interference. The potential capacity enhancement is reported to be threefold in a $\frac{1}{3}$ reuse FHGSM network for an array size of $M = 4$–6.

4. INTERFERENCE CANCELLATION IN TIME DOMAIN

For the purpose of this section, the overall received signal, which is a superposition of N cochannel components received through M antennas, can be represented in the simplified case, when all signals are received bit synchronously as

$$\begin{aligned} \boldsymbol{r} &= (r^{(1)}, r^{(2)}, r^{(3)}, \ldots, r^{(M)})^{-1} \\ r^{(m)} &= \sum_{n=1}^{N} a^{(n)} h^{(m,n)} + n^{(m)} \\ h^{(n,m)} &= c^{(m,n)} * g \end{aligned} \tag{17}$$

where $a^{(n)}$ is data of user n, g is the pulseshape, and $c^{(m,n)}$ is the channel transfer function between the cochannel signal source n and receiving antenna m. The corresponding vector representation is

$$\boldsymbol{r} = \boldsymbol{H}\boldsymbol{a} + \boldsymbol{n} \tag{18}$$

where $\boldsymbol{a}$ and $\boldsymbol{n}$ are vectors with components $a^{(n)}$ and $n^{(m)}$, respectively, and $\boldsymbol{H}$ is the matrix with elements $h^{(n,m)}$. In a real situation the received cochannel signals are not bit synchronous, and (18) should be modified to include two additional components representing the impact of the previous and subsequent bits accordingly, similar to asynchronous CDMA detectors [21]. Details may be found in the paper by Valenti and Woerner [22]. In accordance with Eq. (14), the system capacity can be increased by using more advanced demodulation techniques that provide the same quality of service (QoS) with lower $(C/I)_s$. A number of algorithms have been presented in the literature.

When used for DSCDMA systems, the objective of multiuser detection (MUD) is primarily to jointly detect signals that originate from the same cell (intracell interference) because the most critical interference comes from there. This is quite the opposite of the situation in a TDMA network where the interest is focused on the interference coming from the adjacent cells.

An optimum detector has been introduced [23] as a joint demodulator of cochannel signals. This detector is based on already known solutions for optimum single-user detection with intersymbol interference and Gaussian noise for *M-input/M-output* (MIMO) systems [24,25] and joint maximum-likelihood sequence estimation (MLSE) [26]. A similar approach is used for CDMA systems [27]. Practical results for the Japanese PDC system [28] and for GSM [29] have been shown. The joint MLSE for a hybrid CDMA/TDMA based on the GSM system has also been presented [30].

MLSE-type detectors are so complex and impractical that a number of blind detector algorithms must be considered. These algorithms do not require knowledge of the other signal parameters. See the "Further Reading" section for further information about blind CCI cancellation.

The latest results include cochannel interference suppression with successive cancellation [31], which is a technique already well established in CDMA systems. Performance results show that the cancellation succeeds poorly when the signal levels are comparable. Timing differences can be used for initial signal separation in order to improve performance. Soft subtraction provides further improvement.

When M signals $r^{(m)}$ from Eq. (17) are combined by using maximal ratio combining, then a reliable estimate of the channel coefficients is required. One of the latest references dealing with this problem is that by Grant and Cavers [32].

The most recent development in Turbo decoding has inspired research in the field of iterative multiuser detection, macrodiversity combining, and decoding for the TDMA cellular uplink [22]. In this approach, as the first step, each base station (BS) in a cluster of cochannel cells performs soft-output multiuser detection of the desired signal (originating from its cell) and the interfering

signals (originating from other cells in the cluster). So the multiuser detector will produce a loglikelihood ratio (LLR) for each mobile in the cluster. These LLRs for each user are then summed up across the BS cluster, which in effect produces a diversity combining signal. After that the signal may be deinterleaved and decoded. If the decoder also produces soft outputs, this may be reinterleaved and fed back to the multiuser detector to be used as a priori information in the next iteration. Once again one should be aware that the system places an additional burden on the backhaul links. Since soft information is now shared among BSs more capacity is needed on the links between BSs and the base station controller (BSC).

BIOGRAPHIES

Savo Glisic is Professor of Electrical Engineering at the University of Oulu, and Director of Globalcomm Institute for Telecommunications. He was a Visiting Scientist at Cranfield Institute of Technology, Cranfield, England (1976/77) and the University of California at San Diego (1986/87). He has been active in the field of spread-spectrum and wireless communications for 20 years and has published a number of papers and five books. He is doing consulting in this field for industry and government. He has served as Technical Program Chairman of The Third IEEE ISSSTA'94, The 8 IEEE PIMRC'97, and IEEE ICC'01. Dr Glisic was Director of IEEE ComSoc MD programs.

Pekka Pirinen received the M.S. and Lic.Tech. degrees in electrical engineering from the University of Oulu, Oulu, Finland, in 1995 and 1998, respectively. He started his career as Research Assistant in the Telecommunication Laboratory, University of Oulu, in 1994. Since 1995, he has been with the Telecommunication Laboratory and Centre for Wireless Communications, University of Oulu, as a Research Scientist in various wireless communication research projects, including the European ACTS project FRAMES. His research interests are focused on multiple access techniques, radio network planning, modeling, capacity, and performance evaluation issues. Mr. Pirinen is currently pursuing a doctoral degree in electrical engineering at the University of Oulu.

CODE-DIVISION MULTIPLE ACCESS

Branimir R. Vojčić

George Washington University
Washington, District of Columbia

1. INTRODUCTION

Multiple-access communications is a means by which many individual, geographically dispersed users access a shared medium and/or resources in order to transmit/receive information. Multiple access is used for local-area networks (LAN), satellite and cellular terrestrial radio networks, and other applications. Conventional multiple access schemes include random access such as ALOHA and its successor CSMA/CD, which is used in LANs, and structured orthogonal signals multiple access such as *frequency-* and *time-division multiple access* (FDMA, TDMA), which are used in satellite systems and terrestrial cellular radio. *Code-division multiple access* (CDMA) is a multiuser communications method, which uses spread-spectrum signals with uniquely addressable signature waveforms that permit the separation of each signal at the receiver. The main paradigm change in spread spectrum is that all users use the entire available spectrum simultaneously. It is possible, in some instances, to arrange for the signature waveforms to be orthogonal at the receiver, so that this separation can be affected by means of a linear correlator, wherein the desired users' signal is extracted while the other users' signals are completely suppressed. However, even when orthogonality is not perfect, for design or practical reasons, the spread-spectrum processing gain causes undesired multiuser signals to be significantly suppressed. In conventional CDMA receivers, such linear correlators are used and, to the extent that the *multiple-access interference* (MAI) is suppressed by the processing gain, it is tolerated. Naturally, this effect results in the characteristic "MAI-limited" channel whose capacity in terms of number of users is thereby limited according to what performance objective is specified. The two principal CDMA approaches are based on *direct-sequence* (DS) spreading and *frequency hopping* (FH). The FH transmission is conceptually very similar to conventional narrowband schemes, except that the carrier frequency is changed pseudorandomly over the spread spectrum bandwidth. In addition, it appears that DSCDMA is a less costly approach for commercial applications. Consequently, in our discussion we will mainly address DSCDMA and provide only a brief discussion of FHCDMA.

A major shortcoming of conventional detection CDMA systems is that, since each user contributes interference in proportion to their received power level, users that either generate excessive power, or whose power is received as larger than the desired signal (e.g., by virtue of being close to the receiver), degrade performance. This effect, sometimes called the "near–far problem," is a major impediment to practical CDMA using conventional detectors. The near–far problem is usually mitigated by exercising tight, closed-loop power control on all users so that all the received signals are of equal power at the receiver.

In Section 2 we first address the fundamental principles of CDMA using the notion that spread spectrum may be viewed as a way of embedding a signal into a high-dimensionality signal space and show how conventional CDMA receivers deal with MAI and its effects on both performance and user capacity. Next, in Section 3, we introduce some well-established performance measures by which, in addition to *signal-to-noise-and-interference ratio* (SNIR) and *bit-error probability* (BER), we can assess the behavior of multiuser systems. In Section 4, we examine the effect of the near–far problem and demonstrate, by an example, the consequences of imperfect power control. The obvious question is that since all the "signature" waveforms are presumable known at the receiver, why must we tolerate the MAI as if they were not known? Indeed, the optimum, maximum likelihood multiuser detector attempts to demodulate all received signals *jointly*. In Section 5, we will examine both the performance and complexity of this optimum approach and subsequently examine several suboptimal schemes, which exhibit significantly reduced complexity, and their performance. It appears that some of the multiuser detection schemes are practically feasible and, as such, can be exploited to improve the CDMA capacity, especially in situations in which tight power control is not achievable.

2. DIMENSIONALITY, PROCESSING GAIN, AND MULTIPLE ACCESS

A fundamental issue in CDMA is how this technique affords multiple simultaneous transmissions using a common bandwidth. The underlying principle is that of distributing relatively low-dimensional data signals in a high-dimensional environment. This is accomplished by means of spreading codes (signature waveforms), unique for each user so that all multiple-access signals are mutually nearly orthogonal. The idea of using quasiorthogonal signature waveforms (noiselike waveforms) for multiple access is originally due to Claude Shannon [2,3]. He perceived it as a democratic way of sharing the frequency spectrum: "If more people (signals) were there (in the

crowded radio spectrum), gradually the noise level would increase on each channel. But everyone could still talk, even though it might be a pretty noisy 'cocktail party' by that time" (this is now called a graceful degradation in CDMA).

In the "standard" problem of digital transmission, the set of M signaling waveforms $\{s_i(t), 0 \le t \le T, 1 \le i \le M\}$, known to both transmitter and receiver, is used to transmit $(\log_2 M)/T$ bps (bits per second). If, for example, $s_i(t)$ is sent, the received signal is $r(t) = s_i(t) + n_w(t)$, $0 \le t \le T$, where T denotes the symbol duration and $n_w(t)$ is additive, white Gaussian noise (AWGN) with two-sided power spectral density $N_0/2$ W/Hz. It is well known that the signal set can be completely specified by a linear combination $D \le M$ orthogonal basis functions. The dimensionality D, of the signal waveforms, is approximately equal to $2B_DT$, where B_D is the total (approximate) spectral occupancy of the employed signal set [4]. If the total *available* bandwidth is B_N, corresponding to an N-dimensional signal space, the maximum number of simultaneously active users, each one using D dimensionality, with orthogonal multiplexing is $K = N/D$. With quasiorthogonal multiplexing, however, it is possible to accommodate more than K users in the same bandwidth, but with some mutual multiple-access interference. In addition to sharing the bandwidth, the quasiorthogonal users share interference as well. The quasiorthogonal multiplexing is usually accomplished by means of *pseudonoise* (PN) spreading (signature) sequences, which have desired cross-correlation properties. At least one sequence is available to the cooperating transmitter and receiver, which may or may not know the PN sequences employed by other transmitter/receiver pairs.

A general model, which conveys the idea of CDMA, is as follows. Consider K simultaneous binary antipodal ($D = 1$) transmissions embedded in an N-dimensional signal space. Assuming jointly synchronous transmission, the aggregate of all transmitted signals can be represented by

$$x(t) = \sum_{i=1}^{K} x_i(t), \quad 0 \le t \le T \tag{1}$$

where the transmitted signal of the ith user is

$$x_i(t) = \sqrt{W_i} b_i s_i(t), \quad 0 \le t \le T \tag{2}$$

where W_i represents the signal energy per bit, b_i is the bit value (± 1) and $s_i(t)$ is the unit energy signature waveform of the ith user, defined as

$$s_i(t) = \sum_{k=1}^{N} s_{ik} \varphi_k(t), \quad 0 \le t \le T \tag{3}$$

where

$$s_{ik} = \int_0^T s_i(t) \phi_k(t)\, dt \tag{4}$$

and where $\{\phi_k(t), 1 \le k \le N\}$ is an orthonormal basis spanning the space:

$$\int_0^T \phi_l(t) \phi_m(t)\, dt = \delta_{lm} = \left\{ \begin{array}{ll} 1, & l = m \\ 0, & l \ne m \end{array} \right\} \tag{5}$$

Note that each binary antipodal signal requires one dimension ($D = 1$) for transmission, while N dimensions are employed to generate K distinct signaling waveforms. The factor N is usually called *spreading factor* or *processing gain*. The term spreading factor reflects the fact that the actual transmission bandwidth B_N (Fourier bandwidth), is N times larger than the Shannon bandwidth[1] of the modulated signal. The latter term, processing gain, stems from the capability of the spread signal to suppress interference by exploiting spectral redundancy and will be discussed subsequently.

In general, the PN sequence of the ith user, $\{s_{il}, \ldots, s_{iN}\}$, is chosen so as to have minimal possible cross-correlation with PN sequences of other users $\{s_{jl}, \ldots, s_{jN}\}, j = 1, \ldots, K$ and $j \ne i$. Here we assume, for the time being, that the sequences are random such that

$$E[s_{ij}] = 0, \quad \forall i, j, \quad i = 1, \ldots, K, \quad j = 1, \ldots, N \tag{6}$$

$$E[s_{il} s_{im}] = \frac{1}{N} \delta_{im}, \quad \forall i \tag{7}$$

$$E[s_{il} s_{jm}] = 0, \quad i \ne j, \quad \forall l, m \tag{8}$$

Although the spreading sequences are generated randomly, they are known to the communicators (at least to communicating pairs).

Consider next the conventional DSCDMA receiver, where the received signal is given by $r(t) = x(t) + n_w(t)$. The output of the ith correlation receiver is given by

$$\begin{aligned} U_i &= \int_0^T r(t) s_i(t)\, dt \\ &= \sum_{k=1}^{n} \left(\sqrt{W_i} b_i + \sum_{\substack{i=1 \\ l \ne i}}^{K} \sqrt{W_l} b_l s_{lk} s_{ik} + s_{ik} n_k \right), \end{aligned} \tag{9}$$

where

$$n_k = s_{ik} \int_0^T n_w(t) \phi_k(t)\, dt. \tag{10}$$

In conventional CDMA receivers the multiple access interference (MAI) at the output of correlation receiver is tolerated and a decision is made according to $b_i = \text{sgn}(U_i)$. Under these circumstances, a measure of performance which is monotonically related to the bit error rate (BER) is the SNIR, which can be expressed as

$$\begin{aligned} \text{SNIR}_i &= \frac{E^2[U_i \mid b_i]}{Var[U_i \mid b_i]} \\ &= \left[\frac{N_0}{2W_i} + \frac{1}{NW_i} \sum_{\substack{i=1 \\ l \ne i}}^{K} W_l \right]^{-1} \end{aligned} \tag{11}$$

The first term is due to thermal noise, the second term is due to MAI. It can be seen from the second term that

[1] By Shannon bandwidth we mean one-half the minimum number of orthogonal functions per T seconds that are required in a basis for a signal space in which signal can be represented [12].

MAI is suppressed by the factor N (spreading factor), which explains why the spreading factor is often called the processing gain. If we let $W_i/N_0 \to \infty$ (MAI dominates) and assume $W_i = W_l, \forall i, l$, then

$$\lim_{W_i/N_0 \to \infty} \text{SNIR}_i = \frac{N}{K-1} \tag{12}$$

This last result reveals the fundamental difference between orthogonal and quasiorthogonal multiplexing when conventional, single-user detection is employed; even for vanishingly small noise, the SNIR is finite. Hence, in a "cocktail party" of this example, to use Shannon's words, the number of simultaneous transmissions is $K \leq N/\text{SNIR}_{\text{REQ}} (K \gg 1)$, where SNIR_{REQ} corresponds to the desired transmission quality. Depending upon whether $\text{SNIR}_{\text{REQ}} < 1$ or $\text{SNIR}_{\text{REQ}} > 1$, more than N or less than N users, respectively, can transmit simultaneously.

Consider now the probability of error when the sign decision on U_i is employed. For large N we can invoke the central-limit theorem and assume that the MAI is Gaussian. Then it is easy to see that the conditional probability of error for the ith user is given by

$$P(i)\Big|_{\rho_{il}} = \frac{1}{2^{K-1}} \sum_{\text{all } b_l} Q\left[\sqrt{\frac{2W_i}{N_0}}\left(1 - \sum_{\substack{l=1 \\ l \neq i}}^{K} \sqrt{\frac{W_l}{W_i}} b_l \rho_{il}\right)\right] \tag{13}$$

where the first summation is over all possible combinations of data bits of interfering users and

$$\begin{aligned} \rho_{il} &= \int_0^T s_i(t) s_l(t)\, dt \\ &= \sum_{k=1}^{n} s_{ik} s_{lk} \end{aligned} \tag{14}$$

is the (random) cross-correlation between signature waveforms of the ith and lth user signature waveforms. For vanishingly small N_0, the probability of error is dominated by the term corresponding to the worst combination of interfering bits, so that

$$P(i)_{\text{wc}}\Big|_{\rho_{il}} = \frac{1}{2^{K-1}} Q\left[1 - \sum_{\substack{l=1 \\ l \neq i}}^{K} \sqrt{\frac{W_l}{W_i}} |\rho_{il}|\right]. \tag{15}$$

Since random spreading sequences were assumed, we obtain the following, after averaging over all signature waveforms, according to Jensen's inequality:

$$P(i)_{\text{wc}} \geq \frac{1}{2^{K-1}} Q\left[\sqrt{\frac{2W_i}{N_0}}\left(1 - \frac{1}{N} \sum_{\substack{l=1 \\ l \neq i}}^{K} \sqrt{\frac{W_l}{W_i}}\right)\right]. \tag{16}$$

Hence, we can see that if

$$\left(1 - \frac{1}{N} \sum_{\substack{l=1 \\ l \neq i}}^{K} \sqrt{\frac{W_l}{W_i}}\right) \leq 0$$

$P(i)_{\text{wc}}$ does not vanish as $W_i/N_0 \to \infty$. This phenomenon is not inherently a CDMA characteristic, but is rather a consequence of suboptimum detection. We will return to this in a subsequent section.

In a synchronous CDMA system, it is possible to choose spreading sequences, which are mutually orthogonal, as long as the number of signals does not exceed the dimensionality of the signal space. In that case we have orthogonal multiplexing (MAI free) and the probability of error is given by

$$P(i)_{\text{ort}} = Q\left(\sqrt{\frac{2W_i}{N_0}}\right) \tag{17}$$

Again with the Gaussian assumption[2] on MAI which we will relate below. Moreover, this is possible to achieve as long as the spreading sequences of K users are linearly independent [11]. At this point we abandon the analysis tool of random signature sequences and merely assume that they have *known* cross-correlations.

We now show that the signals can be processed at both transmitter and receivers so that the $\text{sgn}(U_i)$ is optimal and individual probabilities of error are given by Eq. (17).

Consider the vector of sufficient statistics (vector of correlation receivers' outputs in (9) for demodulation of all K signals jointly), given by

$$\mathbf{U} = \mathbf{RWb} + \mathbf{N}_w \tag{18}$$

where $\mathbf{R} = \{\rho_{ij}\}_{K \times K}$ is the cross-correlation matrix of signature waveforms $\mathbf{W} = \text{diag}(\sqrt{W_i})$ is a diagonal $K \times K$ matrix of signal amplitudes, $\mathbf{b}$ is the $K \times 1$ data vector, and $\mathbf{N}_w$ is a $K \times 1$ zero-mean Gaussian noise vector with covariance matrix $\mathbf{R}_N = \mathbf{R}N_0/2$. Hence, each component of the vector $\mathbf{U}$ contains the desired signal component, multiuser interference and a Gaussian noise component. When the matrix $\mathbf{R}$ is positive-definite, which is equivalent to the linear independence of K signature waveforms, there exist a unique Cholesky decomposition [18] of the matrix $\mathbf{R}$, such that $\mathbf{R} = \mathbf{G}^T\mathbf{G}$, where $\mathbf{G}$ is an upper triangular matrix. Consider a linear transformation $\mathbf{G}^{-1}$ at the transmitter such that the transmitted signal $x(t)$ is given by

$$x(t) = \mathbf{s}(t) T \mathbf{G}^{-1} \mathbf{W} \mathbf{b} \tag{19}$$

where $\mathbf{s}(t)$ is $K \times 1$ vector of signature waveforms. Then the vector of correlation receiver outputs is given by

$$\mathbf{U} = \mathbf{G}^T \mathbf{W} \mathbf{b} + \mathbf{N}_w \tag{20}$$

and by applying the linear transformation $(\mathbf{G}^T)^{-1}$ on the vector $\mathbf{U}$ in the receiver, we obtain

$$\mathbf{U}_0 = \mathbf{W}\mathbf{b} + \mathbf{Z} \tag{21}$$

where $\mathbf{Z}$ is a $K \times 1$ zero-mean Gaussian noise vector with covariance matrix $\mathbf{R}_Z = \mathbf{I}N_0/2$ and where $\mathbf{I}$ is the identity

[2] The additive noise is always assumed to be Gaussian in this regard.

matrix. Hence, by means of a pair of linear transformations $\mathbf{G}^{-1}$ and $(\mathbf{G}^T)^{-1}$, in the transmitter and the receiver, respectively, K users are decoupled and the resultant noise vector $\mathbf{Z}$ is white. Thus, individual sign decisions on the components of $\mathbf{U}_0$ will be optimal. Moreover, it is easy to see that the total transmit energy per bit interval is independent of the vector $\mathbf{b}$ and is equal to $W_{\text{tot}} = \sum_{i=1}^{K} W_i$, as it would be if orthogonal multiplexing were used in the first place. Indeed, the linear transformation $\mathbf{G}^{-1}$ in the transmitter gives rise to K orthogonal signature waveforms $\mathbf{p}(t)^T = \mathbf{s}(t)^T\mathbf{G}^{-1}$ and, similarly, by employing a bank of corresponding matched filters in the receiver, an orthogonal *multiuser communication system* results. A block diagram of the resulting end-to-end system is shown in Fig. 2. Actually, one could use the signature waveforms $\mathbf{p}(t)$ in the first place, or another set of orthogonal waveforms, in many multiple access scenarios, but there may be advantages to forcing this condition. Other decompositions of the correlation matrix, such as $\mathbf{R} = \mathbf{R}^{1/2}\mathbf{R}^{1/2}$ and $\mathbf{R} = \mathbf{Q}^T\mathbf{\Lambda}\mathbf{Q}$, where $\mathbf{Q}$ is an orthogonal matrix and $\mathbf{\Lambda}$ is the diagonal eigenvalue matrix, yield the same result as Cholesky decomposition, but the Cholesky decomposition is preferred due to its numerical stability. An adaptive scheme for joint transmitter–receiver optimization suitable for asynchronous channels is described elsewhere [38].

The described method of coordinated linear transformations in the transmitter and receiver in synchronous multiuser channels orthogonalizes the multiple access users, with no transmit power or noise enhancement penalties whatsoever, when users are linearly independent. It will be always possible to choose $\mathbf{s}(t)$ to have linearly independent users when the number of users is such that $K \leq N$. For $K > N$, this will not be possible for then the matrix $\mathbf{R}$ is singular so that the described coordinated transmitter/receiver linear transformations are not feasible. However, the use of joint transmitter/receiver processing with other criteria is not precluded.

At this point we would like to generalize the assertion presented above to the case where modulated signals may have different Shannon bandwidths but occupy the same Fourier bandwidth, such that the spreading factor of the ith user is $\gamma_i, i = 1, \ldots, K$. This generalization is succinctly summarized by the following proposition [12].

Proposition 1. Suppose that K users send their modulated signals to a single receiver, using a common Fourier bandwidth. Then zero interuser interference (IUI) is possible at the receiver only if the users transmit spread-spectrum signals whose spreading factors satisfy

$$\sum_{i=1}^{K} \frac{1}{\gamma_i} \leq 1 \tag{22}$$

It should be noted that in many practical multiple access channels, characterized by multipath propagation and loss of synchronization, for example, the single-user performance (no IUI) may not be achievable even when the conditions stated above are satisfied.

3. PERFORMANCE MEASURES

The SNIR and BER, introduced in the previous section, are the most common performance measures in digital communications. In multiuser communications, these performance measures very often do not admit analytic evaluation, whereas some asymptotic performance measures (corresponding to vanishingly small noise) may be readily found. To facilitate the comparison of different schemes in subsequent sections, we introduce the *asymptotic multiuser efficiency* (AME) and *near–far resistance*, originally proposed by Verdú [17].

Definition 1. The asymptotic multiuser efficiency of a multiuser detector, characterized by the probability of error for the ith user equal to $P(i)$, is given by

$$\eta_i = \sup\left\{ 0 \leq r \leq 1 : \lim_{N_0 \to 0} \frac{P(i)}{Q\left(\sqrt{r\frac{2W_i}{N_0}}\right)} < +\infty \right\} \tag{23}$$

or equivalently

$$\eta_i = \lim_{N_0 \to 0} \frac{W_{eff}(i)}{W_i} \tag{24}$$

where $W_{eff}(i)$ represents the effective signal energy of the ith user, reduced by the presence of MAI, such that the corresponding probability of error can be expressed as $P(i) = Q(\sqrt{2W_{eff}(i)N_0})$.

Definition 2. The near–far resistance of a multiuser detector for the ith user represents the minimum asymptotic efficiency over the relative energies of all other users:

$$\overline{\eta}_i = \inf_{\substack{W_j > 0 \\ j \neq i}} \eta_i \tag{25}$$

The AME measures the slope at which $P(i)$ goes to 0 in the high signal-to-noise ratio region for a given set of signal amplitudes of the desired and interfering users. On the other hand, the near–far resistance represents the AME for the worst-case combination of interfering signal amplitudes relative to the desired signal amplitude.

In the next sections, we use the AME and the near–far resistance to demonstrate the relative performance of conventional CDMA compared to optimal, or near-optimal, CDMA detectors.

4. CDMA, NEAR–FAR EFFECT, AND POWER CONTROL

Consider again the synchronous CDMA system of Section 2, whereby users employ *deterministic* spreading sequences with the cross-correlation between the ith and the jth spreading waveform given by ρ_{ij}. The probability of error for the ith user, when the conventional correlation receiver is employed, similarly as in (13), is given by

$$P(i) = \frac{1}{2^{K-1}} \sum_{\text{all } b_l} Q\left[\sqrt{\frac{2W_i}{N_0}}\left(1 - \sum_{\substack{l=1 \\ l \neq i}}^{K} \sqrt{\frac{W_l}{W_i}} b_l \rho_{il}\right)\right] \tag{26}$$

The corresponding AME is found as

$$\eta_i = \left[\max \left(1 - \sum_{\substack{i=1 \\ l \neq i}}^{K} \sqrt{\frac{W_l}{W_i}} |\rho_{il}| \right) \right]^2 \tag{27}$$

It can be easily seen from (27) that the AME of the conventional detector can take the value 0 for a user with relatively small W_i. Indeed, the near–far resistance of the; conventional receiver is 0 if at least one $\rho_{il} \neq 0, i \neq l, il = 1, \ldots, K$. The situation in which a strong interferer overwhelms the desired signal is usually referred to as the near–far effect. To provide the same performance to all receivers, power control is used so as to have all received signal energies the same ($W_i = W_l, \forall i, l$). The effect of imperfect power control on conventional CDMA, when the aggregate MAI was approximated by equivalent Gaussian noise,[3] was thoroughly analyzed in an earlier study [19]. To illustrate the near–far effect and the effect of power control error, consider a two-user example.

Let the cross-correlation between signature waveforms of users 1 and 2 be equal to ρ. Then, the probability of error for user 1 is given by

$$P(1) = \frac{1}{2} Q \left[\sqrt{\frac{2W_1}{N_0}} \left(1 - \sqrt{\frac{W_2}{W_1}} \rho \right) \right] + \frac{1}{2} Q \left[\sqrt{\frac{2W_1}{N_0}} \left(1 + \sqrt{\frac{W_2}{W_1}} \rho \right) \right]$$

and the corresponding AME is given by

$$\eta_1 = \left[\max \left(1 - \sqrt{\frac{W_2}{W_1}} \rho \right) \right]^2$$

Hence, we can see that $\eta_1 = 0$ for $W_2/W_1 \geq 1/\rho^2$. To provide the same performance to both users, we need $W_1 = W_2$, in which case $\eta_i = (1 - \rho)^2, i = 1, 2$.

To illustrate the effect of power control error, without examining specific power control mechanisms, we consider a simplified model of power control error. Let us assume that the received energy per bit for the ith user is $\alpha_i W_i, i = 1, 2$, where α_1 and α_2 are independent and identically distributed with the probability mass function given by

$$f_\alpha(\alpha_l) = \left\{ \begin{array}{ll} \Lambda, & \text{with probability } \dfrac{1}{4} \\ 1, & \text{with probability } \dfrac{1}{2} \\ \dfrac{1}{\Lambda}, & \text{with probability } \dfrac{1}{4} \end{array} \right\}, \quad i = 1, 2$$

[3] It should be noted that the Gaussian approximation for the MAI yields satisfactory performance estimation accuracy for the conventional correlation receiver, for low to moderate values of W_i/N_0 and when the number of interfering users and/or the processing gain are relatively large. This should not be mistaken for near optimality of the correlation receiver in the presence of MAI, which is in fact non-Gaussian.

Then, it is easy to calculate the AME in the presence of the power control error, by comparing the two-user performance with the single-user performance with the same distribution of the power control error; it is given by

$$\eta_1 = \left[\max \left(0, 1 - \sqrt{\frac{W_2}{W_1}} \rho \Lambda \right) \right]^2$$

The detrimental effect of power control error is apparent. Essentially, as can be seen from the formula for the AME, the power control error has an equivalent effect on the performance as an increase in the correlation coefficient between signature waveforms or/and an increase in the number of users; thus, it eats up the available capacity. In the next section we will see that multiuser detectors do not exhibit such a sensitivity to the imbalance in received signal amplitudes, and that the performance/capacity can be significantly improved, even compared to the conventional detector with perfect power control. Moreover, some multiuser detectors achieve optimal performance when the received energies are quite dissimilar.

5. MULTIUSER DETECTION AND INTERFERENCE CANCELLATION

As indicated in the previous section, the near–far effect is detrimental to conventional CDMA. This is a consequence of suboptimum detection, which ignores the interference from other users. When interfering signals are accounted for in the detection process, the adverse near–far problem can be eliminated. Moreover, these schemes, which we refer to as *multiuser detection* or *interference cancellation*, provide better performance than does a conventional correlation receiver, even when all signals arrive at the same power level at the common receiver (no near–far effect). The correlation receiver (optimum for AWGN channels) was often considered near optimum, based on the conjecture that the aggregate multiple access interference is approximately Gaussian, which may not be a good approximation for a finite-user population with dissimilar power levels. The non-Gaussian nature of the MAI is what enables optimum or near-optimum multiuser detectors to outperform, in some cases significantly, the conventional single-user correlation receiver. To obtain some insight into possible performance improvements and the incurred complexity, we will discuss some characteristic multiuser detection schemes. More detailed surveys of multiuser detection and interference cancellation schemes can be found in the literature [13,29,42].

Without loss of generality, we continue to use the synchronous model introduced in Section 2. The likelihood function (conditional probability density function of the channel output given the binary data vector $\mathbf{b}$ from all the K users) is given by

$$f_{r(t)}[r(t), t \in [0, T] | \mathbf{b}] = C \exp \left\{ -\frac{1}{N_0} \int_0^T \left[r(t) - \sum_{i=1}^{K} \sqrt{W_i} b_i s_i(t) \right]^2 dt \right\}. \tag{28}$$

The maximum-likelihood multiuser detector selects the most likely hypothesis given observation, choosing $\hat{b}$, which maximizes the likelihood function:

$$\hat{b} = \arg \min_{b \in \{-1,1\}^K} \int_0^T \left[r(t) - \sum_{i=1}^{K} \sqrt{W_i} b_i s_i(t) \right]^2 dt$$
$$= \arg \min_{b \in \{-1,1\}^K} (2\mathbf{U}^T - \mathbf{b}^T \mathbf{W}\mathbf{R})\mathbf{W}\mathbf{b} \tag{29}$$

To make a decision, 2^K hypotheses must be examined. Hence, the optimum multiuser detector has exponential complexity in the number of users, which may be restrictive for moderate and large values of K. In the asynchronous case, the optimum detector is the maximum-likelihood sequence detector operating on the sequences of MF outputs, again characterized with exponential complexity with respect to the number of users. It is the complexity of the optimum detector that has motivated research for suboptimum multiuser detectors with polynomial complexity.

One of the best-known multiuser detectors with linear complexity in the number of users is the *decorrelator* detector, first proposed in 1979 [16], but later thoroughly analyzed and correctly characterized [17]. The decorrelator detector follows immediately from the vector of sufficient statistics in (20). By applying the linear transformation $\mathbf{T} = \mathbf{R}^{-1}$ on the vector of sufficient statistics, we obtain

$$\mathbf{U}_0 = \mathbf{R}^{-1}\mathbf{U} = \mathbf{W}\mathbf{b} + \mathbf{Z} \tag{30}$$

where the transformed noise vector has the covariance matrix $\mathbf{R}_Z = \mathbf{R}^{-1}N_0/2$ and the MAI is decoupled. The receiver is completed by applying the sign rule, $\hat{\mathbf{b}} = \text{sgn}(\mathbf{U}_0)$, which is not optimal because the noise vector is not white. The MAI is completely eliminated at the expense of noise enhancement. It should be noted that this detector does not need the knowledge of received amplitudes, unlike the optimum detector, and achieves optimum near–far resistance. Moreover, the decorrelator is the maximum likelihood solution when signal amplitudes are not known. The probability of error for the decorrelator detector has the simplest form of all multiuser detectors and is given by

$$P_d(i) = Q\left(\sqrt{\frac{2W_i}{N_0} \frac{1}{R_{ii}^1}} \right) \tag{31}$$

where R_{ii}^1 represents the ith diagonal element of $\mathbf{R}^{-1}$. The corresponding AME is

$$\eta_d(i) = \frac{1}{R_{ii}^1} \tag{32}$$

It can be shown that the AME of the decorrelator detector is bounded, when the signature waveforms are linearly independent, according to [15]

$$\frac{4\lambda_{\max}\lambda_{\min}}{(\lambda_{\max} + \lambda_{\min})^2} \le \frac{1}{R_{ii}^1} \le 1 \tag{33}$$

where $\lambda_{\min}$ and $\lambda_{\max}$ represent the minimum and maximum eigenvalues of $\mathbf{R}$, respectively. Hence, as the system becomes heavily loaded and/or eigenvalue spread increases, the lower bound on the asymptotic efficiency decreases. When the matrix R becomes singular (loss of linear independence of signature waveforms), the near–far resistance of the decorrelator detector becomes equal to 0.[4] A generalization of the decorrelator detector to the asynchronous case can be found elsewhere [20].

For the two-user case of Example 1, the AME of the decorrelator detector is $\eta_d = 1 - \rho^2$ while the AME of the optimum detector was obtained [17] as $\eta_{ml} = \min[1, 1 + W_2/W_1 - 2\rho\sqrt{W_2/W_1}]$. In Fig. 1 we compare the AMEs of these two multiuser detectors with that of the conventional receiver; in all cases, perfect power control was assumed and $\rho = 0.7$. The advantage of multiuser detectors over the conventional receiver is apparent, even in the absence of the near–far effect and power control error ($W_1 = W_2$). It is a simple exercise to see that the AME of the decorrelator detector remains unchanged in the presence of power control error, and hence, the near–far resistance of the optimum detector does not degrade, either.

Another linear multiuser detector that is closely related to decorrelator detector is the *minimum mean-square-error* (MMSE) detector, originally proposed in the context of multiuser detection for asynchronous channels [21]. For the synchronous case, it is defined by Proposition 2:

Proposition 2. The MMSE detector for the synchronous multiuser system corresponding to the vector of sufficient statistics in (18) is defined by

$$\mathbf{T}^* = \left(\mathbf{R} + \frac{N_0}{2}\mathbf{W}^{-2} \right)^{-1} \tag{34}$$

$$\hat{\mathbf{b}} = \mathbf{T}^*\mathbf{U} \tag{35}$$

Proof: The MMSE criterion leading to the desired estimator is given by

$$\mathbf{T}^* = \arg \min_{\mathbf{T} \in R^{K*K}} E_{\mathbf{b},\mathbf{N}} \|\mathbf{T}\mathbf{U} - \mathbf{b}\|^2 \tag{36}$$

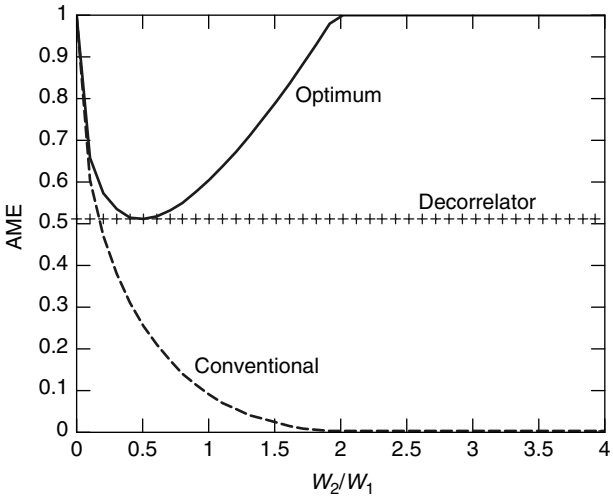

Figure 1. Comparison of AME for decorrelator, conventional, and optimum detectors.

[4] When signature waveforms are not linearly independent, no multiuser detector is near–far-resistant, in the synchronous case [17].

By applying the orthogonality principle, the optimum detector is obtained from

$$E[(\mathbf{TU} - \mathbf{b})\mathbf{U}^T] = 0 \tag{37}$$

from which we obtain

$$\mathbf{T}^* = \mathbf{W}^{-1}\left(\mathbf{R} + \frac{N_0}{2}\mathbf{W}^{-2}\right)^{-1} \tag{38}$$

and since the sign decision on $\mathbf{T}^*\mathbf{U}$ suffices, the factor $\mathbf{W}^{-1}$ is irrelevant and (34) follows. It should be noted that for vanishingly small noise the MMSE detector tends to the decorrelator detector, that is $\lim_{N_0 \to 0} \mathbf{T}^* = \mathbf{R}^{-1}$.

The most important feature of the MMSE detector is its suitability for adaptive implementation, whereby no information about interfering signals is required. Only the timing of the desired signal and a training sequence is required for the adaptive receiver to converge to its optimum setting. This adaptive MMSE detector was analyzed, in various forms, in Refs. 22–24 and references cited therein. Since the adaptive MMSE receiver does not need the knowledge of the signal attributes of interfering users, it represents a natural choice for mobile receivers in cellular or packet radiocommunications. Its performance in the steady state is superior to that of a conventional CDMA receiver, especially in near–far scenarios. Even in the presence of perfect power control, this receiver achieves roughly 2 times larger communication capacity than the conventional receiver [23].

A blind adaptive multiuser detector, closely related to the adaptive MMSE receiver was proposed [25]. The main advantage of this blind receiver is in that the training mode is not required and only an approximate knowledge of the signature waveform of the desired user is needed. The latter characteristic is important in mobile channels in which transmitted waveforms usually suffer from distortion. For a survey of adaptive multiuser detection schemes, the reader is referred to Verdu [26].

Finally, we would like to discuss an important class of multiuser detectors that is based on the cancellation of the estimated MAI in a feedback fashion [27–29]. Although nonlinear in structure, these detectors are characterized by linear complexity in the number of users. A simplified block diagram of one such detector, proposed by Varanasi and Aazhang, is shown in Fig. 2; for simplicity the first two detection stages are shown completely only for user 1.

This multistage detector employs the decorrelator receiver in the first stage to get an initial estimate of interfering bits. These bit estimates are multiplied by the corresponding correlation coefficients and amplitudes of interfering signals to reconstruct the MAI. The estimated MAI is subtracted from the matched filter output of the corresponding user, user 1, and a new decision is made on the thus obtained decision statistics. Since the matched filter output is used to obtain the decision statistics for the second stage, the noise enhancement effect of the decorrelator detector is not explicitly present in later stages. However, the effect of noise enhancement in the first stage propagates into subsequent stages through the tentative first stage decisions. The original version of the multistage detector employed conventional receivers in the first stage [27]. The version with the decorrelator

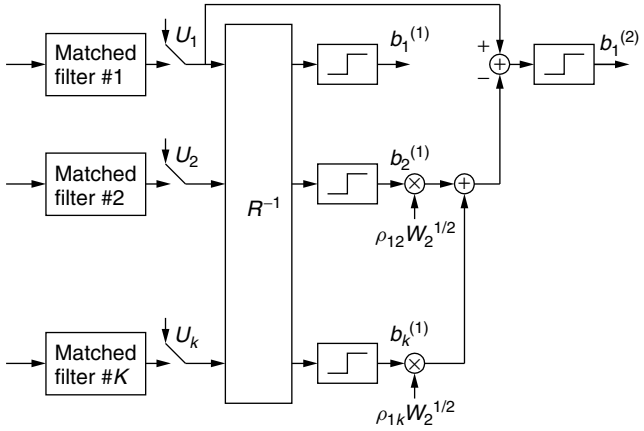

Figure 2. Block diagram of a two-stage detector with the decorrelator receiver in the first stage.

detector in the first stage achieves better performance and admits simpler analysis. The tentative decisions in the first stage are obtained by applying the sign decision on the vector of decision statistics defined in (30), that is, $\mathbf{b}_{(l)} = \text{sgn}(\mathbf{R}^{-1}\mathbf{U}_0)$. The vector of decision statistics for the second stage is formed as

$$\mathbf{Y} = \mathbf{Wb} + (\mathbf{R} - \mathbf{I})\mathbf{W}(\mathbf{b} - \hat{\mathbf{b}}) \tag{39}$$

The second-stage decisions are made according to $\mathbf{b}^{(2)} = \text{sgn}(\mathbf{Y})$. It is apparent that this detector results in the isolated transmission performance in the second stage when the first-stage tentative decisions are perfect. However, when the decision errors are made in the first stage, the corresponding interference terms double, thus adversely affecting the decisions in the second stage.

Returning to our two-user example, it is easy to show, by exploiting the results in Ref. 28, that the probability of error for user 1 in the second stage is given by

$$\begin{aligned} P(1)^{(2)} = {} & Q\left(\sqrt{\frac{2W_1}{N_0}}\right) \times \left[1 - Q\left(\sqrt{\frac{2W_2(1-\rho^2)}{N_0}}\right)\right] \\ & + \frac{1}{2}Q\left(\sqrt{\frac{2W_2(1-\rho^2)}{N_0}}\right) \\ & \times \left\{Q\left[\sqrt{\frac{2W_1}{N_0}}\left(1 - 2\rho\sqrt{\frac{W_2}{W_1}}\right)\right]\right. \\ & \left. + Q\left[\sqrt{\frac{2W_1}{N_0}}\left(1 + 2\rho\sqrt{\frac{W_2}{W_1}}\right)\right]\right\} \end{aligned}$$

It can be shown that the AME in this case is

$$\eta_{\text{ms}} = \min(\alpha, 1)$$

where

$$\alpha = (1-\rho^2)\frac{W_2}{W_1} + \left[\max\left(0, 1 - 2\rho\sqrt{\frac{W_2}{W_1}}\right)\right]^2$$

To minimize the effect of doubling the interference when wrong decisions are made, soft interference cancellation

can be employed. The idea here is to make soft tentative decisions at the decorrelator output in such a way that decisions are somehow weighted according to their reliability. It was shown [30] that two-stage detection with soft interference cancellation can significantly outperform its hard-interference cancellation counterpart, and in the two-user case achieves optimum AME. Specifically, for $K = 2$, it was shown that a linear clipper as a soft weighting nonlinearity achieves the optimum AME when the threshold of the clipper is chosen according to

$$\delta\left(\rho, \sqrt{\frac{W_2}{W_1}}\right) = \sqrt{W_1}\max\left[0, \frac{|\rho|\left(\sqrt{\frac{W_1}{W_2}} - |\rho|\right)}{1-\rho^2}\right] \quad (40)$$

Hence, when the decorrelator output is larger than δ, a hard decision is made, otherwise the decorrelator output is scaled proportionally to the linear part of the clipper, before feedback cancellation. In the K user case the soft limiting nonlinearity is optimized on a pairwise basis according to (40). For numerical results on possible improvements with soft interference cancellation, the reader is referred to Ref. 30. Similar performance improvements for the asynchronous case have been demonstrated [32].

BIOGRAPHIES

Branimir R. Vojčić is a professor in, and chairman of, the Department of Electrical and Computer Engineering at the George Washington University, Washington, D.C. He has received his D.Sc. degree from the University of Belgrade, Yugoslavia. His current research interests are in the areas of communication theory, performance evaluation and modeling mobile and wireless networks, code division multiple access, multiuser detection, adaptive antenna arrays and space-time coding and ad-hoc networks. He has also been an industry consultant in these areas and has published and lectured extensively in these areas. Dr. Vojcic is a senior member of IEEE, was an associate editor for IEEE Communications Letters and a receipient of 1995 National Science Foundation CAREER Award.

Raymond L. Pickholtz is a professor in, and former chairman of, the Department of Electrical and Computer Engineering at The George Washington University, Washington, D.C., and received his Ph.D. in electrical engineering from the Polytechnic Institute of Brooklyn, New York. He was an editor of the *IEEE Transactions on Communications*, and guest editor for special issues on computer communications, military communications spread spectrum systems and social impacts of technology. He is currently the coeditor of chief of the *Journal of Communications and Networks*. He has published scores of papers (several award winning), acts as a consultant to industry, and holds six U.S. patents.

Dr. Pickholtz is a fellow of the IEEE, AAAS, and the Washington Academy of Sciences. He was elected president of the IEEE Communications Society in 1991. He received the Donald W. McLellan Award in 1994. He was a visiting Erskine fellow at the University of Canterbury, Christchurch, New Zealand, 1997. He was awarded the IEEE Third Millenium Medal in 2000.

CODING FOR MAGNETIC RECORDING CHANNELS

LIH-JYH WENG
Maxtor Corporation
Shrewsbury, Massachusetts

1. INTRODUCTION

Since 1990, the areal magnetic recording density for rigid disks has been growing at a rate of 60% annually and the trend is accelerating [1]. This is one of the most important factors for the magnetic recording capacity of more recent rigid disks to double every nine months. To maintain this pace of density increase and to meet the stringent requirement of today's digital storage systems in both the data integrity and recording density increase, error-correcting codes (ECCs) become both indispensable in achieving the low postdecoding bit error rate and effective in overall recording density optimization. An ECC encoder first encodes the user data into ECC codewords; these code words are then mapped, using a modulation code, into a form suitable for the write circuit to record the encoded data to the disk surfaces. During a read, the process is reversed; the readback signal is first processed to recover the codewords for the modulation code; the role of the ECC is to correct all errors that may have occurred during the entire read/write process. Figures 1 and 2 give the logical flow of the entire process. The main purpose of the ECC is to ensure that the user data in Fig. 1 are identical to the user data of Fig. 2. In more conventional communication systems, the main emphasis is to communicate reliably

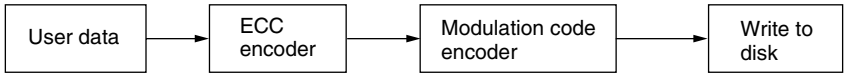

Figure 1. Logic flow of writing data to disks.

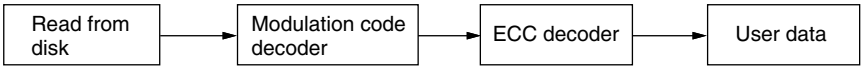

Figure 2. Logic flow of retrieving data from disks.

from one point to another with an acceptable amount of delay. On the other hand, disk and tape drives serve the purpose of storing data at one time instant and reading them back reliably at another instant.

Some of the modern modulation codes have the capability of performing a limited amount of error correction by themselves [2]. However, the error rate at the output of the modulation code decoder, in most cases, does not achieve the stringent low error rates required of present storage systems. An ECC is a simple and effective way to bring the error rate at the output of the modulation code decoder to the level specified by the user. Furthermore, with the separation of the modulation code and ECC, each component can be more effectively designed to achieve the overall optimality of the entire recording system.

2. REED–SOLOMON CODES: ORIGIN AND BASIC CHARACTERISTICS

In the early days, the recording density was relatively low, and, hence, the main concern was a single burst in a sector. The single-burst correcting codes and codes that correct a small number of errors were the dominant ECCs at the time. Reference 2 is a good source for early ECC implementations. When the recording density increases, the most likely errors are not confined to single bursts; therefore, codes that can deal with both random and burst errors are necessary to adequately protect the written data. Reed–Solomon codes have such characteristics and also possess efficient encoding and decoding algorithms, which can be readily implemented. Consequently, they are presently the most widely used codes for magnetic disk drives. All the techniques discussed here are applicable to rigid disk drives and tape drives as well as optical drives. When complexity is a main concern, tape drives also use other coding techniques. On tape drives, the error bursts tend to be much longer than those observed in disk drives. Some structure is usually introduced among code blocks to deal with long bursts. Specifically, tape drives often employ so-called two-dimensional codes. This can be pictured with data arranged in a two-dimensional array; both the rows and the columns of the array are protected by ECCs, or some sort of redundancy is introduced both vertically and horizontally. Furthermore, redundancies can be introduced diagonally or along any line of a given slope in the array. The main reason for using codes along more than two directions is to use very simple codes, such as single-parity-check binary codes along each direction to provide sufficient protection. Array codes [4] provide such advantages.

The Reed–Solomon codes employed in recording systems need to satisfy some special constraints, which may be different from those in other applications. In the following discussion, several important considerations for applying Reed–Solomon codes in magnetic recording systems are addressed. First, a simple example is presented to introduce some terminology commonly used in Reed–Solomon codes as well as more generally in ECCs. Other related issues concerning the code applications to magnetic recording such as implementation, block synchronization, interleaving, performance, and error detection are discussed. Finally, some remarks concerning tape drives, RAID (reductant array of independent disks) systems, soft decoding and increasing the sector size are also addressed.

2.1. An Example of a Reed–Solomon Code

A Reed–Solomon (10,3,8) code over Galois Field code GF(2^4) is selected for illustration purposes. The meaning of the parameters 10, 3, and 8 will be given shortly. First, the field is a Galois field, commonly denoted as GF(2^m), where m is 4 in this example. This field is used to perform all arithmetic operations needed for the Reed–Solomon code. Therefore, the definition and essential properties for the GF(2^m) should be given first. GF(2^m) is often referred to as an *extension field* of GF(2) = {0, 1}. A more concrete way of viewing a GF(2^m) field is to list the field elements as all possible m-bit binary representation of the integer $0, 1, 2, \ldots, 2^m - 1$. For this example, $m = 4$, the field elements of GF(2^4) are the set {0000, 0001, 0010, 0011, 0100, 0101, 0110, 0111, 1000, 1001, 1010, 1011, 1100, 1101, 1110, 1111}. A field needs two basic operations: addition (+) and multiplication (∗) (symbol ∗ used to indicate Galois field multiplication). The addition of two elements (a, b, c, d) and (e, f, g, h) are defined to be $(a + e, b + f, c + g, d + h)$, where a, b, c, d, e, f, g, h are either one or zero, the elements of GF(2) = {0, 1}. The same symbol + is used for addition over GF(2) and addition over GF(2^m). The addition over GF(2) is modulo-2 addition, which follows the rule that $0 + 0 = 0$, $0 + 1 = 1 + 0 = 1$, and $1 + 1 = 0$. For example, $(1010) + (1100) = (0110)$. The multiplication rule over GF(2) is defined by $0 * 0 = 0 * 1 = 1 * 0 = 0$, and $1 * 1 = 1$. In more familiar engineering terms, the addition is equivalent to an EXOR (exclusive OR) operation and the multiplication is the same as the AND operation commonly seen in logic. To define the multiplication rules for GF(2^m), an irreducible binary polynomial of degree m is needed. A degree m binary polynomial, where the coefficients are either 0 or 1, is said to be irreducible if it is not divisible by any binary polynomial of degree lower than m except the trivial degree 0 polynomial, specifically, the constant 1. In the case of $m = 4$, $p(x) = x^4 + x + 1$ is an irreducible polynomial. Each element of GF(2^m) is associated with a unique polynomial of degree $m - 1$ or lower. The elements of GF(2^4) can be expressed in two convenient ways: GF(2^4) = {0000, 0001, 0010, 0011, 0100, 0101, 0110, 0111, 1000, 1001, …} = $\{0, x^0, x, x + 1, x^2, x^2 + 1, x^2 + x, x^2 + x + 1, x^3, x^3 + 1, \ldots\}$. Let $a(x)$ and $b(x)$ be two elements of GF(2^m); then the multiplication rule is given by $c(x) = a(x) * b(x) \bmod p(x)$. Since the degree of $p(x)$ is m, the degree of $c(x)$, which is the remainder of $a(x) * b(x)$ divided by $p(x)$, is less than m. Next an element of GF(2^m) is selected whose powers generate every possible nonzero element of the field by multiplying itself many times. In this selected field, any of the following nonzero elements can be used as such a generating element: $x, x^2, x + 1, x^2 + 1, x^3 + 1, x^3 + x + 1, x^3 + x^2 + 1$, and $x^3 + x^2 + x$. Let the generating element be x, then $x^0 = 1, x^1 = x, x^2 = x^2, x^3 = x^3, x^4 = x + 1, x^5 = x * x^4 = x * (x + 1) = x^2 + x, x^6 = x * x^5 = x * (x^2 + x) = x^3 +$

$x^2, x^7 = x * x^6 = x * (x^3 + x^2) = x^4 + x^3 = x + 1 + x^3 = x^3 + x + 1, x^8 = x * x^7 = x * (x^3 + x + 1) = x^4 + x^2 + x = x + 1 + x^2 + x = x^2 + 1, x^9 = x * x^8 = x * (x^2 + 1) = x^3 + x,$ .... Expressed as powers of the generating element, the field elements are written as $\mathrm{GF}(2^4) = \{0000, 0001, 0010, 0100, 1000, 0011, 0110, 1100, 1011, 0101, 1010, \ldots\} = \{0, x^0, x^1, x^2, x^3, x^4, x^5, x^6, x^7, x^8, x^9, \ldots\}$. In this case, all the nonzero elements of the field can be expressed as distinct powers of x. There are exactly $2^m - 1$ distinct powers $x^j \bmod p(x)$ for $j = 0, 1, 2, \ldots, 2^m - 2$. The class of polynomials, powers of whose roots generate all nonzero field elements, is collectively called *primitive polynomials*. A nonprimitive polynomial can also be used to form the field. For example, the polynomial $p'(x) = x^4 + x^3 + x^2 + x + 1$ is irreducible but not primitive. This can be easily checked by the fact that $x^4 = x^3 + x^2 + x + 1 \bmod p'(x)$ and $x^5 = x * x^4 = x * (x^3 + x^2 + x + 1) = x^4 + x^3 + x^2 + x = (x^3 + x^2 + x + 1) + x^3 + x^2 + x = 1 \bmod p'(x)$. Since x is not a primitive element for the field defined by $p'(x)$, a different element must be used. Let $\alpha = x + 1$, then the successive powers of $\alpha^j \bmod p'(x)$ for $j = 0, 1, 2, \ldots, 2^m - 2$, are all distinct. Therefore, another $\mathrm{GF}(2^4)$ can be generated by $p'(x)$ using α^j as a nonzero element. It is convenient to represent $\mathrm{GF}(2^m)$ as $\{0, \alpha^0, \alpha^1, \alpha^2, \alpha^3, \ldots\}$, where α is a primitive element. For the primitive irreducible $p(x)$ shown above, $\alpha = x$. For all primitive polynomials, the generating element α can be selected to be x. For the remaining discussion, the binary primitive polynomial $p(x)$ is used. The generating element α is sometimes referred to as the *primitive element*.

With α^j defined for $j = 0, 1, 2, \ldots, 2^m - 2$, the product of two elements α^i and α^j can be obtained in at least two ways: (1) express α^i and α^j as polynomials, find the product as the polynomial multiplication of $\alpha^j * \alpha^j \bmod p(x)$; (2) using the simple exponent addition rule, namely $\alpha^i * \alpha^j = \alpha^k$ with $k = i + j \bmod 2^m - 1$. There are $2^m - 1$ nonzero distinct elements, each corresponding to a distinct power $0, 1, 2, \ldots, 2^m - 2$. It should be noted that $\alpha^s = \alpha^0$ if $s = 2^m - 1$. The identity element for $\mathrm{GF}(2^m)$ multiplication is α^0. The identity element for $\mathrm{GF}(2^m)$ addition is the zero element. In $\mathrm{GF}(2^m)$, the subtraction operation is the same as the addition operation and the "division" a/b can be considered as $a * (b^{-1})$ for any nonzero element b. The element b^{-1} can be obtained from b by examining the exponent of b; namely, if $b = \alpha^j$, then $b^{-1} = \alpha^k$ such that $j + k = 0 \bmod 2^m - 1$. For example, in the example of $\mathrm{GF}(2^4)$, to find the inverse of $x^3 + x$, which is α^9, the exponent is 9; it is a simple matter to determine that $9 + 6 = 15 = 0 \bmod 2^4 - 1$. Therefore, $(\alpha^9)^{-1} = \alpha^6$. References 5 and 6 provide more detailed properties of Galois fields.

In software or firmware implementations, the most common method of computing the inverse of a field element is by making use of a logarithm table and an antilogarithm table. The logarithm table associates every nonzero element with an exponent; for example, in the $\mathrm{GF}(2^4)$ above, the logarithm table gives the elements 0100 and 1001 their respective exponents 3 and 14. On the other hand, the antilogarithm table takes the exponents 3 and 14 as inputs and produces the elements 0100 and 1001, respectively. The approach of finding the inverse is very similar to the real-number computation using a logarithm table and an antilogarithm table [6]. In a hardware implementation, the logarithm table and the antilogarithm table are seldom provided. To find the inverses, a special algorithm is employed; the algorithm is often dependent on the symbol size m selected and sometimes depends on the irreducible polynomial generating the field [7,8].

2.2. Reed–Solomon Encoder

A Reed–Solomon code can now be defined over the field $\mathrm{GF}(2^m)$. One way to specify a Reed–Solomon code is to define the roots of the generator polynomial of the code. The generator polynomial can be written as

$$g(x) = (x + \alpha^L) * (x + \alpha^{L+1}) * (x + \alpha^{L+2}) * \cdots * (x + \alpha^{L+R-1}) \tag{1}$$

This is the generator polynomial of a Reed–Solomon (n, k, d) code, where n is the code length, k is the number of information symbols, and d is the minimum distance (or Hamming distance) among all possible codewords, where the distance between two codewords is equal to the number of symbols at which these two codewords differ. The code rate of a code is defined as the ratio k/n, which is a number between 0 and 1. In magnetic recording, high-rate codes are frequently employed. The value L can be selected arbitrarily; n is at most $2^m - 1$ for easy hardware implementation; and $d = n - k + 1 = R + 1$, where R is equal to the number of redundant symbols of the code or the degree of the generator polynomial. In other words, there are n symbols in a codeword, among which k symbols can be assigned arbitrarily as information symbols or data symbols. The degree of the generator polynomial is equal to $R = n - k$. The one requirement for the roots is that they must be consecutive roots $\alpha^L, \alpha^{L+1}, \alpha^{L+2}, \ldots, \alpha^{L+R-1}$. The choice of the value L does not change the code minimum distance. Let $n = 10, k = 3, R = 7$ or $d = 8$, and set $L = 11$. Then the generator polynomial is given by

$$\begin{aligned} g(x) &= (x + \alpha^{11}) * (x + \alpha^{12}) * (x + \alpha^{13}) * (x + \alpha^{14}) \\ &\quad * (x + \alpha^0) * (x + \alpha^1) * (x + \alpha^2) \\ &= \alpha^0 * x^7 + \alpha^1 * x^6 + \alpha^3 * x^5 + \alpha^{12} * x^4 + \alpha^{11} * x^3 \\ &\quad + \alpha^0 * x^2 + \alpha^{11} * x + \alpha^8 \end{aligned} \tag{2}$$

All the codewords of this Reed–Solomon (10,3,8) code can be expressed in polynomial form such as

$$c(x) = c_9 * x^9 + c_8 * x^8 + c_7 * x^7 + c_6 * x^6 + c_5 * x^5 + c_4 * x^4 + c_3 * x^3 + c_2 * x^2 + c_1 * x + c_0 \tag{3}$$

The requirements for $c(x)$ to be a codeword are (1) its degree is no higher than 9 and (2) it must be a multiple of the generator polynomial [i.e., $c(x) = m(x) * g(x)$]. To simplify the notation, the polynomial is often written as a vector:

$$c(x) = (c_9, c_8, c_7, c_6, c_5, c_4, c_3, c_2, c_1, c_0) \tag{4}$$

For example, $g(x) = (0, 0, \alpha^0, \alpha^1, \alpha^3, \alpha^{12}, \alpha^{11}, \alpha^0, \alpha^{11}, \alpha^8)$ and $x * g(x) = (0, \alpha^0, \alpha^1, \alpha^3, \alpha^{12}, \alpha^{11}, \alpha^0, \alpha^{11}, \alpha^8, 0)$. It is clear that both $g(x)$ and $x * g(x)$ are codewords because they are both multiples of the generator polynomial $g(x)$. Another way of specifying a code is by a generator matrix. The generator matrix of this (10,3,8) code is given as

$$G = \begin{bmatrix} 0, 0, \alpha^0, \alpha^1, \alpha^3, \alpha^{12}, \alpha^{11}, \alpha^0, \alpha^{11}, \alpha^8 \\ 0, \alpha^0, \alpha^1, \alpha^3, \alpha^{12}, \alpha^{11}, \alpha^0, \alpha^{11}, \alpha^8, 0 \\ \alpha^0, \alpha^1, \alpha^3, \alpha^{12}, \alpha^{11}, \alpha^0, \alpha^{11}, \alpha^8, 0, 0 \end{bmatrix} \quad (5)$$

With the help of the generator matrix, a codeword can be expressed as

$$(c_9, c_8, c_7, c_6, c_5, c_4, c_3, c_2, c_1, c_0) = (m_2, m_1, m_0) * G \quad (6)$$

where m_2, m_1, m_0 are arbitrary elements of GF(2^m). It should be noted that not all codes possess generator polynomials or generator matrices. A class of codes, called *cyclic codes*, can be specified by generator polynomials. Another class of codes, called *linear codes*, have generator matrices. The Reed–Solomon codes are both cyclic and linear; therefore, they have rich algebraic properties and structure, which provide the foundation of being well studied and understood. As a result, Reed–Solomon codes are widely employed. As mentioned previously, the distance between two codewords is the number of symbols at which these two codewords differ. For example, the distance between $g(x)$ and $x * g(x)$ is 9 (symbols.) If all possible codewords of this Reed–Solomon (10,3,8) code are listed, every pair of distinct codewords differs in at least eight (8) symbols. Therefore, any combination of three or fewer symbol errors will not change a codeword closer to another codeword. Consequently, this code can correct all possible combinations of three or fewer errors. In addition, any error pattern of four symbol errors cannot change a codeword closer to another codeword; in the worst case, the codeword corrupted by a four-error pattern can be at the same distance from many codewords. As a result, the decoder cannot decode the erroneous code word to a unique codeword. In this case, the errors are detected but not corrected. In general, a distance d Reed–Solomon code is capable of correcting any combination of t symbol errors per code block if $t < or = \lfloor d/2 \rfloor$, where $\lfloor x \rfloor$ denotes the greatest integer less than or equal to x ($\lfloor x \rfloor$ is referred to as the "floor function" of x). A more interesting way of employing a distance d Reed–Solomon code is to use a distance d code to correct t or fewer errors and detect with certainty if there are $t+1, t+2, \ldots, e$ symbol errors per code block provided $t + e < d$ and $t < e$ [6,9–11]. In this application, it is very important that the value t be used to determine the postdecoding symbol or block error rate and the value e be designed to ensure that the miscorrection probability meets the stringent requirement for data storage applications. It should also be noted that for highly redundant Reed–Solomon codes, the value of e can be set to be very close to or the same as t. In other words, very little or no additional symbol detection is needed to achieve the level of miscorrection probability demanded by the data storage systems.

In the last paragraph, the distance is measured by symbols. Because every symbol contains m bits, it is also possible to measure the distance in bits. For example, the Reed–Solomon (10,3,8) code over GF(2^4) is also a binary (40,12,10) code. The minimum distance of the binary code is now measured in bits. This binary code can correct four (4) random bit errors and detect five (5) random bit errors with certainty. The minimum symbol distance of a Reed–Solomon code can be easily determined as $d = n - k + 1$. However, the minimum distance of its binary expansion version cannot be determined easily except that the lower bound of the minimum distance is d, the same as the symbol minimum distance. This lower bound may not be very tight, as can be seen from the example presented above.

The encoding process of a Reed–Solomon (n, k, d) code is often achieved through a division process, which ensures that the codeword $c(x)$ is a multiple of the generator polynomial $g(x)$. It is possible to achieve this with the additional condition that the data symbols of $c(x)$ are unaltered. This class of codes is called *systematic codes*.

2.3. Reed–Solomon Decoder

In decoding, the first step is also by division. For error-detection purposes, a corrupted codeword $c'(x)$ is divided by $g(x)$. If the remainder of the division is zero, the decoder assumes that the codeword is error-free; otherwise, the decoder assumes the codeword is corrupted. Instead of dividing by the generator polynomial $g(x)$, an equivalent method is to divide the corrupted codeword by each factor $x + \alpha^{L+j}$ of $g(x)$. The results of the divisions are called syndromes S_{L+j}. Therefore, for an uncorrupted codeword, all the syndromes S_{L+j} must be zero. The syndrome polynomial $S(x)$ is a degree $R-1$ polynomial defined as

$$S(x) = S_L + S_{L+1} * x + S_{L+2} * x^2 + S_{L+3} * x^3 + \cdots + S_{L+R-1} * x^{R-1} \quad (7)$$

In most algebraic coding textbooks [6,9–11], the starting point of decoding Reed–Solomon codes is the syndrome polynomial, which contains all the necessary information to find error locations and error values. In Reed–Solomon codes over GF(2^m), the symbol positions within a code block are denoted by $\alpha^0, \alpha^1, \alpha^2, \ldots, \alpha^{n-2}, \alpha^{n-1}$, with α^p corresponding to symbol position P. The first data symbol occupies position $n-1$, and the last redundant symbol occupies position 0. The common decoding algorithms for high-rate (n, k, d) Reed–Solomon codes are divided into the following four major steps:

1. Compute the syndrome polynomial $S(x)$ from a corrupted codeword $c'(x)$.
2. Solve the key equations $\sigma(x) * S(x) = \omega(x) \bmod x^R$, where $R = n - k$ and $\sigma(x)$ is the error locator polynomial containing all the error location information and $\omega(x)$ is the error evaluator polynomial, which can be used in conjunction with the error locator polynomial to find the error values.
3. Find the roots of $\sigma(x) = (\alpha^{a1} * x + 1) * (\alpha^{a2} * x + 1) * \cdots * (\alpha^{at} * x + 1)$. The following conditions can be used to abort the decoding process: (a) if the number of roots found is less than the degree of $\sigma(x)$, (b) any

roots found does not correspond to a location between 0 and $n-1$, and (c) if repeated roots are found.

4. For each root α^{ai} of $\sigma(x)$ find the error values with the help of $\sigma(x)$, $\omega(x)$ using the Forney formula. The error value at location α^{ai} is given by $\omega(x) * x^{(L-1)} * /\sigma'(x)$ evaluated at $x = \alpha^{ai}$, where $\sigma'(x)$ is the formal derivative of $\sigma(x)$. Over GF(2^m), if $\sigma(x). = \sigma_0 + \sigma_1 * x + \sigma_2 * x^2 + \sigma_3 * x^3 + \sigma_4 * x^4 + \sigma_5 * x^5 + \sigma_6 * x^5 + \sigma_7 * x^7 + \cdots$, then $\sigma'(x). = \sigma_1 + \sigma_3 * x^2 + \sigma_5 * x^4 + \sigma_7 * x^6 + \cdots$. In other words, $\sigma'(x)$ contains only even-powered terms of x.

To complete the decoding process, the errors values computed in step 4 should be added to the corrupted code symbol indicated by the respective decoded error locations.

The most time-consuming steps are steps 1 and 3. The most difficult step to understand is step 2. Again, most coding textbooks provide detailed information about solving the key equations [6,9–11]. Two competing algorithms for solving the key equations are the Berlekamp–Massey algorithm and the Euclidean algorithm. The former may use fewer gates to implement, but the latter can be understood more easily for first-time readers. In addition, there are other decoding algorithms, which can be found in Refs. 12 and 13.

The most frequently used technique for finding the roots of the error locator polynomial is the well-known Chien search [6,9–11], which is a systematic and efficient trial-and-error root testing technique. Every possible root, one root for each possible error location, is tested as a possible solution to the error locator polynomial $\sigma(x)$. Therefore, this is usually a very time-consuming process.

It may be helpful to continue the example with errors introduced. Let the codeword be $c(x) = x * g(x) = (0, \alpha^0, \alpha^1, \alpha^3, \alpha^{12}, \alpha^{11}, \alpha^0, \alpha^{11}, \alpha^8, 0)$. Let the two introduced errors be one at position 0 and one at position 8. The error value at position 0 is α^3 and the error value at position 8 is α. Then the corrupted codeword $c'(x)$ becomes $c'(x) = x * g(x) = (0, \underline{\alpha}^4, \alpha^1, \alpha^3, \alpha^{12}, \alpha^{11}, \alpha^0, \alpha^{11}, \alpha^8, \underline{\alpha}^3)$. The underlined symbols are erroneous. The first step of the decoding process is to compute the syndrome polynomial, which is $S(x) = \alpha^0 + \alpha^4 * x + \alpha^{14} * x^2 + \alpha^{13} * x^3 + \alpha^9 * x^4 + \alpha * x^5 + \alpha^6 * x^6$. Either the Berlekamp–Massey or the Euclidian algorithm will produce the error locator polynomial $\sigma(x) = 1 + \alpha^2 * x + \alpha^8 * x^2$ and the error evaluator polynomial $\omega(x) = 1 + \alpha^{10} * x$. It can be checked that $\sigma(x) * S(x) = \omega(x) \bmod x^R$. The next step is to find the roots of $\sigma(x)$, which is equivalent to the complete factorization of $\sigma(x)$. The result of this process is $\sigma(x) = (x+1) * (\alpha^8 * x + 1)$. The two roots α^0 and α^{-8} correspond to errors at symbol locations 0 and 8, respectively. To find the error values, the Forney formula is used, as follows. At symbol location i, the error value is given by $Y_i = \omega(x)x^{L-1}/\sigma'(x)$ evaluated at $x =$ root i of $\sigma(x)$. In this case, the results are $Y_0 = \alpha^3$ and $Y_1 = \alpha^1$.

2.4. Comparison of Decoding Algorithms

The Reed–Solomon codes employed in most magnetic storage devices are high-rate codes. As mentioned previously, the major steps involved in the decoding algorithms are (1) syndrome computation (2) error locator polynomial and error evaluator polynomial determination, and (3) error value computation. Step 2 has the most variations. When the maximum number of errors to be corrected is small — typically, four or fewer errors — the most efficient way of obtaining the error locator polynomial is to compute all the coefficients of the error locator polynomial directly from the syndromes using a special and simple technique [14]. For higher numbers of errors, usually the well-known Berlekamp–Massey algorithm or the Euclidean algorithm is used. Most of the algebraic coding books give detailed descriptions of these two algorithms [6,9–11]. These two algorithms are both iterative and equivalent but they have two interesting opposite characteristics, which may be the determining consideration in algorithm selection. In the Berlekamp–Massey algorithm, the degrees of the polynomials used in the iteration increases as the procedure continues and the total number of iterations is a fixed number. On the other hand, in the Euclidean algorithm, the maximum polynomial degree decreases from iteration to iteration and the number of iterations to complete the procedure is variable. Another notable thing is that the Berlekamp–Massey algorithm can be used to find either the error locator polynomial alone or both the error locator polynomial and the error evaluator polynomial. On the other hand, in the Euclidean algorithm, both of these polynomials are computed at the same time. It is not very efficient to use the Euclidean algorithm to compute the error locator polynomial alone.

3. OTHER ASPECTS OF REED–SOLOMON CODING

3.1. Hardware Versus Firmware Implementations

The entire encoding and/or decoding process can be implemented either by microprocessor firmware or by hardware. Typically, the encoding is done in hardware to improve the speed of the process of writing to disk. Also, the complexity of an all-hardware encoder is much lower than that of the hardware decoder. Disk drives have the luxury of rereads, which are equivalent to requests for retransmission in communication systems. When hardware gates were expensive, the ECCs employed in magnetic recording systems made use of rereads to reduce the cost of hardware implementation. The hardware complexity is a function of the number of symbol errors corrected. Therefore, one way to save gates or hardware complexity is to correct only a smaller number of symbol errors than the designed error-correcting capability in hardware; when the hardware decoder fails, the firmware decoder is then used to correct all the errors. For example, when the ECC is designed to correct six errors per interleave, the hardware decoder can be designed to correct two or fewer errors and the firmware decoder to correct three, four, five, and six errors per interleave. Data throughput is affected every time the firmware algorithm is employed. The hardware encoder can also be designed to perform the syndrome computation with simple modification [15]. This design further reduces the total complexity of the hardware decoding.

There is a mode of error correction that may be different from other communication systems. Occasionally, a small particle may get in contact with the read head resulting in an increase in temperature. The heat produced by the contact may cause a long burst of errors to occur. This phenomenon is called a thermal asperity. Fortunately, the location of a thermal asperity can be detected by the signal processing system prior to ECC decoding. As a result, a more powerful error–erasure decoding algorithm can be used to deal with the long burst in the event that the normal error-only decoding algorithm fails to correct the errors. This decoding algorithm is capable of correcting e erasures and t symbol errors when $2 * t + e < d$, where an erasure is an error with known location. This algorithm is also given in most coding textbooks [6,9–11].

3.2. Block Missynchronization Detection

As can be seen from the example, a Reed–Solomon code word is likely decoded to a different codeword if a shift in the symbol position occurs. As mentioned previously, the Reed–Solomon code is a cyclic code, which means that a cyclic rotation of a nonshortened codeword is also a codeword. If $(c_{n-1}, c_{n-2}, c_{n-2}, \ldots, c_2, c_1, c_0)$ is a codeword of a nonshortened Reed–Solomon code over GF(2^m), that is, $n = 2^m - 1$, then both cyclic shifted versions $(c_{n-2}, c_{n-2}, \ldots, c_2, c_1, c_0, c_{n-1})$ and $(c_0, c_{n-1}, c_{n-2}, c_{n-2}, \ldots, c_2, c_1)$ are also codewords of the same code. As a result, Reed–Solomon codes are susceptible to miscorrection when symbol synchronization errors occur. To minimize this possibility, block synchronization must be assured for each sector prior to ECC decoding. This is accomplished with a specially designed sequence called an *address mark*. In other words, the data of a sector are preceded by an address mark. The address mark is designed to ensure correct block synchronization before the ECC attempts error correction. There is a preamble preceding the address mark. The main purpose of the preamble is for training the phase-locked loop (PLL) to acquire the bit synchronization. The secondary purpose of the preamble is to assist the address mark to establish a distinct position in the bitstream, which, in turn, enables the system to find the beginning of the first symbol of the ECC block. To facilitate the PLL training, a repeated pattern is used as the preamble. This pattern is often a long sequence of identical bits, such as a sequence of ones. In the following discussion, let a long sequence of ones (1s) serve as the preamble, which precedes the address mark. Let the address mark be a 12-bit sequence 000010100110 with the bit on the left preceding the bit on the right in time. The pattern, including the preamble and address mark, recorded on the disk is $\cdots$ 111111111111000010100110, where the underlined bits are the address mark. As soon as the bit synchronization is established by the phase-locked loop, a circuit compares every 12 consecutive bits with the address mark. The Hamming distance between the address mark and the 12 ones is 8 (bits), because there are 8 zeros in the address mark. Let the distance from the address mark to an out-of-phase sequence be $d_a(s)$. An out-of-phase sequence consists of s ones of the preamble followed by the first 12 s bits of the address mark. It can be checked that $d_a(s)$ is 7,8,9,8,8,7,6,7,7,7,7,0 for $s = 11,10,9,8,7,6,5,4,3,2,1,0$, respectively. Other than the case of $s = 0$, the minimum distance for this address mark from the out-of-phase sequences is 7. Therefore, this address mark can tolerate three errors. In other words, with three or fewer errors in any span of 12 consecutive bits prior to the last bit of the address mark, the position of the address mark can be correctly established. This address mark is called a "3-error-tolerance address mark." Let t be any threshold with t less than or equal to 3. Then the correct address mark is assumed found if any span of 12 consecutive bits differs from the correct address mark by t or fewer bits. By varying the value t, the performance of the address mark can be controlled to a certain degree. There are two important probabilities associated with an address mark for a specified threshold t. The probability of failure to synchronize is the probability that the system fails to find the correct synchronization position; this occurs when there are more than t errors on the address mark retrieved from the disk. This probability for the case of independent errors is given by the dominant term of the probability

$$P_{\text{failure\_to\_synchronize}} \approx C(L, t+1)p^{(t+1)}(1-p)^{(L-t-1)} \tag{8}$$

where L is the length of the address mark in bits, p is the raw bit error rate, t is the threshold, and $C(L, t+1)$ is the binomial coefficient of $x^{(t+1)}$ in the expansion of $(x+1)^L$. For most cases of interest, p is a small number. Therefore, the $1-p$ term approaches 1. Consequently, the probability of failure to synchronize is decreased as the threshold is increased. The other important probability is the probability of false synchronization. This is the probability that a span of L bits prior to the correct address location is mistakenly identified as the address mark. This probability is lower bounded by

$$P_{\text{false\_synchronization}} \approx C(d_a, d_a - t)p^{d'}(1-p)^t \tag{9}$$

where d_a is the minimum distance between the address mark and any span of L bits prior to the correct address mark position and $d' = d_a - t$. As can be seen, the probability is proportional to $p^{d'}$, and this probability increases as the threshold decreases.

Therefore, these two probabilities put conflicting requirement on the threshold t. One obvious solution is to increase the length of the address mark L, which leads to higher values of error tolerance; as a result, there are more values of threshold to select to meet the demand for both probabilities. Unfortunately, a longer address mark means larger overhead and more complicated circuits for detecting the address mark. The other choice is not to increase the length of the address mark and rely on the ECC to help in detecting the false synchronization. Using the 12-bit address mark with a raw bit error rate of $p = 1.0 \times 10^{-4}$ and $t = 3$ as an example, the two probabilities are $P_{\text{failure\_to\_synchronize}} \approx 9.92 \times 10^{-21}$ and $P_{\text{false\_symchronization}} \approx 7.00 \times 10^{-15}$. The probability of failure to synch is acceptable but the probability of false synchronization is

too high for the data storage application. Reed–Solomon codes over GF(2^m) are susceptible to synchronization errors when the bit slippage is a multiple of m, the symbol size. Therefore, the miscorrection probability is of the order of $P_{\text{false\_symchronization}}/m$. With a false synchronization probability of 7.00×10^{-15}, the miscorrection probability is of the order of 1.00×10^{-18}, which is too high. A solution to this situation is to use a coset instead of the code itself for recording purposes.

A coset consists of the set $\text{cl}(x) + c(x)$, where $c(x)$ is any codeword of the Reed–Solomon code and $\text{cl}(x)$ is a fixed sequence or vector of length n, called the coset leader. During recording, a member of the coset is recorded in the disk. When a sector is retrieved, the coset leader is added to the sequence resulting in $c(x)$, the codeword, assuming no errors and perfect synchronization. When out of synchronization, the retrieved sector contains $\text{cl}'(x) + \text{c}'(x)$, where $\text{cl}'(x)$ and $\text{c}'(x)$ are respectively shifted versions of $\text{cl}(x)$ and $\text{c}(x)$ with proper truncation and padding under error-free conditions. With $\text{cl}(x)$ added before decoding, the decoder sees $c'(x)$, a codeword plus possible errors due to truncation and padding, with $\text{cl}(x) + \text{cl}'(x)$. Therefore, with proper selection of $\text{cl}(x)$, $\text{cl}(x) + \text{cl}'(x)$ contains many nonzero terms. Each of these nonzero terms appears as an error to the ECC decoder. A well-designed $\text{cl}(x)$ results in more errors than the ECC correcting capability most of the time. Therefore, the decoder cannot correct these "errors." Consequently, the miscorrection probability is substantially lower than the value $P_{\text{false\_symchronization}}/m$. In fact, it is given by $\{P_{\text{false\_symcronization}}/m\} * \{\text{probability of decoding } \text{cl}(x) + \text{cl}'(x) + c'(x) \text{ as a codeword}\}$. With proper design of $\text{cl}(x)$ and sufficiently long redundant symbols, the probability of decoding $\text{cl}(x) + \text{cl}'(x) + \text{c}'(x)$ as a codeword can be made very small. Therefore, the miscorrection probability is significantly reduced. Reference 16 provides a way to find the coset leaders. In the event that the bit slippage is not a multiple of the symbol size m, the miscorrection probability caused by the false synchronization is given by $\{(1-m) * P_{\text{false\_synchronization}}/m\} * \{\text{probability of decoding } \text{cl}(x) + \text{cl}'(x) + \text{c}'(x) \text{ as acodeword }\}$; however, in this case, $c'(x)$ looks like a random sequence to the decoder, and so does the sequence $\text{cl}(x) + \text{cl}'(x) + \text{c}'(x)$. Therefore, the probability that a randomlike sequence is decoded as a codeword can be easily computed or approximated [17] to be a small number. Consequently, with a properly designed coset leader, the threshold t for the address mark can be simply set according to the requirement for $P_{\text{failure\_to\_synchronize}}$ alone. From a different point of view, a shorter length for address mark can be used with the help of the coset leader. Another similar approach for avoiding false synchronization is to initialize the encoder to a nonzero state prior to the encoding. This approach is more appropriate for cases where that the decoder needs to compute the remainder of the corrupted codeword as the first decoding step. More detailed information can be found in Ref. 18. Either approach will enhance the performance of the address mark, because the address mark deals mainly with one probability, the probability of failure to synchronize.

3.3. Interleaving Versus Noninterleaving

Let the symbols in a sector be orderly numbered as 0,1,2,3,4,5,6,7,8,9,.... Assuming that there are three codewords in a sector, there are many ways to associate the symbols with code symbols: $a[0], a[1], a[2], \ldots, b[0], b[1], b[2], \ldots, c[0], c[1], c[2], \ldots$, where $a[k], b[k]$, and $c[k]$ are kth symbols of code a, code b, and code c, respectively. Let the code length of each code be L. Then the first way of interleaving is $a[0], a[1], a[2], \ldots, a[L-1], b[0], b[1], b[2], \ldots, b[L-1], c[0], c[1], c[2], \ldots, c[L-1]$. Namely, $a[0], a[1], \ldots, a[L-1]$ are the symbols $0, 1, \ldots, L-1$ of the sector, respectively; $b[0], b[1], \ldots, b[L-1]$ are the symbols $L, L+1, \ldots, 2L-1$, of the sector, respectively; and $c[0], c[1], \ldots, c[L-1]$ are the symbols $2L, 2L+1, \ldots, 3L-1$ of the sector, respectively. This arrangement of three codewords has the main advantage that the single decoder can be used sequentially. However, the error-correction power of Reed–Solomon coding is not "enhanced." The more commonly used arrangement is $a[0], b[0], c[0], a[1], b[1], c[1], a[2], b[2], c[2], \ldots$. This arrangement is called *interleaving*. The number of code words involved is denoted by I and called the *depth of interleaving*. The main advantage of this arrangement is that a burst of I symbols can affect at most one symbol for each codeword. Therefore, from the entire sector point of view, the I code words in a sector form a t-burst correction code if each codeword can correct t-symbol errors.

A primary consideration for code selection involves the decision for determination of the degree of interleaving. The length of a Reed–Solomon code over GF(2^m) is limited to $2^m - 1$ symbols or $(2^m - 1) * m$ bits. Let the degree of interleaving be I. Then the minimum depth of interleaving is given by the equation $I * (2^m - 1) * m >$ or $= 4096 +$ number of redundant bits per sector. For $m = 8$, the minimum value of I is 3. The smallest value of m for I as 1 (the case of noninterleaving) is 9. In addition to code length, the ease of decoding sometimes plays an important role in determination of interleaving depth. For example, for the case of $m = 9$ and $I = 2$, each interleave needs to correct t errors when there are t bursts, where each burst corrupts no more than two 9-bit symbols. This design is much simpler than the design of using a single code to correct $2t$-symbol errors, especially when t is a small value such as 1, 2, 3, or 4 [14]. It should be noted that the ECC can correct any combination of $2t$ symbol errors for the noninterleaved case and that the interleaved case can correct only the "well behaved" $2t$ or fewer symbol errors. By a "well-behaved" pattern, the $2t$ or fewer errors are distributed in such a way that each interleave sees t or fewer symbol errors. As a result, the noninterleaved case is more powerful in terms of ECC correction power. However, the interleaved implementation may be the right design if the errors are frequently in bursts and complexity is the main concern.

3.4. Performance

The main purpose of using an ECC is to bring the raw bit error rate at the output of the modulation code decoder to an acceptable level. The raw bit error rate at the output of the modulation code decoder is often targeted at 1.0×10^{-6}

or higher. The required bit error rate at the output of the ECC is usually below 1.0×10^{-15}. Traditionally, the error rate specification is given in terms of bit error rate. However, for Reed–Solomon codes, it is easier to perform the error rate computation on the basis of the symbol error rate and the code block error rate. Therefore, the definitions and relationships among various error rates should first be clarified.

3.5. Error Rate Definitions

The commonly used definition of bit error rate is as follows:

$$\text{Bit error rate} = \frac{\text{total number of bits in error}}{\text{total number of bits observed}} \tag{10}$$

Similarly, symbol error rate is defined as

$$\text{Symbol error rate} = \frac{\text{total number of symbols in error}}{\text{total number of symbol observed}} \tag{11}$$

$$\text{Block error rate} = \frac{\text{total number of blocks in error}}{\text{total number of blocks observed}} \tag{12}$$

The denominators of these three definitions have very simple relations:

$$\text{Total number of bits observed} = m * (\text{total number of symbols observed}) \tag{13}$$

$$\text{Total number of symbols observed} = n * (\text{total number of blocks observed}) \tag{14}$$

$$\text{Total number of bits observed} = n * m * (\text{total number of blocks observed}) \tag{15}$$

where m is the number of bits per symbol and n is the number of symbols per code block. If the relationship among the numerators can be made as simple, then the conversion from one error rate to another becomes straightforward. With different modulation codes and signal processing techniques, the relationships among the numerators may not be simple. However, bounding techniques and approximations can be used to obtain estimated results, which often provide sufficient information from a designer's point of view. The relationships among the various error rates at the output of the modulation code decoder can be obtained more readily. The error rates at the output of the modulation code decoder are often measurable quantities as the total number of bits to be observed or counted is no more than a few million if the bit error rate is 1.0×10^{-6} or worse. The relationships among various error rates at the output of an ECC system are often difficult to quantify. Therefore, the following discussion deals with the decoded error rates.

When a t-symbol error-correcting code is employed, the most likely errors for which the ECC fails to correct are error patterns containing $(t+1)$-symbol errors. Therefore, the following relationship can be established:

$$\text{The total number of symbols in error} \approx (t+1)(\text{the total number of blocks in error})$$

The number of bits in error in an erroneous symbol can be anywhere from 1 to m, where m is the total number of bits per symbol. In fact, this number depends on the modulation code used. If this number can be obtained from the modulation code, it should be a number between 1 and m. For a completely random system the number is approximately $m/2$. A good modulation code tends to make this number less than $m/2$. Therefore, the following relationship can be established:

$$\begin{aligned}\text{Total number of bits in error} &= am(\text{total number of symbols in error}) \\ &\approx am(t+1)(\text{the total number of blocks in error})\end{aligned}$$

(with $0 < a \leq 1$, for random data $a = 0.5$). With these approximations, it is straightforward to show that

$$\begin{aligned}\text{Bit error rate} &\leq a * (\text{symbol error rate}) \quad (\text{with } 0 < a \leq 1) \\ \text{Symbol error rate} &\approx \frac{t+1}{n}(\text{block error rate}) \\ \text{Bit error rate} &\leq a\frac{t+1}{n}(\text{block error rate}) \quad (\text{with } 0 < a \leq 1).\end{aligned}$$

For the commonly used symbol sizes of $m = 8$ and 10, whether the true value of a or its upper bound is used in the preceding relationship, the results differ less than one order of magnitude. Therefore, in the following discussion, the symbol error rate and the block error rate are used; the results can be readily converted to the desired bit error rate with either the accurate estimate of a or its upper bound. The starting point is the symbol error rate.

Let the raw symbol error rate be P_s at the input of the t-symbol-correcting ECC decoder. For a system in which symbol errors are statistically independent, the decoded block error rate P_b is given by

$$P_b = \sum C(n,j)P_s^j(1-P_s)^{(n-j)} \tag{16}$$

where the summation limits are from $j = t+1$ to $j = n$ and $C(n,j)$ is the binomial coefficient for expanding the polynomial $(1+x)^n = \sum C(n,j)x^j$. Knowing the decoded block error rate, we can obtain the decoded symbol error rate. In fact, the decoded symbol error rate P_d can be computed directly from the formula

$$P_d \cong \frac{1}{n}\sum C(n,j)jP_s^j(1-P_s)^{(n-j)} \tag{17}$$

where the summation limits are from $j = t + 1$ to $j = n$. The results in Eqs. (16) and (17) can be obtained using combinatorial arguments. The reason Eq. (17) is an approximation is that when there are more than t-symbol errors, the decoder may introduce additional errors. Reference 17 provides the formula for the exact expression for Reed–Solomon codes under the condition that the symbol errors are statistically independent. Equations (16) and (17) both indicate that the decoded error rate is proportional to $P_s^{(t+1)}$. This can be seen from the observation that every term in the summation contains $P_s^{(t+1)}$ as a factor. Therefore, as t increases, the decoded error rate decreases. However, using more powerful ECC results in a lower code rate, which has the effect of making P_s worse. As a result, an ECC system cannot arbitrarily increase the correcting power to gain better overall decoded error rates. For the cases where the symbol errors are not statistically independent, the preceding arguments also hold. For more detailed information, see Ref. 19, where a soft bit error rate (SBER) is defined as (total number of error events)/(total bits read that are protected by the ECC system); therefore, it is equal to 1/b times the bit error rate defined by Eq. (10), where b is the average number of bits in error per error event.

3.6. Separate EDC or Embedded EDC

When a disk drive or a tape drive is used to store data, the miscorrection probability must be many orders of magnitude better than the probability that the ECC cannot decode the code block. There are two common ways of achieving this goal. The first approach is to use a separate error-detecting code (EDC) and let the error-correcting code decode to the limit of its error correcting capability. In this case, an odd-distance error-correcting code is often employed and the code corrects t errors, where t is equal to $(d-1)/2$, where d is the minimum distance of the code. The second approach is to correct t errors only with $t < (d-1)/2$. Let the number of bits in the EDC for the first approach be r_1 and the relationship for the second approach be $r_2 = (d - 1 - 2t) * m$, where m is the symbol size. Then r_2 can be considered as the effective number of bits in the second approach reserved for error detection. When $r_1 = r_2$, and t is the same for both approaches, the miscorrection probabilities for both approaches are about the same. The main consideration as to which approach to adopt is listed below:

1. Approach 1 is more flexible. The value of r_1 can be more or less arbitrarily selected to achieve any desirable miscorrection probability. For approach two, the value for r_2 needs to be a multiple of m, the symbol size.
2. Approach 1 needs the additional step for checking the correctness of EDC after the error-correction procedure. This verification process is often time-consuming and complex. For approach 2, the EDC is automatically satisfied at the end of the decoding algorithm if the algorithm is properly designed and employed.
3. When it is required to provide the data block to the host computer, which may require that the data block have its own EDC, it may be mandatory to use approach 1.

In practice, both approaches are sometimes employed simultaneously. Both embedded EDC and separated EDC are used. The embedded EDC assures the low probability of miscorrection, while the separate EDC is used to communicate with the host computer. Often, the separate EDC itself is covered by the ECC with embedded EDC. As a result, the separate EDC is not checked as the embedded EDC provides the necessary detection power.

The separate EDC has another advantage in that it may not be affected by cyclic shifts of symbols. Therefore it can reduce the miscorrection probability due to symbol shift. As a result, the selection of the coset leader for missynchronization detection may be easier if the EDC is of sufficient length.

3.7. Tape Drive ECC

All the coding techniques employed in disk drives can be readily applied to tape drives. Tape drives support multiple tracks; in other words, a read head reads several tracks simultaneously. This provides the opportunity to apply a code across the tracks. Usually, the ECC along a single track corrects a limited number of symbol errors or none at all, but with sufficient redundancy to make sure that the miscorrection or mis-detection probability is extremely small. Whenever a track fails to correct, the errors are detected. The ECC across the track then corrects the errors indicated by the tracks whose ECC fail to correct. In other words, the symbols on the tracks, which are known to contain erroneous symbols as indicated by the ECC, are treated as erasures for the ECC across the tracks. An erasure is an error with known location. The more powerful error–erasure decoding algorithm is then used to correct both errors and erasures across the tracks. An example for this approach can be found in Ref. 20.

Another way of protecting data on tape drives is to use array codes [4]. This can be understood again by visualizing the two-dimensional structure of tape recording. Simple codes, preferably the single-parity-check codes, are introduced on both the longitudinal direction (the direction following the head movement) and the direction across the tracks as well as the directions that are at constant angle with respect to the longitudinal direction. Therefore, a symbol is protected by several simple parity-check equations, one for each direction. When one or more of these directions contains one or no errors, the symbol can be correctly recovered [4].

3.8. Codes for RAID

In redundant array of independent disks (RAID), inter-relations are introduced to several disk drives to form redundancy among sectors, one sector from each drive. The codes are in fact so-called concatenated codes. These are also two-dimensional codes. The code in one dimension

is the Reed–Solomon code presently used in each sector. The code used across the sectors is usually a very simple single-parity-check code. Namely, if the information symbols are $c[n-1], c[n-2], \ldots, c[2], c[1]$, then the redundant symbols are given by $c[0] = c[1] + c[2] + \cdots + c[n-1]$. The reason this is used is because the recovery of a failed drive can be achieved simply. The only limitation for this simple scheme is that it can protect against the case that a single drive fails. More sophisticated distance d Reed–Solomon codes can also be used to protect against the case that $d-1$ or fewer drives fail simultaneously. However, the reconstruction of the failed sectors often involves many reads and writes of the related sectors from different drives; also, the data recovery from the failed sectors needs more complicated operations than the simple exoring. Therefore, there is no reason not to employ more powerful Reed–Solomon codes across the drives. The time delays and extensive read and write operations may be the deciding factor for future adoption of more powerful codes.

3.9. Decoding Beyond $(d-1)/2$ for Reed–Solomon Codes

The decoding algorithms for Reed–Solomon codes presently employed in magnetic recording are the so-called hard-decoding algorithm and the error–erasure algorithm. In a hard-decoding algorithm, the channel outputs a bit-stream to the ECC decoder, where each bit is either 1 or 0. Each bit can be either right or wrong. The symbols at the input to the ECC decoder are symbols with predetermined "hard" values. In the error–erasure decoding algorithm, the channel also provides the locations of symbols, which are erasures whose values may not be correct. Therefore, in the case of error–erasure decoding, each symbol is associated with a reliability information, that is, with reliability information of 1 bit. For example, a one indicates that the symbol is reliable and a zero indicates that the symbol is not reliable; therefore, it is an erasure.

The present "hard" error-only decoding algorithm for a minimum distance d Reed–Solomon codes attempts to correct all possible error patterns, which are at a distance no more than $(d-1)/2$ symbols away from a codeword. New algorithms have been designed to provide a list of codewords, which are no more than $n*(1-r^{1/2})$ symbols away from the n symbol sequence to be decoded [21]. (Here $r = k/n$ is the code rate.) Conventional hard decoding can correct $(d-1)/2 = (n-k)/2 = n*(1-r)/2$ symbols, which is smaller than $n*(1-r^{1/2})$ symbols. The advantage of this new decoding algorithm is more significant when the code rate r is low. With a properly selected algorithm and code rate, this approach has the potential to enhance the performance for Reed–Solomon codes. More information can be found in Refs. 21 and 22.

Another direction is soft-decision decoding. Instead of providing a symbol with one bit of reliability information like the erasure information, many bits of reliability information are associated with a symbol. The decoding algorithm makes use of this reliability information to further enhance code performance. There are many encouraging results for soft-decision decoding algorithms employed with binary codes. References 23 and 24 are examples for soft-decision decoding for nonbinary codes. The performance gain for soft-decision decoding in Reed–Solomon codes over hard-decision decoding is an interesting and important area of research in magnetic recording. If it proves to provide a significant improvement, the algorithm no doubt will soon be adopted in magnetic recording applications.

3.10. Larger Sector Size

Strictly from a coding point of view, the sector size for hard-disk drives should be larger than the present 512 bytes. For the same code rate, code performance improves as block size increases. For example, the Reed–Solomon (440,410,31) code over GF(2^{10}) can correct 15 symbol errors among 440 symbols, while the (880,820,61) code can correct 30 symbols among 880. By Eq. (16), the shorter code has the decoded block error rate proportional to P_s^{16}, while the longer code has the decoded block error rate proportional to P_s^{31}. It can be easily seen that for a very large range of P_s, the longer code gives lower decoded block error rate for the same raw symbol error rate P_s. In addition, there are other overhead savings such as preambles and address marks. Unfortunately, many operating systems assume a 512-byte sector size. A change in disk drive sector size would require corresponding modification to these operating systems. At present, the 512-bytes data constitute the one sector size that the disk industry must provide.

COMMUNICATION SATELLITE ONBOARD PROCESSING

STEVEN BERNSTEIN
MIT Lincoln Laboratory*
Lexington, Massachusetts

1. INTRODUCTION TO ONBOARD PROCESSING

The primary purpose of communication satellites is to receive signals from one or more sources and relay them to intended recipients. With the exception of early passive on-orbit reflectors, the relay function is accomplished by some form of active processing carried out on board the satellite. The most common form of active processing is the "translating repeater" or "transponder," which simply amplifies whatever is received in a given uplink frequency band and retransmits it in a different downlink frequency band. While this could be called "onboard processing," we will reserve this term for techniques that manipulate the signals passing through a satellite in more complex ways.

Digital circuit and signal processing technology has progressed to the point that it is feasible to consider very ambitious onboard processing functions. In this article we will concentrate on concepts, confident that technology will soon enable virtually all the ambitious techniques to be described.

1.1. Conventional (Nonprocessing) Communication Satellites

Figure 1 is a block diagram of a translating repeater, the workhorse of conventional (nonprocessing) communication satellites. This is also sometimes called a "bent pipe" because it simply takes in a band of frequency spectrum on its uplink and bends it back to earth. An onboard oscillator and mixer is used to translate the uplink band

* This work was sponsored by the Air Force under Air Force Contract FI9628-00-C-0002. Opinions, interpretations, conclusions, and recommendations are those of the author and are not necessarily endorsed by the United States Air Force.

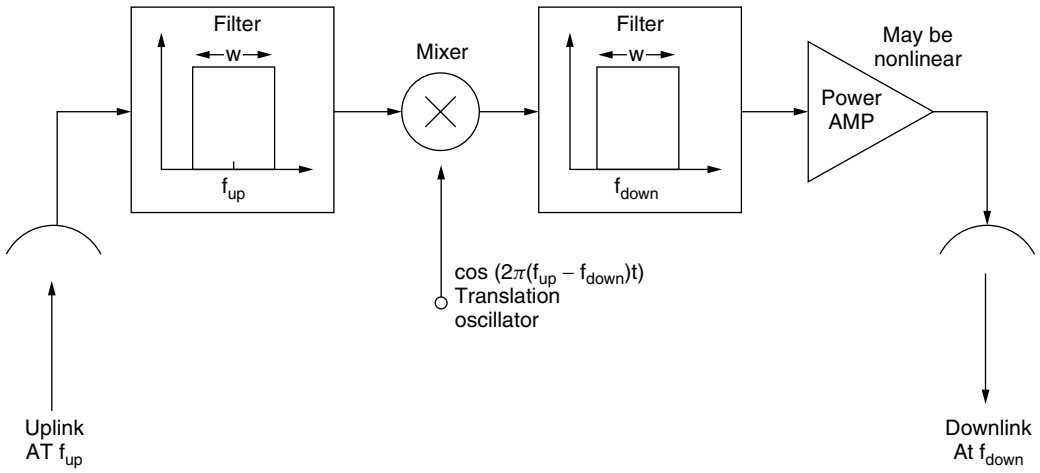

Figure 1. Translating repeater.

to a different downlink band in order to isolate the input and output communication signals. For example, many C-band commercial satellites operate with uplink signals around 6 GHz and downlink signals around 4 GHz. Most such satellites are built with a number of translating repeaters, each operating at a slightly different frequency.

The amplifier shown may be linear or nonlinear. Linear amplifiers are often used in order to minimize crosstalk due to intermodulation products when there are multiple signals within the operating band. Automatic gain control (AGC) is sometimes used to keep the amplifier in a linear region. Nonlinear amplifiers, often operating in a saturated mode, are used when it is desired to maximize prime-to-RF power efficiency. In the nonlinear case, using signals that rely on amplitude modulation may not be feasible; constant envelope phase modulated signals would be more appropriate.

Also shown is a representation of a single antenna beam on the uplink and a single one on the downlink. The antenna beam patterns may be quite complex (e.g., shaped to cover a single country), but all signals in each direction share a common beam. (The uplink and downlink beam shapes and positions, however, may be different.)

1.2. Limitations of Conventional Satellite Architecture

While appealingly simple (and useful), the translating repeater has a number of limitations. Many of these stem from the fact that the power of the single RF amplifier must be shared.

1.2.1. Multiple Access. If a number of communication signals are being relayed simultaneously as in an FDMA (frequency division multiple access) system, then care must be taken to ensure that each user signal arrives at its downlink destination with sufficient signal-to-noise ratio. In order to achieve this, coordination is required among the uplink transmitting stations, especially with regard to power control. For example, an uplink signal that is 3 dB stronger than necessary may capture twice as much transponder power as it entitled to, thus acting as though it were two users. (In this case, even if the amplifier were operating in a linear mode, the amplifier gain, and consequently the downlink power transmitted, would need to be reduced.)

In a system where the user population is heterogeneous, such as operating with different rates and with different terminal antenna sizes, the power control problem becomes quite complex and real-time system monitoring and control is used. This is summarized in Fig. 2.

An approach that reduces the power control complexity is to use TDMA (time-division multiple access). In this design only one user transmits through the transponder at a time and hence may use full uplink power. However, power control in the form of burst data rate and duty cycle is still needed so that each downlink signal obtains at least the minimum required signal-to-noise ratio at the receiving terminal.

1.2.2. Uplink Interference. In some systems uplink interference (intentional or natural) is a major factor to consider. In order to illustrate this, consider the simple scenario consisting of a single user signal and uplink interference that is equivalent to flat Gaussian noise over the system bandwidth, W Hz. Assume that the transponder signal power is shared proportionately between the communication signal and the interference.

Define other needed parameters as

Total satellite power received at the downlink terminal = Pr

Background noise density at the downlink terminal = N_0

Uplink signal power received at the satellite = S

Uplink interference power received at the satellite (which would include the satellite's own receiver noise) = I

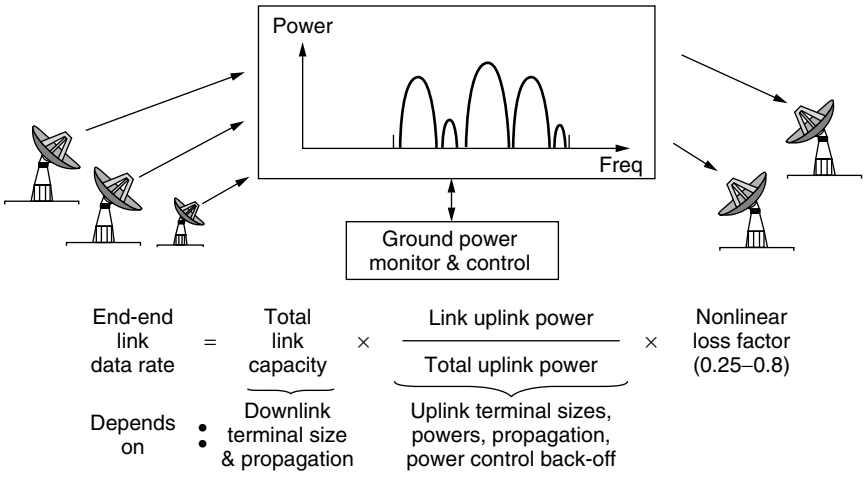

Figure 2. Transponder, multiple access.

Required signal-energy-to-noise-ratio per bit determined by the modulation/coding scheme used $= (E_b/N_0)_{\text{req}}$

The useful signal power received at the downlink terminal is $(S/(S+I))\text{Pr}$, and the interference power retransmitted by the satellite will be $(I/(S+I))\text{Pr}$. The total noise density at the downlink terminal will be the sum of the background and retransmitted amounts $N_0 + (I/(S+I))\text{Pr}/W$. Hence the effective carrier power : noise density ratio will be

$$\left(\frac{\text{Pr}}{N_0}\right)_{\text{eff}} = \frac{\dfrac{S}{S+I}\dfrac{\text{Pr}}{N_0}}{N_0 + \dfrac{I}{S+I}\dfrac{\text{Pr}}{W}}$$

From this we can find the data rate that can be supported as

$$R = \frac{\left(\dfrac{\text{Pr}}{N_0}\right)_{\text{eff}}}{\left(\dfrac{E_b}{N_0}\right)_{\text{req}}}$$

$$= \frac{W}{\left(\dfrac{E_b}{N_0}\right)_{\text{req}}}\frac{S}{I}\frac{\dfrac{\text{Pr}}{N_0 W}}{1+\dfrac{\text{Pr}}{N_0 W}} \quad \text{bps}$$

This relationship is shown qualitatively in Fig. 3 as a function of the total downlink signal-to-noise ratio, $\text{Pr}/N_0 W$. We assume that $I \gg S$.

We observe that when $\text{Pr}/N_0 W \gg 1$, the supportable data rate is given by

$$R = \frac{W}{\left(\dfrac{E_b}{N_0}\right)_{\text{req}}}\frac{S}{I} \quad \text{bps}$$

which is not a function of the downlink signal to noise ratio; however, it is a function of system bandwidth, W. This is called the *bandwidth-limited case* because increasing the bandwidth W would directly improve performance; there would be no improvement if the satellite power were increased. This is a goal sought after in designing systems to counter uplink interference, such as jamming. It will be shown later that onboard processing can approach this goal.

On the other hand, if $\text{Pr}/N_0(W) \ll 1$, then the supportable data rate is

$$R = \frac{\left(\dfrac{\text{Pr}}{N_0}\right)}{\left(\dfrac{E_b}{N_0}\right)_{\text{req}}}\frac{S}{I} \quad \text{bps}$$

which is not a function of the system bandwidth, W. This is called the *power-limited* case because the only satellite parameter we can change to improve performance is to increase the downlink power. We see that in this case the interference is working by an effect called "power robbing." This is a serious limitation of transponder-based systems. We will return to this example when discussing onboard processing techniques.

It should be noted that in either case, a nonlinear transponder can degrade performance by an additional 1 dB through a small-signal suppression effect. If the interference had a constant envelope, the degradation could reach 6 dB.

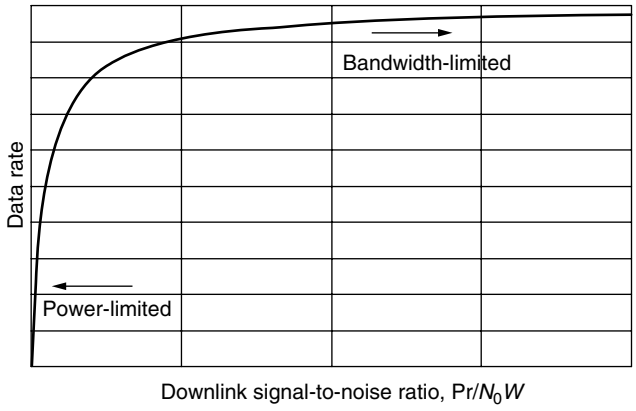

Figure 3. Power- and bandwidth-limited performance of transponder with uplink interference.

1.2.3. User Interconnection. Many satellite systems have multiple antenna beams on both the uplink and downlink. Multiple beams can provide more gain in the direction of ground terminals and permit the reuse of the same frequencies in different parts of the earth. Observe, however, from Fig. 1 that no provision in a simple translating repeater is made for anything more than a simple beam-to-beam connection. Although this is often acceptable, it is a significant limitation in other scenarios.

1.3. What Is Onboard Processing?

Onboard processing includes a wide variety of techniques: analog and digital, RF and baseband, circuit-oriented and packet-oriented. Following the discussion above it is instructive to relate these techniques to the limitations of the model of nonprocessing, the translating repeater.

Table 1 lists some of the main onboard processing techniques that address the limitations, which will be discussed further below. (Note that not all systems with onboard processing necessarily employ all of these techniques.)

2. ONBOARD PROCESSING TECHNIQUES

This section describes some of the principal onboard processing techniques.

2.1. Antenna Beam Switching

Many satellites are deployed with multiple antenna beams. A principal reason for doing so is to increase capacity by taking advantage of the high gain of narrow beams. This is illustrated in Fig. 4, which shows typical link capacities for several diameter geosynchronous satellite

Table 1. Onboard Processing Techniques

Translating Repeater Limitation	Onboard Processing Technique
Limited means of sharing resources without significant user cooperation	Demodulation–remodulation
	Access control
	Circuit multiplexing and switching
	Packet switching
Significant vulnerability to uplink interference	Demodulation–remodulation
	Adaptive antennas
	Despreading of spread-spectrum signals
Fixed interconnectivity	Antenna beam switching and crosslinks
	Adaptive antennas
	Demodulation–remodulation
	Access control
	Circuit multiplexing and switching
	Packet switching

spot beams as a function of ground terminal diameter. (It is assumed that the link is limited by signal-to-noise ratio, not bandwidth.) The link capacity varies inversely with the square of the diameter of the beam on the earth. The motivation for using spot beams should be clear.

A second reason for using spot beams is to reuse frequency assignments in different (usually nonneighboring) beams. The smaller the beam size, the greater number of times the frequency can be reused in a region of coverage.

The presence of multiple beams raises the question of how to interconnect users in different beams to each other. One way to do this is with RF crossbar switches as illustrated in Fig. 5. This is the architecture used in a portion of the NASA ACTS satellite [1]. The crossbar switch can be controlled quasistatically from the ground or, as shown, can respond dynamically to a signal structure such as TDMA. The beam–beam switch can also be combined with frequency filters to switch bands of the frequency spectrum to designated beams.

While uplink and downlink beams are being used for illustration, the same technique can be combined with satellite-to-satellite crosslinks.

2.2. Adaptive Antennas

While many satellites are launched with antenna systems that form carefully designed beam shapes to cover a specific country or region, few can adapt their patterns to meet changing user needs. Pattern adaptation can take several forms, including

- Steerable narrow beams for both uplink and downlink
- Formation of shaped uplink and downlink beams to provide enhanced gain to one or more specific regions
- Formation of spatial uplink "nulls" to reduce the effect of interference sources

The steering of individual narrow beams is usually implemented with mechanically steered dishes. The implementation of more complex shapes can be achieved with

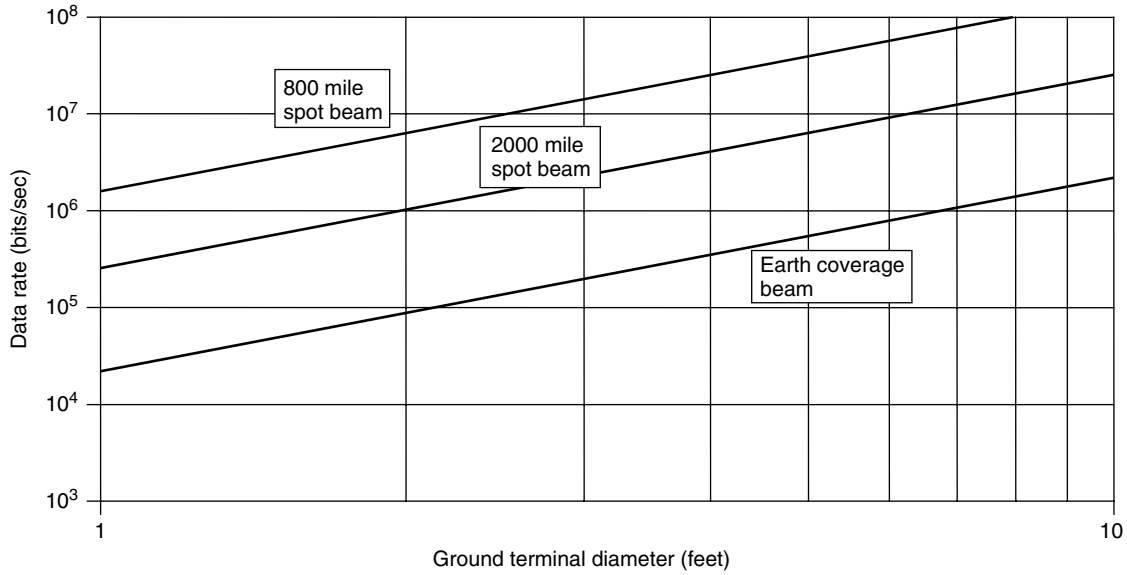

Figure 4. Typical total link capacity for geosynchronous satellites.

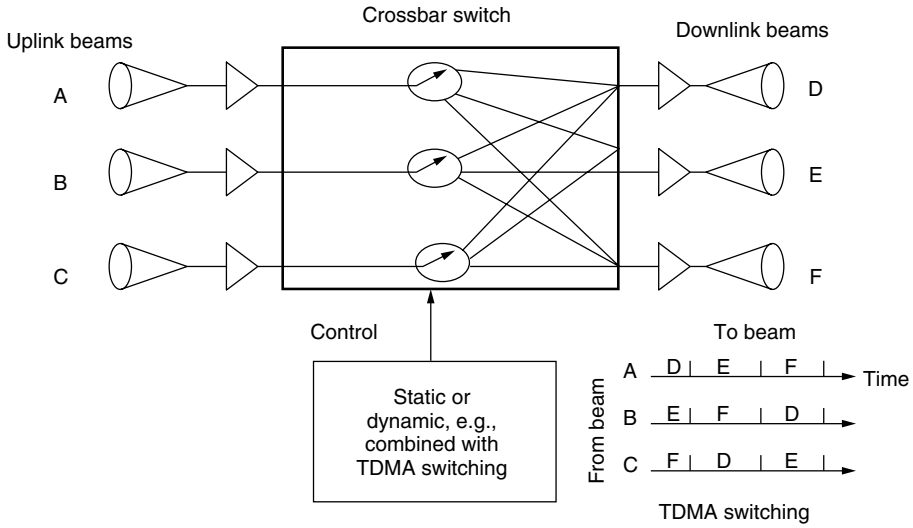

Figure 5. Interconnecting spot beams.

microwave lens antennas or phased arrays [2]. The control of the antenna patterns is usually performed on the ground, but some systems are autonomous in space. More recent approaches to adaptive designs often use *digital beamforming*, whereby the output of each antenna element is downconverted and sampled for subsequent digital signal processing.

It should be noted that adaptive antenna processing could be applied to both analog and digital communication systems.

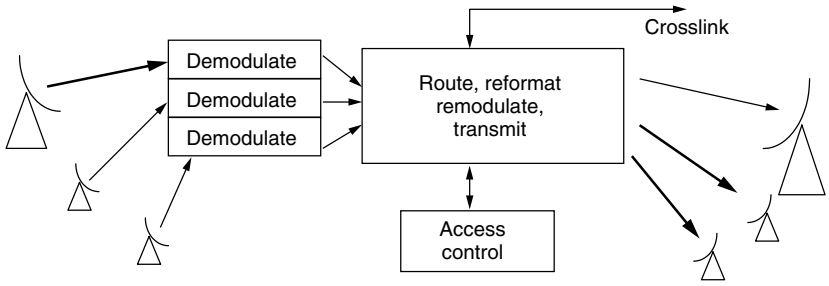
2.3. Demodulation–Remodulation

Demodulation–remodulation is one of the most powerful onboard processing techniques. This is illustrated in Fig. 6, which shows each user uplink being demodulated to a bit stream. The user bit streams are then processed by a digital switching subsystem that can route and reformat the streams and finally remodulate them onto one or more downlinks. (Specific system designs might take advantage of only a subset of these functions. There are also a number of intermediate degrees of processing, such as demodulating user datastreams for error-control coding of parity symbols without decoding to information bits.)

The advantages of this approach are numerous, particularly compared with those of translating repeaters:

1. *Satellite transmitter power is used more efficiently*. Satellite processing permits the renormalization of downlink power sharing. For example, an uplink signal that is received at a power level 3 dB higher than that of all the other signals would capture 3 dB more downlink power than its "fair share" in a translating repeater system. However, with a processor on board, the downlink signal can be renormalized to its fair value. (Of course, some degree of uplink power control must be utilized to guarantee that the uplink signal-to-noise : interference ratio on the uplink permits onboard demodulation.) In addition, an onboard processor can adjust the amount of power devoted to each downlink stream to match the capabilities of each downlink terminal's receiver. Thus a broad system capacity maximization can be approached with minimal complexity imposed on individual terminals.

2. *Downlink power is not wasted on retransmitted noise*. Uplink demodulation, in effect, strips off uplink noise that may come from natural sources, uplink interference, or the satellite's receiver front end. Translating repeaters would



- Reduces need to power balance uplink
- Doesn't waste downlink power retransmitting uplink noise
- Allocates downlink power where needed
- Connects users in different narrow beams
- Optimizes uplink and downlink resources independently

Figure 6. Onboard demodulation–remodulation.

repeat such sources of noise, wasting downlink power. Uplink signals that are below a specified quality measure, such as bit error rate, can be rejected by the satellite processor and not transmitted on the downlink. This property is advantageous for multiple access systems and for systems countering uplink interference such as jamming. The effect is to bring the system into the *bandwidth-limited* regime discussed previously since the power-robbing effect is virtually eliminated. This advantage in power sharing is illustrated in Fig. 7.

3. *Users in different antenna beam ranges can be interconnected*. The routing capability of an onboard processor permits uplink and downlink users in different satellite antenna beams to interconnect. This gives the system designer significant degrees of freedom in the design of antenna patterns. For example, a satellite with numerous high-gain narrow beams can be utilized without limiting connectivity to users to in the same beam. Various interconnectivity structures can also be accommodated, including point-to-point, broadcast, multicast, and many-to-one connections.

4. *Uplink and downlink signal structures can be independently optimized*. Onboard processing effectively permits the uplink and downlink signal structures (and antenna designs) to be optimized independently. This is a very powerful degree of freedom for the system designer.

A generic example that combines several of the concepts discussed above is shown in Fig. 8. In this example a number of simultaneous uplink antenna beams are used to permit small user terminals to transmit at low power into high-gain satellite receive beams. Uplink user signals are prevented from interfering with each other by a combination of FDMA (frequency-division multiple access)

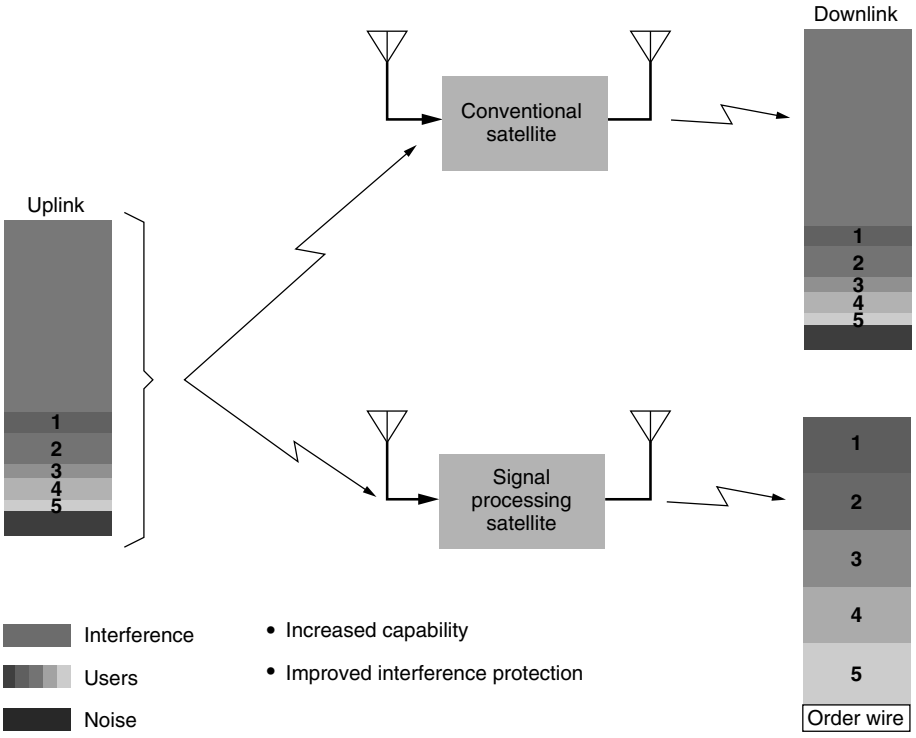


Figure 7. Power sharing advantage of onboard signal processing.

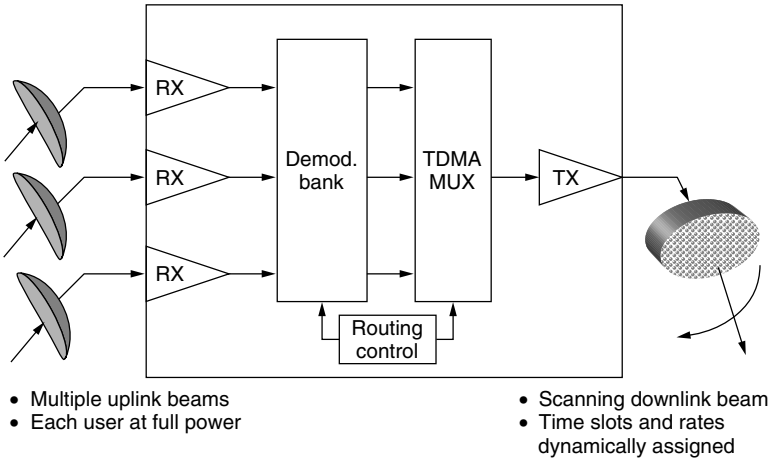

Figure 8. Onboard demodulation–remodulation example with beam switching.

for users in the same beam and low beam-to-beam sidelobe ratios. The satellite processor includes a bank of receivers and demodulators. The downlink consists of a single high-rate TDMA (time-division multiple access) datastream that carries all the downlink data. The burst rate of the data destined for an individual user can be adjusted in accordance with the receive capability of the user terminal. The TDMA downlink beam position is rapidly switched in synchronism with the TDMA stream to place downlink power on the location of the intended user. A downlink satellite transmitter can be used at high efficiency if the TDMA stream uses constant envelope modulation.

2.4. Despreading of Spread-Spectrum Signals

Additional techniques related to demodulation-remodulation can also be used to advantage. One is the onboard despreading of spread-spectrum signals, without complete demodulation.

Consider, for example, a frequency-hopped spread-spectrum system utilizing system bandwidth W Hz. An onboard processor consisting of a synchronized frequency-hopped local oscillator followed by a filter could be used to despread the uplink signal to its baseband bandwidth, approximately equal to the data rate, R bps. The resulting (analog) signal could then be transmitted on the downlink. Note that any broadband uplink noise or interference would be reduced by the ratio R/W, thus reducing the amount of retransmitted noise by the same factor. Although not quite as effective as complete demodulation, this would greatly reduce the "power robbing" caused by uplink interference. In a similar manner, a direct-sequence spread-spectrum system could be designed with an onboard despreader.

2.5. Access Control

Onboard access control places some of or all the functions of user system admission, such as interconnection control or usage monitoring, on the satellite. It provides the designer with a number of degrees of freedom to split these necessary functions between space and ground implementations. Its advantages lie with such factors as system security and survivability, system response times, and efficient use of control links. While some satellite systems require little real-time access control, such as those servicing television broadcasting, others must respond in real-time to user demands (e.g., telephone voice calls). A fully implemented spaceborne access control system would be a "switchboard in the sky."

System security and survivability can be enhanced by exposing fewer links that reach to ground control centers. An autonomous space system reduces the need for such links. In a hostile environment this could be an important factor.

System response times are reduced by not requiring a lot of control data traffic to make two ground-to-space-to-ground round trips between users and ground control sites. Whether this is a important consideration depends on the response time needed by the user community.

Efficient use of control links would reduce the requirements for uplink and downlinks devoted mainly to control. Virtually all satellite systems require control links for satellite on-orbit health maintenance. However, systems that must respond in real time to user demands have greater need for control dataflow. Placing control function on board reduces the data load on the control links, which could be advantageous in some system designs.

2.6. Circuit Multiplexing and Switching

Circuit switching was discussed in the context of onboard demodulation–remodulation of datastreams. Here we want to elaborate on the point that onboard processing can also serve as an *add–drop multiplexer*, a standard subsystem of the ground telecommunications industry. An uplink datastream from an individual user terminal might actually consist of a number of multiplexed substreams. Each of these substreams could have a different ground terminal as its destination. The onboard processors could demultiplex the uplink substreams, switch each substream to its intended downlink, and multiplex all the downlink substreams intended for a given terminal before transmission. By matching each substream to its intended downlink beam and terminal, satellite resources are used most efficiently.

2.7. Packet Switching

In data transmission technology, there is a strong trend toward the use of packet transmission protocols, particularly the IP (Internet Protocol) suite. Onboard processing is directly applicable to this approach. Indeed, aside from specific points made regarding data circuits or datastreams in the preceding sections, the basic advantages of onboard processing apply, and even more strongly to packet-switched systems.

Consider the following advantages to packet switching onboard the satellite:

- Packets can be routed to downlink users and satellite beams as needed, thus making efficient use of downlink resources without requiring dedicated circuits that might be used only in bursts.
- Multicast routing (one-to-many) is easily accomplished.
- With sufficient caching of packets on board, latency can be reduced by halving the user-to-user satellite transmission time.
- Data-link-layer protocols can be utilized to mitigate satellite link impairments, including path blockage due to the motion of ground terminals.

A major decision that needs to be made in the design of an onboard packet-switched system is the choice of protocol layer or layers to be implemented. If only the *physical* and *data-link layers* (layers 1 and 2 of the OSI Reference Model) are implemented, the satellite system is analogous to the connectivity of a LAN (local-area network). The system could directly interconnect satellite users to each other, but would rely on ground-based gateways for connectivity to users that are external to the system and possibly to satellite users that are connected to different satellites of a global system.

Onboard processing systems that include routers that operated at the next higher protocol layer, namely, the *network layer* (OSI layer 3), would be able to interconnect users in more capable ways within and external to the system in accordance with global networking standards. It would also be more effective in routing traffic between users within a global system that are attached to different satellites.

Operating the onboard processor at higher protocol layers could also be considered. For example, operation at the *transport layer* (OSI layer 4) would permit the caching of TCP packets that could be retransmitted with only a single round trip to the satellite to reduce latency. Operation at even higher layers, for example, the *application layer* (OSI layer 7), might also be considered with email and Web servers on board. (Store-and-forward messaging is a simplified version of this.)

2.8. Ground Processing Tradeoffs

The point of view taken in this article has been to illuminate the advantages and capabilities of onboard processing. However, it must be acknowledged that onboard processing comes with a price, namely, the need to place hardware on the satellites with the corresponding burdens of additional complexity, power, and weight. Whether this tradeoff is worthwhile depends on the system application. For example, satellites used for wide-area television broadcasting would gain little from processing; high-power translating repeaters generally suffice.

Another major tradeoff issue is where to place the processing functions that may be desired — in space or on the ground? Figure 9 illustrates some of these tradeoffs. Strong feeder links could, in principle, be used to relay all signals (from all antenna beams) received at the satellite in analog (or sampled) form to the ground. Virtually all processing functions (demodulation–remodulation, antenna beamshaping, packet routing, etc.) could then be done on the ground and relayed on strong links back to the satellite for subsequent retransmission, although at the cost of additional latency.

Designers of different systems may come to different conclusions regarding the use of processing and where to implement it. The next section presents selected system implementations that represent a range of processing applications and the range of design choices made.

3. EXAMPLES OF ONBOARD PROCESSING SYSTEMS

This section provides examples of satellite systems that have included onboard processing to varying degrees. Each will be described briefly to relate it to the types of processing described in the preceding sections.

3.1. Government Systems

A number of pioneering onboard processing systems were developed under U.S. government sponsorship:

- **Lincoln Laboratory Experimental Satellites 8 and 9 (LES-8 and 9)**, shown in Fig. 10, launched in 1976, were among the first to include onboard demodulation–remodulation and spread-spectrum despreading. These feature were included to demonstrate satellite-to-satellite crosslinks, UHF–Ka-band frequency crossbanding, and antijamming protection for a variety of military platforms. A more complete description can be found in Ward's study [3].
- The **Defense Satellite Communication System (DSCS)** [4], operating in the SHF region of the spectrum since the early 1970s, is an example of a system that utilizes flexible antenna patterns both to shape coverage areas and reject interference. Microwave lens antennas and steerable parabolic dishes are used. The signal processing that supports the beamforming is shared between the satellite and the ground.
- The NASA **Advanced Communication Technology Satellite (ACTS)** [1] has several onboard processing features. It includes a number of narrow beams, some of which can be rapidly steered. It also carries a signal processor very much like that shown in Fig. 5.
- The **Fleetsat EHF Packages (FEPs)** built by Lincoln Laboratory were launched in 1986 and 1989. The FEPs took jamming-resistant onboard processing a significant step forward with the

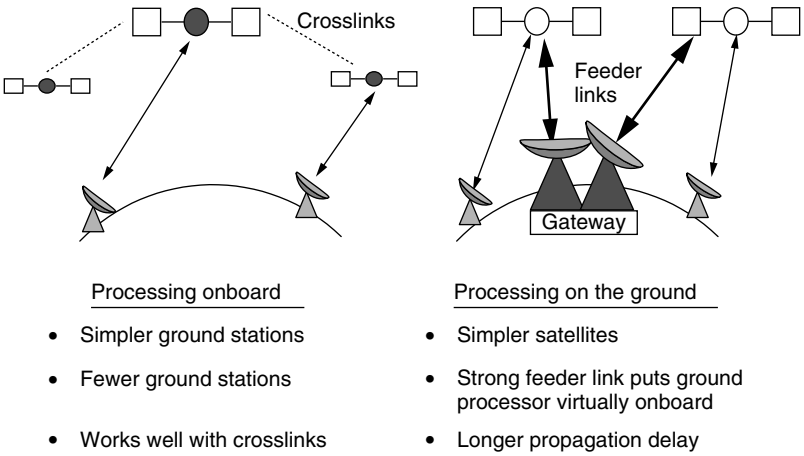

Figure 9. Processing onboard compared to processing on the ground.

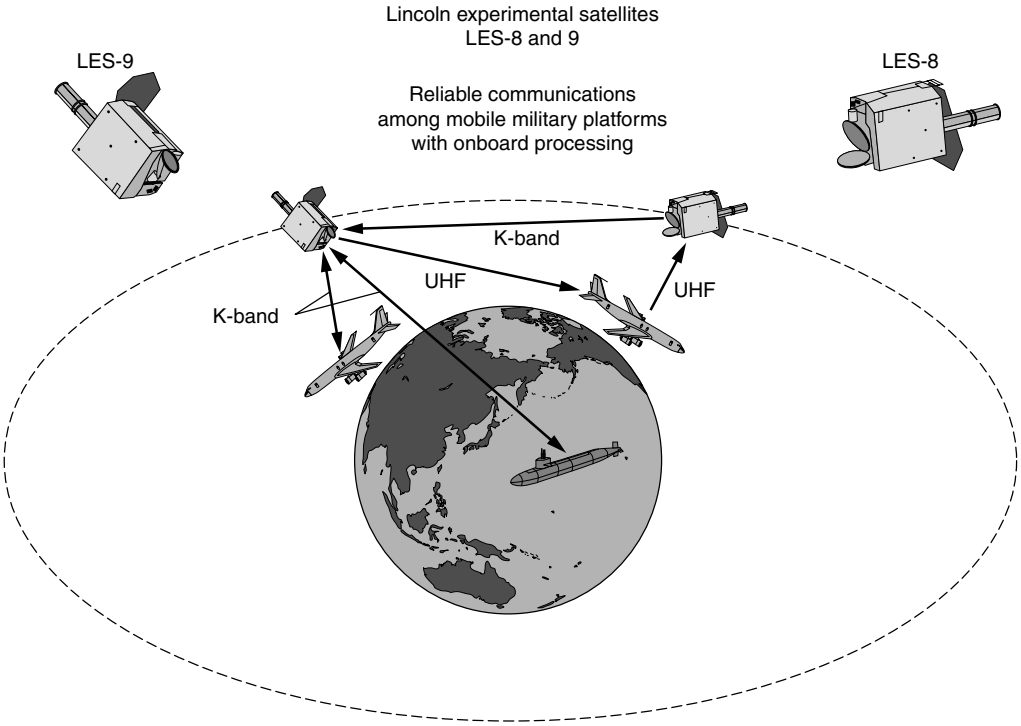

Figure 10. Lincoln laboratory experimental satellites 8 and 9 (LES-8 and 9).

inclusion of extensive demodulation–remodulation of multiple-user onboard access control realizing a true "switchboard in the sky" [5] and a steerable antenna. The FEPs can operate as a self-contained demand-assigned circuit-switched system. The FEPs are the forerunners of the Milstar [6] system, which includes more antennas, more channels, higher data rates, and satellite-to-satellite crosslinks.

3.2. Commercial Systems

A growing number of commercial system are using or are expected to use onboard processing.

Iridium provides worldwide digital voice and paging services to handheld user terminals [7]. The system makes extensive use of onboard processing. The spaceborne part of the system consists of 66 low-orbit (780-km-altitude) satellites in six orbital planes. Each satellite projects 48 narrow beams onto the earth; each beam is about 30 mi in diameter. In order to provide worldwide connectivity, the satellites are crosslinked to each other. A user signal (at L band) emanating from a handheld terminal is demodulated on board and crosslinked (at K band) around the Iridium constellation until it is downlinked to a gateway terminal connected to the terrestrial telecommunication infrastructure.

The **Thuraya** system provides voice and data services to most of Europe and portions of Asia and Africa. Each of its geosynchronous satellites includes a 12.25-m antenna that is used to form 250–300 spot beams. Its onboard processing is described as [8] follows:

- On-board digital signal processing (DSP) to facilitate interconnectivity between the common feeder link coverage and the spot beams to make effective use of the feeder link band and to facilitate mobile to mobile links between any spot beams
- Digital beamforming capability that will allow Thuraya to reconfigure beams in the coverage area, to enlarge beams, and to activate new beams. It also allows the system to maximize coverage of "hot spots," or those areas where excess capacity is required
- The flexibility to allocate 20% of the total power to any spot beam
- The flexibility to reuse the spectrum up to 30 times and therefore use the spectrum efficiently

The **Teledesic** [9] and **Astrolink** [10] systems have been under development since the mid-1990s. They both aim at providing broadband data services to small terminals around the world. As originally conceived, the Teledesic would have included a constellation of numerous low-orbiting satellites with extensive onboard demodulation–remodulation, routing, and crosslinking. Astrolink uses geosynchronous satellites with onboard ATM (asynchronous transfer mode) switches. Both systems' satellites have multibeam antennas.

It is too soon to predict the commercial success or failure of any these ventures. However, they are all pioneers in the technology of onboard processing, which will inevitably become a key part of the global information infrastructure.

BIOGRAPHY

Steven Bernstein received the S.B. and S.M. Degrees in Electrical Engineering from the Massachusetts Institute of Technology in 1964 and the Degree of Electrical Engineer from MIT in 1966. In 1966 he joined the Communication Division in of MIT Lincoln Laboratory, where he has

worked on and led a wide variety of communication and networking projects. His early assignments included work on a pioneering Air Force frequency-hopping UHF satellite communication system and the development of an ELF system for communication to submerged submarines. Following these staff assignments, he managed a succession of satellite communication projects at UHF and EHF for the U.S. Navy, Army, and Air Force. Following a one-year leave of absence to teach graduate level courses in digital communication at ENST (Paris, France), he returned to Lincoln and was given the responsibility to lead the development of a new satellite operations center. He also has managed the Optical Communication Technology Group, which developed novel techniques for optical ground and space communication. He is currently the Associate Leader of the Applied Communications and Information Technology Group. His areas of technical interest are satellite communication systems, channel coding/decoding, optical transmission, and applying these technologies to practical problems.

COMMUNICATION SYSTEM TRAFFIC ENGINEERING

APOSTOLOS K. KAKAES
Cosmos Communications
Consulting Corporation
Centreville, Virginia

1. INTRODUCTION AND MOTIVATION

At its core, the traffic engineering problem is very easy. At least stating the problem is! Indeed, traffic engineering falls into the relatively small set of problems that happen to be relatively easy to articulate, but whose solutions provide a window to a world that is new and in many ways surprisingly complex. Even though our current emphasis is on communication systems and networks, the problems and associated solutions have much broader applicability. We will occasionally refer to these other areas of applications, as they can also aid in the understanding of some of the underlying principles.

In a somewhat abstract sense, the problem can be formulated as follows (see Fig. 1). To a given pool of resources, consisting of N "servers," "customers" arrive with the intention (or need) to use one of the servers for a certain amount of time. Indeed, if one of the resources is available, it is "held" or "occupied" by the arriving customer. If no resources are available, the arriving customer is blocked. Thus we observe that the entire "offered load" is "split" into what becomes "served load" and "blocked load." The basic question then appears to be simple and final: "What is the probability that the system will be full, and thus will be unable to serve a potential customer, that is, how much of the offered load is served and how much is blocked?" Once this relationship is fully understood, it can be exploited to design, or size, a given system to meet certain performance objectives, or at least determine what the performance may be for a given set of conditions.

Note that the set of resources can be, for example

- Channels between points A and B (as is often the case in communication networks)
- Tellers at the bank
- Check-in counters at an airport

Also note that the language is not always helpful in uniquely identifying the problem! Arriving "customers" can be telephone calls or passengers who need to board a plane. Similarly, one would not ordinarily state that "a customer at a bank held (or occupied) the bank teller." In an abstract sense, however, these statements all refer to the same situation, where the resource is being used by an arriving entity, thus is unavailable for use by others, until, of course, it is "released." Once again, in this article, as a rule, we will refer to arrivals as *calls* that attempt to use one *channel* for a certain amount of time, called the *holding time*. Similarly, the terms "resource," "channel," and "server" will be used interchangeably, as indeed they are so used in the real world.

As we will see in detail later, one of the most important quantities that arise in the analysis of such a system,

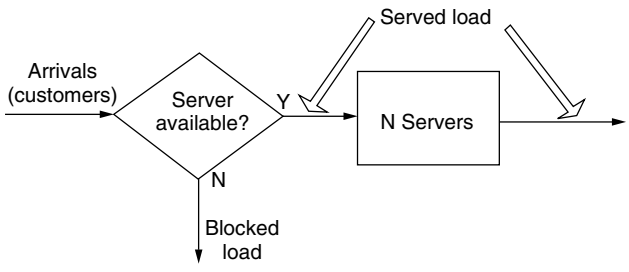

Figure 1. Schematic diagram of a service facility.

is the product of the average call arrival rate, commonly denoted by λ, and the average holding time, also commonly denoted by $1/\mu$. We thus define the *offered load*, A, by

$$A = \lambda \times \frac{1}{\mu} = \frac{\lambda}{\mu}$$

What are the units of the offered load? λ has the units of time^{-1} ("calls" is dimensionless), whereas $1/\mu$ clearly has the units of time. Thus A is dimensionless.[1]

It is in honor of the Danish mathematician A. K. Erlang, the father of traffic engineering, that a load A is referred to as "A erlangs." The basic problem can be stated very concisely as follows. An offered load of A erlangs is offered to a pool of N servers. What is the blocking probability, that is, the probability that an arbitrary arrival finds no server available? As it turns out, the process of answering this seemingly simple question entails more complexity than one might think! It is intuitively clear that, for a given value of N, the blocking probability will increase with increasing offered load, A, thus with increased values of the arrival rate and/or the average service time. What is not necessarily as obvious, is that the *arrival statistics* play a vital role. One can easily appreciate this by considering two particularly simple examples. These examples will also allow us to introduce a number of concepts used later in this article. We will assume that the

- Number of channels, $N = 1$
- Average arrival rate, $\lambda = 1$ arrival/min
- Average holding time, $1/\mu = 1$ min, and it is *constant* for each and every call

Examples 1 and 2 differ only in the way in which calls arrive to our one and only channel, as follows. We should emphasize that for now, we will not worry about how realistic (or unrealistic) these examples are. This point will be amply discussed later when we discuss modeling arrival processes in realistic situations.

Example 1. Calls arrive every minute on the minute. One might think of this as being "organized" by an external entity that coordinates the call arrivals to occur in this fashion: on the minute every minute.

Since each arrival occupies the channel for precisely one minute, it departs just as the next call arrives, and the new call occupies the channel.

We can easily see that the fraction of calls that find the system unavailable is 0, that is, that the blocking probability is 0.

Similarly, it is just as easy to see that the system utilization is 1, that is, the system is fully utilized, or as the Chief Financial Officer would say "we are making money at 100% of the potential to make money." From a practical perspective, the question of utilization is often of importance, as it is the *utilization* of the system that generates revenue!

This is perfection! No user is disappointed (blocked) and we (the network provider) make as much money as possible.

Example 2. All 60 calls arrive within the first minute following the first call's arrival, say, at the beginning of an hour. Once again, one might think of this as being "organized" by an external entity that coordinates the call arrivals to occur in this fashion: a whole bunch of them close together and then nothing for the remaining hour.[2]

It is clearly seen that the first arrival in the hour occupies the channel, and all remaining 59 calls find the channel occupied, thus are blocked. Thus the fraction of calls that find the system unavailable is $\frac{59}{60}$, with a blocking probability of almost 1.

Similarly, it is just as easy to see that the system utilization is $\frac{1}{60}$, that is, we are making money a mere 1.67% of the potential to make money. This is about as bad as it can get! Almost all users are disappointed (blocked), and we (the network provider) make essentially no money — this is one way to get into bankruptcy!

We can summarize Examples 1 and 2 in a manner that will also prove useful later, as shown in Fig. 2. Note that this is a two-dimensional space representing all the possible values of blocking probability, in the range [0,1] and utilization, also in the range [0,1]. Any point (x, y) in this space represents a system for which the blocking probability is x and the utilization is y. As a result, the points (0,1) and (1,0) represent the limiting cases discussed in the two previous examples, respectively. Clearly, in general, we would like to be operating at a point (x, y) with x as small as possible and y as large as possible, specifically, in the upper left quadrant of the unit square, as shown in Fig. 2.

What is the *only* difference in the two examples? The *arrival process*. Thus it becomes important that we undertake a study of the arrival process statistics in order to investigate the traffic engineering problem. We do so

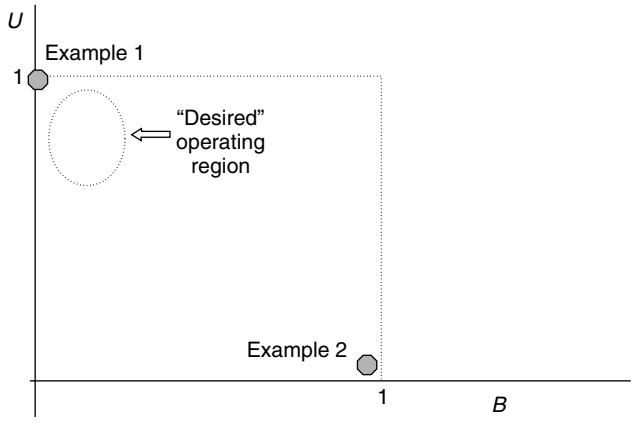

Figure 2. Utilization and blocking for different arrival statistics.

[1] It is worthwhile to note that, as we will see later, μ is called the "service rate" and then the load becomes the ratio of two rates: the arrival rate and the service rate.

[2] Note that the average arrival rate is still 1 call per minute and the average holding time is still 1 minute, thus the offered load is still 1 erlang, exactly as in Example 1.

in Section 2. In Section 3 we analyze the most common models used in traffic engineering: the Erlang B model, followed by the Erlang C and the Poisson models. The fundamental similarity and difference of these models lies in the way in which blocked arrivals are treated: In Erlang B it is assumed that blocked calls depart the system unserved. In Erlang C, it is assumed that arrivals that find the system full, thus are blocked, enter a queue, which is served in a first-in first-out (FIFO) manner. However, it is important to note early on that the Erlang C model assumes that blocked arrivals are willing to wait an unbounded amount of time for service. Thus, one might consider the Erlang B and the Erlang C as diametrically opposite models: One assumes that the arrivals are willing to wait 0 time, while the other assumes that the blocked arrivals are willing to wait as long as it takes. Clearly, there ought to be a model for some sort of in-between case! Indeed, the Poisson model is precisely such a model. We will elaborate on these three models, individually and collectively, in Section 3.

Finally, in Section 4 we discuss the problem of random access, which is of a somewhat different flavor, as articulated in time; while often not associated with conventional traffic engineering problems, the random access problem is indeed a traffic engineering problem and thus needs to be discussed herein.

2. MODELING THE ARRIVAL PROCESS

Clearly, the tools of statistics and random processes are needed in order to characterize the arrival process. This can get very technical and, while these technicalities are important, one can miss the essence of the problem. Our present discussion is limited to an intuitive level and the technicalities can be found in any number of books on probability theory and on random processes, such as the classic books by Feller [1,2]. We discuss the more critical concepts, in particular as they impact traffic engineering issues.

2.1. Stationarity

As noted earlier, load is measured in erlangs, a dimensionless quantity. First and foremost, defining the load has little to do with a period of time. Many practicing engineers, unfortunately, think of one Erlang as being "one call occupying one channel for one full hour." While this statement can be interpreted correctly (we will not attempt to do that here), it is very open to misinterpretation, which unfortunately happens too often. This is one reason why we will not make such usage here and we will use the definition of load in a way that leaves no room for misinterpretation. However, to do that, we need the concept of stationarity. Indeed, implicit in most of traffic engineering is the assumption that the problem is stationary.

Although the mathematical definition of stationarity is not too difficult, we will avoid such technical issues, appealing to one's intuition instead. Simply put, we require that the statistical nature of the underlying problem remain the same over time. As a trivial but helpful example is that of a sequence of flipping the same coin. While each outcome is in general different from the other outcomes, stationarity implies that the probability distributions that govern these outcomes remain the same. Note that we are *not* saying that it is a fair coin — it can be any coin. Stationarity merely says that whatever the statistical behavior is, it remain the same over time.

In a way the question is simple: Is the statistical nature of calls arriving to our resources (say a switch) the same at all times? Clearly, from a purist's perspective the answer must be "no," since things do change, people behave differently over time, and so on. Thus we do not have stationarity. But from a practical perspective, we can ask a slightly different question: Is it realistic to assume that over some nontrivial amount of time, the statistical nature of the problems remains constant? If so, then we need to ensure that such a period of time is long enough so that enough events take place, and yet not too long, so that the underlying statistical dynamics of the problem remain constant. In general, how long is long enough and not too long? While the technical definition of stationarity could be called on, we will appeal more to one's intuition. Clearly, what happens at 3 A.M. is different than what happens at 9 A.M. But how about 8 A.M. and 9 A.M. — is it sufficiently the same, from a statistical nature point of view, or is it changed and thus needs to be considered separately? The traditional answer to the question has been to not pay too much attention to it! In the early days of developing telecommunication networks (when the voice network was the prime example) the computing power to do a more elaborate analysis was simply not available, thus the technical community used a one-hour period as being long enough and not too long to be considered as a period of stationarity. Clearly, then, the hourly division of the 24-h day made some sense. Although some of the original premises are no longer valid, we still tend to use hourly data. To some extent, this has become a chicken-and-egg problem: switch manufacturers tend to default their software programs and so on, into one-hour periods because practicing engineers are used to that. Practicing engineers, in turn, tend to use hourly data because the switch provides these data! Even though in many of today's switches there are options of keeping and reporting other statistics, most engineers do not know that such options even exist, let alone how they might use it. So that brings us to the traditional hourly engineering. We, however, will not make any such assumptions. We will treat the problems from a slightly more abstract point of view, and simply assume that stationarity exists and not be concerned over how long it lasts for.

2.2. Busy-Hour Engineering

The discussion above naturally brings us to the notion of *busy-hour engineering*. As discussed above, there is nothing particular or important about a one-hour period. It was just convenient at one time. Second, the definition of *busy hour* is straight forward, albeit with its own difficulties. If we accumulate load on an hourly basis, then there are 24 measurements for a day, and the highest one is the busy hour. Assuming that the statistical nature of the problem does not change over days (which may or may

not be true), we can aggregate the same-hour data over a number of days and thus generate the concept of "busy hour" over periods of many days, weeks, or even months. Once again, stationarity can play an important part here: In an area serving ski resorts, clearly the statistics change from winter to summer months, so we need to be aware of the stationarity issues both in the small and the larger scale of time constants! As we indicated earlier, we will follow the usual approach and assume that the problem is stationary. A detailed analysis of the complexities arising from considering the *day-to-day variation* can be found in the book by Ash [3].

Two different fundamental questions are

- *Why* do we do busy-hour engineering?
- *Should* we do busy-hour engineering?

The answer as to *why* lies in history! Without getting into a deep historical retrospective, suffice it to say that in the (traditional) regulated monopoly environment, there were both regulatory and business reasons that were pointing toward taking a busy hour engineering approach to the network design problem. It is intuitively obvious that such an approach resulted in a network that was more expensive than it might otherwise be. This observation notwithstanding, the combination of business and regulatory issues in a regulated monopoly provided sufficient justification to indeed adopt such practices quite widely.

The question of continuing to do busy hour engineering in the new days of deregulation of telecommunications on a worldwide basis is a harder one to answer! Indeed, we will not answer it, as it becomes an economic analysis. Any such analysis must be interdisciplinary by nature. In this article we provide the traffic engineering tools needed to carry out such an analysis, but the point should be raised as too often methodologies are adopted only because "that's how it has always been done."

2.3. Definition of Load

As indicated earlier, the proper measure of load is the product of the average arrival rate times the average holding time. This product is referred to as "*A* erlangs." Even though on its way out, an old-fashioned measure still exists, so one should be aware of it: 100 call-seconds per hour (CCS). (The acronym is derived as follows: C, from the Latin initial for hundred; C, call; S, seconds; per hour, by common agreement or convention.) Some, especially older, systems still use CCS, but its usage is strongly discouraged. As will become apparent later, one can easily convert CCS to erlangs: 36 CCS = 1 erlang. Furthermore, the relationship of CCS to erlangs is analogous to that of degrees to radians in measuring angles; the first is arbitrary and based on some agreed-on convention. (Why does a complete rotation correspond to an angle of 360°? Why 360 and not, say 480? The number 360 is just as arbitrary as 480 or any other number! It only "feels" better because we have been used to it!) Much as radians are dimensionless measures of angles and defined as the ratio of two lengths, the erlang is dimensionless and is the ratio of two rates, which is an item we will return to shortly, For now, suffice it to say, that we will use only erlangs from here on, but one must be aware of the possibility of encountering CCS!

2.4. The Poisson Arrival Process

One of the most commonly made assumptions is that the arrivals occur according to a *Poisson process*. What does that mean? What are the practical implications of such an assumption? What are the practical and theoretical implications if this assumption does not hold? Before we attempt to answer some of these questions, we must develop at least some understanding of this concept, which is indeed of paramount importance.

Consider an arrival process of, for example, calls to a switch that satisfies one of the following three properties. We will consider them one at a time, and then use them to define the arguably most fundamental modeling assumption in traffic engineering: The Poisson process.

Property 1: The Infinitesimal Generator. Suppose that the arrival process is such that over an infinitesimal period of time h, the probability of exactly one arrival and exactly zero arrivals are given respectively by[3]

$$P(1 \text{ arrival}) = \lambda h + o(h)$$

$$P(0 \text{ arrivals}) = 1 - \lambda h + o(h)$$

Note that, in a very general sense, for arbitrarily small amount of time h, specifically, in the limit as h goes to 0, the probability of 1 arrival goes to 0 and the probability of no arrivals goes to 1! What we are saying here is much more profound, albeit not obviously so! We are saying that, in the limiting sense as time goes to 0, P (1 arrival) goes to 0, *linearly* with time, with constant of proportionality λ. Similar statement can be made about the probability of zero arrivals.

It is a direct consequence of these assumptions that the probability of two or more arrivals is $o(h)$. In other words, the probability of two or more arrivals over a small interval of time *goes to 0 very rapidly*. As it turns out, from a practical point of view $o(h)$ functions can be disregarded without any harm.

Thus, we are stipulating that over an arbitrarily small interval of time h (and thus the term "infinitesimal generator"), "essentially" (i.e., we ignore $o(h)$ terms) the following happen:

- One arrival occurs with probability λh.
- No arrivals occur with probability $1 - \lambda h$.
- Two or more arrivals occur with probability 0.

[3] The notation $o(h)$ (read as "little o of h") is common and is used to designate any function that satisfies the following limiting property:

$$\lim_{x \to 0} \frac{f(x)}{x} = 0$$

i.e., the function $f(x)$ approaches 0 (as x goes to 0) **faster** than x itself goes to 0.

We further assume that the arrivals in disjoint intervals are independent events, thus the number of such arrivals are independent random variables.

This "infinitesimal" property of arrivals may or may not appeal to one's intuition as being a good model for our problems. We will table further discussion of this model/property until we discuss two other options and then come back and compare all three of them.

Property 2: Poisson Distribution of Number of Arrivals. Here we consider an arbitrary period of time T — no longer an infinitesimal one — and ask the question of how many arrivals occur in it. Let's suppose that the number of arrivals K in the time period T has the Poisson distribution with parameter, λ. Recall then, that the probability distribution of the number of arrivals, K, is given by

$$P(K = k) = \frac{(\lambda T)^k}{k!} e^{-\lambda T} \quad k = 0, 1, 2, \ldots$$

We further assume that the number of arrivals in disjoint intervals of times T_1 and T_2 are independent random variables.

Property 3: Exponentially Distributed Interarrival Times. Here we assume yet another property of some arrival process: The time between two successive arrivals (called the *interarrival time*), X are independent random variables, exponentially distributed with some parameter λ. Recall that X has the exponential distribution if its probability density function is given by

$$f(x) = \lambda e^{-\lambda x} \qquad \text{for} \qquad x \geq 0$$

Among other natural and useful questions to ask, from the engineering perspective, are the followings:

- Which of these three models, if any, is a realistic model for traffic arrivals to a switch or to a set of channels?
- How would one go about confirming or rejecting the modeling assumption that one of these models is indeed a good one?
- If one of these models is not quite good enough, could another one of them be better (or worse for that matter), but harder (or easier) to work with?
- If none of these three models is valid in a given practical situation, and we have established methodology to discover that fact, how do we go about finding a better one?
- Continuing with the previous item, how much error in our performance evaluation and/or design are we making by using the wrong model? It may be worthwhile to use an easier model, even if it is not quite right, if the deviations from the more accurate one are small.
- Assuming that we do find a better model, what will the performance be?

This may come as somewhat of a surprise, and it is intuitively not obvious at all, but the following is a fundamental theorem with many practical implications:

Theorem 1. If an arrival process satisfies any one of properties 1, 2, or 3, then it satisfies *all* of them and the arrival process is called a *Poisson arrival process*, or simply a *Poisson process*. The constant of proportionality λ is the same in all three defining properties and is called the average arrival rate of the arrival process. It is also referred to as the *arrival rate*, or even just the *rate*, or the *parameter* of the Poisson process.

In this article we will forego all proofs, but if this is the first time one sees this, it is highly recommended that one try to prove the equivalence of these three properties, as indeed they form the defining properties of the Poisson process.

While we could spend a large amount of time in investigating the deeper properties of the Poisson process, in the interest of brevity, we will not; however, we will briefly point out some of the more important salient points:

2.4.1. "Random" Arrivals. As it turns out, if a large population generates "arrivals" in a manner that involves *no external* control, the overall resulting arrivals will constitute a Poisson arrival process. This is precisely the reason why the Poisson arrival assumption has been used in telephony so much: when a user A makes a call is not "controlled" by any entity. Thus, precisely when user B makes a call is neither influencing nor is being influenced by user's A actions. This is also why some refer to the Poisson process as being one in which arrivals occur "at random." This, however, can be misleading, since "random" arrivals can obey any number of statistical properties and does not necessarily have to be Poisson. We must also emphasize that in practice the external controls *may* be there implicitly, thus "destroying" what might have otherwise been a Poisson arrival process! The requirement is that there be *no controls*, explicit or implicit ones!

2.4.2. Merging of Poisson Processes

Theorem 2. If n independent Poisson processes with rates $\lambda_1, \lambda_2, \ldots, \lambda_n$ are merged, then the resulting process is Poisson with rate $\lambda = \lambda_1 + \lambda_2 + \cdots + \lambda_n$. In other words, merging several (independent) Poisson processes preserves the Poisson property.

2.4.3. Splitting a Poisson Process. How about the converse? Does splitting the arrivals of a Poisson process into two (or more) subprocesses preserve the Poisson property? As we are about to discover, the converse problem is a bit more complicated, the results are a bit more surprising, and the practical applications a bit more intriguing.

Suppose that a Poisson process with rate λ is "split", or bifurcated, into two (or more) sub processes. The question then is whether each subprocess is or is not Poisson (see Fig. 3). The mechanism labeled "load regulator" routes each arrival to the set of resources (channels) labeled

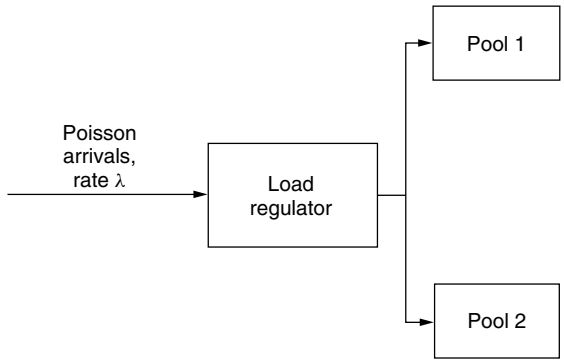

Figure 3. Bifurcation of Poisson arrivals.

"pool 1" or to the one labeled "pool 2." The mechanism by which it decides where to route each call is critical and we will be elaborating on this in the next few paragraphs.

As a first step, assume that the load regulator routes each call to the two pools in an alternating fashion. For convenience, we may assume that the first call is routed to, say, pool 1. Once again, assuming that the original process is Poisson with rate λ, the question is what can be said about each subprocess, i.e., the arrivals as seen by each pool of channels. The answer is provided in the next theorem.

Theorem 3. A stream of Poisson arrivals with rate λ is split into n substreams. Each call is routed to substream i with probability p_i, *independently* of all other calls, or the state of the system (thus of prior arrivals, etc.) Then each sub stream is also Poisson with rate $p_i\lambda$. Conversely, if the routing decision is made in some dependent fashion, including based on the state of the system, then the sub processes are *not* Poisson.

This is a good illustration of the fact that the Poisson process is a "delicate" entity. It is very easy to destroy it! Two practical examples will illustrate the point.

Example 3. Consider a network, a portion of which is as shown in Fig. 4. The direct route between nodes A and B is preferable, so the "load regulator" sends calls to the direct route, unless all channels are occupied in which case it sends the call via the alternative route, namely, via node C. Then, from a practical perspective, it is important to ask if the set of channels on the alternative path, links A–C and C–B are offered a Poisson arrival stream.[4] Since the decision to send the call to the A–B link or the A–C–B one is based on the state of the system, the substream of offered calls to the alternative route is not Poisson, even though the original traffic arrivals is assumed to have satisfied the Poisson assumption.

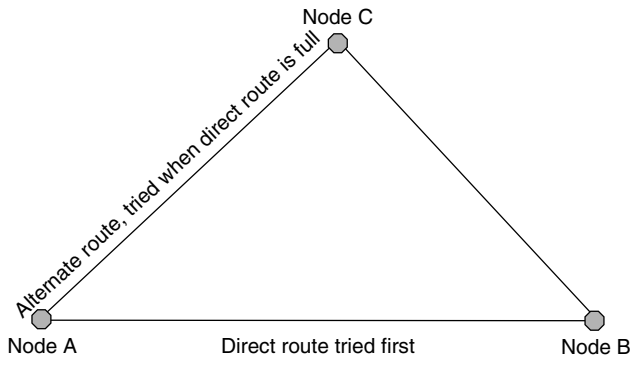

Figure 4. A simple 3-node network.

Example 4. In modern mobile communications networks, it is not uncommon for a given region to be capable of being served by two (or even more) cells. This is an example of the well-established concept of underlay/overlay. We will not get into the pros and cons of such designs or the radio engineering issues surrounding them, but the concept is simple. A given geographic region is divided into small cells as well as large ones (sometimes called "umbrella cells"). A given call is first attempted on the small cell, and if all channels are busy, it is then attempted on the large one. It is obvious that this is a problem equivalent to the one above. The point is the same — the offered load to the alternative set of resources is no longer Poisson.

As one can see, the mechanics and perhaps the reasons by which the load is "split" is rather irrelevant. However, destroying the Poisson property is not all that difficult to do! Both from a theoretical and a practical vantage point, we must be aware of that possibility and take appropriate measures.

2.4.4. Modeling Assumptions. From either a theoretical or a practical perspective, it is often the case that one needs to confirm or refute the assumption that arrivals form a Poisson process. It is often easy to make such an evaluation using one of the three properties of the Poisson process, whereas using the other two properties may be very difficult and/or impractical. We emphasize that these three properties are equivalent and one should avail oneself of whichever one is easier to work with. Furthermore, if one of these properties is shown not to hold, the others do not hold either and the assumption of the arrival process being Poisson is not valid. From the practical perspective this can have very significant implications to which we will return shortly.

2.4.5. If Not Poisson, Then What? If an arrival process is not Poisson, is there anything we can say about it? Yes, indeed there is. The Poisson process is merely one particular point in a continuum of possibilities. What is particular about it can be summarized in one sentence — its peakedness is 1. Peakedness is defined as the ratio of the variance of the number of arrivals to the mean number of arrivals. If the arrivals are Poisson, then we recall that the number of

[4] Clearly in a network environment this is only a portion of the problem. We are specifically and narrowly concerned with this particular portion of the traffic. In network designs, we obviously need to integrate this into a considerably larger set of issues. The reader is referred to Ash's treatise [3] for a comprehensive analysis of the issues in such network designs.

arrivals over any time of duration T satisfies the following conditions:

- Mean number of arrivals = λT.
- Variance of the number of arrivals = λT.
- Thus peakedness = variance/mean = $\lambda T/\lambda T = 1$.

Arrivals for which the peakedness $Z > 1$ is called "peaked" traffic, whereas if the peakedness $Z < 1$ we say that the traffic is "smooth."

We observe that the arrival processes discussed at the outset of this article satisfied:

- When arrivals arrive on the minute every minute, then variance = 0; thus peakedness $= 0 \ll 1$, thus we say that the traffic is very smooth.
- When arrivals came all "bunched up," the variance was large (with the same mean), thus peakedness $Z \gg 1$; thus, we had very peaked traffic.

Recalling our earlier discussion of Poisson traffic being often referred to as "random" traffic, we can make the additional observations that

- If no controlling mechanism exists, then arrivals will be in accordance with the Poisson assumption: $Z = 1$.
- If a controlling mechanism (implicit or explicit) "coordinates" arrivals to occur on a "regular" basis (thus lowering the variance), then the traffic exhibits some smoothness, where $Z = 0$ is the limiting case where there is no variability in the arrival stream.
- If, on the other hand, the controlling mechanism tends to "bunch up" traffic, then it is peaked traffic and the peakedness Z is arbitrarily large, according to the degree to which the "bunching up" takes place.

2.4.6. Time versus Call Congestion. Finally, Poisson versus smooth versus peaked traffic can be seen to have one more impact that needs to be discussed. Two related concepts are those of

- *Call congestion* (CC)—the fraction of call arrivals that find the system full. This is indeed what we have been referring to as probability of blocking.
- *Time congestion* (TC)—The fraction of time that the system is fully occupied and thus can not admit a new arrival.

Note that there is no a priori reason that these two measures of congestion should be equal to each other. Indeed, if the arrivals do form a Poisson process, they are. Otherwise they are not. Figure 5 summarizes the relationship where the time congestion and the call congestion occupy the two sides of a balance beam. In Fig. 5a arrivals are assumed to be Poisson ($Z = 1$); thus CC = TC. Figure 5b illustrates smooth traffic ($Z < 1$). In that case TC > CC. Note that this, in principle, is desirable, as it implies that utilization is higher while blocked arrivals are fewer (than would be the case with $Z = 1$). Of course, the converse is shown if Fig. 5c, where

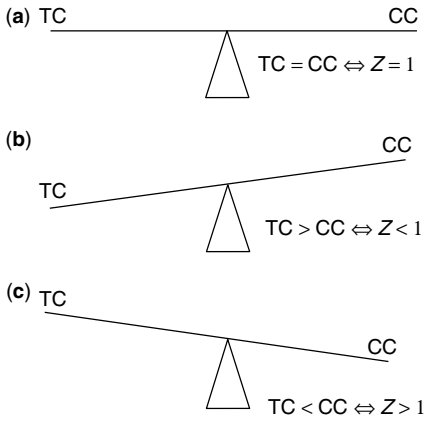

Figure 5. Time congestion versus call congestion.

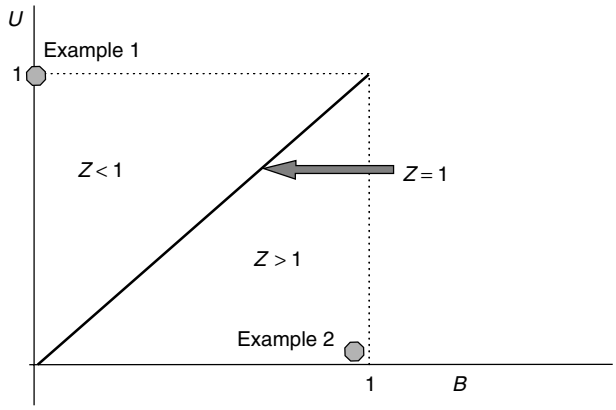

Figure 6. Utilization versus blocking for Poisson arrivals and $N = 1$.

$Z > 1$. Indeed, see Fig. 6, which is a generalization of what we discussed earlier in Fig. 2 for the case that $N = 1$. As the offered load ranges from 0 to infinity, one can see that a path is traced in the unit square of (B, U). The precise path depends on the peakedness. If $Z = 1$, the path is on the "45°" line, as indeed $U = B$ (for the case $N = 1$; we will shortly return to the more interesting case where $N > 1$). This line separates the unit square into two regions: One for smooth traffic ($Z < 1$) and one where traffic is peaked ($Z > 1$) as illustrated in the figure. While the straight line is a direct result of the system having just one channel ($N = 1$), the general concept is valid and will be generalized shortly, after we obtain the so-called result of the Erlang B model.

3. THE ERLANG *B* MODEL

As mentioned earlier, the most common model used for determining the quantitative relationship between the offered load A, the number of channels N, and the blocking probability $B(A, N)$ is the Erlang B model.

The Danish mathematician A. K. Erlang developed what is now known as the Erlang B model early this century, just as telephony was being born.

3.1. Modeling Assumptions and Associated Notation

The Erlang B model is used so widely, often without adequate understanding of the underlying assumptions.

Although a variety of modifications to the basic model are possible, and we will point to some of them, the basic model makes the following fundamental assumptions:

- The "service facility" or the "system" consists of a fixed number of "servers" or channels, N.
- Calls arrive to the system according to a Poisson process with an average arrival rate of λ calls per second.
- If a server, or channel, is available on a call's arrival, the call seizes a server. If more than one server is available, any one of them is seized — it makes no difference which one, as all servers are equivalent in all senses.
- A call occupies the server for an amount of time that is exponentially distributed with parameter, or rate μ, and independent of all other calls, arrivals, system state, or anything else. Thus the average service time, or average holding time is $1/\mu$. It is precisely the desire to express the service statistics in terms of the service rate (rather than the average service time itself) that early on we had the somewhat surprising notation of $1/\mu$ for the average holding time.
- If all servers are occupied at a call's arrival instant, the call departs the system unserved. In particular, it does *not* attempt to be served "a little bit later," try again, or any variant thereof.

Before we proceed, a brief notational comment. The system that we just described is often referred to as an $M/M/N/N$ queueing system. The notation is straight forward, and we present it in a somewhat more general context in the next paragraph.

In general, the notation $F_1/F_2/F_3/F_4/F_5$ implies the following service facility:

- In field F_1, a letter designates the interarrival times, namely, the arrival process. So, for example, M implies that the arrival process is Poisson. Maybe it should be P, you say! It is M, because a Poisson arrival process contributes to the system being a *Markov* chain, thus the letter M. In general, one can have other letters, For example, E_r, implying that the interarrival times have the r-stage Erlangian distribution. G stands for "general" distribution, and so on.
- In field F_2, once again a letter designates the service time distribution. So, for example, M implies that the service time is exponentially distributed. Once again, one might think that it should be E! It is M, because exponential service time is the other component that contributes to the Markovian behavior of the system. In general, one can have other letters; For example, D stands for deterministic (i.e., all service times are the same, etc.).
- Field F_3 is a numeric field, indicating the number of servers available at the service facility.
- Field F_4 is also a numeric field, indicating the "capacity" of the service facility. The term "capacity" is often used in many different ways, so we need to be careful! Field F_4 indicates the maximum number of customers that can be in the service facility, not necessarily being served. So, for example, $M/M/10/15$ represents a system to which arrivals (calls) occur according to a Poisson process, service times are exponentially distributed, there are 10 servers (channels), but there is room for 5 $(15 - 10 = 5)$ arrivals (calls) to be "waiting" for service. In other words, the maximum number of arrivals or users or calls in the system is indeed 15, but only 10 can be in service at any one time.
- Finally, field F_5 is also numeric and it represents the overall population from which arrivals can occur. In our work, and whenever it is much greater than the value in F_4, we just assume it is infinite.
- Also, if any of the numeric fields is missing, it is assumed to be infinite, so in our example above $M/M/10/15$, indeed we assumed that the population base is infinite, indeed a good approximation as long as the population base is much larger than 15.

Note that the $M/M/N/N$ system implies that there is no "waiting room," which is consistent with our assumptions. Indeed, this is an assumption that is often in conflict with human nature. For instance, if I try to make a call and do not get through, I am more likely than not to try again, and that very action violates the assumption at hand. We will return to this point, but for now we'll just say that this assumption, which is somewhat in conflict with human nature, is a weakness of the model and we have to take the model at its face value, else we can not proceed!

3.2. State-Space and State-Transition Diagrams

The mathematical definition of *state space* and the resulting *state-transition diagram* are nontrivial and involve a fair amount of mathematical formalism. The reader is referred to the excellent presentations in Refs. 4 and 5. Here we present a summary of how these tools become useful in analyzing a variety of traffic engineering problems. We accomplish this through the analysis of the $M/M/N/N$ system, which in turn leads us to the development of the so-called Erlang B formula.

As it turns out, for a Markovian system [1,2,4], the number of customers in the system is a state.[5] For non-Markovian systems, the interested reader is referred to the treatise by Akimaru and Kawashinia [6]. The set of states constitutes the state space, as illustrated in Fig. 7. Once all states have been identified, they can be represented in any convenient manner. Traditionally, we simply draw a circle, with the state label inside it, as in Fig. 7a. However, in general, one can think of software tools and therefore other representations of the state space.

The next concept is critical: The *state-transition diagram*. Transitions from one state to another are clearly possible, as indicated on a state-transition diagram (Fig. 7b). The transitions are indicated by an arrow going from or to the respective states. The arrows are labeled

[5] Why this is not necessarily so in general is a difficult and deep question beyond our scope. While not obvious at all, it is the fact that all underlying times (interarrival times and service times) are independent and exponentially distributed that makes this statement possible. For a deeper understanding, the interested reader is strongly encouraged to pursue this in the references.

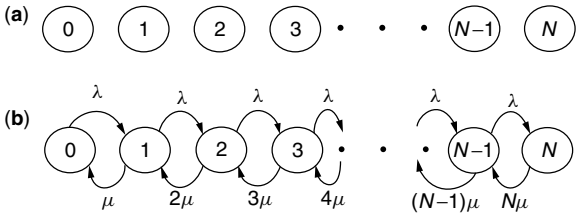

Figure 7. (**a**) State space; (**b**) state-transition diagram for the M/M/N/N system.

with the rate at which a "departure" from a given state to another state occurs. Once this set of states and associated transitions are identified, the entire "thing" is called the state-transition diagram. The state-transition diagram becomes useful in finding the steady-state probability distribution of being in each state. Note that although the state space consists of $N + 1$ states in this example, in general the state space can be finite or infinite. Similarly, drawing the state-transition diagram may be easy or not viable at all, depending on the complexities of the state space and associated transitions.

3.3. Flow Conservation Principle and the Erlang *B* Formula

The fundamental property that makes the state space a useful definition is the notion of flow conservation. As do other conservation laws in physics (conservation of energy, conservation of momentum, etc.), they tend to be rather technical in their proof, but once we accept them, their utility becomes very clear. How many readers have read the proof of conservation of energy? We all learned about it though! Similarly, here we will take the law of conservation of flow as given and work with it. Once again, the interested reader is referred to the references for further reading, specifically the volumes by Kleinrock [4,5].

What is the law of conservation of flow? First, let's define "flow." Referring to Fig. 8, consider a closed surface encompassing state i. Let P_i be the steady-state probability that the system is in state i. Consider a transition from state i to some other state with some rate λ as shown by the arrow (without necessarily indicating which state the transition is into). As it turns out, the natural definition of flow is very easy and quite intuitive: Flow out of state i is the product λP_i.

The flow conservation law, as you might guess, simply states that the flow out of a state is equal to the flow into the state. In fact, it is more general! It states that across any closed surface, containing any set of states, the flow into the closed surface equals the flow out of it. The choice of which states to include in the closed surface is entirely

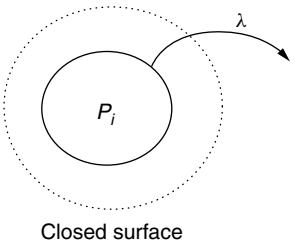

Figure 8. Definition of flow.

up to us! Judicious choices will result in a set of equations that can be solved for the probabilities P_i, i.e., the steady state probability distribution of the various states can be obtained and then applied in a variety of ways.

Once again, the state-transition diagram for the $M/M/N/N$ system is shown in Fig. 7b. Note that transitions from any state $i < N$ to state $(i + 1)$ occur with rate λ, as that is the arrival rate of new calls. Similarly, if the system is in state 1, then the one existing call departs with rate μ, so the transition to state 0 occurs with rate μ. On the other hand, if the system is in state 2, then there are two ongoing calls in the system. Departure of either one of the two, moves the system to state 1. But each call occupies its channel for an independent, exponentially distributed time, with parameter μ. Thus, the departure from state 2 to state 1 occurs with exponential time, with rate $\mu + \mu = 2\mu$. Similarly, if the system is in state $i \leq N$ it departs for state $(i - 1)$ with rate $i\mu$.

The Erlang B formula is essentially one step away! Let us consider the sequence of closed surfaces that enclose

1. State 0
2. States 0 and 1
3. States 0,1, and 2
4. ....
5. States 0,1,2,... $(N - 1)$

Applying the flow conservation principle to these surfaces, one gets the following system of N equations, with the probabilities $P_i (i = 0, 1, 2, \ldots, N)$ as the $(N + 1)$ unknowns:

$$\lambda P_0 = \mu P_1 \tag{1}$$

$$\lambda P_1 = 2\mu P_2 \tag{2}$$

$$\cdots \tag{3}$$

$$\lambda P_{N-1} = N\mu P_N \tag{4}$$

As the reader can see, an easy inductive argument will show that

$$P_n = \frac{1}{n!}\left(\frac{\lambda}{\mu}\right)^n P_0$$

Finally, the last equation comes from the normalization step, that is, from the fact that all probabilities must sum to 1 which allows us to compute P_0:

$$P_0 = \frac{1}{\sum_{n=0}^{N} \frac{A^n}{n!}}$$

Note that this last normalization step is often one that is quite difficult to perform in more complex systems. Nevertheless, for our problem, we finally get that the probability of being in the blocking state (state N), which is indeed the blocking probability is simply

$$B(A, N) = \frac{\frac{A^N}{N!}}{\sum_{n=0}^{N} \frac{A^n}{n!}}$$

where we have obviously given the term λ/μ the name it deserves. Load A, which as discussed earlier is dimensionless and indeed the ratio of two rates: the arrival rate and the service rate. This is the famous Erlang B formula, a cornerstone of traffic engineering.

3.4. Important Points and Issues

Several points need to be made about the Erlang B formula/result:

1. In Erlang's days, computing power was simply not available. Thus, in the interest of making his result easily applicable and accessible to the engineering community, he developed the *Erlang B tables*, which is a tabulation of the Erlang B formula relating the offered load, the number of available channels, and the resulting blocking probability.
2. For a given number of channels (N) and a desired maximum blocking probability, the table provides the maximum offered load that would result in the said probability of blocking. An illustration of the Erlang B table is presented in Table 1. It should be noted that the granularity of neither N nor $B(A, N)$ is fixed. Some tables provide finer granularity than others, but they are all referred to as "the Erlang B table."
3. While until a few years ago, the Erlang B table was indispensable to a traffic engineer, these days, there are much more efficient numerical techniques that can be implemented in a few lines of code that work much more accurately, for instance, than a table lookup approach. One such approach is the iterative formula is

$$\frac{1}{B(A,N)} = 1 + \frac{N}{A}\frac{1}{B(A,N-1)}$$

It should be noted that there are other approaches, but they are beyond our scope. Notably, the Erlang B formula can be generalized to noninteger values of N, in particular when dimensioning networks. The interested reader is referred to Girard's treatise [7], where, in addition, the dimensioning problem is treated comprehensively.

4. It is clear that the relationship between N, A, and $B(A, N)$, has certain intuitively obvious monotonic behavior e.g., for a fixed number of channels, as the load goes up, the blocking probability goes up. However, the relationship is anything but linear! Interpolations and extrapolations are very dangerous, as the nonlinear behavior of the blocking probability can result in significant errors.
5. What is meant by *capacity*? As is often in engineering problems, this term must be defined in relationship to some performance objective. This is where the commonly made definition of N as capacity is rather inaccurate and possibly misleading. In traffic engineering terms, *capacity* is defined as the maximum offered load that a system can sustain at a given level of performance, that is, at a given blocking probability. For, example, referring to Table 1, we see that a system consisting of five channels and a desired blocking probability of no more than 0.02 (2%) has capacity of 1.66 erlangs. If the number of available channels were to be increased to 10 (i.e., doubled), the capacity would become 5.08 erlangs, about 3.1 times more than with five channels. If one were thinking that the capacity is doubled, the error made would be significant. So one needs to be careful when referring to capacity one must distinguish between the amount of resources (N) and the maximum offered load at a given performance level.[6] Indeed, this nonlinearity is often referred to as *economies of scale*, or *trunking efficiency*, a point to which we return in item 7 below.
6. Unfortunately, increasing the number of channels by a certain factor does not uniformly increase the capacity by the same, or even a constant, factor. The reader should consider what happens if the number of channels is increased from, say, 20 to 40, again a factor of 2, as in the previous example. Similarly, these capacity increases are different, depending on what value we have selected for the blocking probability.
7. It is worth our effort to return to a more general version of Fig. 6, shown in Fig. 9. Recall that as the offered load increases from 0 to infinity, the point (x, y) representing the blocking and utilization of the system traces some path in the $B \times U$ unit square from the point (0,0) to the point (1,1). That

Table 1. The Erlang *B* Table

B(A,N) *N*	1%	2%	5%	10%	30%	50%
5	1.36	1.66	2.22	2.88	5.19	8.44
10	4.46	5.08	6.22	7.51	12.0	18.3
15	8.11	9.01	10.6	12.5	18.9	28.2

25	16.1	17.5	20.0	22.8	33.0	48.1
30	20.3	21.9	24.8	28.1	40.0	58.1
35	24.6	26.4	29.7	33.4	47.1	68.1
40	29.0	31.0	34.6	38.8	54.2	78.1
45	33.4	35.6	39.6	44.2	61.3	88.1
50	37.9	40.3	44.5	49.6	68.5	98.1
55	42.4	44.9	49.5	55.0	75.6	108.1
60	46.9	49.6	54.6	60.4	82.7	118.1
65	51.5	54.4	59.6	65.8	89.8	128.1
70	56.1	59.1	64.7	71.3	96.9	138.1
75	60.7	63.9	69.7	76.7	104.1	148.0
80	65.4	68.7	74.8	82.2	111.2	158.0
85	70.0	73.5	79.9	87.7	118.3	168.0
90	74.7	78.3	85.0	93.1	125.5	178.0
95	79.4	83.1	90.1	98.6	132.6	188.0
100	84.1	88.0	95.2	104.1	139.7	198.0

[6] This problem has been quite prevalent in the mobile communications community, where, depending on technology used, and other variables, the number of available channels is increased by a certain factor (e.g., by a factor of 3). It is widely reported, then, that the capacity is increased threefold. As we have seen that is not quite accurate, and as traffic engineers we should not make such oversimplifications.

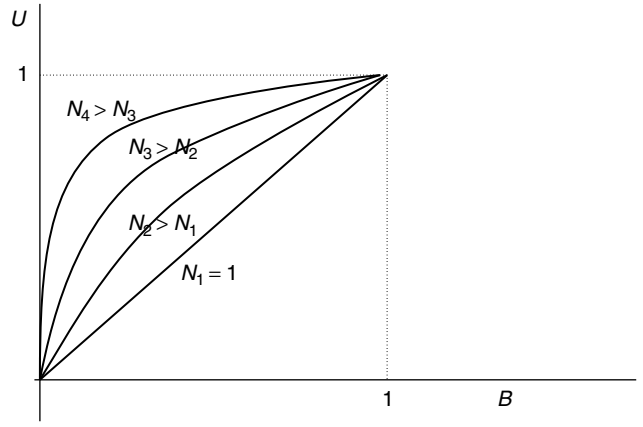

Figure 9. Utilization versus blocking for Poisson arrivals and arbitrary number of channels, N.

"curve" is shown in Fig. 9 for a system in which the number of channels is $N_1 = 1$ (as we did in Fig. 6) to progressively larger values $N_2, N_3, \ldots$. Although not illustrating a precise quantitative relationship, one can see why the larger system is said to be more efficient; for a given level of blocking, the utilization is higher. We ought to note that the curves in Fig. 9, also partition the unit square into two parts: one above and one below the "curve" that joins (0,0) with (1,1) for any given N. Points that lie on that curve represent the situation where arrivals occur according to a Poisson process. As before, the region above that curve represents what would happen if the peakedness is less than 1 and the region below the curve represents the situation where traffic is peaked.

8. Since a fraction of the offered load is blocked, we can now easily introduce the concept of carried load, $C(A, N)$:

$$C(A, N) = A[(1 - B(A, N))]$$

9. Although not necessarily obvious, it is relatively easy to prove that the carrier load is always less than the number of channels N. In fact, it is also easy to show that the ratio $C(A, N)/N$ is a measure of utilization of the system and is indeed a number in the range [0,1). We note that if the offered load A is Poisson, A = 1 erlang and $N = 1$, then $C(1, 1) = \frac{1}{2}$ and the utilization is also $\frac{1}{2}$. Compare this result with what happened when the same 1 erlang of load had peakedness $Z = 0 \ll 1$ and when $Z \gg 1$.
10. Solving the system of equations resulting from the flow conservation equations is not always an easy task. Numeric techniques can be employed, and the interested reader is referred to the treatise by Robertazzi [8], where the problem of a network of such queues is analyzed and numerical techniques are also presented.

3.5. The Erlang *C* Model and Blocked Calls Delayed

While the terminology "blocked calls delayed" and "blocked calls held" is not sufficiently clear and differential, it has been widely adopted by the community at large, so one has to be aware of the differences of the Erlang C model to be discussed here and the Poisson model to be discussed later.

Analysis of the Erlang C model is quite straightforward. Once we realize that the basic assumptions are the same as before (in the Erlang B model), with only one exception, the process is strikingly similar. The exception is that we assume that arrivals that find the system full, simply enter a queue and are served by the service facility on a first-come, first-served basis, else known as *FIFO* (first-in, first-out). We thus have an $M/M/N$ system.[7]

The state-transition diagram is shown in Fig. 10. Obtaining the steady-state probability distribution is quite straightforward as before, but with a couple of important observations:

1. The state space is infinite. This is a direct consequence of assuming an unbounded queueing room capacity.
2. The transition rates are just as before up to state N. Once the system is full, only one of the N customers that are in service can depart, so from that point on, the departure rate (from states k to state $k - 1$, for $k > N$) is always $N\mu$.
3. The fact that the state space is infinite implies that the sum of all probabilities, must converge. As we will see in a moment, the convergence requirement translates into the requirement that the offered load A must satisfy $A < N =$ number of channels in the system.
4. The term "blocking probability" has quite a different meaning in the Erlang B and the Erlang C models. Note that when blocked calls are cleared, they depart the system without being served, so indeed the term "blocking probability" is reflective of what happens. In the Erlang C model, *no* arrival is *blocked* in the sense that *all* arrivals do get served. It is only a question of being served immediately on arrival or having to first enter the queue for some time $T > 0$. Thus when one refers to blocking probability in the Erlang C model, one refers to the probability that an arbitrary arrival has to enter the queue, and thus be subjected to some delay, before being served. By the way, this is also the reason why this model is often referred to as *blocked-calls delayed model*.
5. A natural and important question arises from consideration of paragraph 4. Not only is the "blocking probability" important; probability of the

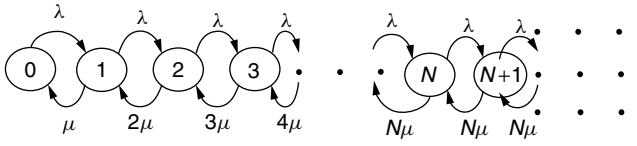

Figure 10. State-transition diagram: Erlang C model.

[7] Recall that the convention is that if a numeric field is absent it is assumed to be infinity. Thus we are making the explicit assumption that the waiting room is infinite.

delay exceeding some threshold may be even more important and critical. Thus we need to quantify the delay distribution, namely, the probability that the waiting time T exceeds some value t, $P(T > t)$. In what follows we show both the probability of finding the system full (blocking probability, or queueing probability) as well as the distribution of the delay. Which of these two expressions is *the* Erlang C formula is somewhat unclear. Some authors refer to one of these expressions — others, to the other one of these expressions — as being the Erlang C formula.

Application of the flow conservation equations reveals that the steady-state probabilities P_k, if they exist, must satisfy

$$P_k = \begin{cases} P_0 \dfrac{A^k}{k!} & \text{if } k \le N \\ P_0 \dfrac{A^k N^{N-k}}{N!} & \text{if } k > N \end{cases}$$

The normalization step requires that the infinite sum of probabilities be summable to 1; in particular, it must converge. As is easy to see, the infinite sum converges if and only if $A < N$. Indeed, from here on we will assume that the load A satisfies $A < N$, that is, that there exists a steady-state solution. While the mathematics forces us directly into making that assumption, it is worthwhile contemplating the practical aspects of this requirement. What would happen if $A > N$? After all, the offered load is whatever it is, and there is no reason why it could not be greater than the number of channels. The answer is strikingly simple — the system never reaches steady state, and thus it becomes unstable. The state-transition diagram of Fig. 10 is helpful in understanding what happens in that case. Recall that we can consider the flows as a "tendency" toward certain states. $A > N$ is equivalent to $\lambda > \mu N$. Note that the arrival rate λ, tends to "push" the system into the higher states. On the other hand, the service rate μ tends to push it into the lower states. In steady state ($\lambda < \mu N$) there is a balance of sorts; the systems drifts up and down and reaches all states, each one with a given probability, precisely the steady state probability of the given state. If, on the other hand, λ is large enough, then μ looses the battle, and the drifting toward the higher states is overwhelming. In such a case, the queue builds up without bound, and every arrival is assured of finding the system full — indeed, the queue is growing without bound as time evolves. The only way to stabilize the system is to reduce the offered load. (or, of course, increase the number of servers N).

Finally, one can show that as long as the system is stable ($A < N$), the complimentary cdf of the waiting time T is given by

$$P(T > t) = \frac{NB(A,N)}{N - A[1 - B(A,N)]} e^{-t\mu(N-A)}$$

where A = offered load
N = number of channels (and recall $N > A$)
μ = service rate (i.e., $1/\mu$ is the average holding time)
$B(A,N)$ = Erlang B blocking for offered load A and system of N channels

It follows trivially that the "Erlang C blocking probability," or as it is sometimes called, the "queueing probability," is given by

$$P_Q(A,N) = P(T > 0) = \frac{NB(A,N)}{N - A[1 - B(A,N)]}$$

Note that it is a simple algebra problem to show that $P_Q(A,N) > B(A,N)$ for all values of A and N. Although this is true, one should be aware of the discussion earlier regarding the direct comparison of these probabilities. Also, depending on the author, either of these two formulas is referred to as the *Erlang C formula*. Since the second one is a special case of the first one, it is the preference of some to refer to the first of these formulas as the Erlang C formula, but the terminology is by no means consistently used.

Note that, technically speaking, if $A < N$ is violated, nothing can be said, since the system is unstable. However, it is often stated that if $A > N$, the blocking probability is 1, thus, in that case, effectively all arrivals enter the queue. In any case, one should also note that as A approaches N, the waiting time grows without bound.

What is the capacity of such a system, operating in accordance with the Erlang C model? Recall that in the Erlang B model, capacity is defined as the maximum offered load that can be sustained at a given blocking probability. Thus, referring to Table 1, a system of 20 channels in which the maximum blocking probability is 2% has capacity of 13.2 erlangs. If the acceptable blocking probability were to be 5%, then the system capacity would be increased to 15.2 erlangs. Capacity is intimately tied to performance. What is the corresponding performance metric in the Erlang C case? Unfortunately, the answer is not as clear-cut. Just as there is some confusion about which formula is *the* Erlang C formula, there is plenty of confusion what performance objectives one should adopt. Some opt to just require that the blocking probability be no more than some value, say, 2%. Others require that some delay threshold be met most of the time; for instance the probability that the delay exceeds $\frac{1}{2}$ normalized units[8] be no more than 2%. As was the case with the Erlang B model, the more relaxed performance requirements we pose, the more capacity the system has. However, if one examines the Erlang C formula a little closer, one will observe that as the delay objective is relaxed from 0 to some positive value, the capacity increases rather sharply. But then, as the delay requirement is relaxed further, the marginal capacity improvement is small. Conversely, one could make the observation that at some point, even small increases of the load, result in large increases in the delay threshold, for a given probability of exceeding that threshold.

[8] Rather than using seconds, minutes, or whatever unit of time one might find convenient in a given situation, the uniformly most convenient unit is one that is normalized to the average service time. Thus a normalized delay of $\frac{1}{2}$ simply refers to the fact that the wait time is $\frac{1}{2}$ of the average service time. Clearly, such a unit is dimensionless.

Table 2. The Erlang *C* Table

Number of Channels	Offered Load	Blocking Probability (%) for Erlang *B*	Blocking Probability (%) for Poisson	Blocking Probability (%) for Erlang *C*
5	2.5	6.97	10.88	13.04
	3.0	11.01	18.47	23.62
	3.5	15.41	27.46	37.78
	4.0	19.91	37.12	55.41
	4.5	24.30	46.79	76.25
	5.0	28.49	55.95	100.00
	5.5	32.41	64.25	100.00
	6.0	36.04	71.49	100.00
10	5.0	1.84	3.18	3.61
	6.0	4.31	8.39	10.13
	7.0	7.87	16.95	22.17
	8.0	12.17	28.34	40.92
	9.0	16.80	41.26	66.87
	10.0	21.46	54.21	100.00
	11.0	25.96	65.95	100.00
	12.0	30.19	75.76	100.00
20	10.0	0.19	0.35	0.37
	12.0	0.98	2.13	2.41
	14.0	3.00	7.65	9.36
	16.0	6.44	18.78	25.61
	18.0	10.92	34.91	55.08
	20.0	15.89	52.97	100.00
	22.0	20.90	69.40	100.00
	24.0	25.71	81.97	100.00

For the sake of an example, we have tabulated a small portion of the "Erlang *C* table" in Table 2. Note that once again, table lookup was a shortcut when the numerical calculations were not readily available. As is easily seen today one could easily make the calculations, even in a basic spreadsheet, so the need for a table is obsolete.

As noted earlier, the Erlang *B* and the Erlang *C* models are diametrically opposite; one assumes that the blocked user waits no time, the other model assume that such a blocked user is willing to wait an unbounded amount of time. Clearly, from a practical perspective, we'd like an "in between" modeling approach. Indeed the Poisson model, examined next, is precisely that.

3.6. The Poisson Model and Blocked Calls Held

This is the $M/M/\infty$ model. It assumes an infinite waiting room, as in the Erlang *C* model, but it assumes that arrivals that have entered the queue can depart unserved. Before we proceed, the reader should be alerted that the term "Poisson model" can be misleading. As Poisson was very prolific, many things have been named after him possibly causing confusion! In all three models, we should remind ourselves, it is assumed that arrivals occur according to a Poisson process. This assumption is no more or no less true in the Poisson model. In many ways, it would have been much simpler if this had been termed the "Erlang *D*" model, but such is not the case! Or maybe the "Erlang *H* model," *H* for *held*, as this is also referred to the situation where blocked calls are "held" until a server becomes available, or they give up and depart unserved. Had we picked such a terminology, it would be clearer that all models make the same fundamental assumptions. They differ only as to how a blocked call is handled. Be that as it may, the acceptable terminology is "Poisson model" and we are not about to try to change that.

However, we have not completely specified the model as yet. What is the statistical nature of the waiting time? In other words, what assumptions does the Poisson model make about the willingness of blocked customers to wait in the queue for service? Indeed, that is a critical component of the Poisson model. Recall that in all models, it is assumed that the service time distribution is the exponential distribution with some parameter μ. The Poisson model assumes that the waiting time has the same exponential distribution as the underlying service time. Intuitively speaking, the Poisson model assumes that if a given arrival were to keep the channel for a certain amount of time t drawn from the exponential distribution with mean $1/\mu$, the amount of time that the customer would be willing to wait in the queue for service would be drawn from the same distribution. Of course, once the service begins, it all "starts fresh" and the holding time is whatever it is.[9]

Since any customer, whether in service or not, is allowed to depart, the departure rates are not quite the same as they were in the Erlang *C* model. They are shown as part of the state-transition diagram shown in Fig. 11.

As before, one can estimate the steady-state probability distribution. From that we obtain the blocking probability,

[9] This is not as strange as one might think. Actually, it is a direct consequence of the memoryless property of the exponential distribution, which itself is somewhat counterintuitive, until one develops a deeper understanding of the exponential distribution. The interested reader is referred to good books on probability theory [e.g., 1,4].

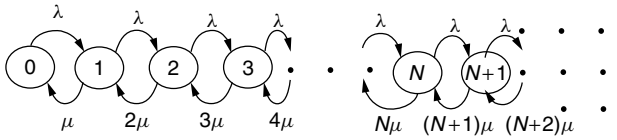

Figure 11. State-transition diagram: Poisson model.

that is, the probability that the system will be found full by an arbitrary arrival and thus it has to enter the queue:

$$P(\text{system full}) = 1 - e^{-A} \sum_{n=0}^{N-1} \frac{A^n}{n!}$$

Note that this is valid, that is, the infinite sum converges, for all values of offered load A. Unlike in the Erlang C case, we do not need to make the assumption of the load being $A < N$. Why is this so? From a mathematical perspective the answer is trivial — the infinite sum of steady-state probabilities converges, regardless of A. From a practical/intuitive perspective, the fact that departures occur with progressively higher rates as the system finds itself in the higher states, creates a stabilization force of sorts. Indeed, if we compare the state-transition diagrams of the Erlang C and the Poisson models (Fig. 10 and 11), we see that their fundamental difference was that the departure rate was the same (μN) for all states k after state N for the Erlang C model, whereas in the Poisson model the rates continue to increase indefinitely; specifically, for sate k, the rate is μk, for all values of k.[10]

As was the case with the Erlang C model, there is a semantic difficulty with respect to the term "blocking probability," but there is an even more pronounced difficulty here. Whereas in both the Erlang B and the C models there are two "classes of citizens," here there are three. Indeed, on arrival, here are the set of possibilities:

- Erlang B model
  - The call is served immediately and departs after its service is completed.
  - The call departs immediately, without being served (blocked calls).
- Erlang C model
  - The call is served immediately and departs after its service is completed.
  - The call first enters a queue, waits as long as necessary and then is served, leaving the system when service is completed (blocked calls).
- Poisson model
  - The call is served immediately and departs after its service is completed.
  - The call first enters a queue, waits for some time and departs unserved.
  - The call enters a queue, waits for some time and a server becomes available, at which time it starts its service. It departs on completion of its service.

[10] One might also note that there were no such considerations in the Erlang B model, as the state space there is finite, so there are no convergence issues.

Although it is clear that unserved calls should be counted as "blocked calls," what about those that had to wait but eventually were served? There are rational arguments that one can make for counting those calls with either the "blocked" ones or the complement, that is, the nonblocked ones. Which of these arguments may be more persuasive is irrelevant! The Poisson model allows us to (relatively easily) find the probability that the system is full and anything above and beyond that can get rather difficult. As such, the blocking probability refers to the probability that an arbitrary arrival finds the system full, thus has to enter the queue. What fraction of these "blocked" calls eventually is served is not part of the modeling question under consideration! Thus one ought to be careful, when interpreting data, that the statement that the blocking probability is 5% in fact implies that 95% of the calls were served immediately on their arrival and some fraction of the 5% were also served, but we do not know how big of small that fraction may be.

Although the term "blocking probability" has a different interpretation in each of the three models, we often find it convenient to compare the results. See Table 2 for such a comparison. Indeed, it is easy to see that the intuitive placement of the Poisson model as "in between"; the Erlang B Erlang C differentiation makes sense. From a practical perspective, we can make an even stronger statement. In practice, it is very unlikely that either extreme occurs. Namely, it is not likely that:

- Arrivals wait for no time at all. In fact, some systems provide for explicit queues, but even if no such queueing capability is explicitly provided for, customers tend to "redial," or try again in some way, thus creating somewhat of a virtual queue.[11]
- Arrivals that find the system full, "wait forever," that is, an unbounded amount of time.

Indeed, assuming some waiting time is a reasonable modeling assumption. Assuming whether the specific distribution of the Poisson model is the right one or not is almost irrelevant. If for no other reason, it is rarely the case that we have a high confidence in our assumptions as to customer behavior. Thus it is unlikely that our model will be an accurate one to start with.

Given the points outlined above, what is one to do? Very simply, if one looks at these three models as simply three data points in a continuum of possibilities, one can get a lot of insight into the problem. Indeed, in an intuitive sense, system performance is a continuous function of the waiting-time distribution. Thus by making certain assumptions about the waiting time distribution, one can check the predicted performance versus what one

[11] It is important to note that unlike in Erlang C, this virtual queue is not served in a FIFO manner. The most appropriate model for this type of situation is *random service order* (RSO); the Erlang C delay distribution needs to be modified to account for this. However, as it turns out, the probability of the system being full is the same, so we can use the Erlang C results for the blocking probability, even on this case where the service discipline is not FIFO.

is measuring in a real situation and use that information in a feedback loop to better calibrate the model of the problem at hand.

Thus it is often unreasonable to ask "Which model is the best?" More often than not, it is the case that we need to understand all these models and see which one best describes the underlying dynamics of the problem at hand.

4. OTHER RELATED TOPICS

A number of problems and applications emerge from the fundamental concepts presented thus far. They are far reaching and their fair treatment is not possible in this article. However, we will briefly discuss some of them.

4.1. Random-Access Protocols

In "conventional" traffic engineering, it is assumed that the need for a channel is made known to the system by some other means. For example, in traditional telephony, when one picks up the telephone receiver, a dial tone is allocated, which in effect activates the existing line between the telephone and the central office. The traffic engineering problem in its core concentrates on whether a line between your central office and that of the called party exists. The lines to/from one's telephone are "always" there, waiting to be activated by the dial tone or by the incoming call. The need for a channel between points A and B is known to the system by the dialed digits. In many other applications, however, the need for a channel is not known by any such external mechanism. A good example is found in the exploding area of mobile communications, even though the problem had been identified much earlier within the domain of computer networks. The terms used might be different but the underlying concepts are identical. For instance, in Fig. 12, a "central entity," labeled node A, is "in charge" of the system. It may be a base station in a mobile communications network or a host computer in a data network. It allocates idle channels to entities that request one. These entities may be mobile or peripheral devices, such as terminals, printers, or card readers — this does go back to the days of punchcard readers! The problem is very simple to state: how does the base station (node A) become aware of the need for a channel by the mobile units?[12] Note that any "central control" is precluded as they are impractical and are made possible only with unacceptably high overhead. Thus we are forced into what are called *random-access protocols*. Each mobile transmits whenever it feels like! As a moment's reflection makes clear, such transmissions are subject to collisions, as they must use the same mechanism for accessing the base station. These protocols were first analyzed in 1970 by N. Abramson of the University of Hawaii, and the simplest of a family of such protocols is called ALOHA, appropriately enough. The interested reader is referred to Rom and Sidi's study [9] for more detailed analysis and discussion of these problems. Here we present some of the most basic ideas.

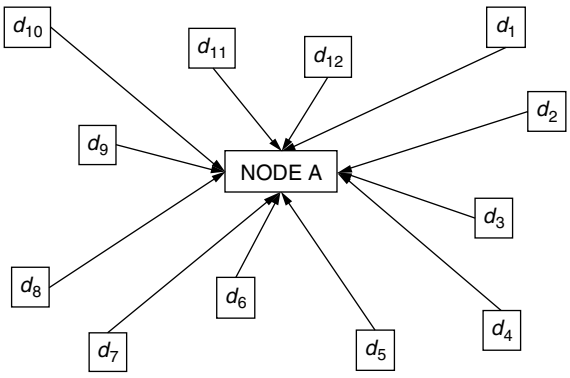

Figure 12. Abstract representation of a base station in a mobile communications network.

In the ALOHA protocol, each mobile would, quite literally, transmit whenever it feels like transmitting. The base station is assumed to receive the information successfully if and only if there is only one ongoing transmission. Any overlap of two (or more) transmissions renders all of them worthless, as even partially received data are ultimately discarded as being corrupted. The fundamental question is then *not* how many channels are available, but what is the throughput of such a system. Throughput is defined as the fraction of time that the channel is used successfully. Idle time and time spent in a colliding state count against throughput. As one can readily conjecture, the throughput of such systems is not great. If the offered load is low, most time is spent in the idle mode. As traffic increases, more collisions occur, thus more of the time is spent in the colliding state, leaving a small fraction for success! Thus the graph of Fig. 13, showing the throughput as a function of offered load, makes intuitive sense. We will return to this graph momentarily.

However, quantifying this intuitively obvious result is not trivial. We will only make some key observations here. The concept of "load" must be defined differently for this class of traffic-engineering-related problems. It should be obvious that holding time is irrelevant. What matters is the number of attempts being made per unit time. It has become common practice in these problems to normalize

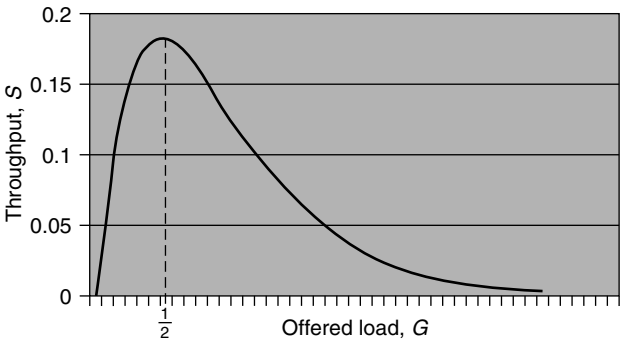

Figure 13. Throughput, S, versus offered load, G, in the ALOHA system.

[12] We will word the rest of this discussion within the framework of a hypothetical mobile communications network, as this simplifies the discussion and reflects the growing area of mobile communications.

the unit time to the average length of the transmission. Owing to the birthplace of these problems in packet switching, this is often called "packet time." Thus one talks about arrivals per packet time. Further, since the transmission is often "a packet" the arrival rate is often referred to as G packets per packet time, or G arrivals per packet time. Clearly, if the world were perfect and ultimate control and coordination were possible, the maximum value of G would be $G = 1$. In such a hypothetical case, the coordinating process would ensure that there were no collisions and that time was constantly utilized for the successful transmission of arriving packets, resulting in a throughput, S, having the ideal value of $S = 1$. Clearly this is not the case, as we realistically have to account for collisions.

Whatever the arrival rate is, collisions will occur. Furthermore, it is common to assume that arrivals form a Poisson process with rate G arrivals per packet time. What happens to colliding arrivals? Once again, the usual models assume that such arrivals are retransmitted at some future instance in time. Note that this creates an instability in the system. Colliding attempts appear at a later time, increasing the probability of future collisions, thus the need for additional transmissions, thus higher probability of collisions, and so on. This is a classic example of positive feedback, thus unstable behavior. If a system reaches such a state, then from a practical perspective it has simply collapsed. Naturally, such catastrophic events must be prevented from occurring. We will return to this subject momentarily.

Under a number of technical conditions, one can show that the throughput is expressed as a function of the offered load by

$$S = Ge^{-2G}$$

This expression is graphed in Fig. 13. However, this simple relationship can be misleading, so we need to clarify a few points:

1. As one can see by elementary calculus, it appears that the maximum throughput is $1/(2e)$, or about 18% and it occurs when $G = 0.5$ arrivals/packet time.
2. However, as G approaches 0.5 from below, the delay, D, associated with retransmissions that have been necessitated approaches infinity. The exact relationship of delay to the offered load G is too complex, requires a number of assumptions and is beyond the scope here. What is important to recognize is that regardless of the specific details, the delay does tend to infinity. Thus from a realistic perspective, one needs to back away to values of G below 0.5.
3. The region of the graph for which $G > 0.5$ is somewhat misleading. If G exceeds 0.5, the system is unstable. If G were to be larger than 0.5, it would drift to infinity as a result of retransmissions, the collisions would dominate, and the throughput would tend to 0, that is, the system would collapse. As a result, authors often refer to the region of $G > 0.5$ as being an "unstable region."
4. While this is correct, it often is interpreted as meaning that the region $G < 0.5$ as being "stable." Unfortunately, this is not the case, in the strict sense of the word "stable." Once again, under a broad set of technical assumptions, sooner or later any system will go unstable, for any value of $G > 0$.[13] However, the amount of time it will take the system to "exit" this so-called "stable region" and enter the doomed instabilities increases rapidly with the distance $0.5 - G$ [for G in the range (0,0.5)], that is, as we back away from $G = 0.5$.[14]
5. One is then entitled to pose the reasonable question of what is the highest value that G should be allowed to be. While this question has a number of interesting theoretical components [e.g., 9], no firm practical answers are agreed to by the practitioners of the trade! Apparently, it is more of a question of how much risk and what kind of safety valves have been put in place than anything else. Conservative designers want to keep G below about 0.1. More risk taking (with appropriate safety mechanisms in place, one would assume) would allow one to be at about $G = 0.2$. However, these values are debatable, subject to a number of conditions, thus should be treated as a rule of thumb rather than precise guidelines! Finally, one sees that at $G = 0.2$, $S = 0.13$, thus one often also talks about the throughout S as being no more than some value in the range of 0.1–0.2.

In conclusion, we see that the throughout of such channels operating in the ALOHA mode is quite small. One way to improve it is slotted ALOHA. In such systems, time is organized into "slots," as shown in Fig. 14. Any mobile station that at time $t = t_0$ decides that it wants to transmit, must wait until the beginning of the next slot. Clearly, collisions are still possible, though less likely, as the "vulnerability period" is cut in half, from two packet transmission times to one packet transmission time. As a result, the offered load–throughput relationship is changed to

$$S = Ge^{-G}$$

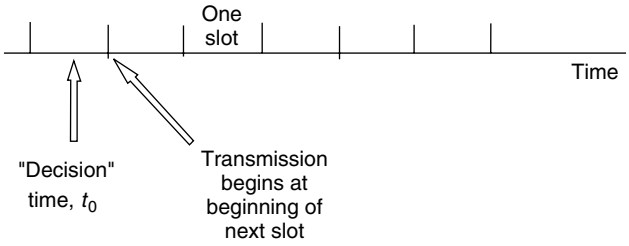

Figure 14. "Slotting" of time for Slotted ALOHA.

[13] Mathematically, the point $G = 0$ is stable, but from a practical perspective this is a useless piece of information. It simply states that a system which has no traffic is stable!

[14] Under certain conditions, this time increases exponentially with the amount by which G is less than 0.5.

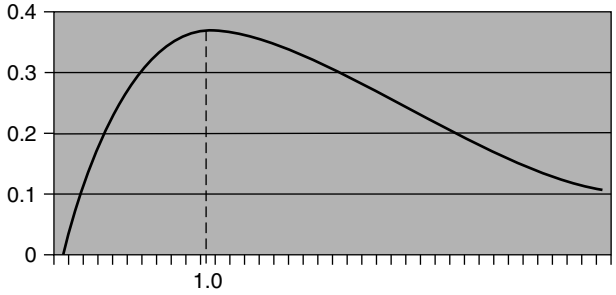

Figure 15. Throughput, S, versus offered load, G, in the Slotted ALOHA system.

This is plotted in Fig. 15. As we can see, this is very reminiscent of the behavior of the ALOHA system, except that the maximum occurs when $G = 1$ and it is $1/e$ or about 36%. While this is double of what it is in the ALOHA case, the entire discussion of the ALOHA system issues, relating to stability, delays, and other factors carries over here as well. Once again, there is no uniform agreement on what acceptable values of G (and thus of S) are, but it is certain that they are higher than in the ALOHA case. This increase in utilization comes at the expense of needing to maintain synchronization information. Whereas in some systems synchronization is necessary because of a number of other independent issues (and thus the incremental cost is virtually zero), in other systems, this additional requirement of synchronization may be prohibitive and the increased throughput may not justify the additional complexity and cost. Indeed, these are some of the problems that both theoretical and applied research addresses in specific situations.

4.2. Network Design

The concepts presented here form the basis for analyzing more realistic systems, such as large networks, consisting of nodes and links joining these nodes. These links have varying capacities, and calls can be routed trough such networks according to a number of algorithms. While space and scope limitations do not allow us to diverge into these topics, the interested reader will find the topic of network design discussed in a number of references [e.g., 3,6,7,10]. In particular, Ash has discussed the problems related to routing algorithms in circuit-switched networks in detail [3]. Similarly, Bertsekas and Gallager have discussed the problem of routing and capacity assignments in packet-switched networks [10].

In a network environment, where routing decisions are influenced by the state of the system, what might originally be Poisson traffic can be offered to various resources as non-Poisson traffic. The traffic engineering problem then increases in complexity and a number of approximate techniques can be used. Both from the theoretical and the practical perspective, these problems become quite complex and there are excellent treatments of these problems in the literature [3–5,7,8].

5. CONCLUSION

In summary, we note that traffic engineering involves a fair amount of mathematical detail that, if not accounted for, may lead to significant errors in the analysis and design of networks. Allocation of resources thus becomes a multidisciplinary problem involving many aspects of engineering, economics, and social behavior, to mention only a few.

Although the problem is quite easy to state in its most elementary form, the solutions to the real problems in a networked environment become quite more complex. Furthermore, the random-access problem, albeit originally a traffic engineering problem, presents us with quite a different set of challenges and ways of looking at a problem.

BIOGRAPHY

Apostolos K. Kakaes received his B.S. and M.S. degrees in applied mathematics with a minor in electrical engineering in 1978 and 1980, respectively, from the University of Colorado. He received a Ph.D. degree in EE from the Polytechnic University in 1987. He had joined AT&T Bell Laboratories in 1980, where he stayed until 1987 working on traffic engineering and network design in both circuit and packet switched networks. In 1987, he joined the faculty of the Department of Electrical Engineering and Computer Science of the George Washington University where his interests in both the physical layer issues and networking problems lead him to work on wireless networks. In 1996, he founded and has since been running Cosmos Communications Consulting, an independent consulting company specializing in mobile communications.

He has published, conducted IEEE tutorials, and lectured extensively around the world in all aspects of both fixed and mobile communications, including traffic engineering issues in current as well as emerging high-speed fixed and mobile communications networks.

1. INTRODUCTION

Intelligent transportation systems (ITSs) have been investigated for many years in Europe, North America, and Japan, with the aim to provide new technologies capable of improving the safety and efficiency of road transport [1–5]. In this context several technologies and applications have been investigated and demonstrated with reference to onboard communication networks, and short- and long-range communication systems [6].

Going back to the evolution of guidance support, the first efforts date back several decades (from the time of writing) and were essentially aimed at diffusing traffic information by means of road signs and FM broadcasting. An amazingly significant step in the direction of improving transport safety, featured the adoption of a millimeter-wave radar sensor installed in the front grille of vehicles in order to promptly detect obstacles and to warn drivers when they reach an unsafe distance. This technology has been improved and adopted by several car manufacturers that integrated the radar with an onboard cruise control [7]. This solution offers the possibility, for instance, to automatically maintain an optimal following distance behind cars traveling ahead, thus reducing the risk of collisions as well as the burden on the driver during long trips.

However, as soon as the first ITS systems were implemented, it was clear that their effectiveness would be greatly improved by the possibility to establish a bidirectional communication link between the different entities (cars, pedestrians, ITS service providers, etc.) acting in the road transport scenario. In this regard, the communication-based systems can play a fundamental role in the context of ITS, since they can overcome the main limitations of self-sufficient systems (those relying on passive sensors, radars, videocameras, etc.) that are solely based on the unilateral perception of the environment surrounding the vehicle. To provide advanced ITS services, localization systems will also be suitably exploited in conjunction with mobile communications.

Different technologies were investigated in Europe at the beginning of the ITS research activity, during the 1980s: infrared communications, millimeter-wave communications, and mobile radio. The first two appeared to be the most interesting at that time, and were oriented to the implementation of short-range mobile communication networks, whereas since the early 1990s, some projects have developed the concept of using cellular radio for providing ITS services [e.g., 8]; it is to be pointed out that, at that time, only second-generation (2G) systems were available, such as the Global System for Mobile communications (GSM), characterized by a limited ability to provide advanced data services with high quality levels and flexibility.

In the near future third-generation (3G) systems should be available, enabling advanced data services to be provided to mobile users in the 2000-MHz frequency band, in both Japan, where they have been under development, and Europe, where their introduction is planned for the year 2003 [9]; these systems will be able to provide different bit rates [$\leq$2 Mbps (megabits per second)], different levels of quality of service (QoS), and much more flexibility than that offered by 2G networks.

However, the evolution from 2G to 3G systems will not be sharp, and is based on the implementation of some 2.5G solutions, such as the GPRS (General Packet Radio Service) in Europe, providing intermediate bit rates (up to $\sim$100 kbps) in the GSM band (900 and 1800 MHz), based on packet-oriented techniques and flexible operating modes. Therefore, GPRS is thought to be a suitable candidate to offer services to the ITS context, too.

The increasing interest on wireless personal-area networks (WPANs) and the consequent penetration of low-cost portable devices equipped with the emerging Bluetooth technology [10], has suggested the possibility of adopting WPAN devices for the provision of short-range ITS services as well.

In this article, following a brief introduction to the typical ITS services, we first show some of the results of the research carried out in Italy and Japan concerning the role of communications in ITS; then we discuss the suitability of 2.5G and 3G systems and Bluetooth for ITS applications.

2. ITS SERVICES

The ITS services based on communication devices rely, essentially, on three kinds of techniques: *roadside-to-vehicle communication* (RVC), based on the use of an infrastructure network covering the service area, intervehicle communication (IVC), establishing a direct communication link among automobiles, and target-to-vehicle communication (TVC), based on proper active devices mounted on vehicles with the aim of detecting the presence of the unprotected road user (the target, hereafter) through suitable communication interfaces. Hereafter we provide a synthetic overview of the services that can be provided by the systems described above.

Although sometimes at an early stage, RVC based services have already been introduced in Europe, Japan, and the United States; we can mention, for example, the following applications:

- *Automatic tolling*, probably nowadays the communication-based ITS service most widely used by road users; it proved to be amazingly effective in reducing traffic congestion and improving driver convenience by cashless payment. It is based on RVC techniques.
- The *services for guidance support*, providing the user with information related to traffic, weather

conditions, and so on; they are still at a very early stage of development, and in many cases are based on traditional techniques such as road signs or broadcasting through FM stations (RVC techniques).

- The *services for traffic control*, based on the joint concepts of navigation and communication (RVC techniques).

Still based on RVC systems and not yet introduced, the *services for driving safety* should play a very important role in the future, providing the driver with real-time information concerning possible emergency situations such as those due to fog (banks), traffic accidents, or road hazards. These services are the most difficult to provide because of the stringent requirements of the application; this is the case, for instance, of the "emergency warning" service, which should be based on the possibility to inform all the vehicles in the vicinity of a dangerous situation within a short amount of time from its occurrence, and this requires a prompt system response. Consequently the introduction of such services is still seen as a long-term goal; nevertheless, we show the suitability of GPRS for this application, even if with limitations on the system response promptness.

A significant step in the evolution of ITS should be the introduction of the *cooperative driving* service, which belongs to the class of *services for driving safety* and is based on IVC systems. It consists in forming groups (platoons) of vehicles exchanging data on their status (speed, acceleration, position, etc.) in order to improve the safety and efficiency of the vehicles flow by keeping the intervehicle distances under control in all situations (sudden change of speed, position, etc.). The data exchanged among the cooperating vehicles can be processed by automatic agents and used to control the onboard actuators (brakes, etc.), or presented to the driver through suitable (e.g., vocal) interfaces. Each vehicle of the platoon must be equipped with a communication device, and direct intervehicle communication (IVC) is the only way to provide the requested promptness.

TVC-based services are finally a challenging issue for researchers since the communication link involves pedestrians, cyclists, and others whose communication devices have to be lightweight, small, low-power-consuming, and, possibly, cheap; by means of TVC systems it will be possible to prevent car accidents involving pedestrians and cyclists by means of onboard warning devices. In Europe PROTECTOR, an ITS project, developed research in this area.

3. WIRELESS STANDARDS FOR ITS: DEDICATED SOLUTIONS

3.1. Past Activities

Since the early 1980s remarkable research activity has been carried out in the United States within the context of ITS. One of the most important actors in this scenario is the Californian PATH [11], a joint venture of the University of California, the California Department of Transportation (CALTRANS), and private industry, established in 1986 to develop more efficient transit and highway systems. The goal of PATH is to increase the capacity of the busiest highways and to decrease traffic congestion, air pollution, accident rates, and fuel consumption and to perform field operational tests.

PATH participation in U.S. DoT (Federal Department of Transportation) ITS programs includes several projects within the Intelligent Vehicle Initiative (IVI) program [12], developing research in the fields of

- Sensor-friendly vehicle and roadway systems
- Forward-collision warning systems
- Rear-collision warning systems
- Automotive collision avoidance systems (ACASs)

In Europe and Japan some major research programs (e.g. DRIVE, PROMETHEUS, VASCO) in Europe, AHS and JSK programs in Japan [13–23] have been involved in the definition and testing of telecommunication systems for the field of road transportation, such as systems for automatic tolling, fleet management, traffic control, and cooperative driving; most of them were based on dedicated solutions, explicitly designed for ITS applications. Suitable frequency allocations have been proposed in order to avoid more congested bands. On the other hand, in some cases this represents an obstacle to the introduction of these systems, due to the initial high costs of dedicated solutions when entering the mass market.

For both IVC and the RVC systems, the 60–64-GHz band was chosen among the possible candidates within the DRIVE and PROMETHEUS projects in Europe for reasons related to the size of RF devices, the amount of available bandwidth, and the advantages provided by oxygen absorption, which causes spatial filtering and frequent channel reuse, suitable for short-range systems such as those based on IVC.

The results of all these programs were based on dedicated radio interfaces; we leave the interested reader to refer to the literature [13–23]. In the following we simply provide, as a synthetic view, an example of the results obtained within the TELCO project (1995–1997), which was funded in Italy by Consiglio Nazionale delle Ricerche, after the conclusion of PROMETHEUS with the aim of investigating on the possible use of the millimeter-wave band, and we mention some of the experimental test beds realized in Japan.

3.1.1. RVC at 60–64 GHz: Research in Italy. The 60–64-GHz band is characterized by a peak of oxygen absorption. To highlight the main features of the use of this band, let's consider a simple monodimensional scenario, in urban context, with beacons serving the area and separated by a distance $2R$ [18]. The multiple-access method employed is TDMA. Let's denote by N and Br the channel reuse factor and the overall bit rate, respectively. Figure 1 shows the outage probability, for a given transmission system, as a function of the cell radius with the reuse factor and the bit rate as parameters. The *outage probability* is defined as the probability that the signal-to-noise and the signal-to-interference ratios are

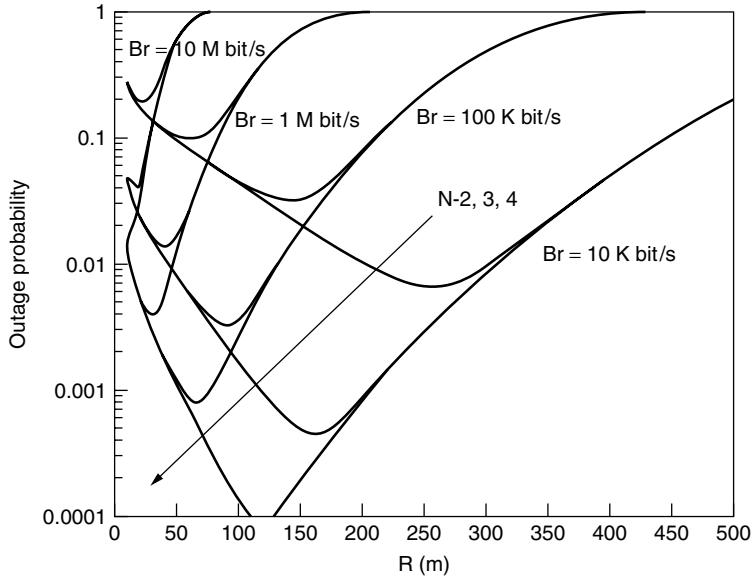

Figure 1. The outage probability as a function of the cell radius, with the reuse factor and the bit rate as parameters (© IEEE, 2000).

below specified thresholds that are defined as functions of the transmission techniques implemented. A noncoherent MSK unprotected system is considered here, as a simple reference, and omnidirectional antennas are assumed. The figure shows that a minimum outage probability is obtained for a given value of R, as a compromise between the effects of noise and interference. This is typical of the 60–64-GHz band, due to the effects of oxygen absorption: no optimum value of R would be found in a frequency band unaffected by the additional attenuation due to oxygen, or rain. As can be expected the optimum outage probability decreases when N increases or Br decreases. It is also interesting to note that, with the system parameters chosen, the values of R are $\sim$100–250 ms, thus giving a large number of beacons per kilometer and suggesting the implementation of these systems in urban areas where the number of users can be large. Suitable scaling of the bit rates and of the optimum cell size can be obtained by employing more sophisticated transmission techniques, directional antennas, or other means. In any case, the typical cell size remains below 1 km.

3.1.2. IVC at 60–64 GHz: Research in Italy. The advantages of using the 60-GHz band for IVC have been shown in several studies [13,15,17,19,20], and the results of these studies provided the design of suitable multiple-access techniques for cooperative driving applications. We let the interested reader refer to these papers.

3.1.3. IVC Experiments in Japan. In Japan, JSK carried out some IVC experiments based on infrared technology in 1996, and some new experiments were performed during the year 2000 at 5.8 GHz. The AHS project is now extending its research studies from RVC to road sensing; the RVC frequency should be more than 5 GHz due to the lack of frequency bands at lower frequencies. Road sensing uses infrared, 60-, and 90-GHz technologies.

Infrared technology was initially selected among all candidates for IVC, for economical and practical reasons, in spite of its weather-dependent characteristics. JSK carried out an experiment in 1996 to verify the possibility of networking between traveling vehicles, as a preliminary testbed in order to plan a new experiment based on microwave technology [16].

Figure 2 shows the experimental vehicles used, equipped with two infrared radiators separated by a 1-m distance on the roofs, a photodetector, a videocamera, and a processor. The distance between forward and backward vehicles was measured by the videocamera, which could record the images of the two radiators on its CCD film. These radiators not only enabled distance measurement but also sent information to the vehicle behind. The test demonstrated the feasibility of IVC, while pointing out that some features, such as network aspects, deserve thorough consideration [16].

3.1.4. CDMA or TDMA for IVC: Research in Japan. The controversy about CDMA and TDMA in cellular communications in the early 1990s concluded CDMA to be preferred to TDMA for channel capacity reasons and its ability to counteract interference. What about both access methods in IVC? Few research works about this matter have been published. Michael and Nakagawa [21] show that analysis of the interference from oncoming vehicles reveals CDMA to be better than TDMA. Since the main information from each vehicle is related to control data of the vehicle, it is characterized by regular occurrence. Consequently each vehicle should transmit periodic data bursts to other vehicles. The interval of the data bursts should be the same for all vehicles. However, if the data bursts of an

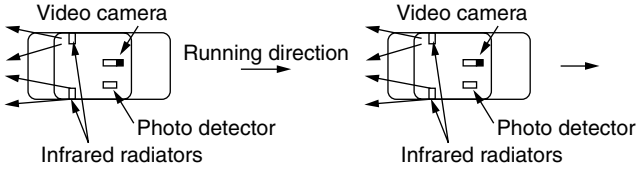

Figure 2. Top view of vehicles in the infrared experiment performed by JSK in Japan in 1996 (© IEEE, 2000).

oncoming vehicle group collide with those of the ongoing vehicle group, the collision is kept for a while and a large amount of data are lost if a TDMA scheme is used. CDMA can save the data from this type of collision; this is the main reason for the selection of CDMA for applications based on IVC. On the other hand, if different carriers were used for communications in the two directions, the problem discussed above would vanish, but this would require a centralized allocation of carriers to the vehicles.

3.1.5. Spread-Spectrum Radar and FM-CW Radar: Research in Japan. FM-CW radar was standardized for a radar system to be mounted on vehicles to detect the presence of other vehicles. When there are a number of vehicles on a road, interference between the radar signals from all the vehicles should be considered. Shiraki et al. [22] show simulation results for the FM-CW radar and spread-spectrum (SS) radar. The SS radar shows much better performance than FM-CW radar as reported in Fig. 3, in terms of signal-to-interference ratio (SIR).

This result also suggests the investigation of the possible integration of radar and communication systems, based on a common frequency band (e.g., the millimeter-wave band) and processing (e.g., SS) techniques.

3.2. Current Activities

A brief overview of the current ITS applications and testbeds is presented in order to explain to the reader which is the state of the art in this field [7].

3.2.1. Services for Guidance Support. The next generation of communication technology for guidance support is being developed behind the steering wheel and, more recently, on the wireless handset. The emerging trend in this field is to offer location-based voice and data communication tools that provide "smart" information, tailored to where the customers are and to what they are doing,

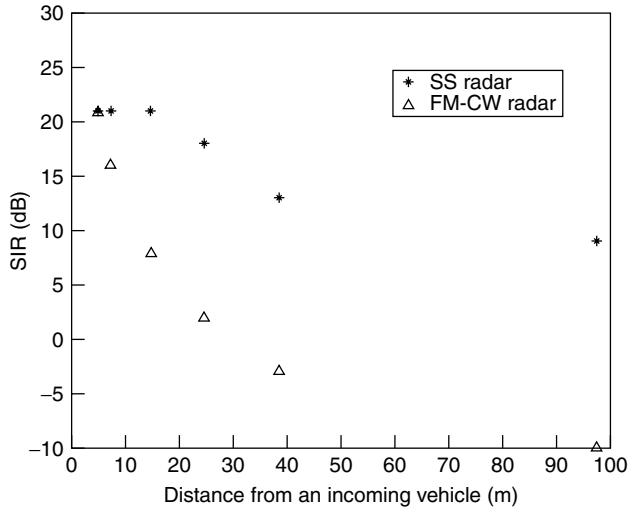

Figure 3. The ratio between the useful received power from the target and the radar interference power received from an oncoming vehicle at the same distance (© IEEE, 2000).

providing enhanced security, navigation, and convenience to mobile consumers.

The adoption of wireless terminals in this currently deeply investigated context is proving to be extremely effective, greatly improving the usefulness of ITS services; in the greater metropolitan Paris area, on the Boulevard périphérique and the Paris city roads, for instance, the time needed to travel the distance between two points is displayed by variable message signs (VMSs). Thanks to portable terminals, this information is available in the car (the terminal can be easily installed) and to people who are not on the road (they can take the terminal along). In this manner route planning is improved by conveying information on travel times before the journey commences.

3.2.2. Automatic Tolling System. The well-known system for Automatic Tolling of the Italian Autostrade S.p.A., namely, Telepass, is the first system in the world for toll collection where drivers do not need to stop at toll stations [7].

3.2.3. Services for Traffic Control. Congestion is steadily worsening on the streets of Europe's cities as more people choose to travel by car. Buses, trams and trains take less space, thus increasing their share of trips can help reduce congestion. Unfortunately, many public transport services get caught in traffic and are reputed for poor reliability. Public transport performance can be improved by better controlling and managing traffic generally. The City of Turin, as an example, has implemented a system — named 5T — that integrates nine ITS subsystems under the co-ordination of a tenth system, the "traffic and transport supervisor," which monitors and controls all the other subsystems. Among the 5T subsystems, public transport vehicle location and urban traffic control subsystems provide priority to public transport vehicles at traffic signals, particularly to those that are running late. Similar priority can be given to emergency service vehicles [7].

3.2.4. Services for Driving Safety. In the case of an accident on the motorway, significant danger is caused by vehicles that block the road (cars involved in the accident, emergency services, a tailback or bottleneck of cars that cannot pass the location). Secondary accidents, which are often more serious than the original one, can be avoided if the accident is detected immediately and the scene of the accident is cordoned off right away. In Germany, an advanced warning system that automatically detects incidents and provides immediate warning to drivers has been proposed. Beacons equipped with a light unit and additional electronics are installed along the emergency lanes.

The beacons are interconnected by cable and linked to a traffic computer center, where an operator views the accident on a computer screen, via an appropriate monitoring interface. The light units can be activated from the control centre, to flash warnings until the police arrive to cordon off the area. The light flashes, initiated within seconds of the accident, warn approaching traffic of problems downstream, and invite the drivers to slow down.

3.2.5. Dedicated Short-Range Communications. Dedicated short-range communications (DSRC) systems aim at providing one-way or two-way high-speed radio links between a fixed roadside unit and onboard equipment: ITS-related information is exchanged within the communication area, made up of the roadside antenna, therefore configuring a RVC system. DSRC systems have been deeply studied in the United States, Europe, Korea, and Japan, and several proposals have been presented so far [24–27]. The various solutions adopt different modulation formats as well as different data rates, ranging from hundreds of kilobits per second to a few megabits per second, and operate in different bands within the microwave region.

4. WIRELESS STANDARDS AND ITS

The abovementioned considerations on the difficult penetration of ITS dedicated systems in the mass market suggested that researchers investigate the possibility of providing ITS services by means of already standardized systems such as the 2.5G [28] and 3G cellular systems as well as Bluetooth [29]. The capability of these standards to offer packet-switched services will be studied in order to show how they can be exploited for the provision of services for driving safety, such as "emergency warning," and for traffic control and guidance support as well.

4.1. A GPRS-Based System for Emergency Warning, Traffic Control, and Guidance Support

GPRS supports packet switched services, based on a radio interface almost identical to that of GSM, at different rates, roughly 9–100 kbps, which can be obtained by assigning multiple GSM slots per frame to the same user. On the other hand, if the user bit rate is very low, GPRS can allocate the radio resource depending on real needs, thus preventing the inefficient use of the radio spectrum and allowing the user to pay for the amount of data actually transferred.

Let's consider a typical European highway trunk, consisting of three plus three lanes, as a reference scenario to describe the system investigated (see Fig. 4). If we assume that the whole trunk is covered by the public GPRS network, we can exploit its capability to support packet-switched services and priority-based scheduling [30].

To provide a prompt "emergency warning" (EW) service, in fact, each vehicle has to establish a connection with the network at the entrance of the trunk, in order to reserve some radio resource units to be used when needed (e.g., if a dangerous situation is monitored by the onboard computer, which also controls airbag deployment, sudden braking, etc); this event is considered to be a very infrequent but significant situation. The connection is relinquished at the output of the trunk. The packet transmission mode controlled by the network should also rely on a suitable scheduling procedure, taking the priority of services into account. In this manner, once the different vehicles have allocated their radio resource units, the system could also support other services characterized by lower priority.

Therefore, we assume that each vehicle has allocated a minimum radio resource every T_{cycle} milliseconds; the minimum radio resource should be given by a RLC (radio-link control) block, which in the GPRS is transmitted over four GSM bursts; with this choice, the packet size (at network level) is around a few hundreds of bits, but this is enough to provide an EW message.

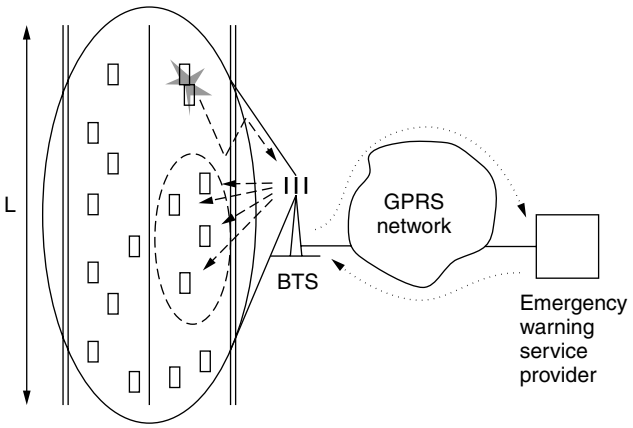

Figure 4. An ITS scenario based on GPRS: the service provider receives the Warning message from a mobile, and sends it to all the vehicles that can be involved in the information, considering the location, speed, and direction of the mobiles, the traffic conditions and the requirements of the application (© IEEE, 2000).

When a packet is generated by a mobile, it is transmitted through the GPRS network to a fixed node (representing the serving entity introduced by the service provider) that retransmits the message in multicast mode to all the vehicles in the vicinity of the source (see Fig. 4). The subset of vehicles to be addressed by the warning message has to be carefully determined taking different aspects into account, such as the speed of mobiles, the traveling direction of the source (it can be assumed that only the vehicles behind that involved in the dangerous event should be warned), and the traffic density; all these data can be known at the service provider if all vehicles periodically inform the network with their locations, speed, and other specifics. Therefore, communication, location and traffic management aspects have to be considered at the centralized node.

The implementation of a centralized control on the network side has the main advantage that the message generated on the vehicle has a fixed destination address; therefore, the determination of the subset of vehicles that should receive the warning message is controlled by the service provider, and this can be efficiently performed if all vehicles periodically inform the network of their locations. On the other hand, this choice implies a double connection, and double transfer delay, so special attention should be paid to this assessment.

The time spent in the network by the packet is subject to the delays introduced by the network entities and the time needed for radio access. The choice of T_{cycle} is of relevance, since it is a measure of the maximum delay that the message can suffer due to the radio access: in any case, the value of T_{cycle} should be small, in order to avoid a large contribution to the overall message delivery delay. On the other hand, the number of vehicles that can be served is proportional to T_{cycle}; hence, T_{cycle} should be

fixed as a tradeoff between the network capacity and the desired promptness.

It is worth noting, however, that the number of vehicles that can be served is also proportional to the number m of GPRS carriers used for the service, hence, having fixed T_{cycle}, the service coverage can be improved increasing the value of m.

Let's assume, in the six lanes of our scenario, an average intervehicle distance, d_{iv}; consequently the number of vehicles present in a trunk of length L served by the same BTS, is given by $N_{\text{veh}} = 6L/d_{\text{iv}}$; let's assume, furthermore, that the percentage of vehicles equipped with the GPRS terminal is 100 k, where k is the penetration factor.

Figure 5 shows the maximum value of the cell size L that is compatible with a traffic of kN_{veh} vehicles as a function of the penetration k; both cases of one and two GPRS carrier(s) are considered, and the intervehicle distance is fixed at 25 m.

Figure 5 shows that, for $m = 1$, at the first stage of service provision (when the penetration is low), cell sizes of around tens of kilometers; that is, the typical cell sizes of the GSM network in suburban environments, can be used, thus allowing the utilization of the existing sites. On the other hand, once the penetration becomes much larger (e.g., $k = 0.25$), new investments should be introduced, either by adding new GPRS carriers or by reducing the cell sizes; however, this would be the case of a very mature service used by millions of users, such as by a successful business.

Finally, it is worth noting that, when no packets with highest priority (i.e., EW packets) have to be transmitted, the radio resources can be dynamically reallocated to other services; therefore, the GPRS carrier(s) is (are) not dedicated to the EW service, since it (they) can be shared by other services having lower priority. For instance, the provision of information concerning traffic and weather conditions (on subscription, or on demand) or the transmission of roadmaps could be offered to the user through the same physical channels. All these services,

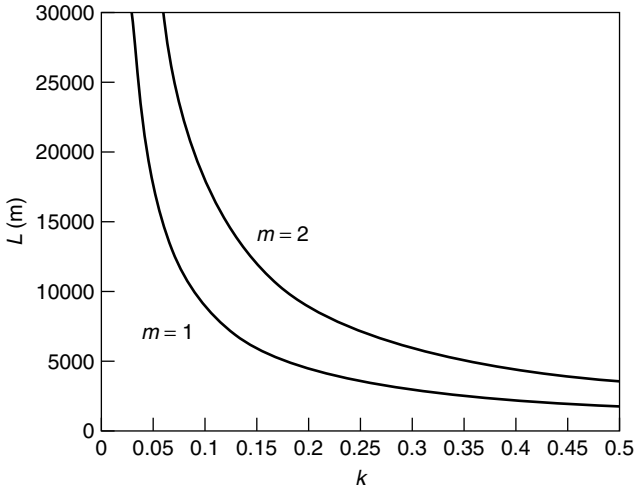

Figure 5. The maximum cell size (having fixed $T_{\text{cycle}} = 500$ ms) as a function of the penetration of users, with $m = 1, 2$ GPRS carriers and for an average intervehicle distance fixed at 25 m (© IEEE, 2000).

together with the selection of vehicles to be included in the multicast group to which the warning message should be delivered, require the knowledge (with different degrees of precision) of the vehicle locations. A mobile terminal can solve the problem of self-localization in a number of ways (through the capabilities of GSM, or through a GPS receiver, etc); in any case, the information concerning the vehicle position should be transmitted periodically to the network and this could be done by means of the allocated radio resource units.

4.2. The Role of 3G Networks

GPRS is expected to become a successful standard in the near future; however, it should only represent an evolutionary path toward more sophisticated systems such as UMTS (Universal Mobile Telecommunication System) [9], the 3G cellular network, which should replace the previous 2G/2.5G systems. It seems reasonable to assume that in many countries the 3G core network will be initially based on, or will also embrace, the GSM/GPRS core network; the main difference compared to the previous standards will be on the air interface, which in 3G systems will rely on CDMA techniques, unlike those for GSM and GPRS. However, the use of multistandard (multimode) terminals will determine a potential integration of the different air interfaces (e.g., GPRS or wideband CDMA). Therefore, the most revolutionary concept introduced by 3G solutions, that is, the possibility of having a full-coverage cellular system based on packet switching, thus allowing the extension of many services based on IP (Internet Protocol) and the adoption of a "pay what you send" billing method to the wireless context, will be introduced with GPRS. In this regard, it should be emphasized that UMTS will stimulate this concept by providing larger bandwidths.

The previous example of potential application of GPRS in the field of ITS shows some limitations; for instance, the limited bandwidth of 2.5G systems affects the promptness of the "warning message" service, as well as the delays introduced by the fixed network.

The portion of spectrum allocated to 3G standards is larger than that dedicated to 2G (and 2.5G) systems; therefore, the provision of EW services through GPRS can be seen as a first step toward a more sophisticated solution, which could be provided by means of 3G networks. In fact, the delays introduced by the GPRS network depend partly on the limited bandwidth of the GPRS system, as shown before. Within this context, the main role that 3G systems will be able to play, with respect to GPRS, will be given by the larger bandwidths that could affect the quality of the services offered.

The larger the overall bit rate, the smaller the radio access delay, the smaller the delay of message delivery, and the higher the spatial resolution of the warning message. With GPRS, taking its network delays into account, it can be expected that, at a speed of 120 km/h, a vehicle can be alerted to avoid an accident that occurred about 150–200 ms ahead. This is not enough to elude all possible events. On the other hand, this could be sufficient to avoid the catastrophic highway "chain accidents" (occurring sometimes in the presence of huge banks of fogs,

typical of different areas in Italy) that in some cases involve many cars, separated by distances much greater than 100 m. A rough EW service based on GPRS could save some human lives. The larger bandwidth of 3G standards could do even better.

However, this does not reduce the importance of the investigation of dedicated systems for ITS, which could provide even more complex services, such as "cooperative driving," which should be considered in the long term to be a very important target for increasing the safety and efficiency of road transport.

4.3. The Role of Bluetooth

The main disadvantage of the adoption of cellular communication (GSM, GPRS, or UMTS) for ITS service provision relies on the fact that direct communication between the interacting entities would not be possible; the exchange of data between the two would be performed via the cellular network. This would require suitable integration of the cellular service with localization aspects, would make the service provision prone to the network malfunction, and would increase the packet transfer delay.

An alternative solution is represented by the adoption of devices with the capability, on one hand, to automatically detect the presence of other similar devices located nearby and, on the other hand, to establish a direct communication link (hence without the need of an infrastructure network).

The Bluetooth technology, the most recent development in the field of WPANs (wireless personal-area networks), fulfills both the abovementioned requirements; furthermore, Bluetooth-based devices are expected to be lightweight, small, and economic, therefore representing a perfect candidate not only for RVC systems but also for TVC systems.

The aim of the Bluetooth technology is to allow the establishment of effortless, wireless, instant, and low-cost connections between various communication devices. The Bluetooth radio is built into a small microchip, which is estimated to cost just a few dollars, and operates in a globally available frequency band [the ISM (industrial–scientific–medical)-band at 2.4 GHz] thus ensuring communication compatibility worldwide.

Two or more units communicating one with the other(s) form a *piconet*, where one unit acts as a "master," controlling the whole traffic in the piconet and the other units act as "slaves."

The master implements a centralized control; only communications between the master and one or more slaves are possible, and there is a strict alternation between master and slave transmissions.

A simple binary, Gaussian-shaped FSK modulation scheme (GFSK) is applied in order to reduce costs and device complexity and a symbol rate of 1 Mbps can be achieved. Three different power classes are defined within Bluetooth, as reported in Table 1, where P_0 is the maximum transmitted power.

4.3.1. Estimation of the Maximum Range. An important aspect to be investigated is the maximum distance between the transmitting and receiving devices that ensures possibility of communicating.

Table 1. Bluetooth-Defined Power Classes

Power Class	Maximum Transmitter Power
1	$P_0 = 100$ mW
2	$P_0 = 2.5$ mW
3	$P_0 = 1$ mW

A precise assessment of the maximum range allowed, by the Bluetooth technology under nonideal conditions requires an experimental testbed; hence we carried out a measurement campaign with the aim to evaluate the performance of a Bluetooth link in an outdoor scenario and in different propagation conditions.

A data communication link between two commercial class 1 Bluetooth devices separated by a distance d was established and the time needed to perform a 1.57-MB (megabyte) FTP (File Transfer Protocol) transmission measured. The scope of this test was to evaluate the limit distance that determines a significant increase in the file transfer delay (T_d) due to the retransmissions requested by the ARQ strategy adopted by Bluetooth; this experiment was performed considering both a "free-space-like" [i.e., Line-of-Sight (LoS)] and a partially obstructed LoS environment.

In the first case we ensured that the volume enclosed in the ellipsoid defined by the first Fresnel zone was free from obstacles; in the second case the electromagnetic propagation was partially obstructed by the presence of the terrain (we considered the transmitter and the receiver placed at a height of 45 cm from the terrain).

In Fig. 6 the file transfer delay, T_d, is reported as a function of the distance d between the two Bluetooth devices in the case of "free-space-like" propagation conditions; as we can observe, T_d is not affected by the value of d until the distance between the two devices becomes larger than about 110 m, after which T_d rapidly increases. Ten transfers were performed.

Consequently, under the conditions considered, the maximum communication range can be estimated to be

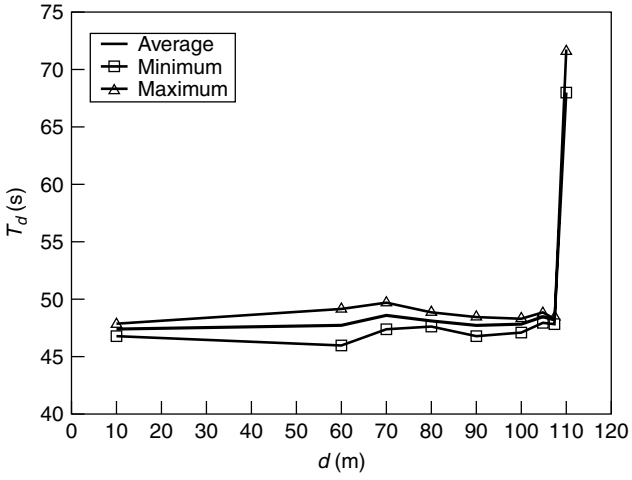

Figure 6. File transfer delay between two Bluetooth devices: "free-space-like" condition.

around 100 m for RVC systems, which are typically experiencing LOS conditions, owing to the possibility to place the beacon in suitable positions.

The experiment described above was repeated assuming partially obstructed LoS conditions: the transmitter and the receiver were placed at distances 45 cm above the terrain, made up of an asphalted surface, representing an obstruction for the first Fresnel ellipsoid when the distance d is >7 ms. This scenario could be representative of an IVC system for, example.

In Fig. 7 the result of this measurement campaign is shown. As we can observe, when the distance between the transmitting and receiving devices is lower than 60 m, the file transfer delay is not affected by the presence of the terrain, which later determines a rapid increase of T_d. Consequently, under the conditions considered, the threshold distance value that marks the transition between LoS and non-LoS conditions is significantly larger than the theoretical value of 7 ms; this observation leads to the conclusion that the reflections produced by the road can improve communication by extending the coverage distance with respect to what is predicted by simple modeling.

Analytic estimation of the maximum range, as in every wireless system, requires the assessment of a suitable propagation law, which is complex because of the presence of many vehicles and other obstacles, thus requiring the specification of the operating environment.

In this section we merely give an approximate evaluation of the maximum range, taking only free-space loss into consideration.

The minimum level of the received power, on the input to the receiver, required for a bit error rate equal to 10^{-3} is $P_r = -70$ dBm [31]; therefore, the maximum loss $L_{\max}$ (dB) $= P_0$ (dB) $- P_r$ (dB) depends on the power class and is reported in the second column of Table 2.

Knowing the $L_{\max}$ value, we can assess the maximum allowable distance $d_{\max}$; let's assume free-space loss (optimistic conditions), so that, assuming the value of carrier frequency equal to 2.4 GHz, we obtain

$$L_{\max} = 40 + 20\log(d_{\max}) - G_e - G_r$$

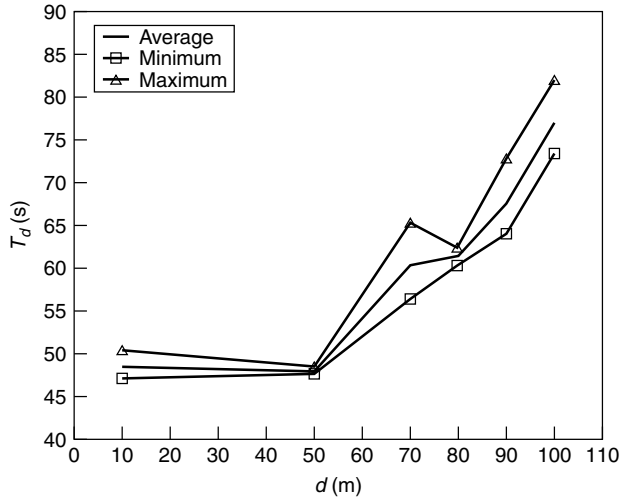

Figure 7. File transfer delay between two Bluetooth devices: "non-LoS" condition.

Table 2. Minimum Received Power Required for BER = 10^{-3}

Power Class	$L_{\max}$ (dB)	$d_{\max}$ (m) ($G_e = G_r = 0$ dB)
1	90	316
2	74	50
3	70	32

where G_e and G_r are the transmitter and receiver antenna gains, respectively.

Under the simple assumption of omnidirectional antennae ($G_e = G_r = 0$ dB), with free-space loss, we have

$$L = 40 + 20\log(d_{\max})$$

which gives the values reported in the third column of Table 2.

The coverage range calculated with our very simplified approach, which doesn't take nonideality typical of a real system into account, is in the case of class 1 devices, around a few hundreds of meters, not too different from the measured values reported above, which were obtained with commercial products, probably not transmitting at the maximum allowed level of power.

However, free-space loss is a rather optimistic assumption that in many cases could not be fulfilled in realistic conditions, especially in urban scenarios. The assessment of a loss formula taking multipath into account should be considered, but is beyond the scope of this work, as it would depend on the particular environment (urban, suburban), including the traffic conditions and the number of scatterers (cars, buildings, etc.).

4.3.2. Effects of Vehicle Speed and Multipath. We note that the Bluetooth technology was designed for static indoor environments (communication between computers, printers, etc.); the possibility of using it in an outdoor scenario, with moving terminals at different speeds, must be carefully investigated by taking the protocol and physical aspects of Bluetooth technology into account and considering the typical aspects related to the propagation of electromagnetic waves in outdoor urban environments, characterized by fading and multipath effects.

This analysis requires the consideration of the consequences of the Doppler effect (viz., the effects of the speed of terminals) on the modulation/demodulation format and the protocols.

Concerning signal dispersion, the following preliminary considerations lead to the conclusion that the dispersion due to multipath should not represent a serious drawback: Bluetooth is a short-range communication system; hence the coherence bandwidth is expected to be around tens of megahertz, that is, well beyond the signal bandwidth (1 MHz), and this renders the performance insensitive to the amount of signal dispersion. A more precise consideration of this aspect would be very complex because of the characteristics of the Bluetooth technology.

As far as the effects of speed are concerned, an analytic model has been exploited to assess the bit error rate

of a Bluetooth device under the conditions stated above (neglecting the benefits of the channel code). It is worth noting that the modulation format is nonlinear and its performance is evaluated in the presence of flat fading.

In Fig. 8 the BER (for a Bluetooth terminal neglecting the effects of channel coding, which will further improve the performance) as a function of average signal-to-noise ratio W_m, is reported where the average is made with respect to fading statistics, considered to be flat Rayleigh. The computation takes the effect of the speed of terminals into account (viz., the Doppler effect, for a relative speed equal to 110 km/h, considering a vehicle and a target running in opposite directions, one toward the other, i.e., on a "head-on collision course"). Since the implementation of the receiver characteristics is not fixed by the standard a limiter–discriminator device is assumed, as a reference, with a 4-pole Butterworth filter having normalized bandwidth equal to 1. It is expected that many implementations of the Bluetooth technology will be based on limiter–discriminator detection, which is known to be simple and efficient under hostile propagation conditions. The choice related to the filter has proved not to have a deep impact on the results.

The results show that an error floor is found, due to the speed of the terminal, at BER $= 10^{-6}$. We assume that this level of BER is sufficiently large to fulfill the performance requirement in terms of false-alarm rate. Therefore, the movement of terminals does not seem to introduce limiting effects on the performance (let's bear in mind that the effect of channel coding was not considered, and it will further lower the error floor).

In order to verify the results of our analysis, we carried out experimental activities to test the Bluetooth transmission reliability in a dynamic scenario. A communication link was established between a static class 1 Bluetooth transmitter placed on the pavement beside an urban road, at 50 cm above the terrain, and a Bluetooth receiver placed on a vehicle traveling at a constant speed and passing in front of the transmitter at a minimum distance of 3 ms.

The experiment was repeated assuming different speeds of the mobile device, and we ensured that the transmission was performed correctly even when traveling at 100 km/h, therefore confirming our expectation on the sturdiness of Bluetooth communications.

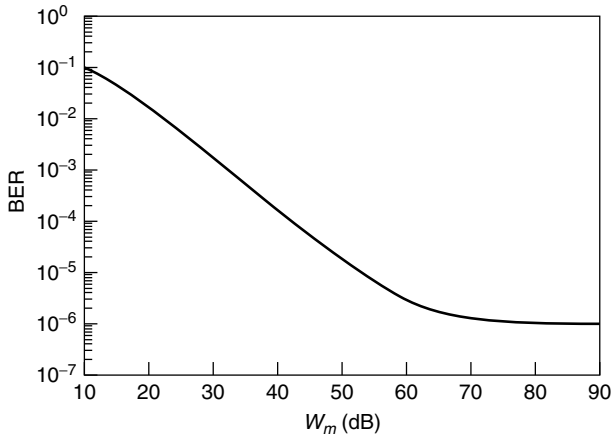

Figure 8. Bluetooth link: the effect of mobility.

As a consequence of the previous observations, we can state that link performance is not limited by the speed of the vehicle but is determined by the amount of signal-to-noise ratio and, consequently, by the transmitted power. On the other hand, it is well known that Bluetooth uses a polling technique at the MAC (media access control) level, and this means that, in the presence of many vehicles, the MAC protocol can cause a performance degradation.

5. CONCLUSIONS

This article presented an overview of the evolution of research in the field of communications for ITS. Starting from the activities oriented to dedicated solutions, the discussion then focused on the assessment of existing relevant standards in mobile communications to define and activate new ITS services. As far as dedicated solutions are concerned, this article showed some results related to radars as well as 60-GHz and infrared communication systems specifically designed for RVC and IVC. The issue of ITS service provision by means of an already standardized system was then addressed, and, as an example, the feasibility of an "emergency warning" service based on GPRS was considered. Finally, the performance of Bluetooth-based RVC and TVC links was addressed by both analytically and experimentally.

ACRONYMS

AHS	Automated highway system
ARQ	Automatic Repeat reQuest; automatic repeat request (generic)
BER	Bit error rate
BTS	Base transceiver station
CCD	Charge-coupled device
CDMA	Code-division multiple access
DSRC	Dedicated short-range communication
FM	Frequency modulation
FM-CW	Frequency-modulated continuous wave
FSK	Frequency shift keying
FTP	File Transfer Protocol
GFSK	Gaussian frequency shift keying
GPRS	General Packet Radio Service
GPS	Global Positioning System
GSM	Global System for Mobile Communications
IP	Internet Protocol
ISM	Industrial–scientific–medical
ITS	Intelligent transportation system
IVC	Intervehicle communications
JSK	Association of Electronic Technology for Automobile Traffic and Driving (Japan)
LOS	Line of sight
MAC	Medium access control
MSK	Minimum shift keying
RF	Radiofrequency
RLC	Radio link control
RVC	Roadside-to-vehicle communication
SIR	Signal-to-interference ratio
SS	Spread spectrum
TDMA	Time-division multiple access

TVC	Target-to-vehicle communication
UMTS	Universal Mobile Telecommunication System
USDOT	United States Department of Transportation
VMS	Variable message sign
WPAN	Wireless personal-area network

BIOGRAPHIES

Oreste Andrisano was born in Bologna, Italy, on February 14, 1952. He received the Dr. Ing. degree in electronic engineering cum laude from the University of Bologna, Bologna, Italy, in 1975. In the same year he joined the University of Bologna, where he became a Professor of Electrical Engineering in 1985. Since 1992 he has been the Director of CSITE (Centro di studio per l'Informatica e i Sistemi di Telecomunicazioni), University of Bologna and Consiglio Nazionale delle Ricerche, Roma. Since 2000 he has been the Director of the Laboratorio Nazionale di Comunicazioni Multimediali, Napoli (Consorzio Nazionale Interuniversitario per le Telecomunicazioni, CNIT). In the period 1996-2001 he was an Editor of the IEEE Transactions on Communications (Modulation for fading channels). His research activity has been concerned with different fields in the digital communication area, such as digital signal processing, data transmission for satellite and fixed radio links applications, local wireless and mobile radio networks. He has also been active in the Intelligent Transportation Systems (ITS) area, with reference to vehicle-to-vehicle and vehicle-to-infrastructure communication systems. In 1987 and 1988 he cooperated in the definition phase of PROMETHEUS (EUREKA), as a European coordinator for the transmission systems research area. Then, he was in the Steering Committee of Project DACAR (Data Acquisition and Communication Techniques and their Assessment for Road Transport) in the framework of DRIVE I, ECC, 1988-1991. In the period 1991-1997 he was responsible for the ITS communication activities in Italy (coordination of PROCOM and TELCO). Since 1998 he is the national coordinator of the project Multimedia Systems funded at national level by MIUR and CNR (Roma). Oreste Andrisano is a member of the IEEE Communication and Vehicular Technology Societies and of the IEEE Radiocommunication Committee.

Masao Nakagawa was born in Tokyo, Japan, in 1946. He received the B.E., M.E., and Ph.D. degrees in electrical engineering from Keio University, Yokohama, Japan, in 1969, 1971 and 1974 respectively. Since 1973, he has been with the Department of Electrical Engineering, Keio University, where he is now Professor. His research interests are in CDMA, consumer communications, mobile communications, ITS (Intelligent Transport Systems), wireless home networks, and optical communication with lighting. He received 1989 IEEE Consumer Electronics Society Paper Award, 1999-Fall Best Paper Award in IEEE VTC, IEICE Achievement Award in 2000, IEICE Fellow Award in 2001. He was the executive committee chairman of International Symposium on Spread Spectrum Techniques and Applications in 1992 and the technical program committee chairman of ISITA (International Symposium on Information Theory and its Applications) in 1994. He is an editor of Wireless Personal Communications and was a guest editor of the special issues on "CDMA Networks I, II, III and IV" published in IEEE JSAC in 1994(I and II) and 1996(III and IV). He chairs the Wireless Home Link subcommittee in MMAC (Multimedia Mobile Access Communication Promotion Committee).

Gianni Pasolini received his Laurea degree in telecommunications engineering from the University of Bologna, Italy, in March 1999. In May 1999 he joined CSITE-CNR (Centre for Studies in Computer Science and Telecommunication Systems of the National Research Council), and he is currently working toward his PhD. His research activity is concerned with Wireless Local Area Networks, Digital Communications and Radio Resource Management. He is a student member of IEEE.

Roberto Verdone was born in Bologna, Italy, in 1965. He received his Laurea degree in Electronic Engineering (with honours) and his Ph.D. in Electronic Engineering and Computer Science from the University of Bologna, Italy, in March 1991 and October 1995, respectively. In April 1996 he became a researcher at CSITE-CNR (Centre for Studies in Computer Science and Telecommunication Systems of the National Research Council) in Telecommunications. Since November 2001 he is a Full Professor in Telecommunications at the University of Bologna. His research activity is concerned with Digital Transmission, Cellular and Mobile Radio Systems, Wireless Local Area Networks, Digital Broadcasting and Intelligent Transportation Systems. In 1992 he was involved in the European research program PROMETHEUS. Since 1995 to 1997 he worked in the context of the National research program TELCO (TELecommunications network for COoperative Driving). He is also responsible for the activities of CSITE in projects funded by ESA and MIUR (Italy). Since 1997 to 2000 he has participated to the COST259 Action. Since 2001 he is chairman of the WG on Network Aspects within the follow-on Action COST273. He is a member of IEEE.

COMMUNITY ANTENNA TELEVISION (CATV) (CABLE TELEVISION)

ROGER FREEMAN*
Independent Consultant
Scottsdale, Arizona

1. INTRODUCTION

The principal thrust of community antenna television (CATV) is entertainment. Lately, CATV has taken on some new dimensions. It is indeed a broadband medium, providing up to 1 GHz of bandwidth at customer premises. It was originally a unidirectional system, from the point of origin, which we call the *headend*, toward customer premises. It does, though, have the capability of being a two-way system by splitting the band, say, from 5 to 50 MHz for upstream traffic (i.e., toward the headend), and the remainder is used for downstream traffic (i.e., from the headend to customer premises). CATV is certainly a major and viable contender for *last-mile communications*.

We will briefly discuss one approach to provide capability for two-way traffic, usually voice and data. First, however, conventional CATV will be described, and it includes the concept of supertrunks and HFC (hybrid fiber–coaxial cable systems). We will involve the reader with such topics as wideband amplifiers in tandem, optimum amplifier gain, IM (intermodulation) noise, beat noise, and cross-modulation products. System layout, hubs, and last-mile or last-100-ft considerations will also be covered. There will also be a brief discussion of the conversion to a digital system using some of the compression techniques now employed on modern cable television systems. The section includes overviews of the three important competing standards for broadband hybridcoax (HFC) CATV systems. These provide the user, besides conventional TV downstream, upstream, and downstream connectivity for megabit Internet, IP intranet, various data services, still-image transmission, and POTS* telephony.

* Roger Freeman took an early retirement from the Raytheon Company, Equipment Division, in 1991 where he was principal engineer to establish *Roger Freeman Associates*, Independent Consultants in Telecommunications. He has been writing books on various telecommunication disciplines for John Wiley & Sons, since 1973. Roger has seven titles that he keeps current, including *Reference Manual, Inc. for Telecommunication Engineers* now in its third edition. His Website *www.rogerfreeman.com*, and his email address is *rogerf@pcslink.com.*

* POTS-plain old telephone service.

2. THE EVOLUTION OF CATV

2.1. The Beginnings

Broadcast television, as we know it, was in its infancy around 1948. Fringe-area problems were much more acute in that period. By "fringe area," we mean areas with poor or scanty signal coverage. A few TV users in fringe areas found that if they raised their antennas high enough and improved antenna gain characteristics, they could receive an excellent picture. Such users were the envy of the neighborhood. Several of these people who were familiar with RF signal transmission employed signal splitters so that their neighbors could share the excellent picture service. It was soon found that there was a limit on how much signal splitting could be done before signal levels got so low that they were snowy or unusable.

Remember that each time a signal splitter (even power split) is added, neglecting insertion losses, the TV signal dropped by 3 dB. Then someone got the bright idea of amplifying the signal before splitting. Now some real problems arose. One-channel amplification worked fine, but two channels from two antennas with signal combining became difficult. Now we are dealing with comparatively broadband amplifiers. Among the impairments we can expect from broadband amplifiers and their connected transmission lines (coaxial cable) are

- Poor frequency response. Some part of the received band had notably lower levels than other parts. This is particularly true as the frequency increases. In other words, there was fairly severe amplitude distortion; thus equalization became necessary.
- The mixing of two or more RF signals in the system caused intermodulation products and "beats" (harmonics), which degraded reception.
- When these TV signals carried modulation, cross-modulation (Xm) products further degraded or impaired reception.

Several small companies were formed to sell these "improved" television reception services. Some of the technicians working for these companies undertook ways of curing the ills of broadband amplifiers. What these service companies did was to install a reasonably high tower in an appropriate location. Comparatively high gain antennas were installed such that a clear, line-of-sight signal could be received from TV emitters within range. The high-tower receiving site was called a *headend*. The headend had RF amplifiers, TV line amplifiers, signal combiners, translators, and all that was necessary to process and distribute multiple TV signals to CATV subscribers. The distribution system was entirely based on coaxial cable. To keep the signal strength to a usable level, broadband amplifiers were installed at convenient intervals along the distribution line.

A subscriber's TV set was connected to the distribution system, and the signal received looked just the same as if it was taken off the air with its own antenna. In fringe areas signal quality, however, was much better than own antenna quality. The key to everything was that no changes were required in the users' TV set. This was just an extension of his/her TV set antenna. Such a simple concept is shown in Fig. 1.

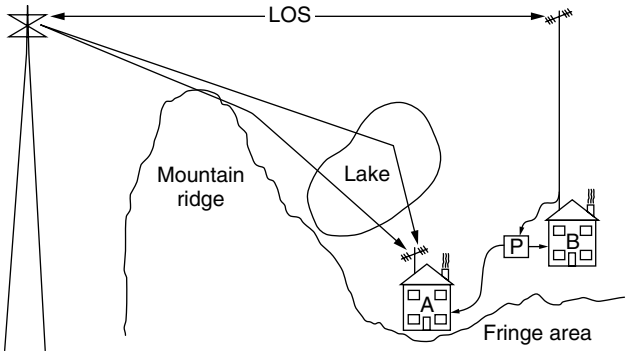

Figure 1. CATV initial concept (P = power split).

Note in Fig. 1 that home A is in the shadow of a mountain ridge and receives a weakened diffracted signal off the ridge and a reflected signal off a lake. Here is the typical multipath scenario resulting in ghosts in A's TV screen. The picture is also snowy, meaning it is noisy, as a result of a poor carrier-to-noise ratio. Home B extended the height of the antenna to be in line of sight of the TV transmitting antenna. Its antenna is of higher gain; thus it is more discriminating against unwanted reflected and diffracted signals. Home B has an excellent picture without ghosts. Home B shares its fine signal with home A by use of a 3-dB power split (P).

2.2. Early System Layouts

Figure 2 illustrates an early CATV distribution system (ca. 1968). Taps and couplers (power splits) are not shown. These systems provided 5–12 channels. A microwave system brought in channels from distant cities (50–150 mi). We had direct experience with the Atlantic City, NJ system where channels were brought in from Philadelphia and New York by microwave (MW). A 12-channel system resuited which occupied the entire assigned VHF band (i.e., channels 2–13).

As UHF TV stations began to appear, a new problem arose for the CATV operator. It was incumbent on that operator to keep the bandwidth as narrow as possible. One approach was to convert UHF channels to vacant VHF channel allocations at the headend.

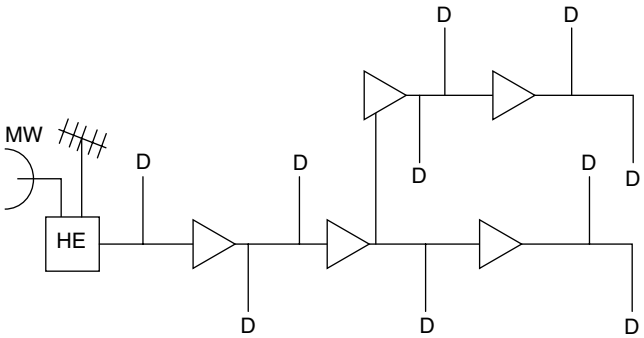

Figure 2. An early CATV distribution system (HE = headend; D = drop wire to residence; MW = microwave connectivity).

Satellite reception at the headend doubled or tripled the number channels that could be available to the CATV subscriber. Each satellite has the potential of adding 24 channels to the system. Note how the usable cable bandwidth is "broadened" as channels are added. We assume contiguous channels across the band, starting at 55 MHz. For 30 channels, we have 55–270 MHz; 35 channels, 55–300 MHz, 40 channels, 55–330 MHz; 62 channels, 55–450 MHz; and 78 channels, 55–550 MHz. These numbers of channels were beyond the capability of many TV sets of the day. Settop converters were provided that converted all channels to a common channel, an unoccupied channel, usually channel 2, 3 or 4 to which the home TV set is tuned. This approach is still very prevalent today.

In the next section we discuss impairments and measures of system performance. In Section 4, hybrid fiber–coaxial cable systems are addressed. The replacement of coaxial cable trunk by fiberoptic cable made a major stride to improved performance and system reliability/availability.

3. SYSTEM IMPAIRMENTS AND PERFORMANCE MEASURES

3.1. Overview

A CATV headend places multiple TV and FM broadcast (from 30 to 125) carriers on a broadband coaxial cable trunk and distribution system. The objective is to deliver a signal-to-noise ratio (S/N) of 42–45 dB at a subscriber's TV set. If the reader has background in the public switched telecommunications network (PSTN), he/she would expect such impairments as the accumulation of thermal and intermodulation noise. We find that CATV technicians use the term *beat* to mean intermodulation (IM) products. For example, there is triple beat distortion, defined by Bill Grant [6], as "spurious signals generated when three or more carriers are passed through a non-linear circuit (such as a wideband amplifier). The spurious signals are sum and difference products of any three carriers, sometimes referred to as 'beats.' Triple beat distortion is calculated as a voltage addition."

The wider the system bandwidth is and the more RF carriers transported on that system, the more intermodulation distortion, "triple beats" and cross-modulation we can expect. We can anticipate combinations of all the above such as *composite triple beat* (CTB), which represents the pile up of beats at or near a single frequency.

Bill Grant [6] draws a dividing line at 21 TV channels. On a system with 21 channels or less one must expect cross-modulation (Xm) to predominate. Above 21 channels, CTB will predominate.

3.2. dBmV and Its Applications

The value 0 dBmV is defined as 1 millivolt (mV) across an impedance of 75 Ω. The 75-Ω value is the standard impedance used in CATV. From the power law

$$P_w = E^2/R$$

$$P_w = 0.001^2/75 \tag{1}$$

$$0 \text{ dBmV} = 0.0133 \times 10^{-6} \text{ watts or } 0.0133 \ \mu\text{W}$$

By definition, then, 0.0133 *watts* (W) is +60 dBmV.

If $0 \text{ dBmV} = 0.0133 \times 10^{-6}$ W and 0 dBm = 0.001 W, and gain in $\text{dB} = 10\log(P_1)/(P_2)$, or in this case $10\log(0.001/0.0133 \times 10^{-6})$, then 0 dBm = +48.76 dBmV.

Remember that when working with decibels in the voltage domain, we are working with the E^2/R relationship, where $R = 75\ \Omega$. With this in mind, the definition of dBmV is

$$\text{dBmV} = 20\log(\text{voltage in millivolts})/(1 \text{ mV}) \tag{2}$$

If a signal level is 1 volt (V) at a certain point in a circuit, what is the level in dBmV?

$$\text{dBmV} = 20\log(1000)/1 = +60 \text{ dBmV}$$

If we are given a signal level of +6 dBmV, what voltage level does this correspond to?

$$+6 \text{ dBmV} = 20\log(X_{\text{mV}})/1 \text{ mV}$$

Divide through by 20:

$$\frac{6}{20} = \log(X_{\text{mV}})/1 \text{ mV}$$

$$\text{Antilog}\left(\frac{6}{20}\right) = X_{\text{mV}}$$

$$X_{\text{mV}} = 1.995 \text{ mV or } 2 \text{ mV or } 0.002 \text{ V}.$$

These signal voltages are RMS (root mean square) volts. For peak voltage, divide by 0.707. If we are given peak signal voltage and wish the RMS value, multiply by 0.707.

3.3. Thermal Noise in CATV Systems

The lowest noise levels permissible in a CATV system: at antenna output terminals, at repeater (amplifier) inputs or at a subscriber's TV set, without producing snowy pictures, are determined by thermal noise.

Consider the following, remembering that we are in the voltage domain. Any resistor or source that appears resistive over the band of interest, including antennas, amplifiers, and long runs of coaxial cable, generates thermal noise. In the case of a resistor, the noise level can be calculated on the basis Fig. 3.

To calculate the noise voltage, e_n, use the following formula:

$$e_n = (4RBk)^{1/2} \tag{3}$$

where V = an electronic voltmeter measuring the noise voltage
e_n = RMS noise voltage
R = resistance (Ω)
B = bandwidth of the measuring device (electronic voltmeter) (Hz.)

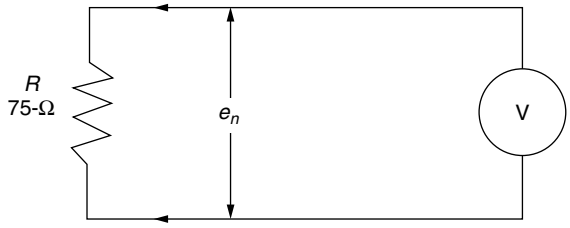

Figure 3. Resistor model for thermal noise voltage, e_n.

k = a constant equal to 40×10^{-16} at standard room temperature.

Letting the bandwidth, B, be equal to that of an NTSC TV signal be rounded to 4 MHz, the open-circuit noise voltage for a 75-Ω resistor is

$$e_n = (4 \times 75 \times 4 \times 10^{-16})^{1/2}$$
$$= 2.2\ \mu\text{V RMS}$$

Figure 4 shows a 2.2 μV noise-generating source (resistor) connected to a 75-Ω (noiseless) load. Only half of the voltage (1.1 μV) is delivered to the load. Thus the noise input to 75 Ω is 1.1 μV RMS or −59 dBmV. This is the basic noise level, the minimum that will exist in any part of a 75-Ω CATV system. The value, −59 dBmV, will be used repeatedly below.

The noise figure of typical CATV amplifiers ranges between 7 and 9 dB [4].

3.4. Signal-To-Noise Ratio (S/N) Versus Carrier-To-Noise (C/N) Ratio in CATV Systems

S/N (signal-to-noise ratio) and C/N (carrier-to-noise ratio) are familiar parameters in telecommunication transmission systems. In CATV systems S/N has a slightly different definition: *This relationship is expressed by the "signal-to-noise ratio," which is the difference between the signal level measured in dBmV, and the noise level, also measured in dBmV, both levels being measured at the same point in the system* [3].

S/N can be related to C/N on CATV systems as

$$\text{C/N} = \text{S/N} + 4.1\ \text{dB} \tag{4}$$

This is based on work by Carson [5], where the basis is "noise just perceptible" by a population of TV viewers, NTSC 4.2-MHz bandwidth TV signal. Here the S/N is 39 dB and the C/N is 43 dB.

Adding noise weighting improvement (6.8 dB), we obtain

$$\text{S/N} = \text{C/N} + 2.7\ \text{dB} \tag{5}$$

It should be noted that S/N is measured where the signal level is peak to peak and the noise level is RMS. For C/N, both the carrier and noise levels are rms. These values are based on a VSB-AM TV signal with 87.5% modulation index.

For comparison, consider another series of tests conducted by the Television Allocations Study Organization (TASO) and published in their report to the U.S. FCC in 1959. Their ratings, corrected for a 4-MHz bandwidth, instead of the 6 MHz bandwidth they used, are shown below:

TASO picture rating	S/N ratio (dB)
1. Excellent, no perceptible noise	45
2. Fine (snow just perceptible)	35
3. Passable (snow definitely perceptible, but not objectionable)	29
4. Marginal (snow somewhat objectionable)	25

Once a tolerable noise level is determined, the levels required in a CATV system can be specified. If the desired S/N has been set at 43 dB at a subscriber TV set, the minimum signal level required at the first amplifier would be −59 dBmV + 43 dB or −16 dBmV, considering thermal noise only. Actual levels would be quite a bit higher because of the noise generated by subsequent amplifiers in cascade.

It has been found that the optimum gain of a CATV amplifier is about 22 dB. When the gain is increased, intermodulation/cross-modulation products become excessive. For gains below this value, thermal noise increases, and system length is shortened or the number of amplifiers must be increased, neither of which is desirable.

There is another rule-of-thumb we should be cognizant of. Every time the gain of an amplifier is increased 1 dB, intermodulation products and "beats" increase their levels by 2 dB. And the converse is true; every time gain is decreased 1 dB, IM products and beat levels are decreased by 2 dB.

With most CATV systems, coaxial cable trunk amplifiers are identical. This, of course, eases noise calculations. We can calculate the noise level at the output of one trunk amplifier. This is

$$N_v = -59\ \text{dBmV} + \text{NF}_{\text{dB}} \tag{6}$$

where NF is the noise figure of the amplifier in decibels.

In the case of two amplifiers in cascade (tandem), the noise level (voltage) is

$$N_v = -59\ \text{dBmV} + \text{NF}_{\text{dB}} + 3\ \text{dB} \tag{7}$$

If we have M identical amplifiers in cascade, the noise level (voltage) at the output of the last amplifier is:

$$N_v = -59\ \text{dBmV} + \text{NF}_{\text{dB}} + 10 \log M \tag{8}$$

This assumes that all system noise is generated by the amplifiers, and none is generated by the intervening sections of coaxial cable (3).

Example 1. A CATV system has 30 amplifiers in tandem, and each amplifier has a noise figure of 7 dB. Assume that the input of the first amplifier is terminated in 75 Ω resistive. What is the thermal noise level (voltage) at the last amplifier output?

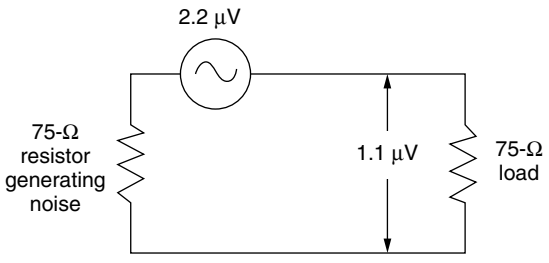

Figure 4. Minimum noise model.

Use Eq. (6):

$$N_v = -59 \text{ dBmV} + 7 \text{ dB} + 10 \log 30$$
$$= -59 \text{ dBmV} + 7 \text{ dB} + 14.77 \text{ dB}$$
$$= -37.23 \text{ dBmV}$$

For carrier-to-noise ratio (C/N) calculations, we can use the following procedures. To calculate the C/N at the output of one amplifier:

$$\text{C/N} = 59 - \text{NF}_{\text{dB}} + \text{input level (dBmV)} \quad (9)$$

Example 2. If the input level of a CATV amplifier were +5 dBmV and its noise figure were 7 dB, what would the C/N a the amplifier output be?

Use Eq. (9):

$$\text{C/N} = 59 - 7 \text{ dB} + 5 \text{ dBmV}$$
$$= 57 \text{ dB}$$

With N cascaded amplifiers, we can calculate the C/N at the output of the last amplifier, assuming all the amplifiers were identical, by the following equation:

$$\text{C/N}_L = \text{C/N(single amplifier)} - 10 \log N \quad (10)$$

Example 3. Determine the C/N at the output of the last amplifier with a cascade (in tandem) of 20 amplifiers, where the C/N of a single amplifier is 62 dB.

Use Eq. (10):

$$\text{C/N}_L = 62 \text{ dB} - 10 \log 20$$
$$= 62 \text{ dB} - 13.0 \text{ dB}$$
$$= 49 \text{ dB}$$

Another variation for calculating C/N is when we have disparate C/N ratios in different parts of a CATV system. CATV systems are usually of a tree topology where the headend is the base of the tree. There is a trunk branching to limbs and further branching out to leaf stems supporting many leaves. In the case of CATV, there is the trunk network, bridger, and line extenders with different gains, and possibly different noise figures. To solve this problem we must use a relationship of several C/N values in series:

$$\text{C/N}_{\text{sys}} = 1/[1/\text{C/N}_1) + (1/\text{C/N}_2) - - - + (1/\text{C/N}_n)] \quad (11)$$

Example 4. Out of a cascade of 20 trunk amplifiers the C/N was 49 dB; out of a bridger, 63 dB and two line extenders, 61 dB, calculate the C/N at the end of the system described.

Use Eq. (11), but first convert each decibel value to a value in decimal units and then take its inverse ($1/X$):

$$49 \text{ dB:antilog}(\tfrac{49}{10}) = 79,433\tfrac{1}{X} = 12,589 \times 10^{-9}$$
$$63 \text{ dB:antilog}(\tfrac{63}{10}) = 2,000,000\tfrac{1}{X} = 500 \times 10^{-9}$$
$$61 \text{ dB:antilog}(\tfrac{61}{10}) = 1,258,925\tfrac{1}{X} = 794 \times 10^{-9}$$

We can now sum the inverses because they all have the same exponent. Sum $= 13,883 \times 10^{-9}$. Take the inverse: 72,030. $10 \log_{(72,030)} = 48.57$ dB. Remember that the "sum" of C/N series values must be something less than the worst value of the series. That is a way of self-checking.

3.5. The Problem of Cross-Modulation (Xm)

Many specifications for TV picture quality are based on the judgment of a population of viewers. One example was the TASO ratings for picture quality given above. In the case of cross-modulation (X-mod or Xm) and CTB (composite triple beat), acceptable levels are −51 dB for Xm and −52 dB for CTB. These are good guideline values [6].

Cross-modulation is a form of third-order distortion so typical of a broadband, multicarrier system. Xm varies with the operating level of an amplifier in question and the number of TV channels being transported. Xm is derived from the amplifier manufacturer specifications. The manufacturer will specify a value for Xm (in dB) for several numbers of channels and for a particular level. The level in the specification may not be the operating level of a particular system. To calculate Xm for an amplifier to be used in given system, using manufacturer's specifications, the following formula applies:

$$\text{Xm}_a = \text{Xm}_{(\text{spec})} + 2(\text{OL}_{\text{oper}} - \text{OL}_{\text{spec}}) \quad (12)$$

where Xm_a = Xm for the amplifier in question
$\text{Xm}_{(\text{spec})}$ = Xm specified by the manufacturer of the amplifier
OL_{oper} = desired operating output signal level (dBmV)
OL_{spec} = manufacturer's specified output signal level

We spot the "2" multiplying factor and relate it to our earlier comments, namely, increase the operating level 1 dB, third-order products increase 2 dB, and the contrary for reducing signal level. And as we said, Xm is a form of third-order product.

Example 5. Suppose a manufacturer tells us that for an Xm of −57 dB for a 35-channel system, the operating level should be +50.5 dBmV. We want a longer system and use an operating level of +45 dBmV, what Xm can we expect under these conditions.

Use Eq. (12):

$$\text{Xm}_a = -57 \text{ dB} + 2(+45 \text{ dBmV} - 50.5 \text{ dBmV})$$
$$\text{Xm}_a = -68 \text{ dB}$$

CATV trunk systems have numerous identical amplifiers. To calculate Xm for N amplifiers in cascade (tandem), our approach is similar to that of thermal noise:

$$\text{Xm}_{\text{sys}} = \text{Xm}_a + 20 \log N \quad (13)$$

where N is the number of identical amplifiers in cascade, Xm_a is the Xm for one amplifier, and Xm_{sys} is the Xm value at the end of the cascade.

Example 6. A certain CATV trunk system has 23 amplifiers in cascade where Xm_a is -88 dB, what is Xm_{sys}?

Use Eq. (13):

$$\begin{aligned} Xm_{sys} &= -88 \text{ dB} + 20 \log 23 \\ &= -88 + 27 \\ &= -61 \text{ dB} \end{aligned}$$

To combine unequal Xm values, we turn to a technique similar to Eq. (11), but now, because we are in the voltage domain, we must divide through by 20 rather than 10 when converting logarithms to equivalent numerics.

Example 7. At the downstream end of our trunk system the Xm was -58 dB and taking the bridger/line extender system alone, their combined Xm is -56 dB. Now, from the headend through the trunk and bridger/line extender system, what is the Xm_{sys}? Convert -56 and -58 dB to their equivalent decimal numerics and invert ($1/X$):

$$\begin{aligned} -56 \text{ dB:antilog} - \tfrac{56}{20} &= 0.001584 \\ -58 \text{ dB:antilog} - \tfrac{58}{20} &= 0.001259 \\ \text{Sum} &: 0.002843 \end{aligned}$$

Take 20 log this value.

$$Xm_{sys} = -50.9 \text{ dB}$$

3.6. Gains and Levels for CATV Amplifiers (3)

Setting both gain and level settings for CATV broadband amplifiers is like walking a tightrope. If levels are set too low, thermal noise will limit system length (i.e., number of amplifiers in cascade). If the level is set too high, system length will be limited by excessive CTB and cross-modulation (Xm). On trunk amplifiers available gain is between 22 and 26 dB [6]. Feeder amplifiers will usually operate at higher gains, trunk systems at lower gains. Feeder amplifiers usually operate in the range of 26–32 dB gain with output levels in the range of +47 dBmV. Trunk amplifiers have gains of 21–23 dB, with output levels in the range of +32 dBmV. If we wish to extend the length of the trunk plant, we should turn to using lower loss cable. employing fiberoptics in the trunk plant is even a better alternative (see Section 4).

The gains and levels of feeder systems are purposefully higher. This is the part of the system serving customers through taps. These taps are passive and draw power. Running the feeder system at higher levels improves tap efficiency. Because feeder amplifiers run at higher gain and with higher levels, the number of these amplifiers in cascade must be severely limited to meet CTB and cross-modulation requirements at the end user.

3.7. The Underlying Coaxial Cable System

The coaxial cable employed in CATV plant is nominally 75 Ω. A typical response curve for such cable ($\frac{7}{8}$-inch, air dielectric) is illustrated in Fig. 5. This frequency response of coaxial cable is called "tilt" in the CATV industry.

For 0.5-inch cable, the loss per 100 ft at 50 MHz is 0.52 dB; for 550 MHz, 1.85 dB. Such cable systems require equalization. The objective is to have a comparatively "flat" frequency response across the entire system. An equalizer is a network that presents a mirror image of the frequency response curve, introducing more loss at the lower frequencies and less loss at the higher frequencies. These equalizers are often incorporated with an amplifier.

Equalizers are usually specified for a certain length of coaxial cable, where length is measured in dB at the highest frequency of interest. Grant [6] describes a 13-dB equalizer for a 300-MHz system, which is a corrective unit for a length of coaxial cable having 13 dB loss at 300 MHz. This would be equivalent to approximately

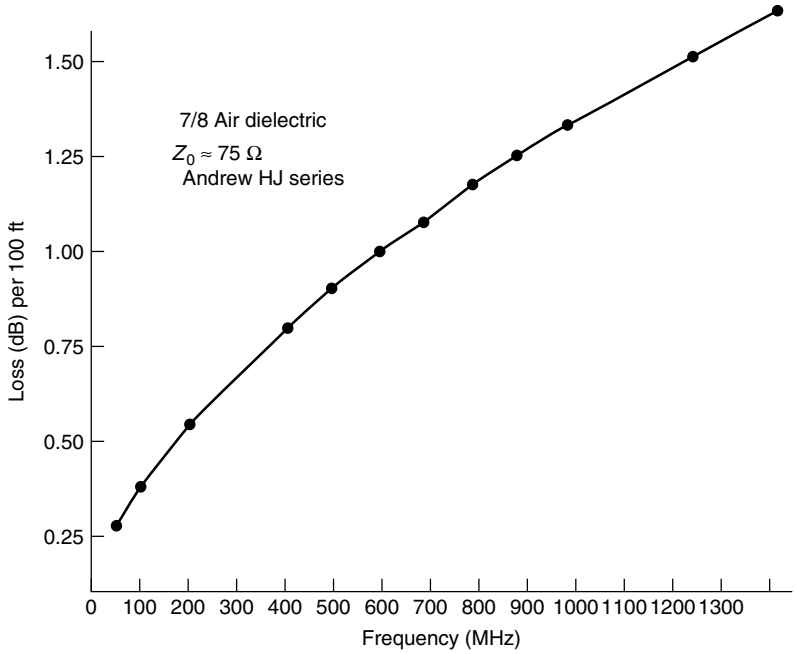

Figure 5. Attenuation–frequency response for $\frac{7}{8}$-in. coaxial cable, air dielectric, $Z_0 = 75$, Andrew HJ series heliax.

1000 ft of $\frac{1}{2}$-inch coaxial cable. Such a length of cable would have 5.45 dB loss at 54 MHz and 13 dB loss at 300 MHz. The equalizer would probably present a loss of 0.5 dB at 300 MHz and 8.1 dB at 54 MHz.

3.8. Taps

A *tap* is similar to a directional coupler. It is a device inserted into a coaxial cable that diverts a predetermined amount of its input energy to one or more tap outputs for the purpose of feeding a TV signal into subscriber drop cables. The remaining balance of the signal energy is passed on down the distribution system to the next tap or distribution amplifier. The concept of the tap and its related distribution system is shown in Fig. 6.

Taps are available to feed 2, 4, or 8 service drops from any one unit. Many different types of taps are available to serve different signal levels that appear along a CATV cable system. Commonly, taps are available in 3-dB increments. For 2-port taps, the following tap losses may be encountered: 4, 8, 11, 14, 17, 20, 23 dB. The insertion loss for the lower value tap loss may be in the order of 2.8 dB, and once the tap loss exceeds 26 dB, the insertion is 0.4 dB and remains so as tap values increase. Another important tap parameter is isolation. Generally, the higher the tap loss, the better the isolation. With 8 dB tap loss, the isolation may only be 23 dB, but with 29 dB tap loss (2-port taps), the isolation can be as high as 44 dB. Isolation in this context is the isolation between the two tap ports to minimize undesired interference from a TV set on one tap to the TV set on the other tap. For example, a line voltage signal level is +34.8 dBmV entering a tap. The tap insertion loss is 0.4 dB, so the level of the signal leaving the tap to the next tap or extender amplifier is +34.4 dBmV. The tap is 2-port. We know we want at least a +10.5 dBmV at the port output. Calculate +34.8 dBmV $-X$dB = +10.5 dBmV. Then $X = 24.3$ dB, which would be the ideal tap loss value. Taps are not available off-the-shelf at that loss value; the nearest value is 23 dB. Thus the output at each tap port will be +34.8 dBmV −23 dB = 11.8 dBmV.

4. HYBRID FIBER-COAX SYSTEMS (HFC)

The following advantages accrue by replacing the coaxial cable trunk system with optical fiber:

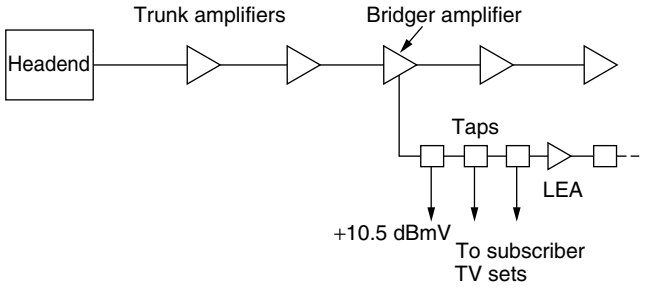

Figure 6. A simplified layout of a CATV system showing its basic elements. The objective is to provide a +10.5-dBmV signal level at the drops (tap outputs) (LEA = line extender amplifier).

- Reduces the number of amplifiers required per unit distance to reach the fartherest subscriber
- Results in improved C/N, reduced CTB and Xm levels
- Also results in improved reliability (i.e., by reducing the number of active components)
- Has the potential to greatly extend a particular CATV serving area.

Figure 7 shows the basic concept of an HFC system. One disadvantage is that a second fiber link has to be installed for reverse direction, or a form of WDM is needed, when two-way operation is required and/or for the CATV management system (used for monitoring the health of the system, amplifier degradation or failure). Figure 8 illustrates an HFC system where there are no more than three amplifiers to a subscriber tap. Note that with this system layout there cannot be a catastrophic failure. For the loss of an amplifier, only $\frac{1}{16}$ of the system is affected, worst case; with the loss of a fiber link, the worst case would be $\frac{1}{6}$ of the system.

4.1. Design of the Fiberoptic Portion of an HFC System

There are two approaches to fiberoptic transmission of analog CATV signals. Both approaches take advantage of the intensity modulation characteristics of the fiberoptic source. Instead of digital modulation of the source, amplitude modulation (analog) is employed. The most common method takes the entire CATV spectrum as it would appear on a coaxial cable and uses that as the modulating signal. The second method also uses analog amplitude modulation, but the modulating signal is a grouping of subcarriers that are each frequency-modulated. One off-the-shelf system multiplexes in a broad FDM configuration, 8 television channels, each on a separate subcarrier. Thus, a 48-channel CATV system would require six fibers, each with eight subcarriers (plus 8 or 16 audio subcarriers).

4.1.1. Link Budget for an AM System. Assume a model using a distributed feedback (DFB) laser with an output of +5 dBm coupled to the pigtail. The receiver is a PINFET, where the threshold is −5 dBm. This threshold will derive approximately 52 dB S/N in a video channel. Compared to digital operation, the C/N is around 49.3 dB, assuming that the S/N value is noise-weighted (see Section 3.4). This is a very large C/N value and leaves only 10 dB to be allocated to fiber, splice loss, and margin. If we allocated 2 dB for the link margin, only 8 dB is left for fiber/splice loss.

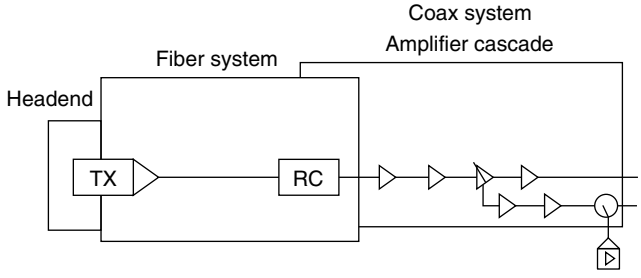

Figure 7. The concept of a hybrid fiber–coaxial cable CATV system (TX = fiberoptic transmitter, RC = fiberoptic receiver).

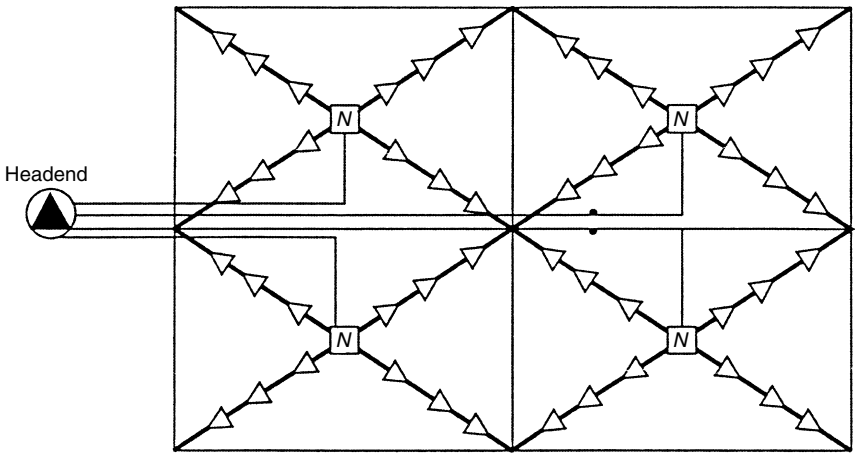

Figure 8. An HFC system layout for optimal performance (one-way). (N = node fiber) interface with coaxial cable).

At 1550-nm operation, assuming a conservative 0.4 dB/km fiber/splice loss, the maximum distance to the coax hub or fiberoptic repeater is only 8/0.4 or 20 km. Of course if we employ a EDFA (erbium-doped fiber amplifier) with, say, only a 20-dB gain, this distance can be extended by 20/0.4 or an additional 50 km. Figure 9 illustrates a typical laser diode transfer characteristic showing the amplitude-modulated input drive.

Representative design goals for the video/TV output of a fiber optics trunk are

$$\text{CNR} = 50 \text{ dB}$$

$$\text{CSO } \textit{products} = -62 \text{ dBc}$$

$$\text{CTB} = -65 \text{ dBc}$$

(where CSO = composite second order). One common technique used on HFC systems is to employ optical couplers where one fiber trunk systems feeds several hubs. A *hub* is a location where the optical signal is converted back to an electrical signal for transmission on coaxial cable. Two applications of optical couplers are illustrated in Fig. 10. Keep in mind that a signal split includes not only splitting the power but also the insertion loss of the coupler. The values shown in parentheses in Fig. 10 give the loss in the split branches (e.g., 5.7 dB and 2.0 dB).

4.1.2. FM Systems. FM systems are more expensive than their AM counterparts, but provide improved performance. EIA-250C, a well-known and respected standard for television transmission, specifies a signal-to-noise ratio of 67 dB for short-haul systems. With AM systems it is impossible to achieve this S/N, whereas a well-designed FM system can conform to EIA-250C. AM systems are degraded by dispersion on the fiber link; FM systems, much less so. FM systems can also be extended further. FM systems are available with 8, 16, or 24 channels, depending on the vendor.

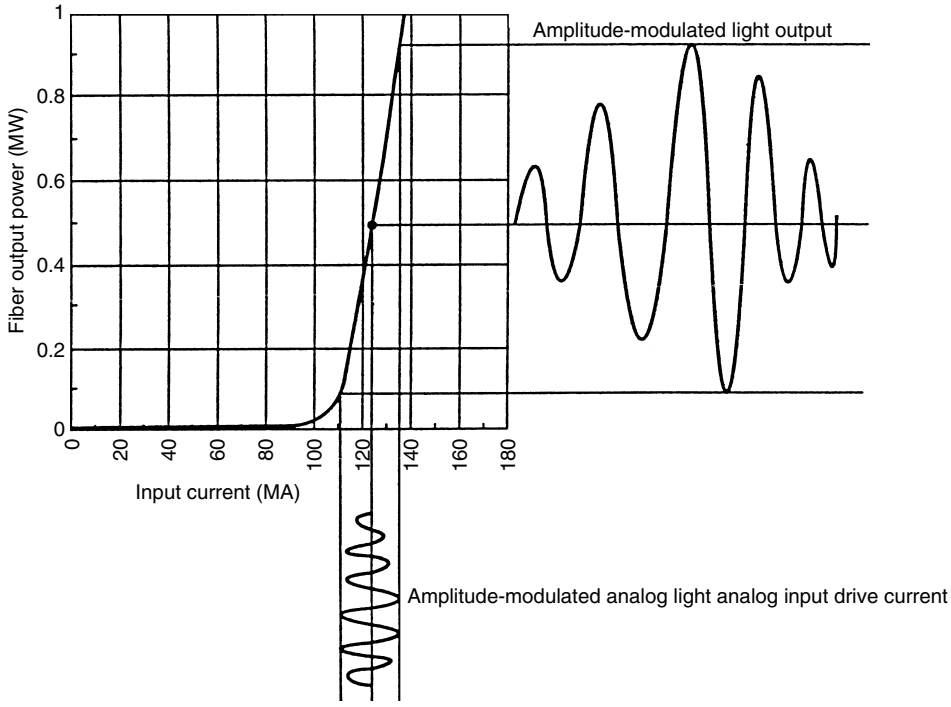

Figure 9. Laser transfer characteristics.

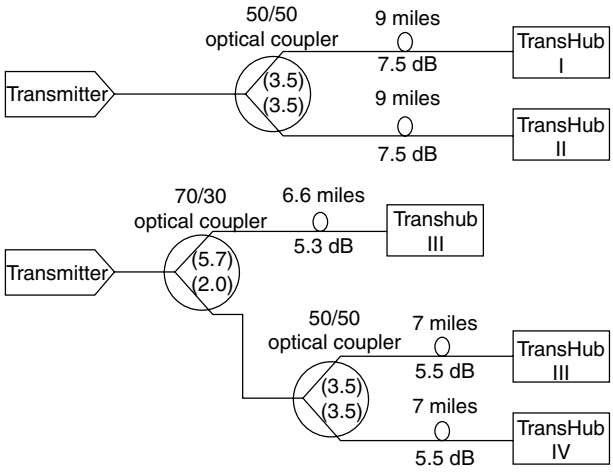

Figure 10. Two-way and three-way splits of a light signal transporting TV.

Figure 11 shows an 8-channel per fiber frequency plan, and Fig. 12 is a transmit block diagram for the video portion of the system. Figure 13 is a layout of a typical fiber hub, and Fig. 14 is a plot of optical receiver input threshold power (dBm) versus signal-to-noise ratio of individual channels derived from an FM HFC system.

Figure 12 is an FM system model. At the headend, each video and audio channel is broken out separately. And as shown in Fig. 11, each channel FM modulates a subcarrier. Note that there is a similar but separate system for the associated audio (aural) channels with 30 MHz spacing starting at 70 MHz and these audio channels may be multiplexed before transmission. Each video carrier occupies a 40 MHz slot. These RF carriers, audio and video, are combined in a passive network. The composite RF signal intensity-modulates a laser diode source. Figure 13 shows a typical fiber/FM hub.

4.1.2.1. Calculation of Video S/N for an FM System. Given the C/N (CNR) for a particular FM system, the S/N of a TV video channel may be calculated as shown in Example 8.

$$\mathrm{SNRw} = K + \mathrm{CNR} + 10\log\frac{B_{\mathrm{IF}}}{B_{\mathrm{F}}} + 20\log\frac{1.6\Delta F}{B_{\mathrm{F}}}$$

where K = a constant ($\sim$23.7 dB) made of weighting network, deemphasis, and rms to p-p conversion factors
CNR = carrier-to-noise ratio in the IF bandwidth

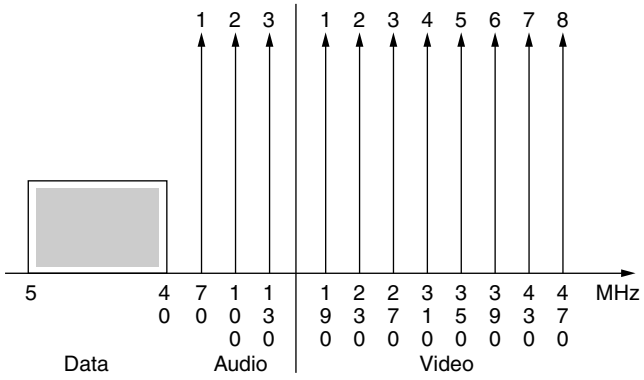

Figure 11. Eight-TV-channel frequency plan for an FM system.

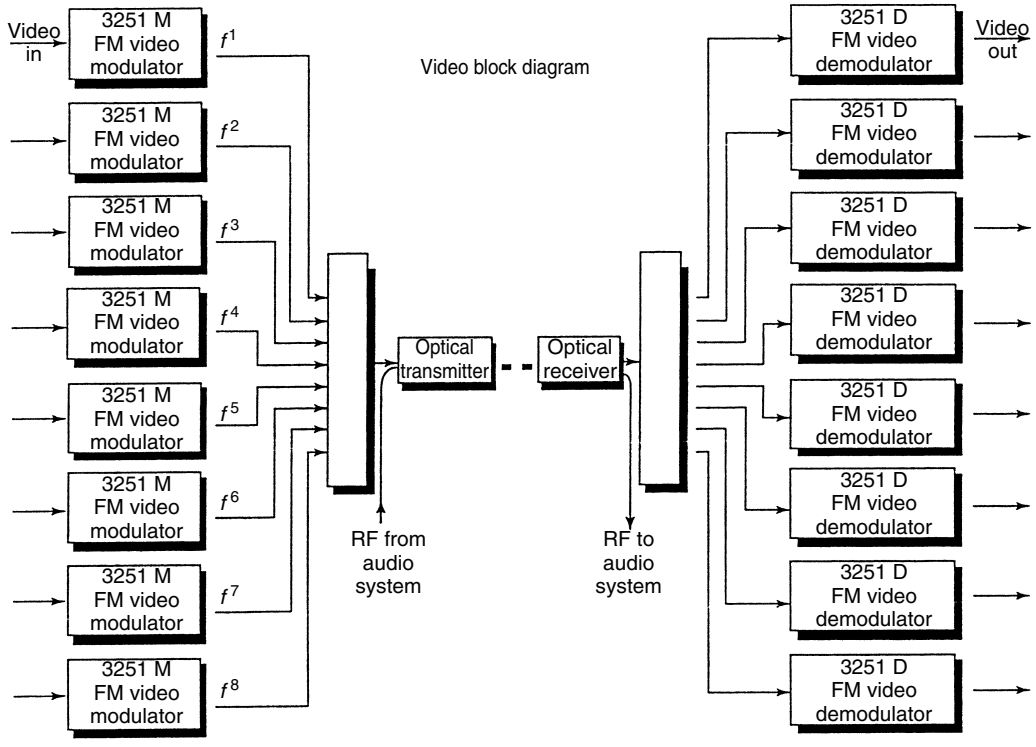

Figure 12. FM system model block diagram for video transmission subsystem. (Courtesy of Catel Corp.)

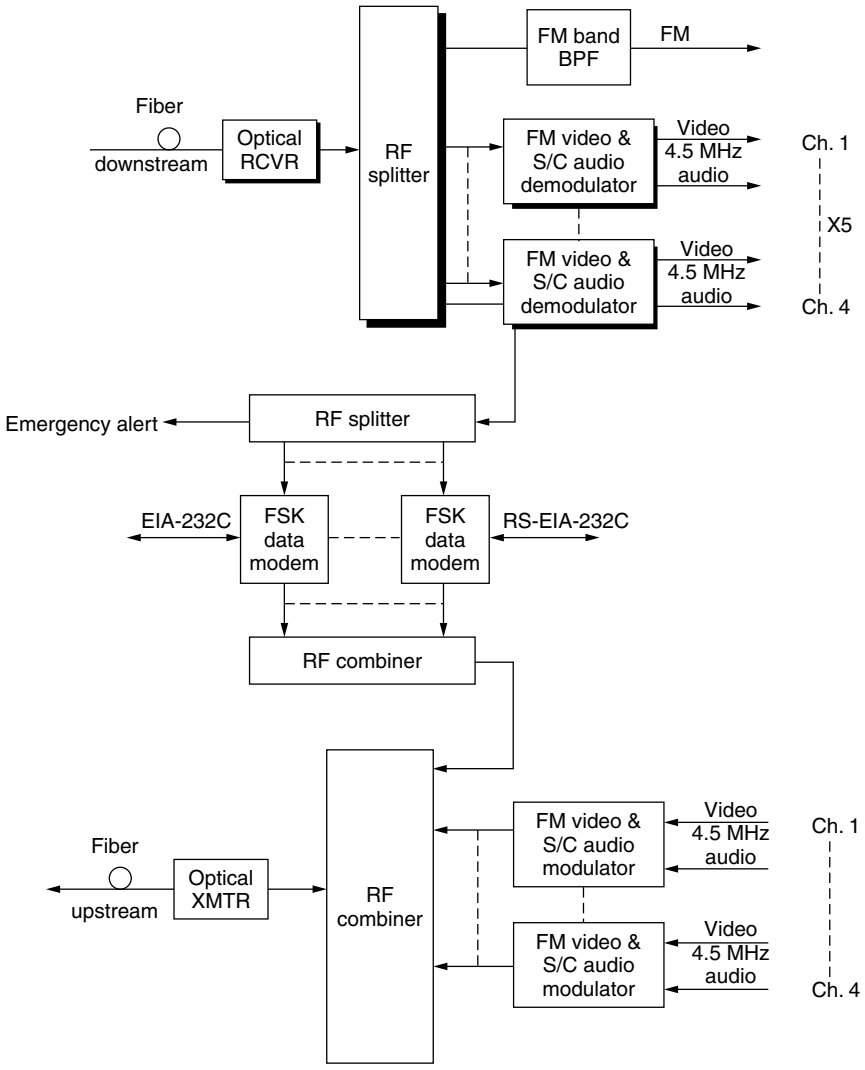

Figure 13. A typical FM/fiber hub.

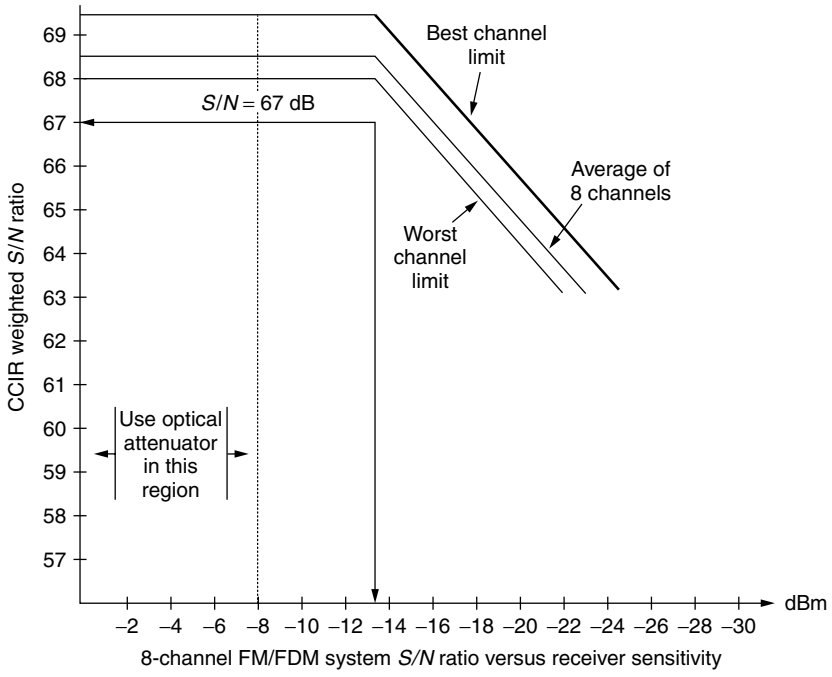

Figure 14. Link performance of an FM system. (Courtesy of Catel Corp.)

B_{IF} = IF bandwidth
B_F = baseband filter bandwidth
ΔF = sync tip-to-peak white (STPW) deviation

With $\Delta F = 4$ MHz, $B_{IF} = 30$ MHz, and $B_F = 5$ MHz, the SNRw is improved by approximately 34 dB above CNR.

Example 8. If the C/N on an FM fiber link is 32 dB, what is the S/N for a TV video channel using the values given above?

Use Eq. (14):

$$\begin{aligned} \text{S/N} &= 23.7\text{ dB} + 32\text{ dB} + 10\log(\tfrac{30}{5}) + 20\log(1.6 \times \tfrac{4}{5}) \\ &= 23.7 + 32 + 7.78 + 2.14 \\ &= 65.62\text{ dB} \end{aligned}$$

Figure 14 illustrates the link performance of an FM fiberoptic system for video channels.

Table 1 shows typical link budgets for an HFC AM system.

5. DIGITAL TRANSMISSION OF CATV

5.1. Approaches

There are two approaches to digitally transmit TV, both audio and video. The first is to transport raw, uncompressed video. The second method is to transport compressed video. Each method has advantages and disadvantages. Some advantages and disadvantages are application-driven. For example, if the objective is digital to the residence or office, compressed TV may be the most advantageous. In either case the ability to regenerate is a distinct advantage.

5.2. Transmission of Uncompressed Video on CATV Trunks

Video is an analog signal. It is converted to a digital format using techniques with some similarity to the 8-bit PCM so widely employed in the PSTN. A major difference is in the sampling. Broadcast quality TV is generally *oversampled*. Here we mean that the sampling rate is greater than the Nyquist rate. The Nyquist rate, as we remember, requires the sampling rate to be twice the highest frequency of interest. In our case this is 4.2 MHz, the bandwidth of a TV signal. Thus, the sampling rate is greater than 8.4×10^6 samples per second.

Typically, the sampling rate is based on the frequency of the color subcarrier. For NTSC television, the color subcarrier is at 3.58 MHz and we call this frequency f_{sc}. In some cases the sampling rate is set at three times this frequency ($3f_{sc}$) and in other cases four times the sampling rate ($4f_{sc}$). Thus, for NTSC color television, the sampling rate for the A/D converter is either $3 \times 3.58\text{ MHz} = 10.74 \times 10^6\text{ s}^{-1}$ or $4 \times 3.58\text{ MHz} = 14.32 \times 10^6$/s. For PAL television, the color subcarrier is 4.43 MHz and the sampling rate then may be $3 \times 4.43 = 13.29 \times 10^6$ MHz or $4 \times 4.43\text{ MHz} = 17.72 \times 10^6\text{ s}^{-1}$.

A major advantage of digital transmission is the regeneration capability just as it is in PSTN 8-bit PCM. As a result, there is no noise accumulation on the digital portion of the network. These digital trunks can be extended hundreds or more miles. The complexity is only marginally greater than an FM system. The 10-bit system can easily provide an S/N at the conversion hub of 67 dB in a video channel and an S/N of 63 dB with an 8-bit system. With uncompressed video, BER requirements are not very stringent because video contains highly redundant information.

5.3. Compressed Video

MPEG types of compression are widely used today. A common line bit rate for MPEG[2] is 1.544 Mbps. Allowing 1 bit per Hz of bandwidth, BPSK modulation and a cosine rolloff of 1.4, the 1.544 TV signal can be effectively transported in a 2 MHz bandwidth. Certainly 1000 MHz coaxial cable systems are within the state of the art. With simple division we can see that 500-channel CATV systems are technically viable. If the modulation scheme utilizes 16-QAM (4 bits per Hz theoretical), three 1.544 Mbps compressed channels can be accommodated in a 6-MHz slot. We select 6 MHz because it is the current RF bandwidth assigned for one NTSC TV channel.

6. TWO-WAY CATV SYSTEMS

6.1. Introduction

Panels (a) and (b) of Fig. 15 are two views of the CATV spectrum as it would appear on coaxial cable. Of course, with conventional CATV systems, each NTSC television channel is assigned a 6 MHz slot just as it is done with conventional broadcast television. In Fig. 15a, only 25 MHz is assigned for upstream services. Not all of this bandwidth

[2] MPEG = Motion Picture Experts' Group, a standardization agency, most know for motion picture (television) compression schemes.

Table 1. Typical Link Budgets for an AM Fiber Link

Distance (mi)	Distance (km)	Fiber Loss/km	Total Fiber Loss	Splice Loss/2 km	Total Splice Loss	Total Path Loss	Link Budget	Link Margin
Mileage, Losses, and Margins — 1310 nm								
12.40	19.96	0.5 dB	9.98	0.1 dB	1.00	10.98	13.00	2.02
15.15	24.38	0.4 dB	9.75	0.1 dB	1.22	10.97	13.00	2.03
17.00	27.36	0.35 dB	9.58	0.1 dB	1.37	10.94	13.00	2.06

22.75	36.61	0.25 dB	9.15	0.1 dB	1.83	10.98	13.00	2.02

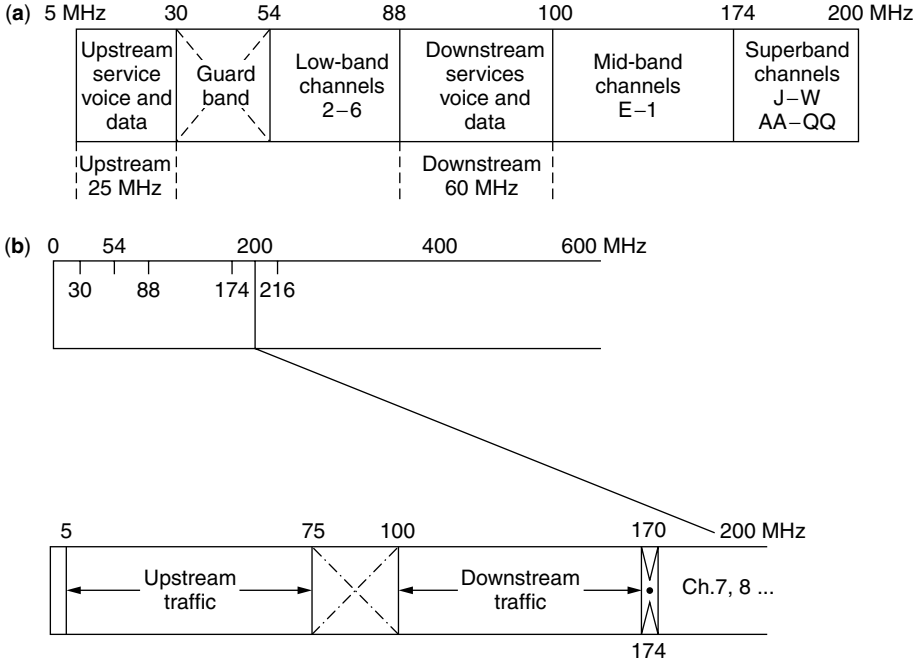

Figure 15. (**a**) CATV spectrum based on Grant [6] showing additional upstream and downstream services — note the bandwidth imbalance between upstream and downstream; (**b**) CATV spectrum with equal upstream and downstream bandwidths for other services [part (a) based on Ref. 6; part (b) prepared by the author]. On the other hand, downstream has 60 MHz assigned. In this day of the Internet, this would be providential, for the majority of the traffic would be downstream.

may be used for voice and data. A small portion should be set aside for upstream telemetry to monitor active CATV equipment. On the other hand, downstream has 60 MHz assigned. In this day of the internet, this would be providential, for the majority of the traffic would be downstream.

6.2. Comments on Fig. 15

Large guard bands isolate upstream from downstream TV and other services, with 24 MHz in A and 25 MHz in B. A small guardband was placed in the slot from 170 to 174 MHz to isolate downstream data and voice signals from conventional CATV television. We assume that the voice service will be "POTS" (plain old telephone service) and that both the data and voice would be digital.

In another approach, downstream voice, data and special video are assigned the band 550 to 750 MHz, which is the highest frequency segment portion of this system. (Ref. 12) In this case, we are dealing with a 750-MHz system.

The optical fiber trunk terminates in a node or hub. This is where the conversion from optical to the standard CATV coaxial cable format occurs. Let a node serve four groupings of subscribers, each with a coaxial cable with the necessary amplifiers, line extenders, and taps. Such subscriber groups consist of 200–500 terminations (TV sets). Assume that each termination has upstream service using the band 5–30 MHz (Fig. 15a). In our example, the node has four incoming 5–30-MHz bands, one for each coaxial cable termination. It then converts each of these bands to a higher-frequency slot 25 MHz wide in a frequency-division configuration for backhaul on a return fiber. In one scheme, at the headend, each 25-MHz slot is demultiplexed and the data and voice traffic are segregated for switching and processing.

An interesting exercise is to divide 25 MHz by 500. This tells us that we can allot each user 50 kHz full period. By taking advantage of the statistics of calling (usage), we could achieve 4–10 times bandwidth multiplier by using forms of concentration. However, upstream video, depending on the type of compression, might consume a large portion of this spare bandwidth.

There are many other ways for a subscriber can gain access, such as by TDMA, FDMA, and contention. Several protocols use combinations of time division and frequency division based on the concept of the minislot.

6.3. Impairments Peculiar to Upstream Service

6.3.1. More Thermal Noise Upstream than Downstream. Figure 16 shows a hypothetical layout of amplifiers in a CATV distribution system for two-way operation. In the downstream direction, broadband amplifiers point outward, down trunks and out distribution cables. In the upstream direction, the broadband amplifiers point inward

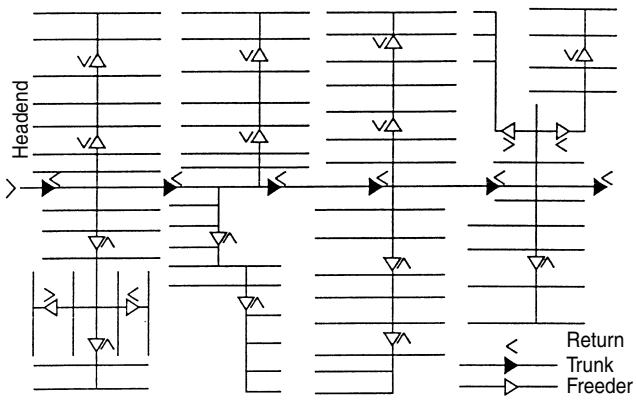

Figure 16. Trunk/feeder system layout for two-way operation. (From Grant [6]. Reprinted with permission.)

toward the headend, and all their thermal noise accumulates and concentrates at the headend. This can account for 3–20 dB additional noise upstream at the headend where the upstream demodulation of voice and data signals takes place. Fortunately, the signal-to-noise ratio requirements for good performance for voice and data are much less stringent than for video, which compensates to a certain extent for this additional noise.

6.3.2. Ingress Noise. This noise source is peculiar to CATV system. It basically derives from the residence/office TV sets that terminate the system. Parts 15.31 and 15.35 of the *FCC Rules and Regulations* govern such unintentional radiators. These rules have not been rigidly enforced.

One problem that the 75-Ω impedance match between the coaxial cable and the TV set is poor. Thus not only all radiating devices in the TV set but other radiating devices nearby in residences and office buildings couple back through the TV set into the CATV system in the upstream direction. This type of noise is predominant in the lower frequencies, that band from 5 to 30 MHz that carries the upstream signals. As frequency increases, ingress noise intensity decreases. Fiberoptic links in an HFC configuration provide some isolation, but it still can be a major problem.

6.4. Data Over Cable Service Interface Specification (DOCSIS)

DOCSIS is a complete specification for transmitting data across a cable television system. The intended service allows transparent bidirectional transfer of IP[5] traffic between the headend and customer facilities, over an all-coaxial or hybrid fiber/coax (HFC) cable network. The concept is illustrated in Fig. 17.

The specification for the cable modem (CMTS) is described in detail in DOCSIS [9,10]. A brief overview of the modulation and coding is given in the following section, which treats digital video transmission.

7. DIGITAL VIDEO TRANSMISSION STANDARD FOR CABLE TELEVISION

Based on document ANSI/SCTE 07 2000, issued Oct. 25, 1996 [9] Courtesy of Dr. Ted Woo, Technical Director, SCTE.

7.1. Introduction

This section describes the framing structure, channel coding, and channel modulation for a digital multiservice television distribution system that is specific to a cable channel. The system can be used transparently with the distribution from a satellite channel, in that many cable systems are fed directly from satellite links. The specification covers both 64- and 256-QAM waveforms. Most features of the two modulation schemes are the same. Where there are differences, the specific details of each modulation scheme are covered in the DOCSIS specification.

The design of the modulation, interleaving and coding is based on test and characterization of cable systems in North America. The modulation is quadrature amplitude modulation (QAM) with a 64-point signal constellation (64-QAM) or with a 256-point signal constellation (256-QAM), transmitter selectable. The forward error correction (FEC) is based on a concatenated coding approach that produces high coding gain at moderate complexity and overhead. Concatenated coding offers improved performance over a block code, at a similar overall complexity. The system FEC is optimized for quasi-error-free operation at a threshold output error event rate of one error event per 15 minutes.

The data format input to the modulation and coding is assumed to be MPEG-2[3] transport. However, the method used for MPEG synchronization is decoupled from the FEC synchronization. For example, this enables the system to carry asynchronous transfer mode (ATM) packets without interfering with ATM synchronization. In fact, ATM synchronization may be performed by defined ATM synchronization mechanisms.

Two modes are supported by this standard. Mode 1 has a symbol rate of 5.056 Msps, and mode 2 has a symbol rate of 5.361 Msps (megasymbols per second). Typically, mode 1 is used for 64-QAM and mode 2 is used for 256-QAM. The system is compatible with future implementations of higher-data-rate schemes employing higher order QAM extensions.

7.2. Cable System Concept

Channel coding and transmission are specific to a particular medium or communication channel. The expected channel error statistics and distortion characteristics are

[5] IP-Internet Protocol

[3] MPEG — Motion Picture Experts Group.

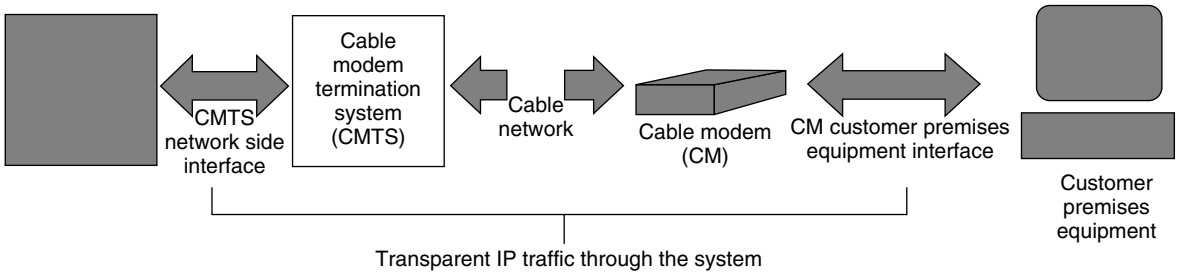

Figure 17. Transparent IP traffic through the data-over-cable system (from DOCSIS [10] Fig. 1.1, p. 2).

critical in determining the appropriate error detection and demodulation. The cable channel, including optical fiber, is regarded primarily as a bandwidth-limited linear channel with a balanced combination of white noise, interference, and multipath distortion. The quadrature amplitude modulation (QAM) technique, together with adaptive equalization and concatenated coding, is well suited to this application and channel.

The basic layered block diagram of cable transmission processing is shown in Fig. 18. The following subsections define these layers from the "outside" in, and from the perspective of the transmit side.

7.3. MPEG-2 Transport Framing

The transport layer for MPEG-2 data is composed of packets having 188 bytes, with 1 byte for synchronization purposes, 3 bytes of header containing service identification, and scrambling and control information, followed by 184 bytes of MPEG-2 or auxiliary data.

The MPEG transport framing is the outermost layer of processing. It is provided as a robust means of delivering MPEG packet synchronization to the receiver output. This processing block receives an MPEG-2 transport datastream consisting of a continuous stream of fixed-length 188-byte packets. This datastream is transmitted in serial fashion, MSB (most significant bit) first. The first byte of a packet is specified to be a sync byte having a constant value of 47_{HEX}.

7.4. Forward Error Correction

The forward error correction (FEC) definition is composed of four processing layers, as illustrated in Fig. 19. There are no dependencies on input data protocol in any of the FEC layers. FEC synchronization is fully internal and

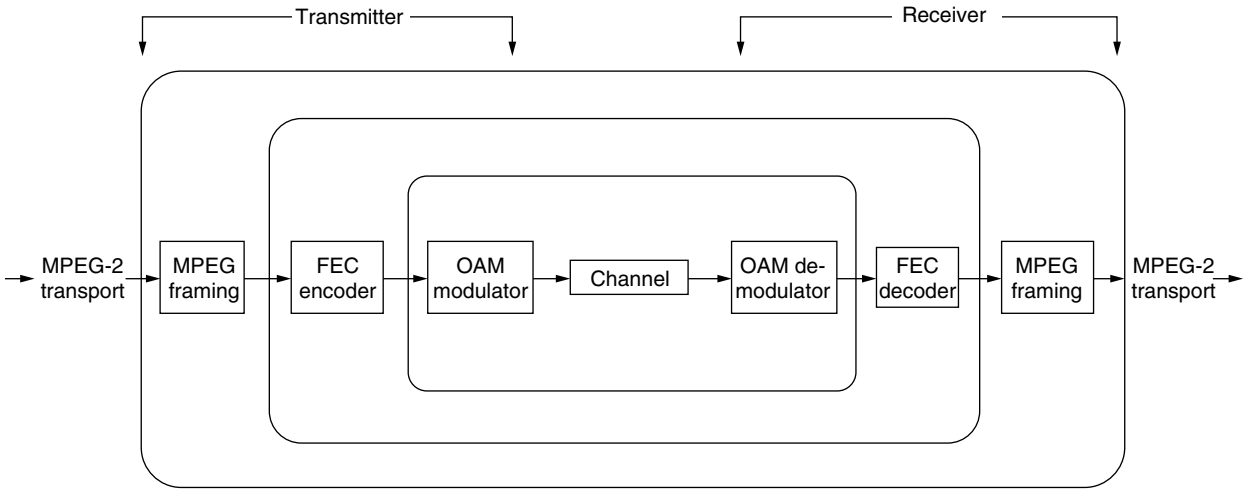

Figure 18. Cable transmission block diagram.

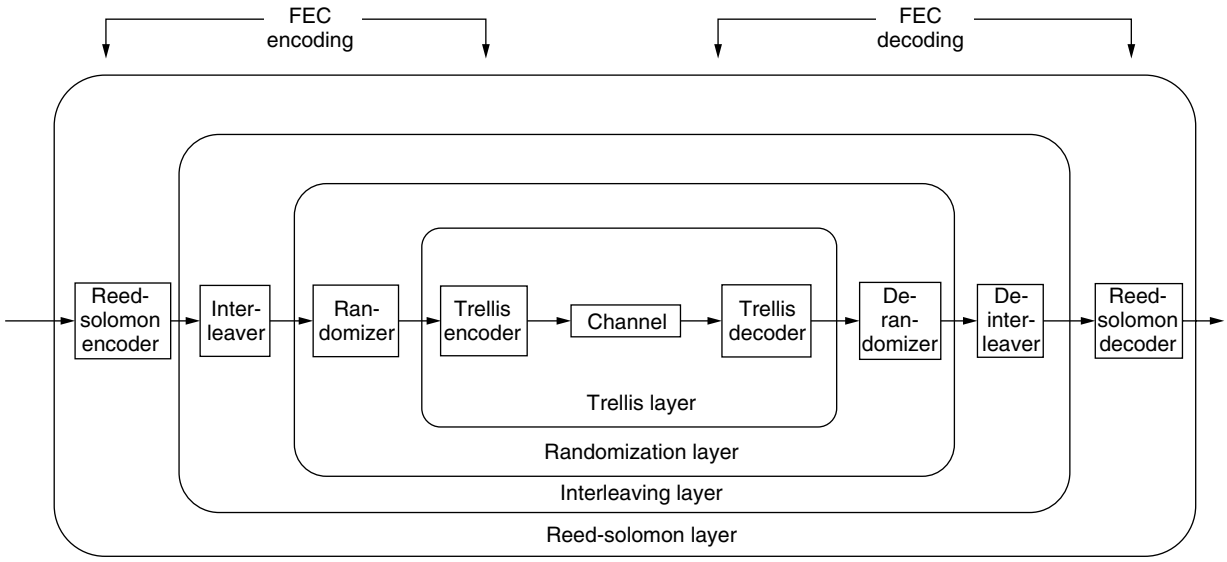

Figure 19. Layers of processing in the FEC.

transparent. Any data sequence will be delivered from the encoder input to the decoder output.

The FEC section uses various types of error-correcting algorithms and interleaving techniques to transport data reliably over the cable channel.

Reed–Solomon (RS) coding — provides block encoding and decoding to correct up to three symbols within an RS block

Interleaving — evenly disperses the symbols, protecting against a burst of symbol errors from being sent to the RS decoder

Randomization — randomizes the data on the channel to allow effective QAM demodulator synchronization

Trellis coding — provides convolutional encoding and with the possibility of using soft-decision trellis decoding of random channel errors

The following subsections define these four layers.

7.4.1. Reed–Solomon Coding. The MPEG-2 transport stream is Reed–Solomon (RS) encoded using a (128, 122) code over GF(128). This code has the capability of correcting up to $t = 3$ symbol errors per R–S block. The same R–S code is used for both 64-QAM and 256-QAM.

7.4.2. Interleaving. Interleaving is included in the modem between the RS block coding and the randomizer to enable the correction of burst noise induced errors. In both 64-QAM and 256-QAM, a convolutional interleaver is employed. The interleaver consists of a single fixed structure for 64-QAM, along with a programmable structure for 256-QAM.

7.4.3. Randomization. The randomizer is the third layer of processing in the FEC block diagram. The randomizer provides for even distribution of the symbols in the constellation, which enables the demmodulator to maintain proper lock. The randomizer adds a pseudorandom noise (PN) sequence of 7 bits over Galois Field GF(128) (i.e., bitwise exclusive-OR) to the symbols within the FEC frame to assure a random transmitted sequence.

7.4.4. Trellis-Coded Modulation. As part of the concatenated coding scheme, trellis coding is employed for the inner code. It allows introduction of redundancy to improve the threshold signal-to-noise ratio (SNR) by increasing the symbol constellation without increasing the symbol rate. As such, it is more properly termed *trellis-coded modulation*.

7.4.5. 64-QAM Modulation. For 64-QAM, the input to the trellis-coded modulator is a 28-bit sequence of four, 7-bit RS symbols, which are labeled in pairs of "A" and "B" symbols. A block diagram of a 64-QAM trellis-coded modulator is shown in Fig. 20. All 28 bits are assigned to a trellis group, where each trellis group forms 5 QAM symbols.

Of the 28 input bits that form a trellis group, each of two groups of 4 bits of the differentially precoded bitstreams in a trellis group are separately encoded by a binary convolutional coder.

The differential precoder allows the information to be carried by the change in phase, rather than by the absolute phase. For 64-QAM the third and sixth bits of the 6-bit symbols are differentially encoded, and for 256-QAM the fourth and eighth bits are differentially encoded.

7.4.6. Binary Convolutional Coder. The trellis-coded modulator includes a punctured rate-$\frac{1}{2}$ binary convolutional encode that is used to introduce the redundancy into the LSBs (least significant bits) of the trellis group. The convolutional encoder is a 16-state nonsystematic rate-$\frac{1}{2}$ encoder with the generator: G1 =

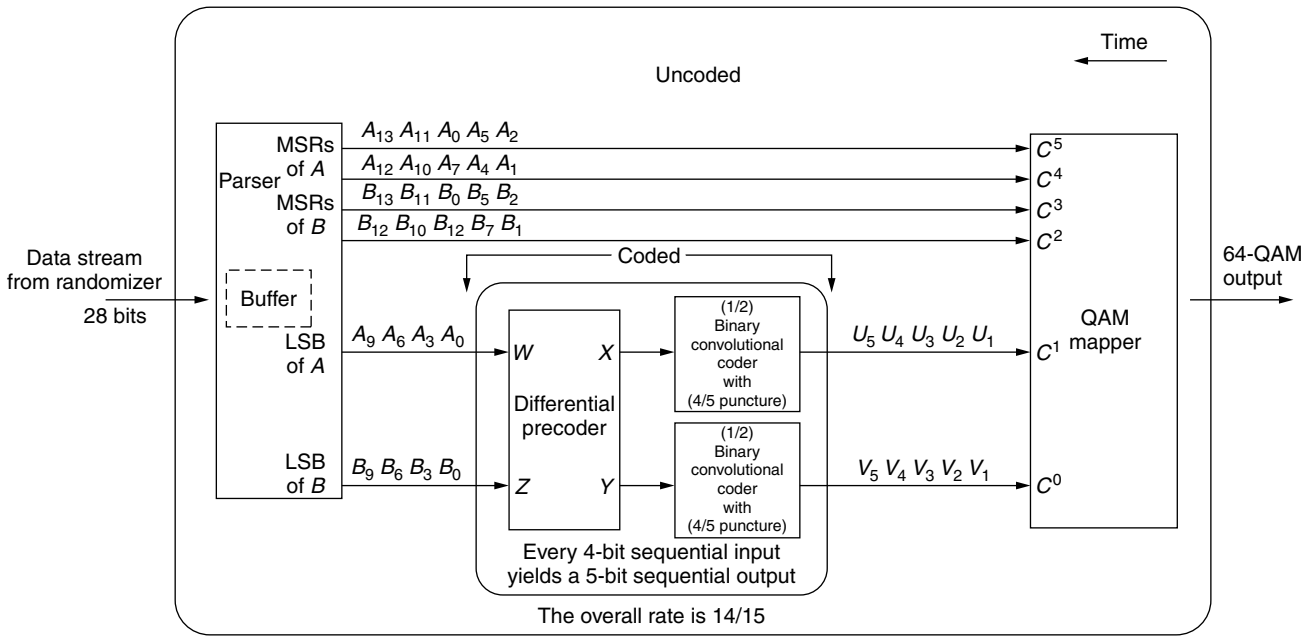

Figure 20. 64-QAM trellis-coded modulator block diagram.

010101, G2 = 011111(15, 37_{octal}), or equivalently the generator matrix[$1 \oplus D^2 \oplus D^4$, $1 \oplus D \oplus D^2 \oplus D^3 \oplus D^4$].

8. CONCLUSION

This concludes our brief description of the digital video transmission standard for CATV. A detailed description of this standard is contained in Ref. 9.

BIOGRAPHY

Roger Freeman has over 50 years experience in telecommunications including a stint in the US Navy and radio officer on merchant vessels. He attended Middlebury College and has two degrees from New York University. He has had assignments with the Bendix Corporation in Spain and North Africa which was followed by five years as a member technical staff for ITT Communications Systems. Roger then became manager of microwave systems for CATV extension at Jerrold Electronics Corporation followed by assignments at Page Communications Engineers in Washington, DC where he was a project engineer on earth stations and on various data communication programs. During this period he was assigned by the ITU as Regional Planning Expert for northern Sourth America based in Quito, Ecuador. From Quito he took a position with ITT at their subsidiary in Madrid, Spain where he did consulting in telecommunication planning. In 1978 he joined the Raytheon Company as principal engineer in their Communication Systems Directorate where he held design positions on military communications such as on the AN/TRC-170, MILSTAR, AN/ASC-30 and on wideband HF. At the same time he taught various telecommunication courses in the evenings at Northeastern University and 4-day seminars at the University of Wisconsin. These seminars were based on his several textbooks on telecommunications published by John Wiley & Sons, New York. He also gives telecommunication seminars (in Spanish) in Monterrey, Mexico City and Caracas. Roger is a contributor and guest editor (Desert Storm edition) of the IEEE Communications magazine and was advanced by the IEEE to senior life member in 1994. He served on the board of directors of the Spain Section of the IEEE and was its secretary for four years. In 1991 Roger took early retirement from the Raytheon Company and organized Roger Freeman Associates, Independent Consultants in Telecommunications. The group has undertaken over 50 assignments from Alaska to South America.

Roger may be reached at *rogerf67@cox.net*; his website is *www.rogerfreeman.com*. Also of interest would be *www.telecommunicationbooks.com* where the reader may subscribe to the on-line Reference Manual for Telecommunication Engineering, 3rd ed, updated quarterly.

COMPANDERS

JOHN G. PROAKIS
Northeastern University
Boston, Massachusetts

1. INTRODUCTION

The word *compander* comes from the words *comp*ressor and exp*ander*. Companders are widely used in communication systems to compress the dynamic range of an information-bearing signal, such as a speech signal, prior to digitizing the signal. In the transmission of analog signal waveforms digitally, the analog signal is usually sampled at some nominal rate that exceeds the Nyquist rate in order to avoid aliasing of frequency components. For example, in digital transmission of speech signals, the analog speech waveform at the transmitter is lowpass filtered to some nominal bandwidth, say, 3.5 kHz, and then sampled at a rate of 8 kHz. Each sample is quantized to one of a set of quantization levels and, then, represented by a sequence of bits that are transmitted via binary modulation to the receiver. The receiver reconstructs the quantized values of the samples from the received binary sequence and synthesizes the analog signal by passing the sampled values through a digital-to-analog converter. In such a system, the compressor is used at the transmitter to compress the dynamic range of the signal samples being quantized and the reverse process is performed at the receiver, where the dynamic range of the compressed signal values is inversely expanded.

Companding will be described below in the context of pulse code modulation (PCM), which is widely used to digitally encode analog signal waveforms.

2. PULSE CODE MODULATION

Pulse code modulation (PCM) is a very simple method for converting an analog signal waveform into a sequence of binary digits. The operations performed at the encoder of a PCM system are illustrated by the functional block diagram shown in Fig. 1.

The sampling is performed at a rate higher than the Nyquist rate to avoid aliasing of high-frequency signal components. The compression of the signal dynamic range is embedded in the quantizer. If the quantizer is selected to be uniform, then no signal compression is performed. On the other hand, if a nonuniform quantizer is selected that maps a signal sample x_n into a value $g(x_n)$, where $g(x_n)$ is some nonlinear function of x_n, then $g(x)$ determines the characteristics of the compressor. It is instructive to consider a uniform quantizer whose input are samples in the range$[-x_{\max}, +x_{\max}]$ and the number of quantization levels N is a power of 2, $N = 2^v$. From this, the length of each quantization region is given by

$$\Delta = \frac{2x_{\max}}{N} = \frac{x_{\max}}{2^{v-1}} \tag{1}$$

The quantized values are chosen to be midpoints of the quantization regions and, therefore, the error $\tilde{x} = x - Q(x)$ is a random variable taking values in the interval $\left(-\frac{\Delta}{2}, +\frac{\Delta}{2}\right]$. In ordinary PCM applications, the number of levels (N) is usually high and the range of variations of the input signal (amplitude variations $x_{\max}$) is small. This means that the length of each quantization region (Δ) is small and, under these assumptions, in each quantization region the error $\tilde{X} = X - Q(X)$ can be well approximated by a uniformly distributed random variable on $\left(-\frac{\Delta}{2} + \frac{\Delta}{2}\right]$. The distortion introduced by quantization (quantization noise) is therefore

$$E[\tilde{X}^2] = \int_{-(\Delta/2)}^{+(\Delta/2)} \frac{1}{\Delta}\tilde{x}^2\, d\tilde{x} = \frac{\Delta^2}{12} = \frac{x_{\max}^2}{3N^2} = \frac{x_{\max}^2}{3 \times 4^v} \tag{2}$$

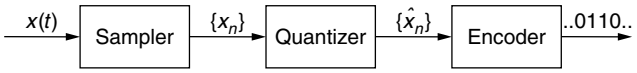

Figure 1. Block diagram of a PCM system.

where v is the number of bits per source sample. The SQNR ratio then becomes

$$\text{SQNR} = \frac{\overline{X^2}}{\overline{\tilde{X}^2}} = \frac{3 \times N^2\overline{X^2}}{x_{\max}^2} = \frac{3 \times 4^v\overline{X^2}}{x_{\max}^2} \tag{3}$$

If we denote the normalized X by $\breve{X}$, that is, $\breve{X} = \dfrac{X}{x_{\max}}$, then

$$\text{SQNR} = 3 \times N^2\overline{\breve{X}^2} = 3 \times 4^v\overline{\breve{X}2} \tag{4}$$

Note that by definition $|\breve{X}| \leq 1$ and, therefore, $\overline{\breve{X}^2} \leq 1$. This means that $3N^2 = 3 \text{ x } 4^v$ is an upperbound to the SQNR for a uniform quantizer. This also means that SQNR in a uniform quantizer deteriorates as the dynamic range of the source increases because an increase in the dynamic range of the source results in a decrease in $\overline{\breve{X}^2}$.

Expressing SQNR in decibels, one obtains

$$\text{SQNR}|_{\text{dB}} = P_{\breve{X}}|_{\text{dB}} + 6v + 4.8 \tag{5}$$

It is seen that each extra bit (increase in v by one) increases the SQNR by 6 dB.

3. COMPANDING

As long as the statistics of the input signal are close to the uniform distribution, a uniform quantizer works fine. However, in coding of certain signals such as speech, the input distribution is far from being uniformly distributed. For a speech waveform, in particular, there exists a higher probability for smaller amplitudes and lower probability for larger amplitudes. Therefore, it makes sense to design a quantizer with more quantization regions at lower amplitudes and less quantization regions at larger amplitudes. The resulting quantizer will be a nonuniform quantizer having quantization regions of various sizes.

The usual method for performing nonuniform quantization is to first pass the samples through a nonlinear element that compresses the large amplitudes (reduces dynamic range of the signal) and then perform a uniform quantization on the output. At the receiving end, the inverse (expansion) of this nonlinear operation is applied to obtain the sampled value. This techniques is called *companding* (compressing–expanding). A block diagram of this system is shown in Fig. 2.

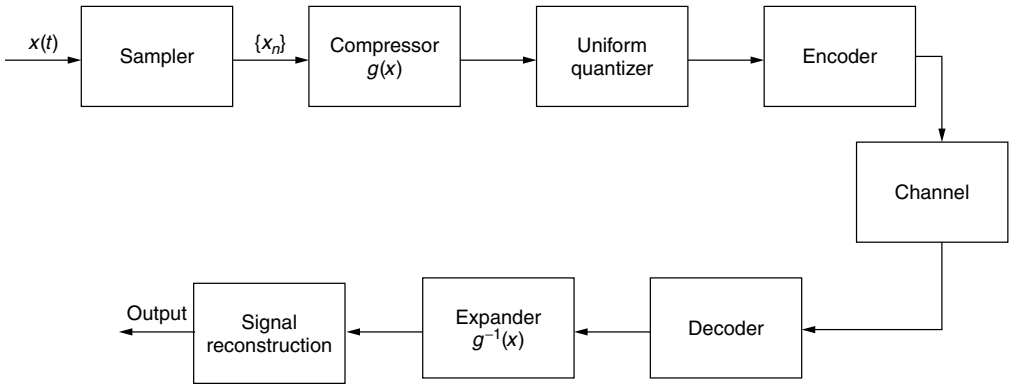

Figure 2. Block diagram of a PCM system employing a compander.

Two types of companders are widely used for speech coding. The μ-law compander used in the United States and Canada employs the logarithmic function at the transmitting side, where $|x| \leq 1$:

$$g(x) = \frac{\log(1 + \mu|x|)}{\log(1 + \mu)} \operatorname{sgn}(x) \tag{6}$$

The parameter μ controls the amount of compression and expansion. The standard PCM system in the United States and Canada employs a compressor with $\mu = 225$, followed by a uniform quantizer with 128 levels (7 bits per sample). Use of a compander in this system improves the performance of the system by ~30 dB. This means that the compander has implicitly provided an additional 5 bits of precision to that obtained by a uniform quantizer. A plot of the μ-law compander characteristics is shown in Fig. 3.

The second widely used logarithmic compressor is the A-law compander. The characteristic of this compander is given by

$$g(x) = \frac{1 + \log A|x|}{1 + \log A} \operatorname{sgn}(x) \tag{7}$$

where A is chosen to be 87.56. The performance of this compander is comparable to the performance of the μ-law compander. The characteristics of this compander are shown in Fig. 4.

4. CONCLUDING REMARKS

In digital coding of analog signals, such as speech signals, that have a nonuniform amplitude distribution, a nonuniform quantizer should be employed in order to reduce the number of bits per sample for a specified signal fidelity. Companding used in conjunction with a uniform quantizer results in a nonuniform quantization of the signal. In the case of speech signals, the μ-law or the A-law compander used in conjugation with a 7-bit/sample uniform quantizer result in an SQNR that is comparable to that obtained with a 12-bit/sample uniform quantizer without a compander. Thus, the use of a compander in the coding of speech signals via PCM has resulted in a significant reduction in the bit rate (by 5 bits per sample) that is to be transmitted over the channel.

COMPENSATION OF NONLINEAR DISTORTION IN RF POWER AMPLIFIERS

SEKCHIN CHANG
EDWARD J. POWERS
University of Texas at Austin
Austin, Texas

1. INTRODUCTION

In all wireless communication systems, whether terrestrial or satellite, an RF power amplifier (PA) is required at the transmitter to ensure the signal will be received at the receiver with sufficient signal-to-noise ratio (SNR). For small signal level inputs, the PA input–output relationship is linear. However, as the input signal level is increased, the output power eventually saturates, causing the input–output relationship to become nonlinear [1].

On one hand, it is desirable to operate a PA near saturation because of increased RF power output (important in, e.g., satellite communications) and increased DC-to-RF power conversion efficiency (important in battery-powered RF devices, e.g., mobile phones). However, operating the PA near saturation results in a number of undesirable nonlinear effects, including amplitude and phase distortion and the generation of in-band and out-of-band intermodulation frequencies. These phenomena associated with nonlinearity lead to an increased bit error rate (BER), in-band interference, and adjacent-channel interference (ACI).

One approach to mitigating the undesirable effects associated with saturation is to back off from saturation into a more linear region, but at the expense of reducing the available RF power output and efficiency. For example, if the RF power output is backed off 10 dB (which is not unreasonable), the available RF output power will be reduced to one-tenth of the maximum output power. For these reasons there is a significant need to mitigate the effects of nonlinearities and, thereby, reduce the amount of backoff required.

To compensate for the deleterious effects of PA nonlinearities, one might try to compensate the distorted signal received at the receiver. Even when this can be done in an efficient and practical matter with some type of equalizer, it does not eliminate the undesirable effects occurring at the transmitter associated with the generation of intermodulation frequencies and the resultant in-band and out-of-band interference. Thus we focus on nonlinear compensation at the transmitter.

To mitigate the efforts of nonlinearities at the transmitter, it is customary to predistort the signal to be transmitted in a way that is equal and opposite to the distortion introduced by the PA. In such a case, the PA output should ideally correspond to the output of an ideal linear amplifier (i.e., one that is linear right up to the saturation point). Of course, no predistortion technique is perfect, so some backoff is required. The next question is how much backoff is required and how one addresses the tradeoff between large backoff (linear operation, but low RF power output) and small backoff (nonlinear operation, but high RF power output). In this article we will address the tradeoff issue via the well-known concept of total degradation versus output backoff in order to determine the optimum output power backoff.

Generally speaking, the deleterious effects of nonlinearities are less severe for constant-amplitude modulation schemes such as various forms of PSK (phase shift keying) (BPSK, QPSK, etc.) versus more bandwidth-efficient multiamplitude modulation schemes such as QAM (quadrature amplitude modulation). Thus in this article we will demonstrate the performance of predistorters using the more challenging case of QAM modulation.

Another factor to be considered involves the use of single-carrier (frequency) versus multicarrier systems. Multicarrier systems, such as OFDM (orthogonal frequency-division multiplexing) are increasingly being used in such systems as digital audiobroadcasting and future-generation personal communication systems because of their robustness to impulse noise and multipath fading. However, such multicarrier systems are characterized by high peak-to-average power ratios (PAR) because the multicarrier signals will occasionally constructively interfere. This constructive interference leads to high peak power levels that drive the PA into the saturation region with all its negative nonlinear consequences. This suggests that, in general, multicarrier systems require more output power backoff than does a single-carrier system. Thus the utilization of predistorters in multicarrier systems is the more challenging case and is, therefore, why we choose to demonstrate the use of predistorters using OFDM in this article.

In the next section we overview some of the nonlinear characteristics of power amplifiers. In Section 3 we consider the sensitivity of OFDM systems to nonlinear distortion, and in Section 4 provide an overview of various approaches to predistorters with emphasis on Volterra-based predistorters. In particular, the ability of the Volterra-based predistorter to reduce BER, total degradation, and output backoff is demonstrated via a simulation experiment using 16-QAM-based OFDM system. Conclusions are stated in Section 5.

2. NONLINEAR CHARACTERISTICS OF POWER AMPLIFIERS

The characteristics of PAs are usually expressed by amplitude modulation–amplitude modulation (AM/AM) and amplitude modulation–phase modulation (AM/PM) conversions, which represent the amplitude and phase distortions, respectively, depending on the input signal magnitude. If $x(n)$ is an input signal to the PA, it can be defined by

$$x(n) = r(n)e^{j\theta(n)} \tag{1}$$

where n denotes discrete time and $r(n)$ and $\theta(n)$ are the amplitude and the phase of the input signal $x(n)$, respectively. Let $A[\cdot]$ and $\Phi[\cdot]$ be AM/AM and AM/PM conversions, respectively. Therefore, if $s(n)$ is the output signal of the PA, it can be expressed as

$$s(n) = A[r(n)]e^{j\{\Phi[r(n)]+\theta(n)\}} \tag{2}$$

After the input signal $x(n)$ is amplified as in Eq. (2), the amplified signal $s(n)$ is transmitted into the wireless channel.

PAs can be broadly classified into traveling-wave tube amplifiers (TWTAs) and solid-state power amplifiers (SSPAs). TWTA PAs usually exhibit higher output power, but lower reliability and more severe nonlinearities than do SSPAs. Therefore, TWTAs are still dominant in applications requiring high levels of RF output power [2]. For TWTAs, the AM/AM and AM/PM conversions are modeled by the following equations [3]

$$A[(r(n)] = \frac{\alpha_a r(n)}{1+\beta_a r^2(n)} \qquad \text{(AM/AM conversion)} \tag{3}$$

$$\Phi[(r(n)] = \frac{\alpha_p r^2(n)}{1+\beta_p r^2(n)} \qquad \text{(AM/PM conversion)} \tag{4}$$

where α_a, β_a, α_p, and β_p are constants, and the subscripts a and p denote amplitude and phase, respectively. Figure 1 illustrates the curves of the AM/AM and AM/PM conversions for the typical values of constants: $\alpha_a = 2.0$, $\beta_a = 1.0$, $\alpha_p = \pi/3$, and $\beta_p = 1.0$ [3]. Note that the input and output amplitudes are normalized to their respective saturation values.

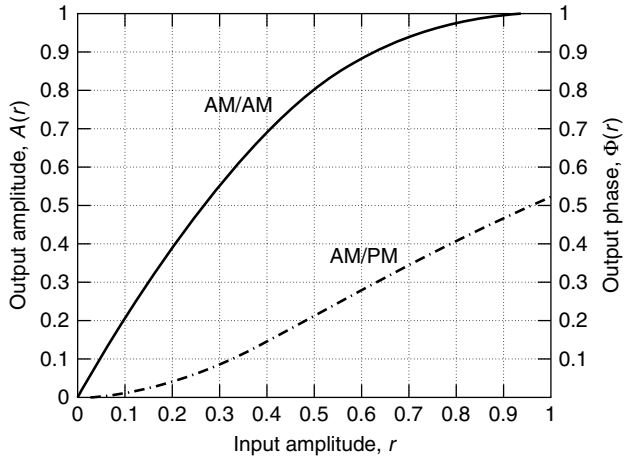

Figure 1. The AM/AM and AM/PM conversions of a traveling-wave tube amplifier (TWTA).

Unlike phase distortions in TWTAs, those in SSPAs are usually smaller [4]. In an SSPA AM/AM conversion is modeled as follows [4]:

$$A[(r(n)] = \frac{v_k r(n)}{\left(1+\left(\frac{v_k r(n)}{A_0}\right)^{2p_k}\right)^{1/2p_k}} \qquad \text{(AM/AM conversion)} \tag{5}$$

where v_k, A_0, and p_k are constants. TWTAs exhibit higher power gain and more severe nonlinearities than do SSPAs [5]. In the ideal case of either TWTAs or SSPAs, the AM/AM conversion curve should be a straight line with a constant slope, and the AM/PM conversion curve should be a constant.

Regardless of the kind of PA, the transmitted signal experiences some nonlinear distortion as indicated in Eq. (2). If the input signal $x(n)$ utilizes a simple modulation scheme such as binary phase shift keying (BPSK) or quadrature phase shift keying (QPSK), the nonlinear distortion has mild effects on the transmitted signal since these modulation schemes exhibit constant amplitude. However, if the input signal corresponds to a channel-efficient modulation scheme such as 16- or 64-QAM (quadrature amplitude modulation) where the amplitude varies, the nonlinear distortion will degrade the system performance severely. Moreover, multicarrier systems such as OFDM systems are more sensitive to nonlinear distortion as explained in Sections 1 and 3.

The degree of PA nonlinear distortion depends on the backoff amount. Backoff may be divided into input backoff (IBO) and output backoff (OBO) which are defined (in decibels) as Eqs. (6) and (7), respectively:

$$\text{IBO} = 10\log_{10}\frac{P_{i,\max}}{P_i} \tag{6}$$

$$\text{OBO} = 10\log_{10}\frac{P_{0,\max}}{P_0} \tag{7}$$

In Eq. (6), $P_{i,\max}$ represents the maximum input power of the PA at saturation and P_i denotes the mean input power of the signal at the PA input. Similarly, in Eq. (7) $P_{0,\max}$ represents the maximum output power of the PA at saturation and P_0 denotes the mean output power of the signal at the PA output. Figure 2 depicts the relationship between IBO and OBO using the AM/AM characteristics of a TWTA PA. Therefore, the operating point can be placed in the linear region of PA by backing off the PA from saturation, which leads to an effective reduction of nonlinear distortion. However, this scheme reduces the power efficiency of the PA and its output power. Therefore, a tradeoff between backoff and nonlinear distortion must be considered.

3. SENSITIVITY OF OFDM SYSTEMS TO PA NONLINEAR DISTORTION

Currently, OFDM is utilized for asymmetric digital subscriber line (ADSL), digital audiobroadcasting (DAB), and wireless local-area networks (WLANs) [6,7]. In

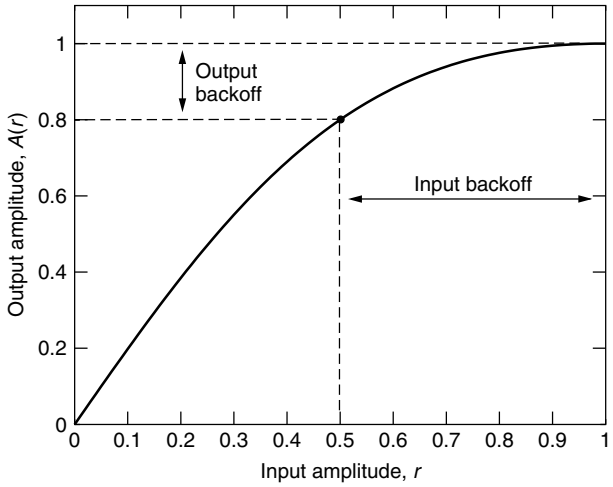

Figure 2. Input and output backoffs for a TWTA.

addition, OFDM is expected to be a strong candidate for wireless multimedia systems. Therefore, OFDM is believed to be a promising technique in wireless as well as wireline systems for high-rate data transmission [8]. OFDM utilizes a multicarrier modulation scheme, and exhibits many advantages over single-carrier modulation. Because of the increased symbol length, OFDM is robust to the effects of impulse noise and severe multipath fading [8,9]. In addition, the effects of the frequency selective fading can be greatly reduced without a high-cost equalizer by using a cyclic prefix.

However, multicarrier systems such as OFDM show great sensitivity to nonlinear distortion introduced by the PA. OFDM and other systems usually have a PA at the RF stage on the transmitter side as shown in Fig. 3 to increase the link fading margin of OFDM signals in a wireless channel. In Fig. 3, the incoming symbol input is a serial stream such as M-ary quadrature amplitude modulation (QAM) signals. After the input symbols are converted from serial to parallel (S/P) to form a vector of N M-ary symbols, the N symbols are modulated onto N subcarriers by the inverse fast Fourier transform (IFFT) and subsequently converted back from parallel to serial (P/S) data symbols. As mentioned by Karam and Sari [10], digital radio systems usually employ baseband pulseshaping at the transmitter. Therefore, the linear filter in Fig. 3 indicates the pulse shaping filter.

Since the input data to the IFFT are generally independent and identically distributed (i.i.d.) in OFDM systems, the modulated signals can be considered random signals with a zero-mean Gaussian distribution according to central limit theorem. Therefore, the signals of OFDM systems exhibit higher peak-to-average power ratio (PAR) than do those of single-carrier systems in the time domain. Therefore, OFDM systems are more sensitive to PA nonlinear distortion than are single-carrier systems because of their larger PAR. In other words, more frequent utilization of the PA's high-power region is inevitable in OFDM systems in order to produce an average output power comparable to that of single-carrier systems, thus resulting in severe performance degradation due to nonlinear distortion introduced by the PA.

4. COMPENSATION METHODS OF NONLINEAR DISTORTION

Nonlinear distortion can be reduced by backing off the PA from saturation. However, as stated earlier, back-off reduces the PA output power. Thus, some form of nonlinear compensation is desirable to mitigate nonlinear distortion while at the same time reducing the amount of backoff required. For the efficient compensation of nonlinear distortion, predistorters have been widely utilized, where the predistorter is placed in front of the PA. The predistorter distorts the input signal in such a way as to compensate for the nonlinear distortion introduced by the PA. Moreover, predistorters may be designed to be adaptive. The adaptation property is very desirable because the characteristics of PAs are time variant due to temperature variation and aging [3].

4.1. Some General Predistortion Schemes

In general, predistorters can be classified into several types according to the predistorter structure and position. Usually, predistorters belong to a minimum mean-square error (MMSE) type or amplitude/phase (AP) type based on predistorter structure. According to the location where the predistorter is placed, it is commonly called an analog or digital (or data) predistorter.

Figure 4 shows an MMSE predistorter. As depicted in this figure, the coefficients of the predistorter are trained to minimize the mean square error between output $y(n)$ of PA and input $x(n)$ to the predistorter. An MMSE predistorter has been proposed [11] and its performance analyzed in OFDM systems [12]. In these articles, the input and output responses were related with third-order polynomials. Generally, the MMSE predistorter can achieve a global compensation of the nonlinear distortion

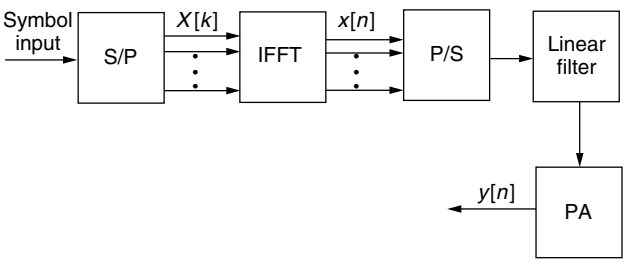

Figure 3. An OFDM system with PA.

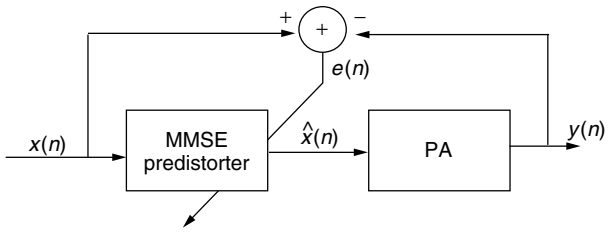

Figure 4. The general structure of a MMSE predistorter.

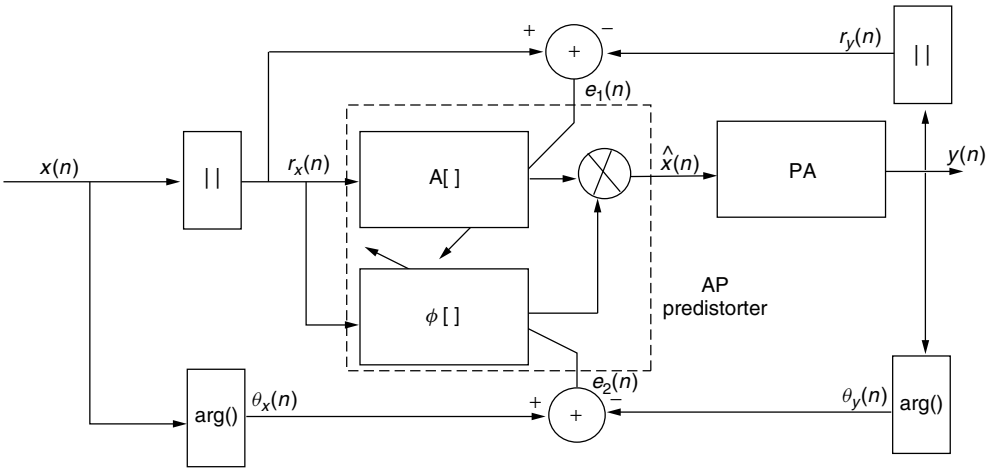

Figure 5. The general structure of an AP predistorter.

of the PA if a proper learning architecture is employed. On the other hand, the MMSE approach requires complex-valued coefficients in the predistorter to compensate for amplitude and phase distortion.

The amplitude/phase (AP) predistorter is illustrated in Fig. 5, which shows that the predistorter consists of amplitude $A[\cdot]$ and phase $\Phi[\cdot]$ coefficients. In other words, the coefficients of each type are separately trained so as to minimize the amplitude and the phase errors between output $y(n)$ of the PA and input $x(n)$ of the predistorter. The AP predistorter was introduced by D'Andrea et al. [13] and its performance was measured in OFDM systems [14]. In these articles, the linearizing functions $A[\cdot]$ and $\Phi[\cdot]$ of the predistorter were separately approximated as polynomials. Usually, each polynomial has real-valued coefficients. Therefore, the AP predistorter can exhibit a faster convergence rate than does the MMSE predistorter in training the predistorter coefficients. However, the predistorter requires additional separation and combination modules for the amplitude/phase of the input signal $x(n)$ because it must obtain separate optimal solutions to compensate for the amplitude and phase distortions of the PA.

Figure 6 depicts general structures of analog and digital (or data) predistorters. As shown in this figure, the analog predistorter is placed after the pulseshaping filter in the RF (or possibly IF) band. On the other hand, the digital predistorter is placed before the pulseshaping filter at baseband. Therefore, while the analog predistorter just compensates the memoryless nonlinearity of the PA, the digital predistorter is required to compensate a nonlinearity with memory due to the series combination of the linear pulseshaping filter, which provides memory, and the PA, which is essentially a memoryless nonlinearity. However, the digital predistorter exhibits more flexibility in determining the predistorter coefficients than the analog predistorter, since the learning algorithm is programmable in the digital predistorter. This suggests that the digital predistorter can be more adaptive to time-variant PAs.

In the following sections, we describe several predistorters that have shown good performance in compensating nonlinear distortion introduced by the PAs. We will emphasize the Volterra-based predistorter, which has been utilized for compensation of nonlinear distortion in OFDM systems. The Volterra-based predistorter belongs to the MMSE and digital class of predistorters. As indicated above, such a predistorter type has a global solution and training flexibility, but also demands a lot of learning time. Therefore, we will also indicate an efficient learning architecture for the predistorter.

4.2. Predistortion Using a Lookup Table

This efficient predistortion scheme has been applied to QAM radio systems with good results [10]. The scheme utilized a lookup table or random-access memory (RAM), which included the predistorter candidates. If an input sequence to the predistorter is given, the candidate that minimizes the error between the input data to the predistorter and the output data of the PA is selected as the output of the predistorter. Each candidate is updated until the error converges to a desired value. Since the input signals exhibit a finite number of data levels regardless of the modulation scheme used in single-carrier systems, the lookup table predistortion scheme can be easily adapted to various PAs. However, it is probably not feasible to

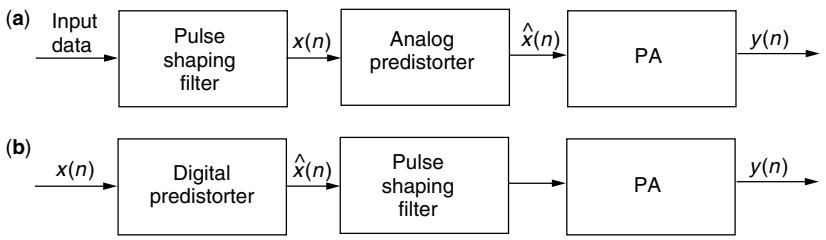

Figure 6. The general structures of analog and digital predistorters for (**a**) analog predistorter and (**b**) digital predistorter.

utilize this scheme in multicarrier systems because these systems usually show many different data levels due to the constructive and destructive interference of the multicarrier components.

4.3. Volterra-Based Predistorter

This adaptive predistorter essentially consists of a Volterra series because the Volterra series has shown excellent performance in modeling and compensating nonlinear phenomena with memory. Thus, it is particularly suitable for use as a digital predistorter. In discrete time, a third-order Volterra series for a causal, finite memory system becomes

$$y[n] = \sum_{k=0}^{N_1-1} h_k^{(1)} x[n-k] + \sum_{k=0}^{N_2-1}\sum_{l=0}^{N_2-1} h_{k,l}^{(2)} x[n-k]x^*[n-l] + \sum_{k=0}^{N_3-1}\sum_{l=0}^{N_3-1}\sum_{m=0}^{N_3-1} h_{k,l,m}^{(3)} x[n-k]x[n-l]x^*[n-m] + e[n] \tag{8}$$

where N_1, N_2, and N_3 respectively denote the memory duration of the first-order, the second-order, and the third-order terms; $x[n]$ and $y[n]$ are the complex input and output, respectively; $h_k^{(1)}$, $h_{k,l}^{(2)}$, and $h_{k,l,m}^{(3)}$ are the complex discrete time domain Volterra kernels of order 1, 2, 3, respectively; and $*$ and $e[n]$ denote the complex conjugate and the modeling error, respectively. In Fig. 6b, the PA is preceded by a linear filter. In digital communication systems, the combination of the PA and linear filter may be regarded as a nonlinear system with memory that is to be compensated [15]. Since the Volterra series may be regarded as a Taylor series with memory, a Volterra-based predistorter exhibits a structure suitable for compensation of such a system.

We may represent the third-order Volterra series of Eq. (8) in matrix form as

$$\hat{d}[n] = \mathbf{h}\mathbf{x}^T[n] \tag{9}$$

where $\hat{d}[n]$ is the estimated output of the Volterra predistorter, the superscript T denotes the transpose of the matrix, $\mathbf{h}$ is the Volterra kernel vector, and $\mathbf{x}[n]$ is the input vector, which are defined by

$$\mathbf{h} = [h_0^{(1)}, h_1^{(1)}, \ldots, h_{N_1-1}^{(1)}, h_{000}^{(3)}, h_{001}^{(3)}, h_{002}^{(3)}, \ldots, \times h_{klm}^{(3)}, \ldots, h_{(N_3-1)(N_3-1)(N_3-1)}^{(3)}] \tag{10}$$

$$\mathbf{x}[n] = [x[n], x[n-1], \ldots, x[n-N_1+1], |x[n]|^2x^*[n], \times |x[n]|^2x^*[n-1], |x[n]|^2x^*[n-2], \ldots, \times |x[n-N_3+1]|^2x^*[n-N_3+1]] \tag{11}$$

where N_1 and N_3 are the memory durations of the first-order term and the third-order term, respectively. In Eqs. (10) and (11), the absence of the second-order term is due to the fact that even-order intermodulation components do not interfere with the in-band signal for a bandpass nonlinear channel [16], since they lie out of band. However, odd-order nonlinearities generate intermodulation frequency components that lie both out of band and in band. Because of this latter fact, odd-order terms are retained in the Volterra series.

Figure 7 shows why only the odd-terms contribute to the bandpass channel. In communication systems, the PA is placed at the RF stage. Therefore, the signal $x(t)$ is upconverted to the carrier frequency f_0. The upconverted signal $r(t)$ is inputted to the nonlinear PA, thus various harmonics of the carrier frequency f_0 appear in the output. As Fig. 7 indicates, only the odd-order nonlinearities contribute to in-band components centered at f_0.

It is well known that Volterra kernels can be assumed symmetric without any loss of generality [17]. Therefore, the third term in Eq. (8) can be rewritten as follows:

$$y_3[n] = \sum_{k=0}^{N_3-1}\sum_{l=k}^{N_3-1}\sum_{m=0}^{N_3-1} h_{k,l,m}^{(3)} x[n-k]x[n-l]x^*[n-m] \tag{12}$$

Taking into account symmetry, the number of kernel coefficients for each order term will be

$$K_1 = N_1 \tag{13}$$

$$K_3 = \frac{N_3^2(N_3+1)}{2} \tag{14}$$

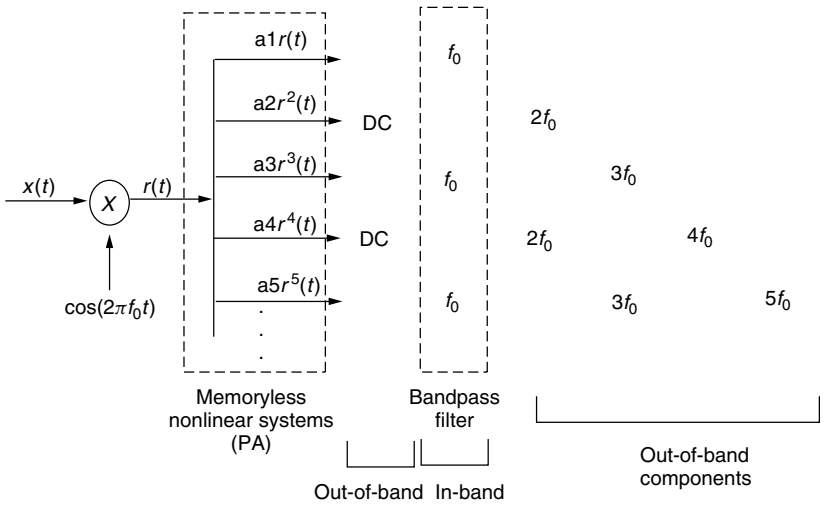

Figure 7. Abscence of even-order terms in a bandpass channel.

and the total number of Volterra coefficients for the predistorter can be represented as

$$K_T = K_1 + K_3 \tag{15}$$

The next challenge is to determine the numerical values of the Volterra coefficients for a given PA.

4.4. Learning Architecture for Volterra-Based Predistorter

The Volterra-based predistorter belongs to the MMSE and digital classes of predistorters. A particular challenge associated with this predistorter (and indeed most predistorters) is to determine the Volterra coefficients, since the desired output of the predistorter is not readily known beforehand. Thus, the predistorter design requires an efficient learning architecture to train the predistorter coefficients rapidly.

A relatively new and efficient training architecture [18] composed of both the indirect and direct learning algorithms is depicted in Fig. 8. In earlier work [15], only the indirect learning scheme was utilized. As seen in Fig. 8, there are two identical models: the actual predistorter and another for training. The two models share the same predistorter coefficient vector **h**. As stated previously, the "PA with memory" in Fig. 8 represents the PA preceded by a linear filter. In the learning structure of Fig. 8, at each iteration the predistorter coefficients are first updated using the indirect learning algorithm, which makes $\alpha[n]$ approach zero, and are then updated using the direct learning algorithm, which makes $\beta[n]$ approach zero. As $\alpha[n]$ and $\beta[n]$ approach zero, $y[n]$ approaches $x[n]$, which implies complete compensation of the PA's nonlinear distortion. These updates continue until the coefficients converge. Since the coefficients are updated twice in each iteration, this training scheme exhibits rapid convergence. Both the indirect and direct learning algorithms utilize the recursive least-squares (RLS) technique [19] for fast updates of the predistorter coefficients. A particular advantage of the approach described here is that one does not first require a Volterra model of the system to be compensated.

Figure 9 shows the learning curves (mean squared error (MSE) vs the number of iterations) for two Volterra-based adaptive predistorters, one of which was trained by the new learning scheme, direct and indirect architecture (DIA), and the other by the old learning scheme, indirect architecture-only (IAO) methods. From this figure, it is seen that the DIA scheme achieves an improvement of up to 5 dB or more in the MSE performance over the IAO scheme for 2000 or more iterations. This result signifies that the new learning algorithm is effective in increasing the convergence rate of the Volterra-based adaptive predistorter.

4.5. Simulation Experiments

In this section we carry out a simulation experiment to give the reader some feeling for the type of advantages one can achieve using predistorters.

An OFDM system with 128 subcarriers and 16-QAM symbols is considered. In this simulation, it is assumed that the nonlinear degree is 3 and the memory length of the linear filter shown in Fig. 3 is 3. Therefore, a third-order Volterra-based predistorter is used, and the first-order memory length (N_1) and the third-order memory length (N_3) for the Volterra predistorter are set to 3 in this simulation. From Eq. (15), the total number of the predistorter coefficients is 21. As mentioned in Section 2, the TWTA is known to be more nonlinear than the SSPA. Thus, we utilize a TWTA in this simulation because it poses a more severe challenge for the predistorter.

Received 16-QAM constellations of the OFDM system with and without the Volterra predistorter are shown in Fig. 10, where E_b/N_0 (energy per bit divided by the

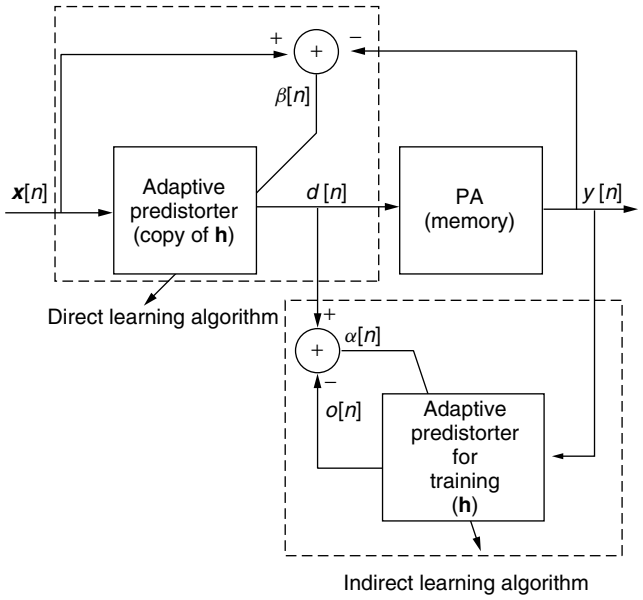

Figure 8. The learning architecture for a Volterra-based predistorter. ([18], © 2000 IEEE).

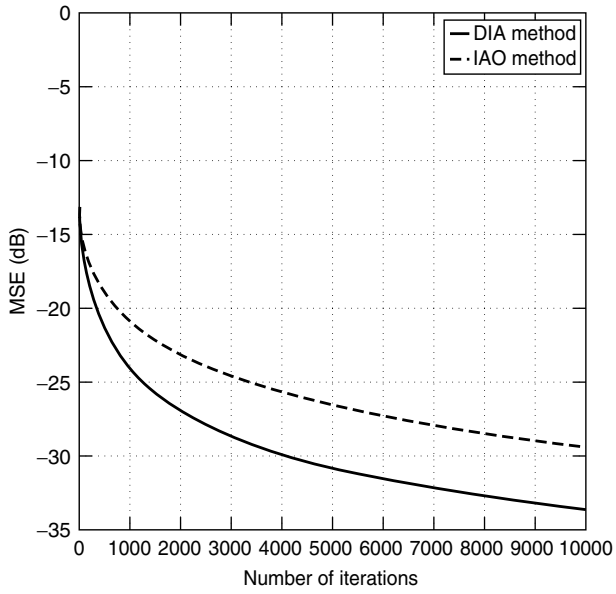

Figure 9. Learning curves of predistorters based on DIA and IAO ([18], © 2000 IEEE).

noise power spectral density) is assumed to be ∞. In the figure captions, the normalized mean-squared error (NMSE) values are also given for numerical comparisons of distorted or compensated constellations. Figures 10a,c show the distorted received signal constellations (no predistortion compensation) at output backoffs (OBOs) of 8.5 and 4.7 dB, respectively. Figures 10b,d show the received signal constellations when compensated by the proposed Volterra predistorter for OBOs of 8.5 and 4.7 dB, respectively. Comparison of Figs. 10a and 10b indicates that the signal distortion is almost perfectly compensated by the Volterra predistorter when the OBO is 8.5 dB. Figure 10d also shows some compensation of the signal distortion seen in Fig. 10c for an OBO of 4.7 dB. The relatively large clustering of Fig. 10d is due to the fact that the predistorter is driven into the saturation region by the large envelope fluctuations characteristic of multicarrier systems since the OBO of 4.7 dB is relatively small.

Therefore, we can see from this simulation result that the performance of the Volterra-based predistorter in compensating nonlinear distortion of PA is dependent on the OBO values. As a performance measure to investigate the tradeoff between nonlinear distortion and OBO in the PA, the total degradation (TD) is usually utilized and defined in decibels by

$$\mathrm{TD} = \left[\frac{E_b}{N_{0_{(\mathrm{NLPA})}}} - \frac{E_b}{N_{0_{(\mathrm{LPA})}}}\right] + \mathrm{OBO} \quad (\mathrm{dB}) \tag{16}$$

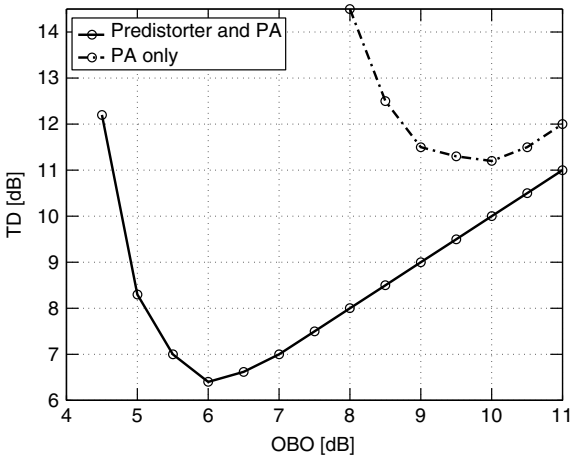

Figure 11. Total degradation versus OBO at a BER of 10^{-4} for the PA with predistorter and the PA-only ([18], © 2000 IEEE).

where $E_b/N_{0_{(\mathrm{NLPA})}}$ represents the required E_b/N_0 to obtain a specific BER when the nonlinear PA is used, and $E_b/N_{0_{(\mathrm{LPA})}}$ denotes the required E_b/N_0 to maintain the same BER, assuming that the amplifier exhibits no nonlinearities. In Fig. 11, the TD is shown for various OBO values for a BER of 10^{-4}. This figure illustrates the cases for the PA with predistorter and for the PA-only. The OBO which minimizes TD is called the *optimum OBO*. As seen in the figure, the minimum TD for the PA-only is 11.2 dB at an OBO of 10 dB, and the minimum TD of the PA with

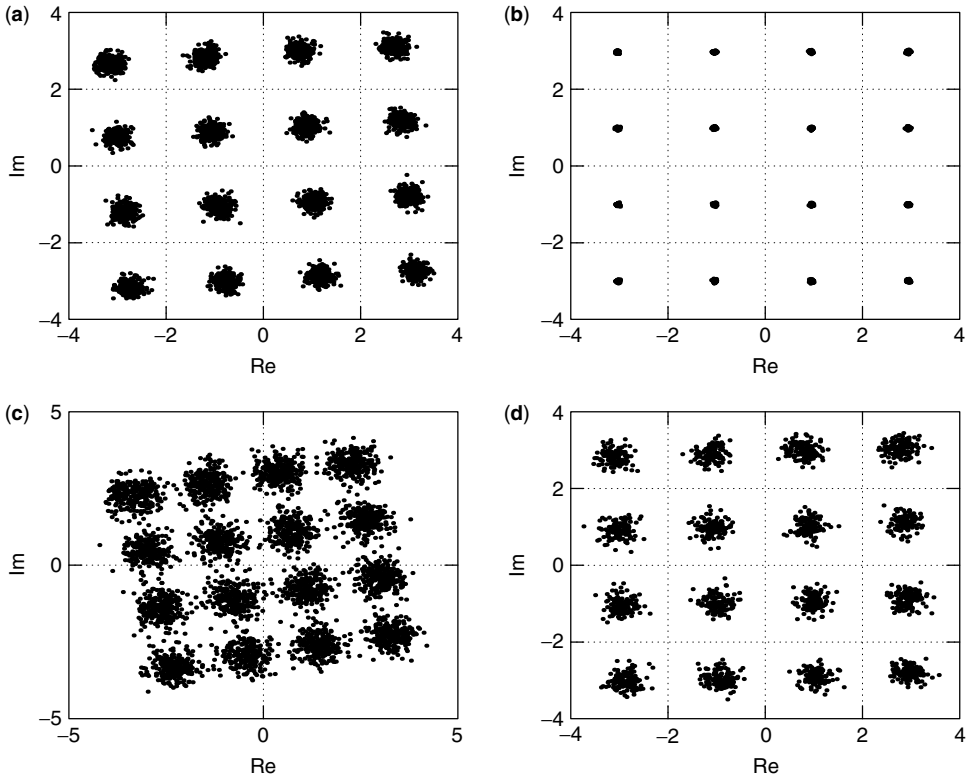

Figure 10. Received 16-QAM constellations for (**a**) PA-only (NMSE = 0.00913) at OBO = 8.5 dB, (**b**) predistorter and PA (NMSE = 0.000071) at OBO = 8.5 dB, (**c**) PA-only (NMSE = 0.0533) at OBO = 4.7 dB, and (**d**) predistorter and PA (NMSE = 0.00825) at OBO = 4.7 dB, respectively. ([18], © 2000 IEEE).

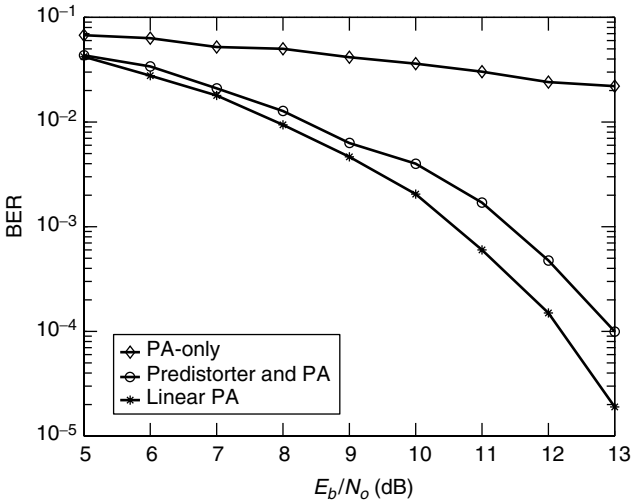

Figure 12. BER performance versus E_b/N_0 at OBO of 6.0 dB for the PA-only, the PA with Volterra-based adaptive predistorter, and the linear PA.

predistorter is 6.4 dB at an OBO of 6.0 dB. Therefore, the PA with predistorter achieves an output power increase of about 4 dB (10 dB − 6 dB) over PA-only case. Furthermore, the TD is reduced by 4.8 dB (11.2 dB − 6.4 dB).

Figure 12 compares the bit error rate (BER) performances for the cases of the PA without any predistortion and with the Volterra-based predistorter, and the ideal case without any nonlinear distortion of the PA (linear PA) at an OBO of 6.0 dB. In Fig. 12, it is shown that the BER performance is severely degraded as a result of nonlinear distortion in the case without predistortion; that is, increasing E_b/N_0 has a relatively small effect on reducing the BER. On the other hand, the BER performance of the combination of the Volterra-based predistorter and PA is fairly close to that of an ideal linear PA, thereby demonstrating the efficacy of the predistorter.

5. CONCLUSION

In this brief article the advantages of using predistorters to mitigate the effects of nonlinear distortion introduced by PAs and to reduce the amount of output backoff have been stressed and demonstrated via a predistorter example using a Volterra-based predistorter. In conclusion, it should be reiterated that there are many approaches to predistorters, some of which were mentioned in this article, and others of which are cited in the bibliography.

BIOGRAPHIES

Edward J. Powers received his B.S., M.S., and Ph.D. degrees from Tufts University, Massachusetts Institute of Technology, and Standford University in 1957, 1959, and 1965, respectively. All degrees were in electrical engineering. From 1959 to 1965 Dr. Powers was employed by Lockheed Missiles and Space Company in Sunnyvale and Palo Alto, California. In 1965, he joined the University of Texas at Austin, where he subsequently became Chair of the Department of Electrical and Computer Engineering from 1981 to 1989. He is currently the Texas Atomic Energy Research Foundation Professor in Engineering and Director of the Telecommunications and Signal Processing Research Center. His current professional interests include applications of higher-order statistical signal processing to detect, analyze, and model time series data associated with nonlinear physical phenomena; and applications of wavelets and time-frequency techniques to detect and classify various transient events in physical systems. He was elected a Fellow of IEEE in 1983.

Sekchin Chang received the B.S. and the M.S. degrees in electronics engineering from Korea University, Seoul, Korea in 1991 and 1993, respectively, and the Ph.D. degree in electrical engineering from the University of Texas at Austin in 2001. From 1993 to 1998, he was with Electronics and Telecommunications Research Institute (ETRI), Taejon, Korea, where he worked on the design and development of IS95 CDMA systems. In 2000, he joined Motorola, Austin, Texas, where he contributed to the design of modems for WCDMA systems, and is currently involved in the development of WLAN systems. His research interests include OFDM, WCDMA, adaptive predistortion, carrier and timing recovery, RAKE receivers, blind equalizers, and MIMO systems.

1. WHAT IS A COMMUNICATION PROTOCOL?

In the "Information Age," concepts such as "communications," "information sharing," and "networking" sometimes seem to monopolize the attention of not only the information technology (IT) experts but also the ever-growing IT end-user community. In this context, "networking" denotes the information exchange between computers or like systems, which can be very different from one another and may be scattered over wide geographic areas.

Outside the network are the computers, databases, terminals, and other devices that need to exchange information. Messages originate at these external hosts, pass into the network, pass from node to node on the communication links, and finally pass out to the external recipients. The nodes of the network, usually computers in their own right, serve primarily to forward the messages through the network.

In order for such external systems to communicate, a common "language" has to be established among them. At the human level, when two people want to communicate (effectively), they have to agree first on a language that both understand, and then on a set of rules that both have to follow; for instance, they must not speak simultaneously (or nobody will be heard), and they have to adjust their voice volume to the environmental conditions (so that voice will not fade away before it reaches the other's ears). All these rules, conventions, and distributed algorithms that communicating parts have to follow are referred to, in total, as a "protocol." Without an agreed-on protocol, communication may be hard or impossible to accomplish.

Similarly, every computer communication is governed by a certain set of rules that have to be agreed on by all the partners involved, prior to communication establishment. These rules make up the protocol of a computer communication and, typically, include items such as the data format to be used, the order in which messages are exchanged, the actions to be taken on receipt of a message, the error detection and handling techniques to be employed, and so on.

From the real world, we already know that a communication task may be rather complex. For example, imagine the case where the commander of the "BLUE" army in a battlefield has to communicate an "attack plan" to the commander of the allied "GREEN" army, who has a different nationality, speaks a different language, probably has a different perception of operations, and is located at the other side of the battlefield, with their common enemy (the "RED" army) operating in between them. To ensure that the "attack order" is correctly received and perceived by the GREEN commander, the BLUE commander has to undertake a number of subtasks. For example:

1. Use a language that the recipient of the message will understand. This can include the use of a mutually accepted language (e.g., English) and the use of a standard terminology to reflect a certain military concept of operations.
2. Use an agreed-on format to compose the message (i.e., use a certain military messaging structured format).
3. Encrypt the message with an appropriate code, so that nobody can read the original contents except for the recipient of the message, who has the proper code to decrypt it.
4. Print the encrypted message on a piece of paper and then put the paper in a stiff envelope, to protect it from environmental conditions, and probably write the recipient's name on it.
5. Give the envelope to a messenger who will carry it to its destination. The messenger must find the appropriate route to follow to arrive at the destination and avoid ambushes while crossing the hostile (RED) ground. En route to the destination, the messenger may have to modify the route, due to an unpredicted roadblock, and thus must know how to use a map, compass, or other device to reorientate.
6. The messenger, on reaching the allied campus, must find the qualified person to hand over the envelope. This person may be the GREEN commander in person, or the commander's authorized secretariat.
7. The GREEN commander or this secretariat signs an appropriate document (a "receipt"), acknowledging

receipt of the envelope, and hands it over (enclosed in a suitable envelope) to the messenger soldier.

8. The messenger then must carry the receipt back to the home campus, again crossing the RED ground, probably following a different return path.
9. The messenger, on reaching the home campus, hands over the receipt envelope to the commander (or to qualified personnel and is then dismissed).

To make things a little closer to reality, suppose now that the messenger is killed while crossing the enemy lines to carry the attack plan, and that if the two allied armies attack simultaneously, the allies win, but if they attack separately, the enemy wins. The two allied army commanders would therefore like to synchronize their attack at some given time, but each of them is unwilling to attack unless assured with certainty that the other will also attack. Thus, the first commander might send a message saying, "Let's attack on Saturday at noon; please acknowledge if you agree." The second commander, hearing such a message, might send a return message saying, "We agree; send an acknowledgment if you receive our message." It is not hard to see that this strategy leads to an infinite sequence of messages, where the last commander who sends a message is unwilling to attack until obtaining a commitment from the other side. What is more surprising is that it can be shown that no strategy (protocol) exists for allowing the two armies to synchronize with certainty. If the conditions are relaxed somewhat so as to require a high probability of simultaneous attack, the problem is solved (e.g., the first army decides on the time of the attack and sends many messengers simultaneously to the other army).

This scenario illustrates the difficulties that arise in the design of protocols, where distributed decisions based on distributed information must be made. We see how complex a communication task may get, how many subtasks have to be considered, and that protocols can be proved to be correct only in a specific, well-defined sense. Computer communications follow, in general terms, principles similar to those described in the previous real-life communication example. Those principles are enforced by certain rules and conventions that make up the various computer communications protocols and are implemented by suitably designed hardware and software components located anywhere between the communicating partners (including themselves).

2. THE OSI MODEL

Since a communication task across a computer network can be too complicated to be efficiently controlled as a whole, it is reasonable to split it up into several simpler, manageable, and cohesive subtasks and associate each subtask with a number of protocols. In this direction, the International Organization for Standardization (ISO) has developed a reference model, the *Open Systems Interconnection* (*OSI*) model, which defines seven communication subtasks arranged in a layered (hierarchical) structure, as shown in Fig. 1. Therefore, each building-block layer of

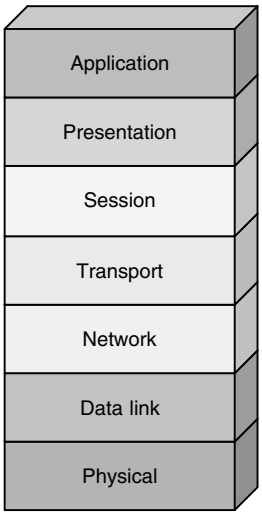

Figure 1. The seven layers of the OSI model.

the OSI model logically groups functions associated with the implementation of a specific communication subtask.

At the bottom of the OSI model, the *physical layer* is responsible for the transmission of the raw bit stream it receives from the next higher layer over the physical transmission medium. This function is usually performed by a *modem* (*mo*dulator–*dem*odulator), which maps a bit stream into a signal suitable for transmission over the underlying physical medium according to the electrical, mechanical, functional, and procedural characteristics of the medium and, at the receiving end, it does the inverse mapping and delivers the bit stream to the higher layer, via an appropriate interface. The physical layer thus provides its upper layers with a *virtual point-to-point bit pipe* and hides from them all the physical medium complexities. The design of the physical layer is usually considered as part of the job done by communication engineers as opposed to network engineers and is outside the scope of this article.

The next layer in the hierarchy, the *data-link control* (*DLC*) *layer*, provides the higher layers a *reliable point-to-point packet pipe over a single link*. It does so by organizing the exchanged bit stream into *frames* (data packets with header/trailer overhead control bits) and providing functions such as error control, retransmissions, and speed matching between sender and receiver.

The *network layer,* one layer above, is very important in internetworking, since it provides the means for end systems to communicate across a collection of communication networks. It is present at every intermediate network node (e.g., router) that interconnects communication networks, and its main purpose is to hide from its upper layers the underlying network technology and topology, providing a *virtual end-to-end packet pipe* between end systems. In order to transfer packets from the source to the destination, the network layer has to implement functions such as routing, addressing, and flow control. These functions convert the link packet pipe provided by the DLC layer to the network layer into an end-to-end packet pipe provided by the network layer to the higher layers. The network layer is considered the most complex layer of

the OSI model, since it requires the cooperation of many nodes (instead of the two end nodes, as is the case for the physical and the DLC layers of a point-to-point link).

The next layer in the hierarchy is the *transport layer,* which ensures end-to-end, reliable message transfer in a transparent way to its upper layers. Its services include message fragmentation and reassembly, and error recovery and flow control between endpoints; however, its functions and complexity vary among different network implementations and depend primarily on the reliability of the underlying network and of the lower-layer services.

The *session layer* establishes, manages, and ends the dialog between applications in end systems, thus providing a virtual session service to the higher layer. Typical functions at this layer include authentication, data grouping, and billing. It is generally considered as a rather "thin" layer.

The next higher layer is the *presentation layer, w*hich deals with the syntax of exchanged data and provides a common data representation to the user applications. Important services here include data encryption, data compression, and code conversion.

The uppermost layer of the OSI model is the *application layer*, which provides the interface of the OSI environment to user applications. It does all the remaining work that is not done by other layer. This layer provides end-application protocols like email, WWW applications (browsers), teleconferencing, FTP, Telnet, and chat services.

The layers of the OSI model are organized hierarchically so that each layer provides services to its next upper layer and is based on services provided to it by its next lower layer. Entities at the same layer between different systems ("peer" entities) communicate on the basis of a mutually agreed-on protocol. Peer entities do not communicate directly; instead, they pass their messages to their next lower layer, which then forwards them to the next lower layer, and so on, until they reach the physical layer, where they are transmitted to the interconnected system. When the messages are received at the other end of the communication medium, they travel all the way up the recipient's lower layers (*demultiplexing*), until they reach the recipient peer entity. This procedure is controlled by headers that are attached successively to each packet (*encapsulation*) by each layer as the packet crosses on its way downward (toward the physical layer) and then stripped off successively by each layer as the packet crosses on its way upward (toward the peer entity of the communication originator), as outlined in Fig. 2. Each layer has to perform its function based only on information included in the header of that layer and cannot look in the body of the message or on the headers added by other layers. This is helpful because if we need to replace the implementation of one layer, this will not affect the operations of other layers.

It is worth noting that the OSI model is not really a communication standard, but rather a framework, or guideline, for developing standards to enable the interconnection of heterogeneous computing systems. Two systems that adhere to some standard developed according to the OSI model will have the same number of layers implementing the same communication functions (although maybe in a different way) and follow a common protocol.

3. THE TCP/IP PROTOCOL SUITE

While the OSI architecture can be considered a guideline for developing communications standards, another firmly

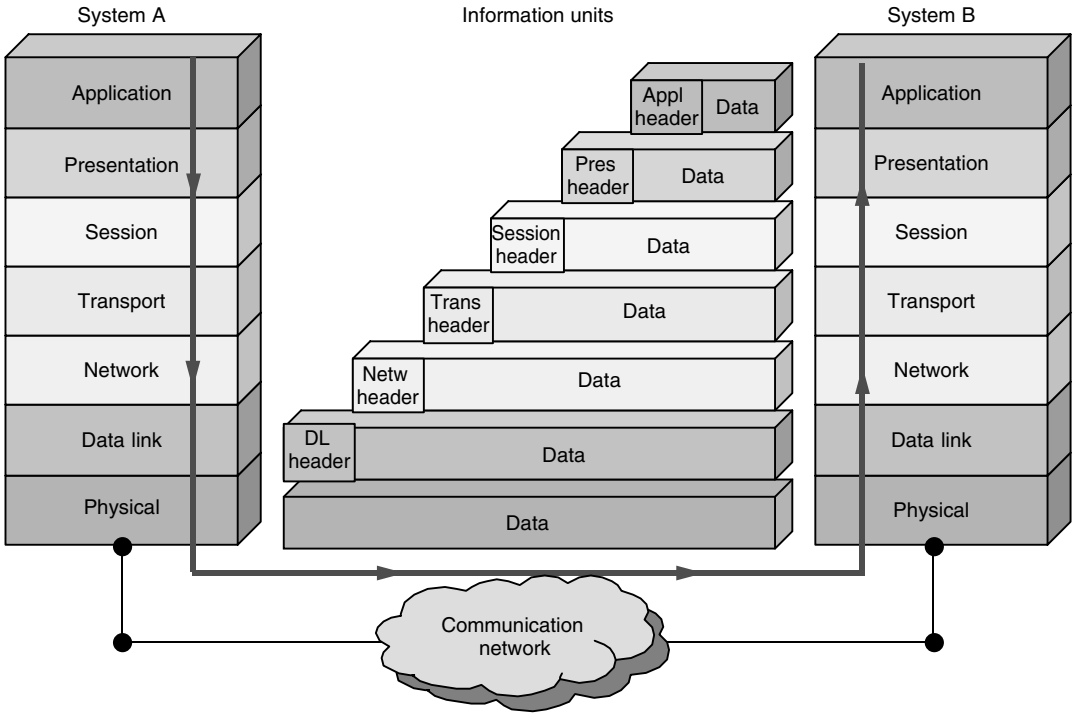

Figure 2. Computer communication through the OSI model.

established architecture has been extensively employed in computer communications. This architecture originates in the U.S. Department of Defense (DoD) efforts to support communications transparently among heterogeneous computer systems over heterogeneous physical communication networks, thus forming a "network of networks" that has nowadays evolved to what is best known as the "Internet." This architecture and its associated standards are collectively known as "TCP/IP."

The acronym *"TCP/IP"* (Transmission Control Protocol/Internet Protocol) does not imply just a pair of communications protocols, but rather refers to a large collection of interrelated protocols and applications (a *protocol suite*); the TCP and IP protocols are the more significant (and widely used) constituent parts of it. Because of its effectiveness and simplicity, the TCP/IP protocol suite has now become the dominant computer communications architecture and is almost synonymous with the terms "Internet" and "computer network."

3.1. TCP/IP Layering

The TCP/IP protocol suite architecture follows a reasoning similar to the one reflected in the OSI model — the whole communication task is divided into a number of smaller and more manageable subtasks, each subtask implemented by one or more protocols. These protocols can be organized conceptually as a hierarchical set of layers (a *protocol stack*), wherein each layer builds on its lower layer, adding new functionality to it. The TCP/IP protocol suite involves four such layers:

1. The application layer
2. The transport layer
3. The internetwork layer
4. The network interface layer

While the top layer (application layer) deals only with application details, the next three lower layers deal with the communication details of an application. Figure 3 illustrates the four layers of the TCP/IP protocol suite, as well as their functionally equivalent layers, in rough terms, in the context of the OSI Reference Model. The

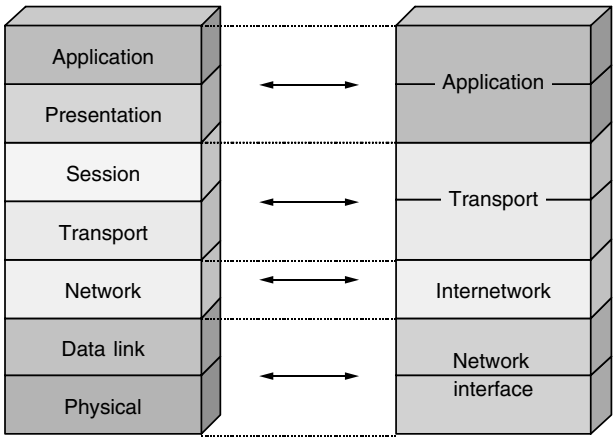

Figure 3. The TCP/IP protocol suite and its correspondence with the OSI Reference Model.

strict use of all layers is not mandated, and the layers are not explicitly stated in the standards.

The lowest layer in the hierarchy (*network interface layer* or *link layer*) forms the interface to the underlying network hardware and hides the network implementation details from the layers above. Protocols at this layer depend on the actual communication network to which the end system is attached and may provide services such as error control.

The purpose of the *internetwork* (or *network*) *layer* is to route data appropriately to the destination host, hiding from its higher layers the internetwork architecture layout between the hosts. The most important protocol at this layer is the Internet Protocol (IP), which provides connectionless services for end systems, without assuming reliability from lower layers.

The *transport layer* provides end-to-end data transfer between peer processes on different hosts. The most important protocol at this layer is the Transmission Control Protocol (TCP), which provides reliable connection-oriented services between peer processes.

Finally, the *application layer*, on top, contains network applications and services, as well as protocols for resource sharing and remote access that are needed to support the user applications. Important protocols at this layer are the Telnet protocol, the File Transfer Protocol (FTP), and the Simple Mail Transfer Protocol (SMTP).

Figure 4 shows a typical TCP/IP communications example between two application processes located at different hosts (end systems) and over two different networks interconnected with a router (an intermediate system).[1] Note in this figure that, while application- and transport-layer protocols are end-to-end, network as well as network interface-layer protocols are hop-by-hop protocols; that is, they are used between end systems and intermediate systems, or between intermediate systems across a collection of communication networks.

TCP/IP employs a two-level addressing scheme; at the low level, every host on an internetwork is assigned a unique (global) address (*IP address*), so that data can be routed to the correct host, while at the high level, every process residing on a host is assigned a unique (within the host) address (*port number*), so that data can be routed to the correct process.[2] Moreover, TCP/IP implements encapsulation and demultiplexing techniques similar to the ones used in the OSI model. On the transmit side, TCP accepts the bytestream from an application, segments it into small data blocks, and appends to each of them a header containing items such as the destination port, sequence number, and checksum for error detection. The resulting data unit, known as a *TCP segment*, is sent down to IP, which appends additional control information relevant to IP functionality (e.g., the destination host address). The resulting

[1] A *router* is a system that attaches to two or more (usually) different physical networks and forwards data packets between the networks. It consists of a network-layer protocol as well as a number of network interface protocols, depending on the actual communication networks it has to interconnect.

[2] The combination of an IP address and a port number is called a "socket" and can uniquely identify a service running on a host.

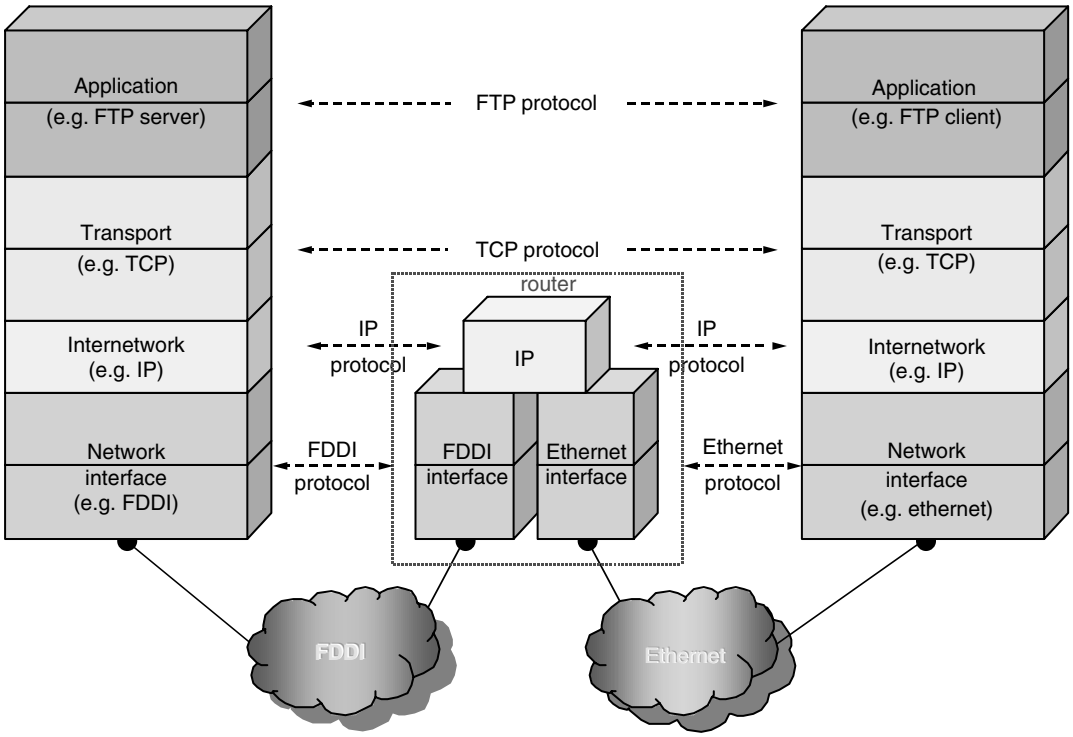

Figure 4. TCP/IP communications over two networks.

data unit, known as an *IP datagram*, is handed over to the network interface layer, which in turn adds its own specific header and transmits the resulting *frame* (which has now the structure shown in Fig. 5) across its attached communication network to the appropriate router. On the receive side, the reverse process takes place; headers are removed and used by the appropriate layers to control the communication procedure within the scope of their layer, until the original bytestream is delivered intact to the recipient application.

3.2. The Internet Protocol

The *Internet Protocol* (IP) is the most widely used internetworking protocol and provides connectionless and unreliable packet delivery services. "Connectionless" indicates that there is no predetermined route through the network between the endpoints but, rather, each packet works its way through the network independently and without any prior coordination. As a result, each packet of a session may follow a different path to reach the same destination, and therefore packets may be delivered out of order; additional services such as sequencing, if required, are dealt with at higher layers (e.g., by TCP). "Unreliable" suggests that IP makes a best effort to get a packet to its destination, but without providing any guarantee of actual delivery. Again, if reliability in the communication is required, it has to be addressed properly at higher layers.

An IP datagram consists of the IP header and the data. Its format is shown in Fig. 6, where the fields have the following meaning:

- *Version* (4 bits)—indicates the IP version number.
- *Header length* (4 bits)—indicates the length of the header (including options) in 32-bit words (i.e., rows in Fig. 6). Its normal value is 5, corresponding to a header length of 20 bytes (no options are used).
- *Type of service* (8 bits)—specifies delay, throughput, reliability, and precedence parameters to request a particular quality of service for the datagram.
- *Total length* (16 bits)—indicates the length of the total IP datagram in bytes. Thus, the maximum IP datagram size is 65,535 bytes (although, in practice, much smaller IP datagrams are used).
- *Identification* (16 bits)—a sequence number that uniquely identifies (along with the source address,

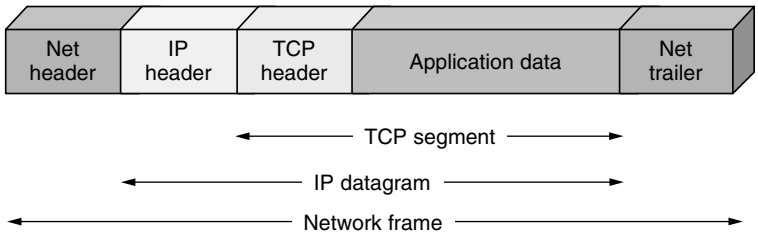

Figure 5. Encapsulation in a TCP/IP frame.

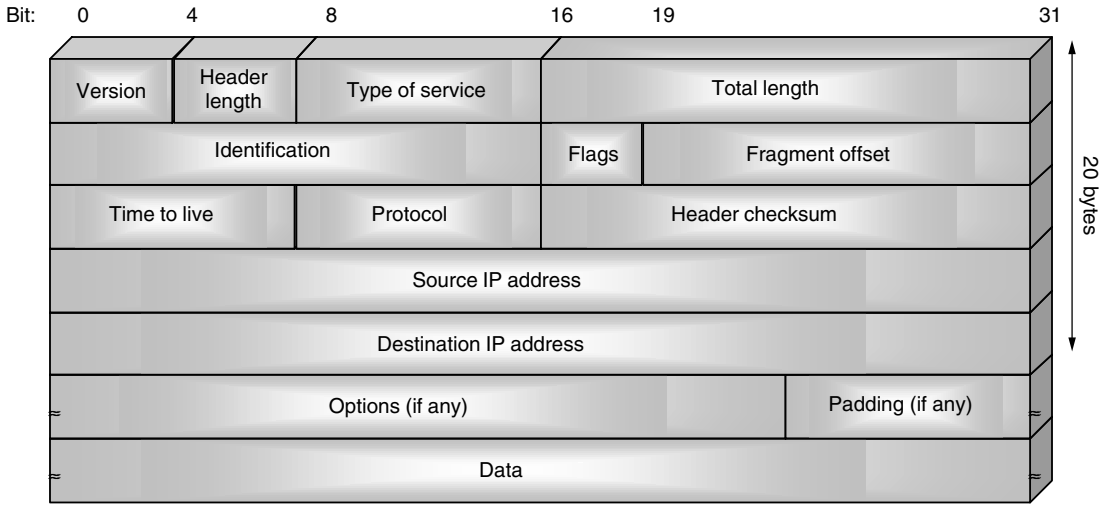

Figure 6. The format of an IP datagram.

the destination address and the protocol used) each datagram transmitted by a sender. It is used for the fragmentation and reassembly of an IP datagram.

- *Flags* (3 bits)—only 2 bits are defined. When an IP datagram is fragmented, the "more" bit is set for each fragment (except the last one). When the "don't fragment" bit is set, the IP datagram will not be fragmented.
- *Fragment offset* (13 bits)—when fragmentation is used, it indicates the offset (in 8-byte units) of this fragment from the beginning of the original IP datagram.
- *Time to live* (8 bits)—is used to prevent IP datagrams from getting caught in routing loops, by specifying the amount of time that a datagram can stay in an internetwork. Practically it has a value of 32 or 64 and is equivalent to a hop count (see Section 5.2 below).
- *Protocol* (8 bits)—indicates the higher-level protocol that has to receive the IP datagram after demultiplexing at the receiver.
- *Header checksum* (16 bits)—is used for error detection and covers only the IP header. It is maintained at each router the datagram comes through.
- *Source address* (32 bits) and *destination address* (32 bits)—indicate the IP addresses of the originator and the recipient(s) of the IP datagram (see Section 5.1.2).
- *Options* (variable length)—indicates the options requested by the sender (e.g., security restrictions, timestamping, route recording). This value is padded by 0s as necessary, to ensure that the header length is a multiple of 32 bits.

3.3. The Transmission Control Protocol

The next widely used protocol of the TCP/IP suite is the *Transmission Control Protocol* (TCP), which builds on the services provided by IP and provides additional functionality to application processes, such as reliable data transfer, error control, and flow control. TCP is implemented in edge systems, and its task is to transform the unreliable delivery service provided by IP into a reliable "connection-oriented" data transmission system, suitable for building network applications. "Reliable" suggests that packets are guaranteed to reach their destination, error-free and in the correct order, while "connection-oriented" indicates that a logical connection is established between the endpoints prior to any data transfer between them and lasts for the duration of a session. Since the actual data packets are transferred by the underlying IP protocol in a connectionless mode, TCP does not in fact set up predefined paths across which all data flow during a given session but, instead, establishes a tight relationship between the end hosts, which can be logically considered as a "virtual circuit." When communication is desired, the initiating TCP first sends a special connection request segment, and awaits a connection response. When it arrives, the initiating TCP confirms connection establishment and begins the reliable communications described earlier.

A TCP segment consists of the TCP header and the data. Its format is shown in Fig. 7, where the fields have the following meaning:

- *Source port* (16 bits) and *destination port* (16 bits)—indicate the TCP port numbers of the source and destination applications.
- *Sequence number* (32 bits)—since two applications exchange a stream of bytes across a TCP connection, the byte in the stream the first data byte in this segment represents is identified by the *sequence number* field.
- *Acknowledgment number* (32 bits)—indicates the sequence number of the next data byte that the sender application is ready to receive (implying that all data bytes with previous sequence numbers were successfully received).
- *Header length* (4 bits)—indicates the length of the header (including options) in 32-bit words (rows in Fig. 7).

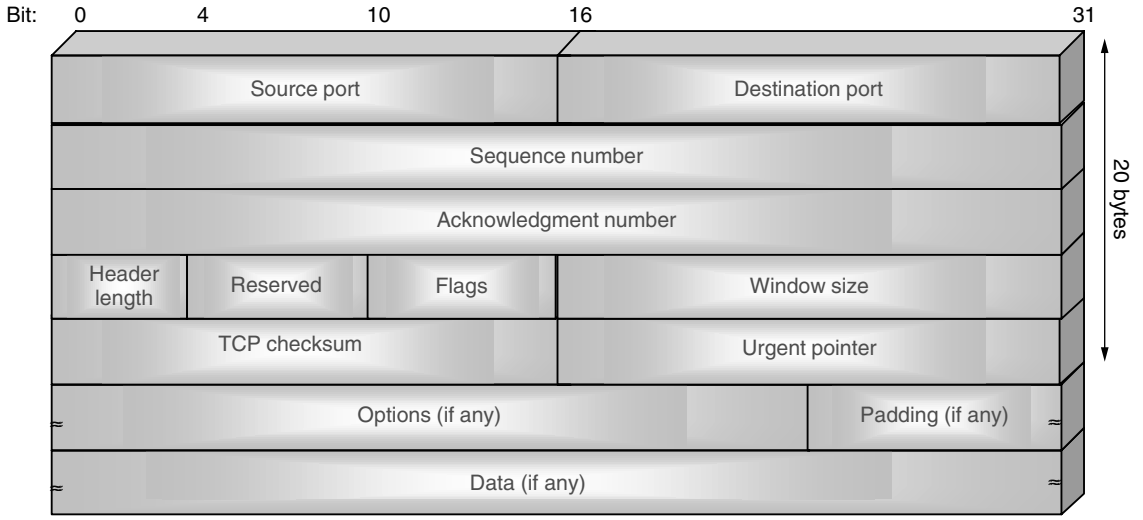

Figure 7. The format of a TCP segment.

- *Reserved* (6 bits) — these bits are reserved for future use.
- *Flags* (6 bits) — there are 6 flag bits (viz., URG, ACK, PSH, RST, SYN, FIN) that are used to control various functions in a TCP connection.
- *Window size* (16 bits) — used for the *flow control* function and indicates the number of data bytes that the sender is willing to accept (starting with the one specified by the acknowledgment number field).
- *TCP checksum* (16 bits) — used for error detection and covers both the TCP header and the TCP data. This checksum is calculated by the sender and verified by the receiver.
- *Urgent pointer* (16 bits) — the sender can transmit urgent data to the receiver, and this field points to the last byte of such data, delimiting in this way the urgent bytes in the bytestream of the segment.
- *Options* (variable length) — indicates the options requested by the sender (e.g., maximum segment size). This value is padded by 0s as necessary, to ensure that the header length is a multiple of 32 bits.

In TCP/IP, the network is simple, and doesn't guarantee anything, except a high probability of packet delivery. The complexity is in TCP, which exists only in edge systems. The edge systems themselves are powerful computers — sufficiently powerful to run TCP. We can say that the end user provides the complexity, while the Internet provides a basic service. This is in contrast to the telephone network, which was designed to provide an expensive (circuit-switched) and reliable service, but whose end systems are extremely simple (telephones).

3.4. The User Datagram Protocol and Some Basic Applications

Another important protocol of the TCP/IP suite is the *User Datagram Protocol* (UDP) at the transport layer. UDP is an alternative to TCP host-to-host protocol that adds no reliability, sequencing, error control, or flow control to IP. These functions, instead, are accommodated by the applications on top of UDP. UDP is connectionless, and its header consists of four 16-bit fields: the source and destination ports, the total length of the UDP segment, and the checksum applied to the entire UDP segment. UDP is used mainly for the exchange of self-contained data packets (or datagrams) between application processes and is extensively employed in real-time applications, like VoIP (Voice over IP) and Net audio.

The following are some basic applications that are part of the TCP/IP suite and exploit the characteristics of TCP and UDP:

1. Telnet (Telecommunications Network), a client/server application that supports terminal emulation and remote logon capability over a TCP connection.
2. FTP (File Transfer Protocol), a client/server application that enables the exchange of text and binary files between host computers, under user command. It uses two TCP connections: one for control messages and the other for the actual file transfer.
3. SMTP (Simple Mail Transfer Protocol), which supports basic electronic mail in text form over a TCP connection. MIME (Multipurpose Internet Mail Extension) is an SMTP extension that provides support for the attachment of other file forms, including audio, graphics, and video.
4. SNMP (Simple Network Management Protocol), which enables the exchange of network management information between host computers (agents) and an SNMP manager, over UDP.

4. DATA-LINK CONTROL PROTOCOLS

The physical layer of the OSI model, as we have already discussed, is responsible for the transmission of a raw bit stream over the physical communication medium. However, to manage this raw bit stream and render it useful, some form of control has to be exercised on top of the physical layer, to account for issues such as link

frame synchronization, link flow control, error control, and retransmissions over a link. This level of control is referred to as *data-link control* and is implemented by protocols residing functionally in the *data-link* layer of the OSI model.

4.1. Flow Control

Since computers that communicate across a network can vastly vary in terms of capabilities, a mechanism has to be set up to account for such inequalities. For example, a fast (high-speed) sender should be prevented from overwhelming with data a slow receiver; otherwise the latter (and maybe the network between them) will become congested. *Flow control* is the function that assumes responsibility for such congestion occurrences and there are two common mechanisms in this direction, known as *stop-and-wait* and *sliding-window*. Both mechanisms are based on the principle that the sender may transmit only when the receiver permits so.

Stop-and-wait is a simple mechanism, according to which a sender, after transmitting a frame, stops transmission and waits until the receiver "acknowledges reception" of the frame. In this way, a slow receiver can avoid getting flooded with frames by sending back reception acknowledgments only after having processed the received frame. In cases, however, where the propagation time over the communication medium is high (e.g., a satellite link), an extended version of the stop-and-wait mechanism is used, the sliding window mechanism, according to which the sender requires an acknowledgment from the receiver after a certain number of frames (determined by the *window size*) have been transmitted. This way, several frames can be in transit at the same time, increasing the utilization of the communication link.

4.2. Error Control

The error control function deals with the detection and, in some cases, correction of errors that occur during the transmission of frames (resulting in lost or damaged frames). Errors are detected at the cost of increasing the frame length by adding some extra information at transmission, which is used by the receiver to either correct the error by itself (*forward error correction*), or ask for retransmission of the frames found in error (*backward error correction*). In most cases, backward error correction is more efficient and there are three common mechanisms in this direction (collectively known as *automatic repeat request* (*ARQ*)): *stop-and-wait ARQ*, *go-back-N ARQ*, and *selective-reject ARQ*. All these mechanisms are based on the flow control techniques described previously.

Stop-and-wait ARQ is based on the principle of the stop-and-wait flow control technique, where the sender transmits a single frame and then waits to get back an acknowledgment for this frame. Only a single frame can be in transit at any one time. If the sender receives either a negative acknowledgment from the receiver or no acknowledgment at all after a certain time period, it retransmits the same frame.

The go-back-*N* ARQ improves the efficiency of the stop-and-wait ARQ but increases its complexity. It is based on the sliding-window technique, where the sender buffers the transmitted frames (up to a number determined by the window size) until an acknowledgment is received. The acknowledgment is cumulative; that is, an ACK for frame *n* acknowledges reception of all previously transmitted frames. If the sender receives a negative acknowledgment for one frame, or no answer at all after a certain time period, then it retransmits all buffered frames from the not-acknowledged frame on.

In the selective-reject ARQ, the go-back-*N* ARQ principle is further refined, by limiting retransmission to only the not-acknowledged (i.e., rejected or timed out) frames. In this way, the amount of retransmission is decreased, at the cost, however, of increasing the receiver's buffer size and both sender's and receiver's complexity.

4.3. Synchronization and Framing

For successful data exchange between computer systems, some form of control has to be imposed on the sequence of bits transmitted over a communication medium, in terms of determining the boundaries between successive frames (*framing*) and maintaining common timing parameters (duration, rate, spacing) for the frame bits between the sender and the receiver (*synchronization*). Synchronization at the data-link layer can be achieved by either asynchronous or synchronous transmission schemes.

In *asynchronous transmission*, data are transmitted one character (5–8 bits) at a time. The beginning and the end of a character are indicated by a start and a stop bit, respectively, while a parity bit before the stop bit is often added for error detection purposes (see Fig. 8). When no character is being transmitted, the communication link is in idle state and, thus, the receiver can resynchronize at each start bit (the beginning of a new character). Asynchronous transmission is widely used (e.g., at PC interfaces with low-volume and low-speed transmissions) because it is simple to implement and the relative equipment is inexpensive. Nevertheless, by using many extra bits per character, it increases the communication overhead, wasting about 20–30% of the available medium bandwidth.

Synchronous transmission, on the other hand, deals with blocks of data, avoiding the overhead of the start/stop bits around each character and providing alternate means (*pre-* and *postamble* bit patterns) to delimit a frame at both ends. In this case, the frame is treated as either a

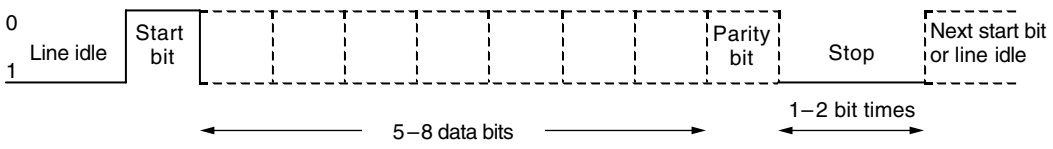

Figure 8. Character format in asynchronous transmission.

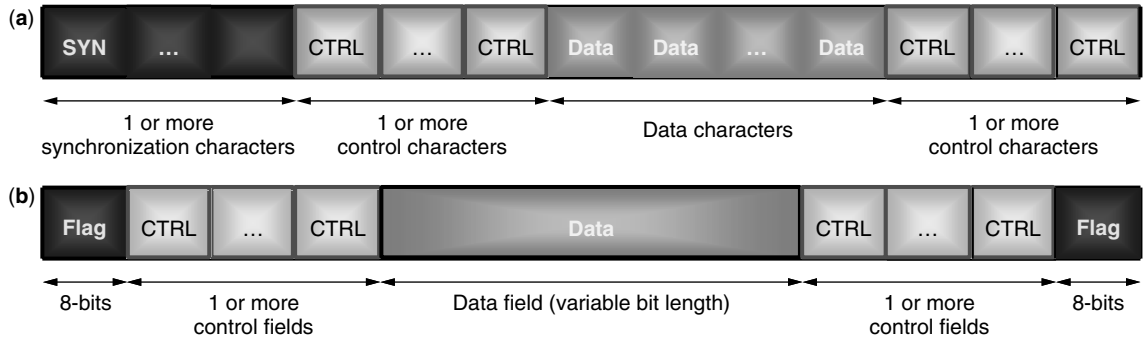

Figure 9. (**a**) Character-oriented and (**b**) bit-oriented frame format in synchronous transmission.

sequence of characters (*character-oriented* transmission) or a sequence of bits (*bit-oriented* transmission), as shown in Fig. 9. Bit-oriented protocols do not depend on specific codes (e.g., ASCII) for line control — as it is required with the character-oriented protocols — and hence they are nowadays widespread. Because of its low overhead (typically ~5%), synchronous transmission is generally used for large-volume and high-speed transmissions.

4.4. The High-Level Data Link Control (HDLC) Protocol

We pause for a moment to examine the most important Data Link Control protocol, the *High-level Data Link Control protocol* (HDLC), which has been standardized by ISO and constitutes the basis for almost all the bit-oriented protocols at the data-link layer that are in common use today: LAP-B (in the X.25 packet-switching network protocol suite), LAP-D (in the ISDN protocol suite), SDLC (in the SNA protocol suite), and IEEE 802.2 LLC (in the IEEE 802 LAN protocol suite). HDLC uses synchronous transmission and supports both full- and half-duplex communications in point-to-point and multipoint link configurations.

To organize data communications between hosts, HDLC defines two basic types of stations: the primary and the secondary stations. The *primary* station is responsible for controlling the data link (e.g., error/flow control) and transmits frames called *commands*. The secondary station responds to commands from a primary station by transmitting frames called *responses*. In a conversation, there is one primary and one or more secondary stations involved. A third type of station, the *combined* station, can also be defined, which combines the features of the primary and the secondary station.

HDLC operates in three data transfer modes:

- *Normal response mode* (NRM), in which secondary stations can transmit only in response to a poll from the primary station. This mode is used in point-to-point or multipoint link configurations (e.g., one host with many terminals attached).
- *Asynchronous response mode* (ARM), in which a secondary station may transmit without explicit permission from the primary station. This mode is used in special cases.
- *Asynchronous balanced mode* (ABM), in which all stations have equal status and may initiate transmission without receiving permission from the other station. This mode is used mainly on full-duplex point-to-point links.

Communication between primary and secondary stations in HDLC is achieved by exchanging frames (commands and responses) that fall in one of the following categories:

- *Information frames*, which are sequentially numbered and contain the user data and, sometimes, piggybacked error and flow control data (using the ARQ mechanism)
- *Supervisory frames*, which contain error and flow control data (not piggybacked as before)
- *Unnumbered frames*, which do not have sequence numbers, but are used for miscellaneous link control and management functions

An HDLC frame consists of a three-field header, the payload, and a two-field trailer, and has the general structure shown in Fig. 10. The *flag* is a special 8-bit sequence (binary 01111110) that identifies the start and the end of the frame (the end flag of one frame can also constitute the start flag of the next consecutive frame). Since the flag is essential to achieve frame synchronization, it is necessary to ensure that the flag sequence does not accidentally appear anywhere in the frame between start and

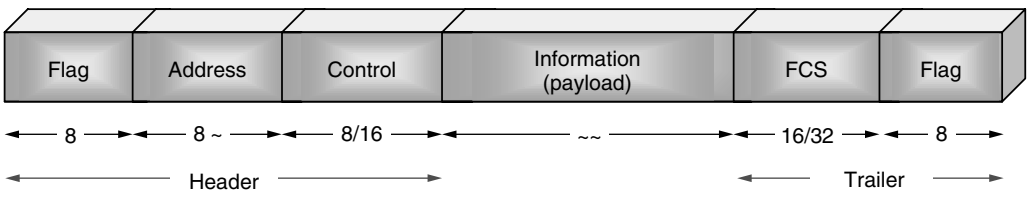

Figure 10. HDLC frame structure and fields' length (in bits).

end flags. To that end, a technique known as *bit stuffing* is used that inserts at transmitter (and deletes at receiver), an additional 0 (zero) bit, after each occurrence of five consecutive 1s in the data between the start and end flags of a frame. The *address* field is usually 8 bits long, but an extended format may also be possible. Depending on the station type of the issuer of the frame, the address field may indicate the sender (in responses) or intended receiver (in commands) of the frame. The *control* field is usually 8 bits long, but an extended format may also be possible. It is used to indicate the type of the frame (information, supervisory, or unnumbered) and it also contains some control information, according to the frame type (e.g., send sequence number for information frames).

The *information* field is the "payload" of the frame that contains the actual user data (any sequence of bits) coming from the higher layers. Its length, though undefined, is usually a multiple of 8 bits. Finally, the *frame-check sequence* (FCS) field goes after the information field and contains a 16- or 32-bit cyclic redundancy check (CRC) value that is used by the receiver to check the address, control, and information fields of the frame for errors. Practically, 16-bit CRC (2 bytes) is used for frames up to 4 KB (kilobytes).

4.5. Local-Area-Network Protocols

Due to the widespread use of local-area-networks (LANs),[3] a great number of standards and protocols have emerged that relate to LAN technology and belong functionally to the data-link layer of the OSI Reference Model. In this context, the data-link layer is usually divided into two sublayers: the *logical link control* and the *medium access control* sublayers.

Protocols in the logical link control sublayer are similar to typical data-link control protocols, like the HDLC. The most commonly used protocol at this level is LLC, described in the IEEE 802.2 standard. LLC supports both connectionless and connection-oriented services and provides mechanisms for addressing and data-link control. Moreover, it is independent of the underlying network topology, medium access control technique, and transmission medium.

Since all devices interconnected via a LAN share a common physical communication medium with a fixed capacity, some procedure has to be established to control access to the underlying medium and provide for an efficient usage of its capacity. Such procedures and techniques are provided by protocols at the medium-access control (MAC) sublayer, which, apparently, are closely dependent to the transmission medium and the network topology used. Common MAC protocols are the *carrier sense multiple access with collision detection* (CSMA/CD), the *token bus* and the *token ring,* each specified in a number of widely used standards, such as IEEE 802.3, IEEE 802.4, and FDDI.

[3] A LAN is a high-speed data network, optimized for use over small geographic areas (like buildings), that usually interconnects personal computers, peripheral devices, and other equipment over a common (shared) physical communication medium.

CSMA/CD falls under the category of contention techniques, in which all communicating parts "contend" for access to network resources. The precursor of CSMA/CD is ALOHA, which was developed in the 1970s for packet radio networks. According to ALOHA, every station transmits its packet on the air whenever it is ready to do so, without any prior coordination with the other stations in the network. In this fashion, collisions between packets of different stations that are transmitted simultaneously are quite common, especially as the number of stations increases. In case of a packet collision, the transmitting station waits for a time interval and then attempts retransmission of the packet. ALOHA is a very simple to implement technique, with a limited efficiency, however. CSMA improves this situation by requiring that each station has to listen to the medium first ("sense the carrier"), and if no other station is transmitting at that time, it can go on transmitting its own packet, or else it has to wait. CSMA can be further improved by having the transmitting station listen to the medium while transmitting, to notice early any possible collision ("collision detection") and stop its transmission (and thus free network resources). The CSMA/CD medium-access technique is used in Ethernet/IEEE 802.3 LANs, over coaxial cable or unshielded twisted pair as transmission media and on bus, tree, or star network topologies.

In the token-passing schemes, network devices access the physical medium based on the possession of a token that circulates when stations are idle. A token is like a permission to transmit, and whoever has the token can transmit or pass it to the next node. Examples of LANs that use such techniques are the *Token Bus* (IEEE 802.4), over coaxial cable or optical fiber and on bus, tree, or star network topologies; the *Token Ring* (IEEE 802.5), over shielded/unshielded twisted-pair cable and on ring topology; and the *Fiber Distributed Data Interface* (FDDI), over optical fiber and on ring topology.

5. INTERNETWORKING PROTOCOLS

In an internetworking environment, where a number of communication networks are interconnected to provide data transfer among the hosts attached to them, an addressing scheme has to be established so that all communicating entities are uniquely identified in the internetwork, to allow data to be directed (or *routed*) to the intended destination. In this section we focus on the protocols and mechanisms behind these two fundamental functions in internetworking: *addressing* and *routing*.

5.1. Addressing and Naming

In the global postal system, a postal carrier knows exactly where to deliver a letter, based on an agreed-on addressing scheme, according to which a house location can be uniquely determined, by specifying some positional parameters (country, city, street, number, etc.) that altogether constitute the recipient's "home address," which is hierarchical, and is written on the envelope of the letter. Addressing in an internetworking environment follows a similar concept; each entity in an internetwork can be reached by means of a unique (global) address, which is usually a number like a telephone number in telephony. Since, however,

humans cannot easily remember numbers, especially in the binary format that computers understand, translation schemes between symbolic names and addresses are practically used that match high-level human-intelligible names to machine-intelligible internetwork addresses and vice versa. This translation process, called *address resolution*, is usually performed in a distributed fashion by special network servers, called *name servers*. In the Internet context, address resolution is performed by the *Domain Name System* (DNS), which is a global network of name servers implementing a distributed database.

5.1.1. The Domain Name System. According to DNS, symbolic names are grouped in domains that are hierarchically organized, like the chain of command reflected in the organization chart of a big company. Within each domain there is one primary (*authoritative*) name server that has the responsibility of performing address resolution through the maintenance of a local database. It is, however, common for domain name servers to delegate authority for their subdomains to other name servers, therefore defining subareas of responsibility. The domain (and subdomains, if any) for which a name server is authoritative is referred to as "zone of authority." Consequently, DNS logically interconnects all name servers into a hierarchical tree of domains and uses a hierarchical naming structure, like the one used in telephone numbers, in which names consist of a sequence of fields [typically a top-level domain,[4] a domain, subdomain(s), and the host name] that jointly identify the entity. For example, *talos.telecom.ntua.gr* refers to the host named *talos* in the Telecommunications Laboratory (*telecom*) subdomain of the National Technical University of Athens (*ntua*) domain, in Greece (*gr*).[5]

Since DNS is a distributed database, a name server doesn't need to know all the names and addresses of hosts in the Internet; its area of knowledge and responsibility is usually confined to its own zone of authority. It does need to know, though, the name servers who are responsible for other domains. When, for instance, we type *www.cis.ohio-state.edu* on our Internet browser, a module called *resolver* tries to look up the requested address locally, if a local name cache is kept. Otherwise, it sends a DNS query to the local name server. The local name server will then follow these steps:

1. Check to see if it already knows (from its database or from a previous query) the address of *www.cis.ohio-state.edu*. If so, it finds the address in its database or cache and replies to the query. The browser then uses this (IP) address to request a connection to the host containing the desired Webpage.
2. If the local name server cannot resolve the address by itself, it will query one of the "root" servers, at the top of the DNS hierarchy, whose addresses are definitely known to all name servers, for the address of *www.cis.ohio-state.edu*.
3. Today, there are 13 root servers on the Internet, and each of them knows the IP addresses of the servers for all the top-level domains (*.com*, *.edu*, *.uk*, etc.). So, ultimately, the root server contacted will refer our name server to (i.e., give the address of) a list of *.edu* name servers.
4. Our name server will query one of the *.edu* servers for the address of *www.cis.ohio-state.edu*.
5. The *.edu* server queried will refer our name server to a list of name servers for the domain *ohio-state.edu*.
6. Our name server will then query one of the *ohio-state.edu* name servers for the address of *www.cis.ohio-state.edu*.
7. If the *ohio-state.edu* name server queried knows the address of *www.cis.ohio-state.edu*, it returns that address to our name server. If there is another name server responsible for the *cis* (delegated) subdomain, the address of that name server will be returned to our name server, which will in turn query that server for the address of *www.cis.ohio-state.edu*.
8. Finally, our browser will be given the requested (IP) address or an error if the query could not be answered.

This is a worst-case scenario that can take many seconds to complete, but actually things are simpler, since, as it was mentioned in the above process, each name server caches for a certain time period all the information it retrieves this way. This way, a huge load is removed from the root and top-level servers.

5.1.2. IP Addresses. IP addresses are 32 bits in length. They are typically written in a format known as "dotted decimal notation," according to which each of the 4 address bytes is expressed in its decimal equivalent value (0–255) and the four values are separated by periods, for example, "147.102.105.18."

IP addresses generally consist of two parts:

- The *network identifier* identifying the TCP/IP subnetwork to which the host is connected
- The *host identifier* identifying a specific host within a subnetwork

To account for networks of different sizes, IP defines several *address classes,* characterized by the length of the network identifier. Class B addresses, for instance, have a 14-bit network identifier and a 16-bit host identifier and thus can address up to 65,536 (2^{16}) hosts per network; therefore, class B addresses are used for moderate-sized networks. Five address classes are defined (A through E), while only classes A, B, and C are used for host addressing.[6]

5.1.3. Address Resolution Protocol (ARP). The *address resolution protocol* is used in specific network implementations where the Internet Protocol (IP) is applied

[4] For instance, *com*, *edu*, *org*, *gov*, or two-letter country codes such as *uk* (United Kingdom) and *it* (Italy).

[5] It is not, however, necessary for a host to be physically located at the country specified by the country code.

[6] Class D addresses are used for IP multicasting, while class E addresses are reserved for future use.

over Ethernet or token ring local-area networks (LANs). Addressing in such LANs is twofold; at the IP level, every entity in the network is assigned a unique IP address (which is contained in the IP datagram) and, at the medium-access control (MAC) level, every entity in the LAN has a unique MAC (hardware) address (6 bytes in length, which is placed in the MAC frame).

An entity's IP address is different from its MAC address. Therefore the address resolution protocol is used to translate between the two types of address, so that a sender's IP process can communicate with the intended receiver's IP process on the same network, when knowing only the receiver's IP address. The process is relatively simple: (1) the sender transmits an ARP Request message using the hardware broadcast address (so that the intended receiver will surely receive the request); (2) the ARP Request advertises the destination IP address and requests the associated MAC address; (3) the intended receiver recognizes its own IP address and forms an ARP Response that contains its own MAC address; (4) since the original Request also includes the sender's MAC address, this address is used by the receiver to unicast its ARP Response to the original sender. To reduce the number of ARP requests in a LAN, hosts maintain a cache of recently resolved addresses. ARP cache entries timeout at regular intervals (typically 20 min), and new queries are made so that changes to the network topology are properly handled.

5.2. Routing

An internetwork can be considered as a collection of communication networks. Attached to each communication network we find devices (usually computers) that support end-user applications or services. These devices are called *end systems*, as opposed to the *intermediate systems* that are used to interconnect the communication networks (and thus form an internetwork), so that end systems attached to different networks can communicate across the internetwork, share information, and provide services to each other.

On their way toward their intended recipient, data packets travel across multiple networks and reach several intermediate systems, called *routers,* that forward them to the next intermediate system/communication network. The process of moving data from source to destination across an internetwork is known as *routing*. Routing includes two basic functions: *optimal path determination* and *switching*.

The optimal path toward an internetwork destination is determined by special algorithms, called *routing algorithms*. These algorithms perform calculations based on multiple metrics, such as pathlength, packet delay, and communication cost. The results of these calculations are used to populate *routing tables* that are maintained within each router and list the next "hop" (i.e., the next router) to which a data packet should be sent on the (optimal) way to its destination. Therefore, routers forward a received data packet according to the packet's destination address and the association for this address that the routing table indicates. The packet's physical address is changed to the next router's physical address, and the packet is transmitted. This way, the packet is switched hop by hop through the internetwork, until it finally reaches its destination.

This routing process, however, can be processor-intensive. In a more efficient alternative, called *multiprotocol label switching* (MPLS), optimum end-to-end paths through the network are calculated in advance (at the network edge) and appropriate routing information is appended as a *label* between the layer 2 and layer 3 packet headers;[7] then, routers along the path use the information in this label to simply switch the packet to the next hop. MPLS is also employed in traffic engineering (i.e., establishing traffic patterns that balance overall network resources utilization) and quality-of-service (QoS) routing (i.e., selecting routes that provide a desirable level of service, e.g., bandwidth, latency, priority requirements). MPLS supports many protocols of the network layer (including IPv4, IPv6, and AppleTalk), as well as the link layer (e.g., Ethernet, token ring, ATM).

5.2.1. Communication Between Routers. Routing algorithms calculate optimal paths on the basis of the routing information available at the router at a certain point in time. This routing information reflects the status of the networks (reachability, traffic delays, etc.) and is exchanged between routers by certain protocols, called *routing protocols*. We can distinguish two broad categories of routing protocols: *interior router protocols* (IRPs) and *exterior router protocols* (ERPs), if they are used between routers within the same or in different *autonomous systems*,[8] respectively. Practically, IRPs exchange a wealth of routing information to help determine optimal paths within an AS, while ERPs exchange only summary reachability information between ASs and, therefore, are simpler than IRPs. Examples of IRPs are the *Routing Information Protocol* (RIP) and the *Open Short Path First* (OSPF), while *Border Gateway Protocol* (BGP) is a typical ERP.

RIP belongs to the distance-vector class of protocols, according to which neighboring routers send all or a portion of their routing tables by exchanging routing update messages periodically and when network topology changes occur. Whenever a router receives a routing update message, it updates its routing table in light of the new information and subsequently transmits new routing update messages (using UDP/IP) to propagate the network changes across the network. RIP uses the "hop count" metric to measure the pathlength between a source and a destination. The maximum number of hops in a path is limited to 15; a value of 16 implies that the host is unreachable. RIP is still used efficiently today in small ASs.

OSPF is a nonproprietary protocol and belongs to the link-state class of protocols, according to which a router broadcasts to all routers only the portion of its routing table that describes the status of its own links. Such updates (using IP directly) produce minimum traffic and

[7] Or, in the virtual path identifier/virtual channel identifier (VPI/VCI) cell header fields, in ATM networks (see Section 6).

[8] An *autonomous system* (*AS*) is a logical portion (i.e., a collection of routers and subnetworks) of a larger internetwork that constitutes a distinct routing domain (and usually corresponds to commercial or administrative entities). An AS is managed by a single authority and may connect to other AS, as well as other public or private networks.

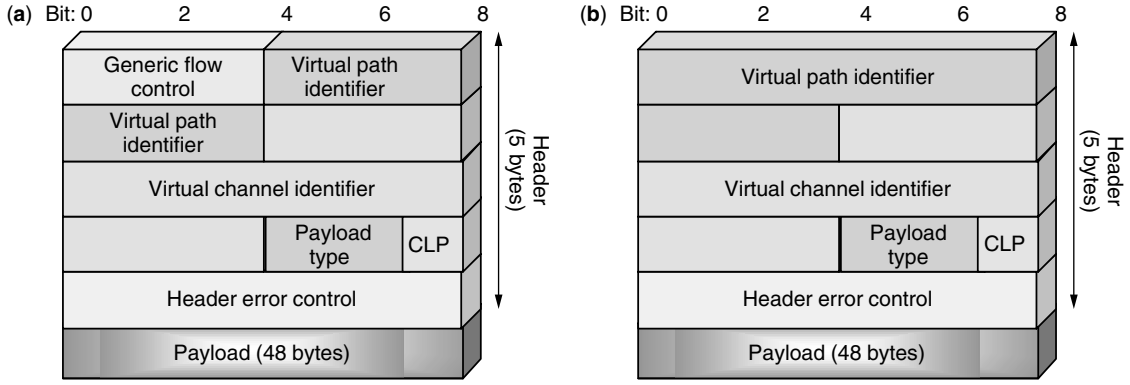

Figure 11. ATM cell format: (**a**) at the user–network interface; (**b**) at the network–network interface.

hence require less network bandwidth. Unlike RIP, OSPF is hierarchical; an AS is partitioned in a number of smaller groups of networks, called *areas*, and an area's topology is invisible to entities outside it. Routing between areas (interarea routing, as opposed to intraarea routing, which takes place within the same area) is handled by an OSPF backbone of routers. The backbone topology is invisible to all intraarea entities. OSPF uses the "shortest path first" or Dijkstra's algorithm to determine optimal paths. OSPF is more efficient and more scalable than RIP and for this reason it is widely used in TCP/IP networks and the Internet.

BGP is a scalable protocol used for the exchange of routing information between different ASs and is widely used on the Internet between the Internet service providers. BGP is a kind of distance vector protocol, with the difference that BGP neighbors don't send routing updates periodically, but exchange full routing information at the beginning (using TCP) and then send updates only about the routes that have changed. Also, a router's BGP table stores the networks that it can reach and the best route to each reachable network. BGP version 4 supports also policy-based routing based on security, legal, economic, and other issues rather than purely technical ones.

6. ASYNCHRONOUS TRANSFER MODE

Asynchronous transfer mode (ATM), also known as *cell relay*, is a high-speed packet transfer technology that tries to combine the benefits of packet switching (efficiency and flexibility for data transfer) with those of circuit switching (guaranteed bandwidth and transmission delay). ATM organizes data in packets of fixed size, called *cells*; this way the processing overhead at switching nodes is minimized. Also, since ATM takes advantage of the inherent dependability of modern communication systems, it uses minimal error control, thus further reducing the processing overhead of ATM cells and allowing for very high data transfer speeds.

The ATM cell consists of a 5-byte header and a 48-byte information (data) field, for a total cell length of 53 bytes. The cell header format is slightly different at the user–network interface and inside the ATM network, as shown in Fig. 11 parts (a) and (b), respectively. The header fields have the following meaning:

- *Generic flow control* (4 bits)—this field is present only at the user–network interface and provides some form of local cell flow control.
- *Virtual path identifier* (VPI) (8/12 bits)—identifies the virtual path a virtual channel belongs to and is used as a routing field in an ATM network. The VPI field is longer (12 bits) at the network–network interface, allowing for a large number of virtual paths to be supported inside the ATM network.
- *Virtual channel identifier* (VCI) (16 bits)—identifies a virtual channel inside a virtual path and is used as a routing field in an ATM network.
- *Payload type* (3 bits)—indicates the type of information contained in the cell's payload (control or user data) and provides some additional control information.
- *Cell loss priority* (CLP) (1 bit)—indicates the priority of the cell in case of network congestion. A cell with a CLP value of 1 is considered of low priority and subject to discard if required by network conditions.
- *Header error control* (8 bits)—used for error detection and single-bit error correction; it covers only the (first 4) bytes of the cell header.

ATM is *connection-oriented*, that is, a logical connection (called *virtual circuit* or, in ATM terminology, *virtual channel*) is established between two end stations prior to data transfer, and all packets follow the same preplanned route in the network and arrive at their destinations in sequence. ATM also defines another type of logical connection, the *virtual path*, which is essentially a bundle of virtual channels that share a large part of their path. Cell routing in an ATM network is based on both the virtual path and the virtual channel identifiers (VPI and VCI) contained in the cell header.

During a virtual channel connection (VCC) setup, a user can specify a set of parameters relating to the desired *quality of service* (QoS) and the input *traffic characteristics* of the VCC. QoS parameters include the *cell loss ratio* (CLR) (i.e., the percentage of cells that are lost in the network—due to error or congestion—to

the total transmitted cells); the *cell transfer delay* (CTD) (i.e., the delay experienced by a cell throughout the ATM network); and the *Cell Delay Variation* (CDV) (i.e., the variance of CTD). Input traffic characteristics parameters that can be negotiated between the user and the network include the *peak cell rate* (PCR), which is the maximum rate at which the user will transmit; the *sustained cell rate* (SCR), which is the average transmission rate measured over a long interval; and the *burst tolerance* (BT) and the *maximum burst size* (MBS), which define the burstiness of the sender.

On the basis of these parameters, five service categories are defined that characterize the different types of traffic that can be transferred by an ATM network:

- *Constant bit rate* (CBR), intended for applications that require a fixed data rate and an upper bound on transfer delay (e.g., videoconferencing, telephony).
- *Real-time variable bit rate* (rt-VBR), intended for applications that transmit at a variable rate and are time-sensitive (i.e., require tight upper bounds on cell transfer delay and delay variation, e.g., interactive compressed video).
- *Non-real-time variable bit rate* (nrt-VBR), intended for applications that transmit at a variable rate but are not time-sensitive (e.g., banking transactions).
- *Available bit rate* (ABR), used by normal (bursty) applications with relaxed delay and cell loss requirements (such as file transfer and email) and expected to be the most commonly used service category. ABR sources use explicit network feedback to control their cell rate.
- *Unspecified bit rate* (UBR), used by applications that are not sensitive to delay and cell loss and provide best-effort services by taking advantage of network capacity not allocated to CBR, VBR, or ABR traffic (e.g., file transfer).

6.1. ATM Congestion Avoidance and Control

ATM was designed so as to minimize the processing and transmission overhead inside the network. The only factor that can lead to cell delay variation is network congestion. ATM handles network congestion with functions that fall within two general categories: congestion avoidance and congestion control.

Congestion avoidance is concerned mainly with (1) establishing *traffic contracts* with the users, which specify the traffic parameters for a connection and the QoS parameters the network will support for that connection; and (2) enforcing the agreed-on traffic contracts, that is, watching that the agreed-on restrictions are met (*traffic policing*). Sometimes, however, congestion avoidance actions may not be effective, in which case some nodes may become congested, and congestion control functions, which are based primarily on network feedback, are brought into play.

The QoS required by CBR and VBR traffic is supported by congestion avoidance techniques based on traffic contracts and policing; cells that violate a traffic contract are discarded or tagged as low-priority cells. Traffic policing can be combined with *traffic shaping* to achieve better network efficiency, fair allocation of resources, and reduced average delays, while meeting the QoS objectives. A common mechanism used for traffic shaping is the "leaky bucket." This mechanism can smooth out a bursty cell flow by buffering arriving cells and then serving the queue (i.e., transmitting the cells) at a constant service rate of r cells per second (see Fig. 12). The leaky bucket example shown can be controlled by adjusting two parameters: the bucket capacity and the bucket leaking rate. As long as the bucket is not empty, the cells are transmitted with the constant rate of r cells per second. In case the bucket capacity is exceeded, a bucket overflow is caused and the excessive cells can be either discarded, or tagged as low priority cells.

These techniques prevent congestion buildup but get no feedback from the network concerning the congestion conditions and, therefore, are called *open-loop control techniques*. Open-loop control may be insufficient in cases where the bandwidth requirements of applications are not known at connection setup time. With ABR traffic, however, dynamic load management is possible by taking advantage of network feedback. In this case, feedback techniques are employed (*closed-loop control* techniques) that support the lossless transport of ABR traffic and the fair capacity allocation.

There are two main closed-loop control techniques: the credit-based and the rate-based. *Credit-based* schemes are based on a window flow control mechanism; each intermediate node on a session's path sends information (credit) to the previous (upstream) node and does so on a per link and per VC basis. A traffic source can transmit on a VC only when it obtains credit from the next node for this connection, which implies that the next node has adequate buffer and can accommodate the number of cells specified by the credit it grants to the source. In *rate-based* schemes, the network sends appropriate information to the user, specifying the bit rate at which the user could transmit, and the feedback control loop may extend end-to-end across the network. The rate-based approach is less expensive in terms of implementation complexity and hardware cost, but it doesn't handle bursty traffic well. The credit-based approach, on the other hand, is well suited for bursty traffic (under ideal conditions, zero cell loss can be guaranteed), but it requires complex bookkeeping at

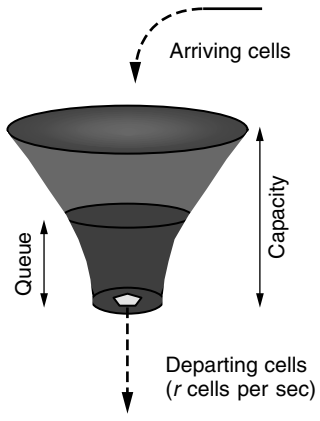

Figure 12. The leaky-bucket mechanism.

the network nodes on a per session (i.e., per VC) basis. The need for per session queuing limits the flexibility of the designer and is one of the main reasons why the ATM Forum has selected rate-based schemes for ABR traffic in ATM networks.

The rate-based scheme adopted for use in ATM uses the following mechanism. The source of an ABR flow inserts among the data cells of the flow some *resource management* (RM) cells, one RM cell after a certain number of data cells. Each RM cell contains three fields that can provide congestion feedback to the source: the *congestion indication* (CI) bit, the *no increase* (NI) bit, and the *explicit cell rate* (ER) field. The values of these fields can be changed by either the destination of the flow or an intermediate ATM switch, to reflect experienced congestion effects. Finally RM cells return to their source, where their fields are examined and corrective actions (rate increase or decrease) are taken to respond to the network or destination conditions. In particular, the source at any time is allowed to transmit cells at any rate between zero and a value called *allowed cell rate* (ACR). ACR is adjusted dynamically according to network feedback and has a lower and an upper limit, called *minimum cell rate* (MCR) and *peak cell rate* (PCR), respectively. If the source gets an RM cell with the CI bit set (signaling congestion), then it reduces ACR by an amount proportional to its current ACR (but down to MCR). If neither CI nor NI is set, then the source increases ACR by an amount proportional to the PCR (but up to PCR). Therefore, rate increases are linear, but rate decreases are exponential, so that sources respond drastically to congestion. Finally, if ACR is bigger than the value contained in the ER field (which is used to explicitly dictate a cell rate), then ACR is reduced to ER.

6.2. Connection Establishment Control Protocols for High-Speed Networks

The rapid developments in optoelectronics technology have substantially increased system transmission rates in optical communication networks since the first systems were installed, in the early–mid-1980s. Having, however, communication links of multigigabit transmission rates does not necessarily result in a communication network of the same effective capacity. An important (but not the only) issue is related to the protocols and algorithms used to perform network control. These protocols should allow full utilization of the network resources in a way that is fair to all users; they should be capable of providing delay and packet loss guarantees to the users (QoS), in the presence of node and link failures, and they should impose small processing requirements on the switches.

6.2.1. Protocols for CBR Traffic and for Traffic Consisting of Long Bursts. A sizable portion of traffic in future multigigabit-per-second networks will involve high-speed transfer of traffic at nearly constant rates (CBR traffic) and would require guaranteed lossless delivery and an explicit reservation of bandwidth. Clearly, the bandwidth–delay product being very large can result in the discarding of substantial amounts of data and retransmissions, unless bandwidth reservations are made in advance, or substantial buffer space is provided. Also, for high-speed file-transfer-type applications, long burst transmissions can easily overload the network, unless they have prenegotiated at least a minimum bandwidth with the network. Therefore, from the point of view of both transmission integrity and network efficiency, traffic of this type should be transferred only after a specific and explicit allocation precedes each data burst. This is especially true for the case of all-optical networks, where buffering has to be very limited because of technological constraints.

A key to efficiently utilizing the large bandwidth of emerging gigabit networks is to devise protocols that can overcome the problems posed by increased propagation latency of such networks. In most reservation protocols [e.g., the FRP/DT protocol, the fast bandwidth reservation schemes and the fast resource management (FRM) protocols], a setup packet is sent to the destination to make the appropriate reservations, and the capacity required by a session at an intermediate node is reserved starting at the time the setup packet arrives at that node. An obvious inefficiency in all these schemes arises because the capacity reserved for the session is not needed immediately, but it is actually needed at least one round-trip delay after arrival of the setup packet at the node. This is because the setup packet has to travel from the intermediate node to the destination, an acknowledgment has to be sent back to the source, and the first data packet of the session has to arrive from the source to the intermediate node (see Fig. 13). Over long transmission distances, the round-trip delay may be comparable to, or even larger than, the holding time of a session. In particular, if a typical session requests capacity r bps (bits per second), and transfers a total of M bits over a distance of L kilometers, the maximum percentage of time that the capacity is efficiently used is $e = (M/r)/[2Ln/c) + (M/r)]$, where c/n is the propagation speed in the fiber. Typical values of these parameters for multigigabit networks may be $r = 10$ Gbps, $M = 0.2$ Gbit, and $L = 1500$ km, which yields $e = 0.57$. This efficiency factor e decreases as r or L increase, or M decreases.

The *efficient reservation virtual circuit* (*ERVC*) protocol was designed to overcome these limitations. It is suitable for sessions that require an explicit reservation of bandwidth, and it does not suffer from the inefficiencies of the reservation protocols mentioned above. The ERVC protocol keeps track of sessions (or burst) durations and

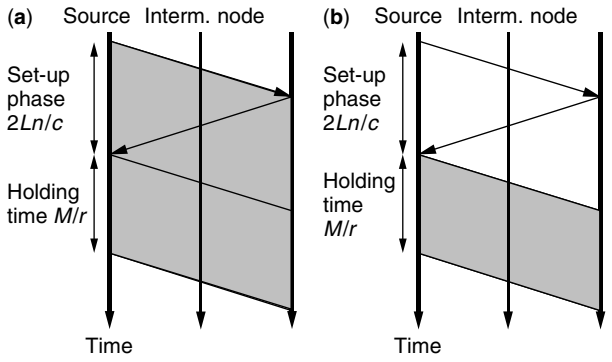

Figure 13. Comparison between (**a**) ERVC and standard reservation (SR) (**b**) protocols (shaded areas represent the time periods during which the capacity is reserved for a particular session).

reserves capacity only for the duration of a session (or burst), thus eliminating the inefficiency that results in existing schemes from holding capacity idle for a round-trip delay before it is actually used by data packets. In the ERVC protocol, session durations (or burst durations) are recorded, and each node keeps track of the utilization profile $r^l(t)$ of each outgoing link l, which describes the amount of residual capacity available on link l as a function of time t. This feature allows capacity to be reserved only for the duration of the session (or burst), starting at the time it is actually needed. Correct timing is crucial in ensuring that data transmission starts *after* all reservations are made and terminates *before* any intermediate node releases the reserved capacity. The ERVC protocol uses capacity on a demand basis, leading to more efficient utilization and a lower blocking probability than previous reservation protocols. It also has the "reservation ahead" feature that allows a node to calculate the time at which the requested capacity will become available and reserve it in advance (provided it is available within the QoS requirements of the session), avoiding in this way the wasteful repetition of the call setup phase. The protocol uses an asynchronous, distributed algorithm that allows the nodes along a session's path to collaborate when reserving capacity and to maintain timing consistency. This ensures that adequate outgoing capacity is available to service the data packets when they arrive at a link, so that the transmission is loss-free. Processing requirements at a node are minimized by using efficient update mechanisms and simple data structures that store a compact representation of the utilization profile of an outgoing link. The information required by the protocol (rates and session durations) can be recorded and processed using a simple linked list structure. The protocol is robust to link and node failures, and it allows soft recovery from processor failures. The efficiency factor e for the ERVC protocol can be as large as $e = 1$, independently of the parameters r, L, and M and efficiency is maintained even for traffic that consists of sporadic bursts of data. Also, the performance of ERVC does not depend on the round-trip delay. This is because for a single link, a different round-trip delay means only that the arrivals of sessions on link l are translated in time by a different amount; therefore, the picture in terms of load (and consequently the blocking) as seen by newly arriving sessions remains the same, irrespective of the round-trip delay.

6.2.2. The Virtual Circuit Deflection Protocol. Traffic in high-speed networks can be switched either optically or electronically. Optical switching has advantages for circuit switching, but substantial disadvantages for packet switching, because effective packet switching requires packet storage at each switch, which is difficult to achieve with current optical technology. Despite this drawback, it is believed that optical switching may open new dimensions in future networking, provided appropriate protocols that take into account its constraints are developed.

To eliminate the need for buffering (but without making advance bandwidth reservations, which requires a round-trip pretransmission delay), a variation of deflection routing, called *virtual circuit deflection* (VCD) protocol can be used. The VCD protocol is a combination of virtual circuit switching and deflection routing, and is appropriate for sessions that simultaneously require minimal pretransmission delay and lossless communication. VCD is a "tell and go" (or "immediate transmission") type of protocol, and does not therefore use end-to-end reservations. In the VCD protocol, a path (called "preferred path") is selected for a new session, based on (possibly outdated) topology and link utilization information available at its source at the time. A setup packet is sent to the destination to establish the connection, followed after a short delay (much shorter than the end-to-end round-trip delay required by reservation protocols) by the data packets. This delay should be large enough to permit the electronic processing of the setup packet, without being overpassed by the data packets. If the available capacity on a preferred link of a session is inadequate, the session may have to follow a different, longer path; we then say that the session is deflected. When the total incoming link capacity is equal to the total outgoing link capacity of a node, as is usually the case in most data networks, it can be shown that there is always adequate available capacity on the outgoing links of an intermediate node to accommodate a new session. This, however, may happen at the expense of interrupting (preempting) an existing session that originates at that node, and/or splitting the new session into two or more smaller subsessions that are routed through different paths (session splitting). Deflection or splitting of sessions at intermediate nodes is infrequent in the VCD protocol, and can happen only when the topology or link utilization information at the source is outdated and the network is congested. Resequencing of packets, which is the major drawback of conventional (datagram) deflection schemes, is much simpler to accomplish in the VCD protocol. If a session is split, a few blocks of data packets (each of which is ordered) will have to be resequenced; this is a considerably easier task to perform than the resequencing of millions of individual packets that are out of order, as is the case in conventional deflection schemes.

Even though the effective utilization of idle links is an advantage, the increase of the number of used links per call is a disadvantage of the VCD protocol. An important performance measure is the *inefficiency ratio* $\eta(\lambda)$, defined as the ratio $\eta(\lambda) = D(\lambda)/D(0)$ of the average path length $D(\lambda)$ taken by a session for a given arrival per node rate λ, over the average shortest pathlength $D(0)$ of a given network topology. Results obtained from experiments on a Manhattan street network topology, indicate that the VCD protocol can be very efficient for high-speed networks, where link capacities are big and links are shared by a large number of small sessions.

7. TCP CONGESTION CONTROL

As we discussed in Section 6.1, TCP implements a credit-based flow control mechanism, using the *window size* field of the TCP header. This way, a destination entity avoids buffer overflow by limiting the dataflow from the source entity. This mechanism, however, can be further enhanced to provide network congestion control.

A source entity using TCP maintains a queue that holds the transmitted but not yet acknowledged segments

of its datastream. If a segment is not acknowledged after a certain time period, then this segment is considered lost and is retransmitted. A critical issue here is the determination of the retransmission timeout period. This is accomplished, in most TCP implementations, on the basis of *round-trip time* (RTT) and *RTT variance* estimates for the transmitted segments. Early TCP implementations calculated RTTs (and checked for timeouts) at "clock ticks" of 500 ms. This clock coarseness, however, led to long timeout intervals and, subsequently, large delays in retransmissions. This was solved by having retransmissions occur when, aside from timeouts (a number of), duplicate ACKs are received. A receiver transmits a duplicate ACK when it cannot acknowledge a segment because an earlier segment is lost. Therefore, when a certain number of duplicate ACKs (usually 3) are received, the source is warned that the segment after the one acknowledged is lost, and so it triggers retransmission. Another parameter that can be managed by congestion control techniques is the size of the TCP window, which can be adapted dynamically to the changing network conditions. A common mechanism for doing this is the *slow-start* mechanism, according to which at the beginning of a transmission or retransmission only one segment is transmitted, and then, for each ACK received, an extra segment is transmitted (in addition to the one acknowledged in the ACK) up to a maximum value. In this way the source probes the network with a small amount of data and increases exponentially its flow up to a certain threshold, after which the flow increases linearly.[9] Increase goes on until segments are lost, which implies that the available bandwidth is exceeded; then the source responds by decreasing its window size. In other words, TCP finds the available bandwidth by congesting the network and causing own fragment losses.

The mechanisms described in the previous paragraph are found in the early TCP implementation known as *Reno*. However, as this field is the focus of extensive research, several alternative and more effective mechanisms came up (and still do!) to enhance the functionality of TCP. Several such modifications were incorporated into the well-known *TCP Vegas* implementation. Vegas is reported to achieve 37–71% better throughput, with one-fifth to one-half the losses as compared to Reno. Specifically, Vegas features a new retransmission mechanism, a congestion avoidance mechanism, and an improved slow-start mechanism. The new retransmission mechanism detects lost segments much sooner than did Reno (and without the need for a second or third duplicate ACK) by using the fine-grain system clock to calculate RTTs.[10] Consequently, when a duplicate ACK is received, the more accurate RTT estimate is compared against the timeout value, and if it is found to be larger, the source retransmits the segment without having to wait for n duplicate ACKs. Moreover, Vegas checks the first couple of nonduplicate ACKs received after a retransmission, and if the calculated (over these ACKs) RTTs exceed the timeout value, then the corresponding segments are retransmitted. In this way any other segment that was lost prior to the retransmission is detected without having to wait for a duplicate ACK. Vegas also implements a congestion avoidance (*proactive*) mechanism, in contrast to the inherently *reactive* congestion detection mechanism of Reno. This mechanism performs a comparison between the *Expected throughput* of the connection [calculated by dividing the size of the current (congestion) window by the minimum of all the measured RTTs] and the measured *Actual throughput* (calculated by dividing the actual number of bytes transmitted during the RTT of a segment by this RTT). The result of this comparison (i.e., *expected throughput* minus *actual throughput,* which is always nonnegative) is used to adjust the congestion window size, and in particular, if the difference is below a low threshold (α), the actual and expected throughput values are too close and therefore the window size is increased linearly to catch up with the available bandwidth. If, on the other hand, the difference is above a high threshold (β), the actual and expected throughput values are too distant and therefore the window size is decreased linearly to react to the network congestion observed. The window size remains constant if the difference is between the two threshold values. The two threshold values practically correspond to the number of network buffers the connection occupies; thus, Vegas detects network congestion and responds to it by trying to limit the number of occupied buffers. Finally, Vegas uses a modified slow-start mechanism, which is integrated with the congestion avoidance mechanism described previously. At the beginning of the connection, this mechanism tries to find the connection's available bandwidth, without incurring the segment losses that Reno does. This is done by allowing the (exponential) growth of the congestion window only every other RTT. In the meantime, the window size remains constant, so that a comparison between the expected and actual rates can signal congestion and trigger a switch to the linear increase/decrease mode, implying that connection's available bandwidth is reached.

[9] The exact value of the threshold is not known during the initial slow start; when, however, a retransmit timeout occurs (indicating congestion), the threshold is set to half the current window size.

[10] The RTT of a segment is calculated by subtracting the segment's transmission time from the corresponding ACK reception time (by the segment source).

BIOGRAPHIES

Emmanouel (Manos) Varvarigos was born in Athens, Greece, in 1965. He received a Diploma in Electrical and Computer Engineering from the National Technical University of Athens in 1988, and the M.S. and Ph.D. degrees in Electrical Engineering and Computer Science from the Massachusetts Institute of Technology, Cambridge, in 1990 and 1992, respectively. In 1990 he was a researcher at Bell Communications Research, Morristown, New Jersey. From 1992 to 1998 he was an Assistant and later an Associate Professor at the department of Electrical and Computer Engineering at the University of California, Santa Barbara. In 1998/99 he was an Associate Professor at the Electrical Engineering Department at Delft University of Technology, the Netherlands. In 1999 he became a Professor in the Department of Computer Engineering

and Informatics at the University of Patras, where he is currently Director of the Hardware and Computer Architecture Division and Head of the Data Transmission and Networking Lab. His research activities are in the areas of protocols and algorithms for high-speed networks, all-optical networks, high-performance switch architectures, parallel and distributed computing, interconnection networks, VLSI layout design, performance evaluation, and ad hoc networks.

Theodora A. Varvarigou received the B.Tech. degree from the National Technical University of Athens, Athens, Greece in 1988, the M.S. degrees in Electrical Engineering (1989) and in Computer Science (1991) from Stanford University, Stanford, California in 1989 and the Ph.D. degree from Stanford University as well in 1991.

She worked at AT&T Bell Labs, Holmdel, New Jersey between 1991 and 1995. Between 1995 and 1997 she worked as an Assistant Professor at the Technical University of Crete, Chania, Greece. Since 1997 she has been working as an Assistant Professor at the National Technical University of Athens.

Her research interests include parallel algorithms and architectures, fault-tolerant computation, and parallel scheduling on multiprocessor systems.

CONCATENATED CONVOLUTIONAL CODES AND ITERATIVE DECODING

WILLIAM E. RYAN
University of Arizona
Tucson, Arizona

1. INTRODUCTION

Turbo codes, first presented to the coding community in 1993 [1,2], represent one of the most important breakthroughs in coding since Ungerboeck introduced trellis codes in 1982 [3]. A turbo code encoder, comprises a concatenation of two (or more) convolutional encoders, and its decoder consists of two (or more) "soft" convolutional decoders that feed probabilistic information back and forth to each other in a manner that is reminiscent of a turbo engine. This chapter presents a tutorial exposition of parallel and serial concatenated convolutional codes (PCCCs and SCCCs), which we will also call *parallel* and *serial turbo codes*. Included here are a simple derivation for the performance of these codes and a straightforward presentation of their iterative decoding algorithms. The treatment is intended to be a launching point for further study in the field and to provide sufficient information for the design of computer simulations. This article borrows from some of the most prominent publications in the field [4–12].

The article is organized as follows. Section 2 describes details of the parallel and serial turbo code encoders. Section 3 derives a truncated union bound on the error rate of these codes under the assumption of maximum-likelihood decoding. This section explains the phenomenon of interleaver gain attained by these codes. Section 4 derives in detail the iterative (turbo) decoder for both PCCCs and SCCCs. Included in this section are the BCJR (Bahl–Cocke–Jelinek–Raviv) decoding algorithm for convolutional codes and soft-in/soft-out decoding modules for use in turbo decoding. The decoding algorithms are presented explicitly to facilitate the creation of computer programs. Section 5 contains a few concluding remarks.

2. ENCODER STRUCTURES

Figure 1 depicts a parallel turbo encoder. As seen in the figure, the encoder consists of two binary rate 1/2 convolutional encoders arranged in a so-called parallel concatenation, separated by a K-bit pseudorandom interleaver or permuter. Also included is an optional puncturing mechanism to obtain high code rates [13]. Clearly, without the puncturer, the encoder is rate $\frac{1}{3}$, mapping K data bits to $3K$ code bits. With the puncturer, the code rate $R = K/(K+P)$, where P is the number of parity bits remaining after puncturing. Observe that the constituent encoders are recursive systematic convolutional (RSC) codes. As will be seen below, recursive encoders are necessary to attain the exceptional performance (attributed to "interleaver gain") provided by

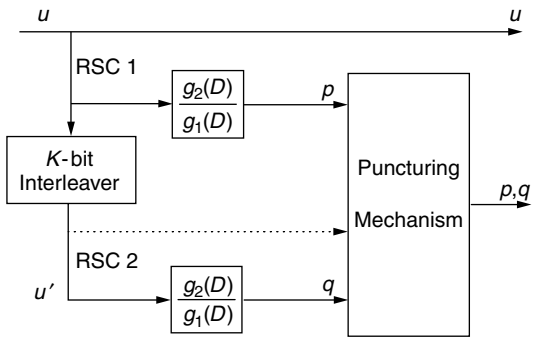

Figure 1. PCCC encoder diagram.

turbo codes. Without any essential loss of generality, we assume that the constituent codes are identical.

Figure 2 depicts a serial turbo encoder. As seen in the figure, the serially concatenated convolutional encoders are separated by an interleaver, and the inner encoder is required to be an RSC code, whereas the outer encoder need not be recursive [6]. However, RSC inner and outer encoders are often preferred since it is convenient to puncture only parity bits to obtain high code rates [14]. Further, an RSC outer code will facilitate our analysis below. The code rate for the serial turbo encoder is $R = R_o \cdot R_i$ where R_o and R_i are the code rates for the outer and inner codes, respectively.

For both parallel and serial turbo codes, the codeword length is $N = K/R$ bits, and we may consider both classes to be (N, K) block codes.

We now discuss in some detail the individual components of the turbo encoders.

2.1. The Recursive Systematic Encoders

Whereas the generator matrix for a rate $\frac{1}{2}$ nonrecursive convolutional code has the form $G_{NR}(D) = [g_1(D)\ g_2(D)]$, the equivalent recursive systematic encoder has the generator matrix

$$G_R(D) = \left[1\ \frac{g_2(D)}{g_1(D)}\right]$$

Observe that the code sequence corresponding to the encoder input $u(D)$ for the former code is $u(D)G_{NR}(D) = [u(D)g_1(D)\ \ u(D)g_2(D)]$, and that the identical code sequence is produced in the recursive code by the sequence $u'(D) = u(D)g_1(D)$, since in this case the code sequence is $u(D)g_1(D)G_R(D) = u(D)G_{NR}(D)$. Here, we loosely call the pair of polynomials $[u(D)g_1(D)\ u(D)g_2(D)]$ a *code sequence*, although the actual code sequence is derived from this polynomial pair in the usual way.

Observe that, for the recursive encoder, the code sequence will be of finite weight if and only if the input sequence is divisible by $g_1(D)$. We have the following corollaries of this fact, which we shall use later.

Fact 1. A weight 1 input will produce an infinite weight output for such an input is never divisible by a (nontrivial) polynomial $g_1(D)$. (In practice, "infinite" should be replaced by "large" since the input length is finite.)

Fact 2. For any nontrivial $g_1(D)$, there exists a family of weight 2 inputs of the form $D^j(1 + D^p)$, $j \geq 0$, which produce finite weight outputs, i.e., which are divisible by $g_1(D)$. When $g_1(D)$ is a primitive polynomial of degree m, then $p = 2^m - 1$. More generally, p is the length of the pseudorandom sequence generated by $g_1(D)$.

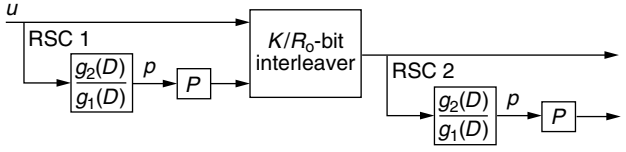

Figure 2. SCCC encoder diagram with RSC component codes. "P" signifies possible puncturing of parity bits.

Proof: Because the encoder is linear, its output due to a weight 2 input $D^j(1 + D^t)$ is equal to the sum of its outputs due to D^j and D^jD^t. The output due to D^j will be periodic with period p since the encoder is a finite-state machine (see Example 1 and Fig. 3); the state at time j must be reached again in a finite number of steps p, after which the state sequence is repeated indefinitely with period p. Now letting $t = p$, the output due to D^jD^p is just the output due to D^j shifted by p bits. Thus, the output due to $D^j(1 + D^p)$ is the sum of the outputs due to D^j and D^jD^p, which must be of finite length and weight since all but one period will cancel in the sum.

In the context of the code's trellis, fact 1 says that a weight-1 input will create a path that diverges from the all-zeros path, but never remerges. Fact 2 says that there will always exist a trellis path that diverges and remerges later, which corresponds to a weight 2 data sequence.

Example 1. Consider the code with generator matrix

$$G_R(D) = \left[1\ \frac{1 + D^2 + D^3 + D^4}{1 + D + D^4}\right].$$

Thus $g_1(D) = 1 + D + D^4$ and $g_2(D) = 1 + D^2 + D^3 + D^4$ or, in octal form, $(g_1, g_2) = (31, 27)$. Observe that $g_1(D)$ is primitive so that, for example, $u(D) = 1 + D^{15}$ produces the finite-length code sequence $(1 + D^{15}, 1 + D + D^3 + D^4 + D^7 + D^{11} + D^{12} + D^{13} + D^{14} + D^{15})$. Of course, any delayed version of this input, say, $D^7(1 + D^{15})$, will simply produce a delayed version of this code sequence. Figure 3 gives one encoder realization for this code. We remark that, in addition to elaborating on Fact 2, this example serves to demonstrate the conventions generally used in the literature for specifying such encoders.

2.2. The Interleaver

The function of the interleaver is to take each incoming block of bits and rearrange them in a pseudorandom fashion prior to encoding by the second encoder. For the PCCC, the interleaver permutes K bits and, for the SCCC, the interleaver permutes K/R_o bits. Unlike the classical interleaver (e.g., block or convolutional interleaver), which

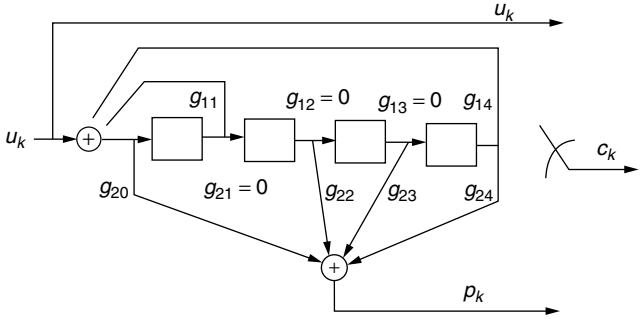

Figure 3. RSC encoder with $(g_1, g_2) = (31, 27)$.

rearranges the bits in some systematic fashion, it is crucial that this interleaver sort the bits in a manner that lacks any apparent order, although it might be tailored in a certain way for weight 2 and weight 3 inputs as will be made clearer below. The $\mathcal{S}$ random interleaver [8] is quite effective in this regard. This particular interleaver ensures that any two inputs bits whose positions are within $\mathcal{S}$ of each other are separated by an amount greater than $\mathcal{S}$ at the interleaver output. $\mathcal{S}$ should be selected to be as large as possible for a given value of K. Also, as we shall see, performance increases with K, and so $K \geq 1000$ is typical.

2.3. The Puncturer

The role of the turbo code puncturer is identical to that of its convolutional code counterpart, that is, to delete selected bits to reduce coding overhead. We have found it most convenient to delete only parity bits, but there is no guarantee that this will maximize the minimum codeword distance. For example, to achieve a rate of $\frac{1}{2}$, one might delete all even parity bits from the top encoder and all odd parity bits from the bottom one.

3. PERFORMANCE WITH MAXIMUM-LIKELIHOOD DECODING

As will be elaborated upon in the next section, a maximum-likelihood (ML) sequence decoder would be far too complex for a turbo code, due to the presence of the permuter. However, the suboptimum iterative decoding algorithm to be described there offers near-ML performance. Hence, we shall now estimate the performance of an ML decoder on a binary input AWGN channel with power spectral density $N_0/2$ (analysis of the iterative decoder is much more difficult).

Armed with the preceding descriptions of the components of the turbo encoders of Figs. 1 and 2, we can easily conclude that it is linear since its components are linear. The constituent codes are certainly linear, and the interleaver is linear since it may be modeled by a permutation matrix. Further, the puncturer does not affect linearity since all the constituent codewords share the same puncture locations. As usual, the importance of linearity in evaluating the performance of a code is that one may choose the all-zeros sequence as a reference. Thus, we shall assume that the all-zeros codeword was transmitted. The development below holds for both parallel and serial turbo codes.

Now consider the all-zeros codeword (the 0th codeword) and the kth codeword, for some $k \in \{1, 2, \ldots, 2^K - 1\}$. The ML decoder will choose the kth codeword over the 0th codeword with probability $Q(\sqrt{2d_k RE_b/N_0})$, where d_k is the weight of the kth codeword and E_b is the energy per information bit. The bit error rate for this two-codeword situation would then be

$$\begin{aligned} P_b(k|0) &= w_k \text{ (bit errors/cw error)} \\ &\quad \times \frac{1}{K} \text{ (cw/ data bits)} \\ &\quad \times Q(\sqrt{2Rd_kE_b/N_0}) \text{ (cw errors/cw)} \\ &= \frac{w_k}{K} Q\left(\sqrt{\frac{2Rd_kE_b}{N_0}}\right) \text{ (bit errors/data bit)} \end{aligned}$$

where w_k is the weight of the kth data word and "cw" = codeword. Now including all of the codewords and invoking the usual union bounding argument, we may write

$$\begin{aligned} P_b &= P_b(\text{choose any } k \in \{1, 2, \ldots, 2^K - 1\} \mid 0) \\ &\leq \sum_{k=1}^{2^K-1} P_b(k \mid 0) \\ &= \sum_{k=1}^{2^K-1} \frac{w_k}{K} Q\left(\sqrt{\frac{2Rd_kE_b}{N_0}}\right) \end{aligned}$$

Note that every nonzero codeword is included in the above summation. Let us now reorganize the summation as

$$P_b \leq \sum_{w=1}^{K} \sum_{v=1}^{\binom{K}{w}} \frac{w}{K} Q\left(\sqrt{\frac{2Rd_{wv}E_b}{N_0}}\right) \tag{1}$$

where the first sum is over the weight w inputs, the second sum is over the $\binom{K}{w}$ different weight w inputs, and d_{wv} is the weight of the v^{th} codeword produced by a weight w input. We emphasize that (1) holds for any linear code.

Consider now the first few terms in the outer summation of (1) in the context of parallel and serial turbo codes. Analogous to the fact that the top encoder in the parallel scheme is recursive, we shall assume that the outer encoder in the serial scheme is also recursive. By doing so, our arguments below will hold for both configurations. Further, an RSC outer code facilitates the design of high-rate serial turbo codes as mentioned above.

$w = 1$. From Fact 1 and associated discussion above, weight 1 inputs will produce only large weight codewords at both PCCC constituent encoder outputs since the trellis paths created never remerge with the all-zeros path. (We ignore the extreme case where the single 1 occurs at the end of the input words for both encoders for this is avoidable by proper interleaver design.) For the SCCC, the output of the outer encoder will have large weight because of Fact 1, and its inner encoder output will have large weight since its input has large weight. Thus, for both cases, each d_{1v} can be expected to be significantly greater than the minimum codeword weight so that the $w = 1$ terms in (1) will be negligible.

$w = 2$. Suppose that, of the $\binom{K}{2}$ possible weight 2 encoder inputs, $u_*(D)$ is the one of least degree that yields the minimum turbo codeword weight, $d_{2,\min}$, for weight-2 inputs. In the presence of the pseudorandom interleaver, the encoder is not time-invariant, and only a small fraction of the inputs of the form $D^j u_*(D)$ (there are approximately K of them) will also produce turbo codewords of weight $d_{2,\min}$. (This phenomenon has been called *spectral thinning* [10].) Denoting by n_2 the number of weight 2 inputs that produce weight $d_{2,\min}$ turbo codewords, we may conclude that $n_2 \ll K$. (For comparison, $n_2 \simeq K$ for a single RSC code as shifts of some worst-case input merely shifts the encoder output, thus maintaining a constant output weight.) Further, the overall minimum codeword weight, $d_{\min}$, is likely to be equal or close to $d_{2,\min}$ since low-degree, low-weight input words tend to produce low-weight

codewords. (This is easiest to see in the parallel turbo code case which is systematic.)

$w \geq 3$. When w is small (e.g., $w = 3$ or 4), an argument similar to the $w = 2$ case may be made to conclude that the number of weight w inputs, n_w, that yield the minimum turbo codeword weight for weight-w inputs, $d_{w,\min}$, is such that $n_w \ll K$. Further, we can expect $d_{w,\min}$ to be equal or close to $d_{\min}$. No such arguments can be made as w increases beyond about 5.

To summarize, by preserving only the dominant terms, the bound in (1) can be approximated as

$$P_b \simeq \sum_{w=2}^{3} \frac{w n_w}{K} Q\left(\sqrt{\frac{2Rd_{w,\min}E_b}{N_0}}\right) \tag{2}$$

where $w \geq 4$ terms may be added in the event that they are not negligible (more likely to be necessary for SCCCs). We note that n_w and $d_{w,\min}$ are functions of the particular interleaver employed. Since $w = 2$ or 3 in (1) and $n_w \ll K$ with $K \geq 1000$, the coefficients out in front of the Q function are much less than unity. (For comparison, the coefficient for a convolutional code can be much greater than unity [10].) This effect, called *interleaver gain*, demonstrates the necessity of large interleavers. Finally, we note that recursive encoders are crucial elements of a turbo code since, for nonrecursive encoders, division by $g_1(D)$ (nonremergent trellis paths) would not be an issue and (2) would not hold [although (1) still would].

When $K \simeq 1000$, it is possible to exhaustively find via computer the weight spectra $\{d_{2v}: v = 1, \ldots, \binom{K}{2}\}$ and $\{d_{3v}: v = 1, \ldots, \binom{K}{3}\}$ corresponding to the weight 2 and 3 inputs. In this case, an improved estimate of P_b, given by a truncation of (1), is

$$P_b \simeq \sum_{w=2}^{3} \sum_{v=1}^{\binom{K}{w}} \frac{w}{K} Q\left(\sqrt{\frac{2Rd_{wv}E_b}{N_0}}\right) \tag{3}$$

We remark that if codeword error rate, P_{cw}, is the preferred performance metric, then an estimate of P_{cw} may be obtained from (2) or (3) by removing the factor w/K from these expressions. That this is so may be seen by following the derivation above for P_b.

Example 2. We consider in this example a PCCC and an SCCC code, both rate $\frac{8}{9}$ with parameters $(N, K) = (1152, 1024)$. We use identical 4-state RSC encoders in the PCCC encoder whose generators polynomials are, in octal form, $(g_1, g_2) = (7, 5)$. To achieve a code rate of $\frac{8}{9}$, only one bit is saved in every 16-bit block of parity bits at each encoder output. The outer constituent encoder in the SCCC encoder is this same 4-state RSC encoder, and the inner code is a rate-1 differential encoder with transfer function $\frac{1}{1 \oplus D}$. A rate of $\frac{8}{9}$ is achieved in this case by saving one bit in every 8-bit block of parity bits. The PCCC interleaver is a 1024-bit pseudorandom interleaver with no constraints added (e.g., no $\mathcal{S}$-random constraint). The SCCC interleaver is a 1152-bit pseudorandom interleaver with no constraints added.

Figure 4 presents performance results for these codes based on computer simulation using the iterative (i.e., non-ML) decoding algorithm of the next section. Simulation results for both bit error rate P_b (BER in the figure) and

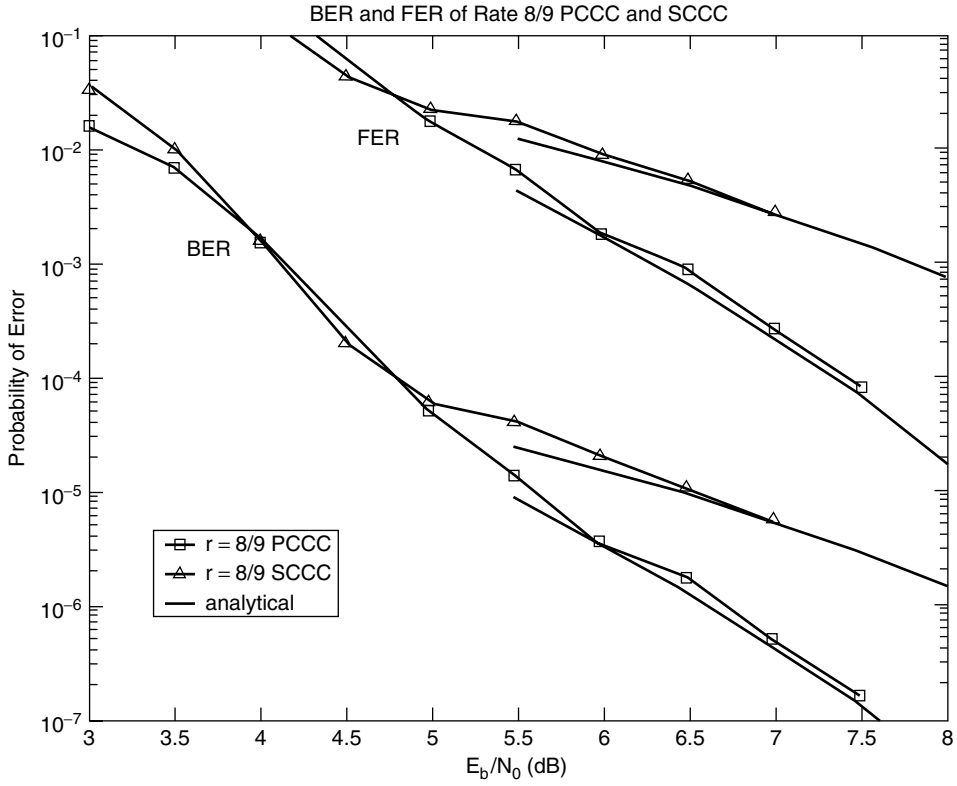

Figure 4. PCCC and SCCC bit error rate (BER) and frame error rate (FER) simulation results together with analytical result in (3).

frame or codeword error rate P_{cw} (FER in the figure) are presented. Also included in the figure are analytic performance curves for ML decoding using the truncated union bound in (3). (P_{cw} is obtained by removing the factor w/K in (3) as indicated above.) We see the close agreement between the analytical and simulated results in this figure.

In addition to illustrating the use of the estimate (3), this example helps explain the "flooring" effect of the error rate curves: it may be interpreted as the usual Q-function shape for a signaling scheme with a modest $d_{\min}$, "pushed down" by the interleaver gain $w^* n_{w^*}/K$, where w^* is the value of w corresponding to the dominant term in (2) or (3).

We comment on the fact that the PCCC in Fig. 4 is substantially better than the SCCC whereas it is known that SCCCs generally have lower floors [6]. We attribute this to the fact that the outer RSC code in the SCCC has been punctured so severely that $d_{\min} = 2$ for this outer code (although $d_{\min}$ for the SCCC is a bit larger). The RSC encoders for the PCCC is punctured only half as much, and so $d_{\min} > 2$ for each of these encoders. We also attribute this to the fact that we have not used an optimized interleaver for this example. In support of these comments, we have also simulated rate $\frac{1}{2}$ versions of this same code structure so that no puncturing occurs for the SCCC and much less occurs for the PCCC. In this case, $(N, K) = (2048, 1024)$ and $\mathcal{S}$-random interleavers were used ($\mathcal{S} = 16$ for PCCC and $\mathcal{S} = 20$ for SCCC). The results are presented in Fig. 5, where we observe that the SCCC has a much lower error rate floor, particularly for the FER curves. Finally, we remark that $w \geq 4$ terms in (2) are necessary for an accurate estimate of the floor level of the SCCC case in Fig. 5.

4. THE ITERATIVE DECODERS

4.1. Overview of the Iterative Decoder

Consider first an ML decoder for a rate $\frac{1}{2}$ convolutional code (recursive or not), and assume a data word of length $K \geq 1000$. Ignoring the structure of the code, a naive ML decoder would have to compare (correlate) 2^K code sequences to the noisy received sequence, choosing in favor of the codeword with the best correlation metric. Clearly, the complexity of such an algorithm is exorbitant. Fortunately, as we know, such a brute-force approach is simplified greatly by the Viterbi algorithm, which permits a systematic elimination of candidate code sequences.

Unfortunately, we have no such luck with turbo codes, for the presence of the interleaver immensely complicates the structure of a turbo code trellis. A near-optimal solution is an iterative decoder (also called a *turbo decoder*) involving two soft-in/soft-out (SISO) decoders that share probabilistic information cooperatively and iteratively. The goal of the iterative decoder is to iteratively estimate the *a posteriori* probabilities (APPs) $\Pr(u_k \mid \mathbf{y})$ where u_k is the kth data bit, $k = 1, 2, \ldots, K$, and $\mathbf{y}$ is the received codeword in noise, $\mathbf{y} = \mathbf{c} + \mathbf{n}$. In this equation, we assume the components of $\mathbf{c}$ take values in the set $\{\pm 1\}$ (and similarly for $\mathbf{u}$) and $\mathbf{n}$ is a noise word whose components

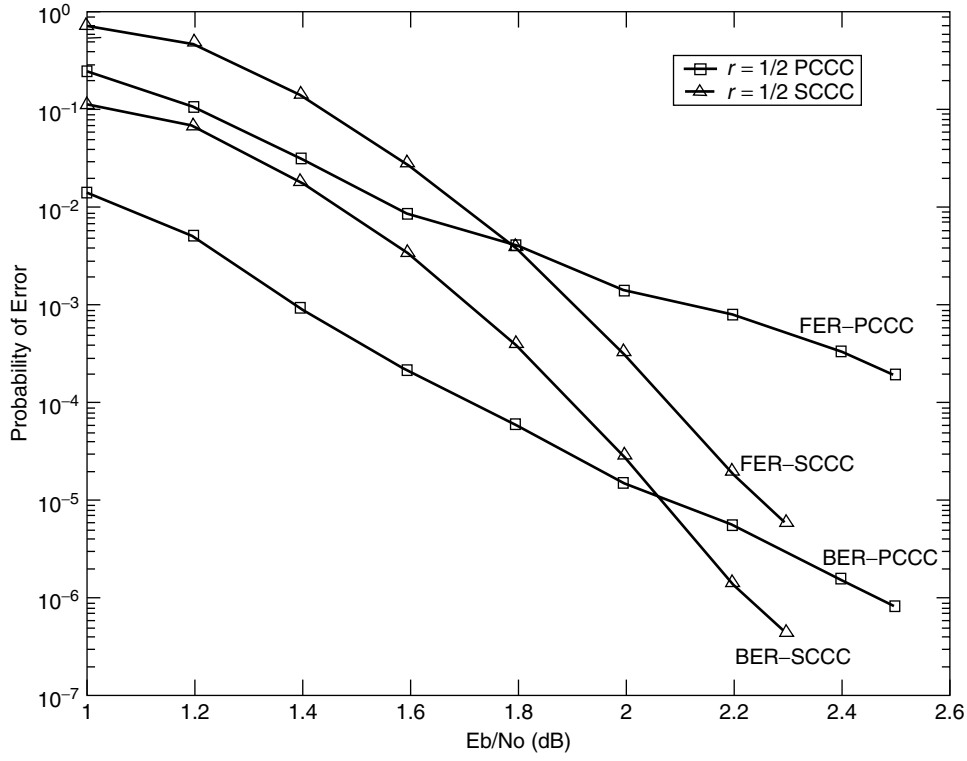

Figure 5. Rate $\frac{1}{2}$ PCCC and SCCC bit error rate (BER) and frame error rate (FER) simulation results.

are AWGN samples. Knowledge of the APPs allows for optimal decisions on the bits u_k via the maximum *a posteriori* (MAP) rule[1]

$$\frac{P(u_k = +1 \mid \mathbf{y})}{P(u_k = -1 \mid \mathbf{y})} \underset{-1}{\overset{+1}{\gtrless}} 1$$

or, more conveniently

$$\hat{u}_k = \text{sign } [L(u_k)]$$

where $L(u_k)$ is the log *a posteriori* probability (log-APP) ratio defined as

$$L(u_k) \triangleq \log\left(\frac{P(u_k = +1 \mid \mathbf{y})}{P(u_k = -1 \mid \mathbf{y})}\right) \tag{4}$$

We shall use the term *log-likelihood ratio* (LLR) in place of log-APP ratio for consistency with the literature.

The component SISO decoders that jointly estimate the LLRs $L(u_k)$ for parallel and serial turbo codes compute the LLRs for component code inputs (u_{ik}), component code outputs (c_{ik}), or both. Details on the SISO decoders will be presented below. For now, we simply introduce the convention that, for PCCCs, the top component encoder is encoder 1 (denoted E1) and the bottom component decoder is encoder 2 (denoted E2). For SCCCs, the outer encoder is encoder 1 (E1) and the inner encoder is encoder 2 (E2). The SISO component decoders matched to E1 and E2 will be denoted by D1 and D2, respectively. Because the SISO decoders D1 and D2 compute $L(u_{ik})$ and/or $L(c_{ik}), i = 1, 2$, we will temporarily use the notation $L(b_k)$ where b_k represents either u_{ik} or c_{ik}.

From Bayes' rule, the LLR for an arbitrary SISO decoder can be written as

$$L(b_k) = \log\left(\frac{P(\mathbf{y} \mid b_k = +1)}{P(\mathbf{y} \mid b_k = -1)}\right) + \log\left(\frac{P(b_k = +1)}{P(b_k = -1)}\right) \tag{5}$$

with the second term representing *a priori* information. Since $P(b_k = +1) = P(b_k = -1)$ typically, the *a priori* term is usually zero for conventional decoders. However, for *iterative* decoders, each component decoder receives *extrinsic* or *soft* information for each b_k from its companion decoder, which serves as *a priori* information. The idea behind extrinsic information is that D2 provides soft information to D1 for each b_k using only information not available to D1, and D1 does likewise for D2. For SCCCs, the iterative decoding proceeds as D2 $\rightarrow$ D1 $\rightarrow$ D2 $\rightarrow$ D1 $\rightarrow \ldots$, with the previous decoder passing soft information along to the next decoder at each half-iteration. For PCCCs, either decoder may initiate the chain of component decodings or, for hardware implementations, D1 and D2 may operate simultaneously.

This type of iterative algorithm is known to converge to the true value of the LLR $L(u_k)$ for the concatenated code provided that the graphical representation of this code contains no loops [15–17]. The graph of a turbo code does in fact contain loops [17], but the algorithm nevertheless provides near-optimal performance for virtually all turbo codes. That this is possible even in the presence of loops is not fully understood.

This section provided an overview of the turbo decoding algorithm in part to motivate the next section on SISO decoding of a single RSC code using the BCJR algorithm [18]. Following the description of the SISO decoder for a single RSC code will be sections that describe in full detail the iterative PCCC and SCCC decoders that utilize slightly modified SISO decoders.

4.2. The BCJR Algorithm and SISO Decoding

4.2.1. Probability Domain BCJR Algorithm for RSC Codes. Before we discuss the BCJR algorithm in the context of a turbo code, it is helpful to first consider the BCJR algorithm applied to a single rate $\frac{1}{2}$ RSC code on an AWGN channel. Thus, as indicated in Fig. 3, the transmitted codeword $\mathbf{c}$ will have the form $\mathbf{c} = [c_1, c_2, \ldots, c_K] = [u_1, p_1, u_2, p_2, \ldots, u_K, p_K]$ where $c_k \triangleq [u_k, p_k]$. The received word $\mathbf{y} = \mathbf{c} + \mathbf{n}$ will have the form $\mathbf{y} = [y_1, y_2, \ldots, y_K] = [y_1^u, y_1^p, y_2^u, y_2^p, \ldots, y_K^u, y_K^p]$, where $y_k \triangleq [y_k^u, y_k^p]$, and similarly for $\mathbf{n}$. As above, we assume our binary variables take values from the set $\{\pm 1\}$.

Our goal is the development of the BCJR algorithm [18] for computing the LLR

$$L(u_k) = \log\left(\frac{P(u_k = +1 \mid \mathbf{y})}{P(u_k = -1 \mid \mathbf{y})}\right)$$

given the received word $\mathbf{y}$. In order to incorporate the RSC code trellis into this computation, we rewrite $L(u_k)$ as

$$L(u_k) = \log \frac{\sum_{U+} p(s_{k-1} = s', s_k = s, \mathbf{y})}{\sum_{U-} p(s_{k-1} = s', s_k = s, \mathbf{y})} \tag{6}$$

where s_k is encoder state at time k, U^+ is set of pairs (s', s) for the state transitions $(s_{k-1} = s') \rightarrow (s_k = s)$, which correspond to the event $u_k = +1$, and U^- is similarly defined. To write (6) we used Bayes' rule, total probability, and then canceled $1/p(\mathbf{y})$ in the numerator and denominator. We see from (6) that we need only compute $p(s', s, \mathbf{y}) = p(s_{k-1} = s', s_k = s, \mathbf{y})$ for all state transitions and then sum over the appropriate transitions in the numerator and denominator. We now provide the crucial results that facilitate the computation of $p(s', s, \mathbf{y})$.

Result 1. The probability density function (pdf) $p(s', s, \mathbf{y})$ may be factored as

$$p(s', s, \mathbf{y}) = \alpha_{k-1}(s') \cdot \gamma_k(s', s) \cdot \beta_k(s) \tag{7}$$

where

$$\alpha_k(s) \triangleq p(s_k = s, \mathbf{y}_1^k)$$

$$\gamma_k(s', s) \triangleq p(s_k = s, y_k \mid s_{k-1} = s')$$

$$\beta_k(s) \triangleq p(\mathbf{y}_{k+1}^K \mid s_k = s)$$

and where $\mathbf{y}_a^b \triangleq [y_a, y_{a+1}, \cdots, y_b]$.

[1] It is well known that the MAP rule minimizes the probability of bit error. For comparison, the ML rule, which maximizes the likelihoods $P(\mathbf{y} \mid \mathbf{c})$ over the codewords $\mathbf{c}$, minimizes the probability of codeword error.

Proof: By several applications of Bayes' rule, we have

$$\begin{aligned} p(s', s, \mathbf{y}) &= p(s', s, \mathbf{y}_1^{k-1}, y_k, \mathbf{y}_{k+1}^K) \\ &= p(\mathbf{y}_{k+1}^K \mid s', s, \mathbf{y}_1^{k-1}, y_k) p(s', s, \mathbf{y}_1^{k-1}, y_k) \\ &= p(\mathbf{y}_{k+1}^K \mid s', s, \mathbf{y}_1^{k-1}, y_k) \\ &\quad \times p(s, y_k \mid s', \mathbf{y}_1^{k-1}) \cdot p(s', \mathbf{y}_1^{k-1}) \\ &= p(\mathbf{y}_{k+1}^K \mid s) \cdot p(s, y_k \mid s') \cdot p(s', \mathbf{y}_1^{k-1}) \\ &= \beta_k(s) \cdot \gamma_k(s', s) \cdot \alpha_{k-1}(s') \end{aligned}$$

where the fourth line follows from the third because the variables omitted on the fourth line are conditionally independent.

Result 2. The probability $\alpha_k(s)$ may be computed in a "forward recursion" via

$$\alpha_k(s) = \sum_{s'} \gamma_k(s', s) \alpha_{k-1}(s') \tag{8}$$

where the sum is over all possible encoder states.

Proof: By several applications of Bayes' rule and the theorem on total probability, we have

$$\begin{aligned} \alpha_k(s) &\triangleq p(s, \mathbf{y}_1^k) \\ &= \sum_{s'} p(s', s, \mathbf{y}_1^k) \\ &= \sum_{s'} p(s, y_k \mid s', \mathbf{y}_1^{k-1}) p(s', \mathbf{y}_1^{k-1}) \\ &= \sum_{s'} p(s, y_k \mid s') p(s', \mathbf{y}_1^{k-1}) \\ &= \sum_{s'} \gamma_k(s', s) \alpha_{k-1}(s') \end{aligned}$$

where the fourth line follows from the third due to conditional independence of $\mathbf{y}_1^{k-1}$.

Result 3. The probability $\beta_k(s)$ may be computed in a "backward recursion" via

$$\beta'_{k-1}(s') = \sum_{s} \beta_k(s) \gamma_k(s', s) \tag{9}$$

Proof: Applying Bayes' rule and the theorem on total probability, we have

$$\begin{aligned} \beta'_{k-1}(s') &\triangleq p(\mathbf{y}_k^K \mid s') \\ &= \sum_{s} p(\mathbf{y}_k^K, s \mid s') \\ &= \sum_{s} p(\mathbf{y}_{k+1}^K \mid s', s, y_k) p(s, y_k \mid s') \\ &= \sum_{s} p(\mathbf{y}_{k+1}^K \mid s) p(s, y_k \mid s') \\ &= \sum_{s} \beta_k(s) \gamma_k(s', s) \end{aligned}$$

where conditional independence led to the omission of variables on the fourth line.

The recursion for the $\{\alpha_k(s)\}$ is initialized according to

$$\alpha_0(s) = \begin{cases} 1, & s = 0 \\ 0, & s \neq 0 \end{cases}$$

which makes the reasonable assumption that the convolutional encoder is initialized to the zero state. The recursion for the $\{\beta_k(s)\}$ is initialized according to

$$\beta_K(s) = \begin{cases} 1, & s = 0 \\ 0, & s \neq 0 \end{cases}$$

which assumes that "termination bits" have been appended at the end of the data word so that the convolutional encoder is again in state zero at time K.

All that remains at this point is the computation of $\gamma_k(s', s) = p(s, y_k \mid s')$. Observe that $\gamma_k(s', s)$ may be written as

$$\begin{aligned} \gamma_k(s', s) &= \frac{P(s', s)}{P(s')} \cdot \frac{p(s', s, y_k)}{P(s', s)} \\ &= P(s \mid s') p(y_k \mid s', s) \\ &= P(u_k) p(y_k \mid u_k) \end{aligned} \tag{10}$$

where the event $'u_k$ corresponds to the event $s' \to s$. Note $P(s \mid s') = P(s' \to s) = 0$ if s is not a valid state from state s' and $P(s' \to s) = \frac{1}{2}$ otherwise (since we assume binary input encoders with equiprobable inputs). Hence, $\gamma_k(s', s) = 0$ if $s' \to s$ is not valid and, otherwise

$$\gamma_k(s', s) = \frac{P(u_k)}{\sqrt{2\pi}\sigma} \exp\left[-\frac{\|y_k - c_k\|^2}{2\sigma^2} \right] \tag{11}$$

$$= \frac{1}{2\sqrt{2\pi}\sigma} \exp\left[-\frac{(y_k^u - u_k)^2 + (y_k^p - p_k)^2}{2\sigma^2} \right] \tag{12}$$

where $\sigma^2 = N_0/2$.

In summary, we may compute $L(u_k)$ via (6) using (7), (8), (9), and (12). This "probability domain" version of the BCJR algorithm is numerically unstable for long and even moderate codeword lengths, and so we now present the stable "log domain" version of it.

4.2.2. Log-Domain BCJR Algorithm for RSC Codes. In the log-BCJR algorithm, $\alpha_k(s)$ is replaced by the *forward metric*

$$\begin{aligned} \tilde{\alpha}_k(s) &\triangleq \log(\alpha_k(s)) \\ &= \log\left(\sum_{s'} \alpha_{k-1}(s') \gamma_k(s', s) \right) \\ &= \log\left(\sum_{s'} \exp(\tilde{\alpha}_{k-1}(s') + \tilde{\gamma}_k(s', s)) \right) \end{aligned} \tag{13}$$

where the *branch metric* $\tilde{\gamma}_k(s', s)$ is given by

$$\begin{aligned} \tilde{\gamma}_k(s', s) &= \log \gamma_k(s', s) \\ &= -\log(2\sqrt{2\pi}\sigma) - \frac{\|y_k - c_k\|^2}{2\sigma^2} \end{aligned} \tag{14}$$

We will see that the first term in (14) may be dropped. Note that (13) not only defines $\tilde{\alpha}_k(s)$ but also gives its recursion. These log-domain forward metrics are initialized as

$$\tilde{\alpha}_0(s) = \begin{cases} 0, & s = 0 \\ -\infty, & s \neq 0 \end{cases} \tag{15}$$

The probability $\beta_{k-1}(s')$ is replaced by the *backward metric*

$$\begin{aligned} \tilde{\beta}_{k-1}(s') &\triangleq \log(\beta_{k-1}(s')) \\ &= \log\left(\sum_s \exp \tilde{\beta}_k(s) + \tilde{\gamma}_k(s', s)\right) \end{aligned} \tag{16}$$

with initial conditions

$$\tilde{\beta}_K(s) = \begin{cases} 0, & s = 0 \\ -\infty, & s \neq 0 \end{cases} \tag{17}$$

under the assumption that the encoder has been terminated.

As before, $L(u_k)$ is computed as

$$\begin{aligned} L(u_k) &= \log \frac{\sum_{U^+} \alpha_{k-1}(s')\gamma_k(s', s)\beta_k(s)}{\sum_{U^-} \alpha_{k-1}(s')\gamma_k(s', s)\beta_k(s)} \\ &= \log\left[\sum_{U+} \exp(\tilde{\alpha}_{k-1}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k(s))\right] \\ &\quad - \log\left[\sum_{U^-} \exp(\tilde{\alpha}_{k-1}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k(s))\right] \end{aligned} \tag{18}$$

It is evident from (18) that the constant term in (14) may be ignored since it may be factored all the way out of both summations. At first glance, Eqs. (13)–(18) do not look any simpler than the probability domain algorithm, but we use the following results to obtain the simplification.

Result 4.

$$\max(x, y) = \log\left(\frac{e^x + e^y}{1 + e^{-|x-y|}}\right)$$

Proof: Without loss of generality, when $x > y$, the right-hand side equals x.

Now define

$$\max^*(x, y) \triangleq \log(e^x + e^y) \tag{19}$$

so that from Result 4, we obtain

$$\max^*(x, y) = \max(x, y) + \log(1 + e^{-|x-y|}) \tag{20}$$

This may be extended to more than two variables. For example

$$\max^*(x, y, z) \triangleq \log(e^x + e^y + e^z)$$

which may be computed pairwise according to the following result.

Result 5.

$$\max^*(x, y, z) = \max^*[\max^*(x, y), z]$$

Proof:

$$\begin{aligned} \text{RHS} &= \log[e^{\max^*(x,y)} + e^z] \\ &= \log[e^{\log(e^x + e^y)} + e^z] \\ &= \log[e^x + e^y + e^z] \\ &= \text{LHS} \end{aligned}$$

Given the function $\max^*(\cdot)$, we may now rewrite (13), (16), and (18) as

$$\tilde{\alpha}_k(s) = \max_{s'}{}^*[\tilde{\alpha}_{k-1}(s') + \tilde{\gamma}_k(s', s)] \tag{21}$$

$$\tilde{\beta}_{k-1}(s') = \max_{s}{}^*[\tilde{\beta}_k(s) + \tilde{\gamma}_k(s', s)] \tag{22}$$

and

$$\begin{aligned} L(u_k) = &\max_{U^+}{}^*[\tilde{\alpha}_{k-1}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k(s)] \\ &- \max_{U^-}{}^*[\tilde{\alpha}_{k-1}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k(s)] \end{aligned} \tag{23}$$

Figure 6 illustrates pictorially the trellis-based computations that these last three equations represent.

We see from Eqs. (21)–(23) how the log-domain computation of $L(u_k)$ is vastly simplified relative to the probability-domain computation. From (20), implementation of the $\max^*(\cdot)$ function involves only a two-input $\max(\cdot)$ function plus a lookup table for the "correction term" $\log(1 + e^{-|x-y|})$. Robertson et al. [11] have shown that a table size of 8 is usually sufficient.

Note that the correction term is bounded as

$$0 < \log(1 + e^{-|x-y|}) \leq \log(2) \simeq 0.693$$

so that $\max^*(x, y) \simeq \max(x, y)$ when $|\max(x, y)| \geq 7$. When $\max^*(x, y)$ is replaced by $\max(\cdot)$ in Eqs. (21) and (22), these recursions become forward and reverse Viterbi algorithms, respectively. The performance loss associated with this approximation in turbo decoding depends on the specific turbo code, but a loss of about 0.5 dB is typical [11].

Finally, observe the sense in which the BCJR decoder is a SISO decoder: the decoder input is the "soft decision" (unquantized) word $\mathbf{y} \in \mathbb{R}^{2K}$ and its outputs are the soft outputs $L(u_k) \in \mathbb{R}$ on which final hard decisions may be made according to (4). Alternatively, in a concatenated code context, these soft outputs may be passed to a companion decoder.

4.2.3. Summary of the Log-Domain BCJR Algorithm. We assume as above a rate $\frac{1}{2}$ RSC encoder, a data block $\mathbf{u}$ of length K, and that encoder starts and terminates in the zero state (the last m bits of $\mathbf{u}$ are so selected, where m is the encoder memory size). In practice, the value $-\infty$ used in initialization is simply some large-magnitude negative number.

Initialize $\tilde{\alpha}_0(s)$ and $\tilde{\beta}_K(s)$ according to Eqs. (15) and (17).
for $k = 1{:}K$
— get $y_k = [y_k^u, y_k^p]$
— compute $\tilde{\gamma}_k(s', s) = -\|y_k - c_k\|^2/2\sigma^2$ for all allowable state transitions $s' \to s$ (note $c_k = c_k(s', s)$ here)[2]
— compute $\tilde{\alpha}_k(s)$ for all s using the recursion (21)
end

[2] We may alternatively use $\tilde{\gamma}_k(s', s) = u_k y_k^u/\sigma^2 + p_k y_k^p/\sigma^2$. (See next section.)

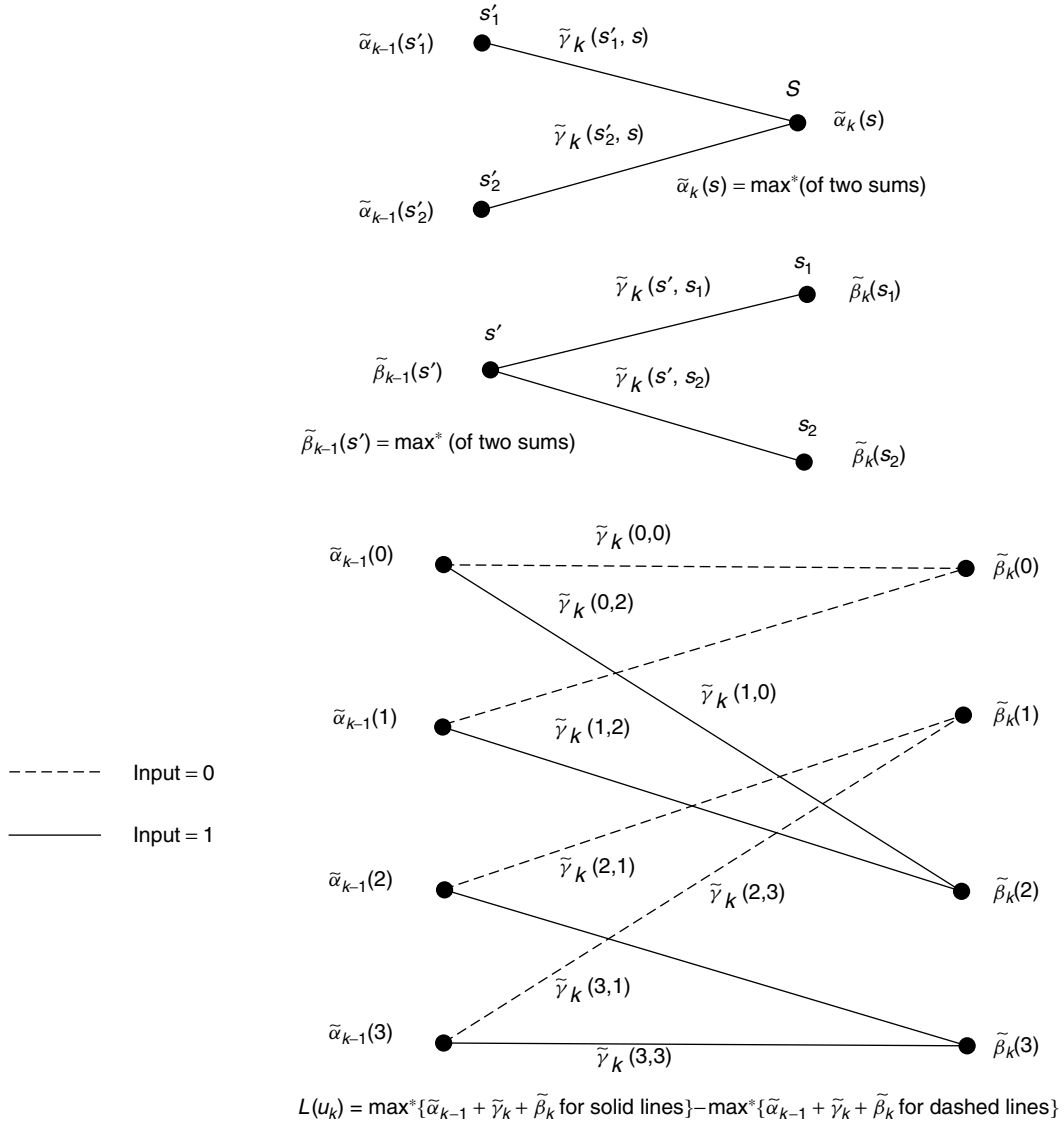

Figure 6. The top diagram depicts the forward recursion in (21), the middle diagram depicts the backward recursion in (22), and the bottom diagram depicts the computation of $L(u_k)$ via (23).

for $k = K: -1 : 2$
— compute $\tilde{\beta}_{k-1}(s')$ for all s' using (22)
end
for $k = 1{:}K$
— compute $L(u_k)$ using (23)
— compute hard decisions via $\hat{u}_k = \text{sign}\left[L(u_k)\right]$
end

4.3. The PCCC Iterative Decoder

We present in this section the iterative decoder for a PCCC consisting of two component rate $\frac{1}{2}$ RSC encoders concatenated in parallel. We assume no puncturing so that the overall code rate is $\frac{1}{3}$. Block diagrams of the PCCC encoder and its iterative decoder with component SISO decoders are presented in Fig. 7. As indicated in Fig. 7a, the transmitted codeword $\mathbf{c}$ will have the form $\mathbf{c} = [c_1, c_2, \ldots, c_K] = [u_1, p_1, q_1, \ldots, u_K, p_K, q_K]$ where $c_k \stackrel{\Delta}{=} [u_k, p_k, q_k]$. The received word $\mathbf{y} = \mathbf{c} + \mathbf{n}$ will have the form $\mathbf{y} = [y_1, y_2, \ldots, y_K] = [y_1^u, y_1^p, y_1^q, \ldots, y_K^u, y_K^p, y_K^q]$, where $y_k \stackrel{\Delta}{=} [y_k^u, y_k^p, y_k^q]$, and similarly for $\mathbf{n}$. We denote the codewords produced by E1 and E2 by, respectively, $\mathbf{c}_1 = [c_1^1, c_2^1, \ldots, c_K^1]$ where $c_k^1 \stackrel{\Delta}{=} [u_k, p_k]$ and $\mathbf{c}_2 = [c_1^2, c_2^2, \ldots, c_K^2]$ where $c_k^2 \stackrel{\Delta}{=} [u'_k, q_k]$. Note that $\{u'_k\}$ is a permuted version of $\{u_k\}$ and is not actually transmitted (see Fig. 7a). We define the noisy received versions of $\mathbf{c}_1$ and $\mathbf{c}_2$ to be $\mathbf{y}_1$ and $\mathbf{y}_2$, respectively, having components $y_k^1 \stackrel{\Delta}{=} [y_k^u, y_k^p]$ and $y_k^2 \stackrel{\Delta}{=} [y_k^{u'}, y_k^q]$, respectively. Note that $\mathbf{y}_1$ and $\mathbf{y}_2$ can be assembled from $\mathbf{y}$ in an obvious fashion (using an interleaver to obtain $\{y_k^{u'}\}$ from $\{y_k^u\}$). By doing so, the component decoder inputs are the two vectors $\mathbf{y}_1$ and $\mathbf{y}_2$ as indicated in the Fig. 7b.

In contrast to the BCJR decoder of the previous sections whose input was $\mathbf{y} = \mathbf{c} + \mathbf{n}$ and whose output was $\{L(u_k)\}$ (or $\{\hat{u}_k\}$), the SISO decoders in Fig. 7b possess two inputs and two outputs. The SISO decoders are essentially the BCJR decoders discussed above, except that the SISO

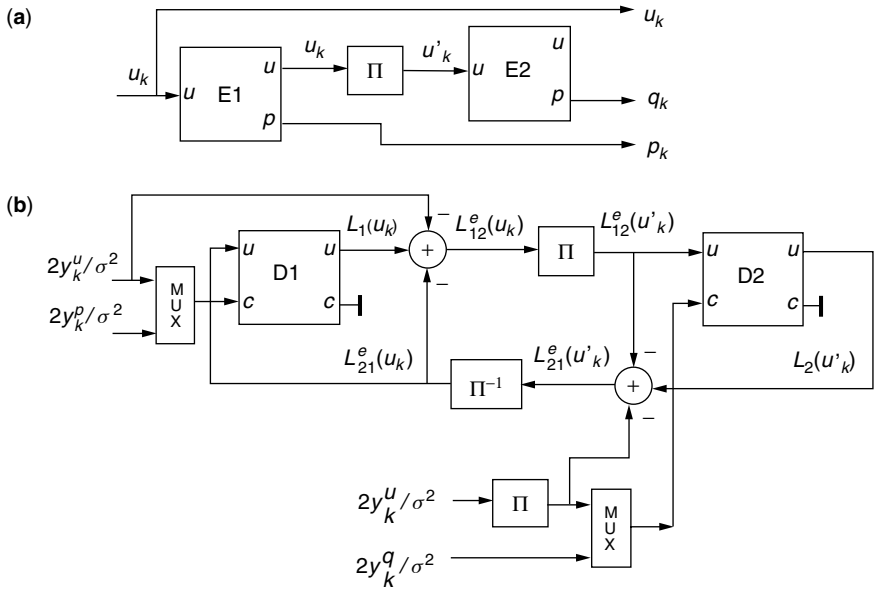

Figure 7. Block diagrams for the PCCC encoder (**a**) and iterative decoder (**b**).

decoders have the ability to accept from a companion decoder "extrinsic information" about its encoder's input (SISO input label '*u*') and/or about its encoder's output (SISO input label '*c*'). The SISO decoders also have the ability to produce likelihood information about its encoder's input (SISO output label '*u*') and/or about its encoder's output (SISO output label '*c*'). Note that the SISO decoder is to be interpreted as a decoding module not all of whose inputs or outputs need be used [7]. (Note that the RSC encoders in Fig. 7a have also been treated as modules.) As we will see, the SISO modules are connected in a slightly different fashion for the SCCC case.

Note from Fig. 7b that the extrinsic information to be passed from D1 to D2 about bit u_k, denoted $L_{12}^e(u_k)$, is equal to the LLR $L_1(u_k)$ produced by D1 minus the channel likelihood $2y_k^u/\sigma^2$ and the extrinsic information $L_{21}^e(u_k)$ that D1 had just received from D2. The idea is that $L_{12}^e(u_k)$ should indeed be extrinsic (and uncorrelated with) the probabilistic information already possessed by D2. As we will see, $L_{12}^e(u_k)$ is strictly a function of received E1 parity $\{y_k^p\}$ which is not directly sent to D2. Observe that $\{L_{12}^e(u_k)\}$ must be interleaved prior to being sent to D2 since E2 and D2 operate on the interleaved data bits u'_k. Symmetrical comments may be made about the extrinsic information to be passed from D2 to D1, $L_{21}^e(u_k)$ (e.g., it is a function of E2 parity and deinterleaving is necessary).

We already know from the previous section how the SISO decoders process the samples from the channel, $\mathbf{y}_i$ $(i = 1, 2)$, to obtain LLR's about the decoder inputs. We need now to discuss how the SISO decoders include the extrinsic information in their computations. As indicated earlier, the extrinsic information takes the role of *a priori* information in the iterative decoding algorithm [see (5) and surrounding discussion]:

$$L^e(u_k) \triangleq \log\left(\frac{P(u_k = +1)}{P(u_k = -1)}\right). \tag{24}$$

The *a priori* term $P(u_k)$ shows up in (11) in an expression for $\gamma_k(s', s)$. In the log domain, (11) becomes[3]

$$\tilde{\gamma}_k(s', s) = \log P(u_k) - \log(\sqrt{2\pi}\sigma) - \frac{\|y_k - c_k\|^2}{2\sigma^2} \tag{25}$$

Now observe that we may write

$$\begin{aligned} P(u_k) &= \left(\frac{\exp[-L^e(u_k)/2]}{1 + \exp\left[-L^e(u_k)\right]}\right) \cdot \exp\frac{u_k L^e(u_k)}{2} \\ &= A_k \exp\frac{u_k L^e(u_k)}{2} \end{aligned} \tag{26}$$

where the first equality follows since it equals

$$\left(\frac{\sqrt{P_-/P_+}}{1 + P_-/P_+}\right)\sqrt{P_+/P_-} = P_+ \text{ when } u_k = +1$$

$$\left(\frac{\sqrt{P_-/P_+}}{1 + P_-/P_+}\right)\sqrt{P_-/P_+} = P_- \text{ when } u_k = -1$$

where we have defined $P_+ \triangleq P(u_k = +1)$ and $P_- \triangleq P(u_k = -1)$ for convenience. Substitution of (26) into (25) yields

$$\tilde{\gamma}_k(s', s) = \log\left(\frac{A_k}{\sqrt{2\pi}\sigma}\right) + \frac{u_k L^e(u_k)}{2} - \frac{\|y_k - c_k\|^2}{2\sigma^2} \tag{27}$$

where we will see that the first term may be ignored.

Thus, the extrinsic information received from a companion decoder is included in the computation through the branch metric $\tilde{\gamma}_k(s', s)$. The rest of the BCJR/SISO algorithm proceeds as before using Eqs. (21)–(23).

[3] For the time being, we will discuss a generic SISO decoder so that we may avoid using cumbersome superscripts until it is necessary to do so.

Upon substitution of (27) into (23), we have

$$L(u_k) = L^e(u_k) + \max_{U^+}{}^* \left[\tilde{\alpha}_{k-1}(s') + \frac{u_k y_k^u}{\sigma^2} + \frac{p_k y_k^p}{\sigma^2} + \tilde{\beta}_k(s) \right] - \max_{U^-}{}^* \left[\tilde{\alpha}_{k-1}(s') + \frac{u_k y_k^u}{\sigma^2} + \frac{p_k y_k^p}{\sigma^2} + \tilde{\beta}_k(s) \right] \quad (28)$$

where we have applied the fact that

$$\|y_k - c_k\|^2 = (y_k^u - u_k)^2 + (y_k^p - p_k)^2 = (y_k^u)^2 - 2u_k y_k^u + u_k^2 + (y_k^p)^2 - 2p_k y_k^p + p_k^2$$

and only the terms dependent on U^+ or U^-, $u_k y_k^u/\sigma^2$ and $p_k y_k^p/\sigma^2$, survive after the subtraction. Now note that $u_k y_k^u/\sigma^2 = y_k^u/\sigma^2$ under the first $\max^*(\cdot)$ operation in (28) (U^+ is the set of state transitions for which $u_k = +1$) and $u_k y_k^u/\sigma^2 = -y_k^u/\sigma^2$ under the second $\max^*(\cdot)$ operation. Using the definition for $\max^*(\cdot)$, it is easy to see that these terms may be isolated out so that

$$L(u_k) = \frac{2y_k^u}{\sigma^2} + L^e(u_k) + \max_{U^+}{}^* \left[\tilde{\alpha}_{k-1}(s') + \frac{p_k y_k^p}{\sigma^2} + \tilde{\beta}_k(s) \right] - \max_{U^-}{}^* \left[\tilde{\alpha}_{k-1}(s') + \frac{p_k y_k^p}{\sigma^2} + \tilde{\beta}_k(s) \right] \quad (29)$$

The interpretation of this new expression for $L(u_k)$ is that the first term is likelihood information received directly from the channel, the second term is extrinsic likelihood information received from a companion decoder, and the third "term" ($\max_{U^+}{}^* - \max_{U^-}{}^*$) is extrinsic likelihood information to be passed to a companion decoder. Note that this third term is likelihood information gleaned from received parity not available to the companion decoder. Thus, specializing to decoder D1, for example, on any given iteration, D1 computes

$$L_1(u_k) = \frac{2y_k^u}{\sigma^2} + L_{21}^e(u_k) + L_{12}^e(u_k)$$

where $L_{21}^e(u_k)$ is extrinsic information received from D2, and $L_{12}^e(u_k)$ is the third term in (29) which is to be used as extrinsic information from D1 to D2.

4.3.1. Summary of the PCCC Iterative Decoder. The algorithm given below for the iterative decoding of a parallel turbo code follows directly from the development above. The constituent decoder order is D1, D2, D1, D2, and so on. Implicit is the fact that each decoder must have full knowledge of the trellis of the constituent encoders. For example, each decoder must have a table (array) containing the input bits and parity bits for all possible state transitions $s' \to s$. Also required are interleaver and de-interleaver functions (arrays) since D1 and D2 will be sharing reliability information about each u_k, but D2's information is permuted relative to D1. We denote these arrays by $P[\cdot]$ and $Pinv[\cdot]$, respectively. For example, the permuted word $\mathbf{u}'$ is obtained from the original word $\mathbf{u}$ via the pseudo-code statement: for $k = 1{:}K$, $u'_k = u_{P[k]}$, end.

We next point out that knowledge of the noise variance $\sigma^2 = N_0/2$ by each SISO decoder is necessary. Also, a simple way to obtain higher code rates via (simulated) puncturing is, in the computation of $\gamma_k(s', s)$, to set to zero the received parity samples, y_k^p or y_k^q, corresponding to the punctured parity bits, p_k or q_k. (This will set to zero the term in the branch metric corresponding to the punctured bit.) Thus, puncturing need not be performed at the encoder for computer simulations. We mention also that termination of encoder E2 to the zero state can be problematic due to the presence of the interleaver (for one solution, see Ref. 19). Fortunately, there is only a small performance loss when E2 is not terminated. In this case, $\beta_K(s)$ for D2 may be set to $\alpha_K(s)$ for all s, or it may be set to a nonzero constant (e.g., $1/S_2$, where S_2 is the number of E2 states).

Finally, we remark that some sort of iteration stopping criterion is necessary. The most straightforward criterion is to set a maximum number of iterations. However, this can be inefficient since the correct codeword is often found after only two or three iterations. Another straightforward technique is to utilize a carefully chosen outer error detection code. After each iteration, a parity check is made and the iterations stop whenever no error is detected. Other stopping criteria are presented in [9] and elsewhere in the literature.

4.3.1.1. Initialization

D1:

$\tilde{\alpha}_0^{(1)}(s) = 0$ for $s = 0$
$= -\infty$ for $\neq 0$

$\tilde{\beta}_K^{(1)}(s) = 0$ for $s = 0$
$= -\infty$ for $s \neq 0$

$L_{21}^e(u_k) = 0$ for $k = 1, 2, \ldots, K$

D2:

$\tilde{\alpha}_0^{(2)}(s) = 0$ for $s = 0$
$= -\infty$ for $s \neq 0$

$\tilde{\beta}_K^{(2)}(s) = \tilde{\alpha}_K^{(2)}(s)$ for all s (set once after computation of $\{\tilde{\alpha}_K^{(2)}(s)\}$ in the *first* iteration)

$L_{12}^e(u_k)$ is to be determined from D1 after the first half-iteration and so need not be initialized

4.3.1.2. The nth Iteration

D1:

for $k = 1{:}K$

— get $y_k^1 = [y_k^u, y_k^p]$

— compute $\tilde{\gamma}_k(s', s)$ for all allowable state transitions $s' \to s$ from (27) which simplifies to [see discussion following (27)]

$$\tilde{\gamma}_k(s', s) = \frac{u_k L_{21}^e(u_{Pinv[k]})}{2} + \frac{u_k y_k^u}{\sigma^2} + \frac{p_k y_k^p}{\sigma^2}$$

[u_k (p_k) in this expression is set to the value of the encoder input (output) corresponding to the transition $s' \to s$]

— compute $\tilde{\alpha}_k^{(1)}(s)$ for all s using (21)

end

for $k = K{:}-1:2$

— compute $\tilde{\beta}_{k-1}^{(1)}(s)$ for all s using (22)

end

for $k = 1{:}K$

— compute $L_{12}^e(u_k)$ using[4]

$$L_{12}^e(u_k) = \max_{U^+}{}^* \left[\tilde{\alpha}_{k-1}^{(1)}(s') + \frac{p_k y_k^p}{\sigma^2} + \tilde{\beta}_k^{(1)}(s) \right] - \max_{U^-}{}^* \left[\tilde{\alpha}_{k-1}^{(1)}(s') + \frac{p_k y_k^p}{\sigma^2} + \tilde{\beta}_k^{(1)}(s) \right]$$

end

D2:

for $k = 1{:}K$

— get $y_k^2 = [y_{P[k]}^u, y_k^q]$

— compute $\tilde{\gamma}_k(s', s)$ for all allowable state transitions $s' \to s$ from

$$\tilde{\gamma}_k(s', s) = \frac{u_k L_{12}^e(u_{P[k]})}{2} + \frac{u_k y_{P[k]}^u}{\sigma^2} + \frac{q_k y_k^q}{\sigma^2}$$

[u_k (q_k) in this expression is set to the value of the encoder input (output) corresponding to the transition $s' \to s$]

— compute $\tilde{\alpha}_k^{(2)}(s)$ for all s using (21)

end

for $k = K{:}-1:2$

— compute $\tilde{\beta}_{k-1}^{(2)}(s)$ for all s using (22)

end

for $k = 1{:}K$

— compute $L_{21}^e(u_k)$ using

$$L_{21}^e(u_k) = \max_{U^+}{}^* \left[\tilde{\alpha}_{k-1}^{(2)}(s') + \frac{q_k y_k^q}{\sigma^2} + \tilde{\beta}_k^{(2)}(s) \right] - \max_{U^-}{}^* \left[\tilde{\alpha}_{k-1}^{(2)}(s') + \frac{q_k y_k^q}{\sigma^2} + \tilde{\beta}_k^{(2)}(s) \right]$$

end

[4] Note here we are computing $L_{12}^e(u_k)$ directly rather than computing $L_1(u_k)$ and then subtracting $2y_k^u/\sigma^2 + L_{21}^e(u_k)$ from it to obtain $L_{12}^e(u_k)$ as in Fig. 5(b). We will do likewise in the analogous step for D2.

4.3.1.3. After the Last Iteration

for $k = 1{:}K$

— compute

$$L_1(u_k) = \frac{2y_k^u}{\sigma^2} + L_{21}^e(u_{p_{inv}[k]}) + L_{12}^e(u_k)$$

— $\hat{u}_k = \text{sign}\,[L(u_k)]$

end

4.4. The SCCC Iterative Decoder

We present in this section the iterative decoder for an SCCC consisting of two component rate $\frac{1}{2}$ RSC encoders concatenated in series. We assume no puncturing so that the overall code rate is $\frac{1}{4}$. Higher code rates are achievable via puncturing and/or by replacing the inner encoder with a rate 1 differential encoder with transfer function $\frac{1}{1 \oplus D}$. It is straightforward to derive the iterative decoding algorithm for other SCCC codes from the special case that we consider here.

Block diagrams of the SCCC encoder and its iterative decoder with component SISO decoders are presented in Fig. 8. We denote by $\mathbf{c}_1 = [c_1^1, c_2^1, \ldots, c_{2K}^1] = [u_1, p_1, u_2, p_2, \ldots, u_K, p_K]$ the codeword produced by E1 whose input is $\mathbf{u} = [u_1, u_2, \ldots, u_K]$. We denote by $\mathbf{c}_2 = [c_1^2, c_2^2, \ldots, c_{2K}^2] = [v_1, q_1, v_2, q_2, \ldots, v_{2K}, q_{2K}]$ (with $c_k^2 \stackrel{\Delta}{=} [v_k, q_k]$) the codeword produced by E2 whose input $\mathbf{v} = [v_1, v_2, \ldots, v_{2K}]$ is the interleaved version of $\mathbf{c}_1$, that is, $\mathbf{v} = \mathbf{c}_1'$. As indicated in Fig. 8a, the transmitted codeword $\mathbf{c}$ is the codeword $\mathbf{c}_2$. The received word $\mathbf{y} = \mathbf{c} + \mathbf{n}$ will have the form $\mathbf{y} = [y_1, y_2, \ldots, y_{2K}] = [y_1^v, y_1^q, \ldots, y_{2K}^v, y_{2K}^q]$ where $y_k \stackrel{\Delta}{=} [y_k^v, y_k^q]$, and similarly for $\mathbf{n}$.

The iterative SCCC decoder in Fig. 8b employs two SISO decoding modules (described in the previous section). Note that unlike the PCCC case, these SISO decoders share extrinsic information on the code bits $\{c_k^1\}$ (equivalently, on the input bits $\{v_k\}$) in accordance with the fact that these are the bits known to both encoders. A consequence of this is that D1 must provide likelihood information on E1 *output* bits whereas D2 produces likelihood information on E2 *input* bits as indicated in Fig. 8b. However, because LLRs must be obtained on the original data bits u_k so that final decisions may be made, D1 must also compute likelihood information on E1 input bits. Note also that, because E1 feeds no bits directly to the

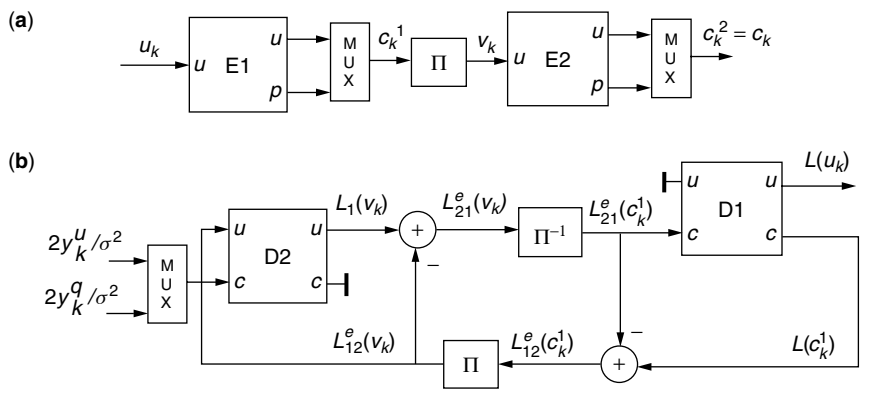

Figure 8. Block diagrams for the SCCC encoder (**a**) and iterative decoder (**b**).

channel, D1 receives no samples directly from the channel. Instead, the only input to D1 is the extrinsic information it receives from D2.

Thus, the SISO module D1 requires two features that we have not discussed in any detail to this point. The first is providing likelihood information on the encoder's input *and* output. However, since we assume the component codes are systematic, we need only compute LLRs on the encoder's output bits $[u_1, p_1, u_2, p_2, \ldots, u_K, p_K]$. Doing this is a simple matter of modifying the summation indices in (6) to those relevant to the output bit of interest. For example, the LLR $L(p_k)$ for the E1 parity bit p_k is obtained via

$$L(p_k) = \log \frac{\sum_{P^+} p(s_{k-1} = s', s_k = s, \mathbf{y})}{\sum_{P^-} p(s_{k-1} = s', s_k = s, \mathbf{y})} \tag{30}$$

where P^+ is set of state transition pairs (s', s) corresponding to the event $p_k = +1$, and P^- is similarly defined. (A trellis-based BCJR/SISO decoder is generally capable of decoding either the encoder's input or its output, whether or not the code is systematic. This is evident since the trellis branches are labeled by both inputs and outputs.)

The second feature is required by D1 is decoding with only extrinsic information as input. In this case the branch metric is simply modified as [cf. (27)]

$$\tilde{\gamma}_k(s', s) = \frac{u_k L^e_{21}(u_k)}{2} + \frac{p_k L^e_{21}(p_k)}{2} \tag{31}$$

Other than these modifications, the iterative SCCC decoder proceeds much like the PCCC iterative decoder and as indicated in Fig. 8b.

4.4.1. Summary of the SCCC Iterative Decoder. Essentially all of the comments mentioned for the PCCC decoder hold here as well and so we do not repeat them. The only difference is that the decoding order is D2, D1, D2, D1, and so on.

4.4.1.1. Initialization

D1:

$$\tilde{\alpha}^{(1)}_0(s) = 0 \text{ for } s = 0$$
$$= -\infty \text{ for } s \neq 0$$

$$\tilde{\beta}^{(1)}_K(s) = 0 \text{ for } s = 0$$
$$= -\infty \text{ for } s \neq 0$$

$L^e_{21}(c^1_k)$ is to be determined from D2 after the first half-iteration and so need not be initialized

D2:

$$\tilde{\alpha}^{(2)}_0(s) = 0 \text{ for } s = 0$$
$$= -\infty \text{ for } s \neq 0$$

$\tilde{\beta}^{(2)}_{2K}(s) = \tilde{\alpha}^{(2)}_{2K}(s)$ for all s (set after computation of $\{\tilde{\alpha}^{(2)}_{2K}(s)\}$ in the *first* iteration)

$L^e_{12}(v_k) = 0$ for $k = 1, 2, \ldots, 2K$

4.4.1.2. The nth Iteration

D2:

for $k = 1{:}\,2K$

— get $y_k = [y^v_k, y^q_k]$

— compute $\tilde{\gamma}_k(s', s)$ for all allowable state transitions $s' \to s$ from

$$\tilde{\gamma}_k(s', s) = \frac{v_k L^e_{12}(v_k)}{2} + \frac{v_k y^v_k}{\sigma^2} + \frac{q_k y^q_k}{\sigma^2}$$

[v_k (q_k) in this expression is set to the value of the encoder input (output) corresponding to the transition $s' \to s$; $L^e_{12}(v_k)$ is $L^e_{12}(c^1_{P[k]})$, the interleaved extrinsic information from the previous D1 iteration.]

— compute $\tilde{\alpha}^{(2)}_k(s)$ for all s using (21)

end

for $k = 2K{:}\,-1 : 2$

— compute $\tilde{\beta}^{(2)}_{k-1}(s)$ for all s using (22)

end

for $k = 1{:}\,2K$

— compute $L^e_{21}(v_k)$ using

$$L^e_{21}(v_k) = \max^*_{V^+}\left[\tilde{\alpha}^{(2)}_{k-1}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}^{(2)}_k(s)\right]$$
$$-\max^*_{V^-}\left[\tilde{\alpha}^{(2)}_{k-1}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}^{(2)}_k(s)\right] - L^e_{12}(v_k)$$
$$= \max^*_{V^+}\left[\tilde{\alpha}^{(2)}_{k-1}(s') + v_k y^v_k/\sigma^2 + q_k y^q_k/\sigma^2 + \tilde{\beta}^{(2)}_k(s)\right]$$
$$-\max^*_{V^-}\left[\tilde{\alpha}^{(2)}_{k-1}(s') + v_k y^v_k/\sigma^2 + q_k y^q_k/\sigma^2 + \tilde{\beta}^{(2)}_k(s)\right]$$

where V^+ is set of state transition pairs (s', s) corresponding to the event $v_k = +1$, and V^- is similarly defined.

end

D1:

for $k = 1{:}\,K$

— for all allowable state transitions $s' \to s$ set $\tilde{\gamma}_k(s', s)$ via

$$\tilde{\gamma}_k(s', s) = \frac{u_k L^e_{21}(u_k)}{2} + \frac{p_k L^e_{21}(p_k)}{2}$$
$$= \frac{u_k L^e_{21}(c^1_{2k-1})}{2} + \frac{p_k L^e_{21}(c^1_{2k})}{2}$$

[u_k (p_k) in this expression is set to the value of the encoder input (output) corresponding to the transition $s' \to s$; $L^e_{21}(c^1_{2k-1})$ is $L^e_{21}(v_{Pinv[2k-1]})$, the de-interleaved extrinsic information from the previous D2 iteration, and similarly for $L^e_{21}(c^1_{2k})$].

— compute $\tilde{\alpha}^{(1)}_k(s)$ for all s using (21)

end

for $k = K: -1 : 2$

— compute $\tilde{\beta}_{k-1}^{(1)}(s)$ for all s using (22)

end

for $k = 1:K$

— compute $L_{12}^e(u_k) = L_{12}^e(c_{2k-1}^1)$ using

$$L_{12}^e(u_k) = \max_{U^+}{}^*[\tilde{\alpha}_{k-1}^{(1)}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k^{(1)}(s)] - \max_{U^-}{}^*[\tilde{\alpha}_{k-1}^{(1)}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k^{(1)}(s)] - L_{21}^e(c_{2k-1}^1)$$

$$= \max_{U^+}{}^*\left[\tilde{\alpha}_{k-1}^{(1)}(s') + \frac{p_k L_{21}^e(p_k)}{2} + \tilde{\beta}_k^{(1)}(s)\right] - \max_{U^-}{}^*\left[\tilde{\alpha}_{k-1}^{(1)}(s') + \frac{p_k L_{21}^e(p_k)}{2} + \tilde{\beta}_k^{(1)}(s)\right]$$

— compute $L_{12}^e(p_k) = L_{12}^e(c_{2k}^1)$ using

$$L_{12}^e(p_k) = \max_{P^+}{}^*[\tilde{\alpha}_{k-1}^{(1)}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k^{(1)}(s)] - \max_{P^-}{}^*[\tilde{\alpha}_{k-1}^{(1)}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k^{(1)}(s)] - L_{21}^e(c_{2k}^1)$$

$$= \max_{P^+}{}^*\left[\tilde{\alpha}_{k-1}^{(1)}(s') + \frac{u_k L_{21}^e(u_k)}{2} + \tilde{\beta}_k^{(1)}(s)\right] - \max_{P^-}{}^*\left[\tilde{\alpha}_{k-1}^{(1)}(s') + \frac{u_k L_{21}^e(u_k)}{2} + \tilde{\beta}_k^{(-1)}(s)\right]$$

end

4.4.1.3. After the Last Iteration

for $k = 1:K$

— for all allowable state transitions $s' \to s$ set $\tilde{\gamma}_k(s', s)$ via

$$\tilde{\gamma}_k(s', s) = \frac{u_k L_{21}^e(c_{2k-1}^1)}{2} + \frac{p_k L_{21}^e(c_{2k}^1)}{2}$$

— compute $L(u_k)$ using

$$L(u_k) = \max_{U^+}{}^*\left[\tilde{\alpha}_{k-1}^{(1)}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k^{(1)}(s)\right] - \max_{U^+}{}^*\left[\tilde{\alpha}_{k-1}^{(1)}(s') + \tilde{\gamma}_k(s', s) + \tilde{\beta}_k^{(1)}(s)\right]$$

— $\hat{u}_k = \text{sign}\left[L(u_k)\right]$

end

5. CONCLUSION

We have seen in this article the how and why of both parallel and serial turbo codes. That is, we have seen how to decode these codes using an iterative decoder, and why they should be expected to perform so well. The decoding algorithm summaries should be sufficient to decode any binary parallel and serial turbo codes, and can in fact be easily extended to the iterative decoding of any binary hybrid schemes. It is not much more work to figure out how to decode any of the turbo trellis-coded modulation (turbo TCM) schemes that appear in the literature. In any case, this article should serve well as a starting point for the study of concatenated codes (and perhaps graph-based codes) and their iterative decoders.

CONSTRAINED CODING TECHNIQUES FOR DATA STORAGE

WIM M. J. COENE

Philips Research Laboratories
Eindhoven, The Netherlands

1. INTRODUCTION

Modulation codes are one of the key elements in digital communication or storage systems such as a CD or DVD recorder, a hard-disk drive (HDD) in a computer, a modem, or a fax. A schematical form of a storage system is shown in Fig. 1. Here, two parts can be distinguished: the transmitting part, including the write channel in which one user stores data on the recording medium; and the receiving part of the system, including the read-channel in which the same or another user tries to restore the original information by reading out the data written on the medium.

In order to realize a sufficiently high level of reliability, the data are first encoded before being stored. This *channel encoding* typically comprises an error-correcting code (ECC) and a modulation code (MC). The channel encoder at the transmitting end consists of the error correction encoder and the modulation encoder, usually cascaded one after the other in that order.

Located at the receiving end of the channel are the physical signal detection with the read head scanning the information on the medium, followed by the bit detection module, which attempts to derive the written bits (also called *channel* bits) from the measured signals as reliably as possible. These blocks precede the channel decoding, which consists of the respective counterparts of the modules at the transmitting end, with first the MC decoder, followed by the ECC decoder.

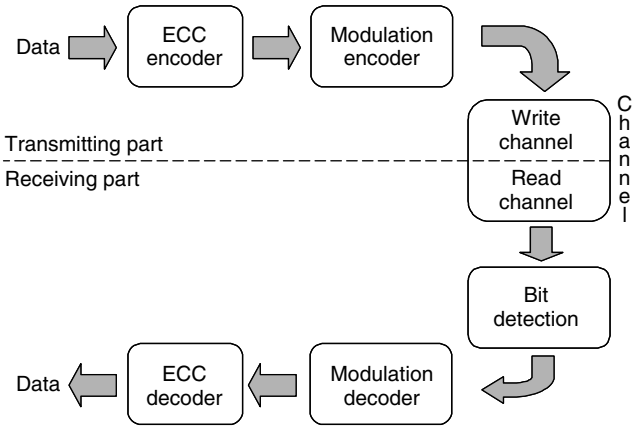

Figure 1. Schematic form of a digital storage system.

The ECC adds redundancy in the form of parity symbols, which makes it possible to restore the correct information in the presence of channel imperfections such as random errors and/or burst errors that may occur during readout from the medium. The modulation code serves to transform arbitrary (binary) sequences into sequences that possess certain "desirable" properties. Note the difference from error-correcting codes, which are used to ensure that *pairs* of encoded sequences have certain properties (i.e., being "very different"), while a modulation code serves to ensure certain properties of *each individual* encoded sequence. Which properties are desirable strongly depends on the particular storage or communication system for which the code is designed. For example, in most digital magnetic or optical recording systems, the stored sequences preferably contain neither very short nor very long runs of successive zeros or ones. The reason for this originates in how a stored sequence is read from the storage medium. The explanation is as follows.

In a storage system, the modulation of the physical signals is concerned with two physical conditions or states of the medium: (1) for magnetic recording, it is the magnetisation of magnetic domains in one of two opposite directions; (2) for optical recording, as shown in Fig. 2, it is the level of reflectivity (high and low) of the marks (or *pits*) and spaces (or *lands*) on the medium. One physical state can be associated with a channel bit (binary) 1, the other state with a channel bit (binary) 0. This representation, where the value of the channel bit represents the physical state (mark or space), is commonly known as *non-return-to-zero inverse* (NRZI), an old term originating from telegraphy. An equivalent representation of a channel bit stream is the *non-return-to-zero* (NRZ) notation, where a 1 bit indicates the start of a new mark or space on the medium, that is, a change of the physical state, and a 0 bit indicates the continuation of a mark or space.

A channel bit stream in NRZI notation can be partitioned into a sequence of phrases or *runs*, where each run consists of a number of consecutive channel bits of the

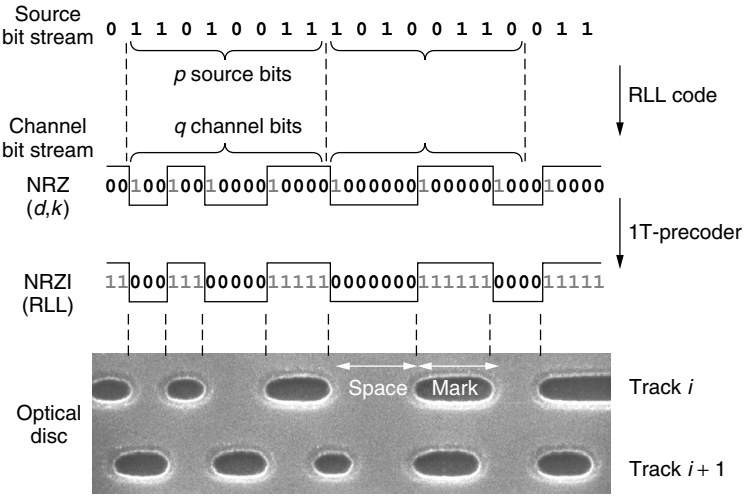

Figure 2. RLL coding in optical recording.

same type. So each run is associated with the physical area of a mark or space on the medium. The number of bits in a run is called the *run length*. As an example of a storage medium, we shall consider an optical disc in a little more detail. On the disk, data are organized in a single spiral; a small part of two successive revolutions of the spiral can be seen in Fig. 2. Along the track, physical marks and the spaces between them alternate. The marks and spaces have lengths that are multiples of the channel bit length T, and a mark or space of length nT represents a run with a run length of n bits.

Very short runs lead to small-signal amplitudes in the readout by the physical detection, and are therefore more prone to errors in the bit detection module (which is positioned directly after the read channel in Fig. 1). This is explained in more detail in Section 2. Moreover, very long runs lead to inaccuracies in the *timing recovery*, which is dealt with by a device called a *phase-locked loop* (PLL). The PLL regenerates the internal "clock" that is matched to the length of the bits on the medium; the bit clock is adjusted at each occurrence of a transition. Areas on the medium with too few transitions may cause "clock drift."

Avoiding very short and/or very long runs is achieved by using a run-length-limited (RLL) code, which typically constrains the allowable minimum and maximum run lengths that occur in the channel bit stream. The RLL constraints are described in terms of two parameters, d and k, and stipulate that the minimum and maximum run lengths are equal to $d+1$ and $k+1$, respectively. Note that the uncoded case corresponds to $d=0$ and $k=\infty$. In NRZ notation, a run of length $m+1$ is represented by a 1 bit followed by m 0 bits, that is, by 10^m in shorthand notation. Hence the (d,k) constraint in NRZ notation requires that the number of 0 bits between two successive 1 bits be at least d and at most k. Sequences that obey this constraint are called (d,k) *sequences*; a code for this constraint is referred to as a (d,k) *code*. Most RLL codes are constructed for a bit stream in NRZ notation. Subsequent transformation from NRZ to NRZI is required to obtain the channel bits that are actually written on the medium; such a transformation is formally carried out by a so-called 1T precoder, which is essentially an integrator modulo 2 (see Fig. 2).

A run-length constraint forms an example of a constraint that is specified by the absence of a finite number of "forbidden patterns." For example, a (d,k) constraint with $d>0$ can be specified in terms of the forbidden patterns $11, 101, \ldots, 10^{d-1}1$, and 0^{k+1}. Such a constraint is commonly referred to as a *constraint of finite type*. Many constraints that occur in practice are of this kind. Forbidding certain specific patterns implies that a sequence of source bits must be translated into a longer sequence of channel bits; the ratio of the length of the original sequence and the length of the encoded sequence is called the *rate* of the code.

Run-length-limited codes originated already in the 1960s through the work of Franaszek [1], Tang and Bahl [2], and others. Since then, various mechanisms for the construction of RLL and other modulation codes have been devised. A very elegant method is the ACH state-splitting algorithm [3], which will be discussed in Section 5. A detailed overview of RLL codes and their construction is given in Immink's book [4]; for other review articles, see, for example, Refs. 5 and 6.

The remainder of this survey is organised as follows. In Section 2, some practical aspects of the use of an RLL code are considered; Section 3 discusses the maximal coding rate (the capacity) of a modulation code; encoder and decoder structures are considered in Section 4; various code construction methods are described in Section 5; and finally Section 6 presents a collection of research topics and more recent trends in modulation coding.

2. PRACTICAL CONSIDERATIONS FOR THE USE OF AN RLL CODE

High-capacity storage applications employ such small bit sizes that the readout signal waveform generated by the physical detection for a given bit location does depend not only on that single bit but also on a limited number of neighboring bits. This bit-smearing effect is better known as *intersymbol interference* (ISI). For a simple read channel with linear readout characteristics, the ISI is

characterized by the impulse response of the channel, or, equivalently, by its Fourier transform, which yields the modulation transfer function (MTF) of the channel [7, Chap. 3.2]. The MTF indicates the (amplitude) response of the channel for each frequency in the system.

For storage systems, the MTF typically has a lowpass character: for instance, in optical recording, the MTF has an almost linear rolloff up to the cutoff frequency of the channel (see Fig. 3). Therefore, short run lengths in the channel bit stream, which lead to high-frequent signals, suffer most from ISI and are thus more prone to errors during read-out. One of the purposes of runlength-limited coding is to impose constraints that do not allow these high-frequency bit sequences; by doing so, the spectral content of the RLL-coded sequences is shaped to have a more lowpass character.

To illustrate this principle, we discuss the effect of employing three different d constraints, for $d = 0$ (uncoded), $d = 1$, and $d = 2$, while maintaining the same density of source bits on the storage medium in all three cases for fair comparison. So let T denote the common physical size of a source bit. Using a d-constrained code at a rate R_d, the physical channel bit size T_d will necessarily satisfy $T_d = R_d T$. Figure 4 shows the respective channel bit lengths and the highest frequency in the system (which correspond to an alternation of runs of minimum run length). Here, we of course have $R_0 = 1$ in the uncoded case. Furthermore, we assume that practical codes are

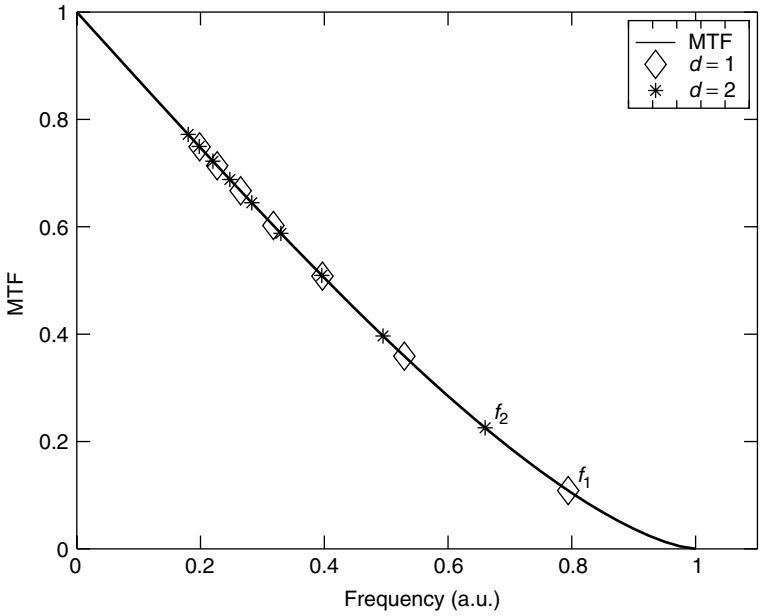

Figure 3. MTF for the optical recording channel as a function of frequency (in arbitrary units) with the frequencies of the pure tones $\ldots |nT_d \mid nT_d| \ldots$ superimposed.

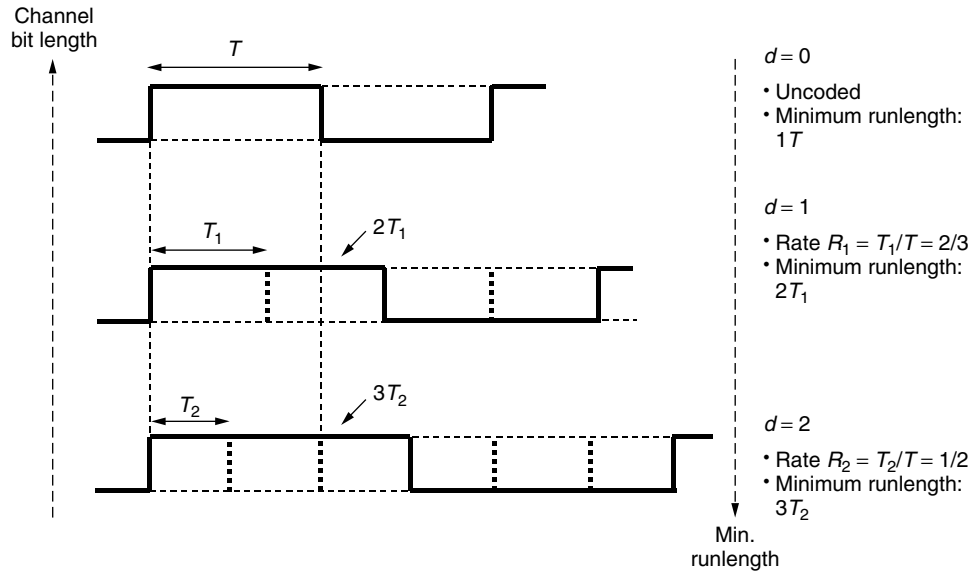

Figure 4. Channel bit length and minimum runlength for different d constraints at the same recording capacity in a storage channel.

used that have rates $R_1 = \frac{2}{3}$ and $R_2 = \frac{1}{2}$. These are reasonably close to the maximal achievable code rates of 0.6942 and 0.5515, respectively (see Section 3). For these rates, the minimum run length for $d = 1$ amounts to $2T_1 = 4/3T$, which is larger than the minimum run length T for $d = 0$; also, the minimum run length for $d = 2$ amounts to $3T_2 = 3/2T$, which is larger than the minimum run length for $d = 1$. Consequently, the highest frequencies f_d in the system for $d = 0, d = 1$, and $d = 2$ are

$$f_0 = \frac{1}{2T} > f_1 = \frac{1}{4R_1T} = \frac{3}{8T} > f_2 = \frac{1}{6R_2T} = \frac{1}{3T}$$

This relation reveals the increasing lowpass character of the code for increasing d constraint, which is the major attractiveness of RLL coding. This can also be observed from Fig. 3, where we have drawn the MTF (as a function of frequency) for the optical recording channel, with the frequencies of the pure tones $\ldots |nT_d \mid nT_d \mid nT_d| \ldots$ for $n = d + 1, d + 2, \ldots$ superimposed.

However, note that the channel bit length (or *timing window*, also known as *detection window*) decreases for increasing d constraint, which leads to a greater sensitivity with respect to *jitter* or *mark-edge noise* in the system. This counteracting effect favours the use of a *lower* d constraint.

The practical choice for a certain d constraint is a compromise between all pros and cons, and depends on many aspects, such as the actual bit detector used in the receiver (e.g., threshold detection, or some form of partial-response maximum-likelihood bit detection [7, Chap. 6]), the characteristics of the write channel, and the characteristics of the various noise sources in the system such as media noise and electronic noise.

3. CODING RATE AND CAPACITY

In the foregoing we have discussed various technical reasons for putting constraints on the sequences that we want to store or to send over a channel. Sequences that satisfy the constraints at hand are called *constrained sequences* or *codewords*, and the collection of all these sequences will be called the *constrained system*. A *modulation code* for a given constrained system consists of an *encoder* to translate arbitrary sequences into constrained sequences, and a *decoder* to recover the original sequence from the encoded sequence. The bits making up the original sequence and the encoded sequence are usually referred to as *source bits* and *channel bits*, respectively.

To achieve encoding, there is a price to be paid. Indeed, since there are more arbitrary sequences of a given length than there are constrained sequences of the same length, the encoding process will necessarily lead to an *increase* in the number of bits in the channel bit stream. This increase is measured by a number called the *rate* of the code. If, on the average, p source bits are translated into q channel bits, then the rate R of the code is $R = p/q$.

All other things being equal, we would, of course, like our code to have the highest possible rate. However, for all practical constraints there is a natural barrier for the code rate, called the *capacity* of the constraint, beyond which no encoding is possible. This discovery by Shannon [8] has been of great theoretical and practical importance. Indeed, once we know the capacity C of a given constrained system, then, on the one hand, we know that the best encoding rate that could possibly be achieved is bounded from above by C; on the other hand, once we have actually constructed a code with a rate R, the number R/C, called the *efficiency* of the code, serves as a benchmark for our engineering achievement.

In what follows, we shall sketch a derivation of Shannon's results. Consider a constrained system $\mathcal{L}$, and let N_n denote the number of constrained sequences of length n. Suppose that we can encode at a rate R. By definition, this means that, for large n, approximately Rn source bits are translated into n channel bits. There are 2^{Rn} distinct source sequences of length Rn, all of which need to be translated into distinct constrained sequences of length n, of which there are only N_n. Therefore, we necessarily have that $2^{Rn} \leq N_n$, or, equivalently, that $R \leq n^{-1} \log N_n$. (Here and in the sequel, all logarithms will be to the base 2.)

We now follow Shannon and *define* the capacity $C(\mathcal{L})$ of the constrained system $\mathcal{L}$ as

$$C(\mathcal{L}) = \lim_{n\to\infty} \frac{\log N_n}{n} \tag{1}$$

provided this limit exists.[1]

Intuitively, the capacity represents the *average amount of information* (measured in bits) *per bit of the constrained sequence*. The reasoning described above shows that encoding at a rate R is possible only if $R \leq C(\mathcal{L})$ and, moreover, suggests the possibility of encoding at rates arbitrarily close to $C(\mathcal{L})$, for example, by using long codewords glued together by a few suitably chosen merging bits.

It turns out that the kind of systems encountered in practice can typically be described in terms of a finite labeled directed *graph*. Here, a graph $G = (V, A)$ consists of a collection V of vertices or *states*, and a collection A of labeled arcs or *transitions* between states. Some authors refer to a "labeled directed graph" as defined above as a *finite-state transition diagram* (FSTD). The constrained system $\mathcal{L}(G)$ *presented* by G consists of all sequences that can be obtained by reading off the labels along a (directed) *path* in the graph, or, as we shall see, the sequences that are *generated* by paths in G. We shall refer to the graph G as a *presentation* of the system $\mathcal{L}(G)$.

Constrained systems that can be presented by some finite labeled directed graph as explained above are called *sofic systems*. Sofic systems are of great theoretical and practical importance. It turns out that about every constrained system encountered in practical applications is in fact a sofic system. (This is less remarkable than it

[1] For *subword-closed* systems, the fact that this limit exists immediately follows from Fekete's lemma [9, p. 233; 10]; namely, if the non-negative numbers a_n are such that $a_{m+n} \leq a_m + a_n$ for all $n, m \geq 0$, then $a^* = \lim_{n\to\infty} a_n/n$ exists and $a^* \leq a_n/n$ for all n. Indeed, if N_n is the number of sequences of length n contained in a subword-closed system, then obviously $N_{m+n} \leq N_m N_n$; hence an application of this lemma with $a_n = \log N_n$ shows that subword-closed systems have a well-defined capacity.

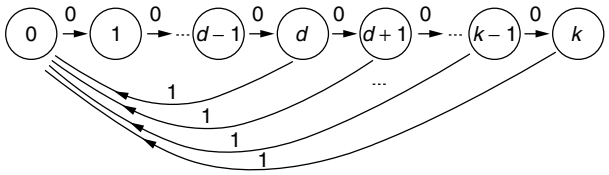

Figure 5. Presentation of a (d, k)-constrained system.

seems once we realize that about any digital device that we build is actually a *finite-state device*, whose possible output sequences necessarily constitute some sofic system.)

For example, a (d, k)-constrained system can be presented by the graph in Fig. 5. Here, the state label indicates the number of terminal zeros of a sequence generated by a path ending in that state. In the case where $k = \infty$, the constraint can be presented by a similar $(d + 1)$-state graph, where state d now indicates *at least* d terminal zeros.

We say that a presentation G is *irreducible* if there is a path in G from any state to any other state; G is said to be *primitive* if moreover all these paths may be chosen to have a fixed length h for some positive integer h.

It can be shown that each presentation can be broken down into irreducible parts. For coding purposes, it is then sufficient to consider only the "richest" component, that is, the component that presents the system with the largest capacity (which is then the capacity of the entire system). An irreducible presentation that is not primitive is in fact s-partite for some integer $s > 1$. That is, the set of states V can be partitioned into sets $V_0, \ldots, V_{s-1}$ such that each arc that starts in some V_i terminates in V_{i+1} (or in V_0 if $i = s - 1$). In that case, the sth power of the presentation (the presentation that generates s labels per arc; see Section 5) consists of s disjoint primitive components, which all have the same capacity sC, where C is the capacity of the original system.

So, for coding purposes we may in general assume that the presentation of the constrained system at hand is primitive. Note that primitivity of the presentation is precisely the property needed to assure that a *fixed* number of h merging bits, for some h, can always be used to glue any two codewords together; the merging bits can be read off from a path of length h connecting the terminal state of a path generating the first codeword to the initial state of the path generating the second codeword [see the discussion following Eq. (1) above]. For further details and proofs, the interested reader is referred, for example, to Ref. 10.

The (labeling of a) presentation is called *lossless* if any two paths with the same initial state and terminal state generate different sequences. This is an important property in connection with capacity computations. Indeed, let $G = (V, A)$ be a presentation, with $m = |V|$ states, say. If G is lossless, then at most m^2 paths can generate a given sequence, so the number P_n of paths of length n in G and the number N_n of sequences of length n presented by G are related by

$$P_n/m^2 \leq N_n \leq P_n \tag{2}$$

Hence the numbers P_n and N_n exhibit the same growth rate.

The growth rate of the numbers P_n can be computed from a matrix describing the underlying graph of the presentation, defined as follows. The adjacency matrix D of G is an $m \times m$ matrix where the entry $D(s, t)$ counts the number of arcs going from state s to state t. Note that the (s, t) entry of the nth power D^n of D counts the number of paths of length n in the graph from state s to state t. So the sum of the entries in D^n equals the number P_n of paths of length n in the graph:

$$P_n = \sum_{s,t \in V} D^n(s, t) \tag{3}$$

Now we can use a result from the classical Perron–Frobenius theory for nonnegative matrices (see e.g., Refs. 11 and 12; note that the adjacency matrix D is of this type), which states that the largest real "Perron–Frobenius" eigenvalue λ_D of a nonnegative matrix D equals its spectral radius and determines the growth rate of the entries of D^n; in fact we have [e.g., 10]

$$\lim_{n \to \infty} \frac{1}{n} \log \sum_{s,t \in V} D^n(s, t) = \log \lambda_D \tag{4}$$

Combining Eqs. (1)–(4), we conclude that the capacity $C(\mathcal{L})$ of a sofic system $\mathcal{L}$ with lossless presentation G is given by

$$C(\mathcal{L}) = \log \lambda_D \tag{5}$$

where λ_D is the largest real eigenvalue of the adjacency matrix D of G. This eigenvalue can be computed, for instance, as the largest real root of the *characteristic equation*

$$\det(\lambda I - D) = 0 \tag{6}$$

Alternatively, the capacity can be obtained by setting up linear recurrence relations for the numbers $P_n(s)$ of paths of length n starting in state s. The theory of such recurrences implies that these numbers grow as $c_s \lambda^n$, where λ is the largest real zero of the characteristic equation associated with this recurrence relation, which turns out to be the same as (6). For further details, see, for example, the book by Immink [13].

For example, the presentation of the (d, k)-constrained system in Fig. 5 is lossless. So we can apply the abovementioned method, and it turns out that the maximum code rate (the capacity) of a (d, k) code is given by the logarithm of the largest real root of the equation

$$x^{k+2} - x^{k+1} - x^{k+1-d} + 1 = 0 \tag{7}$$

if k is finite or

$$x^{d+1} - x^d - 1 = 0 \tag{8}$$

if $k = \infty$.

There are various properties of (the labeling of) a presentation that imply losslessness. All these properties are in fact concerned with the number of paths that generate a given sequence and with their localization in the graph. For example, a presentation has *finite local anticipation* if there is a number a such that any two paths of length

$a+1$ with the same initial state and generating the same sequence have the same initial arc. Similarly, the presentation has *finite local coanticipation* if the presentation obtained by reversing the direction of all arcs has finite local anticipation.

A presentation is *of finite type* if there exists a pair of numbers (m, a) (referred to as the *memory* and *anticipation* of the type) such that all paths that generate a given constrained sequence are equal, with the possible exception of at most m initial and a terminal arcs. Thus, given a (long) constrained sequence, we can reconstruct the path used to generate the sequence, up to a few arcs at the beginning and the end of the path. It turns out that a constrained system is of finite type (i.e., it can be described in terms of a finite number of "forbidden patterns") if and only if it has *some* presentation of finite type [14].

For future reference, we also introduce a slightly weaker property. A labeling is of almost finite type if it has both finite local anticipation and finite local coanticipation. As suggested by this terminology, it can be shown that a labeling of finite type is of almost finite type. A constrained system is said to be of almost finite type if it can be presented by some system of almost finite type.

A labeling with local anticipation 0 has the property that for any state, the outgoing arcs carry distinct labels. Such a labeling is called *deterministic*. This is an important property, for several reasons. Most "natural" presentations of constrained systems [e.g., the presentation of (d, k)-constrained systems in Fig. 5] are already deterministic. Moreover, any presentation G can be transformed into a deterministic presentation G^* by using a variant of the well-known *subset construction* for finite automata (see, e.g., Ref. 15 or 16). Here, G^* has as states all nonempty subsets of states of G, and for each such subset S and each labeling symbol a, the presentation G^* will have an arc $S \xrightarrow{a} T$, where T consists of all states t for which G has an arc $s \xrightarrow{a} t$ for some s in S. It is not difficult to see that indeed G and G^* present *the same* sofic system.

At this point, it is important to realize that a given sofic system can have (infinitely) many different presentations. Fortunately, every *irreducible* sofic system (i.e., one that has an irreducible presentation) has a unique *minimal* (in terms of the number of states) *deterministic* presentation, called the *Shannon cover*. It can be constructed from any irreducible deterministic presentation by an operation called *state merging*, in the following way. The set of sequences that can be generated by paths that start in a given state is called the *follower set* of that state. Now, if two states have the same follower set, then for sequence generation purposes these states are equal and can therefore be combined or *merged* into one state. Now, we repeatedly apply state merging until the follower sets in the states are all distinct. For further details about this construction, we refer to the book by Lind and Marcus [10].

The Shannon cover is important because it is "small" (hence very suitable for capacity computations), and also because many properties of a sofic system can be determined directly from its Shannon cover. For example, a sofic system is of finite type (respectively, of almost finite type) if and only if the labeling of its Shannon cover is of finite type (respectively, is of almost finite type). As a consequence, the Shannon cover is the natural starting point of many code construction methods.

4. ENCODERS AND DECODERS

An *encoder* for a given constrained system $\mathcal{L}$ is a device that transforms arbitrary binary sequences of *source bits* into sequences contained in $\mathcal{L}$. Commonly, the encoder is realized as a *synchronous finite-state device*. Such a device takes *source symbols*, groups of p consecutive source bits, as its input, and translates these into q-bit codewords, where the actual output depends on the input and possibly on the *internal state*, the (necessarily finite) content of an internal memory, of the device. The rate of such an encoder is then $R = p/q$. (To stress the individual values of p and q, we sometimes speak of a "rate $p \to q$" encoder.) Obviously, each codeword must itself satisfy the given constraint. Moreover, the encoder needs to ensure that the bit stream made up of successive codewords produced by the encoder also satisfies the constraint.

The use of the word "code" implies that it should be possible to recover or *decode* the original sequence of p-bit source symbols from the corresponding sequence of q-bit codewords. In practice, a stronger requirement is needed. Since modulation codes are typically used in the context of a noisy channel, it is important that the decoder limits the propagation of input errors. Therefore, we commonly require that the modulation code can be decoded by a *sliding-block decoder*.

A sliding-block decoder for a rate $p \to q$ encoder takes a sequence of q-bit words y_n as its input, and produces a sequence of p-bit symbols x_n as its output, where each output symbol x_n depends only on a corresponding sequence $y_{n-m}, \ldots, y_{n+a}$ of $w = m + 1 + a$ consecutive inputs, for some fixed numbers m and a, $m \le a$. We will refer to the number w as the *window size* of the decoder. (The numbers m and a are referred to as the *memory* and *anticipation* of the decoder.) The name "sliding-block decoder" refers to the image of the decoder sliding a "window" of width w over the sequence to be decoded. In Fig. 6 we depict a sliding-block decoder with $m = 2$, $a = 1$, and

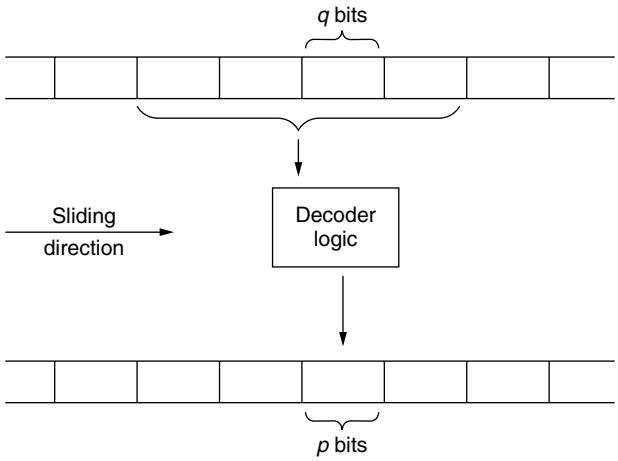

Figure 6. A sliding-block decoder.

window size $w = 4$. Note that an error in the encoded sequence will cause at most w symbol errors in the original sequence. So the *error propagation*, the amount of erroneous bits in the decoder output caused by a single input error, is limited to at most wp bits.

The window size of the decoder is an important parameter of a code: it provides an upper bound on the error propagation of the code, and also gives a good indication of the *size* of the decoder, the amount of hardware necessary to implement the decoder (i.e., it provides an upper bound on the *complexity* of the decoding operation).

Codes with a window size of one codeword (i.e., for which $w = 1$) are called *block-decodable*. For such codes, decoding a given codeword or *block* can be achieved without any knowledge of preceding or succeeding codewords. In many present-day applications, modulation codes are used in combination with symbol-error-correcting codes based on Reed–Solomon codes over some finite (Galois) field GF(2^p). In that situation, the use of a rate $p \to q$ block-decodable modulation code becomes especially attractive, since then a channel-bit error affects at most one p-bit symbol of a Reed–Solomon codeword. Note that this cannot be guaranteed if a non-block-decodable code is used, even if its decoding window size is smaller than q bits.

Note that decoding of a code requires a form of *synchronisation* between encoder and decoder in order to enable the decoder to identify the codeword boundaries in the encoded sequence. In practice this is usually achieved by using *frame-based* codes. Here, codewords are grouped into *frames* and unique *frame headers* are used to signal the beginning of a new frame. For further details, we again refer to the treatise by Immink [13].

5. CODE CONSTRUCTION METHODS

In the simplest case, the encoder translates each source symbol into a unique corresponding codeword, according to some code table. Of course, this will produce an admissible sequence only if any concatenation of these codewords also satisfies the given constraint. Codes of this type are called *block codes* or *block-encodable codes*. Decoding then consists of simply translating the codewords back into their corresponding source symbol, so these codes are block-decodable.

For example, consider the $(1, \infty)$-constrained system, in which the pattern 11 is not allowed to occur in the sequence. It is easily seen that the code where the source symbol 0 is encoded into the codeword 00 and 1 is encoded into 01 is a rate-$\frac{1}{2}$ block-decodable $(1, \infty)$ code. This simple code is called the *frequency modulation* (FM) or *biphase* code.

A slight improvement of this code is the *modified frequency modulation* (MFM) or *Miller* code. This is a rate $1 \to 2$ $(1, 3)$ code that encodes by inserting a *merging bit* between each two consecutive source bits. Here, the merging bit is set to 0 except when both surrounding bits are 0, in which case it is set to 1. Note that the FM code is obtained if the merging bit is always set to 0. Although the MFM code is not a block code, it is still block-decodable. In fact, decoding consists of simple deletion of the merging bits.

The use of merging bits is a well-established technique for constructing block-decodable (d, k) codes. They are often employed in combination with $(dklr)$ sequences, that is, (d, k)-constrained sequences in which the number of leading and trailing zeros is restricted to be at most l and r, respectively [17]. Here, p-bit source symbols are uniquely translated into $(dklr)$ sequences of a fixed length q'; in addition, a fixed number of $q - q'$ merging bits, chosen according to a set of *merging rules*, is employed to ensure that the resulting bit stream is a valid (d, k) sequence. Possible freedom in choosing these merging bits can then be used, for instance, to limit the DC content of the resulting sequence. These ideas can be found, for example, in the EFM recording code for the compact disk (see also Section 6). For some additional information on these methods, we refer to the paper by Weber and Abdel–Ghaffar [18]. A similar idea has been applied [19] to construct *almost-block-decodable* (d, k) codes.

Next, we shall discuss a number of code construction methods that employ an *approximate eigenvector* to guide the construction. We shall first explain this concept and motivate its importance for code construction.

Consider a given constrained system $\mathcal{L}$, presented by some (irreducible deterministic) graph G. Suppose that we wish to design a code with rate $p \to q$, where we assume that $p/q \leq C(\mathcal{L})$. Since we are interested in admissible sequences of q-bit codewords, it is convenient to consider the qth power graph G^q of G. This graph has the same states as G, and has an arc for each path of length q in G, labeled with the q-bit sequence generated by this path. Obviously, G^q essentially generates the same sequences as G, but does so with q bits or one codeword at the time. Note that if D is the adjacency matrix of G, then the adjacency matrix of G^q is given by D^q.

The desired encoder encodes arbitrary sequences of p-bit symbols into sequences of codewords; we shall refer to the collection of all these codeword sequences as the *code system* of the code. Note that each such sequence corresponds to one or more *encoding paths* in G^q.

Intuitively, we would expect that the number $\phi_s^{(n)}$ of encoding paths of length n in G^q that start in state s grows exponentially in 2^p, the number of source symbols. Indeed, under certain assumptions, it can be shown [20] that for each state s the limit

$$\phi_s = \lim_{n \to \infty} \frac{\phi_s^{(n)}}{2^{pn}} \tag{9}$$

exists and takes on an *integer value*. We will write ϕ for the vector with as entries the numbers ϕ_s.

Since an encoding path of length n starting in s consists of a transition in G^q from s to some state t, say, followed by an encoding path of length $n - 1$ starting in t, the vector $\phi^{(n)}$ with the numbers $\phi_s^{(n)}$ as entries satisfies

$$\phi^{(n)} \leq D^q \phi^{(n-1)} \tag{10}$$

(Note that we have an inequality here since not each path of length n obtained in this way needs to be an encoding path.) If we now combine Eqs. (9) and (10), we conclude that

$$2^p \phi \leq D^q \phi \tag{11}$$

A nonnegative integer vector ϕ that satisfies the inequality (11) is called a $[D^q, 2^p]$-*approximate eigenvector*, or a $[G^q, 2^p]$-*approximate eigenvector* if we wish to stress the connection with the presentation. We think of the numbers ϕ_s as weights associated with the states. In terms of these weights, the inequalities state that the sum of the weights of the (terminal states of) arcs leaving a state is at least 2^p times the weight of this state. The discussion above makes precise the idea that in code construction, the weight of a state is an indicator for the *relative encoding power* of that state.

It can be shown [12] that a $[G^q, 2^p]$-approximate eigenvector exists if and only if $p/q \leq C$, the capacity of the system presented by G. The following simple algorithm, first introduced by Franaszek [21], produces such an approximate eigenvector with components not larger than a given number M, provided such a vector exists. In this algorithm, we initially set $\phi_s = M$ for all states s, and then repeatedly perform the operation

$$\phi \leftarrow \min\{\phi, \lfloor 2^{-p} D^q \phi \rfloor\} \tag{12}$$

(where both the rounding operation $\lfloor\ \rfloor$ and taking the minimum are performed componentwise), until either $\phi = 0$ (in which case no such approximate eigenvector exists) or the vector ϕ remains unchanged (in which case ϕ is the desired approximate eigenvector).

Approximate eigenvectors were first introduced by Franaszek. In a series of pioneering papers [1,21–24], he developed a number of code construction methods that all employ approximate eigenvector in an essential way.

For example, the *principal-state method* is based on the observation that the existence of a *binary* $[D^q, 2^p]$-approximate eigenvector is equivalent to the existence of a set of *principal states* with the property that from each principal state there are (at least) 2^p distinct paths of length q in G (i.e., 2^p arcs in G^q) ending in another principal state. (The principal states are the states with weight one.) If it exists, a binary approximate eigenvector can be obtained by the recursive elimination procedure (12) by taking $M = 1$.

Given such a collection of paths in G, we can immediately construct a rate $p \rightarrow q$ encoder as follows. In each principal state, assign each of the 2^p possible source symbols to a q-bit codeword label of a path leaving this state. Now, the encoder moves from one principal state to another, using, for example, an encoding table in each principal state to translate input symbols into codewords. Usually, the encoding tables are implemented by using *enumerative methods* [13,25]. Such codes are called *fixed-length principal-state codes*.

If the constraint is of finite type, then any assignment of source symbols to codewords will lead to a sliding-block decodable code: in that case, the sequence of principal states traversed by the encoder can be reconstructed from the sequence of codewords.

The principal-state method may lead to prohibitively large values of p and q. (Note that these values have a large impact both on the complexity of the source-to-codeword assignment and on the size of the encoding tables.) For example, the minimum codeword lengths of a fixed-length principal-state rate-$\frac{2}{3}(1, 7)$ code and a rate-$\frac{1}{2}(2, 7)$-code are 33 and 34, respectively. Sometimes this problem can be avoided if we allow the coding paths between principal states to have varying lengths. As an example, we consider the design of a rate-$\frac{1}{2}(2, \infty)$ code. (The forbidden patterns are 11 and 101.) The minimum codeword length of a *fixed-length* rate-$\frac{1}{2}$ code for this constraint is 14 [e.g., 13]. The constraint can be presented by a three-state graph G with states named 0, 1, and 2, (see Fig. 7). Here, sequences ending in state 0 or 1 have precisely 0 or 1 terminal zeros, respectively, and a sequence ending in state 2 has at least 2 terminal zeros. The second-power graph G^2 of G needed in the construction of a rate $1 \rightarrow 2$ code is depicted in Fig. 8.

Let the set of principal states consist of the single state 2. Now consider the possible encoding paths, that is, paths in G^2 starting and ending in state 2. By inspection of G^2, we obtain the three paths

$$2 \xrightarrow{00} 2, \quad 2 \xrightarrow{10} 1 \xrightarrow{00} 2, \quad 2 \xrightarrow{01} 0 \xrightarrow{00} 2$$

from which a code can now be designed. The encoding rules are specified as

$$0 \rightarrow 00, \quad 10 \rightarrow 10.00, \quad 11 \rightarrow 01.00$$

The code can be decoded with a sliding-block decoder that has a window size of two codewords.

In general, for this method to succeed we need a (finite) collection $\mathcal{P}$ of paths π in G^q between principal states such that in each principal state s, we have that

$$\sum 2^{-|\pi|} \geq 1 \tag{13}$$

where the sum is over all paths π starting in s (and ending in the same or another principal state) and where $|\pi|$ denotes the *length* (number of transitions in G^q) of π. This condition, the Kraft–McMillan inequality for prefix codes [e.g., 26] is necessary and sufficient for the existence of a

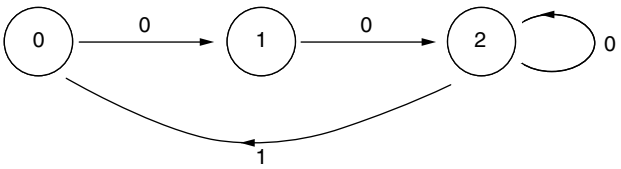

Figure 7. Presentation of the $(2, \infty)$ constraint.

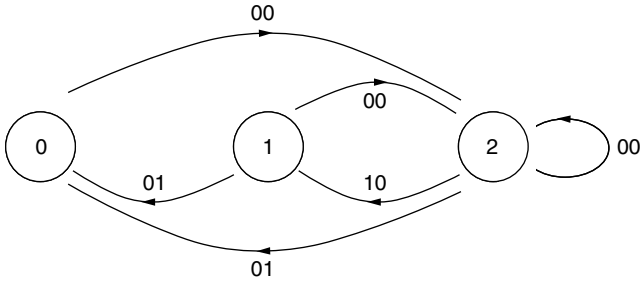

Figure 8. Presentation of G^2.

prefix code (such as the source words 0, 10, and 11 in the preceding example) with wordlengths equal to the path lengths. A similar but more complicated example of the above method is the rate-$\frac{1}{2}(2, 7)$ code [27].

Codes for constraints of finite type found by this method are always sliding-block-decodable. Such codes are called *variable-length principal-state codes* or (synchronous) *variable-length codes*. A special case of this method is the *substitution method*. Here, we set up some simple encoding rules, and then try to remove violations of the constraints by suitable substitutions. For example, consider again the design of a rate-$\frac{1}{2}(2, \infty)$ code. Suppose that we try to use the simple encoding rules $0 \to 00$ and $1 \to 10$. This works fine except when the source sequence contains two consecutive 1s, which produces 1010. These violations can be removed by replacing, from left to right, each occurrence of 1010 in the encoded stream by 0100. Note that we have obtained the same code as the one constructed earlier. A similar but more complicated example is the rate-$\frac{2}{3}(1, 7)$ code ("Jacoby code") [28].

Franaszek [23,24] and Lempel and Cohn [29] also introduced the class of *bounded-delay encodable codes* and the *bounded-delay method* for constructing such codes. Bounded-delay encodable codes involve a finite-state encoder where the encoding of the current source symbol may depend on the present state, on a bounded number of upcoming source symbols (so *lookahead* may be employed), and on a bounded number of previous states (the *history*) in the encoding path. The bounded-delay construction method for such codes employs an approximate eigenvector in an essential way. The idea is to construct in each state a suitable collection of *independent path sets*, each consisting of a set of encoding paths for this state, by exhaustive search up to a fixed maximum pathlength. Although this is a powerful construction method (in fact, much later it was shown [30] to be as powerful as the ACH method to be mentioned next, see also Refs. 31–33, and Ref. 34, Chaps. 4 and 5), there is no easy way to turn this method into an algorithm.

A technique called *state combination* [35] uses an approximate eigenvector with all components equal to 0, 1, or 2 to construct block-decodable codes that can be encoded by employing one-symbol lookahead, a special case of bounded-delay encodable codes. State combination is especially suited to the construction of (d, k) RLL codes. The method has been further developed and extended [32,36].

A breakthrough in code construction was achieved by the discovery of the state-splitting method or *ACH algorithm* [3]. This method employs an approximate eigenvector to construct an encoder, and does so in a number of steps bounded by the sum of the components of the approximate eigenvector. It can be used to prove the following theorem.

Theorem 1. For any given constraint of finite type and for any given rate $p \to q$ for which $p/q \leq C$, the capacity of the constraint, there exists a sliding-block decodable code for that constraint, with a synchronous finite-state encoder that encodes binary data at a constant rate $p \to q$.

Starting point in this method is a pair (H, ϕ), where $H = G^q$ is the qth power of an (irreducible) graph G presenting our constraint and ϕ is a $[H, 2^p]$-approximate eigenvector. (Here we may assume without loss of generality that H is irreducible and that $\phi > 0$.) The algorithm repeatedly transforms the current pair (H, ϕ) into another such pair (H', ϕ') by an operation called *weighted state splitting*. (This operation is called *ϕ-consistent state splitting* in Ref. 37, to which we refer for an excellent overview of the method.) This transformation is guaranteed to succeed except when all nonzero weights are equal. It has the property that the new weights are in some sense "smaller" than the original weights.

So with each transformation the approximate eigenvector gets "smaller" until finally a pair (G, ϕ) is reached where all nonzero components of ϕ are equal. Then the approximate eigenvector inequalities for ϕ show that in each state with a nonzero weight there are at least 2^p transitions leading to other such states, that is, we have obtained an encoder for our constraint.

State splitting, on which the transformation is based, can be understood intuitively as follows. While generating a sequence in the graph, each state encountered stands for a collection of future opportunities (represented by the arcs leaving the state) from which we may choose one. Now subdivide or *split* the state, this collection of opportunities, into *nonempty* parts called *substates* (to each of which we assign the corresponding part of the original arcs). Before this splitting operation, we could move from another state to this state without worrying about which opportunity (which arc) to utilize later, but now we have to choose first, before moving, from *which* of the parts we wish to pick our next opportunity. We do not lose opportunities, but we have to choose earlier.

So if s is a state and A_s is the collection of arcs leaving this state, then to split this state, we proceed as follows. First we partition the set A_s into *nonempty* parts $A_{s_1}, \ldots, A_{s_r}$. Then, in the graph G we replace the state s by states $s_1, \ldots, s_r$ (the substates of s), we replace each arc α in part A_{s_i}, $i = 1, \ldots, r$, by an arc from s_i with the same label and terminal state as α, and then we replace each arc β ending in s by r arcs $\beta_1, \ldots, \beta_r$, with the same label and initial state as β, with β_i ending in s_i, $i = 1, \ldots, r$.

It should be evident from the preceding discussion that the new graph obtained by splitting a state presents the same sequences as the original graph. Moreover, it is not difficult to see that if the original graph is of finite type, then the new graph is again of finite type, with the same memory and with an anticipation that has increased by at most one. Note that if the final graph has memory m and anticipation a, then the encoder obtained from this graph will have a decoding window of size at most $m + 1 + a$.

Weighted state splitting is another type of simple state splitting where we also distribute the weight of the state that is split over the substates (where each substate should receive a *nonzero* amount), and in such a way that the resulting weights constitute an approximate eigenvector for the new graph. A state that allows weighted state splitting can always be found among the states with maximum weight [3], provided not all nonzero weights are equal, and an algorithm is given to find such a state.

Example 1. Consider again the presentation $H = G^2$ in Fig. 8. Take $\phi = (1, 1, 2)$. Obviously, ϕ is a $[G^2, 2]$-approximate eigenvector. We shall split state 2 into two states, 2_1 and 2_2, according to the partition $A_{2_1} = \{2 \xrightarrow{00} 2\}, A_{2_2} = \{2 \xrightarrow{01} 0, 2 \xrightarrow{10} 1\}$. We also distribute the weight of state 2 over the two descendents of state 2 by assigning weight 1 to both 2_1 and 2_2. Since state 2_1 has successor state 2 (i.e., both 2_1 and 2_2) of total weight 2, and since state 2_2 has as successors the states 0 and 1, also of total weight 2, the new weights again form an approximate eigenvector, so the state split is ϕ-consistent. The new approximate eigenvector $\phi' = (1, 1, 1, 1)$ is constant, hence the resulting graph (depicted in Fig. 9) includes an encoder graph. By choosing a suitable assignment of 1-bit source symbols to the arcs (also shown in Fig. 9), we (essentially) obtain the rate-$\frac{1}{2}(2, \infty)$ code constructed earlier.

Ashley and Marcus [31], have shown that the ACH algorithm is *universal* in the sense that, given a sliding-block decoder, a matching finite-state encoder can be obtained by weighted state splitting (see also Refs. 32 and 33 and Ref. 34, Chaps. 4 and 5). However, precisely for that reason, the algorithm offers a large amount of freedom, first in the choice of the approximate eigenvector, then both in the choice of the states to be split and in the actual splits themselves, and it is not clear how to choose in order to obtain a good code.

It is usually best to choose the *smallest possible* approximate eigenvector. This works well in practice; however, pathological cases are known where the best possible code can be produced only by arbitrarily large approximate eigenvectors [20].

Also, some heuristics have been developed to guide the state-splitting process [e.g., 37] in order to minimize the number of encoder states of the resulting encoder. However, in practical applications we are often especially interested in codes with a small *decoding window*. This problem is addressed in Ref. 32, where weighted state splitting is combined with ideas from the bounded-delay method of Franaszek to obtain heuristics to guide the choices of which states to split. For completeness, we mention that Theorem 1 holds even for constraints of almost finite type [14].

Which code construction method to use strongly depends on the structure of the power graph G^q presenting the constraint at the desired rate, and in particular on the maximum number of arcs leaving a state. If this number is relatively *small*, then use an ACH-type method. (An attractive choice is the variant described by Hollmann [32].) On the other hand, if this number is relatively *large*, then such methods are less suitable because of the increasing number of choices for the state-splitting steps. In that case, use a method based on merging bits, or a method for (almost) block-decodable codes such as described in Ref. 35 or 33, or any other more heuristic method that does the job.

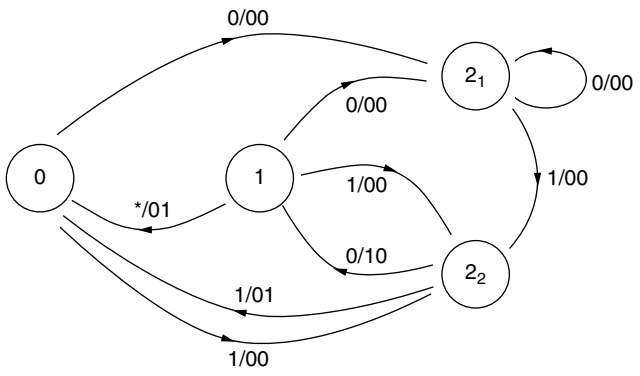

Figure 9. Presentation after state splitting.

Extremely large values of p and q are encountered in the design of high-rate codes, or when the efficiency of the code should be very high. In such cases, methods as *guided scrambling* [38], or a promising variant of enumerative encoding (see Refs. 39 and 40, and Ref. 34, Chap. 1) should be considered. Here, the extremely large block-length imposes a special system architecture to limit error propagation. For further details, we refer to the paper by Immink [40].

6. SELECTION OF RELATED TRENDS AND TOPICS

6.1. DC Control in RLL Codes for Optical Recording

Run-length-limited (RLL) codes have been successfully applied in optical storage, as witnessed by the well-known examples of EFM [41] for CD and EFMPlus [42] for DVD. The EFM and EFMPlus codes both employ a $(2, 10)$ constraint. EFM stands for *8-to-14 modulation*: the EFM code uses a single code table that maps a byte to a 14-bit channel word. Successive channel words are concatenated via the insertion of three merging bits, so the EFM code has rate $\frac{8}{17}$. The EFMPlus code maps a byte to a 16-bit channel word. EFMPlus is an ACH-type sliding-block code (see Section 5) based on a 4-state encoder graph. Both EFM and EFMPlus are byte-oriented, which is desirable for formats with the error correction coding (ECC) based on 8-bit symbols. An overview of the EFM and EFMPlus codes is given by Immink [43]. More recently, the *Blu-Ray Disc* (sic) or BD (formerly known as the DVR system [44]), which is the third generation of optical recording after CD and DVD, employs a code called "17PP" that uses a $(1, 7)$ constraint.

All RLL codes used in optical recording are *DC-free*; that is, they have almost no content at low frequencies. This property is an example of a *frequency-domain constraint*. Here, restrictions are enforced on the energy content per time unit of the sequence at certain frequencies, that is, on the *power spectral density function* of the sequence. (Constraints like run-length constraints are called *time-domain* constraints.) Most of these constraints belong to the family of *spectral null constraints*, where the power density function of the sequence must have a zero of a certain order at certain specific frequencies. The constraint that specifies a zero at DC, the zero frequency, is referred to as the *DC-free* constraint. We shall represent the NRZI channel bits by the bipolar values ± 1. A sequence $x_1, x_2, \ldots$ is called *DC-free* if its *running digital sum* (RDS)

$$\mathrm{RDS}_i = x_1 + \cdots + x_i$$

takes on only finitely many different values. In that case, the power spectral density function vanishes at DC.

One common way to ensure this is to constrain the code sequence to be *N-balanced*; we allow only sequences whose RDS takes on values between $-N$ and N. Note that such a constraint cannot be specified in terms of a finite collection of forbidden patterns; that is, it is not of finite type.

The DC-free property is needed in optical recording for a number of reasons: (1) it is necessary to separate the data signal from low-frequency disk noise such as fingerprints, dust, or defects; (2) DC-free coding is needed for control of the slicer level in the case of nonlinearities in the physical signals like pit–land asymmetries [45]; and (3) servo systems used for tracking of the laser spot position typically require a DC-free data signal.

We shall now discuss a general method to achieve DC control in RLL sequences. As discussed above, DC control is performed via control of the running digital sum (RDS). A very useful concept herein is the *parity*, the number of ones modulo 2, of a sequence of bits. Recall that an NRZ 1 bit indicates the start of a new run in the (bipolar) NRZI bit stream. Hence, because of the 1T precoder between NRZ and NRZI channel bit streams (see Section 1), each 1 bit in the NRZ bit stream changes the polarity in the corresponding NRZI bit stream. Consequently, an *odd* number of ones in a segment of the NRZ bit stream *reverses* the NRZI polarity after that segment while an *even* number of ones leaves the polarity unchanged.

This observation can be used for DC control as follows (see also Fig. 10). Suppose that for a certain segment of the NRZ bit stream, we can choose between two candidate sequences, one with parity 0 and the other with parity 1. Then the part of the NRZI bit stream *after* this segment will have a contribution to the RDS where the *sign* but not the magnitude depends on which of the two sequences is chosen. The *best* choice is, of course, the one that keeps the value of the RDS as close to zero as possible. For obvious reasons, we shall refer to these segments as *DC-control segments*.

In order to realize DC control, we have to insert DC-control segments at regular positions in the bit stream. Such positions are referred to as *DC-control points*. This is the basic mechanism for DC control in RLL codes.

Two types of DC-control segments can be distinguished. One type just serves the primary purpose of parity selection; another type additionally encodes some data bits. Further, we can differentiate between two types of DC-control: one type providing *guaranteed* DC control where parity selection is possible at each DC-control point, and another type providing *stochastic* DC-control where the possibility of parity selection depends on the data that is to be encoded.

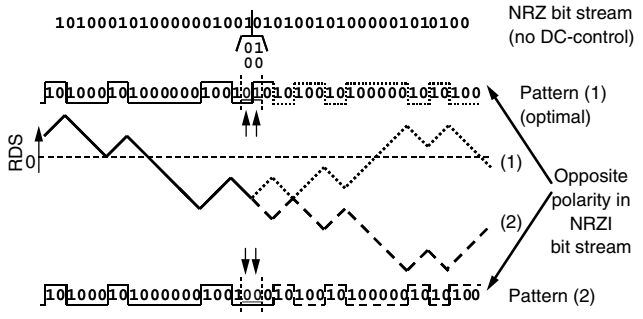

Figure 10. Principle of DC control via insertion of merging bits in a valid $(1, \infty)$ bit stream.

We shall now review several practical design methods for DC control that use the above mechanism in one form or another.

1. Insertion of a DC-control segment of N channel bits in a NRZ bit stream already satisfying a (d, k) constraint. At each DC-control point, the original bit stream is cut open, and the segment is inserted. If we require that both parities (0 and 1) can be selected without violation of the (d, k) constraint, then the minimum possible value of N is $N = 2(d + 1)$ if $2d + 1 \leq k < \infty$ and $N = d + 1$ if $k = \infty$. This can be seen as follows. At a DC-control point, the situation looks like $\ldots 10^i \cdot 0^{r-i}1\ldots$, for some i and r with $0 \leq i \leq r$ and $d \leq r \leq k$. First, let $k = \infty$. A possible segment of odd parity is $0^{d-i}10^i$ if $i \leq d$ or 10^d if $i \geq d$; if $i = 0$, no shorter segment is possible. Of course, the segment 0^{d+1}, of even parity, can always be inserted. Next, suppose that $2d + 1 \leq k < \infty$. Now, a possible segment of even parity is $0^{d-i}10^d10^i$ if $i \leq d$ or 10^d10^d if $i \geq d$; again, if $i = 0$, no shorter segment is possible. Also, a possible segment of odd parity is $0^{2d+1-i}10^i$ if $i \leq 2d + 1$ or 10^{2d+1} if $i \geq 2d + 1$. The case where $k = \infty$ and $d = 1$, which requires only two merging bits, is illustrated in Fig. 10. Here, following the 1 bit, two segments 01 and 00, of opposite parity, can be merged into the sequence; for both choices, the respective RDS traces are drawn. Since the RDS for the first pattern remains close to zero, whereas the RDS trace of the second pattern drifts away, obviously the first pattern is the best choice.

2. Insertion of merging bits between successive NRZ channel words, as is used in the EFM code. The function of the merging bits in EFM is twofold; they (a) serve to prevent violations of the $(2, 10)$ run-length constraint and (b) provide a means for DC control via the available freedom in the choice of the merging bits. Note that whether parity selection is possible depends on the two EFM channel words at hand; that is, the DC control of the EFM code is of a stochastic nature. For example, when the previous EFM word ends in a 1 and the current EFM word starts with 1 or 01, then the only valid merging bit pattern (i.e., not violating the $d = 2$ constraint) is 000, so that no DC control is possible.

3. Use of a substitution table for DC control. Here a code is used where certain source words can be encoded into two NRZ channel words (a *standard* word and a *substitute* word) of opposite parity. This mechanism is used, for example, in the EFMPlus code. Here, code construction via the ACH algorithm yields a 4-state encoder graph. In each state, the main encoding table contains 256 entries; because of the presence of *surplus* words, 88 of these entries have a substitution entry. (Additional DC control in EFMPlus is achievable via occasional swapping of encoder state [43].) Note that the DC-control mechanism via substitution tables (as in EFMPlus) is of a stochastic nature; whether a byte can be used as a DC-control point depends on whether the encoding table has a substitute entry at that location.

4. DC control via the use of a *parity-preserving* code [46]. Such a code preserves the parity on RLL

encoding; that is, the parity of a source word is identical to the parity of the corresponding channel word. The major difference with the previous methods is that single DC-control bits are inserted in the *source* bit stream. Changing a DC-control bit from 0 to 1 changes the parity in the source bit stream and hence also in the NRZ channel bit stream; this property enables the selection of the polarity of the NRZI channel bit stream, and thus allows for DC control.

5. DC control via the use of *combicodes* [47]. This is a typical example of a method where some data bits are encoded in the DC-control segment. A combicode for a given constraint consists of a set of at least two codes for that constraint, possibly with different rates, where the encoders of the various codes share a *common* set of encoder states. As a consequence, after each encoding step the encoder of the current code may be replaced by the encoder of any other code in the set, where the new encoder has to start in the ending state of the current encoder. Typically, one of the codes, called the *standard* code or *main* code, is an efficient code for standard use; the other codes serve to realize certain additional properties of the channel bit stream. Sets of sliding-block decodable codes for a combicode can be constructed via the ACH algorithm; here the codes are jointly constructed starting with suitable presentations derived from the basic presentation for the constraint and using the *same* approximate eigenvector [47].

Coene has used the combicode idea [47] for DC-control as follows. The *main* code has a single channel word for each source word. As a second code, of a lower rate, a *substitution code* is used. This code has for *every* source word a set of two possible channel words, of opposite parity and ending in the same encoder state.

In a practical format, the sequence of uses of the various codes of the combicode needs to be chosen beforehand. This choice will be the result of a tradeoff between the overall rate and the required property (e.g., the amount of DC control) to be realized. Obviously, DC control by use of these combicodes is of the *guaranteed* type.

6.2. Time-Varying Codes

The concept of time-varying codes [48] is related to a generalization of the state-splitting (ACH) algorithm. In this generalization, the starting point is a *periodic* presentation of the constraint where the codeword labels may have different lengths in different phases. Thus, the set V of vertices can be partitioned into subsets $V_0, V_1, \ldots, V_{s-1}$, say, with the property that an arc starting in some part V_i ends in V_{i+1} (or in V_0 if $i = s - 1$); moreover, labels on arcs that start in the same part have the same length. An encoder derived from such a periodic presentation operates cyclically in s phases, where the length of the codeword produced by the encoder depends only on the current phase.

The framework of time-varying codes is useful for the design of efficient codes with reduced error propagation. Note that a time-varying code may be considered as a pair of codes where the order in which the codes have to be used is fixed beforehand; this in contrast with combicodes, where the order in which the various codes can be used is completely free. The concept of multiple phases in a time-varying code [48] is strongly related to the idea of representing a bit by a number of (virtual) *fractional* bits, as used by Coene [47] to generate a highly efficient DC-free combicode for $d = 1$.

6.3. RLL Parity-Check Coding

In the standard digital storage system as sketched in Fig. 1, random channel errors that may occur in the channel bit stream after bit detection are repaired by the ECC error correction decoder situated after the MC decoder. In the early 1990s, it was realized that a *combination* of error correction coding and modulation coding may be quite advantageous in terms of overall efficiency and performance [e.g., 49–52]. RLL parity-check coding focuses on the most prominent error patterns that are left by the bit detector in the receiver. For magnetic recording, the most simple parity-check coding schemes aim at peak shift errors in the NRZ bit stream, where the 1 bits are shifted (to the left or right). For optical recording, where the bit detector regenerates the NRZI bit stream, the most prominent random errors are transition shifts that cause the runs at the left and right sides of the transition to become one or more bits longer or shorter. Because of the 1T precoder, the transition error in the NRZI bit stream corresponds to a peak shift error in the NRZ bit stream. In parity-check coding, the channel bits are partitioned into fixed-length *segments*, and a parity check is generated for each segment. (Subsequently, these parity checks can be handled in various ways.) As a consequence, inspection of the NRZ bit stream after detection will reveal the violation of the parity check in the case that a channel error occurs, thus enabling error detection; for error correction, some side information from the signal waveform is needed. One scheme [52] considers merging of parity blocks into the original NRZ bit stream in such a way that these blocks become an integral part of the corresponding parity-check segment. Another scheme [53] is concatenated parity-check coding, where parity bits that are generated on the NRZ bit stream are separately RLL-encoded. The merging scheme has a low coding efficiency, but the advantage is its simplicity and lack of error propagation. The concatenated scheme has a high efficiency but suffers from error propagation. A promising route is to use a parity-check coding scheme based on a combination of codes [54], like the *combicodes* used for DC control. Apart from a *main* RLL code, a second RLL code, the *parity-check-enabling code*, is required. The latter code is used to set the parity-check constraint of a segment of NRZ bits to a predetermined value. For DC control together with parity-check control, a third code is needed: the *substitution* code. All three codes are jointly constructed, so that the channel words of these codes can be freely concatenated.

6.4. MTR Constraint for Magnetic Recording

The *maximum transition run* (MTR) constraint [55] specifies the maximum number of consecutive 1 bits in the NRZ bit stream. Equivalently, in the NRZI bit stream, the MTR constraint limits the number of successive 1T runs. The MTR constraint can also be combined with a d constraint, in which case the MTR constraint limits the

number of consecutive *minimum runlengths*. An application for $d = 1$ can be found in the paper by Narahara et al. [44]. The basic idea behind the use of MTR codes is to eliminate the *dominant* error patterns, that is, those patterns that would cause most of the errors in the *partial-response maximum-likelihood* (PRML) sequence detectors used for high-density recording. A highly efficient rate $16 \rightarrow 17$ MTR code limiting the number of consecutive transitions to at most two has been described [56].

6.5. (0, G/I) Constraint for Magnetic Recording

In magnetic hard-disk drives using the PR4 or *class 4* partial-response maximum-likelihood (PRML) sequence detectors [57] with response equal to $1 - D^2$, it is advantageous to use modulation coding with so-called $(0, G/I)$ constraints [58,59]. The PR4 detector can be partitioned into two $1 - D$ sequence detectors, where each detector operates at half the bit rate on either the even- or odd-indexed bits. The 0 in $(0, G/I)$ stands for $d = 0$, and the G and the I stand for the *global* and *interleaved* constraint on the maximum number of consecutive zeros in the *joint* and in both *interleaved* bit streams. The global constraint is just a k constraint and is meant for the purpose of timing recovery; the interleaved constraint is introduced in order to limit the effects of truncation of the path memory depths in the separate Viterbi detectors for each of the $1 - D$ responses [7, Chaps. 6 and 7].

6.6. Two-Dimensional Constraints

Two-dimensional (2D) modulation codes have received considerable attention. This research effort is based on the recognition that 2D coding might lead to significant coding gains, especially in technologies such as holographic data storage [60] with a 2D page-based readout mechanism. Just like their 1D counterparts (as explained in Section 2), one of the aims of 2D modulation codes is to combat intersymbol interference (ISI), which is achieved by forbidding certain patterns that lead to high spatial frequencies. 2D lowpass filtering constraints are typically defined in terms of restrictions on neighbouring bits for 2D bit arrays on a rectangular lattice; some examples can be found in Ref. 61 (where they are called "checkerboard codes") and in Ref. 62. Another class of 2D codes are the *multitrack codes* [63], designed for systems where multiple tracks are encoded, written and read in parallel; the d constraint is maintained for each track independently as in the 1D case (in view of ISI), but the k constraint used for timing recovery (or clocking) is defined *jointly* for a set of tracks, since synchronisation is also carried out jointly. Other 2D constraints with potential practical interest are 2D (d, k) constraints, where the 1D (d, k) constraint has to be satisfied in both horizontal and vertical directions. In general, unlike the case for 1D RLL coding, only bounds can be derived for the capacity of 2D (d, k) constraints. This area has been the subject of intensive research (see Refs. 64 and 65 and references cited therein). A practical proposal to use 2D $d = 1$ modulation coding in optical recording can be found in Ref. 66.

Concerning the construction of 2D codes, 2D bit arrays can be encoded in one-dimensional strips containing a number of bit rows (or tracks) as proposed in Refs. 61 and 63. In this way, 2D code construction can be reduced to a 1D problem for which code construction methods such as the ACH sliding-block codes discussed in Section 5 can be used.

Acknowledgments

With great pleasure we thank our colleagues A. H. J. Immink, L. M. G. Tolhuizen, and J.H. van Lint for their many helpful comments made during the preparation of this text.

BIOGRAPHIES

Wim Coene received a Ph.D. in physics from the Center for High-Voltage Electron Microscopy (University of Antwerp) for work on computational modeling of electron diffraction and image formation in a transmission electron microscope (TEM). In 1988 he joined Philips Research Laboratories, where he first worked on signal processing for ultra-high-resolution TEM, in particular on phase retrieval methods used for digital correction of aberration artifacts. In 1996, after one year of work on MPEG-2 video coding, he started to work on signal processing for optical storage in the field of bit detection algorithms and channel modulation codes and techniques. Currently, his research activities are focused on coding and signal processing for next-generation (optical) storage channels.

Henk Hollmann was born in Utrecht, the Netherlands, on March 10, 1954. He received the master's degree in mathematics in 1982, with a thesis on association schemes, and the Ph.D. degree in 1996, with a thesis on modulation codes, both from Eindhoven University of Technology. In 1997, he was awarded the SNS bank prize for the best Ph.D. thesis in fundamental research of this university. In 1982 he joined CNET, Issy-les-Moulineaux, France, where he worked mainly on number-theoretic transforms. Since 1985 he has been with Philips Research Laboratories, Eindhoven, the Netherlands. His research interests include discrete mathematics and combinatorics, information theory, cryptography, and digital signal processing.

1. INTRODUCTION

Transmission cost is often proportional to bandwidth and the radiofrequency spectrum is a limited resource. The motivation for searching for spectrally efficient modulation is thus clear. The available transmitter power is also limited for many applications. For satellite and land-mobile radio applications, modulation with a constant RF (radiofrequency) envelope is advantageous because transmitters use more efficient nonlinear amplifiers. The combination of these factors dictates a coded modulation system based on constant-amplitude sinusoids. In this article we outline the power and spectrum properties of a large class of such signals. This class, continuous-phase modulation (CPM), can be viewed as a generalization of minimum shift keying (MSK) containing such schemes as tamed frequency modulation (TFM) and Gaussian MSK (GMSK). We review the performance of the CPM class with optimum reception and show how the choice of system parameters affects its error performance and the signal bandwidth. We also show how these two trade off against each other. Transmitters and simplified receivers are also discussed.

CPM coding was the first coded modulation class to be extensively studied and marked the advent of a combined energy and bandwidth view in practical coding schemes. It had its origins in the invention of MSK [1] and a related scheme called *fast frequency shift keying* [2]. It gained impetus by several papers [3–5] that introduced continuous-phase frequency shift keying (CPFSK) and its optimal detection in the early 1970s. With Miyakawa et al. [6] and Anderson and Taylor [7] in the mid-1970s, more sophisticated codinglike ideas were introduced; the second paper introduced the modern concepts of distance calculation, trellis decoding, and simultaneous consideration of code energy and bandwidth. CPM reached its full flower as a coded modulation method in 1981 with the basic papers of Aulin, Sundberg and others [8–11].

MSK has attracted new study since the 1970s as well. We will outline methods to improve on MSK while maintaining a constant amplitude. By *improvement* is meant a narrower power spectrum, lower spectral sidelobes, cheaper implementation, better error probability, or all the above. The main part of the article considers a number of methods for constructing constant-amplitude signals that significantly outperform MSK in either energy, bandwidth, or both. An important issue is at what level of complexity these improvements are obtained.

2. THE CPM SIGNAL CLASS

A large class of constant-amplitude modulation schemes is defined by the signal

$$s(t) = \left[\frac{2E}{T}\right]^{1/2} \cos(2\pi f_0 t + \phi(t, \boldsymbol{a})) \tag{1}$$

where the transmitted information is contained in the phase

$$\phi(t, \boldsymbol{a}) = 2\pi h \sum_{i=-\infty}^{\infty} a_i q(t - iT) \tag{2}$$

with $q(t) = \int_{-\infty}^{t} g(\tau)\, d\tau$. Normally the function $g(t)$ is a smooth pulseshape over a finite time interval $0 \le t \le LT$ and zero outside. Thus the parameter L is the length of the pulse (per unit T) and T is the symbol time; E is the energy per symbol, f_0 is the carrier frequency and h is the modulation index. The M-ary data symbols a_i take values $\pm 1, \pm 3 \cdots \pm(M-1)$. M is normally selected to be a power of 2, and we will mainly consider binary, quaternary, and octal systems ($M = 2,4,8$). From the definition above we note that the pulse $g(t)$ defines an instantaneous frequency and its integral $q(t)$ is the phase response. The precise shape of $g(t)$ determines the smoothness of the transmitted information carrying phase. The rate of change of the phase (or instantaneous frequency) is proportional to the parameter h, which is the *modulation index*. The pulse $g(t)$ is normalized in such a way that $\int_{-\infty}^{\infty} g(t)\, dt$ is $\frac{1}{2}$. This means that for schemes with positive pulses of finite length, the maximum phase change over any symbol interval is $(M-1)h\pi$.

By choosing different pulses $g(t)$ and varying the parameters h and M, a great variety of CPM schemes can be obtained. Some of the more popular pulseshapes are listed in Table 1. These include CPFSK, tamed frequency modulation (TFM) [12], generalized TFM (GTFM) [13], Gaussian MSK (GMSK) [14], duobinary FSK (2REC) [15], raised cosine (LRC), and spectrally raised cosine (LSRC). In the table we use the notation LXX for a pulse of length L symbol intervals; thus 3RC is a raised cosine pulse of length $3T$. For spectral raised cosine (LSRC), the main time lobe has width LT. The pulse of length $1T$, namely, 1REC, is another name for CPFSK. The 2REC pulse is also called duobinary.

MSK is obtained as a special case of the signals defined in Eq. (1) by selecting the pulse 1REC ($L = 1$) from Table 1 and using binary ($M = 2$) data with $h = \frac{1}{2}$. The CPM signal can be viewed as phase modulation or as frequency modulation, but for understanding the optimum coherent receiver, it is advantageous to view the signal as phase modulation.

Memory is introduced into the CPM signal by means of its continuous phase. Each information-carrying phase function $\phi(t, \boldsymbol{a})$ is continuous at all times for all combinations of data symbols. Further memory can be built into the CPM signal by choosing a $g(t)$ pulse with $L > 1$. These schemes have overlapping pulse shaping and called *partial-response* techniques. CPM signals with $L \le 1$ are *full-response* schemes. In this case the memory is in the continuous phase only.

Although the CPM signals in Eq. (1) are in principle conceivable for any value of the modulation index h, a key to the design of practical maximum-likelihood detectors is to consider CPM schemes with rational values of h. For $h = 2k/p$ where k and p have no common factors, the phase

Table 1. Definition of the Frequency Pulse Function $g(t)$

LRC	$g(t) = \begin{cases} \dfrac{1}{2LT}\left[1 - \cos\left(\dfrac{2\pi t}{LT}\right)\right]; & 0 \le t \le LT \\ 0 \quad ; & \text{otherwise} \end{cases}$
	L is the pulse length, e.g., 3RC has $L = 3$
TFM[a]	$g(t) = \dfrac{1}{8}[Ag_0(t-T) + Bg_0(t) + Ag_0(t+T)]; \quad A = 1; B = 2$
	$g_0(t) \approx \sin\left(\dfrac{\pi t}{T}\right)\left[\dfrac{1}{\pi t} - \dfrac{2 - \dfrac{2\pi t}{T}\cot\left(\dfrac{\pi t}{T}\right) - \dfrac{\pi^2 t^2}{T^2}}{\dfrac{24\pi t^3}{T^2}}\right]$
LSRC	$g(t) = \dfrac{1}{LT} \cdot \dfrac{\sin\left(\dfrac{2\pi t}{LT}\right)}{\dfrac{2\pi t}{LT}} \cdot \dfrac{\cos\left(\beta \cdot \dfrac{2\pi t}{LT}\right)}{1 - \left(\dfrac{4\beta}{LT} \cdot t\right)^2}; \quad 0 \le \beta \le 1$
GMSK	$g(t) = \dfrac{1}{2T}\left[Q\left(2\pi B_b \dfrac{t - \dfrac{T}{2}}{\sqrt{\ell n 2}}\right) - Q\left(2\pi B_b \dfrac{t + \dfrac{T}{2}}{\sqrt{\ell n 2}}\right)\right]; \quad 0 \le B_b T < \infty$
	$Q(t) = \int_t^{\infty} \dfrac{1}{\sqrt{2\pi}} e^{-\tau^2/2} d\tau$
LREC	$g(t) = \begin{cases} \dfrac{1}{2LT}; & 0 \le t \le LT \\ 0 \quad ; & \text{otherwise} \end{cases}$
	$L = 1$ yields CPFSK

[a] The class of GTFM pulses is obtained by varying A, B, and $g_0(t)$.

$\phi(t, \boldsymbol{a})$ during interval $nT \le t \le (n+1)T$ can be written

$$\phi(t, \boldsymbol{a}) = 2\pi h \sum_{i=n-L+1}^{n} a_i q(t - iT) + \theta_n = \theta(t, \boldsymbol{a}) + \theta_n \qquad (3)$$

where $\theta_n = \left[h\pi \sum_{i=-\infty}^{n-L} a_i \right]$ modulo 2π has only p different values. Thus the total number of states that (at most) is needed to describe the signal in Eq. (1) is $S = pM^{(L-1)}$, where a state is defined as the vector $(\theta_n, a_{n-1}, a_{n-2}, \ldots, a_{n-L+1})$. The state vector consists of the phase state θ_n and $M^{(L-1)}$ *correlative states* for partial response systems. For a full-response system the number of states is p. The finite state description for CPM signals allows the use of a finite Viterbi decoder.

As an example of a CPM scheme, we choose binary 3RC; thus the pulse $g(t)$ is a raised-cosine pulse of length 3 symbol intervals. Figure 1a shows the pulse $g(t)$ and phase response $q(t)$ for 3RC. For comparison, the corresponding functions are also shown for 1REC (CPFSK). The information-carrying phase function $\phi(t, \boldsymbol{a})$ is illustrated both for 1REC and 3RC in Fig. 1b for a particular data sequence. Note that all changes in the 3RC phase take longer time than in the CPFSK scheme. Figure 1c shows all phase functions starting at the arbitrary phase 0° and

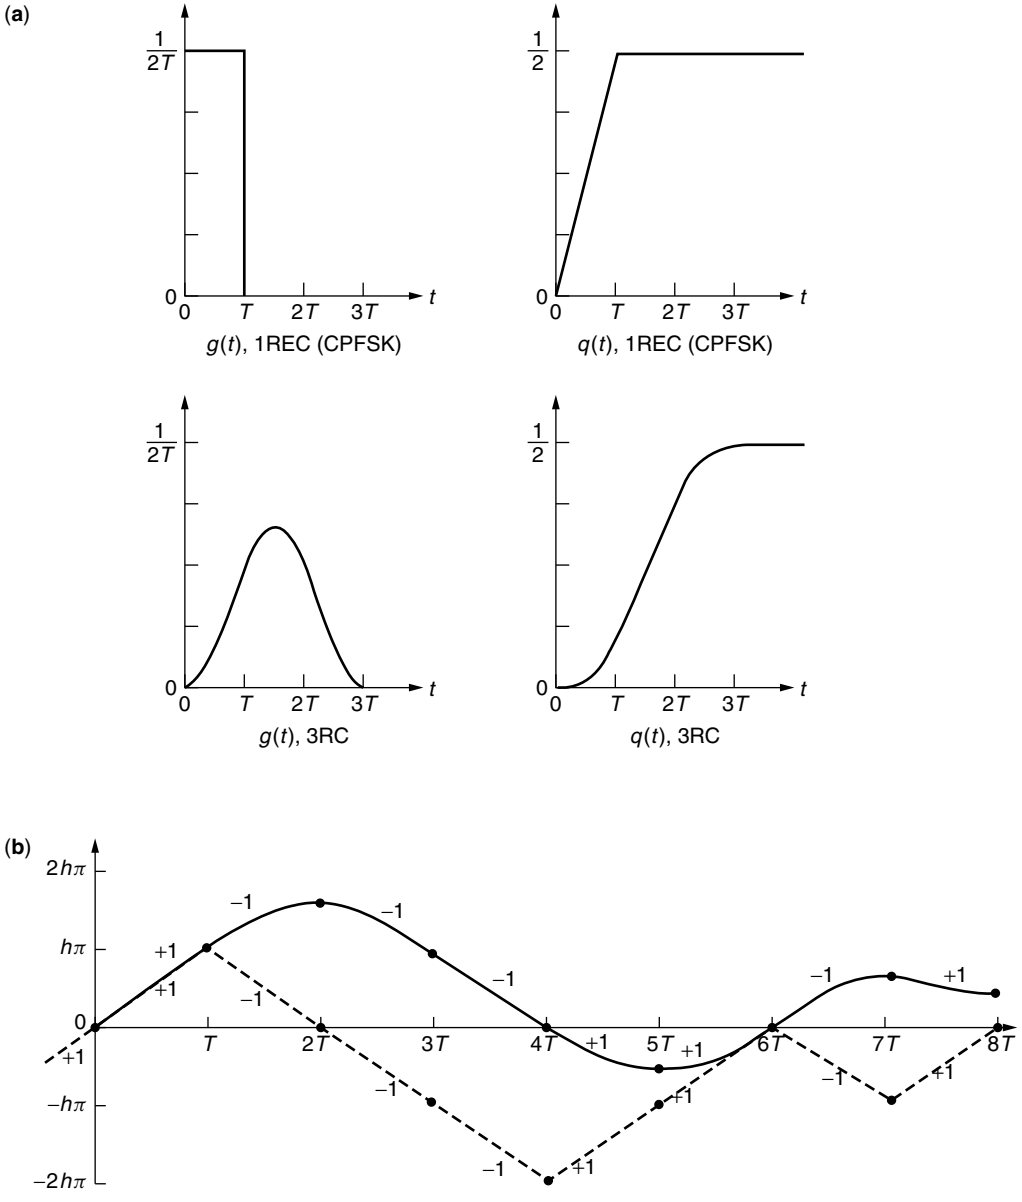

Figure 1. (**a**) Pulseshapes $g(t)$ and phase responses $q(t)$ for the full-response 1REC (CPFSK) and partial response 3RC CPM schemes; (**b**) examples of the phase function $\phi(t, \boldsymbol{a})$ for 1REC (dashed) and 3RC (solid) for the data sequence +1, −1, −1, −1, +1, +1, −1, +1; (**c**) phase tree for binary 3RC with $h = \frac{2}{3}$. The state description of the signal is also given. The transitions with arrows are also shown in Fig. 2a.

time 0, where the two previous data symbols are +1,+1. It is obvious from Fig. 1c that all phase changes are very smooth. The corresponding phase tree for MSK has linear phase changes with sharp corners when the data change. The phase tree in Fig. 1c also displays the state vector at each node.

The finite-state description of the CPM signal implies a trellis description, and this finiteness stems from the modulo-2π property of the phase. By plotting $I = \cos[\phi(t, \boldsymbol{\alpha})]$ and $Q = \sin[\phi(t, \boldsymbol{\alpha})]$ versus time in a three-dimensional plot, all signals appear on the surface of a cylinder. Such a phase cylinder is shown in Fig. 2a for the parameters used in Fig. 1c. This scheme has 12 states. Contrary to Fig. 1c, where restrictions were imposed for $t < 0$, the phase cylinder shows all signals over three symbol intervals. The phase nodes and some of the state vectors are also shown. To clarify the connection between the tree in Fig. 1c and the trellis in Fig. 2a, we have marked three identical transitions with arrows in both figures.

While the appearance of the phase tree does not change with h, the number of phase states does and so does the phase cylinder. Figure 2b shows the simplicity of the phase cylinder for $h = \frac{1}{2}$ and Fig. 2c shows how the complexity has grown for $h = \frac{3}{4}$. It is seen in Fig. 2b that with a proper phase offset, I and Q exhibit quite open-amplitude eye diagrams. We will see that this property leads to simple linear receivers and this is the reason for the popularity of the binary $h = \frac{1}{2}$ schemes.

An interesting generalization of the CPM class is to let the modulation index vary cyclically with time. This gives a so called multi-h scheme. These systems have better performance than the fixed h schemes. Typically most of the available improvement is obtained with two or three different h values.

3. CPM POWER SPECTRA

A large number of methods are available in the literature for calculating the power spectrum of CPM; for a detailed treatment, see, for instance, Ref. 16. Computer simulations can also be employed to estimate the power spectra. As a measure of signal bandwidth in what follows, we will generally take the frequency band around the carrier frequency containing 99% of the signal power. Figure 3 shows the power spectral density of some binary CPM schemes. The term *GMSK4* here means that the GMSK pulse in Table 1 is truncated symmetrically to 4 symbol intervals. The CPM schemes 3RC, GMSK4 with $B_bT = 0.25$, and 3SRC6 have comparable power spectra. The corresponding pulses $g(t)$ are also quite similar as are their detection properties — the rate of reduction of the spectral sidelobes is determined by the smoothness of the pulse $g(t)$. For most applications, the raised-cosine pulses probably have sufficient smoothness. Figure 3 also shows the MSK and 2REC (duobinary) schemes. Notice the lower spectral sidelobes of the smooth partial response schemes.

In comparison, Fig. 4 shows power spectra for some four-level schemes ($M = 4$). Figures 3 and 4 illustrate that a longer pulse $g(t)$ narrows the power spectra for fixed h and M. TFM has a power spectrum similar to binary 3.7 RC and 3.7 SRC. GMSK with $B_bT = 0.18$ corresponds approximately to 4RC and GMSK with $B_bT = 0.2$ to TFM.

The width of the main spectral lobe decreases with increasing L but increases with increasing h and M. The relationship between bandwidth or fractional out of band power and pulseshape $g(t)$ is rather complicated.

4. DETECTION AND ERROR PROBABILITY

Coherent maximum likelihood sequence detection (Viterbi detection) can be performed for all CPM schemes that

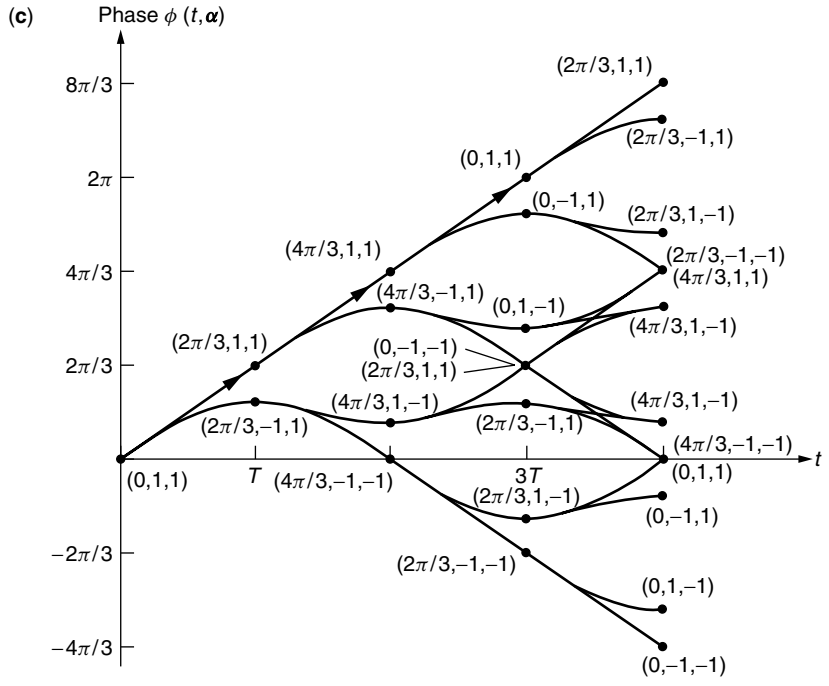

Figure 1. (*Continued*)

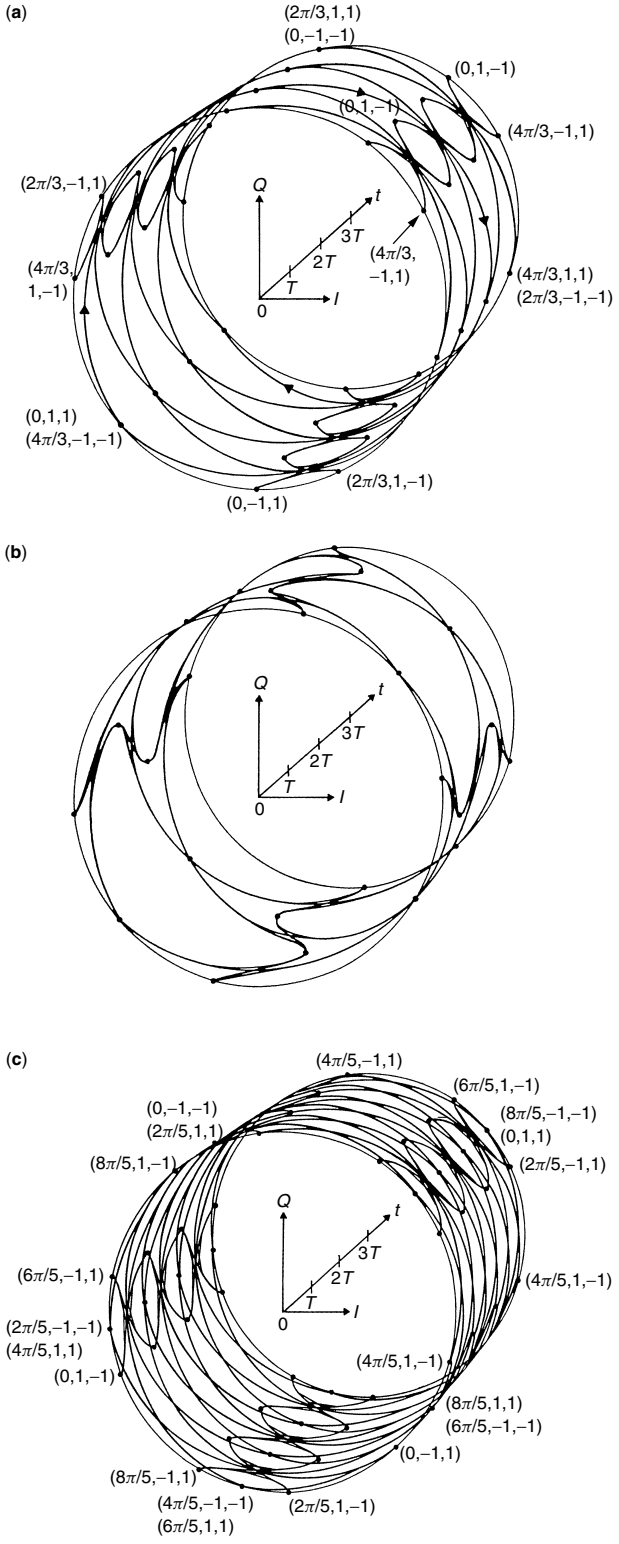

Figure 2. (**a**) Phase cylinder for 3RC with $h = \frac{2}{3}$ and $M = 2$. Compare the phase tree in Fig. 1c. Note the arbitrary phase offset between the phase in the tree in Fig. 1c and the cylinder, in Fig. 2a. Also note that the tree is plotted over T and the cylinder over $3T$. Notice the transitions with arrows; these are also shown in the tree in Fig. 1c. (**b**) phase cylinder for 3RC, $h = \frac{1}{2}$, $M = 2$. (**c**) phase cylinder for $M = 2$, 3RC with $h = \frac{4}{5}$ (10 states).

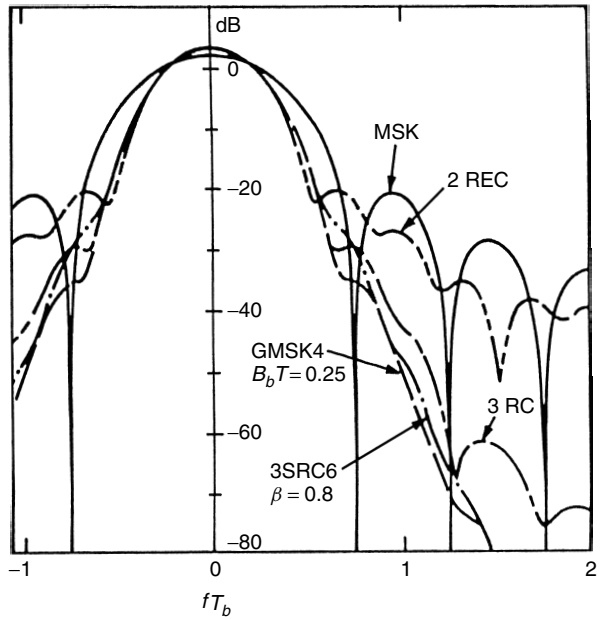

Figure 3. Average power spectrum for some CPM schemes with $h = \frac{1}{2}$ and $M = 2$. See Table 1 for details.

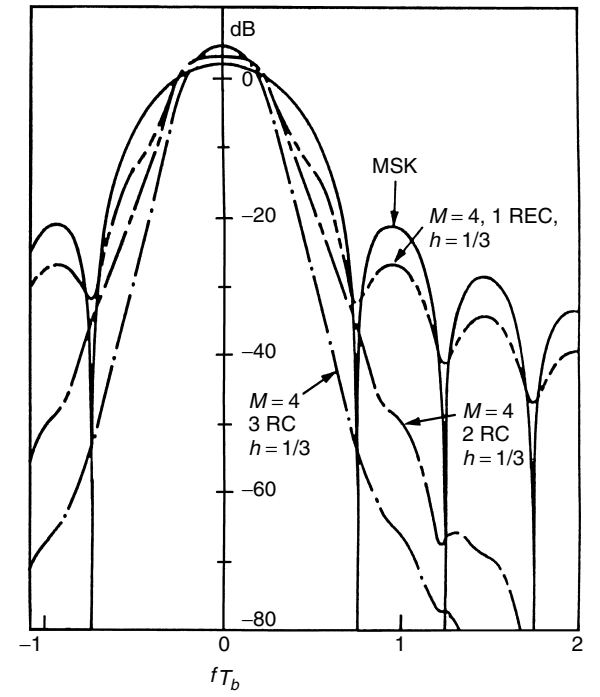

Figure 4. Average power spectra for MSK ($M = 2$, 1REC, $h = \frac{1}{2}$) and the $h = \frac{1}{3}$, $M = 4$ schemes with 1REC, 2RC, and 3RC pulses.

can be described by the finite state and trellis description given above. Although the structure of the optimum ideal coherent receiver for CPM is known [16], it is difficult to evaluate its bit error probability performance. Simulations are required for low channel signal-to-noise ratios. The most convenient and useful parameter for describing the error probability of CPM schemes with maximum-likelihood sequence detection is the minimum Euclidean

distance between all pairs of signals

$$D^2_{\min} = d^2_{\min} \cdot 2E_b = \min\left\{2E_b \log_2(M)\frac{1}{T} \times \int_0^{NT} [1 - \cos[\phi(t, \boldsymbol{a}) - \phi(t, \boldsymbol{b})]]dt\right\} \quad (4)$$

where E_b is the signal energy per bit given by $E_b \log_2 M = E$ and NT is length of the receiver observation interval. When N is sufficiently large, the largest obtainable distance, called the *free distance*, is reached.

For ideal coherent transmission over an additive white Gaussian noise (AWGN) channel, the bit error probability for high signal-to-noise ratios E_b/N_0 is approximately

$$P_b \approx Ce^{-d^2_{\min} E_b/N_0} \quad (5)$$

where C is a constant.

Efficient algorithms are available for computing the minimum distance for different $g(t)$, L, h, and M [16,17]. Figure 5 shows an upper bound d_B^2 to the free distance d_f^2 as a function of h for binary LRC codes; d_B is found by considering certain error events [16]. The term d_B^2 equals the free distance d_f^2 for almost all h values in Fig. 5. Note that the distance grows with L, at least for larger h. The vertical axis of Fig. 5 also has a decibel (dB) scale that gives the gain in E_b/N_0 relative to MSK (which has $d_f^2 = 2$).

The comparisons in Fig. 5 are somewhat artificial, since the bandwidth of a CPM scheme also changes with L and h. Another comparison of CPM schemes is given in the scatterplot in Fig. 6, where each point

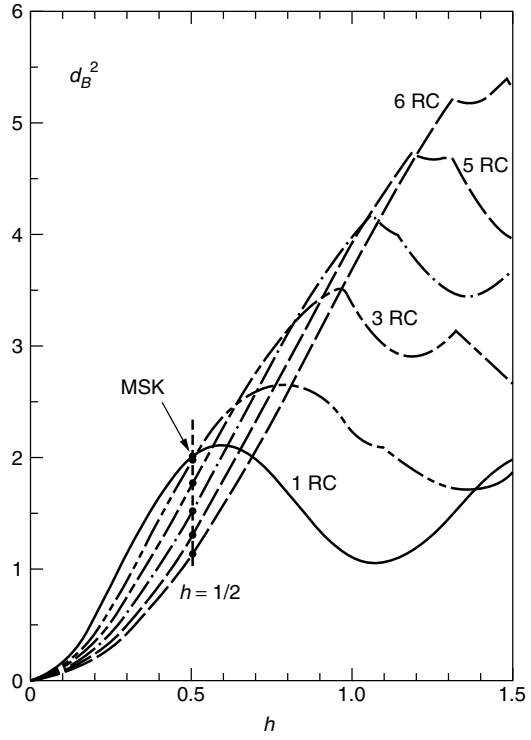

Figure 5. Upper bound d_B^2 on the distance for the binary CPM schemes 1 RC, 2 RC, ..., 6 RC.

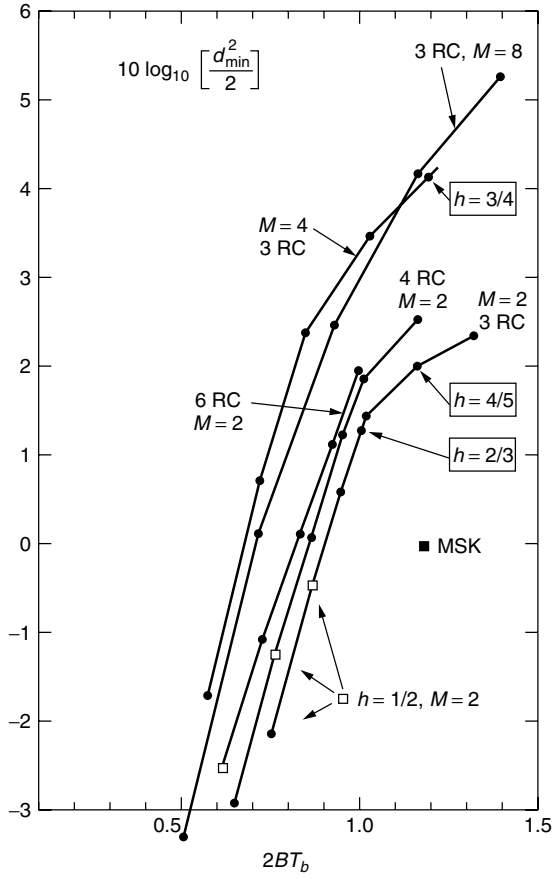

Figure 6. Power–bandwidth tradeoff for CPM schemes using raised-cosine pulses.

represents a system with its 99% power RF bandwidth $2BT_b$ (where $T_b = T/\log_2 M$) and the required signal-to-noise ratio (SNR) relative to MSK in dB at high E_b/N_0. Thus schemes on the same vertical line (for example, through the MSK point) have the same bandwidth at equal data rates; schemes on the same horizontal line have similar error probability for high SNRs. It is evident that larger L and larger M yield more energy- and bandwidth-efficient systems. Not surprisingly, the system complexity increases in the same direction. We have marked some binary $h = \frac{1}{2}$ schemes, some binary 3RC schemes and some quaternary 3RC schemes in Fig. 6. The $h = \frac{2}{3}$ and $\frac{4}{5}$ binary 3RC schemes correspond to the phase cylinders shown above in Fig. 2a,c. For these two schemes, the number of states is 12 and 20, respectively.

The bandwidth and energy of CPM signaling may also be compared to that of other coded modulations. As a class, CPM lies in a middle range of bandwidth and energy; it achieves a moderate error rate ($\sim 10^{-5}$) in 0.5–1.5 Hz·s/data bit and 4–12 dB for E_b/N_0, depending on the code parameters and complexity. Ordinary parity-check coding together with a simple modulation like QPSK work at wider bandwidth and lower energy, and this coding partially overlaps the CPM range on the wideband/low-energy side. In the area of overlap, CPM has the advantage of constant RF envelope. Trellis-coded modulation (TCM) is another coded modulation method

based on set partitioning. It works in a region of narrower bandwidth and higher energy than CPM and partially overlaps it on the other side. In the overlap region, TCM needs either half the bandwidth or 5 dB less energy than CPM. TCM and CPM, however, are not directly comparable because TCM demands a linear channel with accurate amplitude response and CPM does not. Transmitter amplifiers with sufficient linearity for TCM are 2–4 dB less efficient than nonlinear amplifiers of the sort that can be used with CPM signals [18].

5. GENERATING CPM SIGNALS

A conceptual general transmitter structure is shown in Fig. 7. This is based on Eq. (1). This structure demonstrates the fact that CPM is "digital FM"; that is, it is ordinary linear pulsetrain modulation, with pulseshaper $g(t)$, but applied to an FM modulator instead of an amplitude modulator. However, the structure is not easily converted into hardware for coherent systems. The reason is that an exact relation between the symbol rate and the modulation index is required and this requires control circuitry.

The most general and straightforward way of implementing a robust CPM transmitter is to use stored lookup tables. This is seen by rewriting the normalized CPM waveform $S_0(t, \boldsymbol{a}_n) = S(t, \boldsymbol{a}_n)/[2E/T]^{1/2}$ as

$$S_0(t, \boldsymbol{a}_n) = I(t)\cos(2\pi f_0 t) - Q(t)\sin(2\pi f_0 t) \qquad (6)$$

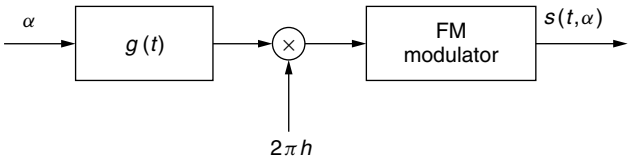

Figure 7. Conceptual modulator for CPM based on Eq. (1).

where $I(t) = \cos(\theta(t, \boldsymbol{a}_n) + \theta_n)$ and $Q(t) = \sin(\theta(t, \boldsymbol{a}_n) + \theta_n)$. The subscript n on $\boldsymbol{a}_n$ indicates that we are considering the data symbol a_n and sufficiently many of the previous symbols. Figure 8 shows a transmitter based on Eq. (6) where the two read only memories contain sampled and quantized versions of $I(t)$ and $Q(t)$ for each data symbol a_n, correlative state vector (the $L-1$ previous data symbols) and phase-state value. The address field for the ROM is roughly $L\log_2 M + [\log_2 p] + 1$ bits and the ROM size is $p \cdot M^L \cdot m \cdot m_q$ bits, where m is the number of samples per symbol time and m_q is the number of bits per quantized sample. The transmitter in Fig. 8 also contains a small sequential machine with a phase state lookup table for calculating the next phase state, given the previous one and the incoming data symbol. The transmitter also contains two D/A converters.

For binary 3RC with $h = \frac{2}{3}$, for example, the ROM (read-only memory) address length is 5-bits and the ROM size is 1024 bits. For a wide range of CPM parameters, the ROM size is manageable. Alternative transmitter structures are possible that have reduced lookup tables.

Several special modulator structures have been devised for MSK. Because MSK is a quadrature-multiplexed modulation scheme, it can be optimally detected by coherently demodulating its in-phase and quadrature components in parallel. The quadrature channels of the modulator and demodulator must be time synchronized, amplitude balanced, and in phase quadrature. The serial method [19] is an alternative approach to parallel modulation and demodulation of MSK which avoids some of these problems.

6. RECEIVERS

Receivers for coherent CPM are an active area of research. For a general CPM scheme with a rational modulation index h and a pulse of finite length L, ideal

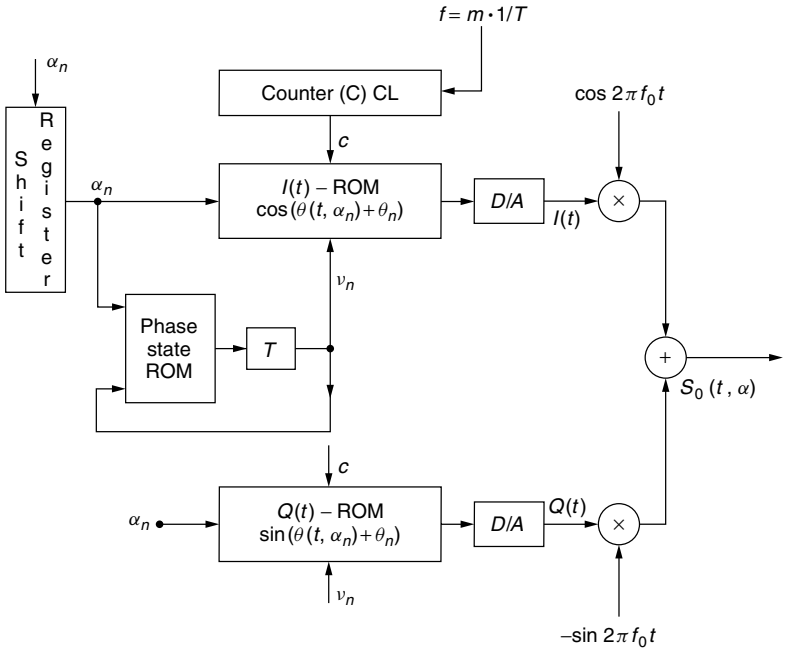

Figure 8. General CPM transmitter with the lookup table principle.

optimum coherent detection can be performed by means of the Viterbi algorithm. The state and trellis description discussed earlier is used. The metric is calculated in a bank of linear filters that are sampled every symbol interval. Figure 9 shows the conceptual diagram for this general receiver. The path memory in the trellis processor causes a delay of N_T symbol intervals. The N_T needed is related to the growth of the minimum distance with the observation interval length. It should be sufficiently large that the free distance is obtained between all paths.

Although there are no special theoretical problems in constructing a receiver based on the principles illustrated in Fig. 9 there are several practical ones. As with all Viterbi detectors, the complexity grows exponentially with signal memory. The limiting factors are the number of states $S = pM^{L-1}$ and the number of filters $F = 2M^L$ for calculating the metrics. For many cases with long smoothing pulses, the optimum receiver can be approximated by a receiver based on a shorter and simpler pulseshape $g_R(t)$ of length $L_R < L$. Thus the complexity of the suboptimum receiver is reduced by a factor of M^{L-L_R} for both the number of states and the number of filters in the filter bank. The simpler pulse shape can be optimized (for large SNRs) for a given transmitter pulseshape and modulation index. The loss in error performance can be very small.

For some cases of CPM it is not necessary to use the Viterbi detector. Much work has been devoted to the so-called MSK-type receiver, which is based on the structure given in Fig. 10. The circuit is inspired by the parallel MSK receiver; it has only two filters and just a small amount of processing. The receiver makes single

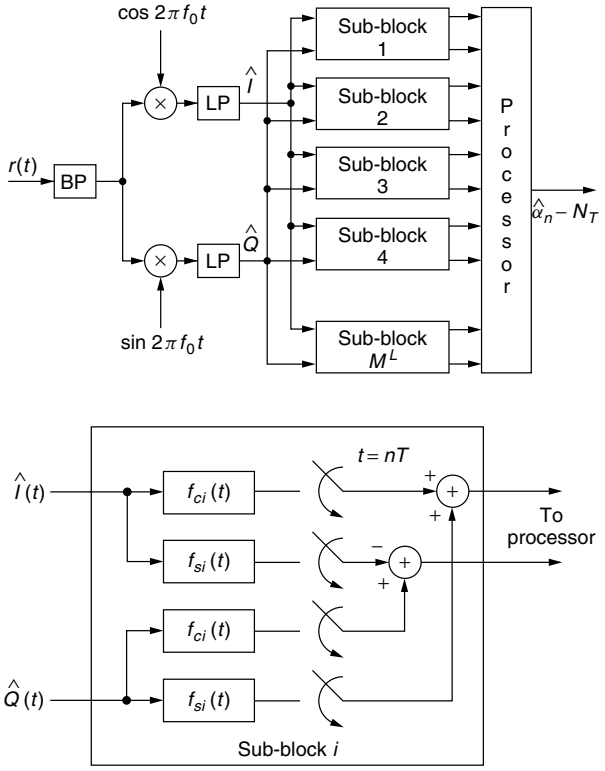

Figure 9. A general receiver structure for CPM based on the Viterbi algorithm. There are $4M^L$ linear filters.

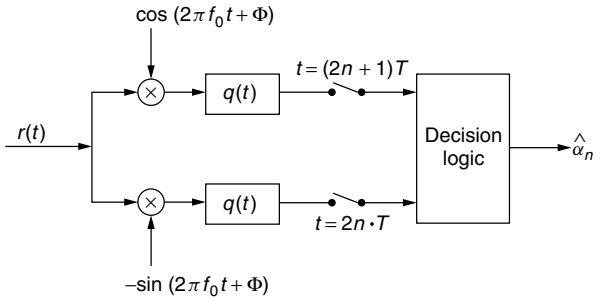

Figure 10. Receiver structure for a parallel MSK-type receiver for binary $h = \frac{1}{2}$ CPM.

symbol decisions. This simplified receiver is suboptimum but it works well for binary modulations with modulation index $h = \frac{1}{2}$. The decisions are made every $2T$ in alternate quadrature arms. Various ideas for selecting the receiver filters are analyzed in the early papers on this subject and an optimum filter has been derived for various correlative FSK schemes (i.e., ones with piecewise linear phase functions) [20] and for smooth pulses [21]. The performance for this type of receiver is almost equal to the optimum Viterbi receiver for schemes with a moderate degree of smoothing, that is, overlapping frequency pulses of length L up to three to four symbol intervals, like 3RC, 4RC, TFM, and some GMSK schemes.

A large literature exists on linear receiver simplifications for CPM. Further details are given in Ref. 16 and the survey article [22].

7. ADVANCED TOPICS

Several topics on more advanced levels are suggested:

Combinations of Convolutional Codes and CPM. The CPM-coded modulations just described may be preceded by an ordinary convolutional code with a rate such as $\frac{1}{2}$ or $\frac{2}{3}$. Pioneering work appeared in [23]. The result is properly considered a concatenated code. Modern techniques of iterative decoding and soft information transfer between the two decoders may be applied, but the joint code trellis is simple enough that outright maximum-likelihood decoding is practical. Convolutional plus CPM code constructions have a wider bandwidth than CPM coding alone, but they have very good minimum distance.

Partially Coherent Detection. A problem of practical interest is how to detect CPM signals when the phase reference is not completely known. Only the derivative of phase (i.e., frequency) may be known, or the phase reference may be stable but subject to an unknown constant offset. In the latter case the minimum distance of CPM is often unaffected.

Reduced-Search Receivers. CPM codes are trellis codes, and as such they can be detected with trellis search algorithms that view only a reduced part of the code trellis. Reduced searching for CPM in fact works well, better than it does for ordinary convolutional codes. Schemes such as the M algorithm need only extend two to four paths

through a complicated trellis. Indicative results are presented in Ref. 24.

Shannon Theory of CPM. An information-theoretic channel that models CPM is unfortunately one with memory, and the problem of computing Shannon information rates for CPM channels is difficult. However, methods exist to compute the cutoff rate, an underbound to capacity that is generally tight at moderate to high signal energy. Cutoff rate studies have been performed by a number of authors, beginning with Ref. 11.

Filtered CPM. An extensive literature exists on CPM that has undergone channel filtering. Early research is discussed in Ref. 16. In general, it can be said that removal of spectral sidelobes by filtering has little effect on CPM detection. More narrow filtering can have a severe effect unless special receivers are used, in which case detection losses are much reduced and can sometimes be removed completely [25].

8. FURTHER READING

A monograph devoted to CPM is Ref. 16. General textbooks that include an introductory chapter about CPM include, for example, Ziemer and Peterson [26] and Proakis [27]. Useful tutorial articles in the literature include Refs. 18 and 22.

BIOGRAPHY

Carl-Erik W. Sundberg received the M.S.E.E. and the Dr. Techn. degrees from the University of Lund, Lund, Sweden in 1966 and 1975 respectively. From 1977 to 1984, he was a Research Professor (Docent) in Telecommunication Theory, University of Lund. From 1984 to 2000, he was a Distinguished Member of Technical Staff (DMTS) at Bell Laboratories, Murray Hill, New Jersey, and during 2001 he was a DMTS at Agere Systems, Murray Hill. He currently is a Senior Scientist at iBiquity Digital Corp., Warren, New Jersey. His research interests include source and channel coding, digital modulation, fault-tolerant systems, digital mobile radio, digital audio broadcasting, spread-spectrum, digital satellite systems, and optical communications. He has published more than 95 journal papers and contributed over 140 conference papers. He has 67 patents, both granted and pending. He is a coauthor of *Digital Phase Modulation*, (New York: Plenum, 1986), *Topics in Coding Theory*, (New York: Springer-Verlag, 1989) and *Source-Matched Digital Communications* (New York: IEEE Press, 1996). In 1986 he received the IEEE Vehicular Technology Society's Paper of the Year Award, and in 1989 he was awarded the Marconi Premium Proc. IEE Best Paper Award. Two of his papers were selected for inclusion in the IEEE Communications Society 50th Anniversary Journal Collection, Volume 2002. He is a Fellow of the IEEE and is listed in *Marquis Who's Who in America*.

John B. Anderson was born in New York State in 1945 and received the Ph.D. degree in electrical engineering from Cornell University in 1972. He has been a faculty member at McMaster University in Canada, Rensselaer Polytechnic Institute in Troy, New york, and since 1998 has held the Ericsson Chair in Digital Communication at Lund University, Lund, Sweden. His researcg work is in coding and digital commuication, bandwidth-efficient coding, and practical application of these. Dr. Anderson has served as president of the IEEE Information Theory Society and editor-in-chief of IEEE Press. He is the author of five textbooks, including the forthcorning *Coded Modulation Systems* (Plenum, 2002). He is fellow of the IEEE (1987) and received the Humboldt Research Prize in 1991 and the IEEE Third Millenmium Medalj in 2000.

CONTINUOUS PHASE FREQUENCY SHIFT KEYING (CPFSK)

THOMAS A. SCHONHOFF
Titan System Corporation
Shrewsbury, Massachusetts

1. INTRODUCTION

Continuous phase frequency shift keying (CPFSK) is a modulation that, as its name implies, can be characterized as a traditional frequency shift keyed (FSK) signal constrained to maintain continuous phase at its symbol time boundaries. This constraint offers two important advantages from a communication point of view:

1. The continuous phase at the symbol boundaries essentially "smooths" the waveform, thereby offering a signal bandwidth that can be considerably smaller than conventional modulations such as FSK or phase-shift-keying (PSK). The spectral characteristics are presented in Section 3.
2. The waveform during each symbol period is dependent on the data and waveforms during previous symbol periods (i.e., the signal waveform contains memory). This memory can be used to improve error rate performance relative to more conventional modulations. The error rate performance is discussed in Section 4.

Historically, CPFSK is a generalization of minimum shift keying (MSK) [1] and, as shown below, MSK is indeed one form of CPFSK. In turn, CPFSK has been generalized to continuous phase modulation (CPM) [2]. Some specific CPM techniques and their relationship to CPFSK are given in Section 2.3.

2. DEFINITION OF CPFSK

During the ith symbol period, the transmitted CPFSK waveform can be written as

$$s(t) = \sqrt{\frac{2E}{T}} \cos\left(2\pi f_c t + \frac{d_i \pi h[t-(i-1)T]}{T} + \pi h \sum_{j=i-1} d_j + \phi\right) \quad (1)$$

where E is the transmitted signal energy during symbol period T and f_c is the carrier frequency. d_i represents the digital data during the ith symbol; for M-ary signaling, $d_i = \pm 1, \ldots, \pm(M-1)$. h is referred to as the deviation ratio. Its importance is made evident in succeeding sections. The starting phase at the beginning of the i^{th} symbol is seen to be $\pi h \sum_{j=i-1} d_j$. This term shows that previous symbols have an effect on the transmitted waveform. ϕ is the initial starting phase.[1]

2.1. Phase Trajectories of CPFSK

From the preceding equation, the phase term is $\vartheta(t) = \frac{d_i \pi h[t-(i-1)T]}{T} + \pi h \sum_{j=i-1} d_j$. This is known as the phase trajectory, and an example for quaternary CPFSK is shown in Fig. 1.

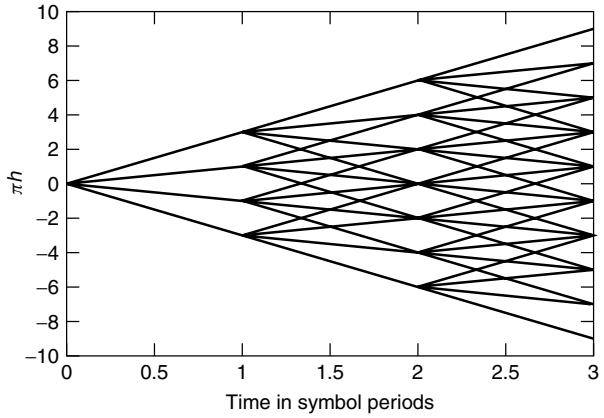

Figure 1. Quaternary CPFSK phase trajectories.

[1] It is assumed that starting phase at time zero is 0.

For the specific case of $h = \frac{1}{2}$, the signal is known as minimum shift keying (MSK) and is widely used in radio systems for which the transmitted frequency is 500 kHz or less.[2]

2.2. Frequency modulation Interpretation of CPFSK

Since the instantaneous transmitted frequency of the signal is the time derivative of the phase, it is clear from Eq. (1) that, during every symbol periods, one of M possible transmitted frequencies are sent, namely $2\pi f_c + \dfrac{d_i \pi h}{T}$, where $d_i = \pm 1, \ldots, \pm(M-1)$.

2.3. Relationship to General CPM

Continuous phase modulation (CPM) is a generalization of CPFSK where the generalization uses the two criteria of performance improvements explained in the Introduction. For example, one approach for CPM is to make the modulation even "smoother" (i.e., make not only the phase continuous but also higher derivatives of the phase continuous). The second approach is to introduce more memory into the modulation by using phase and/or frequency pulse shapes that extend over more than one symbol period. In this case, memory is introduced not only by having continuous phase, frequency, etc. at the symbol boundaries, but also by the pulse shapes themselves. This latter approach has come to be called partial-response CPM.

Adapting the notation of Ref. 4, a general CPM signal can be written in terms of its phase as

$$\vartheta(t;\vec{d}) = 2\pi \sum_{i=-\infty}^{n} d_i h_i q(t - iT), \quad nT \le t \le (n+1)T \qquad (2)$$

In this article, we simply identify the parameters in this equation. The interested reader is directed to Ref. 2 or 4, This equation shows that the phase is determined, in general, by the vector of all past data $\vec{d}$, which represent a sequence of independent M-ary symbols taken from the set $\{\pm 1, \pm 3, \ldots, \pm(M-1)\}$.

Another item of note in Eq. (2) is that, in general, a different value of the modulation index h_i can be used for each symbol period. At present, a popular digital modulation candidate for military UHF satellite systems is a form of this multi-h quaternary modulation. The normalized phase shape $q(t)$ extends over a general L symbol periods and, in general, is constrained only by its end regions. These constraints can be written as

$$q(t) = \begin{cases} 0, & t < 0 \\ \frac{1}{2}, & t \ge LT \end{cases} \qquad (3)$$

3. TRANSMITTED SPECTRAL PROPERTIES OF CPFSK

The general derivation of the power spectral density of CPFSK was first given in Salz [3], although the derivation and terminology of Proakis [4] is used herein. The power spectral density of CPFSK is shown in Ref. 4 to be

$$\Phi(f) = T\left[\frac{1}{M}\sum_{n=1}^{M} A_n^2(f) + \frac{2}{M^2}\sum_{n=1}^{M}\sum_{m=1}^{M} B_{nm}(f) A_n(f) A_m(f)\right] \qquad (4)$$

where

$$A_n(f) = \frac{\sin\pi\left[fT - \frac{1}{2}(2n-1-M)h\right]}{\pi\left[ft - \frac{1}{2}(2n-1-M)h\right]}$$

$$B_{nm}(f) = \frac{\cos(2\pi fT - \alpha_{nm}) - \varphi\cos\alpha_{nm}}{1 + \varphi^2 - 2\varphi\cos 2\pi fT}$$

$$\alpha_{nm} = \pi h(m + n - 1 - M) \qquad (5)$$

and

$$\varphi = \frac{\sin M\pi h}{M \sin \pi h}$$

Figure 2 shows a plot of the one-sided power spectral density of binary CPFSK for three values of the deviation ratio h, namely, MSK, for which h is $\frac{1}{2}$, the value of h that gives the best binary error rate, namely, $h = 0.715$, and an intermediate value of $h = 0.6$.

Figure 3 shows a comparable one-sided power spectral density for three selected values of h for quaternary CPFSK.

4. RECEIVER STRUCTURES AND ERROR RATE PERFORMANCE OF CPFSK

Much of this section is based on the original developments of Refs. 5 and 6. The initial work in Ref. 5 developed the

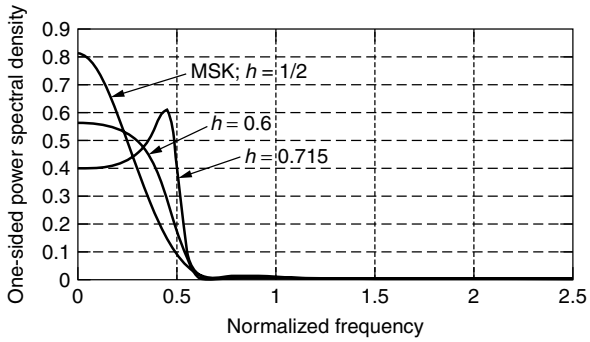

Figure 2. One-sided power spectral density of binary CPFSK.

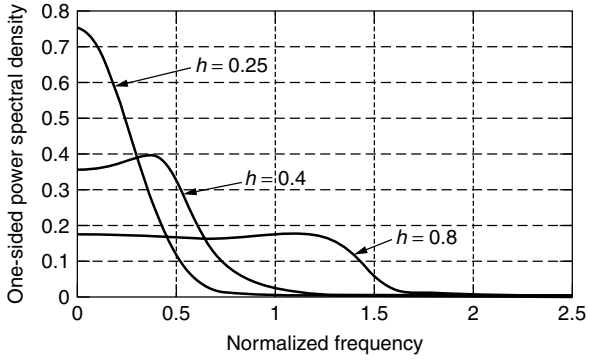

Figure 3. One-sided power spectral density of quaternary CPFSK.

[2] Unfortunately, when $h = \frac{1}{2}$, the memory benefits of CPFSK are significantly reduced so that the error rate performance is theoretically identical to antipodal PSK.

theory and structures for binary signaling, and this was generalized and expanded upon in Ref. 6. Two receiver structures associated with coherent and noncoherent processing, respectively, are presented in Sections 4.1 and 4.2, whereas a compilation of alternative structures is presented in Section 4.3.

4.1. Coherent Structures and Performance

A shorthand notation for the received CPFSK signal can be written as

$$r(t) = \alpha s(t, d_1, D_k) + n(t) \tag{6}$$

where α corresponds to the received signal attenuation, $s(t, d_1, D_k)$ is a compact representation of the transmitted signal of Eq. (1), d_1 is the first symbol on which we wish to make a decision, $D_k = \{d_2, \ldots, d_n\}$ corresponds to the next n symbols, and $n(t)$ is a narrowband zero-mean white Gaussian noise process with a double-sided power spectral density of $N_0/2$. We wish to observe n symbols and make a decision on the first.

It follows that the M likelihood parameters can be written as

$$l_1 = \iiint_{n-\text{fold}} \exp\left(\frac{2}{N_0}\right) \int_0^{nT} r(t)s(t, 1, D_k) f(D_k)\, dD_k$$

$$l_2 = \iiint_{n-\text{fold}} \exp\left(\frac{2}{N_0}\right) \int_0^{nT} r(t)s(t, -1, D_k) f(D_k)\, dD_k$$

$$\vdots$$

$$l_M = \iiint_{n-\text{fold}} \exp\left(\frac{2}{N_0}\right) \int_0^{nT} r(t)s(t, -(M-1), D_k) \times f(D_k)\, dD_k \tag{7}$$

where $f(D_k)$ is the discrete pdf of the $(n-1)$-tuple. Evaluating over these n integrals results in the n decision variables

$$U_1 = \sum_{j=1}^{m} \exp\left(\frac{2}{N_0} \int_0^{nT} r(t)s(t, 1, D_j)\, dt\right)$$

$$U_2 = \sum_{j=1}^{m} \exp\left(\frac{2}{N_0} \int_0^{nT} r(t)s(t, -1, D_j)\, dt\right)$$

$$\vdots$$

$$U_M = \sum_{j=1}^{m} \exp\left(\frac{2}{N_0} \int_0^{nT} r(t)s(t, -(M-1), D_j\, dt\right) \tag{8}$$

where $m = M^{n-1}$ and corresponds to all of the possible sequences of the $(n-1)$-tuple D_j.

Although this set of decision variables is very complicated, it allows us to develop an optimal and a suboptimal receiver structure for coherent CPFSK. From Eq. (8), we can see that an optimum receiver structure can be depicted as shown in Fig. 4. $m = M^{n-1}$ correlators (or matched filters) are used for each of the M possible received symbols. All m correlators associated with one of the symbols (e.g., d_i are added to produce the decision

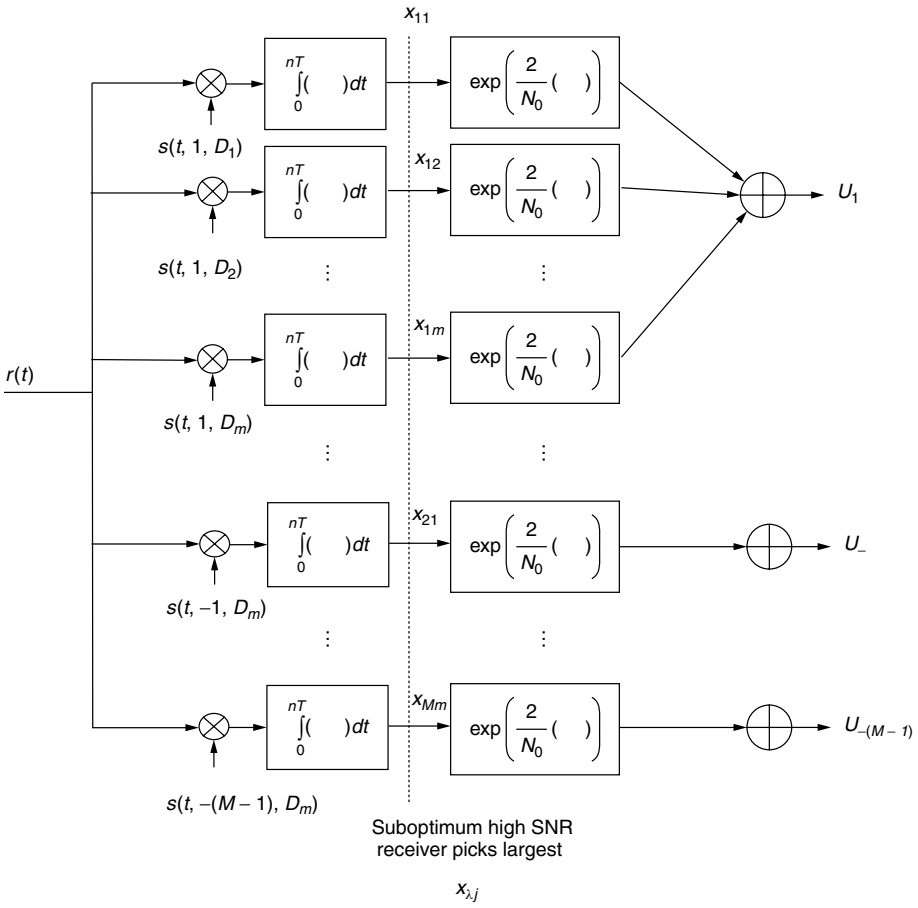

Figure 4. Optimal and suboptimal coherent CPFSK receivers.

variable U_i), and the maximum decision variable is used to estimate which symbol was transmitted during the i^{th} symbol period.

Because of the nonlinear nature of the optimum decision variables, it is analytically impossible to determine the error rate performance of this optimum receiver. Nonetheless, both low snr and high snr bounds can be used to estimate its performance [5,6]. In particular, the high snr approximation uses the fact that the exponential function is monotonic. Thus, if we truncate the receiver structure along the dotted line in Fig. 4, we determine the mM correlator outputs $x_{\lambda j}$, pick the largest, and then base our decision on the subvariable λ. That is, we still make one decision every symbol period, but we use correlators or matched filters that span the last n symbols.

Since the noise is Gaussian, it is clear that each of the correlator outputs is Gaussian and the performance can be estimated using either a union bound as indicated in Refs. 5 and 6 or the minimum distance of all the possible sequences as used in Ref. 2. At high snr, both approaches give comparable estimates. Figures 5 and 6 give binary and quaternary high snr receiver structure error rate performances respectively. These graphs were extracted from the same data as that of [6].

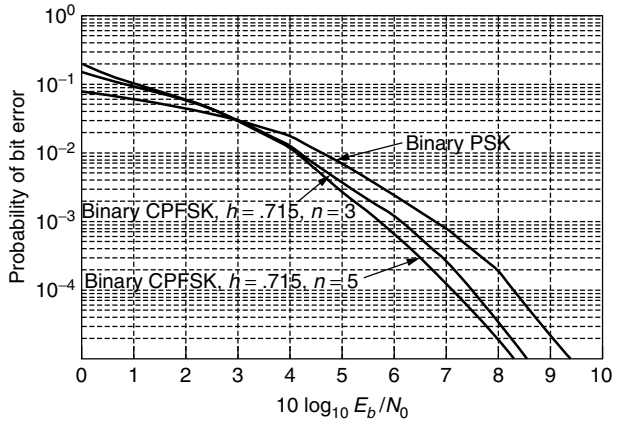

Figure 5. Probability of bit error for selected coherent binary modulations.

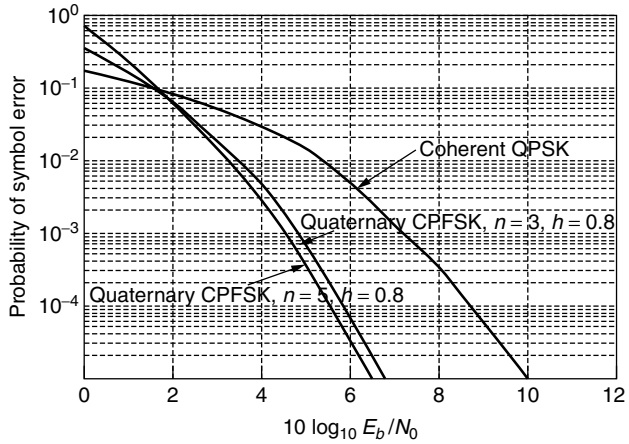

Figure 6. Probability of symbol error for selected coherent quaternary modulations.

For the binary error rate results of Fig. 5, it is known that the optimal value of the deviation ratio is $h = 0.715$. It can be seen from the figure that observing the signal for $n = 3$ or $n = 5$ bits both result in performance improvements over antipodal PSK. For $n = 5$, the improvement is approximately 0.8 dB at an error rate of 10^{-5}.

The results of Fig. 6 show that the improvements of quaternary CPFSK are much more impressive than those of binary CPFSK. Indeed, at an error rate of 10^{-5}, up to 3.5 dB improvement in SNR is possible. The values of h in the last two figures are the optimal values found; however, for quaternary CPFSK in particular, other values of h also result in improved performance. The interested reader is directed to Refs. 2 and 6.

4.2. Noncoherent Structures and Performance

The results of this section again parallel those of the developments in [6]. For noncoherent detection, the initial phase ϕ of Eq. (1) is assumed unknown with a uniform pdf from $(0, 2\pi)$. We use a slightly amended shorthand notation from [6] and model the received signal as

$$r(t) = s(t, d_{n+1}, \Delta_k, \phi) + n(t) \tag{9}$$

where we are observing $2n + 1$ symbols and making a decision on the middle symbol $d_{n+1}.\Delta_k$ is a $2n$-tuple consisting of the symbols before and after the decision symbol $d_{n+1}.\Delta_k$ can then be written as $\Delta_k = \{d_1, d_2, \ldots, d_n, d_{n+2}, \ldots, d_{2n+1}\}$. This implies that the subscript k progresses over $\mu = M^{2n}$ different values. The optimum noncoherent receiver structure is derived from the M likelihood parameters

$$l_1 = \int_\phi \iiint_\Delta \exp\left(\frac{2}{N_0}\int_0^{(2n+1)T} r(t)s(t, 1, \Delta_k, \phi)\,dt\right) \times f(\Delta)f(\phi)\,d\phi\,d\Delta$$

$$l_2 = \int_\phi \iiint_\Delta \exp\left(\frac{2}{N_0}\int_0^{(2n+1)T} r(t)s(t, -1, \Delta_k, \phi)\,dt\right) \times f(\Delta)f(\phi)\,d\phi\,d\Delta$$

$$\vdots$$

$$l_M = \int_\phi \iiint_\Delta \exp\left(\frac{2}{N_0}\int_0^{(2n+1)T} r(t)s(t, -(M-1), \Delta_k, \phi)\,dt\right) \times f(\Delta)f(\phi)\,d\phi\,d\Delta \tag{10}$$

These likelihood ratios can be seen to be similar to those of the coherent receiver structure given by Eq. (7) except for the averaging over the initial phase ϕ which results in a Bessel function of order zero $I_0(x)$. Performing the averages of Eq. (10) results in the M noncoherent decision variables

$$U_1 = \frac{1}{\mu}\sum_{k=1}^{\mu} I_0\left(\frac{2}{N_0}\chi_{1k}\right)$$

$$U_2 = \frac{1}{\mu}\sum_{k=1}^{\mu} I_0\left(\frac{2}{N_0}\chi_{2k}\right)$$

$$\vdots$$

$$U_M = \frac{1}{\mu}\sum_{k=1}^{\mu} I_0\left(\frac{2}{N_0}\chi_{Mk}\right) \tag{11}$$

where χ_{Nk} is a Rician statistical variable defined as

$$\chi_{Nk} = \sqrt{x_{Nk}^2 + y_{Nk}^2} \tag{12}$$

and x_{Nk} and y_{Nk} are the in-phase and quadrature variables, respectively, defined in terms of our shorthand notation as

$$x_{Nk} = \begin{cases} \displaystyle\int_0^{(2n+1)T} r(t)s(t, N, \Delta_k, 0)\,dt & Nodd \\ \displaystyle\int_0^{(2n+1)T} r(t)s(t, \_(N-1), \Delta_k, 0)\,dt & Neven \end{cases} \tag{13}$$

and

$$y_{Nk} = \begin{cases} \displaystyle\int_0^{(2n+1)T} r(t)s\left(t, N, \Delta_k, \frac{\pi}{2}\right)\,dt & Nodd \\ \displaystyle\int_0^{(2n+1)T} r(t)s\left(t, \_(N-1), \Delta_k, \frac{\pi}{2}\right)\,dt & Neven \end{cases} \tag{14}$$

Figure 7 shows the functional block diagram of the optimal noncoherent CPFSK receiver structure, which is developed from Eqs. (11) through (14). As can be seen, a total of M^{2n+1} noncoherent correlators or matched filters are used to make a decision on the middle symbol.

The performance of one example of noncoherently detected CPFSK is shown in Fig. 8. This figure shows that significant improvement is still possible even when the input starting phase is not estimated.

4.3. Other Receiver Structures

The phase trellis, shown in the example in Fig. 1, leads to another receiver structure based on the Viterbi algorithm (VA). This was first identified by Forney in Ref. 7 and explored specifically for CPFSK in Ref. 8. The VA is most useful when the deviation ratio h is a convenient fraction. For example, for binary CPFSK, if $h = \frac{2}{3}$, which is close to the optimum value of 0.715, the phase trellis can be reduced to a phase state diagram as shown in Fig. 9. The VA uses a traditional state history and state metric to determine the most likely path through the trellis or phase-state diagram. References 2 and 8 show that the error rate performance of the VA is virtually indistinguishable from that of the fully implemented multicorrelator receiver as derived in Sections 4.1 and 4.2.

5. CONCLUSION

This article has presented the concept of continuous phase frequency shift keying (CPFSK). Its transmitted spectra is given and examples are presented. Optimal receiver structures for coherent and noncoherent detection are derived, and examples of symbol error rate are presented. Finally, an alternate receiver structure, based on the maximum likelihood sequence estimator (MLSE) or Viterbi algorithm is outlined.

BIOGRAPHY

Thomas A. Schonhoff received his bachelor's degree from M.I.T., his master's degree from Johns Hopkins University, and his Ph.D. from Northeastern University. He has worked at six different corporations, although he has been with LinCom Corporation (now Titan System Corporation, Communication and Software Solutions Division) since 1985. For the past 21 years, Dr. Schonhoff has also taught graduate courses as an adjunct at Worcester Polytechnic Institute.

CONVOLUTIONAL CODES

RICHARD D. WESEL
University of California at Los Angeles
Los Angeles, California

1. INTRODUCTION

Convolutional codes represent one technique within the general class of channel codes. Channel codes (also called *error-correction codes*) permit reliable communication of an information sequence over a channel that adds noise, introduces bit errors, or otherwise distorts the transmitted signal. Elias [1,2] introduced convolutional codes in 1955. These codes have found many applications, including deep-space communications and voiceband modems. Convolutional codes continue to play a role in low-latency applications such as speech transmission and as constituent codes in Turbo codes. Two reference books on convolutional codes are those by Lin and Costello [3] and Johannesson and Zigangirov [4].

Section 2 introduces the shift-register structure of convolutional encoders including a discussion of equivalent encoders and minimal encoders. Section 3 focuses on the decoding of convolutional codes. After a brief mention of the three primary classes of decoders, this section delves deeply into the most popular class, Viterbi decoders. This discussion introduces trellis diagrams, describes the fundamental add-compare-select computation, compares hard and soft decoding, and describes the suboptimal (but commonly employed) finite traceback version of Viterbi decoding.

Section 4 defines the free distance of a convolutional code and describes how free distance may be computed by a specialized application of the Viterbi algorithm. This procedure also yields an analytic lower bound on the decision depth that should be used for finite-traceback decoding. Catastrophic encoders are also discussed in this section. Section 5 describes the generating function that enumerates all the paths associated with error events in the decoder trellis. This section then gives union bounds

on bit error rate that are computed from the generating function. Section 6 provides some final remarks regarding the effective blocklength of convolutional codes and their role today.

2. ENCODER STRUCTURE

As any binary code, convolutional codes protect information by adding redundant bits. A rate-k/n convolutional encoder processes the input sequence of k-bit information symbols through one or more binary shift registers (possibly employing feedback). The convolutional encoder computes each n-bit symbol ($n > k$) of the output sequence from linear operations on the current input symbol and the contents of the shift register(s). Thus, a rate k/n convolutional encoder processes a k-bit input symbol and computes an n-bit output symbol with every shift register update. Figures 1 and 2 illustrate feedforward and feedback encoder implementations of a rate-$\frac{1}{2}$ code. Section 2.1 explores the similarities and differences between feedforward and feedback encoders by examining their state diagrams.

2.1. Equivalent Encoders

Convolutional encoders are finite-state machines. Hence, state diagrams provide considerable insight into their behavior. Figures 3 and 4 provide the state diagrams for the encoders of Figs. 1 and 2, respectively. The states are labeled so that the least significant bit is the one residing in the leftmost memory element of the shift register. The branches are labeled with the 1-bit (single-bit) input and the 2-bit output separated by a comma. The most significant bit (MSB) of the two-bit output is the bit labeled MSB in Figs. 1 and 2.

If one erases the state labels and the single-bit input labels, the remaining diagrams for Figs. 3 and 4 (labeled

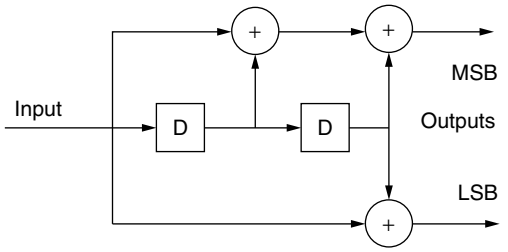

Figure 1. Rate-$\frac{1}{2}$ feedforward convolutional encoder with two memory elements (four states). MSB and LSB refer to the most and least significant bits, respectively.

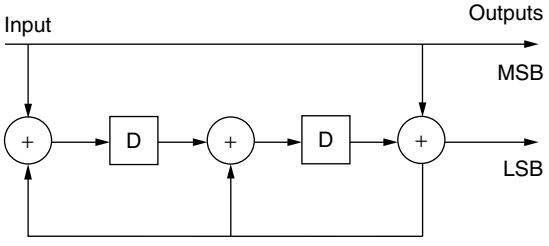

Figure 2. Rate-$\frac{1}{2}$ feedback convolutional encoder with two memory elements (four states).

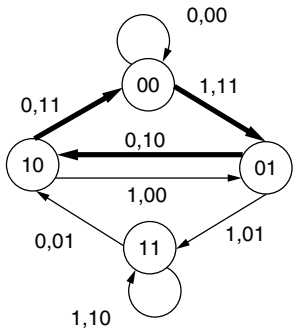

Figure 3. State diagram for rate-$\frac{1}{2}$ feedforward convolutional encoder of Fig. 1.

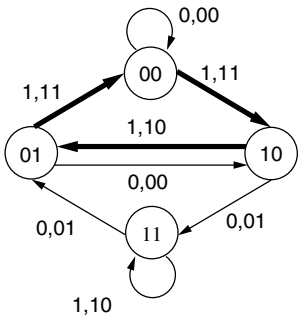

Figure 4. State diagram for rate-$\frac{1}{2}$ feedback convolutional encoder of Fig. 2.

with only the 2-bit outputs) would be identical. This illustrates that the two encoders are equivalent in the sense that both encoders produce the same set of possible output sequences (or codewords). Strictly speaking, a code refers to the list of possible output sequences without specifying the mapping of inputs sequences to output sequences. Thus, as in the above example, two equivalent encoders have the same set of possible output sequences, but may implement different mappings from input sequences to output sequences. In the standard convolutional coding application of transmission over additive white Gaussian noise (AWGN) with Viterbi decoding, such encoders give similar BER performance, but the different mappings of inputs to outputs do lead to small performance differences.

The three-branch paths emphasized with thicker arrows in Figs. 3 and 4 are each the shortest nontrivial (i.e., excluding the all-zeros self-loop) loop from the all-zeros state back to itself. Notice that for Fig. 3, the state diagram corresponding to the feedforward encoder, this loop requires only a single nonzero input. In contrast, for the state diagram corresponding to Fig. 4, this loop requires three nonzero inputs. In fact, for Fig. 4 no nontrivial loop from the all-zeros state to itself requires fewer than two nonzero inputs. Thus the feedforward shift register has a finite impulse response, and the feedback shift register has an infinite impulse response.

This difference is not particularly important for convolutional codes decoded with Viterbi, but it is extremely important to convolutional encoders used as constituents in Turbo codes, which are constructed by concatenating

convolutional codes separated by interleavers. Only feedback encoders (with infinite impulse responses) are effective constituents in Turbo codes. Thus, equivalent encoders can produce dramatically different performance as constituents in Turbo codes, depending on whether or not they meet the requirement for an infinite impulse response.

2.2. Minimal Encoders

A practical question to ask about a convolutional encoder is whether there is an equivalent encoder with fewer memory elements. This question may be answered by performing certain diagnostic computations on the encoder matrix. Furthermore, if the encoder is not minimal, it may be easily "repaired" yielding an encoder that is equivalent but requires fewer memory elements. Forney's classic paper [5] treats this fundamental area of convolutional coding theory elegantly. More recently, Johannesson and Wan [6] extended Forney's results by taking a linear algebra approach. This fascinating area of convolutional code theory is important to convolutional code designers, but less so for "users." Any code published in a table of good convolutional codes will be minimal.

3. DECODING CONVOLUTIONAL CODES

Convolutional code decoding algorithms infer the values of the input information sequence from the stream of received distorted output symbols. There are three major families of decoding algorithms for convolutional codes: sequential, Viterbi, and maximum a posteriori (MAP). Wozencraft proposed sequential decoding in 1957 [7]. Fano in 1963 [8] and Zigangirov in 1966 [9] further developed sequential decoding. See the book by Johannesson and Zigangirov [4] for a detailed treatment of sequential decoding algorithms. Viterbi originally described the decoding algorithm that bears his name in 1967 [10]. See also Forney's work [11,12] introducing the trellis structure and showing that Viterbi decoding is maximum-likelihood in the sense that it selects the sequence that makes the received sequence most likely.

In 1974, Bahl et al. [13] proposed MAP decoding, which explicitly minimizes bit (rather than sequence) error rate. Compared with Viterbi, MAP provides a negligibly smaller bit error rate (and a negligibly larger sequence error rate). These small performance differences require roughly twice the complexity of Viterbi, making MAP unattractive for practical decoding of convolutional codes. However, MAP decoding is crucial to the decoding of Turbo codes. For the application of MAP decoding to Turbo codes, see the original paper on Turbo codes by Berrou et al. [14] and Benedetto et al.'s specific discussion of the basic turbo decoding module [15].

When convolutional codes are used in the traditional way (not as constituents in Turbo codes), they are almost always decoded using some form of the Viterbi algorithm, and the rest of this section focuses on describing Viterbi. The goal of the Viterbi algorithm is to find the transmitted sequence (or codeword) that is closest to the received sequence. As long as the distortion is not too severe, this will be the correct sequence.

3.1. Trellis Diagrams

The state diagrams of Figs. 3 and 4 illustrate what transitions are possible from a particular state regardless of time. In contrast, trellis diagrams use a different branch for each different symbol time. As a result, trellis diagrams more clearly illustrate long trajectories through the states. Figure 5 shows one stage (one symbol time) of the trellis diagram associated with the rate-$\frac{1}{2}$ feedforward encoder of Figs. 1 and 3. Each column of states in the trellis diagram includes everything in the original state diagram. All the branches emanating from states in a particular column are incident on the states in the adjacent column to the right. In other words, each state transition in the trellis moves the trajectory one stage to the right.

To avoid crowding in Fig. 5, branch labels appear at the left and right of the trellis rather than on the branch itself. For each state, the top label belongs to the top branch emanating from or incident to that state. Figure 6 uses thick arrows to show the same path emphasized in the state diagram of Fig. 3. However, in Fig. 3 the beginning and end of the path were not clear. In Fig. 6 the path clearly begins in state 00 and then travels through 01 and then 10 before returning to 00.

3.2. The Basic Viterbi Algorithm

The Viterbi algorithm uses the trellis diagram to compute the accumulated distances (called the *path metrics*) from the received sequence to the possible transmitted sequences. The total number of such trellis paths grows

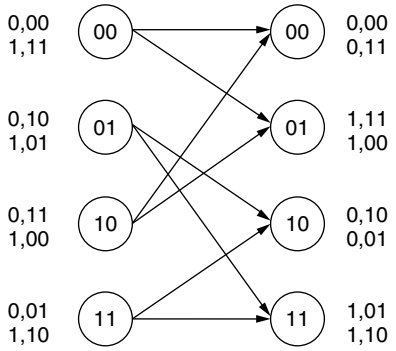

Figure 5. One stage of the trellis diagram for rate-$\frac{1}{2}$ feedforward convolutional encoder of Figs. 1 and 3.

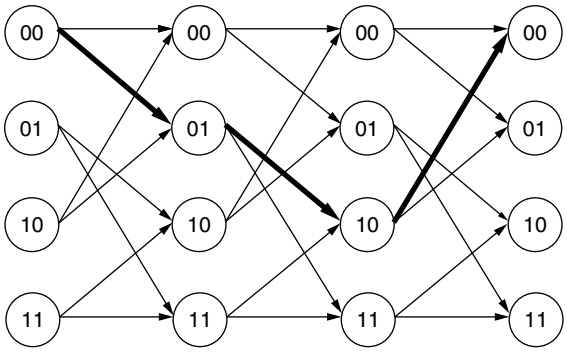

Figure 6. Trellis diagram for the path emphasized in Fig. 3.

exponentially with the number of stages in the trellis, causing potential complexity and memory problems. However, the Viterbi algorithm takes advantage of the fact that the number of paths truly in contention to have the minimum distance is limited to the number of states in a single column of the trellis, assuming that ties may be arbitrarily resolved.

As an example of the Viterbi algorithm, consider transmission over the binary symmetric channel (bit error channel) where the probability of a bit error is less than $\frac{1}{2}$. On such a channel, maximum likelihood decoding reduces to finding the output sequence that differs in the fewest bit positions (has the minimum Hamming distance) from the received sequence. For this example, assume the encoder of Fig. 1 with the state diagram of Fig. 3 and the trellis of Fig. 5. For simplicity, assume that the receiver knows that the encoder begins in state 00.

Figure 7 illustrates the basic Viterbi algorithm for the received sequence 01 01 10. Beginning at the far left column, the only active state is 00. The circle representing this state contains a path metric of zero, indicating that as yet, the received sequence differs from the possible output sequences in no bit positions. Follow the two branches leaving the first column to the active states in the second column of the trellis. Branch metrics label each branch, indicating the Hamming distance between the received symbol and the symbol transmitted by the encoder when traversing that branch. The two hypothetical transmitted symbols are 00 for the top branch and 11 for the bottom (see Fig. 5). Since both differ in exactly one bit position from the received symbol 01, both branch labels are one.

The path metric for each destination state is the sum of the branch metric for the incident branch and the path metric at the root of the incident branch. In the second column, both path metrics are one since the root path metric is zero. These equal path metrics indicate that no path is favored at this point. Now follow the branches from the second column to the third. Exactly one branch reaches each state in the third column. Once again, adding the branch metric and the associated root path metric produces the new path metric.

When following branches from the third column to the fourth, two branches are incident on each state. Only the path with the minimum path metric needs to survive. For example, state 00 (the top state) in the fourth column has a path incident from state 00 in the third column with a path metric of $2 + 1 = 3$. It also has a path incident from state 10 in the third column with a path metric of $3 + 1 = 4$. Only the path with the smaller path metric needs to survive. Figure 7 shows the incident branches of survivor paths with thicker arrows than nonsurvivor paths. Each state in the fourth column has exactly one survivor path, and the values shown indicate the path metrics of the survivor paths.

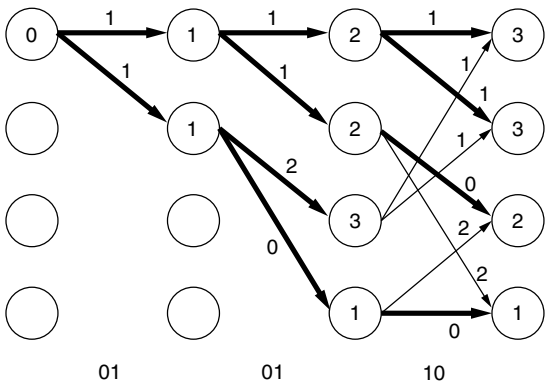

Figure 7. Illustration of the basic Viterbi algorithm on the bit error channel. This is also the trellis for hard Viterbi decoding on the AWGN channel in contrast to the soft Viterbi decoding shown in Fig. 8.

After all received symbols have been processed, the final step in decoding is to examine the last column and find the state containing the smallest path metric. This is state 11, the bottom state, in the fourth column. Following the survivor branches backward from the minimum-path-metric state identifies the trellis path of the maximum likelihood sequence. Reference to Fig. 5 reveals that the maximum likelihood path is the state trajectory $00 \rightarrow 01 \rightarrow 11 \rightarrow 11$. This state trajectory produces the output symbol sequence 11 01 10, which differs in exactly one bit position from the received sequence as indicated by its path metric. The input information sequence is decoded to be 1 1 1.

In this short example, only one trellis stage required path selection. However, once all states are active, path selection occurs with each trellis stage. In fact, if the initial encoder state is not known, path selection occurs even at the very first trellis stage. The basic computational module of the Viterbi algorithm is an add-compare-select (ACS) module. Adding the root path metric and incident branch metric produces the new path metric. Comparing the contending path metrics allows the decoder to select the one with minimum distance. When there is a tie (where two incident paths have the same path metric), a surviving path may be arbitrarily selected. In practice, ties are not uncommon. However, ties usually occur between paths that are ultimately destined to be losers.

3.3. Hard Versus Soft Decoding

The integer branch and path metrics of the binary error channel facilitate a relatively simple example of the Viterbi algorithm. However, the AWGN channel is far more common than the bit error channel. For the AWGN channel, binary phase shift keying (BPSK) represents binary 1 with 1.0 and binary 0 with -1.0. These two transmitted values are distorted by additive Gaussian noise, so that the received values will typically be neither 1.0 nor -1.0. A novice might choose to simply quantize each received value to the closest of 1.0 and -1.0 and assign the appropriate binary value. This quantization would effectively transform the AWGN channel to the bit error channel, facilitating Viterbi decoding exactly as described above. This method of decoding is called hard decoding, because the receiver makes a binary (hard) decision about each bit before Viterbi decoding.

Hard decoding performs worse by about 2 dB than a more precise form of Viterbi decoding known as *soft decoding*. Soft decoding passes the actual received values to the Viterbi decoder. These actual values are called soft values because hard decisions (binary decisions) have

not been made prior to Viterbi decoding. Soft Viterbi decoding is very similar to hard decoding, but branch and path metrics use squared Euclidean distance rather than Hamming distance. Figure 8 works an example analogous to that of Fig. 7 for the case where 1.0 and −1.0 are transmitted over the AWGN channel and soft Viterbi decoding is employed. A fixed-point implementation with only a few bits of precision captures almost all the benefit of soft decoding.

3.4. Finite Traceback Viterbi

The maximum likelihood version of Viterbi decoding processes the entire received sequence and then selects the most likely path. Applications such as speech transmission can conveniently process relatively short data packets in this manner. However, stream-oriented applications such as a modem connection cannot wait until the end of the received sequence before making any decisions about the information sequence. In such cases, a suboptimal form of Viterbi decoding is implemented in which decisions are made about transmitted bits after a fixed delay. This fixed delay is called the traceback depth or decision depth of the Viterbi decoder. The exact choice of the traceback depth is usually determined by simulation, but there is an analytic technique that identifies a good lower bound on what the traceback depth should be. We will discuss this "analytic traceback depth" in the next section, since its computation is a natural by-product of computing the free distance of a convolutional code.

Figures 9 and 10 illustrate finite traceback Viterbi decoding. Figure 9 shows the path metrics and survivor paths (indicated by thick arrows) for a soft Viterbi decoder in steady state. Actually, the selection of survivor paths and path metrics is the same for maximum-likelihood Viterbi decoding and finite-traceback Viterbi decoding. Figure 10 shows the distinguishing behavior of finite-traceback Viterbi decoding. Rather than wait until the end of the received sequence, each k-bit input symbol is decoded after a fixed delay. In Fig. 10 this delay is three symbols. After each update of the path metrics, the path with the smallest metric (identified in Fig. 10 by a thick circle) is traced back three branches and the k-bit input symbol associated with the oldest branch is decoded. Notice that the paths selected by this algorithm do not have to be consistent with each other. For example, the two paths traced back in Fig. 10 could not both be correct, but this inconsistency does not force the decoded bits to be incorrect.

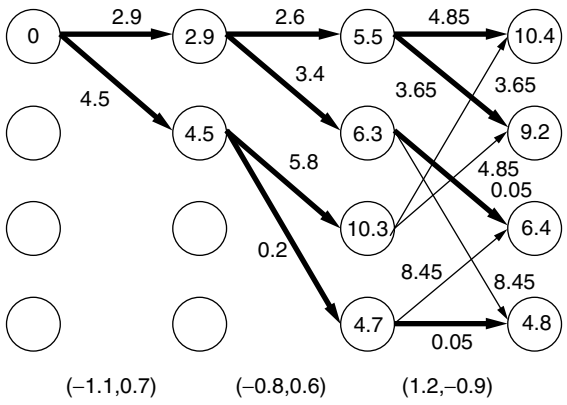

Figure 8. Illustration of soft Viterbi decoding.

4. FREE DISTANCE

The ultimate measure of a convolutional code's performance is the bit error rate (BER) or block error rate (BLER) of the code as a function of signal-to-noise ratio (SNR). However, free distance gives a good indication of convolutional code performance. The free distance of a convolutional code is the minimum distance (either Hamming or Euclidean) between two distinct valid output sequences. Unlike algebraic block codes, which are designed to have specific distance properties, good convolutional codes are identified by an exhaustive search over encoders with a given number of memory elements. Often free distance is the metric used in these searches.

For simplicity, we will restrict the discussion of free distance to free Hamming distance. For BPSK, this restriction imposes no loss of generality since the Hamming and squared Euclidean free distances are related by a constant.

4.1. Computation of Free Distance

The set of distances from a codeword to each of its neighbors is the same for all codewords. Hence, the free distance

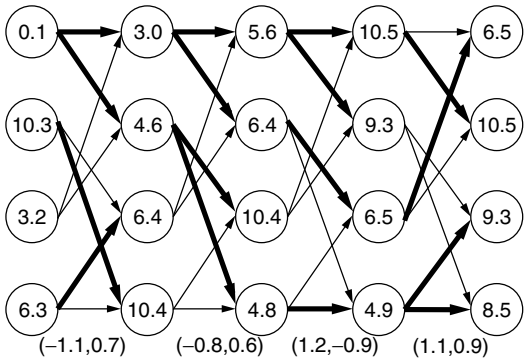

Figure 9. Steady state soft Viterbi state updates. Survivor paths are shown as thick arrows.

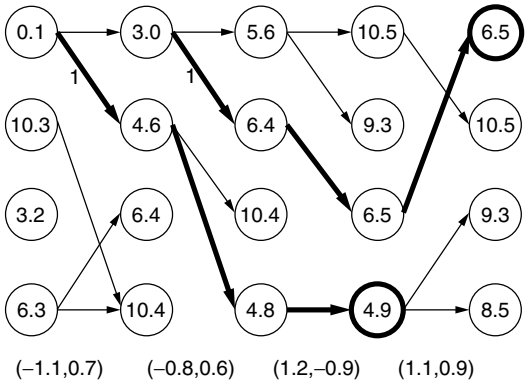

Figure 10. Finite traceback soft Viterbi decoding with a traceback depth of 3. Only the survivor paths of Fig. 9 are shown. Each traceback operation decodes only $k = 1$ bit. Thick arrows identify two such traceback paths.

is the distance from the all-zeros output sequence to its nearest-neighboring codeword. A Viterbi decoding operation with some special restrictions efficiently performs this computation. Viterbi decoding is performed on the undistorted all-zeros received sequence, but the first trellis branch associated with the correct path is disallowed. Thus prevented from decoding the correct sequence, the Viterbi algorithm identifies the nearest-neighbor sequence. Since the received sequence is noiseless, the path metric associated with the decoded sequence is the distance between that sequence and the all-zeros sequence, which is the free distance.

Figure 11 illustrates the computation of free Hamming distance using the Viterbi algorithm for the encoder described in Figs. 1, 3, and 5. The disallowed branch is shown as a dashed line. Only survivor branches are shown, and the thick branches indicate the minimum distance survivor path. Below each column is the minimum survivor path metric, which is called the *column distance*. The *free distance* is formally defined as the limit of the column distance sequence as the survivor pathlength tends to infinity. This limit is 5 in Fig. 11.

For noncatastrophic feedforward convolutional encoders, the free distance is equivalent to the minimum distance of a path that returns to the zero state. In general, the minimum distance path need not be the shortest path. For encoders with more states than the simple example of Fig. 11, there are typically several such paths having the same minimum distance. The number of minimum-distance paths is the number of nearest-neighbor output sequences. This is sometimes called the *multiplicity* of the free distance. If two codes have the same free distance, the code with the smaller multiplicity is preferred.

4.2. Analytic Decision Depth

As mentioned in Section 3.4, the specific decision depth used in finite traceback Viterbi is usually determined by simulation. However, a good estimate of the decision depth helps designers know where to begin simulations. For noncatastrophic feedforward encoders, Anderson and Balachandran [16] compute a useful lower bound on the required decision depth as a by-product of the free-distance computation.

This analytic decision depth is the pathlength at which the survivor path incident on the zero state has a path metric that is the unique minimum distance in the column. In other words, the path metric of the survivor path to the zero state is the only distance in the column equal to the column distance. In Fig. 11, this analytic decision depth is 8; after the eighth branch the path metric of the survivor path to the zero state is the only distance in the column equal to the column distance of 5. For noncatastrophic feedforward encoders, the Viterbi decoding procedure for computing free distance may be stopped when the analytic decision depth is identified. The column distance remains fixed thereafter.

When using this analytic decision depth, finite traceback decoding gives performance consistent with the first-order metrics of free distance and multiplicity. The asymptotic performance (in the limit of high SNR) is the same as maximum-likelihood Viterbi. In practice, a somewhat larger decision depth is often used to capture some additional performance at SNRs of interest by improving second-order metrics of performance (i.e., distances slightly larger than the minimum distance). For example, the analytic decision depth of the standard rate-$\frac{1}{2}$ 64-state feedforward convolutional encoder is 28, but simulation results show that a decision depth of 35 gives a noticeable performance improvement over 28. Decision depths larger than 35 give only negligible improvement.

4.3. Catastrophic Encoders

A convolutional encoder is catastrophic if a finite number of errors in the output sequence can cause an infinite number of errors in the input sequence. With such an encoder, the consequences of a decoding error can be truly catastrophic. Catastrophic encoders are certainly undesirable, and they are never used in practice. In fact, they are easily avoided because they are not minimal encoders. Hence if an encoder is catastrophic it also uses more memory elements than does a minimal equivalent encoder, which is not catastrophic.

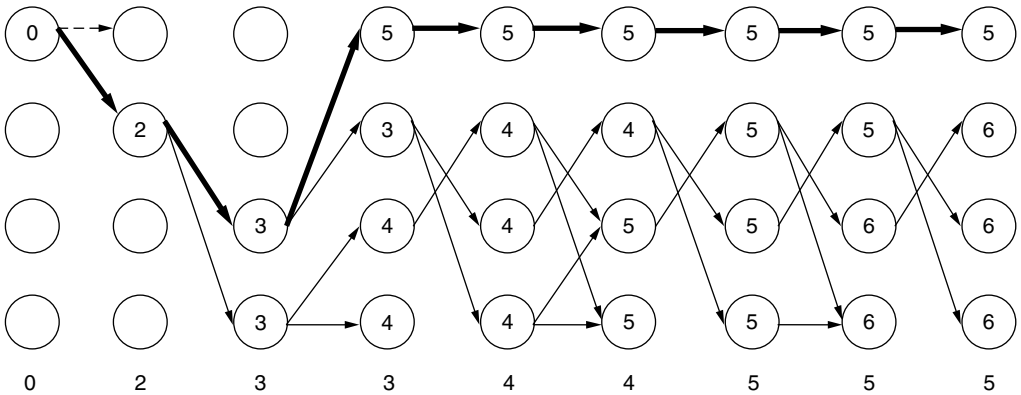

Figure 11. Application of the Viterbi algorithm to identify the free Hamming distance of the code described by Figs. 1, 3, and 5. The column distances are shown below each column. The disallowed branch is shown as a dashed line. Only survivor paths are shown, and the minimum distance path is shown with thick arrows.

An encoder is catastrophic if and only if its state diagram has a loop with zero output weight and nonzero input weight. Catastrophic encoders still have a free distance as defined by the limit of the column distance, but this free distance is seldom equal to the minimum survivor path metric to the zero state. Usually, some of the survivor path metrics for nonzero states never rise above the minimum survivor path metric to the zero state. An additional stopping rule for the Viterbi decoding computation of free distance resolves this problem: If the column distance does not change for a number of updates equal to the number of states, the free distance is equal to that column distance.

Noncatastrophic encoders may also require this additional stopping rule if they have a nontrivial zero-output-weight loop. Such a loop does not force catastrophic behavior if it is also a zero-input-weight loop. Such a situation only occurs with feedback encoders since feedforward encoders do not have loops with zero output weight and zero input weight except the trivial zero-state self-loop. In cases where this stopping criterion is required, the analytic decision depth of Anderson and Balachandran is not well defined. However, a practical place to start simulating decision depths is the pathlength at which the Viterbi computation of free distance terminates.

Because nontrivial zero-output-weight loops indicate a nonminimal encoder, their free distance is not often computed. However, there are circumstances where computation of the free distance is still interesting. As described by Fragouli et al. [17], these "encoders" arise not from poor design but indirectly when severe erasures in the channel transform a minimal encoder into a weaker, nonminimal encoder. An alternative to the additional stopping rule is simply to compute the free distance of an equivalent minimal encoder.

5. BOUNDS ON BIT ERROR RATE

As mentioned at the beginning of Section 4, BER and BLER as functions of SNR are the ultimate metrics of convolutional code performance. Monte Carlo simulation plays an important role in the characterizing BER and BLER performance. However, accurate characterization by Monte Carlo simulation at very low BER or BLER, say, less than 10^{-10}, is not computationally feasible with today's technology. However, analytic upper bounds on BER are very accurate below BER 10^{-5}. Thus, the use of bounds in conjunction with Monte Carlo simulation for high BER provides a good overall performance characterization.

5.1. The Generating Function

To facilitate the bound, a generating function or transfer function enumerates in a single closed-form expression all paths (including nonsurvivors) that return to the zero state in an infinite extension of the trellis of Fig. 11. The bound itself is analogous to the moment generating function technique for computing expectations of random variables. Figure 12 shows an altered version of the state diagram of Fig. 3 where the zero state has been split into a beginning zero state and an ending zero state. This new

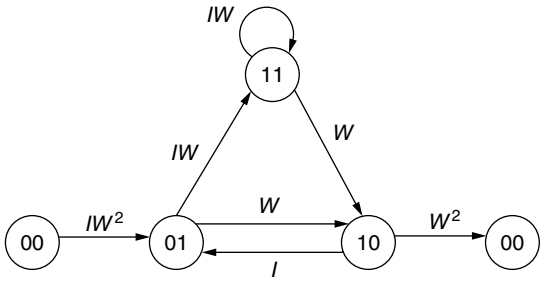

Figure 12. Split-state diagram for the encoder described by Figs. 1, 3, and 5. The exponent of W indicates the Hamming weight of the output error symbol. The exponent of I indicates the Hamming weight of the input error symbol.

diagram is called a *split-state diagram*. For the bound, only the Hamming weights of input and output symbols are needed. These Hamming weights are given as exponents of I and W, respectively. These values appear as exponents, so that when the labels along any path from the beginning zero state to the ending zero state are multiplied, the result is a single expression I^iW^w, where i is the overall input Hamming weight of the path and w is the overall output Hamming weight of the path.

Let A be the matrix of branch labels for all branches that neither begin nor end in a zero state. Each column of A represents a beginning state, and each row represents an ending state for a branch. A zero indicates no branch between the corresponding beginning and ending states. For Fig. 12

$$A = \begin{bmatrix} 0 & I & 0 \\ W & 0 & W \\ IW & 0 & IW \end{bmatrix} \tag{1}$$

Let b be the column of branch labels for all branches that begin in the zero state. For Fig. 12

$$b = \begin{bmatrix} IW^2 \\ 0 \\ 0 \end{bmatrix} \tag{2}$$

Let c be the row of branch labels for all branches that end in the zero state. For Fig. 12

$$c = \begin{bmatrix} 0 & W^2 & 0 \end{bmatrix} \tag{3}$$

The shortest path from the beginning zero state to the ending zero state has three branches; it is the path shown by thick arrows in Fig. 11. The product of the labels for this path may be computed as $cAb = IW^5$. Note that the exponent of 5 is consistent with the path metric of 5 in Fig. 11, which is also the free distance. There is one four-branch path and its label product is $cA^2b = I^2W^6$. There are two five-branch paths and their label products are $cA^3b = I^3W^7 + I^2W^6$. In general, $cA^{L-2}b$ gives the label products of all L-branch paths. Thus, the equation

$$T(W, I) = \sum_{L=3}^{\infty} cA^{L-2}b \tag{4}$$

$$= c(I - A)^{-1}b \tag{5}$$

enumerates the label products of all paths from the beginning zero state to the ending zero state. Note that I is

the input weight indeterminate in Eq. (4) but the identity matrix in Eq. (5). $T(W, I)$ is the generating function (or transfer function) of the convolutional encoder.

5.2. Union Bounds

Manipulation of $T(W, I)$ produces upper bounds on the BER for both the bit error channel and the AWGN channel. These upper bounds compute the sum over all error events e

$$\sum_e i_e P_e \tag{6}$$

where an error event is simply a path from the beginning zero state to the ending zero state. The input Hamming weight i_e associated with the error event e counts the total number of bit errors that all shifts of this error event can induce on a fixed symbol position. P_e is the probability that this path is closer to the received sequence than the transmitted (all-zeros) sequence. Note that (6) is an upper bound because P_e does not subtract probability for situations where more than one path is closer to the received sequence than the all-zeros sequence. For the bit error channel with bit error probability p,

$$\text{BER} \le \frac{1}{k} \left\{ \frac{\partial T(W, I)}{\partial I} \right\}_{I=1, W=2(p-p^2)^{1/2}} \tag{7}$$

For BPSK transmission of $\pm E_s^{1/2}$ over the AWGN channel with noise variance $N_0/2$, we obtain

$$\text{BER} \le \frac{1}{k} Q\left[\left(\frac{2 d_{\text{free}} E_s}{N_0} \right)^2 \right] e^{d_{\text{free}} E_s / N_0} \times \left\{ \frac{\partial T(W, I)}{\partial I} \right\}_{I=1, W=e^{-E_s/N_0}} \tag{8}$$

$$\le \frac{1}{2k} \left\{ \frac{\partial T(W, I)}{\partial I} \right\}_{I=1, W=e^{-E_s/N_0}} \tag{9}$$

where the tighter bound of Eq. (8) requires knowledge of the free distance d_{free}, but the looser bound of Eq. (9) does not.

6. FINAL REMARKS

Although a block code has a well-defined blocklength, convolutional codes do not. Convolutional codes are sometimes considered to have infinite blocklength, and this perspective is valuable for certain derivations, such as the derivation of union bounds on BER presented in Section 5. However, Sections 3.4 and 4.2 demonstrate that most of the useful information for decoding a particular input symbol lies within a relatively small interval of output symbols called the *decision depth*. In two important senses of blocklength, the latency required for decoding and the general strength of the code, the (properly chosen) decision depth is a good indicator the effective blocklength of a convolutional code. The decision depth of standard convolutional codes is small, certainly less than 50 for the standard rate-$\frac{1}{2}$ code with six memory elements in a single shift register.

Shannon's channel capacity theorem [18] (see also the treatise by Cover and Thomas [19]) computes the maximum rate that can be sent over a channel (or the maximum distortion that can be tolerated for a given rate). This theorem applies only as blocklength becomes infinite; in general it is not possible to achieve the performance promised by Shannon with small-blocklength codes. Indeed, convolutional code performance is hampered by their relatively small effective blocklength. For a bit error rate (BER) of 10^{-5}, they typically require about 4 dB of additional signal-to-noise ratio (SNR) beyond the Shannon requirement for error free transmission in the presence of AWGN. In contrast, for a BER of 10^{-5} Turbo codes and low-density parity-check codes, which both typically have blocklengths on the order of 10^3 or 10^4, require less than 1 dB of additional SNR beyond the Shannon requirement for error-free transmission in AWGN.

On the other hand, the performance of convolutional codes is actually quite good, given their short blocklengths. Applications such as speech transmission that require very low latency continue to employ convolutional codes because they provide excellent performance for their low latency and may be decoded with relatively low complexity. Furthermore, since Turbo codes contain convolutional encoders as constituents, a good understanding of convolutional codes remains essential even for long-blocklength applications.

BIOGRAPHY

Richard D. Wesel received both B.S. and M.S. degrees in electrical engineering from MIT in 1989 and the Ph.D. degree in Electrical Engineering from Stanford University in 1996. From 1989 to 1991 he was with AT&T Bell Laboratories, where he worked on nonintrusive measurement and adaptive correction of analog impairments in AT&T's long-distance network and the compression of facsimile transmissions in packet-switched networks. He holds patents resulting from his work in both these areas.

From July 1996 to July 2002 he was an Assistant Professor in the Electrical Engineering Department of the University of California, Los Angeles. Since July 2002 he is an Associate Professor at UCLA. His research is in communication theory with particular interests in the topics of channel coding the distributed communication. In 1998 he was awarded a National Science Foundation CAREER Award to pursue research on robust and rate-compatible coded modulation. He received an Okawa Foundation Award in 1999 for research in information and telecommunications, and he received the 2000 TRW Excellence in Teaching Award from the UCLA School of Engineering and Applied Science. Since 1999 he has been an Association Editor for the *IEEE Transactions on Communications* in the area of coding and coded modulation.

CRYPTOGRAPHY

IAN F. BLAKE
University of Toronto
Toronto, Ontario, Canada

1. INTRODUCTION

The need for secure communications has existed for centuries, and many ciphers such as substitution, transposition, and other types were in use by the Middle Ages. An excellent account of the historical development of cryptography is given in the comprehensive book of Kahn [3].

The first and most influential contribution of the modern era is the work of Claude Shannon [8], where fundamental notions of secrecy systems, including the principles of diffusion and confusion, unicity distance, and an information-theoretic approach to secrecy, were introduced. The notions of diffusion and confusion are very much in evidence in the design of the Data Encryption Standard, introduced in 1977 and used worldwide to this time. Only relatively recently has a replacement been announced, the Advanced Encryption Standard. These two block ciphers, as well as other so-called symmetric key ciphers, including stream ciphers, are considered in the next section.

It is the paper by Diffie and Hellman [1] that has ushered in the modern era of cryptography and decisively changed the landscape. It proposed the notions of asymmetric key (public key) cryptography, one-way functions, trap-door one-way functions, and digital signatures (called *one-way authentication* there) that have revolutionized secure communications in a networked world. Perhaps the most elegant incarnation of their ideas is that of RSA [6] (standing for Rivest, Shamir, and Adleman, the inventors), which includes the first realization of a digital signature. The notion of a cryptographic protocol, a sequence of steps to achieve a given purpose, arose out of these works and continues as a vital area of research.

This article overviews the subject of modern cryptography in a manner that those with a technical background will hopefully find useful, while omitting mathematical proofs.

Three excellent reference works on cryptography are those by Schneier [7], which gives a comprehensive and readable account of the subject and those by Menezes et al. [5] and Stinson [9], which give a more detailed and mathematical account that those interested in current research directions and implementation will find invaluable. Both of these last two references will be referred to liberally in this article.

The Website of the National Institute of Standards and Technology (NIST) contains an organized, authoritative, and up-to-date reference on standards, documentation and ongoing activity on the theory and practice of cryptography that is invaluable. It publishes the standards in documents referred to as *Federal Information Processing Standards* (FIPS), which invariably become de facto worldwide standards. These will be referred to throughout the article.

This article attempts to cover many of the important aspects of modern cryptography. A guide to this has been the list provided by NIST on its Website, which lists the following items in its cryptographic toolkit:

- Encryption
- Digital signatures
- Prime-number generation
- Modes of operation
- Authentication
- Random-number generation
- Secure hashing
- Key management

Each category contains references and links to standards and further materials, as appropriate. It is a reference list

for proper cryptographic practice in all of its important aspects. The list is used as a guide for this article. Authentication here is taken to include both entity authentication and data integrity.

Cryptography has among its goals to achieve confidentiality, data integrity, authentication, identification, and nonrepudiation of data transmission, storage, and transactions, and this article will outline how cryptography is used to achieve these goals. Formally, *cryptography* is the study of "secret writing," and *cryptanalysis* is the study of breaking a cryptographic technique. Together they are referred to as *cryptology*.

The following section first considers symmetric key encryption systems, including both block and stream ciphers, where the transmitter and receiver must have a common key. Before proceeding to examine public key cryptosystems, we briefly consider the mathematical problems and their complexity on which such systems are based. The main functions that public key systems are used for, including key exchange, encryption, digital signatures, and authentication techniques, are then presented. The article concludes with a brief look at prime-number and random-number generation and some indication of future directions of cryptography.

2. SYMMETRIC KEY ENCRYPTION SYSTEMS

Symmetric key encryption systems require a common key at both the transmitter and receiver. In a network environment this might mean that each pair of users requires a unique shared key, implying that each user in a community of n users is required to store $\binom{n}{2}$ keys, often a prohibitively large number. An efficient solution to this problem will be considered below.

The set of symmetric key systems is divided into block and stream systems. In a block system the input data are divided into blocks of equal length and produces equal length ciphertext blocks of output, usually of the same length as the input blocks. A stream cipher encrypts one symbol at a time using a system that produces a long sequence of symbols in some complex manner. They are typically generated by hardware, tend to be faster than block ciphers and require less complex hardware and storage. They find particular application in constrained devices such as wireless systems.

2.1. Symmetric Key Ciphers

As noted, a block cipher, represented in Fig. 1, operates on a block of plaintext P bits with a key K to produce a block of ciphertext bits, C. The decryption process uses the same key as the encryption process.

The best known and most widely used block cipher has been the Data Encryption Standard (DES). Originally introduced in 1977, it was the result of a solicitation by NIST (then the National Bureau of Standards) for an encryption method for computer data and was derived from a submission by IBM. A detailed description of its operation is given in FIPS 46 (1977) (and modifications given in FIPS 46-1, 1988 and FIPS 46-2, 1993).

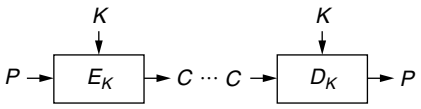

Figure 1. Basic block encryption.

The operation of DES is briefly described, with some details omitted. It operates on input plaintext data blocks of length 64 bits, producing ciphertext blocks of the same length. While its key length is 64 bits, only 56 bits are used in the algorithm itself; every 8th bit is a parity bit that is ignored in producing ciphertext. The first step of the algorithm is a fixed permutation of the block held in a register. After this step, the data are divided into left and right halves, each of 32 bits. The algorithm proceeds in 16 rounds with a typical round represented in Fig. 2.

At each of the 16 rounds, a different 48 bit subkey, K_i, is derived from the 56 bit key K in a simple and deterministic manner, not given here. The function f takes the 32 bit R_i together with the 48-bit subkey K_i to produce a 32-bit output. The block R_i is first expanded to 48 bits, by repeating certain of the bits, and XORed with the subkey K_i to produce 8 blocks of 6 bits each. Each subblock addresses one of eight so-called S boxes, which are 4×16 arrays containing integers 0–15. The first and last bits of the 6-bit subblock address the row and the middle 4 bits address a column, producing an integer representing 4 bits. Encryption concludes with the inverse of the initial permutation. The decryption process is very similar to the encryption process, with certain parts of the algorithm inverted or run backward as appropriate.

The algorithm is actually used in one of four modes (referred to as the *modes of operation*). The basic technique described is referred to as *electronic codebook* (ECB). The other modes are called *cipher feedback* (CFB), *output feedback* (OFB), and *cipher block chaining* (CBC). These modes introduce feedback and hence dependence between cipher blocks, useful in avoiding certain types of repetition attacks, among other uses. The four modes of operation can actually be used with any block cipher.

It has been observed for many years that the 56-bit key is too short to withstand a brute-force attack on current computing equipment, and indeed DES is now viewed as insecure, and its use is no longer recommended. It is possible to cascade DES ciphers, using double or triple encryption, thereby expanding the key length to 112 or

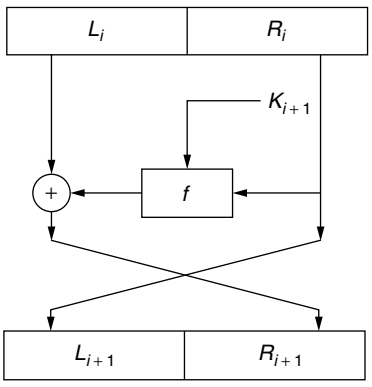

Figure 2. One round of DES.

168 bits, although here also, care must be taken. These so-called double and triple DES versions will likely be in use for many more years as they are in widespread applications in both hardware and software. DES has proved to be a remarkably successful block cipher, far outliving its planned lifetime with no inherent weaknesses discovered.

Recognizing the need for stronger encryption, NIST solicited the cryptographic community for algorithms to replace DES. Of the many submissions received, an algorithm from Belgium, Rijndael, was chosen, after careful consideration of its security, speed in both software and hardware, and suitability on a variety of platforms. The algorithm as adopted by NIST is referred to as the Advanced Encryption Standard (AES), and it is described in detail in FIPS 197 (Dec. 2001). An overview of the algorithm is given here to contrast it with the DES algorithm described above. The algorithm supports key lengths of 128, 192, and 256 bits. While the original Rijndael algorithm was designed to support block lengths 128, 192, and 256, only the data block length 128 is supported in the current standard.

The algorithm is byte- and word-oriented (4 bytes to a word) and involves two types of arithmetic. For arithmetic on bytes, the 8-bit sequence $(a_0, a_1, \ldots, a_7)$ is interpreted as the polynomial $a(x) = a_0 + a_1x + a_2x^2 + \cdots + a_7x^7$. Arithmetic in the finite field with 256 elements, $\mathbb{F}_{2^8}$, is taken as the arithmetic of polynomials of degree <8 over $\mathbb{F}_2$, modulo the irreducible polynomial $m(x) = 1 + x + x^3 + x^4 + x^8$. In particular, the inverse of a byte is defined for all nonzero bytes (the inverse of the all-zero byte, when called for in the algorithm, is taken as the all-zero byte). The second type of arithmetic involves arithmetic on polynomials with byte coefficients. The array of bytes $\{b_0, b_1, b_2, b_3\}$ is equated with the polynomial $b(x) = b_0 + b_1x + b_2x^2 + b_3x^3$. Arithmetic on such polynomials is taken modulo the (reducible) polynomial $M(x) = x^4 + 1$.

Using these arithmetics, the encryption algorithm is briefly described. Assume a key and block length of 128 bits; the algorithm for the other key sizes is easily derived from this. A *state* matrix is first defined as a 4×4 matrix with each entry a byte, and this is initially set to the input block to be encrypted, the matrix filled in by the data bytes down columns. The state matrix is continually modified at each step of the algorithm, with the final state matrix containing the output ciphertext block. The algorithm uses four basic operations (three described here and the fourth, in the next paragraph): (1) for each byte in the state matrix a *SubBytes* operation is defined as an affine transformation that replaces the byte $b = (b_0, b_1, \ldots, b_7)$ by $b' = (b'_0, b'_1, \ldots, b'_7)$, where $b' = Ab + c$, where A is a circulant matrix with first row [10001111] (as bits) and where the vector c is [11000110]; (2) a *ShiftRows* operation on the state matrix is defined as shifting row i of the matrix i positions to the left, cyclically, for rows $i = 0, 1, 2, 3$; and (3) the last operation, *MixColumns*, is defined on the columns of the state matrix by replacing a column that has a polynomial representation $a(x) = a_0 + a_1x + a_2x^2 + a_3x^3$ (a_i a byte) and multiplying it by the (fixed) polynomial $c(x) = c_0 + c_1x + c_2x^2 + c_3x^3$ modulo $M(x)$ where, in hexadecimal notation $c_0 = 0 \times$ '02', $c_1 = 0 \times$ '01', $c_2 = 0 \times$ '01', $c_3 = 0 \times$ '03' (e.g., $c_3 = [00000011]$).

Finally the encryption process requires the derivation of a number of rounds $N_r + 1$ of a key schedule $K[i]$, $i = 0, 1, \ldots, N_r$. The number of rounds required depends on the key size and is 10, 12, and 14 depending on whether the key size is 4, 6, or 8 words in length. The precise generation of the key rounds from the original key is mechanical and is not described here. Suffice it to say that at the ith round a 4×4 matrix of bytes, $K[i]$, is generated and this matrix is added to the state matrix under byte addition (XOR), in the operation referred to as *AddRoundKey*.

With the operations described, the encryption algorithm is simply described as follows; recall that the initial state matrix is the 128 bits of the data to be encrypted fed in byte-wise down columns:

```
AddRoundKey (state, K[0])
for (i = 1 to Nr − 1) do {
   SubBytes (state);
   ShiftRows (state);
   MixColumns (state);
   AddRoundKey (state, K[i]);
   }
SubBytes (state);
ShiftRows (state);
AddRoundKey (state, K[ Nr]);
```

The encrypted output block is then the state matrix. The decryption process is similar in structure.

The AES will be the block encipherment algorithm of choice for the foreseeable future. Because of the varying block and key lengths, the modes of operation for AES are still under consideration and a *counter* mode has been added to the four standard modes mentioned previously. As with any block cipher, the last block is padded in an appropriate manner to round the data sequence out to an integral number of blocks.

There are numerous other block ciphers in use, some in the public domain and others proprietary [7]. While some may have specific advantages such as speed, use of AES will likely dominate the future of block encryption.

2.2. Stream Ciphers

From an information-theoretic point of view, the only secure cipher is a one-time pad, where purely random bits are recorded and given to the transmitter and receiver. These bits may then be XORed to the bits of the message to form the ciphertext. The plaintext can then be recovered at the receiver by XORing the ciphertexts with the one-time pad bits. Stream ciphers attempt, in some sense, to emulate this situation. More complicated operations than XORing might also be used. A general additive stream cipher is shown in Fig. 3. Here the key K may be the initial

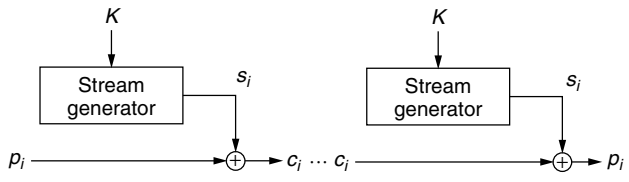

Figure 3. Configuration for an additive stream cipher.

state of the circuit used to generate the bit stream. Clearly the machines at the transmitter and receiver must be initially in the same state to generate the same sequence, allowing the plaintext to be recovered at the receiver.

There is a wealth of literature on the generation of suitable sequences. Many, if not most, of these techniques use maximum-length shift register sequences in some manner. As shown in Fig. 4, these sequences are generated by a shift register of length n, say, where the linear feedback connections are determined by a certain type of polynomial, a primitive polynomial, over the field of two elements, $\mathbb{F}_2$. Tables of such polynomials exist to quite high degrees. Clearly the sequences, coming from a deterministic circuit with a finite number of states, must be periodic. For a given shift register length, these sequences have the maximum length possible, $2^n - 1$ for a register of length n. Such sequences themselves are not secure — it is known the feedback connections of the register may be determined from knowledge of approximately $2n$ bits. However, the outputs of several such registers may be combined in a highly nonlinear Boolean function to produce a binary sequence of much greater complexity more suitable for cryptographic applications.

As noted, such stream ciphers are attractive in some applications for their high speed and relatively low circuit complexity. They have been incorporated in some standards, although many systems use proprietary generation techniques.

3. THE COMPLEXITY OF CERTAIN MATHEMATICAL PROBLEMS

Public key cryptography depends very much on the computational complexity of certain mathematical problems using the currently best known algorithms to solve them, which gives a notion of computational security. A few of the most important such problems, in terms of their use in public key cryptography, are reviewed here. Specifically these will be the problems of integer factorization, modular discrete logarithms, and modular square roots. Only the discrete logarithm problem will be considered in any detail. Informally we classify a problem as being *computationally feasible* or easy, if it is likely that a presumed attacker will have the resources to solve the system in a reasonable amount of time. Otherwise we refer to a problem as being *computationally infeasible*.

A *one-way function* f [5] is one for which it is "easy" to compute $f(x)$ for all elements in its domain X but for a randomly selected value $y \in \mathrm{Im}(f)$ it is computationally infeasible to find a value $x \in X$ such that $f(x) = y$. A *trapdoor one-way function* is a one-way function for which, given some extra information, it becomes computationally feasible to find such a value of $x \in X$, where the trapdoor information is independent of x.

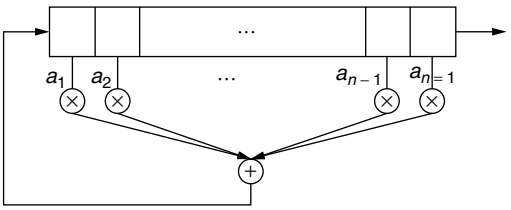

Figure 4. An LFSR for the polynomial $f(x) = a_0 + a_1 x + \cdots + a_{n-1}x^{n-1} + x^n$.

A measure of the computational complexity of the problems that will be of interest for the problems considered, is

$$L_n(a, c) = O(\exp(c + o(1)[(\log(n))^a (\log\log(n))^{1-a}]))$$

where $O(\cdot)$ and $o(\cdot)$ are the standard complexity notation. This function is referred to as *subexponential* in $\log(n)$ since if $a = 1$ it is exponential in $\log(n)$ and if $a = 0$ it is polynomial in $\log(n)$.

The difficulty of factoring an integer plays a central role in many public key systems. It might be argued the hardest integers of a given size to factor are integers that are the product of two large primes of approximately the same size, $n = pq$, where p and q are primes on the order of $\sqrt{n}$. The most efficient factoring algorithm currently, to factor a general integer (one with no special structure), is the general number field sieve (NFS). It has a conjectured complexity [5] of $L_n\left(\frac{1}{3}, c\right)$, where $c = \left(\frac{64}{9}\right)^{1/3}$ in both time and space. The NFS continues to be developed.

The problem of determining square roots in $\mathbb{Z}_n^*$, the group of units of $\mathbb{Z}_n$, where $n = pq$ is the product of two odd primes, is formally equivalent to factoring n of such form. It can also be shown there are efficient algorithms for determining square roots modulo a prime number and for primes of the form $p \equiv 3 \pmod 4$ they are particularly so. In fact a solution to the equation $x^2 \equiv a \pmod p$ for $p \equiv 3 \pmod 4$, when a is a square $(\mathrm{mod}\ p)$, is given by [5]

$$u \equiv \pm a^{(p+1)/4} \pmod p$$

An efficient nondeterministic algorithm for finding such square roots exists for any prime. Determining square roots modulo the product of two primes is also easily accomplished if the two primes are known. For instance, if $n = pq$, p and q primes, to solve the equation $x^2 \equiv a \pmod n$, one first solves it modulo p, then modulo q and combines the solutions by use of the Chinese remainder theorem to determine the (four) solutions modulo n, assuming that the equation has solutions both modulo p and modulo q. Thus determining solutions modulo n is a simple computation if the factorization of n is known. It is surprising, then, that the problem is equivalent to factoring n when the factorization of n is not known, since the factoring problem is a known difficult problem for integers of the assumed form. This is an example of a trapdoor one-way function.

To discuss the discrete logarithm problem (DLP) in prime fields, consider the multiplicative group of the integers modulo a large prime p, $\mathbb{F}_p^*$ and let $\alpha \in \mathbb{F}_p^*$ be a primitive element, namely, an element of order $p - 1$. The discrete logarithm problem in $\mathbb{F}_p^*$ is then

$$\text{DLP: Given } \alpha,\ p,\ \text{and } y = \alpha^x \pmod p,\ \text{find } x \pmod{p-1}$$

While the most efficient algorithm currently available to solve the DLP is an adaptation of the number field sieve

algorithm mentioned previously for factoring integers, a simpler algorithm, referred to as the *index calculus method*, is briefly discussed here. In fact, similar algorithms can be applied to the discrete logarithm problem in any algebraic structure that possesses a norm. In the case of the integers modulo a prime, $\mathbb{F}_p^*$, the first phase of the algorithm considers a *factor base*, $\mathcal{D}$, consisting of all the prime numbers less than some suitably chosen bound, often several hundred thousand. It attempts to establish a sufficient number of random relations between the discrete logarithms of primes in $\mathcal{D}$. One method, for example, might be to choose random powers of the primitive element α, say, $\alpha^u \in \mathbb{F}_p^*$, for randomly chosen u, and determine whether this integer factors in $\mathcal{D}$. If it does, an equation is obtained that relates u with the discrete logs of elements in $\mathcal{D}$. Such an integer would be called *smooth* with respect to the bound on $\mathcal{D}$. If a sufficient number of such relations are found (at least $|\mathcal{D}|$), then matrix reduction techniques should determine the logarithms of all elements in $\mathcal{D}$.

In the second phase of the algorithm, one attempts to find the log of the given element y by multiplying it successively by a random power of α (to yield, say, $w = \alpha^v y \in \mathbb{F}_p^*$) and determine whether it factors entirely over the factor base. If it does, the logarithm of w and hence of y can be found.

This simple idea has turned out to be a powerful one and is the basis of most of the current most effective algorithms for both the DLP and integer factoring. It turns out that most algorithms designed to factor integers can be modified to find discrete logarithms. The current most efficient algorithm to determine logarithms is the number field sieve and it has a conjectured complexity in both time and space of $L_n\left(\frac{1}{3}, c\right)$, where $c \approx \left(\frac{64}{9}\right)^{1/3} \approx 1.923$ the same as the integer factorization problem.

The discrete logarithm problem can take place in any Abelian group and typically, for reasons of security and efficiency, it is possible to reduce it to being in a cyclic group of prime order.

There is an additive version of the DLP, which is briefly described since it is finding increasing favor for cryptography on small devices. The set of solutions to an elliptic curve can be shown to be an Abelian group under point addition. In the case of a curve over a prime field $\mathbb{F}_p$ such a curve can, without loss of generality, be taken to be of the form

$$y^2 = x^3 + ax + b$$

and the Abelian group consists of the points (x, y) satisfying this equation, together with a point at infinity. The operation of point addition is very natural and is discussed here only for the case of $\mathbb{F}_p$.

Another type of finite field, one of characteristic two, is also popular for cryptographic applications and the equations of the curve and for point addition are slightly different for that case. The addition stems from the observation that if a straight line intersects the curve in at least two points, there is a unique third point of intersection. The situation is depicted in the Fig. 5.

For the last equation above, let $E_{a,b}(\mathbb{F}_p) = \{(x, y) \mid y^2 = x^3 + ax + b\}$ and let $P_1 = (x_1, y_1)$, $-P_1 = (x_1, -y_1)$ and $P_3 = (x_3, y_3) = P_1 + P_2$. If $P_1 \neq P_2$ define $\lambda = (y_2 - y_1)/(x_2 - x_1)$,

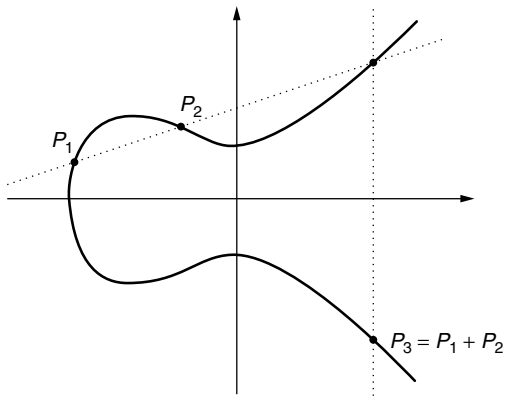

Figure 5. Elliptic curve addition.

$x_1 \neq x_2$, then $x_3 = \lambda^2 - x_1 - x_2$ and $y_3 = (x_1 - x_3)\lambda - y_1$. Similar equations hold if $P_1 = P_2$, in which case the line through the points is a tangent and the addition is referred to as a *point doubling*.

With this notion of point addition, for a given point $P = (x, y)$ one defines a general point multiple $k \cdot P = Q$ and the DLP in this setting is, given Q and P (as well as p and the curve equation), find k. This will be referred to as the ECDLP. The interesting aspect of this problem, for carefully chosen curves, is that no notion of smoothness has been found and hence we have been unable to formulate an index calculus attack on such a problem. As a consequence, the complexity of this ECDLP problem (on carefully chosen curves) is $O(\sqrt{p})$, which is considerably greater than the equivalent DLP in $\mathbb{F}_p^*$. Hence the ECDLP on an elliptic curve over $\mathbb{F}_p$ appears to be a considerably more difficult problem than the DLP in $\mathbb{F}_p^*$ for the same size prime. An implication of this is that the ECDLP on an elliptic curve over $\mathbb{F}_p$ can be used with a much smaller field size, for the same level of security as the DLP in $\mathbb{F}_p^*$.

The subject of elliptic curves has been of interest to mathematicians for over a century and is a deep and fascinating area of research. To use elliptic curves for cryptography it is necessary to know the order of the cyclic subgroup to be used. This requires determining the exact number of points on the elliptic curve and the factorization of this number, from which the order of the subgroup can be found. An important result in this direction is the Hasse–Weil theorem which says that $\#E_{a,b}(\mathbb{F}_p) \in (p + 1 \pm 2\sqrt{p})$. Once the order of the group is known, it is often straightforward to determine a generating point for the cyclic subgroup to be used.

In the following sections the three problems noted here will be used in various cryptographic protocols. The next section discusses the important problem of key exchange.

4. KEY EXCHANGE

In a network environment with a large user community, the use of a symmetric key cryptosystem such as AES described earlier, introduces the problem of establishing unique common keys between each pair of users. A solution to this problem, now in almost universal use in one form or another, is the Diffie–Hellman (DH) key exchange introduced in their 1976 paper [1], based on the discrete

logarithm problem. A version of the protocol in $\mathbb{F}_p$ is as follows. Given public information p, a prime, and $\alpha \in \mathbb{F}_p$, a primitive element, user A generates a random $a \in [1, p-1]$ and computes α^a which is sent to user B. User B chooses $b \in [0, p-1]$ at random and sends α^b to A. Both parties are now able to compute α^{ab}, which is now used to form the common key. Typically this might be used to encrypt larger messages with a faster symmetric key cryptosystem.

An eavesdropper observing the information transmissions in this protocol sees α^a, α^b and would like to compute α^{ab} and this is referred to as the *Diffie–Hellman problem* (DHP). Certainly if one is able to compute discrete logarithms in $\mathbb{F}_p$, then this can be accomplished. The more general question as to whether the DHP and DLP are computationally equivalent problems remains open, although some progress has been reported in special cases.

It is clear that the DH protocol can take place in any group, for example, the additive group of the points on an elliptic curve. In this structure the DH protocol (ECDH) is, for a fixed curve and point P on the curve of known order, all public information, user A transmits aP to A and receives bP from which the common key abP is computed by both users. The previous comments on the security of the system, specifically, the complexity of the ECDLP problem, as compared to the DLP in $\mathbb{F}_p^*$, apply to this case as well. For security reasons, the cyclic group is always taken to have prime order since any small factors of the group order tend to weaken the system for the given bit length.

A weakness of the DH key exchange protocol is the *person-in-the-middle attack*, where a user E inserts herself in the middle; users A and B believe they are exchanging keys with each other but in fact are each exchanging keys with E in the middle. The remedy for such an attack is to use an *authenticated key exchange*, where some public and private information as exists with a public key system, discussed in the next section, is incorporated in the key exchange to authenticate the user identity.

The key management problem extends far beyond the simple key exchange protocol noted above. In a large user community of users, the use, distribution, and management of keys is a critical aspect of system operation. Questions of the privileges associated with keys, the revocation and updating of keys, the generation and storage of keys, and so on are all vital aspects of the problem.

5. ASYMMETRIC OR PUBLIC KEY CRYPTOGRAPHY

The notions of public key cryptography, where the encrypting and decrypting keys are different, were introduced in the landmark paper of Diffie and Hellman mentioned previously. The paper included applications as to what might be achieved with such an asymmetric system under certain assumptions. These included the notion of one-way authentication and digital signatures as well as the use of the discrete logarithm for DH key exchange discussed earlier.

Apart from the results in that paper, perhaps the most important public key system is the RSA system. To introduce this system let $\mathbb{Z}_n$ denote the set of integers modulo the positive integer n, $\mathbb{Z}_n = \{0, 1, 2, \ldots, n-1\}$. Let $\mathbb{Z}_n^*$ denote the set of invertible elements in $\mathbb{Z}_n$, namely, those elements in $\mathbb{Z}_n$ that have a gcd with n of 1:

$$\mathbb{Z}_n^* = \{x \in \mathbb{Z}_n \mid \gcd(x, n) = 1\}$$

Such a set forms a multiplicative group, the group of units of $\mathbb{Z}_n$ and has order $\phi(n)$, where $\phi(\cdot)$ is the Euler phi function. For an arbitrary positive integer n with prime factorization $n = \prod_i p_i^{e_i}$, e_i a positive integer, $\phi(n) = \prod_i p_i^{e_i - 1}(p_i - 1)$. Euler's theorem then states that:

$$a^{\phi(n)} \equiv 1 \pmod{n}, \qquad a \in \mathbb{Z}_n^*$$

It is actually true that $a^r \equiv a^s \pmod{n}$ for all $r \equiv s \pmod{\phi(n)}$ and all $a \in \mathbb{Z}_n$. The case of interest for the RSA system is when $n = pq$, where p and q are large primes on the order of $\sqrt{n}$. An encryption exponent $e \in \mathbb{Z}_{\phi(n)}^*$ is chosen and a decryption exponent d such that $ed \equiv 1 \pmod{\phi(n)}$ is computed. A message m is interpreted as an element in $\mathbb{Z}_n$ via a suitable embedding from the message space to the integers. The encryption of m is then

$$c \equiv m^e \pmod{n}$$

By Euler's theorem the decryption of c is

$$c^d \equiv m^{ed} \equiv m^{k\phi(n)+1} \equiv m \pmod{n}$$

for some integer k, and the message m is recovered. To use such a system, user A places in a public directory the information n_A, e_A, their RSA modulus and encrypting modulus, respectively. The user retains as secret information the factorization of n_A, p_A, q_A, and the decryption exponent d_A. Another user wishing to send a message to user A, sends $c_A \equiv m^{e_A} \pmod{n_A}$. As only user A knows the decryption exponent d_A, only they are able to decrypt the message.

The security of this system is believed, in general, to be equivalent to the difficulty in factoring the modulus n. Certainly if the decryption exponent can be found, the system is broken. If one is able to find $\phi(n)$, one can determine the decryption exponent and, indeed, factor the modulus. The system is an example of a trapdoor one-way function in that determining m from c is computationally infeasible for a properly chosen modulus and encryption exponent, but knowing the factorization of the modulus makes it easy.

Another public key encryption system based on the difficulty of finding square-roots modulus a composite number is the Rabin encryption scheme. Again, assume that user A publishes a modulus $n_A = p_A q_A, p_A, q_A$, primes, where n_A is placed in a public directory with user A's identity and the factorization is kept secret. Another user wishing to send $m \in \mathbb{Z}_n^*$ to A sends $c \equiv m^2 \pmod{n_A}$. User A, on receiving c, computes the square roots of c modulo the factors p_A and q_A, which is a simple task. The (four) square roots of $c \pmod{n}$ are then found by computing the square roots modulo p_A and modulo q_A and combining them via the CRT noted earlier. The correct square root is then found by context (it is unlikely that more than one of the square roots makes sense), or else some prearranged type

of message padding is used prior to encryption. As noted previously, the operation of finding modular square roots is a trapdoor one-way function in that finding square roots modulo n, a product of two primes, is formally equivalent to factoring if the factorization is not known, yet simple if the factorization is known.

The final public key encryption system discussed is that of ElGamal [2], based on the DLP. The DLP is a one-way function with no trapdoor and a little more work is needed to make a cryptosystem (i.e., an encryption system) out of it. User A's public key consists of a prime p_A, a primitive element α (or else a generator of a prime order cyclic subgroup) in $\mathbb{F}_{pA}$, and an element $y = \alpha^a \pmod{p_A}$ for a secret exponent a. For another user to send to user A an encrypted message m, assuming an element of $\mathbb{F}_p^*$, they first choose a random (one-time) integer $x \in [1, p-2]$ (where $[1, p-2]$ denotes the range of integers $\{1, 2, \ldots, p-2\}$) and compute $\gamma \equiv \alpha^k \pmod{p_A}$ and $\delta \equiv my^k \pmod{p_A}$. The ciphertext is then the pair of elements (γ, δ). Since user A knows the secret exponent a, they are able to compute $\gamma^{-a} \equiv \alpha^{-ak} \pmod{p_A}$ and then $\delta\alpha^{-ak} \equiv m \pmod{p_A}$. Notice the system has message expansion since two elements are passed to convey one message element.

These public key systems have uses well beyond the encryption functions outlined here. For example, while the Diffie–Hellman key exchange of the previous section requires two passes, with the notion of a public directory containing user public keys, a user can transport the key to be used in a symmetric system by encrypting with the intended users public key in a single pass. Other, more symmetric, protocols use the notion of public keys for authenticated key exchange to defeat the person-in-the-middle attack noted earlier. The public key systems also have critical properties that can be used for more general authentication and the establishment of trust in a network.

6. DIGITAL SIGNATURES AND HASH FUNCTIONS

The notion of a written signature is central to transactions of all kinds, especially to financial ones. Such signatures have characteristics in terms of forgeability and detection of forgeries that are central to many legalities. The idea of a digital signature is, in a sense, even stronger in that it is composed by a machine and constructing a forgery requires the solution of a computationally infeasible problem. It has obtained a legal standing in several countries in terms of acceptability in court actions.

To illustrate the notion of a digital signature, suppose that a message m can be embedded in some unique way into $\mathbb{Z}_n$. Let n_A, e_A, and d_A be the public and private parameters of user A's RSA system. For user A to sign the message m, the quantity $s_A(m) \equiv m^{d_A} \pmod{n_A}$ is computed as A's signature for m. Any other user may verify the signature by computing $s_A(m)^{e_A} \equiv m \pmod{n_A}$, thereby recovering the message at the same time. It is clear that only user A could have created the signature and that the signature is bound with the message m; thus, for example, the signature is invalid when associated with any other message. This is referred to as a *signature with message recovery* scheme since the message is recovered in the process of authenticating the signature.

This system has two disadvantages in that it required the message to be embedded into $\mathbb{Z}_n^*$, and so had to be relatively short to achieve this. In addition, the system described above is susceptible to an *existential forgery attack*, meaning that it is possible for an adversary to produce another bit stream, which is likely not intelligible as a real message, that has the same signature. To overcome both of these problems the notion of hash functions is introduced. A *hash function* is a mapping from binary strings of arbitrary length to strings of fixed length (usually much shorter than the original length, hence providing compression)

$$h: \{0,1\}^* \to \{0,1\}^n$$

$$x \mapsto h(x)$$

with certain properties. The function should be computationally efficient to compute on long strings. It should also have the property of being one-way in the sense that for any given hash value $y = h$ it should be computationally infeasible to determine any x, such that $y = h(x)$, since that would allow forgeries, for example, when the hash function is used for signature generation. This property is often referred to as *preimage resistance*. Furthermore it should have the property that, given x and $y = h(x)$, it should be computationally infeasible to find a second value x' so that $y = h(x) = h(x')$, sometimes referred to as *second preimage resistance*. A slightly different notion is that h is said to be *collision-resistant* if it is computationally infeasible to find any two inputs x, x' that hash to the same value.

The design of hash functions with these properties requires careful attention. There are many such hash functions, but perhaps the most widely used is the SHA-1 (secure hash algorithm) (FIPS 180-1, April 1995), a modification of the earlier FIPS 180. This produces a hash of length 160 bits and is mandated for use in the DSA (digital signature algorithm, to be discussed below). A new family of hash functions is currently under consideration, to be called SHA-256, SHA-384, and SHA-512 with the suffix indicating hash size, to be FIPS 180-2, currently in draft form. These increased size hash functions will be used in an updated DSA in the future.

To return to digital signatures, for user A to sign a long message m using RSA, one might first hash the message to produce $h(m)$, embed this hash value into the integers modulo n_A, and then sign by using as the signature $h(m)^{d_A} \pmod{n_A}$. In such a system, the message is no longer recovered when verifying the signature and so must be transmitted, usually in the clear, along with the message; that is the pair $(m, s_A(h(m)))$ is produced as the signed message by A and verified by any other user. Such a scheme is referred to [5] as a *signature with appendix*, where the signature is an appendix to the message.

Other signature schemes are also of importance. In particular the use of the DLP to produce signatures originated with the work of El Gamal [2]. Since the DLP is simply a one-way function with no trapdoor, more work is required to achieve a signature. In this scheme user A generates a large prime p and finds an α that generates $\mathbb{F}_p^*$. A random integer a is chosen, $y = \alpha^a \pmod{p}$ computed,

and the information (p, α, y) made public with a kept secret. To sign a message m, a random integer k is chosen in $[1, p-2]$ such that $\gcd(k, p-1) = 1$ and let k^{-1} be its inverse modulo $p-1$. The element $r = \alpha^k \in \mathbb{F}_p^*$ is formed and the integer $s \equiv (h(m) - ar)k^{-1} \pmod{p-1}$ computed. The signature for the message m is then the pair (r, s). The scheme is clearly a signature with appendix since it requires the message m to be transmitted in order for the signature to be verified.

To verify the signature, a user retrieves the public information of user A (p, α, y) from the public directory and, using the signature (r, s) and the message m computes

$$u \equiv y^r r^s \equiv \alpha^{ar}\alpha^{ks} \equiv \alpha^{ar+k(h(m)-ar)k^{-1}} \equiv \alpha^{h(m)} \pmod{p}.$$

The hash value $h(m)$ is computed independently and if $v \equiv \alpha^{h(m)}$ is equal to u, the signature is accepted.

This scheme is the forerunner of the Digital Signature Algorithm (Standard) (FIPS 186-2, Feb. 2000) to be described now. For the DSA each user chooses a prime number p with a number of bits $512 + 64\ell$, where ℓ is an integer between 1 and 8. A second prime q with 160 bits is chosen so that $q \mid p-1$ and α is chosen as a generator of the unique subgroup $\mathcal{G}$ of order q in $\mathbb{F}_p^*$. An integer a is chosen and $y = \alpha^a \pmod{p}$. User A's public information is then (p,q,α,y), and secret information is the integer a. From this point the DSA is very similar to the El Gamal signature scheme. A random integer k is chosen in $[1, q-1]$ and $r \equiv (\alpha^k \pmod{p}) \pmod{q}$; thus the element is first taken modulo p and then modulo q. The signature for message m is then the pair (r, s), where $s \equiv k^{-1}(h(m) + ar) \pmod{q}$. The verification is very much as with El Gamal. The point of this system, first suggested by Schnorr, is that even though the cyclic group in which the signature takes place, $\mathcal{G}$ is of order q, the arithmetic in the subgroup is in $\mathbb{F}_p^*$; that is, it is modulo p arithmetic. Any attempt to break this system would also take place in modulo p arithmetic, which is more difficult since p is very much larger than q.

There is also a version of the DSA, in the FIPS 186-2, which uses elliptic curves, referred to as ECDSA. In this system, restricting attention to curves over $\mathbb{F}_p$ as before, let E be an elliptic curve and $P = (x, y)$ a point of prime order q with both the curve parameters, where point P and q represent public information. User A chooses a random integer $a \in [1, q-1]$ and computes $Q = aP$, which is user A's public key; a is maintained secret. To sign a message m a random integer k in $[1, q-1]$ is chosen and $kP = (x_1, y_1)$ computed. Let $x \equiv x_1 \pmod{q}$, recalling that $x_1 \in \mathbb{F}_p$. The signature for the message m is then (r, s), where $s \equiv k^{-1}(h(m) + xr) \pmod{q}$ and if either r or s are 0, the procedure is run again.

To verify the signature, the user obtains A's public key Q and from the accompanying cleartext message m computes $h(m)$. With r, s and $h(m)$ as integers modulo q, the quantities $u \equiv h(m)s^{-1} \pmod{q}$ and $v \equiv rs^{-1} \pmod{q}$ are computed and the point multiple $uP + vQ = s^{-1}(h(m) + rx)P = k \cdot P = (x_2, y_2)$ found. If $x_2 \equiv r \pmod{q}$, the signature is accepted.

The secret keys a and k in the El Gamal, DSA, and ECDSA schemes are referred to as "static keys" and "ephemeral keys," respectively. In particular it is important that the ephemeral keys k be chosen independently and randomly for each message to be signed.

7. AUTHENTICATION AND IDENTIFICATION

The problem of establishing trust in a network environment is central to the application of public key cryptography. The trust includes not only the integrity of a datastream but also the identity of the person communicating. A very large number of techniques are available to address these and similar problems. This section is a brief introduction to some of these.

A simple *manipulation detection code* (MDC) is typically a short appendix to the message formed by an unkeyed hash function. Its only purpose is to detect whether any changes have occurred in the message portion of the transmission, that is, to determine message integrity. If any changes have occurred then with very high probability the MDC computed at the receiver will differ from the appendix attached. A *message authentication code* (MAC) is similar except that the hash function used is keyed, thereby allowing for the verification of the sender, since it is assumed the sender and receiver are in possession of a common key and that it is computationally infeasible for anyone without the key to compute the hash appendix.

The constructions of either type of code begins with a hash function, such as SHA-1 mentioned earlier. A MAC, however, requires the incorporation of a key in some manner and experience has shown that this must be done very carefully — several such hash functions have been broken when subtle faults in their construction were found. A particular type of MAC is the *keyed hash MAC* or HMAC, currently in draft for a FIPS. It recommends the following construction, using any FIPS-approved hash function. For an input block size of B bytes to the hash function (e.g., for SHA-1 $B = 64$), construct an *ipad* of B bytes consisting of the byte (in hexadecimal) of $0 \times$ '36' and an *opad* consisting of the byte $0 \times$ '5c' each repeated B times. If K is the secret shared key, let K_0 be K with zeros appended to form a B byte key. The recommended formation of the HMAC is then the leftmost t bytes of the hash value

$$H((K_0 \oplus opad) \| H((K_0 \oplus ipad) \| text))$$

where $\|$ indicates catenation.

The subject of MACs is much wider than touched on here with many such constructions and concepts used. However, most of them share common features with the above.

Most approaches to the establishment of trust in a network involve public key concepts and the use of a *central authority* (CA) [these are also referred to as a *trusted third party* (TTP) or *trusted authority* (TA)]. The idea here is for the CA to have a public and a private key, with the public key known to all subscribers of the network. The CA establishes in some secure manner the identity of a user and their public key and binds the two together by encrypting the pair with the CA's private key. This is a simple example of a certificate — typically such certificates include other information such as level of authority

given to the individual and time limit for validity of the certificate. The crucial point here is that the CA has verified the information relating the identity of the individual and their public key and bound it together with the CA's private key, as for a signature. Anyone who has received the certificate can verify the information by use of the CA's public key and can assume that the information is as reliable as the CA. The construction of certificates and their maintenance and issuance to clients is the idea behind a *public key infrastructure* (PKI). A client of the PKI may request a certificate for any user in the system thereby assuring identity.

Many cryptographic protocols rely on the existence of a CA, although sometimes the requirements of the protocol are less than the need for a full CA. As an example, consider the Diffie–Hellman key exchange described earlier. It was noted it is susceptible to the person-in-the-middle attack where a third party injects themselves in between users A and B, who end up communicating with each other through the third party, C, who controls the flow of information. A remedy for this situation is the use of a CA where each user obtains sufficient information from the CA and the common key is established using both private and public information of both users. Such a scheme is termed an authenticated key exchange protocol, noted earlier.

Identification protocols [5] usually involve the notions of what a person knows [e.g., a PIN (personal identification number) for an ATM card], what they have (the ATM card with their account number and name on it) and a physical attribute (such as fingerprint, ocular iris characteristics, facial features, and even DNA). Two identification protocols are briefly described here for the interesting features they introduce. Both require the use of a CA although not explicitly the notions of certificates.

In the Schnorr identification protocol ([5,9]), the CA chooses a large prime q such that q is a large divisor of $p-1$ and α is an element in $\mathbb{Z}_p$ of order q. The CA has a public and private key, which allows the creation of signatures for information, $s_{CA}(\cdot)$, and the creation of certificates, $C_{CA}(\cdot)$. Each user A chooses a random integer $a \in [1, q-1]$, a private key, and computes $v \equiv \alpha^{-a} \pmod{p}$ and v is sent to the CA, who creates the certificate $C_{CA} = (I(A), v, s_{CA}(I(A), v))$. For user A to identify his/herself to B, A chooses a random number $k \in [1, q-1]$ and sends $x \equiv \alpha^k \pmod{p}$ to B, along with his/her certificate. User B verifies the certificate, which has bound the public key of A, v, to his/her identity. User B then chooses a random integer $r \in [1, 2^t]$ for some suitably large integer t, say 2^{40} (t is referred to as the security parameter of the scheme), and sends it to user A. User A sends back $y \equiv k + ar \pmod{q}$, which is sent to B. User B then verifies that $\gamma \equiv \alpha^y v^r \pmod{p}$. The protocol uses, in an essential way, the notion of certificates and a CA to establish identity in a reliable manner.

The Fiat–Shamir identification protocol introduces the notions of a *zero-knowledge proof* and a *statistical, interactive proof* which consists of multiple rounds of a three-pass challenge–response protocol. It operates as follows (basic idea only). For user A to prove his/her identity to user B, the CA first chooses the (secret) primes p and q and publishes the modulus $n = pq$. Each user chooses a secret s relatively prime to n, $s \in [1, n-1]$ and registers $v \equiv s^2 \pmod{n}$ with the CA as its public key. For A to identify his/herself to B, the following three steps are performed (and repeated t times):

$$A \to B: x \equiv r^2 \pmod{n}$$

$$A \leftarrow B: e \in \{0, 1\}$$

$$A \to B: y \equiv rs^e \pmod{n}$$

The purpose of user B choosing e in the second step of the protocol is to prevent cheating by A in the sense that if user B always chose $e = 1$, then A could compute $x \equiv r^2/v$ and answer the challenge $e = 1$ with the correct answer $y \equiv r \pmod{n}$; thus, any user knowing s can always answer either challenge while another user can only answer the one question — hence an impostor has a probability of $\frac{1}{2}$ of answering a given question. Repeating this basic protocol t times reduces the probability of success by the impostor to less than $(\frac{1}{2})^t$.

This basic protocol, which can be made much more efficient [e.g., 5,9], illustrates the two notions of a statistical interactive proof and a zero-knowledge proof. The term *zero knowledge* refers to the fact that the protocol reveals no knowledge about the factorization of the modulus n or the value of a users secret key s except for the fact that the public modulus v is in fact a square modulo n.

Many more sophisticated zero-knowledge protocols exist with the preceding example a small introduction to the area.

8. PRIME-NUMBER GENERATION AND PSEUDORANDOMNESS

Much of public key cryptography depends on the difficulty of certain number theoretic problems, such as factoring, discrete logarithms, and taking modular square roots. The setup procedure for these problems invariably involves the generation of large primes, often of several hundred digits. Many standards suggest the use of probabilistic methods to achieve this, and perhaps the most commonly used of these techniques and the most efficient is the *Miller–Rabin* method, which is briefly described [e.g., 5].

In this method, as with many others, an integer n is chosen at random and tested for primality. By the *prime-number theorem*, if $\pi(x)$ is the number of primes less than x, then for large values of x this quantity is well approximated by $x/\ln x$. This gives an estimate of the number of trials that must be made to locate a prime; thus, in the neighborhood of n the average spacing between primes is approximately $\ln(n)$. To find a *probable prime* choose an integer n at random. It is often convenient to trial-divide n for a stored table of small primes to avoid work on integers that are thus easily dismissed. Let $n - 1 = 2^s r$, where $2 \nmid r$. Let a be a randomly chosen integer in $[1, n-2]$ and compute $y \equiv a^r \pmod{n}$. If $y \equiv \pm 1 \pmod{n}$, declare n to be prime. Otherwise if $y \not\equiv \pm 1 \pmod{n}$, then successively square $y \pmod{n}$ up to $s-1$ times. If the result of the squaring never results in $y \equiv \pm 1 \pmod{n}$, then n is declared composite. The procedure rests on the observation that if p is a prime, then for $p - 1 = 2^s r$, r odd, either $a^r \equiv 1 \pmod{n}$ or $a^{2^j r} \equiv -1 \pmod{n}$ for some $j \in [1, s-1]$.

An integer a that fails the test proves conclusively that the integer n is composite and is called a "witness" to the compositeness of n. It can be shown that the probability the test declares a composite number to be prime on any given trial is less than $\frac{1}{4}$. If the test is run t times the probability the test always declares a composite number a prime is less than $(1/4)^t$. Thus for $t = 40$, this probability is $1/2^{80}$, which is usually the recommended level of certainty in standards that suggest the use of this technique, for example, the DSA (FIPS 186-2). Primes produced with this test are termed *probable primes*.

The Miller–Rabin test produces a probably prime with a probability of failing so low that it is regarded as reliable and finds wide use in practice. Maurer [e.g., 5] has devised a test, however, that produces a *provable* prime in almost the time it takes to run one iteration of the Miller–Rabin test. It is based on a modification of Pocklington's theorem of computational number theory. While Maurer's technique on provable primes removes the uncertainty of primality inherent in the Miller–Rabin test, this latter test is still widely used, and with the number of iterations proposed for this test, it yields very acceptable results.

Another frequently needed facility in any cryptographic application is the ability to generate random or pseudorandom numbers. These are used to initialize many functions. Indeed, the security of a system might often be equated to the degree of uncertainty in the random seed. While pure random generators are to be preferred, these are usually only found in hardware devices and chips where the outputs of so-called noisy diodes are often used. Such systems invariably include self-checking devices to ensure that the system has not failed and is still producing sequences that pass recognized statistical tests. In software, it is desirable to use as many different sources of randomness available, such as time between keystrokes, and to put the catenation of such information through a hash function to produce a random seed for a random-number generator. This is still often the weakest point of security of the system. Many systems in use are proprietary, making an assessment of their security difficult.

A commonly used technique to produce pseudorandom numbers is the linear congruential technique. Typically these produce sequences of numbers from an initial seed x_0, often kept secret, with the recursion

$$x_n \equiv ax_{n-1} + b \pmod{m}$$

where a and b are fixed parameters and m is a modulus. Sequences derived from such a system are in fact predictable in that given a part of the sequence, the parameters can often be derived and the entire sequence generated. However, variations on these sequences are sometimes used. Typically it is required that the seed value be sufficiently large that an exhaustive search over all possibilities be infeasible. In addition it is required that the sequence pass statistical properties of randomness in that failure to do so may lead to ways of breaking the sequence.

Other pseudorandom bit generators can be formulated that depend on the use of one-way functions, for example, the Blum–Blum–Shub generator, which depends on modular square roots for its security. While very secure, such generators tend to be very inefficient.

9. COMMENTS

Current cryptographic research goes beyond the standard techniques discussed here and is concerned with applications that can be achieved with cryptographic techniques. A few examples of these are given. One such area is that of zero-knowledge proofs, noted briefly previously, where one user proves to a verifier that they are in possession of knowledge and proves to another that this is so without revealing any information. Protocols exist showing, for example, that a prover knows the discrete logarithm of a given element $y \in \mathbb{F}_p^*$ to some known base α, p also known, without revealing what the logarithm is. Similarly, it is possible to prove to a verifier that a given RSA modulus is indeed a product of two primes without revealing the factorization. Another such protocol shows how to compute an RSA modulus and an encryption exponent, among a number of parties without any of the parties knowing the factorization. At the same time each party obtains a share of the decryption exponent, which must be combined with other user shares to either create a signature or decrypt an encryption. Such a protocol is an example of a secure multiparty distributed computation, and many other such examples exist.

Electronic cash is a payment technique whereby a user is able to spend electronic cash obtained from a bank and spent at a store. The protocol preserves anonymity from the bank as to how the e-cash was spent and prevents double-spending of it by either the individual or the merchant. It involves the notion of a blind signature that also arises in the context of electronic voting. A distributed voting scheme has among its requirements the anonymity, the ability for any participant to verify the tally and the ability to ensure that no one votes more than once.

An example of the key exclusion problem is where a pay-TV provider encrypts a movie and provides sufficient information for those users who paid to decrypt the movie but those who did not pay cannot. Of course, the set of users who view each movie changes frequently, and the challenge is to derive an efficient scheme to achieve this. There is also a problem of "traitor tracing," whereby users who collaborate to form new valid keys can be detected and identified. The research on protocols shows a power and elegance that can be exploited to achieve interesting goals.

Perhaps the single topic of greatest interest to public key cryptography is that of quantum computation. While a description of the idea of a quantum computer is beyond the scope of this article, a few of the implications of the existence of such a computer might be mentioned, and for this the article by Gottesman and Lo [4] is used as a guide. The state of a quantum computer, rather than being a deterministic state as in a classical computer, is actually a superposition of exponentially many basis states, and each of these corresponds to a state of a classical computer of the same size. The result of this is that such a computer would take a very small amount of time to do tasks that are not possible to contemplate on a classical computer. In a celebrated result, Peter Shor of AT&T Laboratories has shown that the two problems of central interest in

cryptography, integer factoring and discrete logarithms, have a complexity in the quantum computing model that is polynomial in the integer lengths, rather than the subexponential complexity, $L(\frac{1}{3}, c)$, mentioned earlier, for the conventional computing model. In a similarly spectacular result, Grover of Bell Laboratories (Lucent Technologies), has shown that a searching algorithm to find one of N items has a classical complexity of order N but a quantum algorithm of complexity of order $\sqrt{N}$. This fact could, for example, be used to search for keys for a block cipher. While a quantum computer has not yet been constructed, informed opinion considers them likely and indeed several corporations are in the process of attempting to construct them. The implications for cryptography are quite clear. Without the notions of one-way functions, the field would have to reconstitute itself in a very different direction.

In spite of the results noted above, it has also been shown that quantum key distribution using quantum systems is entirely practical, and indeed such systems have been successfully constructed and demonstrated by several research groups around the world. While such systems have been shown to be theoretically secure, it is not yet clear how they might withstand practical attacks.

Other aspects of quantum cryptography have been investigated, and some, like quantum bit commitment, have been shown to be insecure. It is clear that quantum computing will have an important impact on cryptography although at this point it is not quite clear precisely what this impact will be.

BIOGRAPHY

Ian F. Blake received his undergraduate education at Queen's University in Kingston, Ontario and his Ph.D. at Princeton University in New Jersey. From 1967 to 1969 he was a Research Associate with the Jet Propulsion Laboratories in Pasadena, California. From 1969 to 1996 he was with the Department of Electrical and Computer Engineering at the University of Waterloo, in Waterloo, Ontario, where he was Chairman from 1978 to 1984 and Director of the Institute of Computer Research from 1990 to 1994. He is currently with the Department of Electrical and Computer Engineering at the University of Toronto, where he is Director of the Bell University Labs program.

His research interests are in the areas of cryptography, algebraic coding theory, digital communications, and spread-spectrum systems.

CYCLIC CODES

STEPHEN B. WICKER
Cornell University
Ithaca, New York

1. INTRODUCTION

Cyclic codes are a class of highly structured algebraic block error control codes. This class includes Golay, BCH (Bose–Chaudhuri–Hocquenghem), and Reed–Solomon codes — codes that have arguably seen greater application than any other error control codes save the simple parity check. A Reed–Solomon decoder, for example, can be found in every compact-disk player. Golay, BCH, and Reed–Solomon codes have also been used in paging, mobile data systems, and deep-space telecommunications. Such cyclic codes have become an important basis for practical error control for a variety of reasons. First, they can be implemented using shift-register-based encoders and decoders, implementations that are of particular importance in high-speed data communication systems. Also, nonbinary cyclic codes, such as Reed–Solomon codes, provide a form of error trapping that is highly effective on fading channels. For this reason alone, Reed–Solomon codes have been used extensively in wireless data applications. In this article I will describe the structure of cyclic codes, paying particular attention to the special cases of Golay, BCH, and Reed–Solomon codes. I will mention several theoretical results, but will provide no proofs — the mathematically inclined reader is referred to Wicker [1] or Lin and Costello [2]. The true disciple is referred to MacWilliams and Sloane [3].

I begin with an historical overview. The general class of cyclic codes was first discussed in a series of technical notes and reports published from 1957 to 1959 by E. Prange at the Air Force Cambridge Research Labs [4–6]. In his work Prange identified cyclic codes with an algebraic structure called an "ideal," a connection that would lead to the development of BCH codes and a reinterpretation of Golay and Reed–Solomon codes a few years later.

Prange himself introduced a class of cyclic codes whose construction is based on quadratic residues. Quadratic residue (QR) codes are linear cyclic codes that generally have rates close to $\frac{1}{2}$ and have large minimum distances. A great deal of recent work on algebraic decoding algorithms for quadratic residue codes has increased their utility in a number of applications [e.g., 7,8].

Prange's work on QR codes showed that they include a small but very important group of codes — the Golay codes — that had been discovered almost 10 years earlier. In his 1948 paper that, among other things, gave birth to the field of information theory, Shannon gave a brief description of Hamming's perfect [7,4] binary code [9]. A code is said to be perfect if it has the maximum possible number of code words for a given error-correcting capability. After reading Shannon's paper, a number of people began searching for other perfect codes, with varying degrees of success. Golay, an engineer at the Signal Corps Engineering Laboratories in Fort Monmouth, New Jersey, published one of the first follow-up papers in June, 1949 [10]. In what is almost certainly the best short paper ever written (it fits on one side of an $8\frac{1}{2} \times 11$-in. sheet of paper, with room to spare), Golay extended the (7,4) Hamming code to a general class of p-ary codes of length $(p^n - 1)/(p - 1)$, where p is a prime.[1] In this same paper, Golay went on to describe a binary triple-error-correcting code and a ternary double-error-correcting code, both of which are perfect. Golay deduced the existence of the Golay codes through an examination of Pascal's triangle and the recognition of the relationship between the triangle's entries and the parameters of perfect codes. He then proceeded to find what we now call the Golay codes through a "limited search" of the triangle. The resulting code has served as fodder for specialists in abstract algebra and combinatorics ever since. On the practical side, Golay codes have seen frequent application in the United States space program, most notably with the *Voyager* I and II spacecraft. The extended binary Golay code served as the primary *Voyager* error control system, providing clear color pictures of Jupiter and Saturn between 1979 and 1981.[2] Golay codes were also used as the basis for a paging standard (called, not surprisingly, Golay).

Several efficient decoding algorithms for the Golay codes have been discovered. The most important was discovered in 1964, when Kasami described a shift register-based "error trapping" decoder [11]. The error trapping decoder is an extension of the shift register decoding techniques that will be discussed in this article.

The next subclass of cyclic codes that I will consider in detail is the BCH codes. Two independent research teams conducted the fundamental work on BCH codes and published their results at roughly the same time. A. Hocquenghem discussed binary BCH codes as "a generalization of Hamming's work" in a 1959 paper entitled "Codes correcteur d'erreurs" [12]. This was followed in March and September 1960 by Bose and Ray-Chaudhuri's publications on error-correcting binary group codes [13,14]. Given their simultaneous discovery of these codes, all three have given their name to what are now called BCH codes. Shortly after these initial publications, Peterson proved that BCH codes were cyclic and presented a moderately efficient decoding algorithm [15]. Gorenstein and Zierler then extended BCH codes from the binary field to arbitrary fields of size p^m, where p is a prime number [16].

Reed-Solomon codes were first described in a June 1960 paper entitled "Polynomial codes over certain finite fields," published in the *SIAM Journal on Applied Mathematics* by Irving Reed and Gus Solomon [17]. Through the work of Gorenstein and Zierler it was later discovered that Reed–Solomon codes and BCH codes are closely related, and that Reed–Solomon codes can be described as nonbinary BCH codes.

In 1960 Peterson provided the first explicit description of a decoding algorithm for binary BCH codes [15]. His "direct solution" algorithm is quite useful for correcting small numbers of errors, but becomes computationally intractable as the number of errors increases. Reed and Solomon discussed a decoding algorithm in their original paper on Reed–Solomon codes [17], but that algorithm was also inefficient for large codes and large numbers of errors corrected. Peterson's algorithm was improved and extended to nonbinary codes by Gorenstein and Zierler [16], Chien [21], and Forney [22], but it was not until 1967 that Berlekamp introduced the first truly efficient decoding algorithm for both binary and nonbinary BCH codes [18]. In 1969 Massey showed that Berlekamp's algorithm was a general solution to the problem of synthesizing the shortest linear feedback shift register capable of generating a given sequence [23]. Massey then demonstrated a fast shift-register-based decoding algorithm for BCH and Reed–Solomon codes that is equivalent to Berlekamp's algorithm.

In 1975 Sugiyama et al. showed that Euclid's algorithm can be used to decode BCH and Reed–Solomon codes [24]. Reed et al. then showed in 1978 that a related technique based on continued fractions and Fermat-theoretic transforms resulted in a fast decoding algorithm for Reed–Solomon codes [25]. Completing the decoding picture, a frequency domain approach to decoding BCH codes was introduced by Gore in 1973 [26]. Blahut provided a more general discussion of spectral decoding techniques in 1979 [27].

In the remainder of this article, I will provide a brief overview of the general theory of cyclic codes, and then turn to the three important classes (the Golay codes, BCH, and Reed–Solomon codes). I will close with a discussion of several important applications.

2. GENERAL THEORY

A code is said to be cyclic if it satisfies a very simple property–every codeword must be the right cyclic shift of another codeword. More formally, an (n, k)[3] code $\boldsymbol{C}$ is said to be cyclic if for every codeword $\mathbf{c} = (c_0, c_1, \ldots, c_{n-2}, c_{n-1}) \in \boldsymbol{C}$, there is also a codeword $\mathbf{c}' = (c_{n-1}, c_0, \ldots, c_{n-3}, c_{n-2}) \in \boldsymbol{C}$. Since the codeword $\mathbf{c}$ in this definition has been

[1] It is a virtual certainty that this result was already known to Hamming [18]. A more detailed discussion of the general class of codes now known as *Hamming codes* is included in Hamming's 1950 paper [19], which was probably delayed due to patent considerations.

[2] A secondary error control system based on Reed–Solomon codes was substituted for the Golay system for the *Voyager* 2 flybys of Uranus and Neptune in the mid-1980s [20].

[3] In this article the usual conventions are adopted — an (n, k) code over GF(q) is a collection of vectors of length n that form a vector space of dimension k over the Galois field GF(q).

arbitrarily selected from among all the codewords in $\boldsymbol{C}$, it follows that all n of the distinct cyclic shifts of $\mathbf{c}$ must also be codewords in $\boldsymbol{C}$. To see this, replace $\mathbf{c}$ with $\mathbf{c}'$ and apply the definition again.

The key to the underlying structure of cyclic codes lies in the association of a *code polynomial* $c(x) = c_0 + c_1x + c_2x^2 + \cdots + c_{n-1}x^{n-1}$ with every codeword $\mathbf{c} = (c_0, c_1, \ldots, c_{n-2}, c_{n-1}) \in \boldsymbol{C}$. If C is an (n, k) code over Galios Field GF(q), it follows that the set of code polynomials associated with $\boldsymbol{C}$ form a vector space as well. The terms *codeword* and *code polynomial* are henceforth used interchangeably. When we look at the definition of cyclic in terms of the code polynomials, some interesting structure comes to light. If the code word $\mathbf{c}'$ is the right cyclic shift of the code word $\mathbf{c} \in \boldsymbol{C}$, then $c'(x) = x \cdot c(x)$ modulo $(x^n - 1) \in \boldsymbol{C}$. This can be seen as follows.

Continuing along this line, we can show that two right cyclic shifts of a code word are equivalent to the multiplication modulo $(x^n - 1)$ of the associated code polynomial by x^2

$$\begin{aligned} x \cdot c(x) \bmod (x^n - 1) &= (c_0x + c_1x^2 + \cdots + c_{n-1}x^n) \bmod (x^n - 1) \\ &\equiv c_{n-1} + c_0x + \cdots + c_{n-2}x^{n-1} \\ &= c'(x) \end{aligned}$$

where three right cyclic shifts are equivalent to multiplication modulo $(x^n - 1)$ by x^3, and so on. Let the cyclic shifts of $\mathbf{c}$ and the associated polynomials be represented as follows.

$$\begin{aligned} \mathbf{c} &= (c_0, c_1, \ldots, c_{n-1}) \leftrightarrow c(x) = c_0 + c_1x + \cdots + c_{n-1}x^{n-1} \\ \mathbf{c}' &= (c_{n-1}, c_0, \ldots, c_{n-2}) \\ &\leftrightarrow c'(x) = c_{n-1} + c_0x + \cdots + c_{n-2}x^{n-1} \\ \mathbf{c}'' &= (c_{n-1}, c_0, \ldots, c_{n-2}) \\ &\leftrightarrow c''(x) = c_{n-2} + c_{n-1}x + \cdots + c_{n-3}x^{n-1} \\ &\vdots \\ \mathbf{c}^{(n-1)} &= (c_{n-1}, c_0, \ldots, c_{n-2}) \\ &\leftrightarrow c^{(n-1)}(x) = c_1 + c_2x + \cdots + c_0x^{n-1} \end{aligned}$$

Let $a(x) = a_0 + a_1x + a_2x^2 + \cdots + a_{n-1}x^{n-1}$ be an arbitrary polynomial in GF(q)[x]/$(x^n - 1)$ [the ring of polynomials with coefficients in GF(q) and maximum degree $n - 1$]. The product $a(x)c(x)$ is a linear combination of cyclic shifts of $\mathbf{c}$. Since $\boldsymbol{C}$ forms a vector space, $a(x)c(x)$ must be a valid code polynomial. This result shows that the space formed by the code polynomials of $\boldsymbol{C}$ has an interesting structure — it is an *ideal* in the ring of polynomials of degree n or less with coefficients in GF(q) (normally written as GF(q)[x]/$(x^n - 1)$). Several interesting, practical properties follow immediately from this result.

2.1. The Basic Properties of Cyclic Codes

Let $\boldsymbol{C}$ be a (n, k) linear cyclic code over GF(q):

- Within the set of code polynomials in $\boldsymbol{C}$ there is a unique monic polynomial $g(x)$ with minimal degree $r < n$. $g(x)$ is called the *generator polynomial* of $\boldsymbol{C}$.
- Every code polynomial $c(x)$ in $\boldsymbol{C}$ can be expressed uniquely as $c(x) = m(x)g(x)$, where $g(x)$ is the generator polynomial of $\boldsymbol{C}$ and $m(x)$ is a polynomial of degree less than $(n - r)$ in GF(q)[x].
- The generator polynomial $g(x)$ of $\boldsymbol{C}$ is a factor of $(x^n - 1)$ in GF(q)[x].

The proof for these statements follows from the definition of ideal; the interested reader is referred to Wicker [1]. or MacWilliams [3]. The last of the three properties leads to some very interesting structural issues for cyclic codes, but to see this, we have to introduce some additional abstract algebra.

Let β be an element in the Galois field GF(q^m). The *conjugates of β with respect to the subfield GF(q)* are the elements $\beta, \beta^q, \beta^{q2}, \beta^{q3}$, and so on. Note that, since the field is finite, this series of elements has to start repeating at some point. These conjugates form a set called a *conjugacy class*. The elements in a Galois field can be partitioned into conjugacy classes with respect to a subfield of the Galois field. For example, the elements in the field GF(8) can be partitioned into conjugacy classes with respect to GF(2) in the following way. Let α be a primitive element in GF(8) (a "primitive" element is an element whose powers generate all the nonzero elements in the field). The various powers of α fall into three conjugacy classes with respect to GF(2): $\{\alpha^0 = 1\}$, $\{\alpha, \alpha^2, \alpha^4\}$, and $\{\alpha^3, \alpha^5, \alpha^6\}$. The fourth and final conjugacy class is $\{0\}$.

Rather than deal with a given conjugacy class itself, it is often easier to focus on the exponents of the powers of α that form the conjugacy class. The result is a *cyclotomic coset*. The cyclotomic cosets associated with the nonzero conjugacy classes in the above example are $\{0\}$, $\{1, 2, 4\}$, and $\{3, 5, 6\}$. If we want to include the zero element, we can adopt a symbol, say, an asterisk $\{^*\}$, to formally represent $\log_\alpha 0$, but this will not be necessary for what follows. If we ignore the zero element, the cyclotomic cosets modulo n with respect to GF(q) are a partitioning of the integers $\{0, 1, \ldots, n - 1\}$ into sets of the form $\{a, aq, aq^2, aq^3, \ldots, aq^{d-1}\}$.

With a bit of effort, the preceding development and some Galois field mathematics yield the following key result: the roots of a polynomial with coefficients in GF(q) must be the union of one or more conjugacy classes with respect to GF(q) (see, e.g., Wicker [1]). To see what this means, consider a generator polynomial $g(x)$ for a binary cyclic code of length 7. According to our properties of cyclic codes, $g(x)$ must be a divisor of $x^7 - 1$. The key result says that any binary polynomial that is a divisor of $x^7 - 1$ must have roots that are the union of one of the conjugacy classes with respect to GF(2) that we listed above. Since zero is not a root of $x^7 - 1$, we have to focus on the three nonzero conjugacy classes. Each of these classes is associated with a *minimal polynomial*, a polynomial whose roots are the elements of a single conjugacy class.

Conjugacy Class	Associated Minimal Polynomial
$\{\alpha^0 = 1\}$	$M_0(x) = (x - 1) = x + 1$
$\{\alpha, \alpha^2, \alpha\}$	$M_1(x) = (x - \alpha)(x - \alpha^2)(x - \alpha^4)$ $= x^3 + x + 1$
$\{\alpha^3, \alpha^6, \alpha^5\}$	$M_3(x) = (x - \alpha^3)(x - \alpha^6)(x - \alpha^5)$ $= x^3 + x^2 + 1$

We conclude that the only generator polynomials for binary, cyclic codes of length 7 are $M_0(x)$, $M_1(x)$, $M_3(x)$, $M_0(x)M_1(x)$, $M_0(x)M_1(x)$, and $M_1(x)M_3(x)$. In general, the binary polynomials that are available for use as generator polynomials for cyclic codes are the products of one or more minimal polynomials.

2.2. Systematic Encoding

An encoding for a given error control code is said to be *systematic* if the codeword consists of a set of parity symbols followed by the message itself. This greatly facilitates decoding, for if a parity check indicates that there are no errors in the received word, the parity symbols can be deleted and the remaining message forwarded to the application. By exploiting the algebraic structure of cyclic codes, it is possible to develop a simple systematic encoder.

Consider an (n, k) cyclic code $\boldsymbol{C}$ with generator polynomial $g(x)$. A k-symbol message $\mathbf{m} = (m_0, m_1, \ldots, m_{k-1})$ is encoded as follows. Multiply the corresponding message polynomial $m(x)$ by x^{n-k}, obtaining $x^{n-k}m(x) = m_0x^{n-k} + m_1x^{n-k+1} + \cdots + m_{k-1}x^{n-1}$. This product is associated with an n-symbol block $(0, 0, \ldots, 0, m_0, m_1, \ldots, m_{k-1})$ whose first $(n-k)$ coordinates are zero. Now divide $x^{n-k}m(x)$ by $g(x)$ to obtain $x^{n-k}m(x) = q(x)g(x) + d(x)$, where $d(x)$ is the remainder. Since $c(x) = [x^{n-k}m(x) - d(x)] = q(x)g(x)$ is a multiple of $g(x)$, it must be a valid code polynomial. Now note that the remainder $d(x)$ has a degree less than $(n-k)$, the degree of the generator polynomial $g(x)$. The term $-d(x)$ can be associated with an n-symbol block whose last k coordinates are zero: $-d(x) \leftrightarrow (-d_0, -d_1, \ldots, -d_{n-k-1}, 0, 0, \ldots, 0)$. The codeword associated with the code polynomial $c(x) = [x^{n-k}m(x) - d(x)]$ thus has the form

$$c(x) = [x^{n-k}m(x) - d(x)] \leftrightarrow (-d_0, -d_1, \ldots, -d_{n-k-1}, m_0, m_1, \ldots, m_{k-1})$$

where $m(x)$ has been systematically mapped to a codeword. The encoding algorithm is summarized below:

1. Multiply the message polynomial $m(x)$ by x^{n-k}.
2. Divide the result of step 1 by the generator polynomial $g(x)$. Let $d(x)$ be the remainder.
3. Set $c(x) = x^{n-k}m(x) - d(x)$.

As an example, consider the systematic encoding of a (7,3) binary code with generator polynomial $g(x) = x^4 + x^3 + x^2 + 1$; we will encode the message block (101):

1. $x^{n-k}m(x) = x^4(x^2 + 1) = x^6 + x^4$
2. $$\begin{array}{r|l} x^4+x^3+x^2+1 & x^2+x+1 = q(x) \\ & \underline{x^6+x^4} \\ & \underline{x^6+x^5+x^4+x^2} \\ & \underline{x^5+x^2} \\ & \underline{x^5+x^4+x^3+x} \\ & \underline{x^4+x^3+x^2+1} \\ & x+1 = d(x) \end{array}$$
3. $c_m(x) = x^{n-k}m(x) - d(x) = 1 + x + x^4 + x^6$ $\leftrightarrow \boldsymbol{c}_m = (1100101)$

2.3. Shift Register Encoders and Decoders for Cyclic Codes

Data rates in the hundreds or even thousands of megabits per second are common in many applications. Unfortunately, such data rates severely limit the device technologies that can be used to implement error control systems, and within a given technology, the complexity of the circuits. It is extremely important to note that encoders and decoders for cyclic codes can be implemented using simple exclusive-OR gates, switches, shift registers, and, in the case of nonbinary encoders and decoders, finite-field adder and multiplier circuits. Shift registers are among the simplest of digital circuits, consisting of a collection of flipflops connected in series. They are operable at speeds quite close to the maximum speed possible for a single gate using a given device technology.

The systematic encoding procedure described above has a simple shift register implementation, as shown in Fig. 1. The first step — multiplication of the message polynomial — is implemented by inserting the message into the shift register circuit on the right side [this is equivalent to padding the message block with an initial $(n-k)$ zeros]. Polynomial division is then performed through the use of a linear feedback shift register (LFSR).

Encoding proceeds as follows. During the first step of the encoding operation the three switches are placed in position X and the k message symbols are fed into the

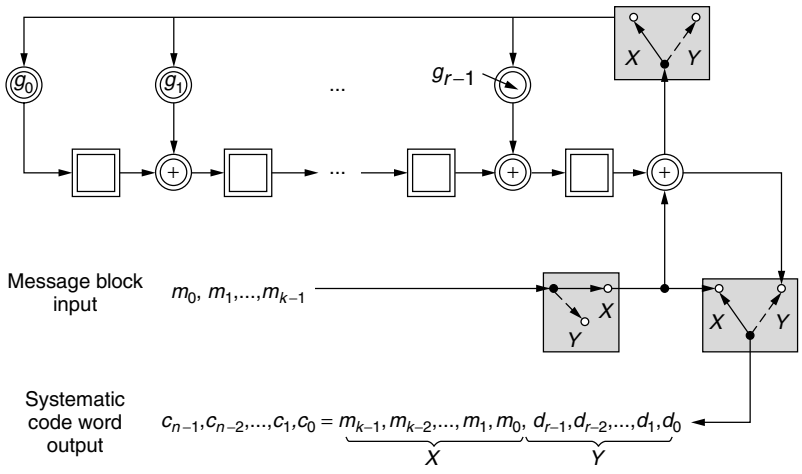

Figure 1. Systematic shift register encoding circuit for cyclic codes [1].

encoder in order of decreasing index. The k symbol bits are simultaneously sent to the transmitter, for they represent the last k coordinates of the systematic codeword. This, by the way, is the primary rationale for placing the message symbols at the end of a systematic code word. After the kth message symbol has been fed into the shift register, the switches are moved to position Y. At this point the shift register cells contain the remainder generated by the division operation. These symbols are then shifted out of the shift register and to the transmitter, where they constitute the remaining systematic codeword coordinates.

Cyclic codes allow for a number of highly convenient techniques for detecting errors using shift register circuits. For example, consider the following:

1. Since the transmitted codeword was systematically encoded, we can construct an estimated message block $\mathbf{m}'$ and estimated remainder block $\mathbf{d}'$ using the values in the message and parity positions of the received word $\mathbf{r}$.
2. Encode $\mathbf{m}'$ using an encoder identical to that used by the transmitter and obtain an estimated remainder block $\mathbf{d}''$.
3. Compare $\mathbf{d}'$ to $\mathbf{d}''$. If they are not the same, then $\mathbf{r}$ is not a valid codeword, indicating the presence of errors in the received word.

This approach to error detection has a significant advantage. The encoder and error detection circuits are essentially identical, and the design process is correspondingly simplified.

The error detection technique described above can be used as the first steps in an error-correcting algorithm. The difference $\mathbf{s} = \mathbf{d}' - \mathbf{d}''$ is called the *syndrome* for the received word $\mathbf{r}$. Maximum-likelihood error correction is performed by computing the syndrome for a received vector, determining the most likely error pattern among those associated with the syndrome, and subtracting this error pattern from the received vector. The primary drawback to this approach is usually the size of the syndrome lookup table. For an arbitrary (n, k) q-ary code, the syndrome table must contain $q^{n-k}n$-tuples — one for each possible syndrome. Cyclic codes have an interesting property that allows us to cut the size of the syndrome table to $1/n$th its original size.

> Let $s(x)$ be the syndrome polynomial corresponding to a received polynomial $r(x)$. Let $r^{(1)}(x)$ be the polynomial obtained by cyclically shifting the coefficients of $r(x)$ once to the right. Then the remainder obtained when dividing $xs(x)$ by $g(x)$ is the syndrome $s^{(1)}(x)$ corresponding to $r^{(1)}(x)$.

Let's consider this result in terms of the shift register syndrome circuit. Given a received vector $\mathbf{r}$, the corresponding syndrome $\mathbf{s}$ is obtained by entering $\mathbf{r}$ into a shift register division circuit. When the last symbol of $\mathbf{r}$ has been shifted into the circuit, the shift register cells contain the syndrome. The input to the circuit of an additional zero at this point is equivalent to multiplying s(x) by x and dividing by $g(x)$. The remainder $s^{(1)}(x)$ is now in the shift register cells. According to the result given above, $s^{(1)}(x)$ is the syndrome for $r^{(1)}(x)$. This process can be repeated n times, bringing us back to the starting point with the original syndrome in the shift register cells. We need only store one syndrome $\mathbf{s}$ for an error pattern $\mathbf{e}$ and all cyclic shifts of $\mathbf{e}$. A syndrome decoder with a reduced-size lookup table is used as follows.

2.4. Syndrome Decoder for Cyclic Codes

1. Set a counting variable j to the value 0. Compute the syndrome $\mathbf{s}$ for a received vector $\mathbf{r}$.
2. Look for the error pattern $\mathbf{e}$ corresponding to $\mathbf{s}$ in the syndrome lookup table. If there is such a value, go to step 7.
3. Increment the counter j by 1 and enter a zero into the shift register circuit at the input, computing $\mathbf{s}^{(j)}$.
4. Look for the error pattern $\mathbf{e}^{(j)}$ corresponding to $\mathbf{s}^{(j)}$ in the syndrome lookup table. If there is such a value, go to step 6.
5. Go to step 3.
6. Determine the error pattern $\mathbf{e}$ corresponding to $\mathbf{s}$ by cyclically shifting $\mathbf{e}^{(j)}j$ times to the left.
7. Subtract $\mathbf{e}$ from $\mathbf{r}$, obtaining the codeword $\mathbf{c}$.

So in general, there are fast, simple encoding and decoding circuits for cyclic codes of modest size. To get truly powerful error control with limited complexity, however, it is necessary to turn to one of the special cases.

3. QUADRATIC RESIDUE CODES AND GOLAY CODES

The nonzero squares modulo p, p a prime, are called the quadratic residues modulo p. Quadratic residues can be found by simply squaring every integer modulo p. For example, note that, using modulo 7 arithmetic, $1^2 = 6^2 = 1$, $2^2 = 5^2 = 4$ and $3^2 = 4^2 = 2$. So 1, 2, and 4 are the three quadratic residues modulo 7. In showing how quadratic residues can lead to some interesting codes, we have to indulge in some abstract algebra. The reader interested solely in applications and other practical matters can safely skip the next few paragraphs.

The set of integers modulo p, p a prime, form the field GF(p) under modulo p addition and multiplication. Let Q be the set of quadratic residues modulo p and N the set of corresponding nonresidues. Since GF(p) is a Galois field, there must exist at least one primitive element $\gamma \in \mathrm{GF}(p)$ that generates all the elements in Q and N. It follows that γ must be a quadratic nonresidue; otherwise there exists some element $\sqrt{\gamma} \in \mathrm{GF}(p)$ that generates $2(p-1)$ distinct elements in GF(p), contradicting the order of GF(p). One can then see that $\gamma^e \in Q$ if and only if e is even; otherwise, $\gamma^e \in N$. We conclude that all the elements in Q correspond to the first $(p-1)/2$ consecutive powers of γ^2, and that Q is a cyclic group under modulo p multiplication.

Now consider a field GF(s^m) that contains a primitive pth root of unity. Such a field exists for a given s, m, and p whenever $p|s^m$-1. We add the further restriction that s must be a quadratic residue modulo p. This can be somewhat restrictive; for example, if $s = 2$, then p must be of the form $p = (8k \pm 1)$. Since Q is a cyclic group,

multiplication of any element in Q by any other element in Q must result in an element in Q. It follows that the conjugates with respect to GF(s) of any element in Q must also be in Q. We conclude that Q is the union of one or more cyclotomic cosets modulo p with respect to GF(s).

Let α be primitive in GF(s^m). The results above show that the following polynomials have coefficients in the subfield GF(s):

$$q(x) = \prod_{i \in Q} (x - \alpha^i)$$

$$n(x) = \prod_{i \in N} (x - \alpha^i)$$

The *quadratic residue codes* of length p are defined by the generator polynomials $q(x)$, $(x-1)q(x)$, $n(x)$, and $(x-1)n(x)$, respectively.

The *binary Golay code* $\mathbf{G}_{23}$ is the (23,12,7) quadratic residue code with $p = 23$ and $s = 2$. The construction of this code proceeds as follows. The quadratic residues modulo 23 are $Q = 1, 2, 3, 4, 6, 8, 9, 12, 13, 16, 18$. Let β be a primitive 23rd root of unity [22 different β values can be found in GF(2^{11}) and its extensions]. The distinct powers of β form two cyclotomic cosets modulo 23 with respect to GF(2):

$$C_1 = \{1, 2, 3, 4, 6, 8, 9, 12, 13, 16, 18\}$$

$$C_5 = \{5, 7, 10, 11, 14, 15, 17, 19, 20, 21, 22\}$$

The term $x^{23} + 1$ factors into three binary irreducible polynomials:

$$x^{23} + 1 = (x + 1)(x^{11} + x^{10} + x^6 + x^5 + x^4 + x^2 + 1) \times (x^{11} + x^9 + x^7 + x^6 + x^5 + x + 1)$$

Depending on the selection of β, there are two possible generator polynomials for $\mathbf{G}_{23}$:

$$g_1(x) = x^{11} + x^{10} + x^6 + x^5 + x^4 + x^2 + 1$$

$$g_2(x) = x^{11} + x^9 + x^7 + x^6 + x^5 + x + 1$$

Using either of these generator polynomials, the resulting code can be shown to be triple-error correcting. Given that $\mathbf{G}_{23}$ has dimension 12, it can be shown that $\mathbf{G}_{23}$is perfect. Each codeword is associated with a decoding sphere containing all vectors that are Hamming distance ≤ 3 from the codeword. Since the vectors have length 23, the decoding spheres have cardinality:

$$\begin{aligned} V_2(23, 3) &= \binom{23}{0} + \binom{23}{1} + \binom{23}{2} + \binom{23}{3} \\ &= 1 + 23 + 253 + 1771 \\ &= 2^{11} \end{aligned}$$

Through the addition of a parity-check bit, $\mathbf{G}_{23}$ can be extended to form $\mathbf{G}_{24}$, the triple-error-correcting, quadruple-error-detecting code that was used on the *Voyager* spacecraft.

The ternary [i.e., defined over GF(3)] Golay code ternary Golay code $\mathbf{G}_{11}$ is the quadratic residue code with $p = 11$ and $s = 3$. An analysis similar to that for $\mathbf{G}_{23}$ yields the factorization of $x^{11} - 1$ into three irreducible polynomials in GF(3)[x]:

$$x^{11} - 1 = (x - 1)(x^5 + x^4 - x^3 + x^2 - 1) \times (x^5 - x^3 + x^2 - x - 1)$$

Again there are two possible generator polynomials:

$$g_1(x) = x^5 + x^4 - x^3 + x^2 - 1$$

$$g_2(x) = x^5 - x^3 + x^2 - x - 1$$

$\mathbf{G}_{11}$ has length 11, dimension 6, and minimum distance 5, and is perfect.

4. BCH AND REED–SOLOMON CODES

When constructing an arbitrary cyclic code, there is no guarantee as to the resulting minimum distance. Given a generator polynomial $g(x)$, we must conduct a computer search of all corresponding nonzero code words $c(x)$ to determine the minimum-weight codeword and thus the minimum distance of the code. BCH codes, on the other hand, take advantage of a useful result that ensures a minimum "design distance" given a particular constraint on the generator polynomial. This result is known as the *BCH bound*.

4.1. The BCH Bound

Let $\boldsymbol{C}$ be a q-ary (n, k) cyclic code with generator polynomial $g(x)$. A *primitive* nth *root of unity* is defined to be an element β such that $\beta^n = 1$, but there is not smaller nonzero integer j such that $\beta^j = 1$. If GF(q^m) is the smallest extension field of GF(q) that contains a primitive nth root of unity, then we say that m is the multiplicative order of q modulo n. The BCH bound developed as follows. Let α be a primitive nth root of unity. Select $g(x)$ to be the minimal degree polynomial in GF(q)[x] such that $g(\alpha^b) = g(\alpha^{b+1}) = g(\alpha^{b+2}) = \cdots = g(\alpha^{b+d-2}) = 0$ for some integers $b \geq 0$ and $d \geq 1$. This $g(x)$ has $(d-1)$ consecutive powers of α as zeros. The BCH bound states that the code $\boldsymbol{C}$ defined by such a $g(x)$ has minimum distance $d_{\min} \geq d$.

We can use the BCH bound to construct a t-error-correcting q-ary BCH code of length n in the following way:

1. Find a primitive nth root of unity α in a field GF(q^m), where m is minimal.
2. Select $(d-1) = 2t$ consecutive powers of α, starting with α^b for some nonnegative integer b.
3. Let $g(x)$ be the least common multiple of the minimal polynomials for the selected powers of α with respect to GF(q). (Each minimal polynomial should appear only once in the product.)

Step 1 follows from our design procedure for general cyclic codes. Steps 2 and 3 ensure, through the BCH bound,

that the minimum distance of the resulting code equals or exceeds d and that the generator polynomial has the minimal possible degree. Since $g(x)$ is a product of minimal polynomials with respect to GF(q), $g(x)$ must be in GF(q)[x] and the corresponding code is q-ary with $d_{\min} \geq d$.

If $b = 1$, then the BCH code is said to be *narrow-sense*. If $n = q^m - 1$ for some positive integer m, then the BCH code is said to be *primitive*, for the nth root of unity α is a primitive element in GF(q^m). Let's consider a few binary BCH codes of length 31 to see how the design rule derived from the BCH bound fits in with the earlier discussion of conjugacy classes. Let α be a root of the primitive polynomial $x^5 + x^2 + 1$. It is thus a primitive element in the field GF(32). Since 31 is of the form $2^m - 1$, our BCH codes in this example are primitive. We begin by determining the cyclotomic cosets modulo 31 with respect to GF(2) and the associated minimal polynomials.

Cyclotomic Cosets	Minimal Polynomials
$C_0 = \{0\}$	$\leftrightarrow M_{(0)}(x) = x + 1$
$C_1 = \{1, 2, 4, 8, 16\}$	$\leftrightarrow M_{(1)}(x) = x^5 + x^2 + 1$
$C_3 = \{3, 6, 12, 24, 17\}$	$\leftrightarrow M_{(3)}(x) = x^5 + x^4 + x^3 + x^2 + 1$
$C_5 = \{5, 10, 20, 9, 18\}$	$\leftrightarrow M_{(5)}(x) = x^5 + x^4 + x^2 + x + 1$
$C_7 = \{7, 14, 28, 25, 19\}$	$\leftrightarrow M_{(7)}(x) = x^5 + x^3 + x^2 + x + 1$
$C_{11} = \{11, 22, 13, 26, 21\}$	$\leftrightarrow M_{(11)}(x) = x^5 + x^4 + x^3 + x + 1$
$C_{15} = \{15, 30, 29, 27, 23\}$	$\leftrightarrow M_{(15)}(x) = x^5 + x^3 + 1$

Recall that if a code $\mathbf{C}$ is to be a binary cyclic code, then it must have a generator polynomial $g(x)$ that is the product one or more of the minimal polynomials listed above. According to the BCH bound, if $\mathbf{C}$ is to be t-error correcting BCH code, then $g(x)$ must have as zeros $2t$ consecutive powers of α.

- *One-Error-Correcting Narrow-Sense Primitive BCH Code*. Since the code is to be narrow-sense and single-error-correcting, $b = 1$ and $\delta = 3$. The generator polynomial must thus have α and α^2 as zeros. $M_{(1)}(x)$ is the minimal polynomial of both α and α^2. The generator polynomial is thus

$$g(x) = \text{LCM}(M_{(1)}(x)M_{(2)}(x)) = M_{(1)}(x) = x^5 + x^2 + 1$$

  Since the degree of the generator polynomial $g(x)$ is 5, the dimension of the resulting code is $31 - 5 = 26$. Thus $g(x)$ defines a (31,26) binary single-error-correcting BCH code.
- *Two-Error-Correcting Narrow-Sense Primitive BCH Code*. Again $b = 1$, but δ has been increased to 5. $g(x)$ must thus have as roots α, α^2, α^3, and α^4.

$$\begin{aligned} g(x) &= LCM(M_{(1)}(x), M_{(2)}(x), M_{(3)}(x), M_{(4)}(x)) \\ &= M_{(1)}(x)M_{(3)}(x) \\ &= (x^5 + x^2 + 1)(x^5 + x^4 + x^3 + x^2 + 1) \\ &= x^{10} + x^9 + x^8 + x^6 + x^5 + x^3 + 1 \end{aligned}$$

  Since the degree of $g(x)$ is 10, it defines a (31,21) binary double-error-correcting code.

There are a number of ways to define Reed–Solomon codes. Reed and Solomon's initial definition focused on the evaluation of polynomials over the elements in a finite field [17]. Reed–Solomon codes can also be viewed as a natural extension of BCH codes. Simply put, a Reed–Solomon code is a q^m-ary BCH code of length $q^m - 1$.

Consider the construction of a t-error-correcting Reed–Solomon code of length $(q^m - 1)$. The first step is to note that the required primitive $(q^m - 1)$st root of unity α can be found in GF(q^m) (every finite field of size q contains an element with order $q - 1$). Since the code symbols are to be from GF(q^m), the next step is to construct the cyclotomic cosets modulo $(q^m - 1)$ with respect to GF(q^m). This is a trivial task, for $(s \cdot q^m) \equiv s$ modulo $(q^m - 1)$. The cyclotomic cosets are singleton sets of the form $\{s\}$ and the associated minimal polynomials are of the form $(x - \alpha^s)$.

The BCH bound indicates that $2t$ consecutive powers of a are required as zeros of the generator polynomial $g(x)$ for a t-error-correcting Reed-Solomon code. The generator polynomial is the product of the associated minimal polynomials:

$$g(x) = (x - \alpha b)(x - \alpha^{b+1})(x - \alpha^{b+2}) \cdots (x - \alpha^{b+2t-1}).$$

Consider a two-error-correcting 8-ary Reed–Solomon code of length 7. Let α be a root of the primitive binary polynomial $x^3 + x + 1$ and thus a primitive 7th of unity. The Galois field GF(8) can be represented as consecutive powers of α:

$$\begin{aligned} \alpha &= \alpha & \alpha^5 &= \alpha^2 + \alpha + 1 \\ \alpha^2 &= \alpha^2 & \alpha^6 &= \alpha^2 + 1 \\ \alpha^3 &= \alpha + 1 & \alpha^7 &= 1 \\ \alpha^4 &= \alpha^2 + \alpha & 0 &= 0 \end{aligned}$$

If the resulting code is to be double-error-correcting, it must have $2t = 4$ consecutive powers of a as zeros. A narrow-sense generator polynomial is constructed as follows:

$$\begin{aligned} g(x) &= (x - \alpha)(x - \alpha 2)(x - \alpha 3)(x - \alpha 4) \\ &= x^4 + \alpha^3 x^3 + x^2 + \alpha x + \alpha^3 \end{aligned}$$

Since the generator polynomial has degree 4, the (7,3) Reed–Solomon code it defines has dimension 3 over GF(8) and thus $8^3 = 512$ codewords.

Reed–Solomon codes have a number of interesting properties that are not shared by the other BCH codes. Recall that the minimum distance for BCH codes is in general lower-bounded by the design distance, but in many cases the actual minimum distance exceeds the design distance. One of the most significant properties of Reed–Solomon codes is the fact that an (n, k) Reed–Solomon code always has minimum distance exactly equal to $(n - k + 1)$.

BCH and Reed–Solomon codes can be decoded in a number of different ways. Perhaps the most efficient technique is Berlekamp's algorithm. In this article we provide a

brief description of Berlekamp's algorithm. Readers interested in a detailed exposition are referred to the source in Ref. 18.

The definition of a Reed–Solomon generating polynomial requires that, for some b and t, $g(\alpha^b) = g(\alpha^{b+1}) = \cdots = g(\alpha^{b+2t-1}) = 0$. A binary vector $\mathbf{c} = (c_0, c_1, \ldots, c_{n-1})$ is a codeword if and only if its associated polynomial $c(x) = c_0 + c_1 x + \cdots + c_{n-1}x^{n-1}$ has as zeros these same $2t$ consecutive powers of α. Now consider a received polynomial $r(x)$, which can be expressed as the sum of the transmitted code polynomial $c(x)$ and an error polynomial $e(x) = e_0 + e_1 x + \cdots + e_{n-1}x^{n-1}$. A series of syndromes is obtained by evaluating the received polynomial at the $2t$ zeros. To minimize the complexity of our notation, it is assumed henceforth that all codes under discussion are narrow-sense ($b = 1$). The syndromes are computed as follows:

$$\begin{aligned} S_j &= r(\alpha^j) = c(\alpha^j) + e(\alpha^j) = e(\alpha^j) \\ &= \sum_{k=0}^{n-1} e_k (\alpha^j)^k, \qquad j = 1, 2, \ldots, 2t \end{aligned}$$

The computations in this expression are performed in GF(2^m), the field containing the primitive nth root of unity. Now assume that the received word $\mathbf{r}$ has ν errors in positions $i_1, i_2, \ldots, i_\nu$. We will assume that the code is binary, so the errors in these positions have value $e_{ij} = 1$. The syndrome sequence can be reexpressed in terms of these error locations:

$$S_j = \sum_{l=1}^{v} e_{i_l} (\alpha^j)^{i_l} = \sum_{l=1}^{v} (\alpha^{i_l})^j = \sum_{l=1}^{v} X_l^j, \qquad j = 1, \ldots, 2t$$

The $\{X_l\}$ are *error locators*, for their values indicate the positions of the errors in the received word. Expanding this equation we obtain a sequence of $2t$ algebraic *syndrome equations syndrome equations* in the ν unknown error locations:

$$\begin{aligned} S_1 &= X_1 + X_2 + \cdots + X_v \\ S_2 &= X_1^2 + X_2^2 + \cdots + X_v^2 \\ S_3 &= X_1^3 + X_2^3 + \cdots + X_v^3 \\ &\vdots \\ S_{2t} &= X_1^{2t} + X_2^{2t} + \cdots + X_v^{2t} \end{aligned}$$

Equations of this form are called *power-sum symmetric functions*. Since they form a system of nonlinear algebraic equations in multiple variables, they are somewhat difficult to solve in a direct manner.[4] Peterson showed, however, that the BCH syndrome equations can be translated into a series of linear equations that are much easier to work with [15]. Let $\Lambda(x)$ be the *error locator polynomial* that has as its roots the inverses of the ν error locators $\{X_l\}$:

$$\Lambda(x) = \prod_{l=1}^{v} (1 - X_l x) = \Lambda_v x^v + \Lambda_{v-1} x^{v-1} + \cdots + \Lambda_1 x + \Lambda_0$$

This equation can be used to express the coefficients of $\Lambda(x)$ directly in terms of the $\{X_l\}$. The resulting expressions are the *elementary symmetric functions* of the error locators. Power-sum symmetric functions and elementary symmetric functions are related by *Newton's identities*, which are generally expressed as follows for polynomials over arbitrary fields:

$$\begin{aligned} S_1 + \Lambda_1 &= 0 \\ S_2 + \Lambda_1 S_1 + 2\Lambda_0 &= 0 \\ S_3 + \Lambda_1 S_2 + \Lambda_2 S_1 + 3\Lambda_3 &= 0 \\ &\vdots \\ S_v + \Lambda_1 S_{v-1} + \Lambda_2 S_{v-2} + \cdots + \Lambda_{v-1} S_1 + v\Lambda_v &= 0 \\ S_{v+1} + \Lambda_1 S_v + \Lambda_2 S_{v-1} + \cdots + \Lambda_v S_1 &= 0 \\ &\vdots \\ S_{2t} + \Lambda_1 S_{2t-1} + \Lambda_2 S_{2t-2} + \cdots + \Lambda_v S_{2t-v} &= 0 \end{aligned}$$

If we assume that the codes in question are binary, we can reduce these expressions to the following:

$$\begin{aligned} S_1 + \Lambda_1 &= 0 \\ S_3 + \Lambda_1 S_2 + \Lambda_2 S_1 + \Lambda_3 &= 0 \\ S_5 + \Lambda_1 S_4 + \Lambda_2 S_3 + \Lambda_3 S_2 + \Lambda_4 S_1 + \Lambda_5 &= 0 \\ &\vdots \\ S_{2t-1} + \Lambda_1 S_{2t-2} + \Lambda_2 S_{2t-3} + \cdots + \Lambda_t S_{t-1} &= 0 \end{aligned}$$

Now suppose, for a moment, that we had an infinite number of syndromes available. We could then define an infinite-degree syndrome polynomial as follows:

$$S(x) = S_1 x + S_2 x^2 + \cdots + S_{2t} x^{2t} + S_{2t+1} x^{2t+1} + \cdots$$

Clearly we do not know all of the coefficients of $S(x)$, but fortunately the first $2t$ coefficients are entirely sufficient. $S(x)$ is made into an infinite degree polynomial so that it can be treated as a *generating function*. Define a third polynomial as follows:

$$\begin{aligned} \Omega(x) &\triangleq [1 + S(x)]\Lambda(x) \\ &= (1 + S_1 x + S_2 x^2 + \cdots)(1 + \Lambda_1 x + \Lambda_2 x^2 + \cdots) \\ &= 1 + (S_1 + \Lambda_1)x + (S_2 + \Lambda_1 S_1 + \Lambda_2)x^2 \\ &\quad + (S_3 + \Lambda_1 S_2 + \Lambda_2 S_1 + \Lambda_3)x^3 + \cdots \\ &= 1 + \Omega_1 x + \Omega_2 x^2 + \cdots \end{aligned}$$

where $\Omega(x)$ is called the *error magnitude polynomial*, and is useful in nonbinary decoding. For now we will simply

[4] The general problem of finding solutions to systems of algebraic equations in multiple variables is NP-hard, and is the basis for a number of nice cryptosystems, including the Data Encryption Standard.

note that if the syndrome and error locator polynomials are to satisfy this expression, then the odd-indexed coefficients of $\Omega(x)$ must be zero (see the Newton's identities for the binary case presented above). Given that we know only the first $2t$ coefficients of $S(x)$, the decoding problem then becomes one of finding a polynomial $\Lambda(x)$ of degree less than or equal to t that satisfies

$$[1 + S(x)]\Lambda(x) \cdots (1 + \Omega_2 x^2 + \Omega_4 x^4 + \cdots + \Omega_{2t} x^{2t}) \bmod x^{2t+1}$$

Berlekamp's algorithm proceeds iteratively by breaking this equation) down into a series of smaller problems of the form

$$[1 + S(x)]\Lambda^{(2k)}(x) \cdots (1 + \Omega_2 x^2 + \Omega_4 x^4 + \cdots + \Omega_{2k} x^{2k}) \bmod x^{2k+1}$$

where k runs from 1 to t. A solution $\Lambda^{(0)}(x) = 1$ is first assumed and tested to see if it works for the case $k = 1$. If it does work, we proceed to $k = 2$; otherwise, a correction factor correction factor is computed and added to $\Lambda^{(0)}$, creating a new solution $\Lambda^{(2)}(x)$. The genius of the algorithm lies in the computation of the correction factor. It is designed so that the new solution will work not only for the current case but for all previous values of k as well. We first consider the binary case.

4.2. Berlekamp's Algorithm for Decoding Binary BCH Codes

1. Set the initial conditions: $k = 0$, $\Lambda^{(0)}(x) = 1$, $T^{(0)} = 1$.
2. Let $\Delta^{(2k)}$ be the coefficient of x^{2k+1} in the product $\Lambda^{(2k)}(x)[1 + S(x)]$.
3. Compute

$$\Lambda^{(2k+2)}(x) = \Lambda^{(2k)}(x) + \Delta^{(2k)}[x \cdot T^{(2k)}(x)]$$

4. Compute

$$T^{(2k+2)}(x) = \begin{cases} x^2 T^{(2k)}(x) & \text{if } \Delta^{(2k)} = 0 \text{ or if } \deg[\Lambda^{(2k)}(x)] > k \\ \dfrac{x\Lambda^{(2k)}(x)}{\Delta^{(2k)}} & \text{if } \Delta^{(2k)} \neq 0 \text{ and } \deg[\Lambda^{(2k)}(x)] \leq k \end{cases}$$

5. Set $k = k + 1$. If $k < t$, then go to 2.
6. Determine the roots of $\Lambda(x) = \Lambda^{(2t)}(x)$. If the roots are distinct and lie in the right field, then correct the corresponding locations in the received word and *stop*.
7. Declare a decoding failure and *stop*.

For an example, consider a narrow-sense double-error-correcting code of length 31 with generator polynomial $= 1 + x^3 + x^5 + x^6 + x^8 + x^9 + x^{10}$. Let the received vector and associated polynomial be as follows:

$$\mathbf{r} = (0010000110011000000000000000000)$$

$$\updownarrow$$

$$r(x) = x^2 + x^7 + x^8 + x^{11} + x^{12}$$

A bit of number crunching in GF(32) yields the following syndrome polynomial:

$$S(x) = \alpha^7 x + \alpha^{14} x^2 + \alpha^8 x^3 + \alpha^{28} x^4$$

Applying Berlekamp's algorithm, we obtain the following sequence of solutions.

k	$\Lambda^{(2k)}(x)$	$T^{(2k)}(x)$	$\Delta^{(2k)}$
0	1	1	α^7
1	$1 + \alpha^7 x$	$\alpha^{24} x$	α^{22}
2	$1 + \alpha^7 x + \alpha^{15} x^2$	—	—

$\Lambda^{(4)}(x) = 1 + x\alpha^7 x + \alpha^{15} x^2$ is the error locator polynomial. The error locators are $X_1 = \alpha^5$ and $X_2 = \alpha^{10}$, indicating errors at the fifth and tenth coordinates of $\mathbf{r}$. The corrected word, with the corrected positions underlined, is

$$\mathbf{c} = (0010010110\underline{1}11\underline{0}00000000000000000)$$

$$\updownarrow$$

$$c(x) = x^2 + x^5 + x^7 + x^8 + x^{10} + x^{11} + x^{12} = x^2 g(x)$$

For the nonbinary case, we first note that the syndromes are now a function of the magnitude of the errors as well as their locations. Assuming that some ν errors have corrupted the received word, the syndromes are as follows:

$$S_j = e(\alpha^j) = \sum_{k=0}^{n-1} e_k (\alpha^j)^k = \sum_{l=1}^{v} e_{i_l} X_l^j$$

This expression defines a series of $2t$ algebraic equations in 2ν unknowns:

$$\begin{aligned} S_1 &= e_{i_1} X_1 + e_{i_2} X_2 + \cdots + e_{i_v} X_v \\ S_2 &= e_{i_1} X_1^2 + e_{i_2} X_2^2 + \cdots + e_{i_v} X_v^2 \\ S_3 &= e_{i_1} X_1^3 + e_{i_2} X_2^3 + \cdots + e_{i_v} X_v^3 \\ &\vdots \\ S_{2t} &= e_{i_1} X_1^{2t} + e_{i_2} X_2^{2t} + \cdots + e_{i_v} X_v^{2t} \end{aligned}$$

We can reduce this system of equation to a set of linear functions in the unknown quantities. We first assume an error locator polynomial $\Lambda(x)$ whose zeros are the inverses of the error locators $\{X_i\}$:

$$\Lambda(x) = \prod_{l=1}^{v} (1 - X_l x) = \Lambda_v x^v + \Lambda_{v-1} x^{v-1} + \cdots + \Lambda_1 x + \Lambda_0$$

It follows that for some error locator X_l

$$\Lambda(X_l^{-1}) = \Lambda_v X_l^{-v} + \Lambda_{v-1} X_l^{-v+1} + \cdots + \Lambda_1 X_l^{-1} + \Lambda_0 = 0$$

Since the expression sums to zero, we can multiply through by a constant:

$$e_{i_1} X_l^j (\Lambda_v X_l^{-v} + \Lambda_{v-1} X_l^{-v+1} + \cdots + \Lambda_1 X_l^{-1} + \Lambda_0) =$$

$$e_{i_1} (\Lambda_v X_l^{-v+j} + \Lambda_{v-1} X_l^{-v+j+1} + \cdots + \Lambda_1 X_l^{j-1} + \Lambda_0 X_l^j) = 0$$

Now sum both sides of over all indices l, obtaining an expression from which Newton's identities can be constructed:

$$\sum_{l=1}^{v} e_{i_1}(\Lambda_v X_l^{j-v} + \Lambda_{v-1} X_l^{j-v+1} + \cdots + \Lambda_1 X_l^{j-1} + \Lambda_0 X_l^j)$$

$$= \Lambda_v \sum_{l=1}^{v} e_{i_1} X_l^{j-v} + \Lambda_{v-1} \sum_{l=1}^{v} e_{i_1} X_l^{j-v+1} + \cdots + \Lambda_1 \sum_{l=1}^{v} e_{i_1} X_l^{j-1}$$

$$+ \Lambda_0 \sum_{l=1}^{v} e_{i_1} X_l^j$$

$$= \Lambda_v S_{j-v} + \Lambda_{v-1} S_{j-v+1} + \cdots + \Lambda_1 S_{j-1} + \Lambda_0 S_j = 0$$

From the earlier expressions it is clear that Λ_0 is always one. The preceding equation can thus be reexpressed as

$$\Lambda_v S_{j-v} + \Lambda_{v-1} S_{j-v+1} + \cdots + \Lambda_1 S_{j-1} = -S_j$$

This expression shows that the syndrome S_j can be expressed in recursive form as a function of the coefficients of the error locator polynomial $\Lambda(x)$ and the earlier syndromes $S_{j-1}, \ldots, S_{j-v}$. In 1969 Massey showed that this expression can be given a physical interpretation through the use of a linear feedback shift register (LFSR) [23]. The double-lined elements in Fig. 2 denote storage of and operations on nonbinary field elements.

Part of the problem of decoding BCH and Reed–Solomon codes can be reexpressed as follows. Find an LFSR of minimal length such that the first $2t$ elements in the LFSR output sequence are the syndromes $S_1, S_2, \ldots, S_{2t}$. The taps of this shift register provide the desired error locator polynomial $\Lambda(x)$.

Let $\Lambda^{(k)}(x) = \Lambda_k x^j + \Lambda_{k-1} x^{k-1} + \cdots + \Lambda_1 x + 1$ be the *connection polynomial* of length k whose coefficients specify the taps of a length-k LFSR. Massey's construction of Berlekamp's algorithm starts by finding $\Lambda^{(1)}$ such that the first element output by the corresponding LFSR is the first syndrome S_1. The second output of this LFSR is then compared to the second syndrome. If the two do not have the same value, then the *discrepancy* between the two is used to construct a modified connection polynomial. If there is no discrepancy, then the same connection polynomial is used to generate a third sequence element, which is compared to the third syndrome. The process continues until a connection polynomial is obtained that specifies an LFSR capable of generating all $2t$ elements of the syndrome sequence.

Massey showed that, given an error pattern of weight $\leq t$, the connection polynomial resulting from the Berlekamp algorithm uniquely specifies the correct error locator polynomial.

The algorithm has four basic parameters: the connection polynomial $\Lambda^{(k)}(x)$, the correction polynomial $\mathrm{T}(x)$, the discrepancy $\Delta^{(k)}$, the length L of the shift register, and the indexing variable k. The algorithm proceeds as follows.

4.3. The Berlekamp–Massey Shift Register Synthesis Decoding Algorithm

1. Compute the syndrome sequence $S_1, \ldots, S_{2t}$ for the received word.
2. Initialize the algorithm variables as follows:

$$k = 0, \Lambda^{(0)}(x) = 1, \quad L = 0, \quad \text{and} \quad \mathrm{T}(x) = x$$

3. Set $k = k + 1$. Compute the discrepancy $\Delta^{(k)}$ by subtracting the kth output of the LFSR defined by $\sigma^{(k-1)}(x)$ from the kth syndrome:

$$\Delta^{(k)} = S_k - \sum_{i=1}^{L} \Lambda_i^{(k-1)} S_{k-i}$$

4. If $\Delta^{(k)} = 0$, then go to step 8.
5. Modify the connection polynomial: $\Lambda^{(k)}(x) = \Lambda^{(k-1)}(x) - \Delta^{(k)}\mathrm{T}(x)$
6. If $2L^3 k$, then go to step 8.
7. Set $L = k - L$ and $T(x) = \Lambda^{(k-1)}(x)/\Delta^{(k)}$.
8. Set $T(x) = x \cdot T(x)$
9. If $k < 2t$, then go to step 3.
10. Determine the roots of $\Lambda(x) = \Lambda^{(2t)}(x)$. If the roots are distinct and lie in the right field, then determine the error magnitudes, correct the corresponding locations in the received word, and *stop*.
11. Declare a decoding failure and *stop*.

The Berlekamp–Massey algorithm allows us to find the error locator polynomial, but there remains the problem of finding the error magnitudes. Forney [22]. showed that the following expression will do the trick:

$$e_{i_k} = \frac{-X_k \Omega(X_k^{-1})}{\Lambda'(X_k^{-1})}$$

Consider the following example of double-error correction [1]. using the Berlekamp–Massey algorithm and a (7,3) Reed–Solomon code (from Wicker [1]). Let the received polynomial be $r(x) = \alpha^2 x^6 + \alpha^2 x^4 + x^3 + \alpha^5 x^2$, giving the syndrome sequence $S_1 = \alpha^6$, $S_2 = \alpha^3$, $S_3 = \alpha^4$, $S_4 = \alpha^3$. The algorithm generates the following set of connection polynomials, discrepancies, and correction polynomials [the last column, $T(x)$, Follows at conclusion of step 8:

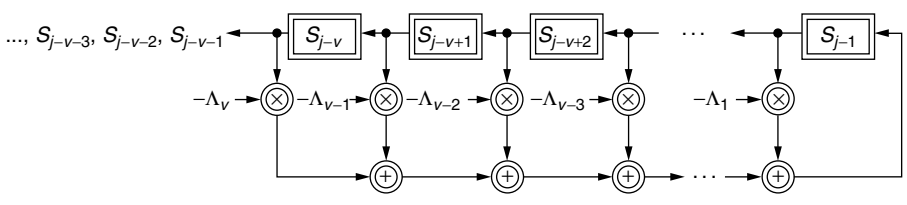

Figure 2. LFSR interpretation.

k	S_k	$\Lambda^{(k)}(x)$	$\Delta^{(k)}$	L	$T(x)$
0	—	1	—	0	x
1	α^6	$1+\alpha^6 x$	$S_1 - 0 = \alpha^6$	1	αx
2	α^3	$1+\alpha^4 x$	$S_2 - \alpha^5 = \alpha^2$	1	αx^2
3	α^4	$1+\alpha^4 x+\alpha^6 x^2$	$S_3 - 1 = \alpha^5$	2	$\alpha^2 x+\alpha^6 x^2$
4	α^3	$1+\alpha^2 x+\alpha x^2$	$S_4 - \alpha^4 = \alpha^6$	—	—

We obtain the error locator polynomial $\Lambda(x) = 1 + \alpha^2 x + \alpha x^2$.

The LFSRs corresponding to the connection polynomials $\Lambda^{(1)}(x)$ through $\Lambda^{(4)}(x)$ are drawn in Fig. 3, along with the initial conditions and the generated output sequence. Consider the LFSR with connection polynomial $\Lambda^{(3)}(x)$. This LFSR correctly generates the first three syndromes, but its fourth output, α^4, is not equal to $S_4 = \alpha^3$. The discrepancy $\Delta^{(4)} = \alpha^6$ is the difference between the two values, as shown in Fig. 3. This discrepancy is used to determine the connection polynomial $\Lambda^{(4)}(x)$, which, as shown in Fig. 3, correctly generates all four syndromes.

The syndrome sequence provides the syndrome polynomial $S(x) = \alpha^6 x + \alpha^3 x^2 + \alpha^4 x^3 + \alpha^3 x^4$. We used the Berlekamp–Massey algorithm to obtain the error locator polynomial $\Lambda(x) = 1 + \alpha^2 x + \alpha x^2$. We can now compute the error magnitude polynomial:

$$\begin{aligned}\Omega(x) &\equiv \Lambda(x)[1 + S(x)] \bmod x^{2t+1} \\ &\equiv (1 + \alpha^{2x} + \alpha^{x^2})(1 + \alpha^{6x} + \alpha^{3x^2} + \alpha^{4x^3} + \alpha^{3x^4}) \bmod x^5 \\ &\equiv (1 + x + \alpha^{3x^2}) \bmod x^5\end{aligned}$$

The errors locators were found to be $X_1 = \alpha^3$ and $X_2 = \alpha^5$ in the first part of this example. Using the Forney algorithm, the error magnitudes are found to be

$$\begin{aligned}e_{i_x k} &= \frac{-X_k \Omega(X_k^{-1})}{\Lambda'(X_k^{-1})} = \frac{-X_k[1 + X_k^{-1} + \alpha^3 X_k^{-2}]}{\alpha^2} \\ &= \alpha^5 X_k + \alpha^5 + \alpha X_k^{-1}\end{aligned}$$

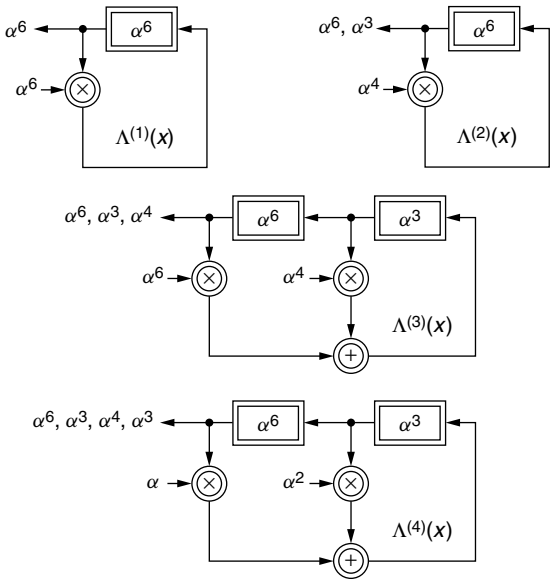

Figure 3. Several different LFSR syndromes.

$$e_3 = \alpha^5 \alpha^3 + \alpha^5 + \alpha\alpha^4 = \alpha$$

$$e_5 = \alpha^5 \alpha^5 + \alpha^5 + \alpha\alpha^2 = \alpha^5$$

The error polynomial is thus $e(x) = \alpha x^3 + \alpha^5 x^5$.

5. APPLICATIONS

The applications of cyclic codes are legion. In this final section we will focus on two of the more interesting applications: digital audio and deep-space telecommunications.

5.1. The Compact-Disk (CD) Player

The most ubiquitous application of cyclic codes (or possibly any error control codes) lies in the CD player. The channel in a CD playback system consists of a transmitting laser, a recorded disk, and a photodetector. Assuming that the player is working properly, the primary contributor to errors on this channel is the contamination of the surface of the disk (e.g., fingerprints and scratches). As the surface contamination surface contamination affects an area that is usually quite large compared to the surface used to record a single bit, channel errors occur in bursts when the disk is played. As we shall see, the CD error control system handles bursts through cross-interleaving and through the burst error-correcting capability of Reed–Solomon codes.

Figure 4 shows the various stages through which music is processed on its way to being recorded on a disk. Each channel is sampled 44,100 times per second, allowing accurate reproduction of all frequencies up to 22 kHz. Each sample is then converted into digital form by a 16-bit analog-to-digital converter.

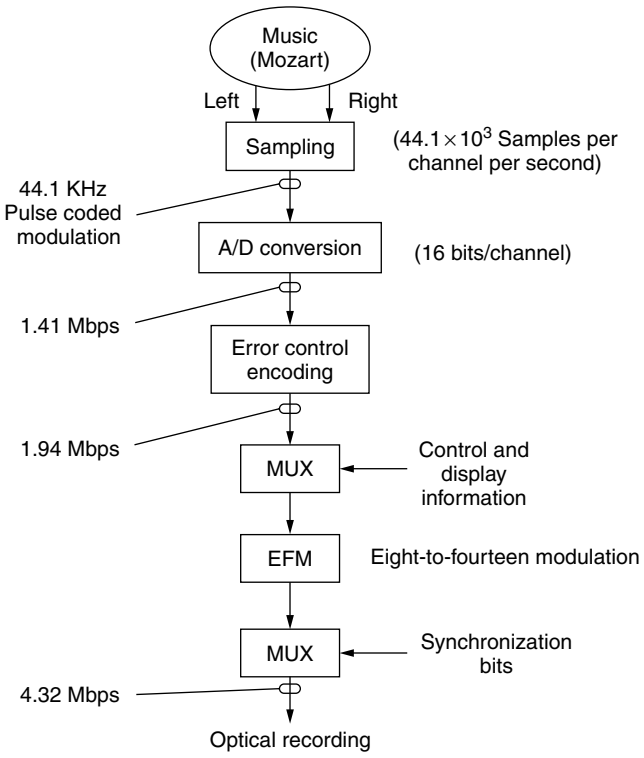

Figure 4. Data processing in the creation of a compact disk [1].

The output of the A/D converter forms a 1.41-Mbps (megabits per second) datastream, which is passed directly to the CIRC encoder. The CIRC encoder, as shown in Fig. 4, uses two shortened Reed–Solomon codes, $\mathbf{C}_1$ and $\mathbf{C}_2$. Both codes uses 8-bit symbols from the code alphabet GF(256). This provides for a nice match with the 16-bit samples emerging from the A/D converter. The "natural" length of the RS code over GF(256) is 255, which would lead to 2040-bit codewords and a relatively complicated decoder. It should be remembered that the decoder will reside in the retail player, and it is extremely important that its cost be minimized. The codes are thus shortened significantly: $\mathbf{C}_1$ is a (32,28) code and $\mathbf{C}_2$ is a (28,24) code. Both have redundancy 4 and minimum distance 5.

Each 16-bit sample is treated as a pair of symbols from GF(256). The samples are encoded 12 at a time by the $\mathbf{C}_2$ encoder to create a 28-symbol codeword. The 28 symbols in each $\mathbf{C}_2$ codeword are then passed through a cross-interleaver ($m = 28$, $D = 4$ symbols) before being encoded once by the $\mathbf{C}_1$ encoder. The resulting 32-symbol $\mathbf{C}_1$ codewords are then processed as shown in the figure above.

The CIRC encoding process for the CD system is standard; no matter where you buy your CDs (standard size), they will play on any CD player. However, the CIRC decoding process is not standardized and can vary from player to player [28]. This was done intentionally to allow the manufacturers to experiment with various designs and to speed the player to market. The basic building blocks of the decoder are shown in the figure. The $\mathbf{C}_1$ decoder is followed by a cross-deinterleaver and a $\mathbf{C}_2$ decoder. Since both codes have minimum distance 5, they can be used to correct all error patterns of weight

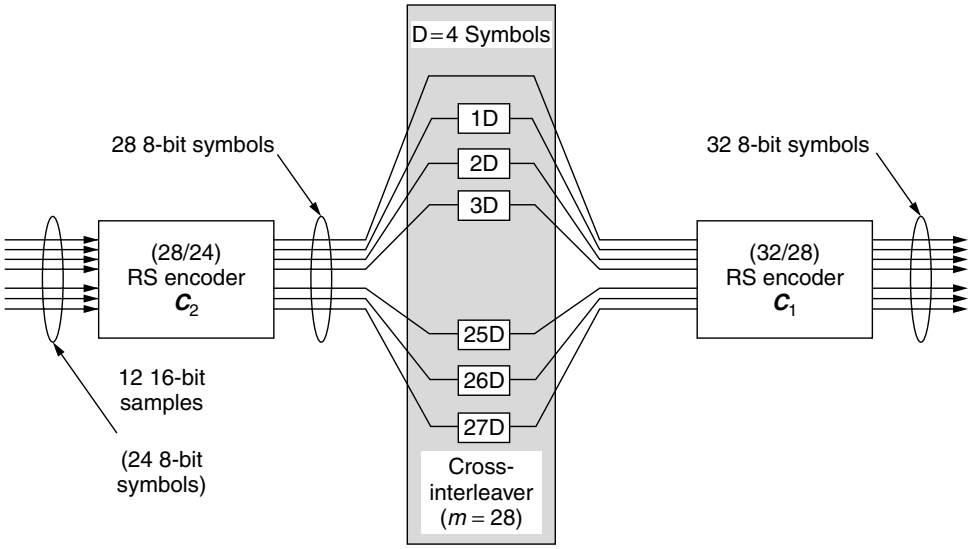

Figure 5. Cross-interleaved encoding [1].

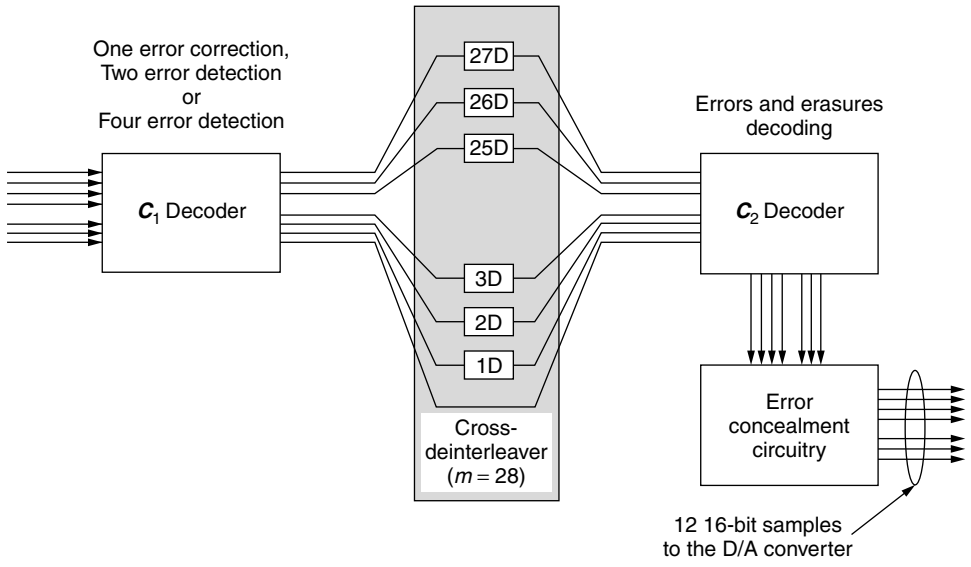

Figure 6. Basic structure of a CIRC decoder [1].

2 or less. Even when the full error correcting capacity of an RS code is used, there remains a significant amount of error detecting capacity. It is also the case that some of the error correction capacity of the RS code can be exchanged for an increase in error detection capacity and a substantial improvement in reliability performance. Most CIRC decoders take advantage of both of these principles. The $\mathbf{C}_1$ decoder is set to correct all single-error patterns. When the $\mathbf{C}_1$ decoder sees a higher-weight error pattern (double-error patterns and any pattern causing a decoder failure), the decoder outputs 28 erased symbols. The cross-deinterleaver spreads these erasures over 28 $\mathbf{C}_2$ codewords. $\mathbf{C}_1$ may also be set to correct double error patterns, or, at the other extreme, may simply be used to declare erasures (the least expensive implementation).

The $\mathbf{C}_2$ decoder can correct any combination of e errors and s erasures, where $2e + s < 5$. It is generally designed to decode erasures only (again, an inexpensive solution) due to the small probability of a $\mathbf{C}_1$ decoder error. Whenever the number of erasures exceeds 4, the $\mathbf{C}_2$ decoder outputs 24 erasures, which corresponds to 12 erased music samples. The error concealment circuitry error concealment circuitry responds by muting these samples or by interpolating values through the use of correct samples adjacent to the correct samples. A number of additional interleaving and delay operations are included in the encoding and decoding operations in order to enhance the operation of the error concealment circuitry. For example, samples adjacent in time are further separated by additional interleavers to improve the impact of interpolation [28].

5.2. Deep-Space Telecommunications

The earliest use of a cyclic code in deep-space telecommunications was in conjunction with the *Mariner* mission in 1971. *Mariner* included an infrared interferometer spectrometer (IRIS) [20,29]. The data from this instrument required a bit error rate on the order of 10^{-5}, and thus needed protection beyond that provided by the then standard Reed–Muller-based system. It was decided to precode the IRIS data using a [6,4] Reed-Solomon code with symbols from GF(2^6), thus creating the first concatenated system designed for use in deep-space telecommunications. The RS outer code was applied only to the IRIS data, thus keeping the overall code rate of the telemetry channel quite close to that of the Reed–Muller system by itself. This use of concatenated schemes to provide selective error protection was revisited in the development of the *Voyager* mission.

The *Voyager* 1 and 2 spacecraft were launched toward Saturn and Jupiter, respectively, in the summer of 1977. They carried a number of scientific instruments and imaging systems for a mission that was to be the most successful in the history of the exploration of deep space. The *Voyager* spacecraft were originally intended to explore Jupiter, Saturn, and their moons. The distances involved were substantial: Jupiter and Saturn are 483 million miles and 870 million miles from the sun, respectively. During the Jupiter flyby, *Voyager* 2 transmitted a 21.3-W signal through an antenna with $G_T = 6.5 \times 10^4$ (48.1 dB). By the time the signal was recovered by a 64-m dish on the earth, the signal measured 3.04×10^{-16} W. The telemetry signal consisted of two basic types of data: imaging and general science and engineering (GSE). The color images were reconstructed from three (800×800) arrays of 8-bit pixels, giving a total of 15,360,000 bits per image [29]. The uncompressed images required a nominal bit error rate of 5×10^{-3}. It was found that the rate-$\frac{1}{2}$ Planetary Standard was sufficient to provide the desired level of reliability. The GSE data, however, required a much lower bit error rate than the imaging data. The configuration in Fig. 7 was adopted. The GSE data was first encoded using the extended (24,12) Golay code discussed earlier in this article. The GSE and imaging data were then both encoded using the rate-$\frac{1}{2}$ Planetary Standard. At a 2.3 dB

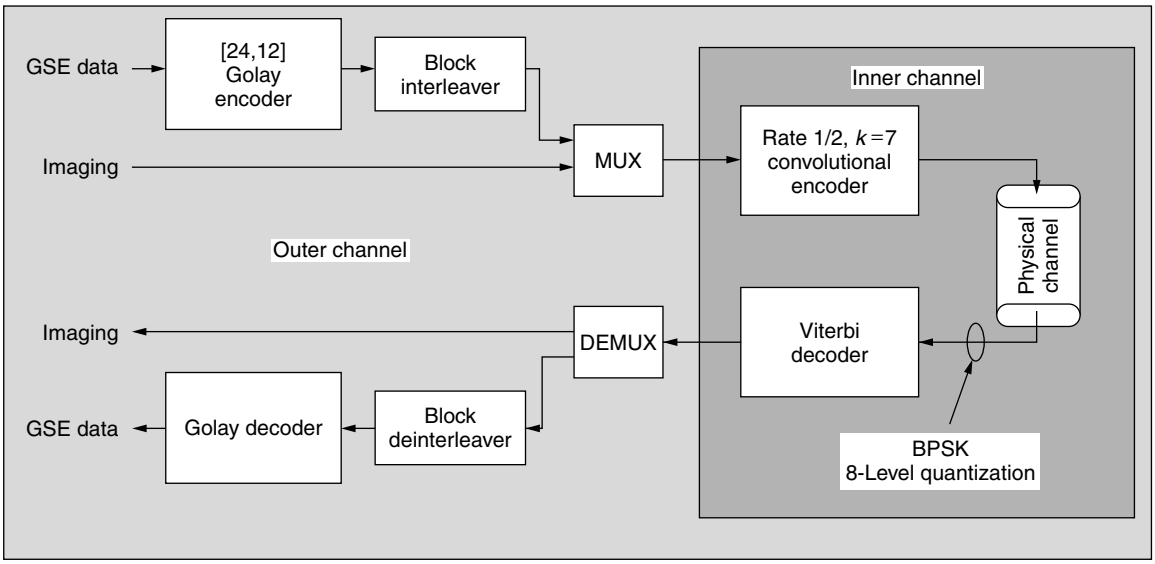

Figure 7. Convolutional/Viterbi and Golay concatenated system for the *Voyager* spacecraft (Jupiter and Saturn flybys) [20].

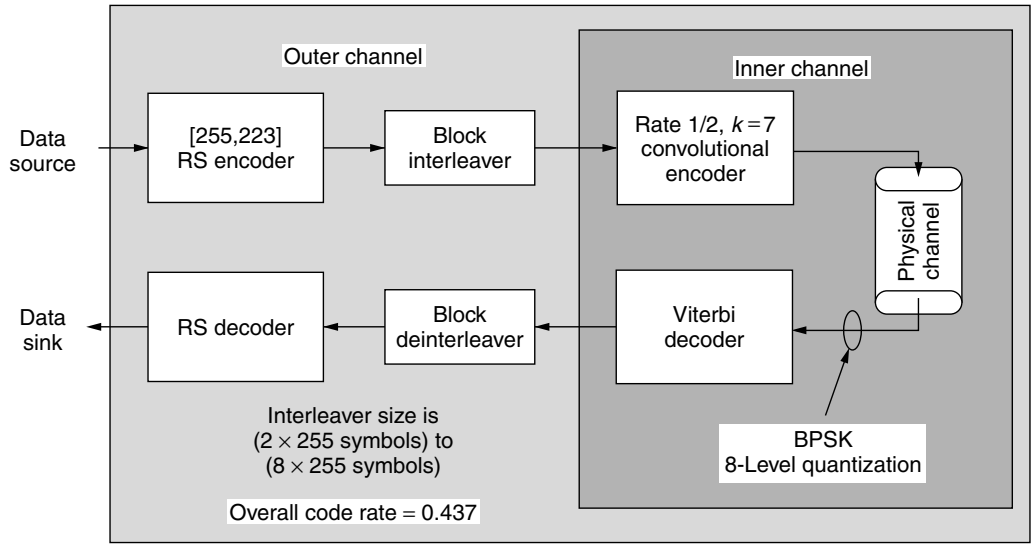

Figure 8. CCSDS Standard for deep-space telemetry links [20].

E_b/N_0, the convolutional code provided an inner channel bit error rate of 5×10^{-3}. The Golay code provides an outer channel bit error rate of less than 1×10^{-5}.

When the *Voyager* mission was extended to cover several of the outer planets, it was necessary to increase the level of error protection. As with the GSE data in the Jupiter and Saturn flybys, the additional reliability requirement was handled through the use of a concatenated system. In this case, however, the extremely low bit error rate requirement and the sensitivity of the link budget to a reduction in code rate pointed towards the use of Reed–Solomon technology for the outer code. The resulting concatenated system later became the basis for the CCSDS standard for deep-space telemetry links [30]. This standard has been used extensively by both NASA and the European Space Agency. In the CCSDS standard, the rate-$\frac{1}{2}$ Planetary Standard is joined by a (255,223) RS outer code with symbols from GF(2^8), as shown in Fig. 8.

1. INTRODUCTION

A modern-day data communication system must be capable of transmitting data of all types, such as text, speech, audio, image or video data. The block diagram in Fig. 1 depicts a data communication system, consisting of *source, encoder, channel*, and *decoder*:

The source generates the data sequence that is to be transmitted through the data communication system. The encoder converts the data sequence into a binary codeword for transmission through the channel. The decoder generates a reconstructed data sequence that may or not be equal to the original data sequence. The encoder/decoder pair in Fig. 1 is the *code* of the data communication system. In Fig. 1, the source and channel are fixed; the choice of code is flexible, in order to accomplish the twin goals of *bandwidth efficiency* and *reliable transmission*, described as follows:

1. *Bandwidth efficiency* — the portion of the available channel bandwidth that is allocated in order to communicate the given data sequence should be economized.
2. *Reliable transmission* — the reconstructed data sequence should be equal or sufficiently close to the original data sequence.

Unfortunately, these are conflicting goals; less use of bandwidth makes for less reliable transmission, and conversely, more reliable transmission requires the use of more bandwidth. It is the job of the data communication system designer to select a code that will yield a good tradeoff between these two goals. Code design is typically done in one of the following two ways.

1. *Separated Code Design*. Two codes are designed, a *source code* and a *channel code*, and then the source code and the channel code are cascaded together. Figure 2 illustrates the procedure. The source code is the pair consisting of the source encoder and source decoder; the channel code is the (channel encoder, channel decoder) pair. The source code achieves the goal of bandwidth efficiency: The source encoder removes a large amount of redundancy from the data sequence that can be restored (or approximately restored) by the source decoder. The channel code achieves the goal of reliable transmission: The channel encoder inserts a small amount of redundancy in the channel input stream that will allow the channel decoder to correct the transmission errors in that stream that are caused by the channel.

2. *Combined Code Design*. One code (as in Fig. 1) is designed to accomplish the twin goals of bandwidth efficiency and reliable transmission. Clearly, combined code design is more general than separated code design. However, previously separated codes were preferred to combined codes in data communication system design. There were two good reason for this: (a) Claude Shannon showed that if the data sequence is sufficiently long, and if the probabilistic models for the source and the channel are sufficiently simple, then there is no loss in the bandwidth versus reliability tradeoff that is achievable using separated codes of arbitrary complexity instead of combined codes of arbitrary complexity; and (b) the code design problem is made easier by separating it into the two decoupled problems of source code design and channel code design. For the communication of short data sequences, or for the scenario in which the complexity of the code is to be constrained, there can be an advantage to using combined codes as opposed to separated codes; consequently, there much attention has focused on the combined code design problem since the mid-1980s. At the time of the writing of this article, however, results on combined code design are somewhat isolated and have not yet been combined into a nice theory. On the other hand, the two separate theories of source code design and channel code design are well developed. The purpose of the present article is to provide an introduction to source code design.

In source code design, one can assume that the communication channel introduces no errors, because the purpose of the channel code is to correct whatever channel errors occur. Thus, we may use Fig. 3 below, which contains no channel, as the conceptual model guiding source code design.

The system in Fig. 3 is called a *data compression system* — it consists of the source and the source code consisting of the (source encoder, source decoder) pair. The data sequence generated by the source is random and is denoted X^n; the notation X^n is a shorthand for the following random sequence of length n:

$$X^n = (X_1, X_2, \ldots, X_n) \tag{1}$$

The X_i values $(i = 1, 2, \ldots, n)$ are the individual *data samples* generated by the source. In Fig. 3, B^K is a

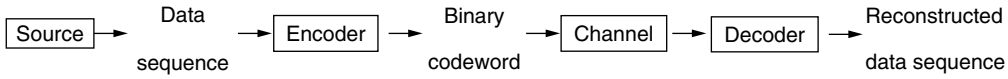

Figure 1. Block diagram of data communication system.

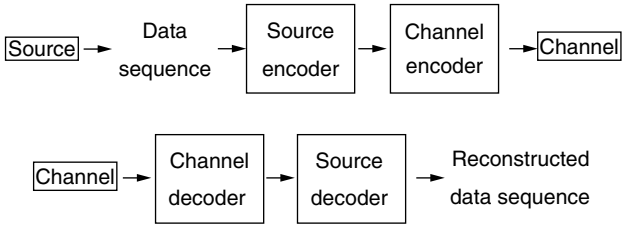

Figure 2. Data communication system with separated code.

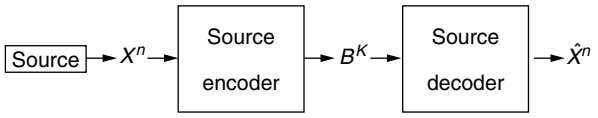

Figure 3. Block diagram of data compression system.

binary codeword generated by the source encoder as a deterministic function of X^n; B^K is random, and its distribution can be computed from the distribution of X^n. Our notational convention means that B^K is a shorthand for

$$B^K = (B_1, B_2, \ldots, B_K) \tag{2}$$

where each $B_i (i = 1, 2, \ldots, K)$, is a *code bit* belonging to the binary alphabet $\{0, 1\}$. The fact that K is capitalized means that K is random; that is, a *variable-length* codeword is used. The reconstructed data sequence generated by the source decoder in Fig. 3 is of length n and has been denoted $\hat{X}^n$. The sequence $\hat{X}^n$ is a deterministic function of B^K, and therefore also a deterministic function of X^n; $\hat{X}^n$ is random and its distribution can be computed from the distribution of X^n. Notationally

$$\hat{X}^n = (\hat{X}_1, \hat{X}_2, \ldots, \hat{X}_n) \tag{3}$$

where each $\hat{X}_i (i = 1, 2, \ldots, n)$ is an approximation to X_i.

1.1. Mathematical Description of Source

We need to give a formal mathematical model describing the probabilistic nature of the source in Fig. 3. Accordingly, a source is defined to be a triple $[n, A_n, P_n]$, where

- n is a positive integer that is the length of the random data sequence X^n generated by the source $[n, A_n, P_n]$.
- A_n is the set of all sequences of length n which are realizations of X^n. (The set A_n models the set of all possible deterministic sequences that could be processed by the data compression system driven by the source $[n, A_n, P_n]$.)
- P_n denotes the probability distribution of X^n; it is a probability distribution on A_n. We have

$$\Pr[X^n \in S_n] = P_n(S_n), S_n \subset A_n$$
$$\Pr[X^n \in A_n] = P_n(A_n) = 1$$

The *alphabet* of the source $[n, A_n, P_n]$ is the smallest set A such that $A_n \subset A^n$, where A^n denotes the set of all sequences of length n whose entries come from A. For a fixed positive integer n, a source $[n, A_n, P_n]$ shall be referred to as an nth-*order source*.

1.2. Memoryless Source

The most common type of source model is the *memoryless source*. In an nth-order memoryless source, the data samples $X_1, X_2, \ldots, X_n$ are taken to be independent, identically distributed random variables. Therefore, the joint probability density function $f(x_1, x_2, \ldots, x_n)$ of the memoryless source output X^n factors as

$$f(x_1, x_2, \ldots, x_n) = f_1(x_1) f_1(x_2) \cdots f_1(x_n)$$

where f_1 is a fixed probability density function.

1.3. Markov Source

The second most common type of source model is the *stationary Markov source*. For an nth-order source, the stationary Markov source assumption means that the joint probability density function $f(x_1, x_2, \ldots, x_n)$ of the source output X^n factors as

$$f(x_1, x_2, \ldots, x_n) = \frac{f_2(x_1, x_2) f_2(x_2, x_3) \cdots f_2(x_{n-1}, x_n)}{f_1(x_2) f_1(x_3) \cdots f_1(x_{n-1})}$$

where f_2 is a fixed 2D (two-dimensional) probability density function, and f_1 is a 1D probability density function related to f_2 by

$$f_1(x_1) = \int_{-\infty}^{\infty} f_2(x_1, x_2)\, dx_2 = \int_{-\infty}^{\infty} f_2(x_2, x_1)\, dx_2$$

1.4. Lossless and Lossy Compression Systems

Two types of data compression systems are treated in this article: *lossless compression systems* and *lossy compression systems*. In a lossless compression system, the set A_n of possible data sequence inputs to the system is finite, the encoder is a one-to-one mapping (this means that there is a one-to-one correspondence between data sequences and their binary codewords), and the decoder is the inverse of the encoder; thus, in a lossless compression system, the random data sequence X^n generated by the source and its reconstruction $\hat{X}^n$ at the decoder output are the same:

$$\Pr[X^n = \hat{X}^n] = 1$$

In a lossy compression system, two or more data sequences in A_n are assigned the same binary codeword, so that

$$\Pr[X^n \neq \hat{X}^n] > 0$$

Whether one designs a lossless or lossy compression system depends on the type of data that are to be transmitted in a data communication system. For example, for textual data, lossless compression is used because one typically wants perfect reconstruction of the transmitted text; on the other hand, for image data, lossy compression would be appropriate if the reconstructed image is required only to be perceptually equivalent to the original image.

This article is divided into two halves. In the first half, we deal with the design of lossless codes, namely, source codes for lossless compression systems. In the second half,

design of lossy codes (source codes for lossy compression systems) is considered.

2. LOSSLESS COMPRESSION METHODOLOGIES

In this section, we shall be concerned with the problem of designing lossless codes. Figure 4 depicts a general lossless compression system. In Fig. 4, the pair consisting of source encoder and source decoder is called a *lossless code*. A lossless code is completely determined by its source encoder part, since the source decoder is the inverse mapping of the source encoder.

Let $[n, A_n, P_n]$ be a given source with finite alphabet. When a lossless code is used to compress the data generated by the source $[n, A_n, P_n]$, a lossless compression system S_n results as in Fig. 4. The effectiveness of the lossless code is then evaluated by means of the figure of merit

$$R(S_n) \triangleq n^{-1} \sum_{x^n \in A_n} P_n(x^n) K(x^n)$$

where $K(x^n)$ is the length of the codeword assigned by the lossless code to the data sequence $x^n \in A_n$. The figure of merit $R(S_n)$ is called *compression rate* and its units are "code bits per data sample." An efficient lossless code for compressing data generated by the source $[n, A_n, P_n]$ is a lossless code giving rise to a compression system S_n for which the compression rate $R(S_n)$ is minimized or nearly minimized. In this section, we put forth various types of lossless codes that are efficient in this sense.

In lossless code design, we make the customary assumption that the codewords assigned by a lossless code must satisfy the *prefix condition*, which means that no codeword is a prefix of any other codeword. If $K_1, K_2, \ldots, K_j$ are the lengths of the codewords assigned by a lossless code, then *Kraft's inequality*

$$2^{-K_1} + 2^{-K_2} + \cdots + 2^{-K_j} \leq 1 \tag{4}$$

must hold. Conversely, if positive integers $K_1, K_2, \ldots, K_j$ obey Kraft's inequality, then there exists a lossless code whose codewords have these lengths. In this case, one can build a rooted tree T with j leaves and at most two outgoing edges per internal vertex, such that $K_1, K_2, \ldots, K_j$ are the lengths of the root-to-leaf paths; the codewords are obtained by labeling the edges along these paths with 0s and 1s. The tree T can be found by applying the Huffman algorithm (covered in Section 2.2) to the set of probabilities $2^{-K_1}, 2^{-K_2}, \ldots, 2^{-K_j}$.

There are two methods for specifying a lossless code for the source $[n, A_n, P_n]$: (1) an encoding table can be given which lists the binary codeword to be assigned to each sequence in A_n (decoding is then accomplished by using the encoding table in reverse), or (2) encoding and decoding algorithms can be given that indicate how to compute the binary codeword for each sequence in $x^n \in A_n$ and how to compute x^n from its codeword. We will specify each lossless code discussed in this section using either method 1 or 2, depending on which method is more convenient. Method 1 is particularly convenient if the codeword lengths are known in advance, since, as pointed out earlier, a tree can be constructed that yields the codewords. Method 2 is more convenient if the data length n is large (which makes the storing of an encoding table impractical).

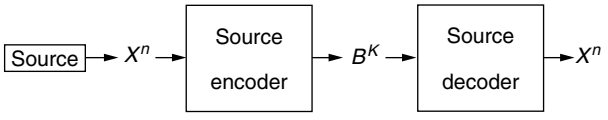

Figure 4. Lossless data compression system.

2.1. Entropy Bounds

It is helpful to understand the entropy upper and lower bounds on the performance of lossless codes. With these bounds, one can determine before designing a lossless code what kind of performance it is possible for such a code to achieve, as well as what kind of performance it is not possible to achieve.

The entropy of the source $[n, A_n, P_n]$ is defined by

$$H_n \triangleq \sum_{x^n \in A_n} (-\log_2 P_n(x^n)) P_n(x^n)$$

Suppose that the random data sequence generated by the source $[n, A_n, P_n]$ is compressed by an arbitrary lossless code and let S_n be the resulting lossless compression system (as in Fig. 4). Then, the compression rate is known to satisfy the relationship

$$R(S_n) \geq \frac{H_n}{n} \tag{5}$$

Conversely, it is known that there exists at least one lossless code for which

$$R(S_n) \leq \frac{H_n + 1}{n} \tag{6}$$

Assume that the data length n is large. We can combine the bounds (5) and (6) to assert that a lossless code is efficient if and only if the resulting compression rate satisfies

$$R(S_n) \approx \frac{H_n}{n}$$

The quantity H_n/n is called the *entropy rate* of the source $[n, A_n, P_n]$. Our conclusion is that a lossless code is efficient for compressing source data if and only if the resulting compression rate is approximately equal to the entropy rate of the source. For the memoryless source and the Markov source, this result can be sharpened, as the following discussion shows.

2.1.1. Efficient Lossless Codes for Memoryless Sources.

Assume that the given source $[n, A_n, P_n]$ is a memoryless source; let A be the finite source alphabet. There is a probability mass function $[p(a): a \in A]$ on A such that

$$P_n(x_1, x_2, \ldots, x_n) = \prod_{i=1}^{n} p(x_i),\ (x_1, x_2, \ldots, x_n) \in A_n \tag{7}$$

Let H_0 be the number

$$H_0 \triangleq \sum_{a \in A} (-\log_2 p(a)) p(a) \tag{8}$$

It is easy to show from (7) that the source entropy satisfies

$$H_n = nH_0$$

and therefore H_0 is the entropy rate of the source $[n, A_n, P_n]$. Assuming that the data length n is large, we conclude that a lossless code for compressing the data generated by the memoryless source $[n, A_n, P_n]$ is efficient if and only if the resulting compression rate is approximately equal to H_0.

2.1.2. Efficient Lossless Codes for Markov Sources. Now assume that the source $[n, A_n, P_n]$ is a stationary Markov source; let A be the finite source alphabet. There is a probability mass function $[p(a): a \in A]$ on A, and a nonnegative matrix $[\pi(a_1, a_2): a_1, a_2 \in A]$ whose rows each sum to one such that both of the following are true:

$$p(a_2) = \sum_{a_1 \in A} p(a_1)\pi(a_1, a_2), \ a_2 \in A \tag{9}$$

$$P_n(x_1, x_2, \ldots, x_n) = p(x_1) \prod_{i=2}^{n} \pi(x_{i-1}, x_i), \ (x_1, x_2, \ldots, x_n) \in A_n \tag{10}$$

Let H_0 be the number (8) and H_1 be the number

$$H_1 \triangleq \sum_{a_1 \in A} \sum_{a_2 \in A} (-\log_2 \pi(a_1, a_2)) p(a_1)\pi(a_1, a_2)$$

It can be shown from these last two equations that

$$H_n = H_0 + (n-1)H_1$$

Thus, for large n, the entropy rate H_n/n of the source is approximately equal to H_1. Assuming that the data length n is large, we conclude that a lossless code for compressing the data generated by the stationary Markov source $[n, A_n, P_n]$ is efficient if and only if the resulting compression rate is approximately equal to H_1.

In the rest of this section, we survey each of the following efficient classes of lossless codes:

- Huffman codes
- Enumerative codes
- Arithmetic codes
- Lempel–Ziv codes

2.2. Huffman Codes

Fix a source $[n, A_n, P_n]$ with A_n finite; let S_n denote a lossless compression system driven by this source (see Fig. 4). In 1948, Claude Shannon put forth the following monotonicity principle for code design for the system S_n: The length of the binary codeword assigned to each data sequence in A_n should be inversely related to the probability with which that sequence occurs. According to this principle, data sequences with low probability of occurrence are assigned long binary codewords, whereas data sequences with high probability of occurrence are assigned short binary codewords. In Shannon's 1948 paper [42], a code called the *Shannon–Fano code* was put forth that obeys the monotonicity principle; it assigns a codeword to data sequence $(x_1, x_2, \ldots, x_n) \in A_n$ of length

$$\lceil -\log_2 P_n(x_1, x_2, \ldots, x_n) \rceil$$

The compression rate $R(S_n)$ resulting from the use of the Shannon–Fano code in system S_n is easily seen to satisfy

$$\frac{H_n}{n} \le R(S_n) \le \frac{H_n + 1}{n} \tag{11}$$

However, the Shannon–Fano code does not yield the minimal compression rate. The problem of finding the code that yields the minimal compression rate was solved in 1952 by David Huffman [22], and this code has been named the "Huffman code" in his honor.

We discuss the simplest instance of Huffman code design, namely, design of the Huffman code for a first-order source $[1, A, P]$; such a code encodes the individual letters in the source alphabet A and will be called a *first-order Huffman code*. If the letters in A are $a_1, a_2, \ldots, a_j$ and K_i denotes the length of the binary codeword into which letter a_i is encoded, then the Huffman code is the code for which

$$P(a_1)K_1 + P(a_2)K_2 + \cdots + P(a_j)K_j$$

is minimized. The Huffman algorithm constructs the encoding table of the Huffman code. The Huffman algorithm operates recursively in the following way. First, the letters a_i, a_j with the two smallest probabilities $P(a_i), P(a_j)$ are removed from the alphabet A and replaced with a single "superletter" $a_i a_j$ of probability $P(a_i) + P(a_j)$. Then, the Huffman code for the reduced alphabet is extended to a Huffman code for the original alphabet by assigning codeword $w0$ to a_i and codeword $w1$ to a_j, where w is the codeword assigned to the superletter $a_i a_j$.

Table 1 gives an example of the encoding table for the Huffman code for a first-order source with alphabet $\{a_1, a_2, a_3, a_4\}$. It is easy to deduce that the code given by Table 1 yields minimum compression rate without using the Huffman algorithm. First, notice that the codeword lengths $K_1, K_2, \ldots, K_j$ assigned by a minimum compression rate code must satisfy the equation

$$2^{-K_1} + 2^{-K_2} + \cdots + 2^{-K_j} = 1 \tag{12}$$

Table 1. Example of a Huffman Code

Source Letter	Probability	Codeword
a_1	$\frac{1}{2}$	0
a_2	$\frac{1}{5}$	10
a_3	$\frac{3}{20}$	110
a_4	$\frac{3}{20}$	111

[Kraft's inequality (2.4) is satisfied; if the inequality were strict, at least one of the codewords could be shortened and the code would not yield minimum compression rate.] Since the source has only a four-letter alphabet, there are only two possible solutions to (12), and therefore only two possible sets of codeword lengths for a first-order code, namely, 1,2,3,3 and 2,2,2,2. The first choice yields compression rate (or, equivalently, expected codeword length) of

$$1\tfrac{1}{2} + 2\tfrac{1}{5} + 3\tfrac{3}{20} + 3\tfrac{3}{20} = 1.8$$

code bits per data sample, whereas the second choice yields the worse compression rate of 2 code bits per data sample. Hence, the code given by Table 1 must be the Huffman code. One could use the Huffman algorithm to find this code. Combining the two least-probable letters a_3 and a_4 into the superletter a_3a_4, the following table gives the Huffman encoder for the reduced alphabet:

Source Letter	Probability	Codeword
a_1	$\frac{1}{2}$	0
a_3a_4	$\frac{6}{20}$	11
a_2	$\frac{1}{5}$	10

(This is immediate because for a three-letter alphabet, there is only one possible choice for the set of codeword lengths, namely, 1,2,2.) Expanding the codeword 11 for a_3a_4 into the codewords 110 and 111, we obtain the Huffman code in Table 1.

2.3. Enumerative Codes

Enumerative coding, in its present state of development, is due to Thomas Cover [11]. Enumerative coding is used for a source $[n, A_n, P_n]$ in which the data sequences in A_n are equally likely; the best lossless code for such a source is one that assigns codewords of equal length. Here is Cover's approach to enumerative code design:

Step 1. Let N be the number of sequences in A_n, and let A be the source alphabet. Construct the rooted tree T with N leaves, such that the edges emanating from each internal vertex have distinct labels from A, and such that the N sequences in A_n are found by writing down the labels along the N root-to-leaf paths of T.

Step 2. Locate all paths in T that visit only unary vertices in between and that are not subpaths of other such paths. Collapse each of these paths to single edges, labeling each such single edge that results with the sequence of labels along the collapsed path. This yields a tree T^* with N leaves (the same as the leaves of T). Label each leaf of T^* with the sequence obtained by concatenating together the labels on the root-to-leaf path to that leaf; these leaf labels are just the sequences in A_n.

Step 3. Assign an integer weight to each vertex v of T^* as follows. If v has no siblings or is further to the left than its siblings, assign v a weight of zero. If v has siblings further to the left, assign v a weight equal to the number of leaves of T^* that are equal to or subordinate to the siblings of v that are to the left of v.

Step 4. To encode $x^n \in A_n$, follow the root-to-leaf path in T^* terminating in the leaf of T^* labeled by x^n. Let I be the sum of the weights of the vertices along this root-to-leaf path. The integer I is called the *index* of x^n, and satisfies $0 \le I \le N-1$. Encode x^n into the binary codeword of length $\lceil \log_2 N \rceil$ obtained by finding the binary expansion of I and then padding that expansion (if necessary) to $\lceil \log_2 N \rceil$ bits by appending a prefix of zeros.

For example, suppose that the source $[n, A_n, P_n]$ satisfies

$$A_n = \{aaa, aba, abb, abc, baa, bba, caa, cba, cbb, cca\} \tag{13}$$

Then steps 1–3 yield the tree T^* in Fig. 5, in which every vertex is labeled with its weight from step 3. [The 10 leaves of this tree, from left to right, correspond to the 10 sequences in (13), from left to right.] The I values along the 10 paths are just the cumulative sums of the weights, which are seen to give $I = 0,1,2,3,4,5,6,7,8,9$. The codeword length is $\lceil \log_2 10 \rceil = 4$, and the respective codewords are

0000, 0001, 0010, 0011, 0100, 0101, 0110, 0111, 1000, 1001

Sometimes, the tree T^* has such a regular structure that one can obtain an explicit formula relating a data sequence and its index I, thereby dispensing with the need for the tree T^* altogether. A good example of this occurs with the source $[n, A_n, P]$ in which A_n is the set of all binary sequences of length n and having a number of ones equal to m (m is a fixed positive integer satisfying

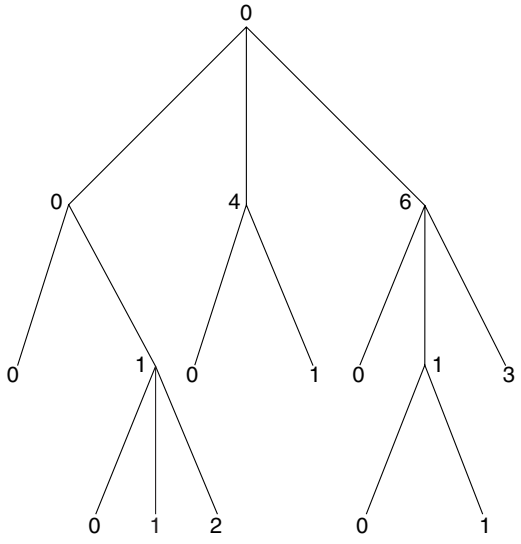

Figure 5. Weighted enumerative coding tree T^*.

$0 \le m \le n$). For a data sequence $(x_1, x_2, \ldots, x_n) \in A_n$, Cover showed that its index I is computable as

$$I = \sum_{j=1}^{n} x_j \binom{j-1}{x_1 + x_2 + \cdots + x_j} \tag{14}$$

There are $\binom{n}{m}$ sequences in A_n. Therefore, Eq. (14) provides a one-to-one correspondence between these sequences and the integers

$$0, 1, 2, 3, \ldots, \binom{n}{m} - 1$$

Having obtained I from $(x_1, x_2, \ldots, x_n)$ via this equation, $(x_1, x_2, \ldots, x_n)$ is encoded by expanding integer I in binary out to $\lceil \log_2 \binom{n}{m} \rceil$ bits. Conversely, $(x_1, x_2, \ldots, x_n)$ is decoded from its bit representation by first finding I, and then finding the unique expansion of I in (14) given by the right-hand side. To illustrate, suppose that $n = 8$ and $m = 4$. Then, A_n contains $\binom{8}{4} = 70$ sequences and I can be any integer between 0 and 69, inclusively. Suppose $I = 52$. To decode back into the data sequence in A_n that gave rise to the index $I = 52$, the decoder finds the unique integers $0 \le j_1 < j_2 < j_3 < j_4 < 8$ satisfying

$$52 = \binom{j_1}{1} + \binom{j_2}{2} + \binom{j_3}{3} + \binom{j_4}{4}$$

The solution is $j_1 = 1, j_2 = 4, j_3 = 5$, and $j_4 = 7$. The data sequence we are looking for must have ones in positions $j_1 + 1 = 2, j_2 + 1 = 5, j_3 + 1 = 6, j_4 + 1 = 8$; this is the sequence (0,1,0,0,1,1,0,1).

2.4. Arithmetic Codes

Arithmetic codes were invented by Peter Elias in unpublished work around 1960, but his schemes were not practical. In the 1970s, other people put Elias' ideas on a practical footing [33,36,37]. This section gives an introduction to arithmetic codes.

Arithmetic coding presents a whole new philosophy of coding. As the data samples in a data sequence $(x_1, x_2, \ldots, x_n)$ are processed from left to right by the arithmetic encoder, each data sample x_i is not replaced with a string of code bits as is done in conventional encoding—instead, each x_i is assigned a subinterval I_i of the unit interval [0, 1] so that

$$I_1 \supset I_2 \supset \cdots \supset I_n \tag{15}$$

and so that I_i is recursively determined from I_{i-1} and $x_i (i \ge 2)$. When the final interval I_n is determined, then the binary codeword $(b_1, b_2, \ldots, b_k)$ into which $(x_1, x_2, \ldots, x_n)$ is encoded is chosen so that the number

$$\frac{b_1}{2} + \frac{b_2}{4} + \frac{b_3}{8} + \cdots + \frac{b_k}{2^k} \tag{16}$$

is a point in I_n, where the codeword length k is approximately equal to $\log_2$ of the reciprocal of the probability assigned by the source to $(x_1, x_2, \ldots, x_n)$.

2.4.1. Precise Description. Arithmetic codes can be constructed for any source. For simplicity, we assume a memoryless source $[n, A_n, P_n]$ in which A_n consists of all sequences of length n whose entries come from the set $\{0, 1, 2, \ldots, j-1\}$, where j is a fixed positive integer. Then, for each data sequence $(x_1, x_2, \ldots, x_n) \in A_n$, the probability assigned by the source is

$$P_n(x_1, x_2, \ldots, x_n) = \prod_{i=1}^{n} p_{x_i}$$

where $p_0, p_1, \ldots, p_{j-1}$ are given nonnegative numbers that sum to one. We specify the arithmetic code for this source by describing algorithms for encoding and decoding. Let $a_0 = 0, a_1 = 1$. Arithmetic encoding of $(x_1, x_2, \ldots, x_n) \in A_n$ takes place according to the following three-step algorithm:

Encoding Step 1. For each $i = 1, 2, \ldots, n$, a subinterval $I_i = [a_i, b_i]$ of [0, 1] is recursively determined according to the formula

$$\begin{aligned} I_i &= [a_{i-1}, a_{i-1} + (b_{i-1} - a_{i-1})p_0], x_i = 0 \\ &= [a_{i-1} + (p_0 + \cdots + p_{x_i - 1})(b_{i-1} - a_{i-1}), a_{i-1} \\ &\quad + (p_0 + \cdots + p_{x_i})(b_{i-1} - a_{i-1})], x_i > 0 \end{aligned}$$

By construction, the last interval I_n will have length equal to $P_n(x_1, x_2, \ldots, x_n)$.

Encoding Step 2. The integer

$$k = \lceil -\log_2 P_n(x_1, x_2, \ldots, x_n) \rceil + 1$$

is determined. This integer will be the length of the codeword assigned by the arithmetic encoder to $(x_1, x_2, \ldots, x_n)$.

Encoding Step 3. The midpoint M of the interval I_n is computed. The codeword $(b_1, b_2, \ldots, b_k)$ assigned to $(x_1, x_2, \ldots, x_n)$ consists of the first k digits in the binary expansion of M.

The following arithmetic decoding algorithm is applied to the codeword $(b_1, b_2, \ldots, b_k)$ in order to reclaim the data sequence $(x_1, x_2, \ldots, x_n)$ that gave rise to it:

Decoding Step 1. Compute the point $\hat{M}$ given by the expression (16). By choice of k, the point $\hat{M}$ will lie in the interval I_n.

Decoding Step 2. There are j possibilities for I_1, depending on what x_1 is. Only one of these possibilities for I_1 contains $\hat{M}$. Using this fact, the decoder is able to determine I_1. From I_1, the decoder determines x_1.

Decoding Step 3. For each $i = 2, \ldots, n$, the decoder determines from I_{i-1} (determined previously) what the j possibilities for I_i are. Since only one of these possibilities for I_i contains $\hat{M}$, the decoder is able to determine I_i. From I_i, the decoder is able to determine x_i.

Example 1. Take the source alphabet to be $\{0, 1\}$, take the probabilities defining the memoryless source to be

$p_0 = \frac{2}{5}, p_1 = \frac{3}{5}$, and take the source to be $[5, \{0,1\}^5, P_5]$ (known to both encoder and decoder). Suppose that the data sequence to be arithmetically encoded is (1, 0, 1, 1, 0). We need to recursively determine the intervals I_1, I_2, I_3, I_4, I_5. We have

$$I_1 = \text{right } \frac{3}{5}\text{ths of } [0,1] = \left[\frac{2}{5}, 1\right]$$

$$I_2 = \text{left } \frac{2}{5}\text{ths of } I_1 = \left[\frac{2}{5}, \frac{16}{25}\right]$$

$$I_3 = \text{right } \frac{3}{5}\text{ths of } I_2 = \left[\frac{62}{125}, \frac{16}{25}\right]$$

$$I_4 = \text{right } \frac{3}{5}\text{ths of } I_3 = \left[\frac{346}{625}, \frac{16}{25}\right]$$

$$I_5 = \text{left } \frac{2}{5}\text{ths of } I_4 = \left[\frac{346}{625}, \frac{1838}{3125}\right]$$

The length of the interval I_5 is $\frac{108}{3125}$. Therefore, the length of the binary codeword must be

$$k = \left\lceil \log_2 \left(\frac{3125}{108} \right) \right\rceil + 1 = 6$$

The midpoint of the interval I_5 is $M = \frac{1784}{3125}$. Expanding this number in binary, we obtain

$$\frac{1784}{3125} = .100100\ldots$$

The binary codeword is therefore $(1,0,0,1,0,0)$. Given this codeword, how does the decoder determine the data sequence that gave rise to it? Since the decoder knows the source description, it knows that the data sequence to be found is of the form $(x_1, x_2, x_3, x_4, x_5)$, where the x_i terms are binary. To decode, the decoder first computes

$$\hat{M} = \frac{1}{2} + \frac{1}{16} = \frac{9}{16}$$

The decoder knows that

$$I_1 = \left[0, \tfrac{2}{5}\right] \quad \text{or} \quad I_1 = \left[\tfrac{2}{5}, 1\right]$$

Since $\frac{9}{16}$ is in the right interval, the decoder concludes that $I_1 = \left[\frac{2}{5}, 1\right]$ and that $x_1 = 1$. At this point, the decoder knows that

$$I_2 = \left[\frac{2}{5}, \frac{16}{25}\right] \text{ or } I_2 = \left[\frac{16}{25}, 1\right]$$

Since $\frac{9}{16}$ is in the left interval, the decoder concludes that $I_2 = \left[\frac{2}{5}, \frac{16}{25}\right]$ and that $x_2 = 0$. The decoder now knows that

$$I_3 = \left[\frac{2}{5}, \frac{62}{125}\right] \text{ or } I_3 = \left[\frac{62}{125}, \frac{16}{25}\right]$$

Since $\frac{9}{16}$ lies in the right interval, the decoder determines that $I_3 = \left[\frac{62}{125}, \frac{16}{25}\right]$, and that the third data sample is $x_3 = 1$. Similarly, the decoder can determine x_4 and x_5 by two more rounds of this procedure.

The reader sees from the preceding example that the arithmetic code as we have prescribed it requires ever greater precision as more and more data samples are processed. This creates a problem if there are a large number of data samples to be arithmetically encoded. One can give a more complicated (but less intuitive) description of the arithmetic encoder/decoder that uses only finite precision (integer arithmetic is used). A textbook [41] gives a wealth of detail on this approach.

2.4.2. Performance. In a sense that will be described here, arithmetic codes give the best possible performance, for large data length. First, we point out that for any source, an arithmetic code can be constructed. Let the source be $[n, A_n, P_n]$. For $(x_1, x_2, \ldots, x_n) \in A_n$, one can use conditional probabilities to factor the probability assigned to this sequence:

$$P_n(x_1, x_2, \ldots, x_n) = p(x_1) \prod_{i=2}^{n} p(x_i \mid x_1, x_2, \ldots, x_{i-1}).$$

The factors on the right side are explained as follows. Let $X_1, X_2, \ldots, X_n$ be the random data samples generated by the source. Then

$$p(x_1) = \Pr[X_1 = x_1]$$

$$p(x_i \mid x_1, x_2, \ldots, x_{i-1}) = \Pr[X_i = x_i \mid X_1 = x_1, X_2 = x_2, \ldots, X_{i-1} = x_{i-1}]$$

To arithmetically encode $(x_1, x_2, \ldots, x_n) \in A_n$, one constructs a decreasing sequence of intervals $I_1, I_2, \ldots, I_n$. One does this so that I_1 will have length $p(x_1)$ and for each $i = 2, \ldots, n$, the length of the interval I_i will be $p(x_i \mid x_1, x_2, \ldots, x_{i-1})$ times the length of the interval I_{i-1}. The rest of the encoding and decoding steps will be as already described for the memoryless source. Suppose a lossless data compression system S_n is built with the given source $[n, A_n, P_n]$ and the arithmetic code we have just sketched. It can be shown that the resulting compression rate satisfies

$$\frac{H_n}{n} \le R(S_n) \le \frac{H_n + 2}{n}$$

where H_n is the entropy of the source $[n, A_n, P_n]$. For large n, we therefore have $R(S_n) \approx H_n$. This is the best that one can possibly hope to do. If the source $[n, A_n, P_n]$ is memoryless or Markov, and n is large, one obtains the very good arithmetic code compression rate performance just described, but at the same time, the arithmetic code is of low complexity. As discussed in Section 2.2, for large n, the compression system S_n built using the Huffman code for the source $[n, A_n, P_n]$ will also achieve the very good compression rate performance $R(S_n) \approx H_n$, but this Huffman code will be very complex. For this reason, arithmetic codes are preferred over Huffman codes in many data compression applications. Two notable successes of arithmetic coding in practical

applications are the PPM text compression algorithm [8] and IBM's Q-coder [34], used for lossless binary image compression.

2.5. Lempel–Ziv Codes

Lempel–Ziv codes are examples of *dictionary codes*. A dictionary code first partitions a data sequence into variable-length phrases (this procedure is called *parsing*). Then, each phrase in the parsing is represented by means of a pointer to that phrase in a dictionary of phrases constructed from previously processed data. The phrase dictionary changes dynamically as the data sequence is processed from left to right. A binary codeword is then assigned to the data sequence by encoding the sequence of dictionary pointers in some simple way. The most popular dictionary codes are the Lempel–Ziv codes. There are many versions of the Lempel–Ziv codes. The one we discuss here is LZ78 [55]. Another popular Lempel–Ziv code, not discussed here, is LZ77 [54]. Two widely used compression algorithms on UNIX systems are Compress and Gzip; Compress is based on LZ78 and Gzip is based on LZ77.

In the rest of this section, we discuss the parsing technique, the pointer formation technique, and the pointer encoding technique employed in Lempel–Ziv coding.

2.5.1. Lempel–Ziv Parsing. Let $(x_1, x_2, \ldots, x_n)$ be the data sequence to be compressed. Partitioning of this sequence into variable-length blocks via *Lempel–Ziv parsing* takes place as follows. The first variable-length block arising from the Lempel–Ziv parsing of $(x_1, x_2, \ldots, x_n)$ is the single sample x_1. The second block in the parsing is the shortest prefix of $(x_2, x_3, \ldots, x_n)$ that is not equal to x_1. Suppose that this second block is $(x_2, \ldots, x_j)$. Then, the third block in Lempel–Ziv parsing will be the shortest prefix of $(x_{j+1}, x_{j+2}, \ldots, x_n)$ that is not equal to either x_1 or $(x_2, \ldots, x_j)$. In general, suppose that the Lempel–Ziv parsing procedure has produced the first k variable-length blocks $B_1, B_2, \ldots, B_k$ in the parsing, and $x^{(k)}$ is that part left of $(x_1, x_2, \ldots, x_n)$ after $B_1, B_2, \ldots, B_k$ have been removed. Then the next block B_{k+1} in the parsing is the shortest prefix of $x^{(k)}$ that is not equal to any of the preceding blocks $B_1, B_2, \ldots, B_k$. [If there is no such block, then $B_{k+1} = x^{(k)}$ and the Lempel-Ziv parsing procedure terminates.]

By construction, the sequence of variable-length blocks $B_1, B_2, \ldots, B_t$ produced by the Lempel–Ziv parsing of $(x_1, x_2, \ldots, x_n)$ are distinct, except that the last block B_t could be equal to one of the preceding ones. The following example illustrates Lempel–Ziv parsing.

Example 2. The Lempel–Ziv parsing of the data sequence

$$(1, 1, 0, 1, 1, 0, 0, 0, 1, 1, 0, 1) \tag{17}$$

is

$$B_1 = (1)$$
$$B_2 = (1, 0)$$
$$B_3 = (1, 1)$$
$$B_4 = (0)$$
$$B_5 = (0, 0)$$
$$B_6 = (1, 1, 0) \tag{18}$$
$$B_7 = (1) \tag{19}$$

2.5.2. Pointer Formation. We suppose that the alphabet from which the data sequence $(x_1, x_2, \ldots, x_n)$ is formed is $A = \{0, 1, \ldots, k-1\}$, where k is a positive integer. After obtaining the Lempel–Ziv parsing $B_1, B_2, \ldots, B_t$ of $(x_1, x_2, \ldots, x_n)$, the next step is to represent each block in the parsing as a pair of integers. The first block in the parsing, B_1, consists of a single symbol. It is represented as the pair $(0, B_1)$. More generally, any block B_j of length one is represented as the pair $(0, B_j)$. If the block B_j is of length greater than one, then it is represented as the pair (i,s), where s is the last symbol in B_j and B_i is the unique previous block in the parsing that coincides with the block obtained by removing s from the end of B_j.

Example 3. The sequence of pairs corresponding to the parsing (19) is

$$(0, 1), (1, 0), (1, 1), (0, 0), (4, 0), (3, 0), (0, 1) \tag{20}$$

For example, $(4, 0)$ corresponds to the block $(0, 0)$ in the parsing. Since the last symbol of (0,0) is 0, the pair (4,0) ends in 0. The 4 in the first entry refers to the fact that $B_4 = (0)$ is the preceding block in the parsing, which is equal to what we get by deleting the last symbol of $(0, 0)$.

For our next step, we replace each pair $(i,\ s)$ by the integer $ki + s$. Thus, the sequence of pairs (20) becomes the sequence of integers

$$I_1 = 2 * 0 + 1 = 1$$
$$I_2 = 2 * 1 + 0 = 2$$
$$I_3 = 2 * 1 + 1 = 3$$
$$I_4 = 2 * 0 + 0 = 0 \tag{21}$$
$$I_5 = 2 * 4 + 0 = 8$$
$$I_6 = 2 * 3 + 0 = 6$$
$$I_7 = 2 * 0 + 1 = 1$$

2.5.3. Encoding of Pointers. Let $I_1, I_2, \ldots, I_t$ denote the integer pointers corresponding to the blocks $B_1, B_2, \ldots, B_t$ in the Lempel–Ziv parsing of the data sequence $(x_1, x_2, \ldots, x_n)$. To finish our description of the Lempel–Ziv encoder, we discuss how the integer pointers $I_1, I_2, \ldots, I_t$ are converted into a stream of bits. Each integer I_j is expanded to base 2, and these binary expansions are "padded" with zeros on the left so that the overall length of the string of bits assigned to I_j is $\lceil \log_2(kj) \rceil$. The reason why this many bits is necessary and sufficient is seen by examining the largest that I_j can possibly be. Let (i,s) be the pair associated with I_j. Then the largest that i can be is $j-1$ and the largest that s can be is $k-1$. Thus the largest that I_j can be is $k(j-1) + k - 1 = kj - 1$, and the number

of bits in the binary expansion of $kj-1$ is $\lceil \log_2(kj) \rceil$. Let W_j be the string of bits of length $\lceil \log_2(kj) \rceil$ assigned to I_j as described in the preceding text. Then, the Lempel–Ziv encoder output is obtained by concatenating together the strings $W_1, W_2, \ldots, W_t$.

To illustrate, suppose that the data sequence $(x_1, x_2, \ldots, x_n)$ is binary (i.e., $k=2$), and has seven blocks $B_1, B_2, \ldots, B_7$ in its Lempel–Ziv parsing. These blocks are assigned, respectively, strings of code bits $W_1, W_2, W_3, W_4, W_5, W_6, W_7$ of lengths $\lceil \log_2(2) \rceil = 1$, $\lceil \log_2(4) \rceil = 2$, $\lceil \log_2(6) \rceil = 3$, $\lceil \log_2(8) \rceil = 3$, $\lceil \log_2(10) \rceil = 4$, $\lceil \log_2(12) \rceil = 4$, and $\lceil \log_2(14) \rceil = 4$. Therefore, any binary data sequence with seven blocks in its Lempel–Ziv parsing would result in an encoder output of length $1+2+3+3+4+4+4=21$ code bits. In particular, for the data sequence (2.17), the seven strings $W_1, \ldots, W_7$ are [referring to (21)]

$$W_1 = (1)$$
$$W_2 = (1, 0)$$
$$W_3 = (0, 1, 1)$$
$$W_4 = (0, 0, 0)$$
$$W_5 = (1, 0, 0, 0)$$
$$W_6 = (0, 1, 1, 0)$$
$$W_7 = (0, 0, 0, 1)$$

Concatenating, we see that the codeword assigned to data sequence (17) by the Lempel–Ziv encoder is

$$(1, 1, 0, 0, 1, 1, 0, 0, 0, 1, 0, 0, 0, 0, 1, 1, 0, 0, 0, 0, 1) \quad (22)$$

We omit a detailed description of the Lempel–Ziv decoder. However, it is easy to see what the decoder would do. For example, it would be able to break up the codeword (22) into the separate codewords for the phrases, because, from the size k of the data alphabet, it is known how many code bits are allocated to the encoding of each Lempel–Ziv phrase. From the separate codewords, the decoder recovers the integer representing each phrase; dividing each of these integers by k to obtain the quotient and remainder, the pairs representing the phrases are obtained. Finally, these pairs yield the phrases, which are concatenated together to obtain the original data sequence.

2.5.4. Performance. Let $[n, A_n, P_n]$ be any data source with alphabet of size k. Let S_n be the lossless data compression system driven by this source that employs the Lempel–Ziv code. It is known that there is a positive constant C_k (depending on k but not on n) such that

$$\frac{H_n}{n} \le R(S_n) \le \frac{H_n}{n} + \frac{C_k}{\log_2 n}$$

where H_n is the source entropy. Thus, the Lempel–Ziv code is not quite as good as the Huffman code or the arithmetic code, but there is an important difference. The Huffman code and arithmetic code require knowledge of the source. The preceding performance bound is valid regardless of the source. Thus, one can use the same Lempel–Ziv code for all sources — such a code is called a *universal code* [13].

In practical compression scenarios, the Lempel–Ziv code has been superseded by more efficient modern dictionary codes, such as the YK algorithm [51].

3. LOSSY COMPRESSION METHODOLOGIES

In this section, we shall be concerned with the problem of designing lossy codes. Recall from Fig. 3 that a lossy compression system consists of source, noninvertible source encoder, and source decoder. Figure 6 gives separate depictions of the source encoder and source decoder in a lossy compression system.

The same notational conventions introduced earlier are in effect here: X^n [Eq. (1)] is the random data sequence of length n generated by the source, $\hat{X}^n$ (1.3) is the reconstructed data sequence, and B^K (2) is the variable-length codeword assigned to X^n. The source decoder component of the lossy compression system in Fig. 3 is the cascade of the "quantizer" and "lossless encoder" blocks in Fig. 6a; the source decoder component in Fig. 3 is the lossless decoder of Fig. 6b. The quantizer is a many-to-one mapping that converts the data sequence X^n into its reconstruction $\hat{X}^n$. The lossless encoder is a one-to-one mapping that converts the reconstructed data sequence $\hat{X}^n$ into the binary codeword B^K from which $\hat{X}^n$ can be recovered via application of the lossless decoder to B^K.

It is the presence of the quantizer that distinguishes a lossy compression system from a lossless one. Generally speaking, the purpose of the quantizer is alphabet reduction — by dealing with a data sequence from a reduced alphabet instead of the original data sequence over the original alphabet, one can hope to perform data compression using fewer code bits. For example, the "rounding-off quantizer" is a very simple quantizer. Let the data sequence

$$X^n = (1.1, 2.6, 4.4, 2.3, 1.7) \quad (23)$$

be observed. Then, the rounding-off quantizer generates the reconstructed data sequence

$$\hat{X}^n = (1, 3, 4, 2, 2) \quad (24)$$

It takes only 10 code bits to compress (24), because its entries come from the reduced alphabet $\{1, 2, 3, 4\}$; it

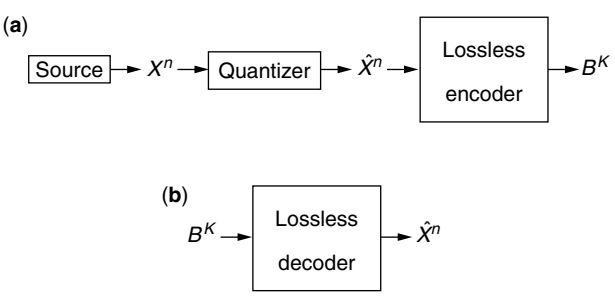

Figure 6. Source encoder (**a**) and decoder (**b**) in lossy compression system.

would take many more code bits to compress the original sequence (23).

As indicated in Fig. 6, a lossy code consists of quantizer, lossless encoder, and lossless decoder. When a lossy code is used to compress the data generated by a source $[n, A_n, P_n]$, a lossy compression system S_n results. The effectiveness of the lossy code is then evaluated by means of two figures of merit, the (compression) rate $R(S_n)$ and the distortion $D(S_n)$, defined by

$$R(S_n) \triangleq \frac{E[K]}{n}$$

$$D(S_n) \triangleq n^{-1} \sum_{i=1}^{n} E[d(X_i, \hat{X}_i)]$$

In the preceding, E denotes the expected value operator, K is the random codeword length of the codeword B^K assigned to X^n in Fig. 5a, and d is a fixed distortion function mapping pairs of source letters into nonnegative real numbers. The distortion function d is typically one of the following two types:

1. *Squared-error distortion*:

$$d(X_i, \hat{X}_i) = (X_i - \hat{X}_i)^2$$

2. *Hamming distortion*:

$$d(X_i, \hat{X}_i) = \begin{cases} 0, & X_i = \hat{X}_i \\ 1, & \text{otherwise} \end{cases}$$

Squared-error distortion is typically used for an infinite source alphabet and Hamming distortion is typically used for a finite source alphabet. When squared-error distortion is used, distortion is sometimes measured in decibels as the figure

$$[D(S_n)]_{\text{dec}} = 10 \log_{10} \left(\frac{n^{-1} \sum_{i=1}^{n} \int_{-\infty}^{\infty} x^2 f_{X_i}(x)\, dx}{D(S_n)} \right)$$

where $X_i (1 \leq i \leq n)$ represents the ith data sample generated by the source $[n, A_n, P_n]$ and f_{X_i} denotes the probability density function of X_i; note that small $D(S_n)$ would correspond to a large decibel measure of distortion.

Suppose that two different lossy codes have been designed to compress the random data generated by a given source $[n, A_n, P_n]$, resulting in lossy compression systems S_n^1 and S_n^2, respectively. Then, one can declare that the lossy code giving rise to system S_n^1 is better than the lossy code giving rise to system S_n^2 if $R(S_n^1) < R(S_n^2)$ and $D(S_n^1) < D(S_n^2)$. However, it may be that neither lossy code is better than the other one in this sense, since the inverse relation between rate and distortion precludes the design of a lossy code for which rate and distortion are simultaneously small. Instead, for a given source, the design goal should be to find a lossy code that yields the smallest rate for a fixed distortion, or the smallest distortion for a fixed rate. The theory detailing the rate–distortion tradeoffs that are possible in lossy code design is called *rate–distortion theory*. Section 3.1 gives an introduction to this subject.

The quantizer employed in a lossy code can be one of two types, either a scalar quantizer or vector quantizer. A *scalar quantizer* quantizes one data sample at a time, whereas for some $m > 1$, a *vector quantizer* quantizes m data samples at a time. Lossy codes that employ scalar quantizers are called "SQ-based codes" and are covered in Section 3.2; lossy codes that employ vector quantizers are called "VQ-based codes" and are covered in Section 3.3. Subsequent sections deal with two other important lossy coding techniques, trellis-based coding, and transform coding.

3.1. Distortion Bounds

In designing a lossy code for a source $[n, A_n, P_n]$ to produce a lossy compression system S_n, the usual approach is the *fixed-rate approach*, in which one attempts to find a lossy code that minimizes or approximately minimizes the distortion $D(S_n)$ among all lossy codes satisfying the rate constraint $R(S_n) \leq R$, where $R > 0$ is a fixed constant. We adopt the fixed-rate approach for the rest of this article.

In this section, we will give upper and lower bounds on the distortion performance of lossy codes for a fixed source, subject to the constraint that the compression rate be no more than R code bits per data sample, on average. With these bounds, one can determine before designing a lossy code what types of performance are and are not possible for such a code to achieve. The upper and lower bounds on distortion performance that shall be developed in this section are expressible using Claude Shannon's notion of *distortion–rate function* [43], discussed next.

3.1.1. Distortion–Rate Function. The concept of *mutual information* will be needed in order to define the distortion–rate function. Let X, Y be two random variables. Let $f(x)$ be the probability density function of X, and let $g(y \mid x)$ be the conditional probability density function of Y given $X = x$. Then, the mutual information $I(X;Y)$ of X, Y is the number

$$I(X;Y) \triangleq \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x) g(y \mid x) \log_2 \times \left[\frac{g(y \mid x)}{\int_{-\infty}^{\infty} f(u) g(y \mid u) du} \right] dx\, dy$$

We are now ready to define the concept of distortion–rate function. For simplicity, we restrict ourselves to the memoryless source $[n, A_n, P_n]$. We suppose that the source alphabet is a subset of the real line; let X be a random variable such that the random data samples $X_i (1 \leq i \leq n)$ generated according to the memoryless source $[n, A_n, P_n]$ are independent copies of X. The distortion–rate function $D(R)$ of the memoryless source $[n, A_n, P_n]$ (for a given nonnegative distortion function d such as Hamming distortion or squared-error distortion) is then defined for each $R > 0$ by

$$D(R) \triangleq \min\{E[d(X,Y)] : I(X;Y) \leq R\} \qquad (25)$$

where Y denotes any random variable jointly distributed with X, and we assume that the minimum in (25) exists and is finite.

Example 4. One important type of memoryless source for which the distortion–rate function has a closed-form expression is the *Gaussian memoryless source* $[n, A_n, P_n]$, which is the memoryless source whose independent random data samples are generated according to a Gaussian distribution with mean 0 and variance σ^2. For the Gaussian memoryless source with squared-error distortion

$$D(R) = \sigma^2 2^{-2R} \tag{26}$$

Sources such as this one in which $D(R)$ can be computed explicitly are rare. However, in general, one can use the Blahut algorithm [6] to approximate $D(R)$ arbitrarily closely.

3.1.2. Distortion Lower Bound. Fix a memoryless source $[n, A_n, P_n]$ with distortion–rate function $D(R)$. Fix $R > 0$, and fix any lossy code for $[n, A_n, P_n]$ for which the resulting compression system S_n satisfies the rate constraint $R(S_n) \le R$. Then, the following well-known [4] distortion lower bound is valid:

$$D(S_n) \ge D(R) \tag{27}$$

Example 5. Assume the nth-order Gaussian memoryless source model and squared-error distortion. Substituting the expression for $D(R)$ in (26) into (27), one concludes that any lossy code with compression rate $\le R$ yields distortion in decibels no greater than $(20 \log_{10} 2)R \approx 6R$. Thus, a Gaussian memoryless source cannot be encoded to yield a better distortion performance than "6 decibels per bit."

3.1.3. Distortion Upper Bound. Let f be a probability density function. For each $n = 1, 2, \ldots$, let $[n, A_n, P_n]$ be the memoryless source in which n independent random data samples are generated according to the density f. Assume finiteness of the distortion–rate function $D(R)$ for these sources [since the distortion–rate function depends only on f, all of these sources will have the same distortion-rate function $D(R)$]. Fix $R > 0$. It is well known [35, 53] that there is a positive constant C such that for every $n = 2, 3, \ldots$, there is a lossy code for $[n, A_n, P_n]$ such that the rate and distortion for the resulting compression system S_n satisfy

$$\begin{aligned} R(S_n) &\le R \\ D(S_n) &\le D(R) + \frac{C \log_2 n}{n} \end{aligned} \tag{28}$$

Combining the distortion upper bound (28) with the distortion lower bound (27), if n is large, there must exist a code for an nth order memoryless source that yields rate $\le R$ and distortion $\approx D(R)$; that is, the distortion–rate function $D(R)$ does indeed describe the distortion performance of the most efficient lossy codes. But, in general, it is not known how to find codes that are this efficient. This represents a clear difference between lossless code and lossy code design; it is known how to construct efficient lossless codes, but it is a computationally difficult problem to find efficient lossy codes [18]. For example, for large n, the nth-order Gaussian memoryless source can be encoded to yield squared-error distortion of roughly "6 decibels per bit" (the distortion–rate function performance), but only since 1990 has it been discovered how to find such codes for this simple source model [29].

3.2. SQ-Based Codes

Let R be a fixed positive integer. A 2^R-*bit scalar quantizer* for quantizing real numbers in the interval $[a, b]$ is a mapping Q from $[a, b]$ into a finite subset of $[a, b]$ of size $N = 2^R$. Let $I_1, I_2, \ldots, I_N$ be subintervals of $[a, b]$ that form a partition of $[a, b]$ (the I_j values are called the *quantization intervals* of Q). Let $L_1, L_2, \ldots, L_N$ be points in $[a, b]$ chosen so that $L_j \in I_j$ for each $j = 1, 2, \ldots, N$ (L_j is called the *quantization level* for interval I_j). The quantizer Q accepts as input any real number x in the interval $[a, b]$. The output $Q(x)$ generated by the quantizer Q in response to the input x is the quantization level L_j assigned to the subinterval I_j of $[a, b]$ containing x. In other words, the 2^R-bit quantizer Q is a nondecreasing step function taking 2^R values.

Let $[n, A_n, P_n]$ be a source (such as a memoryless source) in which each randomly generated data sample has the same probability density function f. Let the alphabet for $[n, A_n, P_n]$ be the interval of real numbers $[a, b]$. Let Q be a 2^R-bit scalar quantizer defined on $[a, b]$. We describe a lossy code for the source $[n, A_n, P_n]$ induced by Q. Referring to Fig. 6a, we must explain how the lossy code quantizes source sequences of length n and losslessly encodes the quantized sequences. The lossy code quantizes each source sequence $(x_1, x_2, \ldots, x_n) \in A^n$ into the sequence $(Q(x_1), Q(x_2), \ldots, Q(x_n))$; this makes sense because each entry of each source sequence belongs to the interval $[a, b]$ on which Q is defined. Assign each of the 2^R quantization levels of Q an R-bit binary address so that there is a one-to-one correspondence between quantization levels and their addresses; then, the lossy code losslessly encodes $(Q(x_1), Q(x_2), \ldots, Q(x_n))$ by replacing each of its entries with its R-bit address, yielding an overall binary codeword of length nR. Let S_n be the lossy compression system in Fig. 6 arising from the lossy code just described, and let d be the distortion function that is to be used. It is not hard to see that

$$\begin{aligned} R(S_n) &= R \\ D(S_n) &= \int_a^b d(x, Q(x)) f(x)\, dx \end{aligned}$$

If in the preceding construction we let Q vary over all 2^R-bit scalar quantizers on $[a, b]$, then we obtain all possible SQ based lossy codes for the source $[n, A_n, P_n]$ with compression rate R.

Let R be a positive integer. Consider the following problem: Find the 2^R-bit scalar quantizer Q on $[a, b]$ for which

$$\int_a^b d(x, Q(x)) f(x)\, dx$$

is minimized. This quantizer Q yields the SQ based lossy code for the source $[n, A_n, P_n]$, which has compression rate R and minimal distortion. We call this scalar quantizer the *minimum distortion* 2^R-bit scalar quantizer.

3.2.1. Lloyd–Max Quantizers. We present the solution given in other papers [17,28,30] to the problem of finding the minimum distortion 2^R-bit scalar quantizer for squared-error distortion. Suppose that the probability density function f satisfies

$$\int_a^b x^2 f(x)\,dx < \infty$$

and that $-\log_2 f$ is a concave function on $[a, b]$. Let Q be a 2^R-bit scalar quantizer on $[a, b]$ with quantization levels $\{L_j\}_{j=1}^N$ and quantization intervals $\{I_j\}_{j=1}^N$, where $N = 2^R$. Let

$$y_0 < y_1 < \cdots < y_{N-1} < y_N$$

be the points such that interval I_j has left endpoint y_{j-1} and right endpoint $y_j (j = 1, \ldots, N)$. We call Q a *Lloyd–Max quantizer* if

$$y_j = (\tfrac{1}{2})[L_j + L_{j+1}],\ j = 1, \ldots, N-1 \tag{29}$$

and

$$L_j = \frac{\displaystyle\int_{y_{j-1}}^{y_j} xf(x)\,dx}{\displaystyle\int_{y_{j-1}}^{y_j} f(x)\,dx},\ j = 1, 2, \ldots, N. \tag{30}$$

There is only one 2^R-bit Lloyd–Max scalar quantizer, and it is the unique minimum distortion 2^R-bit scalar quantizer.

Example 6. One case in which it is easy to solve the Lloyd–Max equations (29) and (30) is the case in which $R = 1$ and f is an even function on the whole real line. The unique Lloyd–Max quantizer Q is then given by

$$Q(x) = \begin{cases} 2\displaystyle\int_0^\infty xf(x)\,dx, & x < 0 \\ -2\displaystyle\int_0^\infty xf(x)\,dx, & x \geq 0 \end{cases}$$

Example 7. Assume that $[a, b]$ is a finite interval. Let the source $[n, A_n, P_n]$ be memoryless with each random data sample uniformly distributed on the interval $[a, b]$. The unique 2^R-bit Lloyd–Max scalar quantizer Q for this source is obtained by partitioning $[a, b]$ into 2^R equal subintervals, and by assigning the quantization level for each interval to be the midpoint of that interval [the Lloyd–Max equations (29) and (30) are easily verified]. The SQ-based lossy code for the source $[n, A_n, P_n]$ induced by Q yields rate R and distortion in decibels equal to $(20 \log_{10} 2)R \approx 6R$. This is another "6 decibels per bit" result. Computation of the distortion–rate function for the memoryless source $[n, A_n, P_n]$ [24] reveals that for large n, $[n, A_n, P_n]$ can be encoded at rate $R = 1$ bit per sample at a distortion level of nearly 6.8 decibels. This clearly cannot be achievable using SQ-based lossy codes — more sophisticated lossy codes would be required.

In general, it may not be possible to solve the Eqs. (29) and (30) to find the Lloyd–Max quantizer explicitly. But, a numerical approximation of it can be found using the LBG algorithm covered in the next section.

3.3. VQ-Based Codes

Fix a positive integer m. Let $\mathcal{R}$ denote the set of real numbers, and let $\mathcal{R}^m$ denote m-dimensional Euclidean space, that is, the set of all sequences $(x_1, x_2, \ldots, x_m)$ in which each entry x_i belongs to $\mathcal{R}$. An *m-dimensional vector quantizer* Q is a mapping from $\mathcal{R}^m$ onto a finite subset $\mathcal{C}$ of $\mathcal{R}^m$. The set $\mathcal{C}$ is called the *codebook* of the m-dimensional vector quantizer Q; the elements of $\mathcal{C}$ are called *codevectors*, and if $x \in \mathcal{R}^m$, then $Q(x)$ is called the *codevector for* x. We define a mapping to be a *vector quantizer* if it is an m-dimensional vector quantizer for some m. The scalar quantizers can be regarded as special cases of the vector quantizers (they are the one-dimensional vector quantizers); the codebook of a scalar quantizer is just the set of its quantization levels, and a codevector for a scalar quantizer is just one of its quantization levels.

Let Q be an m-dimensional vector quantizer with codebook $\mathcal{C}$. We call Q a *nearest-neighbor quantizer* if Q quantizes each $x \in \mathcal{R}^m$ into a codevector from codebook $\mathcal{C}$ that is at least as close to x in Euclidean distance as any other codevector from $\mathcal{C}$. (We use squared-error distortion in this section; therefore, only nearest-neighbor quantizers will be of interest to us.)

Fix a memoryless source $[n, A_n, P_n]$ whose alphabet is a subset of the real line, such that n is an integer multiple of m; let f_m be the common probability density function possessed by all random vectors of m consecutive samples generated by this source. Let Q be a fixed m-dimensional nearest-neighbor vector quantizer whose codebook is of size 2^j. We describe how Q induces a lossy code for the source $[n, A_n, P_n]$ that has compression rate $R = j/m$. Referring to Fig. 6, we have to explain how the induced lossy code quantizes source sequences generated by $[n, A_n, P_n]$, and how it losslessly encodes the quantized sequences. Let $(x_1, x_2, \ldots, x_n) \in A_n$ be any source sequence. Partitioning, one obtains the following n/m blocks of length m lying in m-dimensional Euclidean space $\mathcal{R}^m$:

$$(x_1, x_2, \ldots, x_m)$$

$$(x_{m+1}, x_{m+2}, \ldots, x_{2m})$$

$$\ldots$$

$$(x_{n-m+1}, x_{n-m+2}, \ldots, x_n)$$

The induced lossy code quantizes $(x_1, x_2, \ldots, x_n)$ into $(\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_n)$, where

$$(\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_m) = Q(x_1, x_2, \ldots, x_m)$$

$$(\hat{x}_{m+1}, \hat{x}_{m+2}, \ldots, \hat{x}_{2m}) = Q(x_{m+1}, x_{m+2}, \ldots, x_{2m})$$

$$\ldots$$

$$(\hat{x}_{n-m+1}, \hat{x}_{n-m+2}, \ldots, \hat{x}_n) = Q(x_{n-m+1}, x_{n-m+2}, \ldots, x_n)$$

Each codevector in $\mathcal{C}$ can be uniquely represented using a j-bit binary address. The induced lossy code losslessly encodes the quantized sequence $(\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_n)$ into the binary codeword obtained by concatenating together the binary addresses of the codevectors above that were used to form the quantized sequence; this binary codeword is of fixed length $(n/m)j = nR$, and so, dividing by n, the compression rate R code bits per data sample has been achieved. Let $\mathcal{S}_n$ be the lossy compression system that arises when the lossy code just described is used to compress the data sequences generated by the source $[n, A_n, P_n]$. The resulting rate and distortion performance are given by

$$R(\mathcal{S}_n) = R = \frac{j}{m}$$
$$D(\mathcal{S}_n) = m^{-1} \int_{\mathcal{R}^m} \min_{y \in \mathcal{C}} \|x - y\|^2 f_m(x)\, dx \qquad (31)$$

where $\|x - y\|^2$ denotes the square of the Euclidean distance between vectors $x = (x_i)$ and $y = (y_i)$ in $\mathcal{R}^m$:

$$\|x - y\|^2 = \sum_{i=1}^{m} (x_i - y_i)^2$$

If we let Q vary over all nearest-neightbor m-dimensional vector quantizers whose codebooks are of size 2^j, then the lossy codes for the source $[n, A_n, P_n]$ induced by these are the VQ-based codes of rate $R = j/m$. Obviously, of this large number of lossy codes, one would want to choose one of minimal distortion; however, it is typically an intractable problem to find such a minimum distortion code.

Example 8. Suppose that the source $[n, A_n, P_n]$ for which a VQ-based code is to be designed is a Gaussian memoryless source with mean 0 and variance 1. Suppose that the desired compression rate is 1.5 code bits per data sample. Since $1.5 = \frac{3}{2}$, we can use a two-dimensional vector quantizer with codebook of size $2^3 = 8$. The table below gives one possibility for such a vector quantizer. The left column gives the codevectors in the codebook; the right column gives the binary address assigned to each codevector. The codevectors in this codebook can be visualized as eight equally spaced points along the unit circle in the plane, which is of radius 1 and centered at the origin (0, 0).

Codevector	Address
(1, 0)	000
$(\cos(\pi/4), \sin(\pi/4))$	001
(0, 1)	010
$(\cos(3\pi/4), \sin(3\pi/4))$	011
$(-1, 0)$	100
$(\cos(5\pi/4), \sin(5\pi/4))$	101
$(0, -1)$	110
$(\cos(7\pi/4), \sin(7\pi/4))$	111

The lossy code induced by this 2D vector quantizer, when used to compress data generated by the source $[n, A_n, P_n]$, gives rise to a distortion figure that can be obtained using symmetry considerations. The 2D plane can be partitioned into eight congruent regions over which the integrals of the integrand in (31) are identical. One of these regions is

$$\mathcal{S} = \left\{(x_1, x_2) : x_1 \geq 0, -\tan\frac{\pi}{8}x_1 \leq x_2 \leq \tan\frac{\pi}{8}x_1\right\}$$

The region S is the set of points in the plane $\mathcal{R}^2$ that are closest in Euclidean distance to the codevector (1, 0). Therefore, the distortion is

$$4 \iint_S [(x_1 - 1)^2 + x_2^2] \left(\frac{1}{2\pi}\right) \exp\left(\frac{-(x_1^2 + x_2^2)}{2}\right) dx_1\, dx_2$$

This integral is easily evaluated via conversion to polar coordinates. Doing this, one obtains distortion of 5.55 dB. One can improve the distortion to 5.95 dB by increasing the radius of the circle around which the eight codevectors in the codebook are distributed. Examining the distortion–rate function of the Gaussian memoryless source, we see that a distortion of about 9 dB is best possible at the compression rate of 1.5 code bits per data sample. Hence, we can obtain a >3-dB improvement in distortion by designing a VQ-based code that uses a vector quantizer of dimension >2.

3.3.1. LBG Algorithm. The LBG algorithm [27] is an iterative algorithm for vector quantizer design. It works for any dimension m, and employs a large set T of "training vectors" from $\mathcal{R}^m$. The training vectors, for example, could represent previously observed data vectors of length m. An initial codebook $\mathcal{C}_0$ contained in $\mathcal{R}^m$ of some desired size is selected (the size of the codebook is a reflection of the desired compression rate). The LBG algorithm then recursively generates new codebooks

$$\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3, \ldots$$

as follows. Each codebook $\mathcal{C}_i (i \geq 1)$ is generated from the previous codebook $\mathcal{C}_{i-1}$ in two steps:

Step 1. For each $v \in T$, a closest vector to v in $\mathcal{C}_{i-1}$ is found (with respect to Euclidean distance), and recorded. Let x_v denote the vector that is recorded for $v \in T$.

Step 2. For each vector $y \in \{x_v : v \in T\}$ recorded in step 1, the arithmetic mean of all vectors v in T for which $x_v = y$ is computed. The set of arithmetic means forms the new codebook $\mathcal{C}_i$.

The LBG codebooks $\{\mathcal{C}_i\}$ either eventually coincide, or else eventually keep cycling periodically through a finite set of codebooks; in either case, one would stop iterations of the LBG algorithm at a final codebook $\mathcal{C}_i$ as soon as one of these two scenarios occurs. The final LBG codebook, if used to quantize the training set, will yield smaller distortion on the training set than any of the previously generated codebooks (including the initial codebook). The LBG algorithm has been used extensively since its discovery for VQ-based code design in both

theoretical and practical scenarios. The one-dimensional LBG algorithm can be used to find a good approximation to the unique Lloyd–Max quantizer, if the training set is big enough. However, in higher dimensions, the LBG algorithm has some drawbacks: (1) the final LBG codebook may depend on the initial choice of codebook or (2) the final LBG codebook may not yield minimum distortion. Various stochastic relaxation and neural network–based optimization techniques have been devised to overcome these deficiencies [38, Chap. 14;52].

3.3.2. Tree-Structured Vector Quantizers. In tree-structured vector quantization [19, Chap. 12;32], the 2^j codevectors in the VQ codebook are placed as labels on the 2^j leaf vertices of a rooted binary tree of depth j. Each of the $2^j - 1$ internal vertices of the tree is also labeled with some vector. To quantize a vector x, one starts at the root of the tree and then follows a unique root-to-leaf path through the tree by seeing at each intermediate vertex of the path which of its two children has its label closer to x, whereupon the next vertex in the path is that child; x is quantized into the codevector at the terminus of this path. A tree-structured vector quantizer encodes speedily, since the time for it to quantize a vector using a codebook of size 2^j is proportional to j instead of 2^j. The minimum distortion vector quantizer for a probabilistic source or a training set is typically not implementable as a tree-structured vector quantizer, but there are some scenarios in which a tree-structured vector quantizer yields close to minimum distortion.

3.3.3. Lattice Vector Quantizers. A lattice quantizer is a vector quantizer whose codebook is formed from points in some Euclidean space lattice. Lattice quantizers are desirable because (1) there are fast algorithms for implementing them [9], and (2) for high compression rates, lattice quantizers yield nearly minimum distortion among all vector quantizers for the memoryless source in which the data samples have a uniform distribution. A monograph [10, Table 2.3] tabulates the best-known m-dimensional lattices in terms of distortion performance, for various values of m between $m = 1$ and $m = 24$. For example, for dimension $m = 2$, one should use a hexagonal lattice consisting of the centers of hexagons that tile the plane.

3.4. Trellis-Based Codes

Suppose that one has a finite-directed graph G satisfying the following properties:

- There are a fixed number of outgoing edges from each vertex of G, and this fixed number is a power of two. (Let this fixed number be 2^j.)
- Each edge of G has a label consisting of a sequence of fixed length from a given data alphabet. A. (Let this fixed length be m.)
- The graph G is connected (i.e., given any two vertices of G, there is a finite path connecting them).

Let v^* be any fixed vertex of G (since G is connected, it will not matter what v^* is). Let n be a fixed positive integer that is an integer multiple of m. Let $\mathcal{P}$ be the set of all paths in G that begin at v^* and consist of n/m edges. Then

- Each path in $\mathcal{P}$ gives rise to a sequence of length n over the alphabet A if one writes down the labels on its edges in the order in which these edges are visited.
- Let $R = j/m$. There are 2^{nR} paths in $\mathcal{P}$, and it consequently takes nR bits to uniquely identify any one of these paths.

A *trellis* is a pictorial representation of all of the paths in $\mathcal{P}$. The *trellis-based lossy code* for quantizing/encoding/decoding all the data sequences in A^n works in the following way:

Quantization Step. Given the data sequence $(x_1, x_2, \ldots, x_n)$ from A^n, the encoder finds a "minimal path" in $\mathcal{P}$, which is a path in $\mathcal{P}$ giving rise to a sequence $(y_1, y_2, \ldots, y_n)$ in A^n for which

$$\sum_{i=1}^{n} d(x_i, y_i)$$

is a minimum, where d is the distortion measure to be used. [The sequence $(y_1, y_2, \ldots, y_n)$ is the output of the quantizer in Fig. 6a.]

Encoding Step. Let $R = j/m$. Having found the minimal path in $\mathcal{P}$ for the data sequence $(x_1, x_2, \ldots, x_n)$, the encoder transmits a binary codeword of length nR in order to tell the decoder which path in $\mathcal{P}$ was the minimal path.

Decoding Step. From the received binary codeword of length nR, the decoder follows the minimal path and writes down the sequence $(y_1, y_2, \ldots, y_n)$ to which that path gives rise. That sequence is the reconstruction sequence $(\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_n)$ for the data sequence $(x_1, x_2, \ldots, x_n)$.

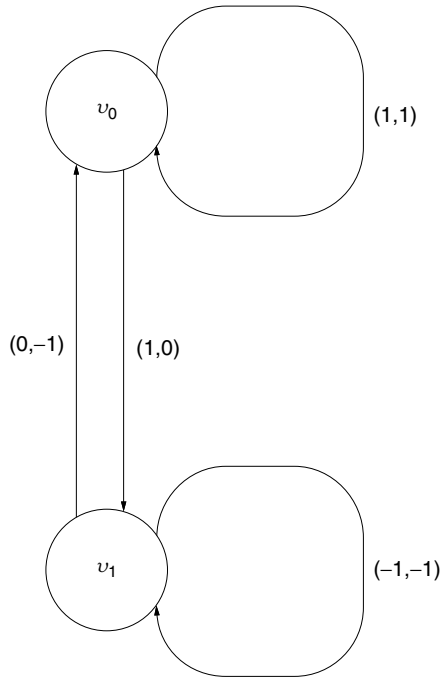
Computation of the minimal path in the quantization step is a dynamic programming problem that can be efficiently solved using the *Viterbi algorithm*.

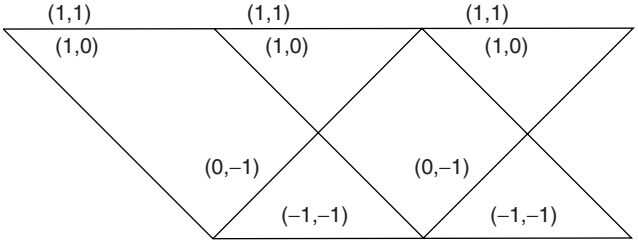
The trellis-based lossy code just described will work for any source $[n, A_n, P_n]$ in which $A_n \subset A^n$. The resulting compression rate is $R = j/m$; the resulting distortion depends on the source model — there is no simple formula for computing it. Trellis-based lossy coding is quite unlike SQ-based or VQ-based lossy coding because of its feedback nature. The best way to understand it is through an extended example, which follows.

Example 9. The graph G is taken as follows:

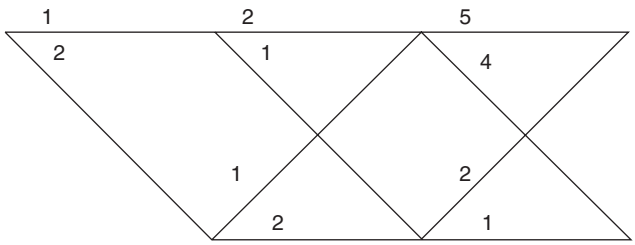
There are two vertices v_0, v_1, four edges with two outgoing edges per vertex ($j = 1$), and the edge labels are of length 2 ($m = 2$). The compression rate for the trellis-based code based on G is $R = j/m = 0.5$ code bits per data sample. Suppose that we wish to encode the data sequence (0, 1, 0, 0, −1, 0) of length $n = 6$, using squared-error distortion. Taking the vertex v_0 as our distinguished vertex v^*, the set of $2^{nR} = 8$ paths $\mathcal{P}$ in

G of length $n/m = 3$ that start at v_0 are then given the trellis representation:

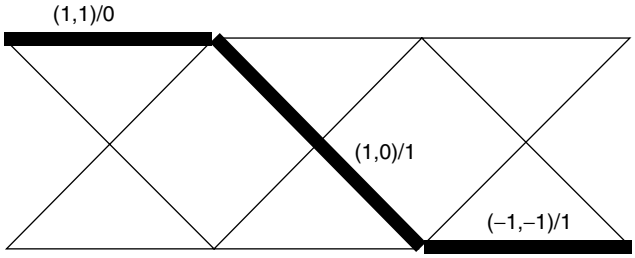




The trellis comes in three stages from left to right, which designate stage 1, stage 2, and stage 3, respectively. In stage 1, one replaces each label with the square of the Euclidean distance between that label and the pair (0,1) consisting of the first two of the six given data samples. In stage 2, one replaces each label with the square of the Euclidean distance between that label and the pair (0,0) consisting of the next two data samples. In stage 3, one replaces each label with the square of the Euclidean distance between that label and the pair $(-1, 0)$ consisting of the final two data samples. This gives us the following trellis whose edges are weighted by these squared Euclidean distances:

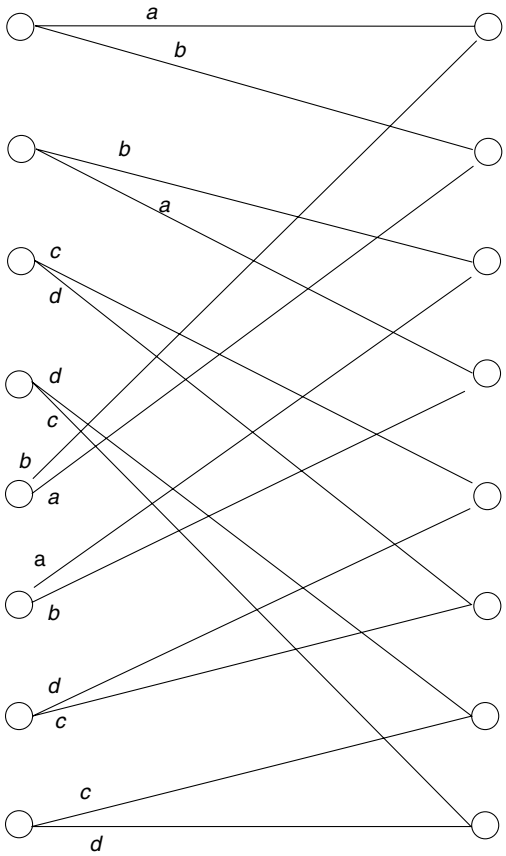


The minimal path is the path whose sum of weights is the smallest; this is the path marked in bold in the following figure:



We have added an additional label to each edge of the minimal path to denote the bit sent to the decoder (bit = 0 means upper branch chosen; bit = 1 means lower branch chosen).

Example 10. Consider the memoryless source $[n, A_n, P_n]$ with alphabet $\{a, b, c, d\}$, in which each random data sample is equidistributed over this alphabet. Suppose that $[n, A_n, P_n]$ is encoded using the trellis-based code, one stage of which is the following:



This code has a compression rate of 1 code bit per data sample. Let Hamming distortion be used; for large n, simulations show that the Hamming distortion is slightly less than 0.25. Hence, for a large number of data samples, this simple code can reconstruct over 75% of the data

samples at the decoder, on average, while transmitting only half of the bits that would be necessary for perfect reconstruction (which would require a compression rate of 2 bits per sample).

3.4.1. Marcellin–Fischer Codes. Marcellin and Fischer [29] developed an important class of trellis-based codes. They use DeBrujn graphs as the basis for their codes — labeling of the edges is done using heuristic symmetry rules motivated by Ungerboeck's work on trellis-coded modulation [48]. Marcellin and Fischer report quite good distortion performance when their trellis-based codes are used to encode Gaussian and uniform memoryless sources.

3.5. Transform Codes

In certain applications, the data samples to be compressed are not one-dimensional quantities; that is, for some $m > 1$, each data sample is a point in m-dimensional Euclidean space.

Example 11. One may wish to compress a large square image by compressing the sequence of 8×8 blocks that are obtained from partitioning the image. Each data "sample" in this case could be thought of as a point in m-dimensional Euclidean space with $m = 64$. (The JPEG image compression algorithm takes this point of view.)

For simplicity, let us assume that the dimension of the data samples is $m = 2$. Let us write the data samples as random pairs

$$\begin{bmatrix} X_i^{(1)} \\ X_i^{(2)} \end{bmatrix}, \quad i = 1, 2, \ldots, n \tag{32}$$

Suppose that one is committed to lossy codes that employ only scalar quantization. The sequence

$$X_1^{(1)}, X_2^{(1)}, \ldots, X_n^{(1)}$$

might have one type of model that would dictate that some scalar quantizer Q_1 be used to quantize these samples. On the other hand, the sequence

$$X_1^{(2)}, X_2^{(2)}, \ldots, X_n^{(2)}$$

might have another type of model that would dictate the use of a different scalar quantizer Q_2. Let us assume that Q_1 is a 2^{R_1}-bit quantizer and that Q_2 is a 2^{R_2}-bit quantizer. The sequence resulting from quantization of (3.32) would then be

$$\begin{bmatrix} \hat{X}_i^{(1)} \\ \hat{X}_i^{(2)} \end{bmatrix}, \quad i = 1, 2, \ldots, n \tag{33}$$

where $\hat{X}_i^{(1)} = Q_1(X_i^{(1)})$ and $\hat{X}_i^{(2)} = Q_2(X_i^{(2)})$. The sequence (33) is transmitted by the encoder to the decoder using $nR_1 + nR_2$ bits, and is reconstructed by the decoder as the decoder's estimate of the original sequence (32). Let us use squared-error distortion. Then, the compression rate R and distortion D for this lossy code are

$$R = R_1 + R_2$$

$$D = n^{-1} \sum_{i=1}^{n} E[(X_i^{(1)} - \hat{X}_i^{(1)})^2] + n^{-1} \sum_{i=1}^{n} E[(X_i^{(2)} - \hat{X}_i^{(2)})^2]$$

Suppose that the compression rate is to be kept fixed at R. Then, to minimize D, one would optimize the lossy code just described by choosing integers R_1 and R_2 so that $R = R_1 + R_2$, and so that

$$\min_{Q_1} \sum_{i=1}^{n} E[(X_i^{(1)} - Q_1(X_i^{(1)}))^2] + \min_{Q_2} \sum_{i=2}^{n} E[(X_i^{(2)} - Q_2(X_i^{(2)}))^2]$$

is a minimum, where in the first minimization Q_1 ranges over all 2^{R_1}-bit quantizers, and in the second minimization Q_2 ranges over all 2^{R_2}-bit quantizers. Finding the best way to split up R into a sum $R = R_1 + R_2$ is called the *bit allocation problem* in lossy source coding.

We may be able to obtain a smaller distortion by *transforming* the original data pairs from $\mathcal{R}^2$ into another sequence of pairs from $\mathcal{R}^2$, and then doing the quantization and encoding of the transformed pairs in a manner similar to what we did above for the original pairs. This is the philosophy behind *transform coding*. In the following, we make this idea more precise.

Let m be a fixed positive integer. The data sequence to be compressed is

$$\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n \tag{34}$$

where each $\mathbf{X}_i$ is an $\mathcal{R}^m$-valued random column vector of the form

$$\mathbf{X}_i = \begin{bmatrix} X_i^{(1)} \\ X_i^{(2)} \\ \vdots \\ X_i^{(m)} \end{bmatrix}$$

We write the data sequence in more compact form as the $m \times n$ matrix $M(X)$ whose columns are the $\mathbf{X}_i$ values:

$$M(X) = [\mathbf{X}_1 \; \mathbf{X}_2 \; \cdots \; \mathbf{X}_n]$$

Let A be an $m \times m$ invertible matrix of real numbers. The matrix A transforms the matrix $M(X)$ into an $m \times n$ matrix $M(Y)$ as follows:

$$M(Y) = AM(X)$$

Equivalently, A can be used to transform each column of $M(X)$ as follows:

$$\mathbf{Y}_i = A\mathbf{X}_i, \quad i = 1, 2, \ldots, n$$

Then, $M(Y)$ is the matrix whose columns are the $\mathbf{Y}_i$ values:

$$M(Y) = [\mathbf{Y}_1 \; \mathbf{Y}_2 \; \cdots \; \mathbf{Y}_n]$$

Let $\mathbf{Y}^{(j)}$ denote the jth row of $M(Y)(j = 1, 2, \ldots, m)$. Then, the matrix $M(Y)$ can be partitioned in two different ways:

$$M(Y) = [\mathbf{Y}_1\ \mathbf{Y}_2\ \cdots\ \mathbf{Y}_n] = \begin{bmatrix} \mathbf{Y}^{(1)} \\ \mathbf{Y}^{(2)} \\ \vdots \\ \mathbf{Y}^{(m)} \end{bmatrix}$$

The row vectors $\mathbf{Y}^{(j)}(j = 1, 2, \ldots, m)$ are the *coefficient streams* generated by the transform code; these streams are separately quantized and encoded for transmission to the decoder, thereby completing the "front end" of the transform code, which is called the *analysis stage* of the transform code and is depicted in Fig. 7a.

Note in Fig. 7a that the rates at which the separate encoders operate are $R_1, R_2, \ldots, R_m$, respectively. The separate quantizers in Fig. 7a are most typically taken to be scalar quantizers (in which case the R_i terms would be integers), but vector quantizers could be used instead (in which case all R_i would be rational numbers). If we fix the overall compression rate to be the target value R, then the bit allocation must be such that $R = R_1 + R_2 + \cdots + R_m$. The m separate bit streams generated in the analysis stage are multiplexed into one rate R bit stream for transmission to the decoder, who then obtains the separate bit streams by demultiplexing — this multiplexing/demultiplexing part of the transform code, which presents no problems, has been omitted in Fig. 7a.

The decoder must decode the separate bit streams and then combine the decoded streams by means of an inverse transform to obtain the reconstructions of the original data samples; this "back end" of the system is called the *synthesis stage* of the transform code, and is depicted in Fig. 7b.

In Fig. 7b, $\hat{\mathbf{Y}}^{(j)}$ is the row vector of length n obtained by quantizing the row vector $\mathbf{Y}^{(j)}(j = 1, 2, \ldots, m)$. The matrix $M(\hat{Y})$ is the $m \times n$ matrix whose rows are the $\hat{\mathbf{Y}}^{(j)}$ terms. The matrix $M(\hat{X})$ is also $m \times n$, and is formed by

$$M(\hat{X}) = A^{-1}M(\hat{Y})$$

Let us write the columns of $M(\hat{X})$ as

$$\hat{\mathbf{X}}_1, \hat{\mathbf{X}}_2, \ldots, \hat{\mathbf{X}}_n.$$

These are the reconstructions of the original data sequence (34).

The distortion (per sample) D resulting from using the transform code to encode the source $[n, A_n, P_n]$ is

$$D = n^{-1} \sum_{i=1}^{n} E[\|\mathbf{X}_i - \hat{\mathbf{X}}_i\|^2] \tag{35}$$

With the compression rate fixed at R, to optimize the transform code, one must select $R_1, R_2, \ldots, R_m$ and quantizers at these rates so that $R = R_1 + R_2 + \cdots + R_m$

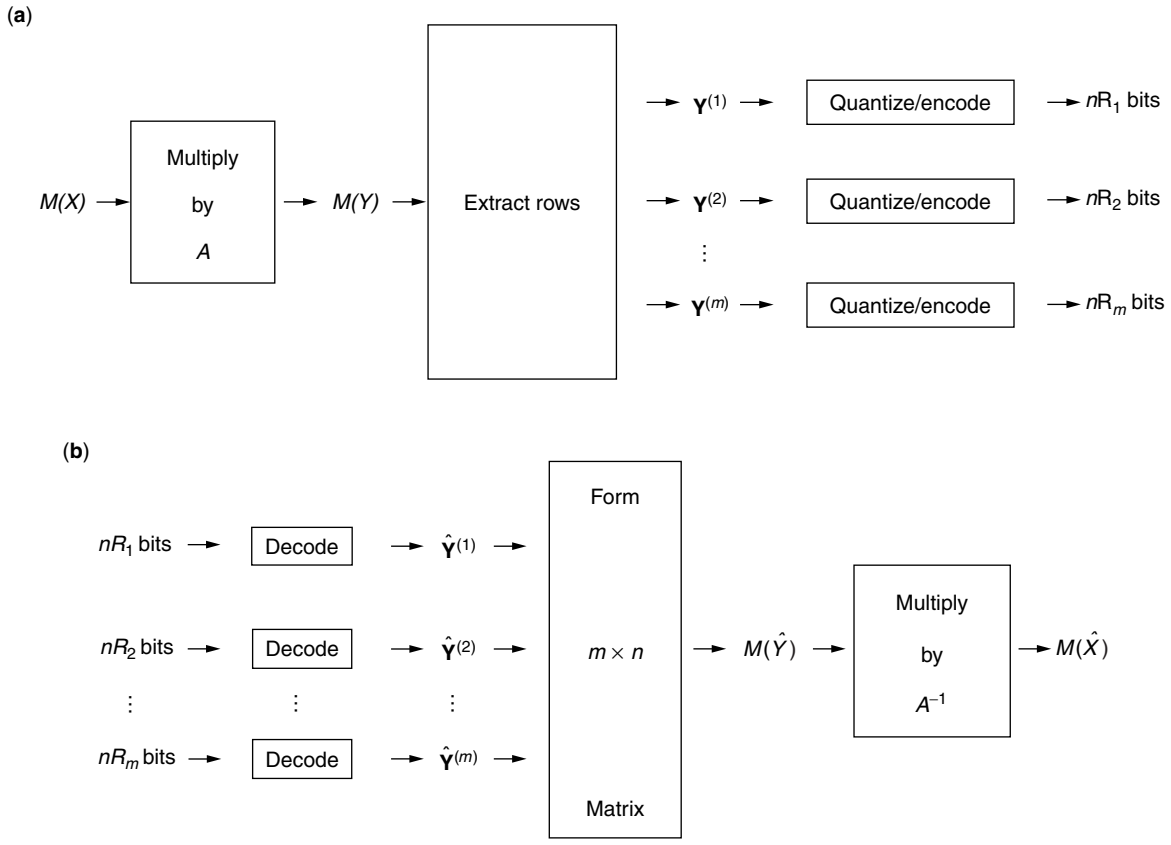


Figure 7. (**a**) Analysis stage and (**b**) synthesis stage of transform code.

and D is minimized. One can also attempt to optimize the choice of the transformation matrix A as well, although, more typically, the matrix A is fixed in advance. If A is an orthogonal matrix (i.e., the transformation is unitary), then the right side of (35) is equal to

$$n^{-1}\sum_{i=1}^{n} E[\|\mathbf{Y}_i - \hat{\mathbf{Y}}_i\|^2]$$

which makes the problem of optimally designing the transform code much easier. However, A need not be orthogonal.

Various transforms have been used in transform coding. Some commonly used transforms are the discrete cosine transform, the discrete sine transform, and the Karhunen–Loeve transform — a good account of these transforms may be found in Ref. 41, Chap. 12. Special mention should be made of the wavelet transform, which is becoming ubiquitous in state of the art compression methods. Various image compression methods employ the wavelet transform, including the EZW method [44], the SPIHT method [39], and the EBCOT method [46]; the wavelet transform is the backbone of the JPEG 2000 image compression standard [47]. The wavelet transform has also been applied to fingerprint compression, speech, audio, electrocardiogram, and video compression — a good account of these applications may be found in Ref. 45, Chap. 11.

Subband coding may be regarded as a special case of transform coding. It originally arose in the middle 1970s as an effective technique for speech compression [12]; subsequently, its applications have grown to include the compression of recorded music, image compression, and video compression. In subband coding, one filters a data sequence of length n by both a highpass filter and a lowpass filter and then throws every other filtered sample away, yielding a stream of $n/2$ highpass-filtered samples and a stream of $n/2$ lowpass-filtered samples; these two streams are separately quantized and encoded, completing the analysis stage of a subband coding system. The highpass and lowpass filters are not arbitrary; these must be complementary in the sense that if no quantization and encoding takes place, then the synthesis stage must perfectly reconstruct the original sequence of data samples. Further passes of highpass and lowpass filterings can be done after the first pass in order to yield several substreams with frequency content in different subbands; in this way, the subband coding system can become as sophisticated as one desires — one can even obtain the wavelet transform via a certain type of subband decomposition. Subband coding has received extensive coverage in several recent textbooks on multirate and multiresolution signal processing [1,49,50].

We have concentrated on lossy transform codes, but there are lossless transform codes as well. A lossless transform code is similar in concept to a lossy transform code; the main difference is that the transformed data sequence is not quantized in a lossless transform code. Good examples of lossless transform codes are (1) the transform code for text compression based on the *Burrows–Wheeler transform* [7]; and (2) grammar-based codes [25,31], which are based on *grammar transforms*.

4. NOTES ON THE LITERATURE

This article has provided an introduction to basic data compression techniques. Further material may be found in one textbook [41] that provides excellent coverage of both lossless and lossy data compression, and in another textbook [40] that provides excellent coverage of lossless data compression. There have been several excellent survey articles on data compression [5,15,20].

Various data compression standards employ the basic data compression techniques that were covered in this article. Useful material on data compression standards may be found in a book by Gibson et al. [21], which covers the JPEG and JBIG still-image compression standards, the MPEG audio and MPEG video compression standards, and multimedia conferencing standards.

4.1. Speech Compression

Speech is notoriously hard to compress — consequently, a specialized body of techniques have had to be developed for speech compression. Since these specialized techniques are not applicable to the compression of other types of data, and since this article has focused rather on general compression techniques, speech compression has been omitted; coverage of speech compression may be found in the textbook by Deller et al. [14].

4.2. Fractal Image Compression

Fractal image compression has received much attention since 1987 [2,3,16,23]. A fractal image code compresses an image by encoding parameters for finitely many contractive mappings, which, when iterated, yield an approximation of the original image. The limitations of the fractal image compression method arise from the fact that it is not clear to what extent natural images can be approximated in this way.

4.3. Differential Coding

Differential codes (such as *delta modulation* and *differential pulsecode modulation*), although not covered in this article, have received coverage elsewhere in this encyclopedia. Differential codes have become part of the standard body of material covered in a first course in communication systems [26, Chap. 6].

BIOGRAPHY

John C. Kieffer received the B.S. degree in applied mathematics in 1967 from the University of Missouri, Rolla, Missouri, and the M.S. and Ph.D. degrees in mathematics from the University of Illinois Champaign — Urbana in 1968 and 1970, respectively. He joined the University of Missouri Rolla (UMR) in 1970 as an Assistant Professor. At UMR he worked on ergodic theory and information theory. Since 1986, he has been a Professor at the University of Minneapolis Twin Cities Department of Electrical

and Computer Engineering, where he has been working on data compression. Dr. Kieffer has 70 MathSciNet publications. He was named a Fellow of the IEEE in 1993. His areas of interest are grammar-based codes, trellis-coded quantization, and the interface between information theory and computer science.

DESIGN AND ANALYSIS OF A WDM CLIENT/SERVER NETWORK ARCHITECTURE

WUSHAO WEN
BISWANATH MUKHERJEE
University of California, Davis
Davis, California

1. INTRODUCTION

The client/server architecture has been one of the driving forces for the development of modern data communication networks. Most of data services, such as distributed database systems, web applications, interactive multimedia services, and so on make use of client-server network architecture. In such an architecture, clients are connected to the server via data networks. The data networks can be local-area networks, such as Ethernet, or can be wide-area networks. The required bandwidth for the client–server network is increasing with the increasing penetration of interactive multimedia and World Wide Web (WWW) applications. In a traditional client–server network, the server bandwidth is limited to several hundred megabits per second (Mbps) at the maximum. Such a bandwidth is sufficient to provide conventional data service. However, with the increasing deployment of multimedia applications and services such as network games, video on demand, virtual reality applications, and similar, the system must provide more bandwidth. For example, a video-on-demand system that provides 1000 videostreams of MPEG2 quality needs about 5–6 Gbps of bandwidth at the server side. Such high-bandwidth requirement cannot be satisfied in conventional client/server systems. The most recent technological advances in optical communication, especially wavelength-division multiplexing (WDM) technology, as well as computer hardware, make the design of such a high-bandwidth server possible. However, what kind of network architecture can we use to construct such high-bandwidth network? How well is the performance of the proposed network architecture? We describe and study a client/server WDM network architecture and its performance. This architecture is suitable for multimedia services, and is unicast-, multicast-, and broadcast-capable.

The remainder of this article is organized as follows. We outline the enabling technologies in Section 2. The WDM networking technology is summarized in Section 3. In Section 4, we describe the system architecture and connection setup protocol. Section 5 describes the system performance and analysis for unicast and multicast services. We discuss the scheduling policy for user requests in Section 6. Finally, Section 7 provides concluding remarks.

2. WDM CLIENT–SERVER NETWORK-ARCHITECTURE-ENABLING TECHNOLOGIES

Optical fiber communication plays a key role to enable high-bandwidth data connection. Now, a single fiber strand has a potential bandwidth of 50 THz corresponding to the low-loss region shown in Fig. 1. To make good use of the potential bandwidth of the fiber, WDM technology is widely used. In WDM, the tremendous bandwidth of a fiber (up to 50 THz) is divided into many nonoverlapping wavelengths, called *WDM channels* [1]. Each WDM channel may operate at whatever possible speed independently, ranging from hundreds of Mbps to tens of Gbps. WDM technology is now deployed in the backbone networks [1,2]. OC-48 WDM backbone networks have already

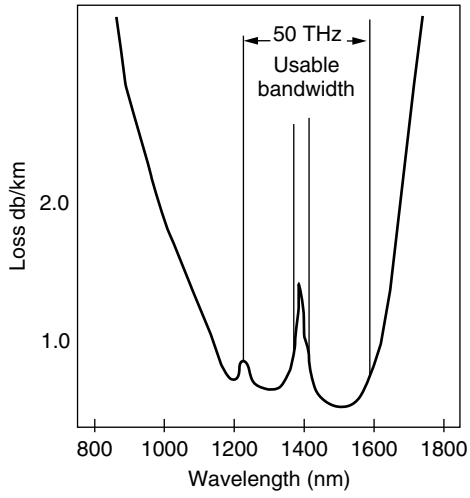

Figure 1. The low-loss region in a single-mode optical fiber.

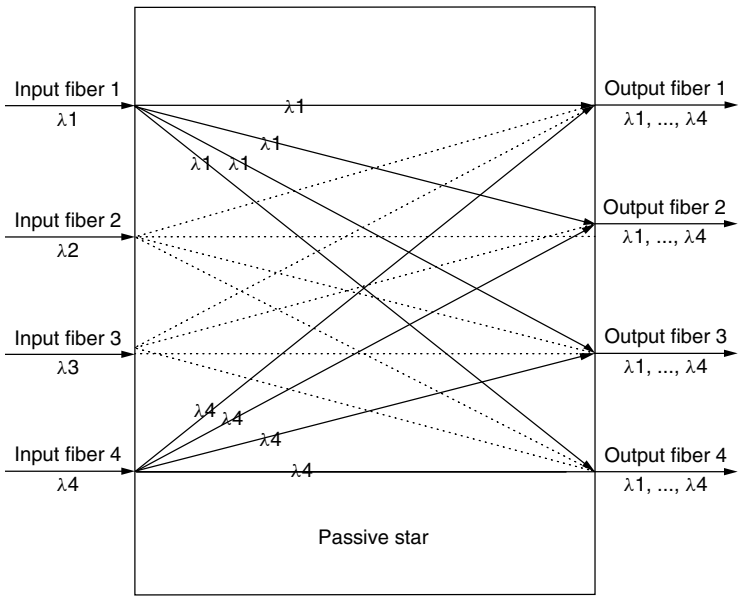

Figure 2. A 4×4 passive star.

been widely implemented, and the OC-192 WDM backbone network is being tested and implemented. The enabling technologies of the WDM client/server network architecture include tunable/nontunable wavelength transmitter and receiver, optical multiplexer, optical tap, and high-performance computer in additional to WDM technology. We outline the basic functions for each optical component.

- *Transmitter and Receiver*. An optical transmitter [1] is used to convert an electrical signal into an optical signal and inject it to the optical transmission media, namely, the fiber. An optical receiver actually consists of an optical filter [1] and an opticoelectrical signal transformer. The transmitter and receiver can be classified as tunable and nontunable. A nontunable transmitter/receiver transmits or receives signal only from a fixed frequency range, implying that only fixed wavelengths can be used. For a tunable transmitter/receiver, the passband can be tuned to different frequencies, which makes it possible to transmit or receive data for different wavelengths at different times. In a WDM system, the bandwidth of an optical fiber is divided into multiple channels (or wavelengths). Communication between two nodes is possible only when the transmitter of the source node and receiver of the destination node are tuned to the same channel during the period of information transfer. There are four types of configuration between two communication end nodes. They are fixed transmitter/fixed receiver, fixed transmitter/tunable receiver, tunable transmitter/fixed receiver, and tunable transmitter/tunable receiver. A tunable transmitter/receiver is more expensive than a fixed transmitter/receiver.
- *Optical Multiplexer*. An optical multiplexer combines signals from different wavelengths on its input ports (fiber) onto a common output port (fiber) so that a single outgoing fiber can carry multiple wavelengths at the same time.
- *Passive Star*. A passive star (see Fig. 2) is a "broadcast" device. A signal that is inserted on a given wavelength from an input fiber port will have its power equally divided among (and appear on the same wavelength on) all output ports. As an example, in Fig. 2, a signal on wavelength λ_1 from input fiber 1 and another on wavelength λ_4 from input fiber 4 are broadcast to all output ports. A "collision" will occur when two or more signals from the input fibers are simultaneously launched into the star on the same wavelength. Assuming as many wavelengths as there are fiber ports, an $N \times N$ passive star can route N simultaneous connections through itself.
- *Optical Tap*. An optical tap is similar to a one-input, two-output passive star. However, the output power in one port is much higher than that in the other. The output port with higher power is used to propagate a signal to the next network element. The other output port with lower power is used to connect to a local end system. The input fiber can carry more than one wavelength in an optical tap.

3. WDM NETWORKING ARCHITECTURE

3.1. Point-to-Point WDM Systems

WDM technology is being deployed by several telecommunication companies for point-to-point communications. This deployment is being driven by the increasing demands on communication bandwidth. When the demand exceeds the capacity in existing fibers, WDM is a more cost-effective alternative compared to laying more fibers.

WDM mux/demux in point-to-point links is now available in product form. Among these products, the maximum number of channels is 160 today, but this number is expected to increase.

3.2. Broadcast-and-Select (Local) Optical WDM Network

A local WDM optical network may be constructed by connecting network nodes via two-way fibers to a passive

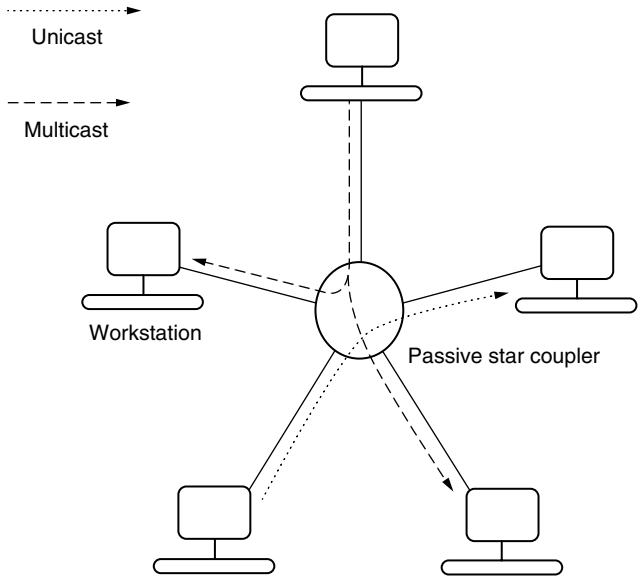

Figure 3. A passive-star-based local optical WDM network.

star, as shown in Fig. 3. A node sends its transmission to the star on one available wavelength, using a laser that produces an optical information stream. The information streams from multiple sources are optically combined by the star and the signal power of each stream is equally split and forwarded to all the nodes on their receive fibers. A node's receiver, using an optical filter, is tuned to only one of the wavelengths; hence it can receive the information stream. Communication between sources and receivers may follow one of two methods: (1) *single-hop* [3] or (2) *multihop* [4]. Also, note that, when a source transmits on a particular wavelength λ_1, more than one receiver can be tuned to wavelength λ_1, and all such receivers may pick up the information stream. Thus, the passive star can support "*multicast*" services.

Detailed, well-established discussions on these network architectures can be found elsewhere, [e.g., 1,3,4].

4. A WDM CLIENT/SERVER NETWORK ARCHITECTURE

4.1. Architecture

In our client/server architecture, the server is equipped with M fixed WDM transmitters that operate on M different wavelengths, and a conventional bidirectional Ethernet network interface that operates on a separate WDM channel is used as the control signaling channel. Every workstation (client) is equipped with a tunable WDM receiver (TR) and an Ethernet network interface. The Ethernet client and server interfaces are connected together and form the signaling channel. All control signals from the clients to the server or vice versa will be broadcast on the control channel by using the IEEE 802.3 protocol [5]. The control channel can be used as a data channel between the clients, or between a client and the server. In the normal data transmission from the server to the clients, the server uses the M data channels to provide data service to the clients. A client can tune its receiver to any of the M server channels and receive data from the server. We show in Fig. 4 a typical client/server WDM system described above. This system can be implemented using a passive star coupler, which connects the server and clients using two-way fibers [1].

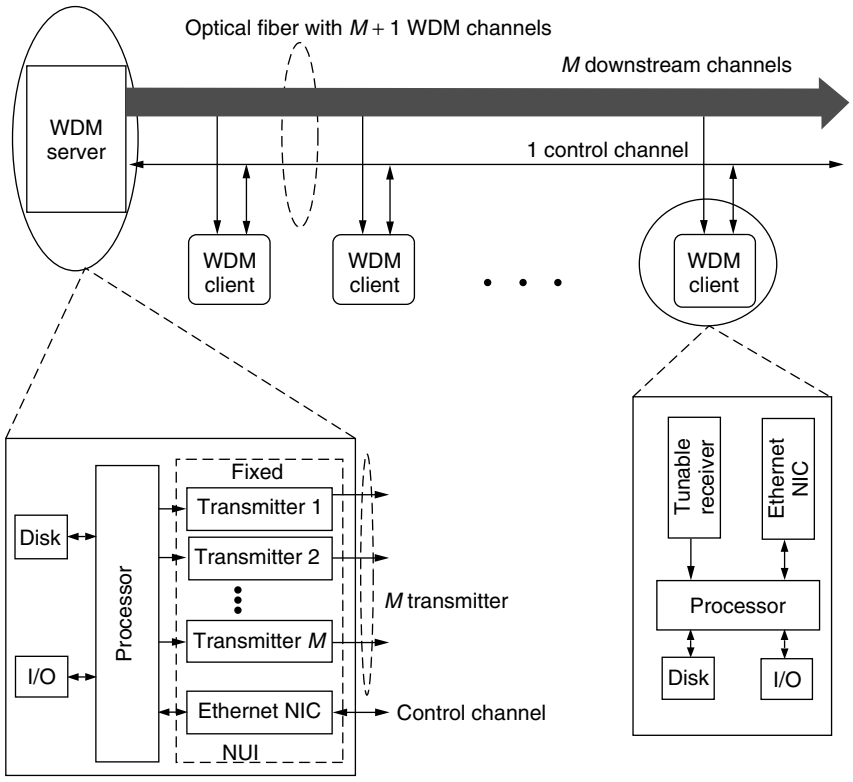

Figure 4. A typical client/server WDM network.

Since a WDM data channel can have a data rate as high as several gigabits per second, a WDM client/server network can be used for those applications that require a high volume of data transfer or those multimedia applications that require high bandwidth. However, a fiber can carry only several hundred wavelengths today, and this may not be enough if we assign a whole wavelength for a single user request. To make good use of the channel capacity, time-division multiplexing (TDM) technology is used to carve a WDM channel into multiple subchannels in time domain. The server can then assign a TDM subchannel to serve the user request. Clients must use some filtering mechanism to get the data from the subchannel. However, the client and the server must communicate with each other to negotiate on which subchannel they plan to use.

This network is also broadcast- and multicast-capable because every client can tune its receiver to any of the M data channels, and more than one client may tune their receivers to the same channel at any given time.

4.2. Operations and Signaling

In a client/server network, the server is able to provide service to clients on request. In such a network, the upstream data traffic volume (from clients to server) is generally much smaller than the downstream data traffic (from server to clients). Therefore, in a WDM client/server network, it is possible to use a single Ethernet channel to fulfill the signaling tasks between the clients and the server. All the clients' upstream traffic and the server's control traffic share the common signaling channel via statistical multiplexing. Figure 5 shows a connection setup procedure of a client's request in the WDM client/server architecture.

Figure 5 indicates that, to setup a connection for a client's request, the network must perform the following operations:

Step 1. A client sends a request message to the server via the common control channel. The message should include information such as the identification of the client, the identification of the requested-file, and the service profile. On receiving the user request, the server will respond with a request–acknowledgment message to the client. This message includes information on the request's status, the server status, and so on.

Step 2. The server processes the client's request. If no data channel or server resource is available, the request is put in the server's request queue and it waits for the server's channel scheduler (SCS) to allocate a data channel or server resource for it. If the request waits for a long time, the server should send keep-alive messages periodically to the client. As soon as the SCS knows that a channel is available, the server's scheduler will select the request (if any) with highest priority and reserve the channel for it. Then, a setup message will be sent to the client via the control channel. The setup message includes information such as the target client's identification information, request ID, the data channel that will be used, the information of the file to be sent out, and the service profile granted for the request.

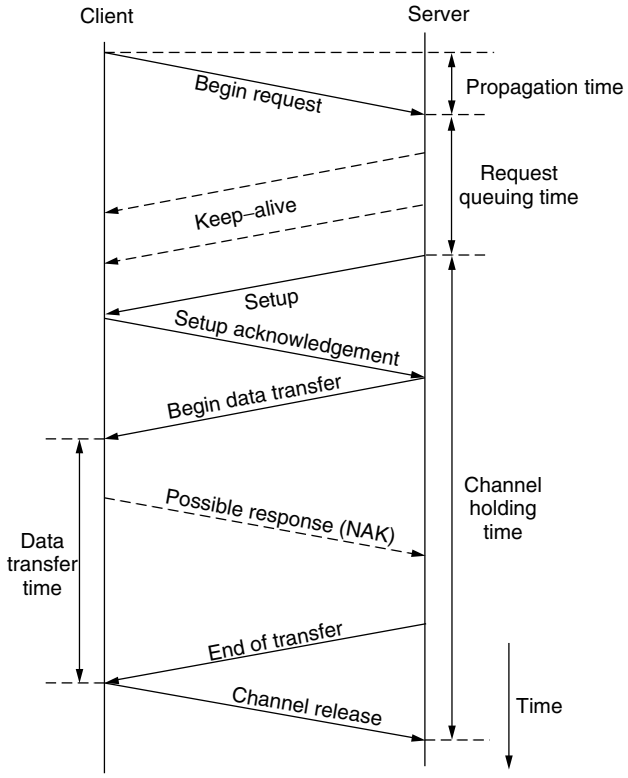

Figure 5. The request setup procedure in a WDM client/server system.

Step 3. On receiving the setup message, the target client's tunable receiver tunes to the assigned channel and sends back a setup acknowledgment message. Now, the client's receiver is waiting for the requested data.

Step 4. When the server receives the setup acknowledgment message, the connection is set up. Then, the server begins to send out the data as soon as the channel is available. If no setup acknowledgment message is received from the client within certain timeout duration, the reserved channel is released and the client's request is discarded.

Step 5. Now the connection is set up and data transfer begins. As we know, the optical channel's bit error rate (BER) is very low, on an order of 10^{-9}–10^{-12}, so it is safe to assume that the data channels have very low packet error rates. Therefore, the system uses NAK signals to indicate any error packets. No acknowledgment signal will be sent out if a packet is correctly received. However, it is possible and helpful for a client to send out some control message to synchronize the data transmission.

Step 6. After the server finishes sending the client's requested data, it sends an end-of-connection

message. The client then responds with a channel-release message to the server. Then, the server tears down the connection and frees the channel.

In this client/server WDM network, the server may receive three kinds of messages: connection request messages, acknowledgment messages, and data transmission control messages. The server should give higher priority to acknowledgment and control messages so that the system can process clients' responses promptly and minimize the channel idle-holding time.[1] It is possible that the requests from the clients come in a bursty manner. Therefore, sometimes, the server may not have enough channels to serve the requests immediately. In that case, the request is buffered. When a channel is available again, there may be more than one client waiting for a free channel. Therefore, the server should have some mechanism to allocate a free channel when it is available. The mechanism used to decide which request should be assigned with the free channel when there are multiple requests waiting for it is called the (SCS) mechanism [6].

4.3. Internetworking Technology

The WDM client/server network architecture is easy to internetwork. In this network architecture, the server has very high bandwidth; therefore, it is not cost-effective to connect the server with the outside network directly. Instead, the clients are connected to outside networks. Figure 6 shows the internetworking scheme where the clients act as proxy servers for outside networks. A client now has two major tasks: handling user requests and caching data. An end user who wants to access some data service, connects to the nearest WDM client. This can be done by a standard client/server service, which implies that no modification is necessary for the end user. On receiving a service request from the end user, the WDM client then analyzes and processes the request. Batching[2] may be used to accommodate requests for the same service from different users. If the user's requested file or program is stored at the WDM client, the request can be served directly without referring to the WDM server; otherwise, the WDM client will contact the server for the data. However, no matter whether the service is provided by the WDM client or the WDM server, it is transparent to the end users.

This internetworking architecture is suitable for multimedia service providers. A service provider can deploy the WDM clients in different cities to provide service to end users. Because the system is broadcast- and multicast-capable, it has very good scalability.

5. SYSTEM PERFORMANCE ANALYSIS

To analyze the system's performance, we consider an example system that uses fixed-length cells (k bytes/cell) to send data from the server to the clients. Every cell occupies exactly one time slot in a WDM channel. The control messages between a client and the server also use

[1] A channel's idle holding time is the time that the channel is reserved for a client but not used for data transfer.

[2] Batching makes use of multicast technology. It batches multiple requests from different users who ask for the same service and use a single stream from the server to serve the users at the same time by using multicasting [6].

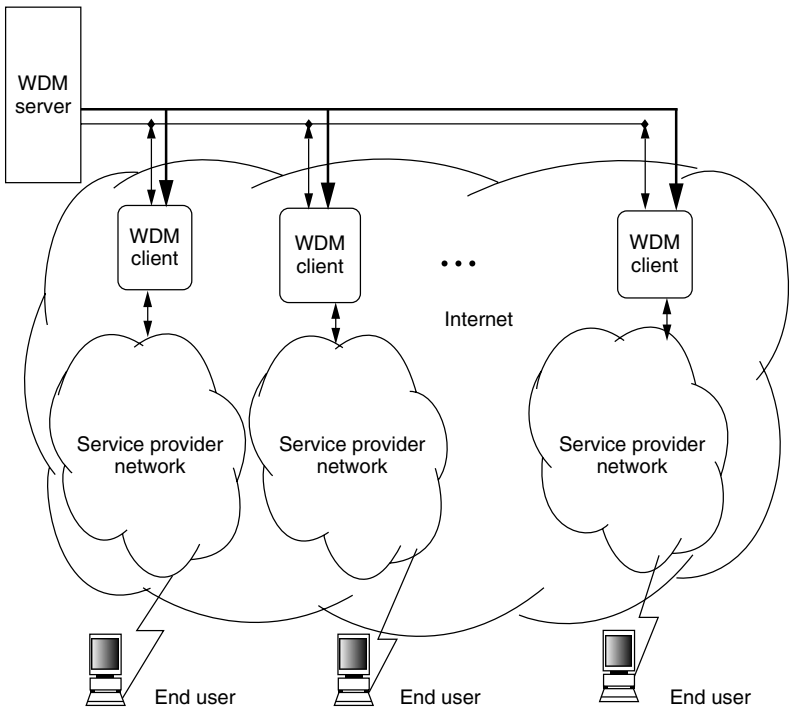

Figure 6. WDM client/server internetworking.

fixed-length cells (k_1 bytes/cell). We use E_1 to represent the bit-error rate (BER) for an optical channel.

5.1. Bottleneck Analysis

5.1.1. Unicast Service. We assume that the system uses negative acknowledgement (NAK) to ask the server to resend the packet that is received with error. It is clear that the expected number of NAK signals per second (denoted as A_1) that will be sent to the control channel is

$$A_1 = \frac{MB}{k}(1 - (1 - E_1)^k) \tag{1}$$

where M is the number of channels and B is the bandwidth for a channel. The BER for an optical channel (E_1) is very small, on the order of 10^{-11}, so Eq. (1) can be simplified as $A_1 = MBE_1$.

Now, suppose the requests from all stations form a Poisson process with average request rate λ_r requests per second. We also assume that the server responds to a user's request by sending back an acknowledgement signal after a random delay. The delay is negative exponential distributed with mean $1/\lambda_r$ minutes. As indicated by the connection setup procedure, the system exchanges five messages via the control channel for every connection in a normal situation.[3] With the additional assumption that the NAK messages are also generated as a Poisson process with average arrival rate λ_n requests/second, the number of cells sent to the Ethernet channel is a Poisson process with total arrival rate λ, ($\lambda = E_1MB + 5\lambda_r$) at the maximum.[4]

Suppose that the mean file size is $\overline{f}$. Then to serve all requests with limited delay, the system should satisfy the condition $\lambda_r * \overline{f} < MB$. So $\lambda_r < MB/\overline{f}$. Therefore, the bandwidth requirement for the control channel should satisfy

$$B_e = \lambda k_1 < \frac{K_1}{p}\left(\frac{E_1MB + 5MB}{f}\right) = \frac{MBk_1}{p}\left(\frac{E_1 + 5}{\overline{f}}\right) \tag{2}$$

where p is the maximum offered load allowed on the control channel. In this above equation, $E_1 \ll 5/\overline{f}$ in the actual system. Figure 7 shows the plot of expected control channel bandwidth (B_e) requirement vs. the average file size ($\overline{f}$) in the server with default parameter $p = 0.5, E_1 = 10^{-8}, M = 10, B = 1$ Gbps, and $k_1 = 40$ bytes. From the plot, we notice that, when $\overline{f}$ is small, B_e must be very high. For example, when $\overline{f} = 1$ kbyte, the system requires a bandwidth of 500 Mbps for the control. However, with $f = 1$ Mbyte, the required bandwidth B_e is only about 0.5 Mbps. Clearly, with such a low bandwidth requirement, the control channel is not a bottleneck. When the average file size $\overline{f}$ is between 10 and 100 kbytes, which is a practical file size, the required bandwidth B_e is between 5 and 50 Mbps. From Fig. 7, we can conclude that the WDM client/server network architecture is useful to provide those services that need to transfer a lot of large files. If the system needs to support small files, then the control channel's bandwidth must be increased.

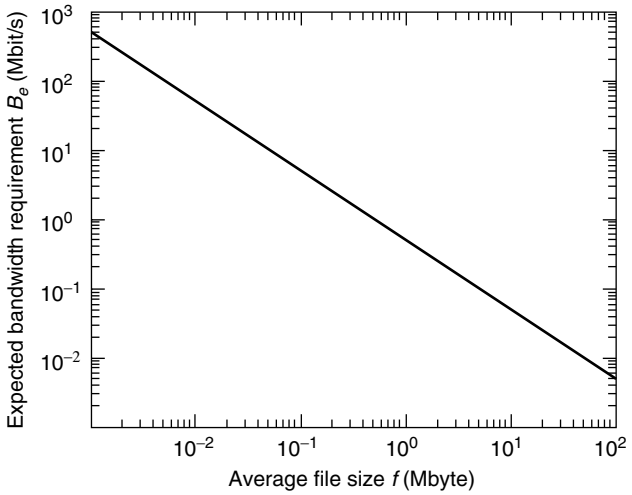

Figure 7. Expected bandwidth requirement of the control channel versus the average file size in the server.

5.1.2. Multicast Service. We have stated that the WDM client-server network is multicast- and broadcast-capable. If the system provides on-demand multicast services, then the server can group together user requests that ask for the same file coming in a certain period and use a single-server channel to multicast the requested file to all users. In an actual implementation, a WDM channel may be carved into several subchannels, and any multicast group will only use a subchannel instead of a whole WDM channel. A multicast service system scales very well even with a limited number of data channels. For example, if a server has 10-Gbps data bandwidth, it can provide about 1800 MPEG2 or 6700 MPEG1 video channels at the same time. A client/server system providing video-on-demand service, which only provides several hundred different video programs at the same time, can easily support any number of user requests by using batching. However, all the request messages and control messages are sent via the Ethernet channel, and the Ethernet channel capacity is limited. Therefore, it is possible that the Ethernet may be a bottleneck. However, in an actual system, this is unlikely to happen. Let us assume, on the average, that every request needs to exchange m 40-byte messages between a client and the server. If we assume $m = 10$ in the multicast system, a control channel with 100 Mbps can accommodate a request rate as high as $\lambda_r = 31{,}250$ requests/s. Such a high request rate is unlikely to happen in any actual system. Therefore, the control channel should not be a bottleneck.

For broadcast service, there is not a lot of interaction between clients and the server. The server notifies the clients what kind of file or program is sent in each channel. A client then chooses its interested channel to receive the

[3] We omit the keep-alive messages in this discussion.

[4] The aggregation of several Poisson processes is also a Poisson process. The average arrival rate of the aggregated process is the sum of the arrival rates of all the original processes.

data. Therefore, bottleneck analysis does not apply in this service mode.

5.2. System Performance Illustrative Study

This subsection studies the system performance in terms of delay, throughput, and average queuing length. Let us first define several keywords:

- *A Request's System Time*. A request's system time is measured from the time that a user sends out the request message to the time that the user receives all data. Let us denote the time as S_t. Then, from Fig. 5, we can express S_t as

$$S_t = 2R + t_q + t_d \tag{3}$$

  where R is the round-trip time between the client and the server; t_q is the request's queuing time, defined as the time from the instant a request reaches the server to the time the request starts to be served by the server; and t_d is the data transfer time. For every client's request, the round-trip time and the data transfer time are fixed. The only optimizable factor is the queuing time for a given system. Therefore, in order to reduce the response time, we should have a good scheduling algorithm in the server so that we can minimize the average request delay.
- *A Request's Channel Holding Time*. The channel holding time for a request, denoted as H, can be expressed by

$$H = 2R + t_d = D - t_q \tag{4}$$

  Therefore, for a given request, the channel holding time is almost nonoptimizable, because the round-trip time and data transfer time are all nonoptimizable for a given request in a specific system.
- *System Throughput*. When the system operates in the stable state, it should be able to serve all user requests. So the system throughput should equal the average request rate multiplied by the average file size. The maximum reachable throughput in the system, denoted as $\theta_{\max}$, can be express as

$$\theta_{\max} = MB\frac{\overline{f}/B}{\overline{f}/B + 2\overline{R}} \tag{5}$$

where M is total number of data channels, B is the channel capacity, $\overline{R}$ is the average round-trip time from the clients to the server, and $\overline{f}$ is the average file size. Here, $2\overline{R}$ is the average overhead conceived by the server to setup a connection.

We analyze a system's performance based on the following assumptions:

- *Clients' requests* form a Poisson process. The request rate is λ_r requests/s. So the interarrival times are negative exponentially distributed with mean $1/\lambda_r$ minutes.
- There are M data channels altogether. Each channel's capacity is B bps.
- *The file sizes* that users request from the server are exponentially distributed with average file size $\overline{f}$. We also assume the average file size to be relatively large. Therefore, the data transfer time is much larger than the round-trip time and the client's receiver tuning time, and we can omit the round-trip time and client's receiver-tuning time in our analysis.
- *The scheduler uses first-come, first-served* (*FCFS*) policy.

Using on the above assumptions, we analyze the system as follows. For FCFS scheduling policy, we can model the system as an $M/M/m$ queuing system. In this system, a data channel is regarded as a server in the model. The service time is equal to the channel holding time. We have assumed that the file sizes that users requested from the server are exponentially distributed with average $\overline{f}$. Therefore, the channel holding time at each channel is negative exponential distributed with mean $\mu = B/\overline{f}$. Let us define $\rho = \lambda_r/M\mu$. Clearly the system should require $0 \le \rho < 1$. If $\rho \ge 1$, then the system's service rate will be smaller than the arrival rate, which means that the waiting queue will be built up to infinity, and the system will become unstable. On the basis of these parameters and the $M/M/m$ model, we have the following results [7]:

- *The average number of busy channels* U_b in the system is given by

$$E[U_b] = M\rho = \frac{\lambda_r}{\mu} \tag{6}$$

- *The throughput* of the system is given by $\lambda_r\overline{f}$. This is because the average number of the served requests and the arrival requests should be in balance.
- *The average queue length* Q_n of the system is given by

$$Q_n = M\rho + \frac{(M\rho)^M}{M!}\frac{\rho}{(1-\rho)^2}\pi_0 \tag{7}$$

  where π_0 is the stationary zero queue-length probability and is given by

$$\pi_0 = \left[1 + \sum_{i=1}^{M-1}\frac{(M\rho)^i}{i!} + \frac{(M\rho)^M}{(M)!}\frac{1}{1-\rho}\right]^{-1} \tag{8}$$

- *The average queuing time* is given by the average system time minus the service time (we omit the

round-trip time here). Therefore, we can calculate the average queuing time from the expression

$$E[t_q] = \frac{1}{\mu}\frac{(M\rho)^M}{M!}\frac{\pi_0}{M(1-\rho)^2} \tag{9}$$

6. SCHEDULING POLICIES

In Section 4, we pointed out that the delay for a client's request can be decreased by reducing the queuing time with a proper scheduler. However, the FCFS scheduling policy does not account for a request's channel holding time in allocating an available channel. Therefore, it is possible that some long-time tasks will occupy the server channels for very long time and the short-time tasks have to wait for very long time to be served. Several scheduling policies, such as priority queues, and feedback priority queues, are available to solve this problem. We discuss these policies below.

Priority Queues (PQ) Scheduling Policy. In a priority-queue scheduling policy, the server maintains several queues with different priorities. When no channel is available, the requests for small files will be assigned a higher priority and placed in the higher-priority queue in FCFS manner, and requests for larger files will be put in lower-priority queue. When a channel is available, it is first allocated to a request in the higher-priority queue. Requests in a lower-priority queue cannot be allocated a channel unless all higher-priority queues are empty. The PQ method can greatly reduce the average queuing time. However, there is a starvation problem in this policy. When the request rate is high, requests that ask for large files may never be served because they remain in the lower-priority queue forever and the channels are always allocated to the requests in the higher-priority queue.

Priority Feedback Queues (PFQ) Scheduling Policy. To avoid the starvation problem in the PQ scheduling policy, we can use the priority feedback queues (PFQ) scheduling policy, which allows a request to move from a lower-priority queue to a higher-priority queue if it waits too long. One possible method is to use a threshold function $T_r = f(i, f, t)$. It is the function of i (the current queue it belongs to), the request's file size f, and the waiting time t. Let $T_h(i)$ be the threshold value for the current queue i. Then, we can set the scheduling policy as follows. If $T_r < T_h(i)$, then the request will remain in the same queue; otherwise, it will move up to the higher-priority queue. A scheduler will always select the request with highest priority and allocate the channel to it.

The PFQ scheduling policy solves the starvation problem, but the implementation is more complex.

7. CONCLUSION

We described a WDM client/server network architecture based on a passive-star-coupler-based broadcast-and-select network. In this architecture, all downstream data traffic uses WDM data channels and all upstream requests, upstream control messages, and downstream control messages use an Ethernet channel (called the *control channel*). This architecture is broadcast and multicast capable. We described a detailed point-to-point connection setup procedure for this architecture. An internetworking scheme was also provided. This system architecture is appropriate for an asymmetric data transmission system in which the downstream traffic volume is much higher than the upstream traffic volume. The system's performance was analyzed in terms of whether the control channel or the data channels are the bottleneck. We also analyzed the request delay, request's channel holding time, and system throughput following the model description. We concluded that the control channel is not a bottleneck in the system. When the user request rate is high, the server channel scheduler is the most important adjustable factor to reduce the user response time. An illustrative analysis of FCFS scheduling policy for the system was also provided. To explore WDM technology further, the literature please refer to [1,10,11].

1. INTRODUCTION

Low-density parity-check (LDPC) codes, first introduced by Gallager [19], are error-correcting codes described by sparse parity-check matrices. The recent interest in LDPC codes is motivated by the impressive error performance of the Turbo decoding algorithm demonstrated by Berrou et al. [5]. Like Turbo codes, LDPC codes have been shown to achieve near-optimum performance [35] when decoded by an iterative probabilistic decoding algorithm. Hence LDPC codes fulfill the promise of Shannon's noisy channel coding theorem by performing very close to the theoretical channel capacity limit.

One of the first applications of the Gallager LDPC codes was related to attempts to prove an analog of the Shannon coding theorem [47] for memories constructed from unreliable components. An interesting scheme of memory constructed from unreliable components was proposed by M. G. Taylor, who used an iterative threshold decoder for periodic correction of errors in memory cells that degrade steadily in time [52]. The number of elements in the decoder per one memory cell was a priori limited by a capacity-like constant C as the number of memory cells approached infinity. At the time, the Gallager LDPC codes were the only class of codes with this property, and therefore were naturally used in the Taylor's memory scheme. For sufficiently small probabilities of the component faults, using Gallager LDPC codes of length N, Taylor constructed a reliable memory from unreliable components and showed that the probability of failure after T time units, $P(T, N)$, is upper-bounded by $P(T, N) < A_1 T N^{-\alpha}$, where $0 < \alpha < 1$ and A is a constant. A similar bound with a better constant α was obtained [26]. In fact, Ref. 26 report even the tighter bound $P(T, N) < A_2 T \exp\{-\gamma N^{\beta}\}$, with a constant $0 < \beta < 1$. Using a slightly different ensemble of LDPC and some other results [60], Kuznetsov [27] proved the existence of LDPC codes that lead to the "pure" exponential bound with a constant $\beta = 1$ and decoding complexity growing linearly with code length. A detailed analysis of the error correction capability and decoding complexity of the Gallager-type LDPC codes was done later by Pinsker and Zyablov [61].

Frey and Kschischang [18] showed that all compound codes including Turbo codes [5], classical serially concatenated codes [3,4], Gallager's low-density parity-check codes [19], and product codes [20] can be decoded by Pearl's belief propagation algorithm [41] also referred to as the *message-passing algorithm*. The iterative decoding algorithms employed in the current research literature are suboptimal, although simulations have demonstrated their performance to be near optimal (e.g., near maximum likelihood). Although suboptimal, these decoders still have very high complexity and are incapable of operating in the >1-Gbps (gigabit-per-second) regime.

The prevalent practice in designing LDPC codes is to use very large randomlike codes. Such an approach completely ignores the quadratic encoding complexity in length N of the code and the associated very large memory requirements. MacKay [35] proposed a construction of irregular LDPC codes resulting in a deficient rank parity-check matrix that enables fast encoding since the dimension of the matrix to be used in order to calculate parity bits turns out to be much smaller than the number of parity check equations. Richardson et al. [44] used the same encoding scheme in the context of their highly optimized irregular codes. Other authors have proposed equally simple codes with similar or even better performance. For example, Ping et al. [42] described concatenated tree codes, consisting of several two-state trellis codes interconnected by interleavers, that exhibit performance almost identical to turbo codes of equal block length, but with an order of magnitude less complexity.

An alternative approach to the random constructions is the algebraic construction of LDPC codes using finite geometries [24,25]. Finite geometry LDPC codes are quasicyclic, and their encoders can be implemented with linear shift registers with feedback connections based on their generator polynomials. The resulting codes have been demonstrated to have excellent performance in AWGN, although their decoder complexities are still somewhat high. Vasic [54–56] uses balanced incomplete block designs (BIBDs) [6,11] to construct regular LDPC codes. The constructions based on BIBD's are purely combinatorial and lend themselves to low complexity implementations.

There have been numerous papers on the application of turbo codes to recording channels [14–16,22] showing that high-rate Turbo codes can improve performance dramatically. More recent work shows that similar gains can be obtained by the use of random LDPC and Turbo product codes [17,28–30]. Because of their high complexity, the LDPC codes based on random constructions cannot be used for high speed applications (>1 Gbps) such as the next generation data storage channels.

In this article we describe how to construct LDPC codes based on combinatorial techniques and compare their performance with random constructions for perpendicular recording channels. In Section 2 we introduce various deterministic construction techniques for LDPC codes. In Section 3 we describe the perpendicular channel under investigation which is followed by the simulation results. Finally, we conclude in Section 4.

2. DESIGN AND ANALYSIS OF LDPC CODES

In this section we introduce several deterministic constructions of low-density parity-check codes. The constructions are based on combinatorial designs. The

codes constructed in this fashion are "well-structured" (cyclic and quasicyclic) and, unlike random codes, can lend themselves to low-complexity implementations. Furthermore, the important code parameters, such as minimum distance, code rate and the graph girth, are fully determined by the underlying combinatorial object used for the construction. Several classes of codes with a wide range of code rates and minimum distances are considered First, we introduce a construction using general Steiner system (to be defined later), and then discuss projective and affine geometry codes as special cases of Steiner systems. Our main focus are regular Gallager codes [19] (LDPC codes with constant column and row weight), but as it will become clear later, the combinatorial method can be readily extended to irregular codes as well. The first construction is given by Vasic [54–56] and exploits resolvable Steiner systems to construct a class of high-rate codes. The second construction is by Kou et al. [24,25], and is based on projective and affine geometries.

The concept of combinatorial designs is well known, and their relation to coding theory is profound. The codes as well as their designs are combinatorial objects, and their relation does not come as a surprise. Many classes of codes including extended Golay codes and quadratic residue (QR) codes can be interpreted as designs (see Refs. 8 and 48 and the classical book of MacWilliams and Sloane [37]). The combinatorial designs are nice tools for code design in a similar way as bipartite graphs are helpful in visualizing the message passing decoding algorithm. Consider an (n, k) linear code C with parity-check matrix H [31]. For any vector $x = (x_v)_{1 \le v \le n}$ in C and any row of H

$$\sum_v h_{c,v} \cdot x_v = 0, 1 \le c \le n - k \tag{1}$$

This is called the *parity-check equation*. To visualize the decoding algorithm, the matrix of parity checks is represented as a bipartite graph with two kinds of vertices [38,58,50]. The first subset (B), consists of bits, and the second is a set of parity-check equations (V). An edge between a bit and an equation exists if the bit is involved in the check. For example, the bipartite graph corresponding to

$$H = \begin{bmatrix} 1 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{bmatrix}$$

is shown in Fig. 1.

2.1. Balanced Incomplete Block Design (BIBD)

Now we introduce some definitions and explain the relations of 2-designs to bipartite graphs. A *balanced incomplete block design* (BIBD) is a pair (V,B), where V is a v-element set and B is a collection of $b \cdot k$-subsets of V, called blocks, such that each element of V is contained in exactly r blocks and any 2-subset of V is contained in exactly λ blocks. A design for which every block contains the same number k of points, and every point is contained in the same number r of blocks is called a *tactical configuration*. Therefore, BIBD can be considered as a special case of a tactical configuration. The notation BIBD(v, k, λ) is used for a BIBD on v *points, block size* k, and index λ. The BIBD with a block size $k = 3$ is called a *Steiner triple system*. A BIBD is called *resolvable* if there exists a nontrivial partition of its set of blocks B into *parallel classes*, each of which in turn partitions the point set V. A resolvable Steiner triple system with index $\lambda = 1$ is called a *Kirkman* system. These combinatorial objects originate from Kirkman's famous schoolgirl problem posted in 1850 [23] (see also Refs. 49 and 43). For example, collection $B = \{B_1, B_2, \ldots, B_7\}$ of blocks $B_1 = \{0, 1, 3\}$, $B_2 = \{1, 2, 4\}$, $B_3 = \{2, 3, 5\}$, $B_4 = \{3, 4, 6\}$, $B_5 = \{0, 4, 5\}$, $B_6 = \{1, 5, 6\}$ and $B_7 = \{0, 2, 6\}$ is a BIBD(7,3,1) system or a Kirkman system with $v = 7$, and $b = 7$.

We define the block-point incidence matrix of a (V, B) as a $b \times v$ matrix $A = (a_{ij})$, in which $a_{ij} = 1$ if the jth element of V occurs in the ith block of B, and $a_{ij} = 0$ otherwise. The point-block incidence matrix is A^T.

The block-point matrix for the BIBD(7,3,1) described above is

$$A = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 & 1 \end{bmatrix}$$

and the corresponding bipartite graph is given in Fig. 2.

Each block is incident with the same number of points k, and every point is incident with the same number r of blocks. If $b = v$, and hence $r = k$, the BIBD is called *symmetric*. The concepts of a symmetric BIBD(v, k, λ) with $k \ge 3$ and of a finite projective plane are equivalent (see Ref. 34, Chap. 19). If one thinks of points as parity-check equations and of blocks as bits in a linear block code, then the A^T defines a matrix of parity checks H of a Gallager code [19,36]. The row weight of A is k, column weight is r, and the code rate is $R = [b - \text{rank}(H)]/b$.

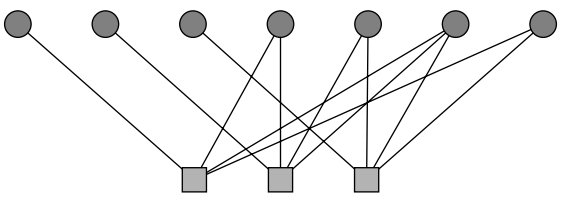

Figure 1. An example of a bipartite graph.

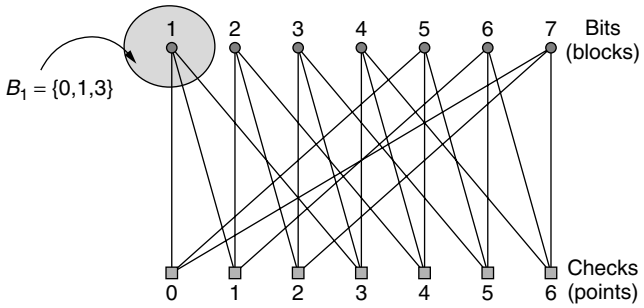

Figure 2. The bipartite graph representation of the Kirkman (7,3,1) system.

It is desirable to have each bit "checked" in as many equations as possible, but because of the iterative nature of the decoding algorithm, the bipartite graph must not contain short cycles. In other words, the graph *girth* (the length of the shortest cycle) must be large [7,51]. These two requirements are contradictory, and the tradeoff is especially difficult when we want to construct a code that is both short and has a high rate. The girth constraint is related to the constraint that every t-element subset of V is contained in as few blocks as possible. If each t-element subset is contained in exactly λ blocks, the underlying design is known as t design. An example of a 5-design is the extended ternary Golay code [8]. However, the codes based on t designs ($t > 2$) have short cycles, and therefore we will restrict ourselves to the 2-designs (i.e., BIBD) or more specifically to the designs with the index $\lambda = 1$. The $\lambda = 1$ constraint means that no more than one block contains the same pair of points or, equivalently, that there are no cycles of length four in a bipartite graph. The lower bound on a rate of a 2-(v, k, λ)-design-based code is given by

$$R \geq \frac{\lambda \dfrac{v(v-1)}{k(k-1)} - v}{\lambda \dfrac{v(v-1)}{k(k-1)}} \tag{2}$$

This bound follows from the basic properties of designs (Ref. 9, Lemma 10.2.1 and Corollary 10.2.2, pp. 344–345). By counting ones in H across the rows and across the columns, we conclude that

$$b \cdot k = v \cdot r \tag{3}$$

If we fix the point u, and find the number of pairs (u, w), $u \neq w$, we arrive to the relation

$$r \cdot (k-1) = \lambda \cdot (v-1) \tag{4}$$

Since the point-block incidence matrix (matrix of parity checks) H has v rows and b columns ($v \leq b$), the rank of A cannot be larger than v, and the code rate, which is $R = [b - \text{rank}(A^T)]/b$ cannot be smaller than $(b-v)/b$. Dividing (3) and (4) yields (2). A more precise characterization of code rate can be obtained by using the rank (and p rank) of the incidence matrix of 2-designs as explained by Hamada [21]. In the case of t-designs, $t > 1$ the number of blocks is $b = \lambda\binom{v}{t}/\binom{k}{t}$ (see Ref. 34, p. 191).

We have shown that the concept of BIBD offers a useful tool for designing codes. Let us now show a construction of Steiner triple systems using difference families of Abelian groups. Let V be an additive Abelian group of order v. Then $t \cdot k$-element subsets of $V, B_i = \{b_{i,1}, \ldots, b_{i,k}\} 1 \leq i \leq t$ form a (v, k, λ) *difference family* (DF) if every nonzero element of V can be represented exactly λ ways as a difference of two elements lying in a same member of a family, that is, it occurs λ times among the differences $b_{i,m} - b_{i,n}, 1 \leq i \leq t, 1 \leq m, n \leq k$. The sets B_i are called *base blocks*. If V is isomorphic with Z_v, a group of integers modulo v, then a (v, k, λ) DF is called a *cyclic difference family* (CDF). For example, the block $B_1 = \{0, 1, 3\}$ is a base block of a (7,3,1) CDF. To illustrate this, we create an array $\Delta^{(1)} = (\Delta_{i,j})$, of differences $\Delta^{(1)}{}_{i,j} = b_{1,i} - b_{1,j}$

$$\Delta^{(1)} = \begin{bmatrix} 0 & 6 & 4 \\ 1 & 0 & 5 \\ 3 & 2 & 0 \end{bmatrix}$$

Given base blocks B_j, $1 \leq j \leq t$, the orbits $B_j + g$ can be calculated as a set $\{b_{j,1} + g, \ldots, b_{j,k} + g\}$, where $g \in V$. A construction of a BIBD is completed by creating orbits for all base blocks. If the number of base blocks in the difference families is t, then the number of blocks in a BIBD is $b = tv$. For example, it can be easily verified (by creating the array Δ) that the blocks $B_1 = \{0, 1, 4\}$ and $B_2 = \{0, 2, 7\}$ are the base block of a (13,3,1) CDF of a group $V = Z_{13}$. The two parallel classes (or orbits) are as given below:

$$B_1 + g = \left\{ \begin{matrix} 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 \\ 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 0 \\ 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 0 & 1 & 2 & 3 \end{matrix} \right\}$$

$$B_2 + g = \left\{ \begin{matrix} 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 \\ 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 0 & 1 \\ 7 & 8 & 9 & 10 & 11 & 12 & 0 & 1 & 2 & 3 & 4 & 5 & 6 \end{matrix} \right\}$$

The corresponding matrix of parity checks is

$$H = \begin{bmatrix} 1&0&0&0&0&0&0&0&0&1&0&0&1&1&0&0&0&0&0&1&0&0&0&0&1&0 \\ 1&1&0&0&0&0&0&0&0&0&1&0&0&0&1&0&0&0&0&0&1&0&0&0&0&1 \\ 0&1&1&0&0&0&0&0&0&0&0&1&0&1&0&1&0&0&0&0&0&1&0&0&0&0 \\ 0&0&1&1&0&0&0&0&0&0&0&0&1&0&1&0&1&0&0&0&0&0&1&0&0&0 \\ 1&0&0&1&1&0&0&0&0&0&0&0&0&0&1&0&1&0&0&0&0&0&1&0&0&0 \\ 0&1&0&0&1&1&0&0&0&0&0&0&0&0&0&1&0&1&0&0&0&0&0&1&0&0 \\ 0&0&1&0&0&1&1&0&0&0&0&0&0&0&0&0&1&0&1&0&0&0&0&0&1&0 \\ 0&0&0&1&0&0&1&1&0&0&0&0&0&1&0&0&0&0&1&0&1&0&0&0&0&0 \\ 0&0&0&0&1&0&0&1&1&0&0&0&0&0&1&0&0&0&0&1&0&1&0&0&0&0 \\ 0&0&0&0&0&1&0&0&1&1&0&0&0&0&0&1&0&0&0&0&1&0&1&0&0&0 \\ 0&0&0&0&0&0&1&0&0&1&1&0&0&0&0&0&1&0&0&0&0&1&0&1&0&0 \\ 0&0&0&0&0&0&0&1&0&0&1&1&0&0&0&0&0&1&0&0&0&0&1&0&1&0 \\ 0&0&0&0&0&0&0&0&1&0&0&1&1&0&0&0&0&0&1&0&0&0&0&1&0&1 \end{bmatrix}$$

This matrix contains only columns of weight 3. Of course, since the order of the group in our example is low, the code rate is low as well ($R \geq \frac{1}{2}$). Generally, given a (v, k, λ) CDF, a $t \cdot k$-element subset of Z_v, with base blocks $B_i = \{b_{i,1}, \ldots, b_{i,k}\}, 1 \leq i \leq t$, the matrix of parity checks can be written in the form

$$H = [H_1 \, H_2 \, \cdots \, H_t] \tag{5}$$

where each submatrix is a circulant matrix of dimension $v \times v$. Formula (5) indicates that the CDF codes have a quasicyclic structure similar to the Townsend and Weldon [53] self-orthogonal quasicyclic codes and Weldon's [57] difference set codes. Each orbit in the design corresponds to one circulant submatrix in a matrix of parity checks of quasicyclic codes.

The codes based on Z_v are particularly interesting because they are conceptually extremely simple and have a structure that can be easily implemented in hardware. Notice also that for a given constraint (v, k, λ) the CDF-based construction maximizes the code rate because for a given v the number of blocks is maximized. The code

rate is independent of the underlying group. Other groups different than Z_v may lead to similar or better codes.

2.2. Constructions for Cyclic Difference Families

As we have shown, it is straightforward to construct a BIBD once the CDF is known. However, finding the CDF is a much more complicated problem and solved only for some values of v, k, and λ. Now we describe how to construct a CDF.

2.2.1. The Netto's First Construction. This scheme (see Refs. 10 and 12, p. 28) is applicable if $k = 3$, and v is a power of a prime, such that $v \equiv 1 \pmod 6$. Since v is a power of a prime, then Z_v is a Galois field [GF(v)]. Let Ψ be a multiplicative group of the field, and let ω be its generator [a primitive element in GF(v)] [39]. Write v as $v = 6t + 1, t \geq 1$, and for d, a divisor of $v - 1$, denote by Ψ^d the group of dth powers of ω in GF($6t + 1$), and by $\omega^i\Psi^d$ the coset of dth powers of ω^i. Then the set $\{\omega^i\Psi^{2t} \mid 1 \leq i \leq t\}$ defines a $(6t + 1, 3, 1)$ difference family [40,59]. In the literature the base blocks are typically given in the form $\{0, \omega^i(\omega^{2t} - 1), \omega^i(\omega^{4t} - 1)\}$ rather than as $\{\omega^i, \omega^{i+2t}, \omega^{i+4t}\}$.

An alternative combinatorial way of constructing a CDF is proposed by Rosa [33]. Rosa's method also generates a $(6t + 3, 3, 1)$ CDF. In Ref. 53 a list of constructions for rate-$\frac{1}{2}$ codes is given. The details are not given here, but the parameters are the same as of Netto construction. In Ref. 12 [p. 28] Colbourn noticed that this construction is perhaps wrongly associated with Netto.

2.2.2. The Netto's Second Construction. This construction [40] can be used to create a cyclic difference family when the number of points v is a power of a prime, and $v \equiv 7 \pmod{12}$. Again let ω be a generator of the multiplicative group and let $v = 6t + 1, t \geq 1$, and Ψ^d the group of dth powers in GF(v), then the set $\{\omega^{2i}\Psi^{2t} \mid 1 \leq i \leq t\}$ defines base blocks of the so called Netto triple system. The Netto systems are very interesting because of the following property. Netto triple systems on Z_v, v power of a prime and $v \equiv 19 \pmod{24}$ are Pasch-free [32,45,46] (see also Ref. 12, p. 214, Lemma 13.7), and as shown in Ref. 56 achieve the upper bound on minimum distance. For example, consider the base blocks of the Netto triple system difference family on $Z_v(\omega = 3)$ where $B_1 = \{0, 14, 2\}$, $B_2 = \{0, 40, 18\}$, $B_3 = \{0, 16, 33\}$, $B_4 = \{0, 15, 39\}$, $B_5 = \{0, 6, 7\}$, $B_6 = \{0, 11, 20\}$, and $B_7 = \{0, 13, 8\}$. The resulting code is quasi-cyclic, has $d_{\min} = 6$, length $b = 301$ and $R \geq 0.857$.

2.2.3. Burratti Construction for $k = 4$ and $k = 5$. For $k = 4$, Burratti's method gives CDFs with v points, provided that v is a prime and $v = 1 \bmod 12$. The CDF is a set $\{\omega^{6i}B{:}\, 1 \leq i \leq t\}$, where base blocks have the form $B = \{0, 1, b, b^2\}$, where ω is a primitive element in GF(v). The numbers $b \in$ GF($12t + 1$) for some values of v are given in Ref. 10. Similarly, for $k = 5$, the CDF is given as $\{\omega^{10i}B{:}\, 1 \leq i \leq t\}$, where $B = \{0, 1, b, b^2, b^3\}, b \in$ GF($20t + 1$). Some Buratti designs are given in Ref. 10.

2.2.4. Finite Euclidean and Finite Projective Geometries. The existence and construction of short designs ($b < 10^5$) is an active area of research in combinatorics. The handbook edited by Colbourn and Dinitz [12] is an excellent reference. The Abel and Greg Table 2.3 in Ref. 12 (pp. 41–42) summarizes the known results in existence of short designs. However, very often the construction of these design is somewhat heuristic or works only for a given block size. In many cases such constructions give a very small set of design with parameters of practical interests. An important subclass of BIBDs are so-called infinite families (Ref. 12, p. 67). The examples of these BIBDs include projective geometries, affine geometries, unitals, Denniston designs and some geometric equivalents of 2-designs (see Refs. 2 and 12, VI.7.12). The known infinite families of BIBD are listed in Table 1 [12,13]. Since q is a power of a prime, they can be referred as to *finite Euclidean* and *finite projective geometries*.

As we explained above, resolvable BIBDs are those BIBDs that possess parallel classes of blocks. If the blocks are viewed as lines, the analogy of BIBD and finite geometry becomes apparent. It is important to notice that not all BIBDs can be derived from finite geometries, but this discussion is beyond the scope of the discussion here. The most interesting projective and affine geometries are those constructed using Gallois fields [GF(q)]. In a m-dimensional projective geometry PG(m, q) a point $\boldsymbol{a}$ is specified by a vector $a = (a_j)_{0 \leq j \leq m}$, where $a_j \in$ GF(q). The vectors $a = (a_j)_{0 \leq j \leq m}$, and $\lambda a = (\lambda a_j)_{0 \leq j \leq m}$, [$\lambda \in$ GF(q), $\lambda \neq 0$] are considered to be representatives of the same point. There are $q^{(m+1)} - 1$ nonzero tuples, and λ can take $q - 1$ nonzero values, so that there are $(q - 1)$ tuples representing the same point. Therefore, the total number of points is $(q^{m+1} - 1)/(q - 1)$. The line through two distinct points $a = (a_j)_{0 \leq j \leq m}$ and $b = (b_j)_{0 \leq j \leq m}$ is incident with the points from the set $\{\mu a + vb\}$, where μ and v are not both zero. There are $q^2 - 1$ choices for μ and v, and each point appears $q - 1$ times in line $\{\mu a + vb\}$, so that the number of points on a line is $(q^2 - 1)/(q - 1) = q + 1$. For example, consider the nonzero elements of GF(2^2) = $\{0, 1, \omega, \omega^2\}$ that represent the points of PG(2,4). The triples $a = (1, 0, 0), \omega a = (\omega, 0, 0)$, and $\omega^2 a = (\omega^2, 0, 0)$, as we ruled, all represent the same point. The line incident with a and $b = (0, 1, 0)$ is incident with all of the following distinct points: a, $b, a + b = \{1, 1, 0\}, a + \omega b = \{1, \omega, 0\}, a + \omega^2 b = (1, \omega^2, 0)$. In the expression $\{\mu a + vb\}$, there are $4^2 - 1 = 15$ combinations of μ and v that are not both zero, but each point has $4 - 1 = 3$ representations, resulting in $\frac{15}{3}$ points on each line.

A *hyperplane* is a subspace of dimension $m - 1$ in PG(m, q); that is, it consists of the points satisfying a homogenous linear equation $\sum_{0 \leq j \leq m} \lambda_j \cdot a_j = 0, \lambda_j \in$ GF(q). A

Table 1. Known Infinite Families of 2-($v, k, 1$) Designs

k	v	Parameter	Name
q	q^n	$n \geq 2$, -power of a prime	Affine geometries
$q + 1$	$(q^n - 1)/(q - 1)$	$n \geq 2$, -power of a prime	Projective geometries
$q + 1$	$q^3 + 1$	q-power of a prime	Unitals
2^m	$2^m(2^s + 1) - 2^s$	$2 \leq m < s$	Denniston designs

projective plane of order q is a hyperplane of dimension $m = 2$ in PG(m, q). It is not difficult to see that the projective plane of order q is a BIBD$[(q^3 - 1)/(q - 1), q + 1, 1]$. The Euclidean (or affine) geometry EG(q, m) is obtained by deleting the points of a one hyperplane in PG(m, q). For example, if we delete a hyperplane $\lambda_0 a_0 = 0$, that is, the hyperplane with $a_0 = 0$, then the remaining q^m points can be labeled by the m-tuples $a = (a_j)_{1 \le j \le m}$. Euclidean or affine geometry EG(q, m) is a BIBD$(q^2, q, 1)$ [37]. For more details, see Kou et al. [25].

2.2.5. Lattice Construction of 2-(v, k,1) Designs. In this section we address the problem of construction of BIBDs of large block sizes. As shown, the Buratti-type CDFs and the projective geometry approach offer a quite limited set of parameters and therefore a small class of codes. In this section we give a novel construction of 2-$(v, k,1)$ designs with arbitrary block size. The designs are lines connecting points of a rectangular integer lattice. The idea is to trade a code rate and number of blocks for the simplicity of construction and flexibility of choosing design parameters. The construction is based on integer lattices as explained below.

Consider a rectangular integer lattice $L = \{(x, y): 0 \le x \le k - 1, 0 \le y \le m - 1\}$, where m is a prime. Let $l: L \to V$ be an one-to-one mapping of the lattice L to the point set V. An example of such mapping is a simple linear mapping $l(x, y) = m \cdot x + y + 1$. The numbers $l(x, y)$ are referred to as *lattice point labels*. For example, Fig. 3 depicts the rectangular integer lattice with $m = 7$ and $k = 5$.

A *line with slope* s, $0 \le s \le m - 1$, *starting at* the point (x, a), contains the points $\{(x, a + sx \bmod m): 0 \le x \le k - 1\}$, $0 \le a \le m - 1$. For each slope, there are m classes of parallel lines corresponding to different values. In our example, the lines of slope 1 are the points $\{1, 9, 17, 25, 33\}$, $\{2, 10, 18, 26, 34\}$, $\{3, 11, 19, 27, 35\}$, and so on. We assume that the lattice labels are periodic in vertical (y) dimension. The slopes $2, 3, \ldots, m$ can be defined analogously.

A set $\boldsymbol{B}$ of all k-element sets of V obtained by taking labels of points along the lines with different slopes s, $0 \le s \le m - 1$ is a BIBD. Since m is a prime, for each lattice point (x, y) there is exactly one line with slope s that go through (x, y). For each pair of lattice points, there is exactly one line that passes through both points. Therefore, the set $\boldsymbol{B}$ of lines is a 2-design. The block size is k, number of blocks is $b = m^2$ and each point in the design occurs in exactly m blocks. We can also show [56] that the $(m, k = 3)$ lattice BIBD is Pasch-free. Consider a periodically extended lattice. The proof is based on the observation that it is not possible to draw the quadrilateral (no sides with infinite slope are allowed) in which each point occurs twice. Figure 4 shows one such quadrilateral. Without loss of generality, we can assume that the ting point of two lines is (0,0). The slopes of four lines in Fig. 4 are $s, p, p + a/2$, and $s - a/2$. The points (0,0), (0,a), (2,2s), and $(2, a + 2p)$ are all different, and each occupies two lines. As long as the remaining four points are concerned, they will be on two lines in one of these three cases: (1) $s = p + a/2$ and $s + a/2 = a + p$; (2) $s = s + a/2$ and $p + a/2 = p + a$; and (3) $s = p + a$ and $p + a/2 = s + a/2$ (all operations are modulo m). Case 1 implies $s - p = a/2$, which means that points (2,2s) and $(2, a + 2p)$ are identical, which is a contradiction. If both equalities in cases 2 and 3 were satisfied, then a would have to be 0, which would mean that two leftmost points are identical, again a contradiction.

By generalizing this result to $k > 3$, we can conjecture that the (m, k) lattice BIBDs contain no generalized Pasch configurations. The lattice construction can be extended to nonprime vertical dimension m, but the slopes s and m must be coprime.

Figure 5 shows the growth of the required code length with a lower bound on a minimum distance as a parameter.

3. APPLICATIONS OF LDPC CODES TO PERPENDICULAR RECORDING SYSTEMS

In this section we consider the performance of LDPC codes based on random and deterministic constructions in perpendicular recording systems. First we give a brief description of the perpendicular recording channel model.

3.1. Perpendicular Recording System

The write head, the magnetic medium, and the read head constitute the basic parts of a magnetic recording system. The binary data are written onto the magnetic medium by applying a positive or negative current to the inductive write head, creating a magnetic field that causes the magnetic particles on the media to align themselves in either of two directions. During playback, the alignment of the particles produces a magnetic field rising that produces a voltage in the read head when it passes over the media. This process can be approximated in the following simplified manner.

If the sequence of symbols $a_k \in C \subseteq \{\pm 1\}$ is written on the medium, then the corresponding write current can be expressed as

$$i(t) = \sum_k (a_k - a_{k-1}) u(t - KT_c)$$

where $u(t)$ is a unit pulse of duration T_c seconds. Assuming the read-back process is linear, the induced read voltage, $V(t)$, can be approximated as

$$V(t) = \sum_k a_k g(t - kT_c)$$

where $g(t)$ is the read-back voltage corresponding to an isolated positive going transition of the write current (transition response). For perpendicular recording systems under consideration $g(t)$ is modeled as

$$g(t) = \frac{2}{\sqrt{\pi}} \int_0^{St} e^{-x^2}\, dx = \operatorname{erf}(St)$$

where $S = 2\sqrt{1n2/D}$ and D is the normalized density of the recording system. There are various ways one can define D. In this work we define D as $D = T_{50}/T_c$, where T_{50} represents the width of impulse response at a half of its peak value.

In Figs. 6 and 7, the transition and dibit response $[g(t + T_c/2) - g(t - T_c/2)]$ of a perpendicular recording system are presented for various normalized densities.

In our system, the received noisy read-back signal is filtered by a lowpass filter, sampled at intervals of T_c seconds, and equalized to a partial response (PR) target. Therefore, the signal at the input to the detector at the kth time instant can be expressed as

$$z_k = \sum_j a_j f_{k-j} + w_k$$

where w_k is the colored noise sequence at the output of the equalizer and $\{f_n\}$ are the coefficients of the target channel response. In this work we investigated PR targets of the form $(1 + D)^n$ with special emphasis on $n = 2$, named PR2 case. The input signal-to-noise-ratio (SNR) is defined as $\mathrm{SNR} = 10 \times \log_{10}(V_p^2/\sigma^2)$, where V_p is the peak amplitude of the isolated transition response which is assumed to be unity.

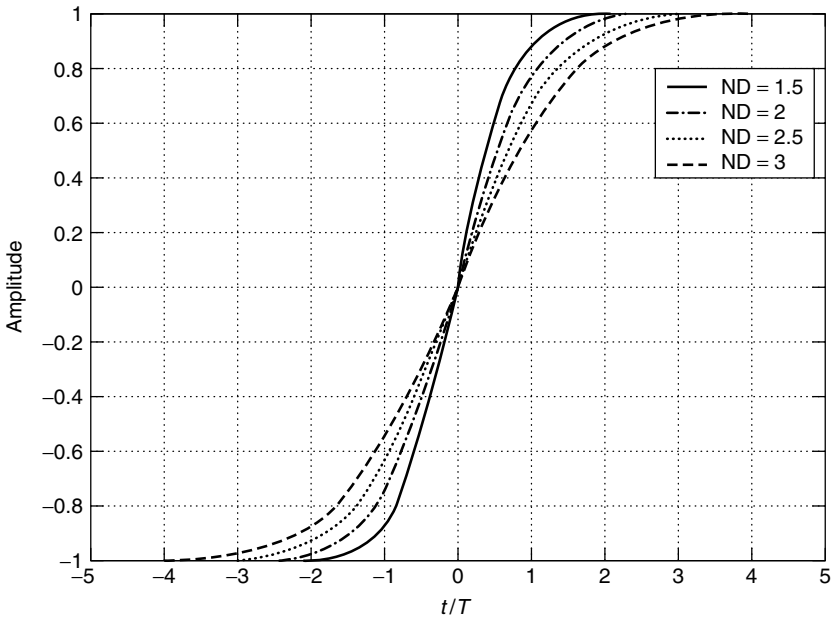

Figure 6. Transition response of a perpendicular recording channel.

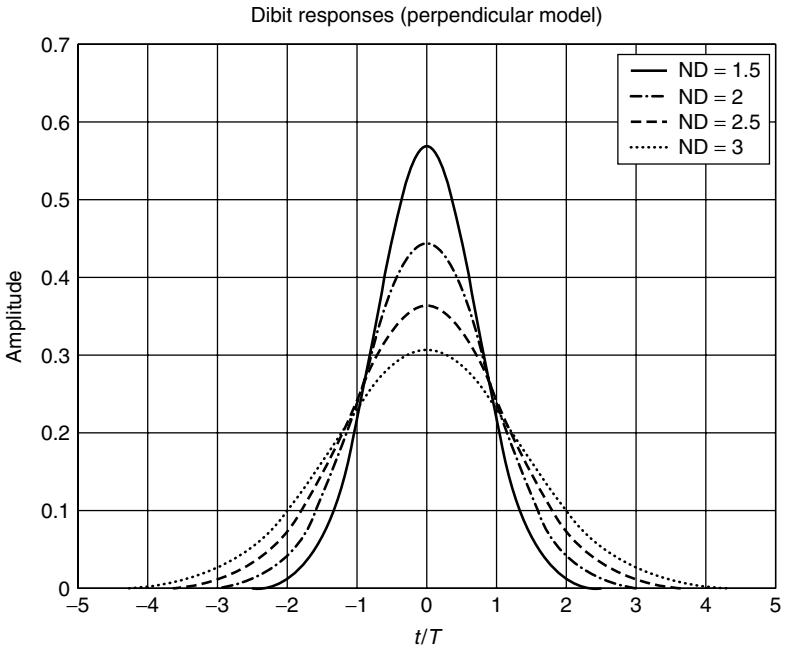

Figure 7. Dibit response of a perpendicular recording channel.

3.2. Simulation Results

We consider an iterative decoding scheme in which the BCJR algorithm [1] is used on the channel trellis, and the message-passing algorithm (MPA) is used for the decoding LDPC codes. The decoding is established by iterating between channel decoder and the outer LDPC decoder. LDPC decoder performs four inner iterations prior to supplying channel decoder with extrinsic information [17].

Throughout our simulations the normalized density for the uncoded system was 2.0 and the coded system channel density was obtained by adjusting with rate, namely, channel density $= D/R$, where R is the rate of the code.

In Fig. 8 we compare the performance of randomly constructed LDPC codes for different column weights, J, and rates. Random LDPC with $J = 3$ outperforms the other two and does not show any error flooring effect.

In Fig. 9 we compare Kirkman codes $(J = 3, v = 121, n = 2420)$ and $(J = 3, v = 163, n = 4401)$ and the random constructions with $J = 3$ and comparable block lengths and rates. It is clear that the LDPC codes based on Kirkman constructions show an earlier error floor than do their random counterparts. However, the lower error floor and less than 0.5 dB superior performance of random LDPC codes over Kirkman types come at a much larger implementation complexity penalty.

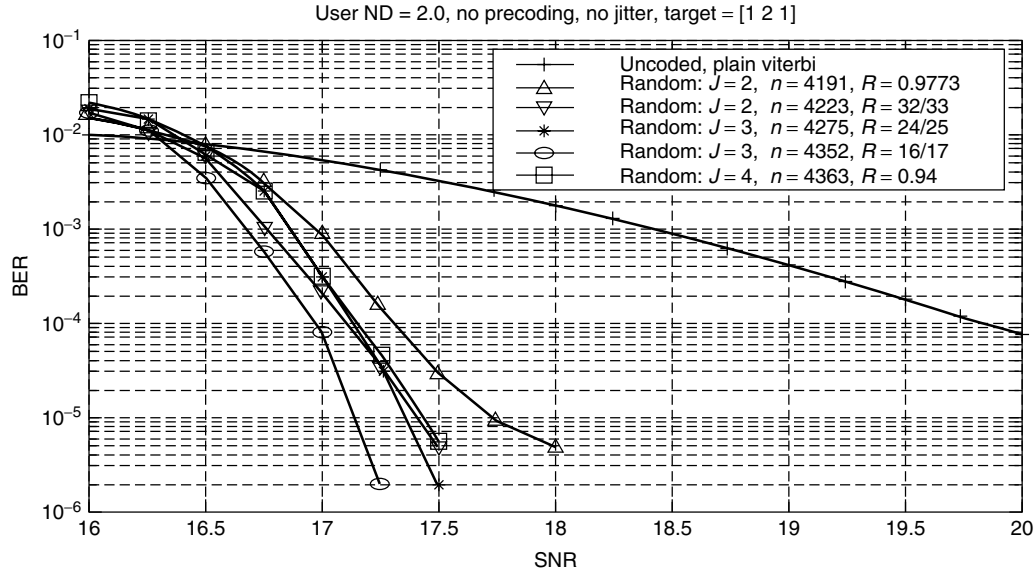

Figure 8. Random LDPC codes with different weights.

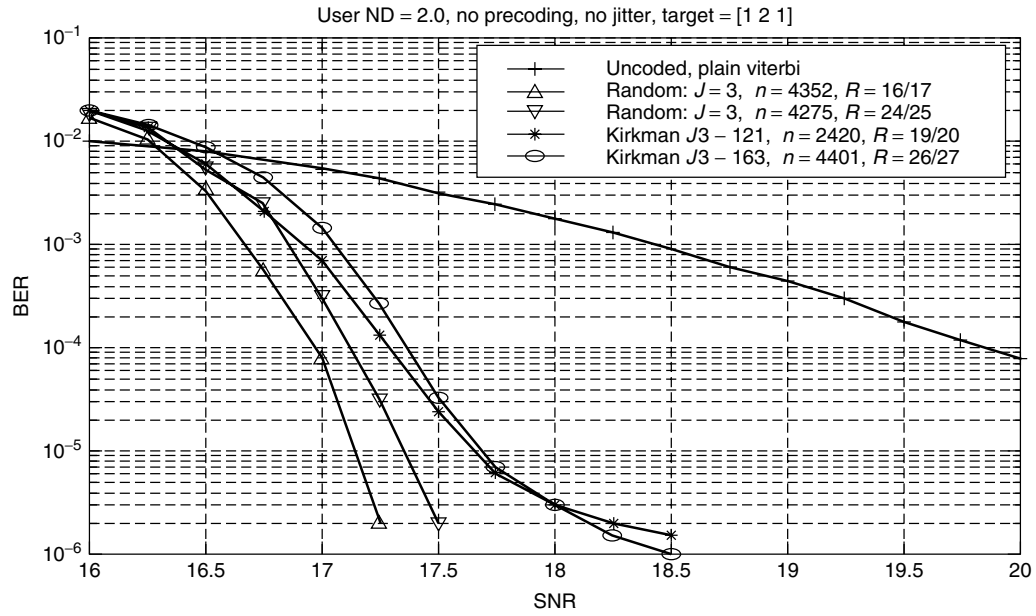

Figure 9. Random versus Kirkman LDPC codes.

Figure 10 makes a similar comparison between random LDPC codes of weights 3 and 4, and lattice designs with weights 4 and 5. As in Kirkman constructions, lattice designs have a higher error floor than do their random counterparts.

4. CONCLUSION

In this work we have presented various designs for LDPC code constructions. We have shown that LDPC codes based on BIBD designs can achieve very high rates and simple implementation compared to their random counterparts. We have analyzed the performance of these codes for a perpendicular recording channel. We have shown the tradeoff between BER performance, error floor, and complexity via extensive simulations.

BIOGRAPHIES

Erozan M. Kurtas received his B.S. degree in electrical and electronics engineering in 1991 from Bilkent University, Ankara, Turkey, and an M.S. and Ph.D. degree in

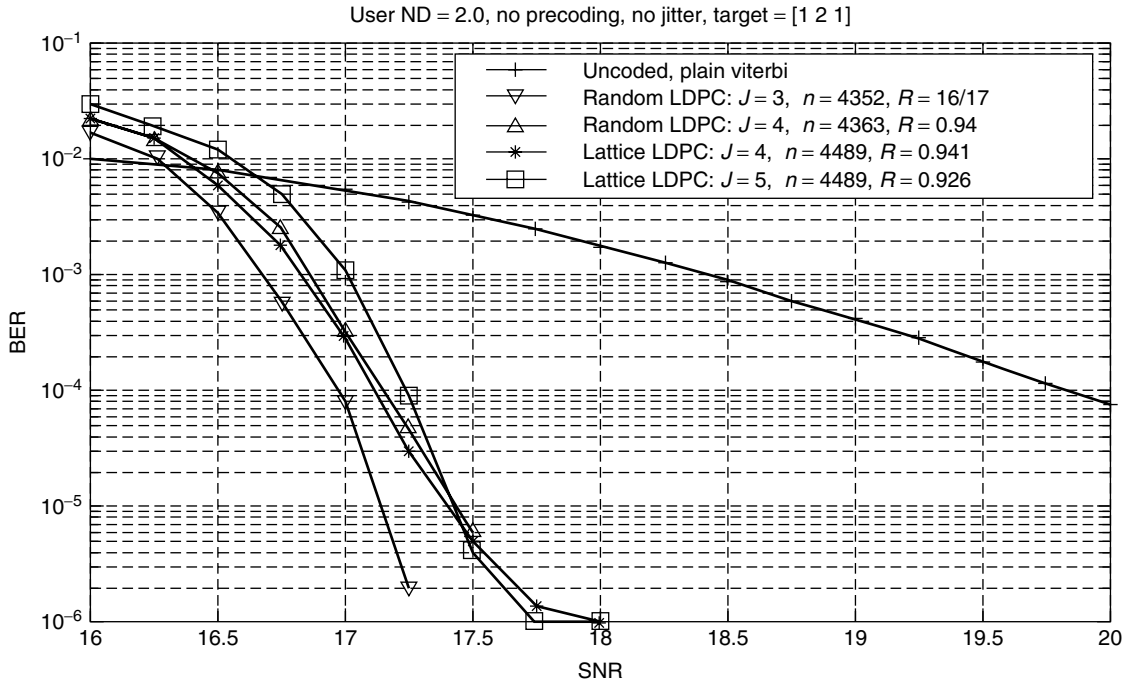

Figure 10. Random versus lattice LDPC codes.

electrical and computer engineering from the Northeastern University, Boston, Massachusetts, in 1994 and 1997, respectively. He joined Quantum Corporation (now Maxtor) in 1996 as a senior design engineer and worked on coding and signal processing for read-channel architectures employed in data storage devices. Since 1999, he has been with Seagate Technology where he is the director of channels research working on future data coding and recovery systems for storage applications. Dr. Kurtas has over 50 papers in various journals and conference proceedings in the general field of digital communications technology. His research interests span information theory, coding, detection and estimation, synchronization, and signal processing techniques. Dr. Kurtas is the recipient of the 2001 Seagate Technology Outstanding Technical Contribution and Achievement Award. Dr. Kurtas has five pending patent applications.

Alexander V. Kuznetsov received his Diploma with excellence in radio engineering and a Ph.D. degree in information theory from the Moscow Institute of Physics and Technology, Moscow, Russia, and the degree of doctor of engineering sciences from the Institute for Information Transmission Problems IPPI, Russian Academy of Sciences, in 1970, 1973, and 1988, respectively. In 1973, he joined the Russian Academy of Sciences as a scientific fellow, where for 25 years he worked on coding theory and its applications to data transmission and storage. On leave from IPPI, he held different research positions at the Royal Institute of Technology and Lund University in Sweden, Concordia University in Canada, Eindhoven Technical University in the Netherlands, Rand African University in RSA, Osaka University and Nara Advanced Institute of Sciences and Technology in Japan, Institute of Experimental Mathematics of Essen University in Germany, CRL of Hitachi, Ltd., in Tokyo, Japan. In 1998–1999, he was a member of technical staff of the Data Storage Institute (DSI) in Singapore, and worked on coding and signal processing for hard disk drives. Currently, he is a research staff member of the Seagate Technology in Pittsburgh, Philadelphia.

Dr. Vasic received his B.S., M.S., and Ph.D., all in electrical engineering from University of Nis, Serbia. From 1996 to 1997 he worked as a visiting scientist at the Rochester Institute of Technology, and Kodak Research, Rochester, New York, where he was involved in research in optical storage channels. From 1998 to 2000 he was with Lucent Technologies, Bell Laboratories. He was involved in research in read channel architectures and iterative decoding and low-density parity check codes. He was involved in development of codes and detectors for five generations of Lucent (now Agere) read channel chips. Presently, Dr. Vasic is a faculty member of the University of Arizona, Electrical and Computer Engineering Department. Dr. Vasic is an author of a more than fifteen journal articles, more than fifty conference papers, and one book chapter "Read channels for magnetic recording," in *CRC Handbook of Computer Engineering*. He is a member of the editorial board of the *IEEE Transactions on Magnetics*. He will serve as a technical program chair for IEEE Communication Theory Workshop in 2003, and as a coorganizer of the Center for Discrete Mathematics and Theoretical Computer Science Workshop on Optical/Magnetic Recording and Optical Transmission in 2003. His research interests include: coding theory, information theory, communication theory, digital communications, and recording.

1. INTRODUCTION

Providing quality of service (QoS) has been an important issue in Internet engineering, as multimedia/real-time applications requiring certain levels of QoS such as delay/jitter bounds, certain amount of bandwidth and/or loss rates are being developed. The current Internet provides only *best-effort* service, which does not provide any QoS. The Internet Engineering Task Force (IETF) has proposed several service architectures to satisfy different QoS requirements to different applications.

The Differentiated Services (Diffserv) architecture has been proposed by IETF to provide service differentiation according to customers' service profile called service-level agreement (SLA) in a scalable manner [1–4]. To provide service differentiation to different customers (or flows), the network needs to identify the flows, maintain the requested service profile and conform the incoming traffic based on the SLAs.

A simple Diffserv domain is illustrated in Fig. 1. In a Diffserv network, most of the work for service differentiation is performed at the edge of the network while minimizing the amount of work inside the network core, in order to provide a scalable solution. The routers at the edge of the network, called boundary routers or edge routers, may monitor, shape, classify, and mark *differentiated services code point* (DSCP) value assigned to specific packet treatment to packets of flows (individual or aggregated) according to the subscribed service. The routers in the network core forward packets differently to provide the subscribed service. The core routers need to provide only several forwarding schemes, called *per-hop behaviors* (PHBs) to provide service differentiation. It is expected that with appropriate network engineering, *per-domain behaviors* (PDBs), and end-to-end services can be constructed based on simple PHBs.

1.1. Differentiated Services Architecture

In the Diffserv network, we can classify routers into two types, *edge or boundary* routers and *core* routers according to their location. A boundary router may act both as an *ingress router* and as an *egress router* depending on the direction of the traffic. Traffic enters a Diffserv network at an ingress router and exits at an egress router. Each type of router performs different functions to realize service differentiation. In this section, we describe each of these routers with its functions and describe how service differentiation is provided.

1.1.1. Boundary Router. A basic function of ingress routers is to mark DSCPs to packets based on SLAs so that

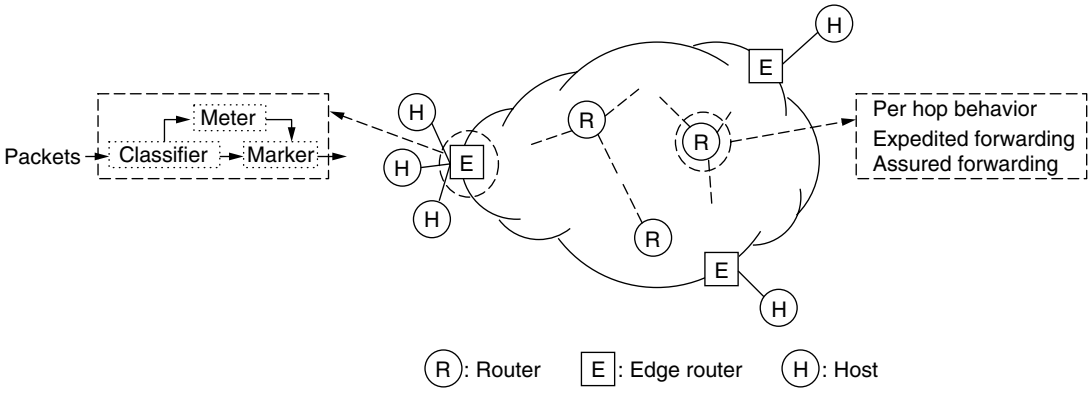

Figure 1. A Diffserv domain.

core routers can distinguish the packets and forward them differently. When a packet arrives at an ingress router, the router first identifies the flow to which the packet belongs and monitors the flow to conform to its contract. If it conforms to its contract, the packet is marked by the DSCP of the contracted service. Otherwise, the packet may be delayed, discarded, or unmarked to make injected traffic conform to its contract.

An egress router may monitor traffic forwarded to other domains and perform shaping or conditioning to follow a traffic conditioning agreement (TCA) with the other domains.

1.1.2. Core Router. In the Diffserv model, functions of core routers are minimized to achieve scalability. A core router provides requested PHB specified in the DS field of the arriving packets. Currently, *expedited forwarding* (EF) [3] and *assured forwarding* (AF) [4] PHBs have been standardized by IETF.

To provide end-to-end QoS, we may consider flows that transit over multiple network domains. While a hop-by-hop forwarding treatment in a Diffserv domain is defined by a PHB, Per-domain behavior (PDB) is used to define edge-to-edge behavior over a Diffserv domain [5]. A PDB defines metrics that will be observed by a set of packets with a particular DSCP while crossing a Diffserv domain. The set of packets subscribing to a particular PDB is classified and monitored at an ingress router. Conformant packets are marked with a DSCP for the PHB associated with the PDB. While crossing the Diffserv domain, core routers treat the packets based only on the DSCP. An egress router may measure and condition the set of packets belonging to a PDB to ensure that exiting packets follow the PDB.

1.1.3. Assured Forwarding PHB. Assured forwarding (AF) PHB has been proposed in [4,6]. In the AFPHB, the edge devices of the network monitor and mark incoming packets of either individual or aggregated flows. A packet of a flow is marked IN (in profile) if the temporal sending rate at the arrival time of the packet is within the contract profile of the flow. Otherwise, the packet is marked OUT (out of profile). Packets of a flow can be hence marked both IN and OUT. The temporal sending rate of a flow is measured using *time sliding window* (TSM) or a *token bucket* controller. IN packets are given preferential treatment at the time of congestion; thus, OUT packets are dropped first at the time of congestion.

Assured forwarding can be realized by employing RIO (RED with IN/OUT) drop policy [6] in the core routers. RIO drop policy is illustrated in Fig. 2. Each router maintains a virtual queue for IN packets and a physical queue for both IN and OUT packets. When the network is congested and the queue length exceeds minTh_OUT, the routers begin dropping OUT packets first. If the congestion persists even after dropping all incoming OUT packets and the queue length exceeds minTh_IN, IN packets are discarded. With this dropping policy, the RIO network gives preference to IN packets and provides different levels of service to users per their service contracts. Different marking policies [7–9] and correspondingly appropriate droppers have been proposed to improve the flexibility in providing service differentiation.

1.1.4. Expedited Forwarding PHB. Expedited forwarding (EF) PHB was proposed [3] as a premium service for the Diffserv network. The EFPHB can be used to guarantee low loss rate, low latency, low jitter, and assured

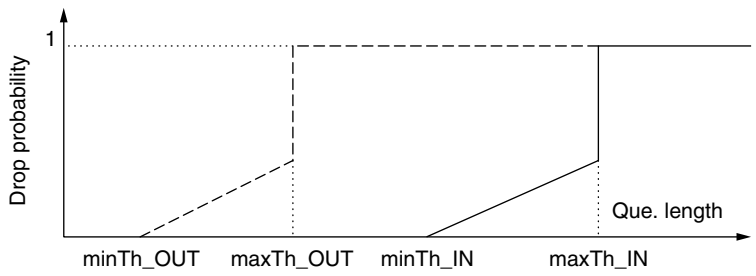

Figure 2. RED IN/OUT (RIO) drop policy.

throughput like a "virtual leased line." According to Jacobson et al. [3], the departure rate of the EF traffic measured over any time interval equal to or longer than a packet time should equal or exceed a configurable rate independent of the intensity of any other traffic.

However, there is evidence [10] that the original EFPHB configuration in Ref. 3 is too strict and hard to implement in practice. In a network where there are many connections frequently established, closed, merged and split, it is hard to maintain each node's arrival rate to be less than its departure rate at timescales required by the EFPHB. Alternatively, it has been proposed [10–12] that the EFPHB should be redefined as "a forwarding treatment for a particular Diffserv aggregate where the node offers to the aggregate a packet scale rate guarantee R with latency E, where R is a configurable rate and E is a tolerance that depends on the particular node characteristics." In a network providing packet scale rate guarantees, any EF packet arriving at a node at time t will leave the node no later than at time $t + Q/R + E$, where Q is the total backlogged EF traffic at time t. Here note that Q is zero in the original EF configuration since the arrival rate is less than the departure rate at any node at any given time.

Several types of queue scheduling schemes (e.g., a priority queue, a single queue with a weighted round-robin scheduler, and class-based queue [13]) may be used to implement the EFPHB.

It is important to understand the QoS delivered to individual applications by the extra support and functionality provided by a Diffserv network. In the next two sections, we present throughput analysis of AFPHB and delay analysis of EFPHBs.

2. TCP PERFORMANCE WITH AFPHB

Popular transport protocol TCP reacts to a packet loss by halving the congestion window and increases the window additively when packets are delivered successfully [14]. This AIMD congestion control policy makes the throughout of a TCP flow highly dependent on the dropping policy of the network. With AFPHB, service differentiation is realized by providing different drop precedences, and thus, TCP throughput with AFPHB is an interesting issue.

In Fig. 3, we present a simulation result using ns-2 [15] to show realized TCP throughput in a simple network with AFPHB. In this simulation, there are five TCP flows sharing one 4-Mbps bottleneck link. Each flow contracts bandwidth $\{0, 0.1, 0.5, 1, 2\}$ Mbps with network provider. From the figure, it is shown that flows with higher contract rates get higher throughput than flows with lower contract rates. However, it is also shown that the flows with 2 Mbps contract rate do not reach 2 Mbps while flows with 0- and 0.1-Mbps contract rates exceed their contract rates.

Similar results have been reported in the literature [9,16,17], and it has been also shown that it is difficult to guarantee absolute bandwidth with a simple marking and dropping scheme [18]. There is a clear need to understand the performance of a TCP flow with the AFPHB.

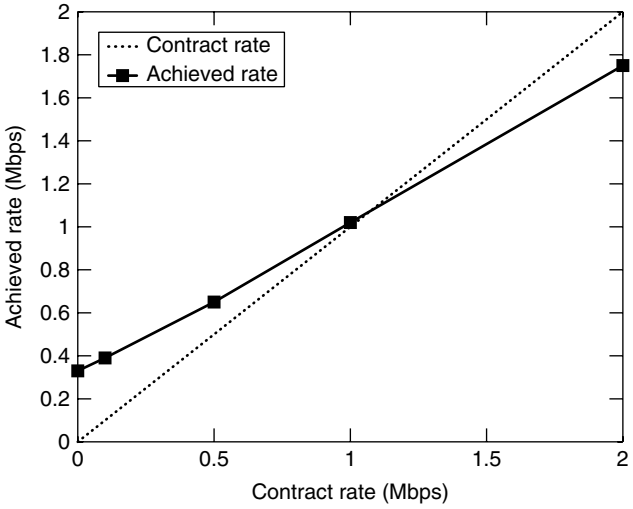

Figure 3. Realized TCP throughput with AFPHB.

In a steady state, a flow can experience different levels of congestion on the basis of its contract rate and the network dynamics. A flow that experiences no IN packet drops is said to observe an undersubscribed path. A flow that does not transmit any OUT packets either because every OUT packet is dropped or because the sending rate is less than the contract profile is said to observe an oversubscribed path. In a reasonably configured network, however, IN packets are expected to be protected, and only OUT packets may be discarded. In this section, we focus on the model for undersubscribed path.[1]

The steady-state TCP throughput, B is given by [19]

$$B = \begin{cases} \dfrac{3k}{4\mathrm{RTT}}\left(\sqrt{\dfrac{2}{p_{\mathrm{out}}}} + R\right) & \text{if } R \geq \dfrac{W}{2} \\ \dfrac{k}{2\mathrm{RTT}}\left(\sqrt{R^2 + \dfrac{6}{p_{\mathrm{out}}}} + R\right) & \text{otherwise} \end{cases} \tag{1}$$

where k is the packet size, p_{out} is the drop rate of OUT packets R is the reservation window defined as (contract rate/packet size $\times$ RTT), and W is the maximum congestion window size in steady state. From Eq. (1), B is proportional to the contract rate and inversely proportional to drop rate.

To illustrate the model described above, we present Fig. 4, where results from the model are compared with simulations. In the simulation, there are 50 TCP flows sharing a 30-Mbps link. Contract rate of each flow is randomly selected from 0 to 1 Mbps. In the figure, squares indicate simulation results, and stars indicate estimated throughput from the model. It is observed that the model can estimate TCP throughput accurately.

To discuss the interaction between contract rate and realized throughput more in depth, we define the

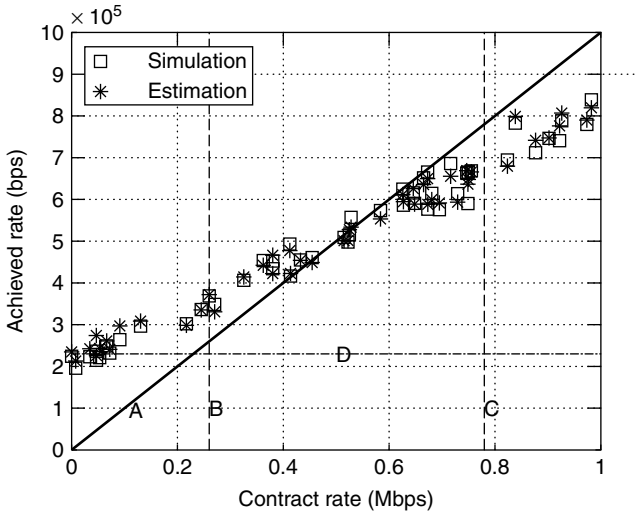
[1] To develop a model for a general situation where both IN and OUT packets are dropped, a model for an oversubscribed path is also required. For the general model, please refer to Ref. 19.

excess bandwidth B_e as the difference between realized throughput and its contract rate. It is given by

$$B_e = \begin{cases} \dfrac{k}{4\text{RTT}}\left(3\sqrt{\dfrac{2}{p_{\text{out}}}} - R\right) & \text{if } R \geq \dfrac{W}{2} \\ \dfrac{k}{2\text{RTT}}\left(\sqrt{R^2 + \dfrac{6}{p_{\text{out}}}} - R\right) & \text{otherwise} \end{cases} \tag{2}$$

If B_e of a flow is positive, this means that the flow obtains more than its contract rate. Otherwise, it does not reach its contract rate. From (2) and Fig. 4, we can observe that

- When a flow reserves relatively higher bandwidth ($R \geq \sqrt{2/p_{\text{out}}}$), B_e is decreased as the reservation rate is increased. Moreover, if R is greater than $3\sqrt{2/p_{\text{out}}}$ (see line C in Fig. 4), the flow cannot reach its reservation rate.
- When a flow reserves relatively lower bandwidth ($R < \sqrt{2/p_{\text{out}}}$; see line B in Fig. 4), it always realizes at least its reservation rate. As it reserves less bandwidth, it obtains more excess bandwidth. TCP's multiplicative decrease of sending rate after observing a packet drop results in a higher loss of bandwidth for flows with higher reservations. This explains the observed behavior.
- Equation (2) also shows that as the probability of OUT packet drop decreases, the flows with smaller reservation benefit more than do the flows with larger reservations. This points to the difficulty in providing service differentiation between flows of different reservations when there is plenty of excess bandwidth in the network.
- The realized bandwidth is observed to be inversely related to the RTT of the flow.
- For best-effort flows, $R = 0$. Hence, $B_e (= k\sqrt{6/p_{\text{out}}}/2\text{RTT}$; see line D in Fig. 4) gives the bandwidth likely to be realized by flows with no reservation.
- Comparing the above mentioned best-effort bandwidth when $R \geq \sqrt{2/p_{\text{out}}}$, we realize that the reservation rates larger than 3.5 times the best-effort bandwidth cannot be met.
- Equation (2) clearly shows that excess bandwidth cannot be equally shared by flows with different reservations without any enhancements to basic RIO scheme or to TCP's congestion avoidance mechanism.



- A: B = Contract rate
- B: $R = \sqrt{\dfrac{2}{p_{\text{out}}}}$
- C: $R = 3\sqrt{\dfrac{2}{p_{\text{out}}}}$
- D: $B = \dfrac{k}{2\text{RTT}}\sqrt{\dfrac{6}{p_{\text{out}}}}$

Figure 4. Observations from the model.

When several TCP flows are aggregated, the impact of an individual TCP sawtooth behavior is reduced, and the aggregated sending rate is stabilized. If the marker neither maintains per-flow state nor employs other specific methods for distinguishing individual flows, an arriving packet is marked IN with the probability, $p_m (= \textit{contract\_rate}/\textit{aggregated\_sending\_rate})$. In the steady state, p_m is approximately equal for all the individual flows. A flow sending more packets then gets more IN packets, and consequently, the contract rates consumed by individual flows is roughly proportional to their sending rates. We call this marking behavior *proportional marking*.

With the assumptions that all packets of aggregated flows are of the same size, k, a receiver does not employ delayed ACK, and the network is not oversubscribed, the throughput of the ith flow and the aggregated throughput B_A of n flows are given in [19] by

$$B_i = \frac{m_i}{\sum_{j=1}^{n} m_j} \cdot \frac{3r_A}{4} + \frac{3k}{4} m_i \tag{3}$$

$$B_A = \sum_{i=1}^{n} B_i = \frac{3k}{4} \sum_{i=1}^{n} m_i \tag{4}$$

where r_A is the contract rate for the aggregated flows, and m_i is $(1/\text{RTT}_i)\sqrt{(2/p_i)}$.

Equation (3) relates the realized throughput of an individual flow to the aggregated contract rate r_A and the network conditions (RTT_i and p_i) observed by various flows within the aggregation. From (4), B_e (the excess bandwidth) of aggregated flows is calculated as follows

$$B_e = \tfrac{3}{4} r_A + B_s - r_A = B_s - \tfrac{1}{4} r_A \tag{5}$$

where $B_s = \frac{3k}{4} \sum_{i=1}^{n} m_i$, and it is approximately the throughput which the aggregated flows can achieve with zero contract rate ($r_A = 0$). According to the analysis above, the following observations can be made:

- The total throughput realized by an aggregation is impacted by the contract rate. The larger the contract

rate, the smaller the excess bandwidth claimed by the aggregation.

- When the contract rate is larger than 4 times B_s, the realized throughput is smaller than the contract rate.
- The realized throughput of a flow is impacted by the other flows in the aggregation (as a result of the impact on p_m) when proportional marking is employed.
- The total realized throughput of an aggregation is impacted by the number of flows in the aggregation.

There are two possible approaches for enhancing better bandwidth differentiation with AFPHB. The first approach tries to enhance the dropping policy of the core routers [20] while the second approach tries to enhance the marking policies of the edge routers [7–9,21]. Below, we briefly outline one approach of enhancing the edge markers.

2.1. Adaptive Marking for Aggregated TCP Flows

The Diffserv architecture allows aggregated sources as well as individual sources [2]. When several individual sources are aggregated, output traffic of the aggregation is not like traffic of one big single source in the following respects: (1) each source within the aggregation responds to congestion individually, and (2) the aggregation has multiple destinations, and each source within the aggregation experiences different delays and congestion. Therefore, when we deal with aggregated sources in the Diffserv network, we need to consider not only the total throughput achieved by the aggregated sources but also the throughput achieved by individual flows.

Given individual target rates for each flow, how does one allocate a fixed aggregate contract rate among individual flows within the aggregation under dynamic network conditions? The most desirable situation is to guarantee individual target rates for all the flows. However, there exist situations in which some targets cannot be met: (1) when there is a severe congestion along the path and the current available bandwidth is less than the target and (2) when the contract rate is not enough to achieve the target. If we try to achieve the target by increasing the marking rate of an individual flow, the congestion along that flow's path may become more severe and result in wasting contracted resources of the aggregation. This is undesirable for both customers and service providers.

To solve this problem, an adaptive marking scheme has been proposed [21]. The proposed scheme achieves at least one of the following for all the flows in an aggregation:

1. Individual target rate when it is reachable.
2. Maximized throughput without IN packet loss when the current available bandwidth is less than the individual target rate.
3. Throughput achieved with a fair marking rate M/n, where M and n are the total marking rate and the number of flows within the aggregation, respectively.

These three goals correspond to (1) meeting individual flow's BW needs, (2) maximization of utility of the aggregated contract rate, and (3) fairness among the flows within the aggregation.

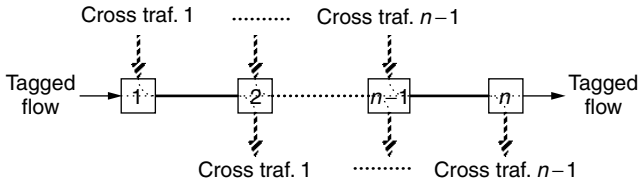


Figure 5. Multihop topology.

To observe how the marking rate is adjusted and an individual flow achieves its target rate, we conducted a set of simulations. We consider a multihop path as shown in Fig. 5. There are n routers, and cross traffic is injected to this network at the ith router and exits at the $(i+1)$th router.

In the simulation, we set the link capacity at 3 Mbps and use 10 TCP flows for cross traffic. The contract rate for each TCP flow is randomly selected from 0 to 1 Mbps, and the total contract of cross-traffic is 2.7 Mbps, so that the subscription level is 90%. The number of routers (n) is 5. For the tagged flow, we use a single TCP flow.

First, to observe path characteristics, we use a static contract rate for the tagged flow. We vary the contract rate from 0 to 0.8 Mbps. In Fig. 6, the solid line shows the achieved rate with static marking rate, and the dashed line indicates that the achieved rate is equal to 75% of the marking rate. The achieved rate increases as the marking rate increases up to 0.5 Mbps. However, the achieved rate does not increase beyond the 0.55-Mbps marking rate. In this example, the maximum achievable rate is about 0.42 Mbps.

Now the tagged flow is an individual flow within an aggregation with aggregated contract rate. The marker for the aggregation employs the adaptive marking. We vary the target rate for the tagged flow from 0.1 to 0.5 Mbps. Figure 6 shows the results. In each figure, dots indicate instantaneous marking and achieved rate, and a square shows the average. In this path, a flow gets 0.15 Mbps with zero contract rate. When the target rate is 0.1 Mbps (Fig. 6a), the marking rate stays around zero. When the target rate is achievable (<0.42 Mbps), the adaptive marking scheme finds the minimum marking rate to realize the target rate (Fig. 6a,b). In Fig. 6c, the marking rate stays below 0.55 Mbps to avoid wasting resources when the target is unachievable.

We present one other experiment to show the utility of the adaptive marker in reducing bandwidth differences due to RTTs as described by the model earlier. We use a topology in which 40 TCP flows are aggregated and compete in a 25-Mbps bottleneck link. The aggregated contract rate is 10 Mbps. The RTT (excluding queueing delay) of each flow is randomly selected from within 50–150 ms. Figure 7 shows the result. The adaptive marker effectively removes RTT bias of TCP flows and realizes QoS goals of individual flows within the aggregation.

The adaptive marker addresses the important problem of establishing a relationship between per-session

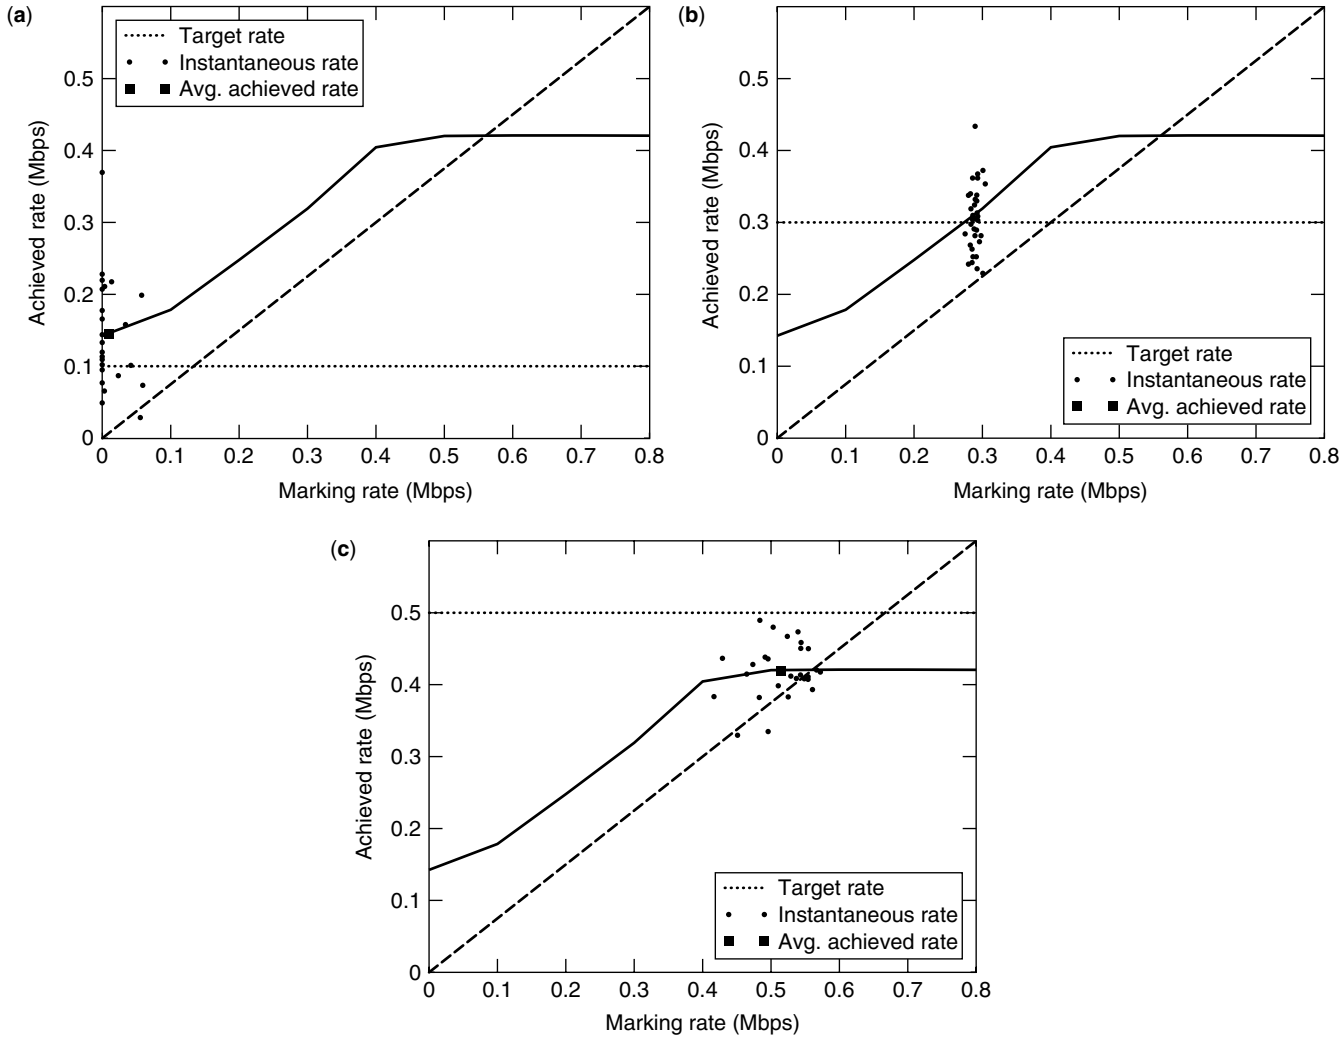

Figure 6. Achieved rates with the adaptive marking, with targets of (**a**) 0.1 Mbps, (**b**) 0.3 Mbps, and (**c**) 0.5 Mbps

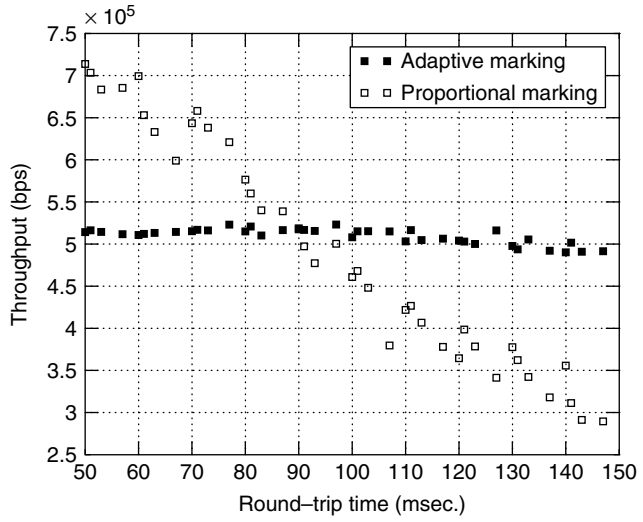

Figure 7. Throughput of flows with different round-trip times

behavior, aggregate packet marking, and packet differentiation within a differentiated services network. The adaptive marking algorithm is based on the TCP performance model within Diffserv networks. The adaptive marker enables reaching specific QoS goals of individual flows while efficiently managing the aggregate resources. Moreover, it shows that with appropriate edge devices, it is possible for applications to realize bandwidth guarantees utilizing the AFPHB.

3. DELAY ANALYSIS OF THE EFPHB

The EFPHB is proposed to provide low delay, jitter, and loss rate. Low loss rate is easily achievable with strict admission control and traffic conditioning. Regarding the EFPHB, providing low delay and jitter is an important issue and has been widely studied. In this section, we introduce studies on delay analysis of the EFPHB and present some experimental work for practical performance evaluation of the EFPHB.

3.1. Virtual Wire Service

Virtual wire (VW) service aims to provide a very low end-to-end delay jitter for flows subscribing to the EFPHB [22]. More precisely, as the term, *virtual wire* suggests, VW service is intended to "mimic, from the point of view of the originating and terminating nodes, the behavior of a hard-wired circuit of some fixed capacity [22]."

To provide VW service, the following two conditions are required: (1) each node in the domain must implement the EFPHB, and (2) conditioning the aggregate so that it's arrival rate at any node is always less than that node's departure rate. If the arrival rate is less than the virtual wire's configured rate, packets are delivered with almost no distortion in the interpacket timing. Otherwise, packets are unconditionally discarded not to disturb other traffic.

In [22], a *jitter window* is defined as the maximum time interval between two consecutive packets belonging to a flow so that the destination cannot detect delay jitter. Consider a constant-bit rate (CBR) flow with rate R. The packets of the flow arrive at an egress router through a link of bandwidth $B(= nR)$ and leave to their destination through a link of bandwidth R as shown in Fig. 8.

Let's consider two consecutive packets: P_0 and P_1. To transmit P_1 immediately after transmitting P_0 and to hide jitter, the last bit of P_1 should arrive at the node before T_1. T_1 is the time when the last bit of P_0 leaves the node and is calculated by

$$T_1 = T_0 + \frac{S}{R} \tag{6}$$

where S is the packet size. Then, the jitter window, Δ, is given by

$$\Delta = \frac{S}{R} - \frac{S}{B} = \frac{S}{R} \times \left(1 - \frac{1}{n}\right) \tag{7}$$

Generally, a packet experiences propagation, transmission, and queueing delay while traveling a network path. As long as the path is identical, propagation and transmission delay are the same. Therefore, as long as the sum of queueing delays that a packet observes in an EF domain is less than Δ, the destination does not observe jitter.

There are three possible sources of queueing delay of a VW packet: (1) non-EF packets ahead of the packet in a queue, (2) the previous VW packet of the same flow, and (3) VW packets of other flows. In a properly configured EF domain, the arrival rate of the EF traffic should be less than the departure rate at any node. Then, the queueing delay caused by the other EF traffic (cases 2 and 3) is zero.

In an EF domain, EF and non-EF packets are separately queued, and EF packets are serviced at a higher priority. Therefore, case 1 occurs only when an EF packet arrives at a node that is serving a non-EF packet. The worst-case delay occurs when the EF packet arrives immediately after the node begins to send a non-EF packet, and it is S/B, where S is the packet size. From (7), n should be at least 2 in order to satisfy the jitter window, and which means that the bandwidth assigned to EF traffic should be configured to be less than half of the link bandwidth.

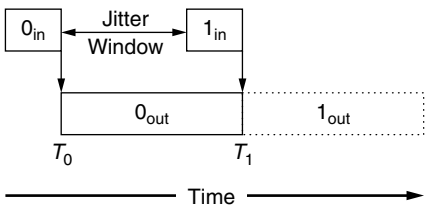

Figure 8. Jitter window.

3.2. Packet-Scale Rate Guarantee

Packet-scale rate guarantee service has been proposed to analyze and characterize the delay of the EFPHB more precisely [10–12]. A node is said to provide packet-scale rate guarantee R with latency E if, all $j \geq 0$, the jth departure time, $d(j)$, of the EF traffic is less than or equal to $F(j) + E$, where $F(j)$ is defined iteratively by

$$F(0) = 0, d(0) = 0 \tag{8a}$$

For all $j > 0$:

$$F(j) = \max[a(j), \min\{d(j-1), F(j-1)\}] + \frac{L(j)}{R} \tag{8b}$$

where $a(j)$ is the arrival time of the jth packet of length $L(j)$.

If a node provides packet-scale rate guarantee, it has been shown [10] that any EF packet arriving at a node at time t will leave that node no later than at time $t + Q/R + E$, where Q is the total backlogged EF traffic at time t. This property infers that a single-hop worst delay is bounded by $B/R + E_p$ when all input traffic is constrained by a leaky-bucket regulator with parameters (R, B), where R is the configured rate, and B is the bucket size. Note that E_p is the error term for processing individual EF packets.

If every node in a Diffserv domain regulates its EF input traffic with the maximum burst size B, then the worst case delay of each packet crossing h hops is just h times the single hop delay. However, the Diffserv architecture performs traffic conditioning only at the ingress and not in the interior. As a result, it is possible for bursty traffic larger than B to arrive at a node in the network even if the EF traffic has been regulated initially at the ingress. This problem may be solved by appropriately distributing traffic and limiting the number of hops traversed by each flow. Therefore, we need to consider topology constraints as well as ingress traffic conditioning when designing an EF service. Topology-independent utilization bounds have been obtained for providing bounded delay service that take network diameter into account [23].

3.3. QBone and Practical Performance Evaluation

QBone (Quality of Service Backbone) has been constructed by Internet2 QoS Working Group to provide an inter-domain testbed for Diffserv [24]. Currently, the EFPHB has been implemented, and the QBone Premium Service (QPS) [25] using the EFPHB is available.

To use the QPS, customers should provide their traffic information, {`source, dest, route, startTime, endTime, peakRate, MTU, jitter`}. This information

is required to configure EF nodes [3]. The parameter `route` specifies a DS-domain-to-DS-domain route. The parameters `startTime` and `endTime` denote the time duration of the traffic, `peakRate` is the peak rate of the traffic, `MTU` is the maximum transmission unit, and `jitter` is the worst-case jitter required. QPS traffic is regulated at an ingress node by a token bucket profiler with token rate of `peakRate` and bucket depth of `MTU`.

The QPS provides low loss rate, low queueing delay, and low jitter as long as the traffic arriving at the ingress node conforms to its token bucket profile. It is necessary to discard the nonconformant packets or to reshape them in order to achieve the desired QoS.

QBone enables us to evaluate and analyze the Diffserv performance more practically through large scale, interdomain experiments. An interesting experiment with video streaming applications has been conducted for observing end-to-end performance of the Diffserv network [26]. Here we present a summary of the experiment and results.

3.3.1. Video Streaming Applications in Diffserv Networks. With faster computer networks and improved compression schemes, video streaming applications are becoming popular. To improve quality of video playback on a given network, the applications deploy new technologies such as FEC (forward error correction) and layered coding to adjust to network dynamics. However, there is a limit to improving the quality without any QoS support from the network. To play back video clips seamlessly, a certain amount of bandwidth, bounded jitter, and low loss rate are required. Therefore, video streaming applications can be good target applications of a Diffserv network.

Experiments with video streaming applications in a Diffserv network with EFPHB have been performed [26]. A local network with several routers configured for EFPHB connected to the QBone network was used as a testbed. *Quality index* and frame loss rate were measured with various token rates and bucket sizes at ingress router policers. *Quality index* was measured by a variant of ITS (Institute of Telecommunication Sciences) video quality measurement (VQM) tool [27]. The VQM captures features of individual and sequence of frames from both the received and original streams, and measures the difference between them. The VQM was originally developed to measure quality of television and videoconferencing systems. The variant was modified from the VQM for measuring quality of video stream transmitted over IP networks.

From the experiments and measurements, interesting relationship between video quality and token bucket parameters of EF ingress policer have been observed: (1) the quality of video stream can be controlled by the ingress policer, (2) frame loss rate itself does not reflect the quality of the video stream, (3) the token rate should be configured to be larger than the video encoding rate for achieving acceptable quality, and (4) a small increase of bucket depth may result in substantial improvement of the video quality.

The first observation confirms that the Diffserv network can provide service differentiation to real-world applications.

4. NOVEL AND OTHER QoS

The Diffserv framework is still in development, and new services are constantly being proposed. In this section, we introduce some of the proposals receiving attention.

4.1. A Bulk Handling Per-Domain Behavior

Some applications need to transfer bulk data such as movie files or backup data over the network without any timing constraints. These transfers do not need any assurance as long as they are eventually completed. A bulk-handling (BH) per-domain behavior (PDB) has been proposed [28] for supporting such traffic. It is reasonable to exclude such traffic from best-effort traffic in order to prevent competition with other valuable traffic.

BHPDB traffic has the lowest priority in a Diffserv network. A BH packet is transferred only when there is no other packet. In the presence of other traffic, it may be discarded or delayed. To implement the BHPDB, only marking for PDB is enough. Policing or conditioning is not required since there is no configured rate, reserved resources or guarantees. BHPDB traffic is different from best-effort (BE) traffic in that there are at least some resources assigned to BE traffic.

4.2. An Assured Rate Per-Domain Behavior

An assured rate (AR) PDB has been proposed [29]. The ARPDB provides assured rate for one-to-one, one-to-few, or one-to-any traffic. Here *one-to-one traffic* means traffic entering a network at one ingress router and exiting at one egress router, and *one-to-few traffic* means traffic having more than one fixed egress routers. *One-to-any traffic* refers to traffic entering at one ingress router and exiting at multiple (any) egress routers. Assured rate can be implemented using the AFPHB.

The ARPDB is suitable for traffic requiring certain amount of bandwidth but no delay bounds. A possible example service with the ARPDB is VPN (virtual private network) services with one-to-few traffic. One-to-any service of the ARPDB can be used to deliver multicast traffic with a single source, but appropriate traffic measurement should be supported since packets in a multicast are duplicated in the interior of the network and the total amount of traffic at the egress routers may be larger than the amount of traffic at the ingress router. The ARPDB stipulates how packets should be marked and treated across all the routers within a Diffserv domain.

4.3. Relative Differentiated Services

Relative differentiated service has been proposed [30] to provide service differentiation without admission control. The fundamental idea of the relative differentiated services is based on the fact that absolute service guarantees are not achievable without admission control. In such cases, only relative service differentiation can be provided since network resources are limited.

A proportional delay differentiation model, which provides delays to each class on the basis of a proportionality constraint, has been proposed [30]. *Backlog-proportional rate* schedulers and *waiting-time priority* schedulers [31]

were proposed as candidate schedulers for such service. Both schedulers were shown to provide predictable and controllable delay differentiation independent of the variations of loads in each class. A proportional loss rate model has also been proposed and evaluated [32].

5. SUMMARY

We have presented the basic architecture of Diffserv networks and showed how service differentiation can be achieved in such networks. The AFPHB has been shown to enable us to realize service differentiation in TCP throughput with appropriate edge marking devices. The EFPHB has been proposed to provide low delay, jitter, and loss rate. While simple scheduling schemes such as priority queueing and class-based queueing are enough to implement the EFPHB in the network core, considerable work in traffic policing and shaping at the network edge is required. Initial experience on QBone points to the possibility that applications can realize the necessary QoS in Diffserv networks. Much research work is in progress in identifying and improving various aspects of a Diffserv network, particularly in traffic management, admission control and routing.

BIOGRAPHIES

A. L. Narasimha Reddy is currently an associate professor in the Department of Electrical Engineering at Texas A&M University, College Station. He received his Ph.D in computer Engineering from the University of Illinois at Urbana-Champaign in August 1990. He was a research staff member at IBM Almaden Research Center in San Jose from August 1990–August 1995.

Reddy's research interests are in multimedia, I/O systems, network QOS, and computer architecture. Currently, he is leading projects on building scalable multimedia storage servers and partial-state based network elements. His group is also exploring various issues related to network QOS. While at IBM, he coarchitected and designed a topology-independent routing chip operating at 100 MB/sec, designed a hierarchical storage management system, and participated in the design of video servers and disk arrays. Reddy is a member of ACM SIGARCH and is a senior member of IEEE Computer Society. He has received an NSF CAREER award in 1996. He received an Outstanding Professor Award at Texas A&M during 1997–98.

Ikjun Yeom received his B.S. degree in electronic engineering from Yonsei University, Seoul, Korea, in February 1995 and his M.S. and Ph.D. degrees in computer engineering from Texas A&M University, College Station, in August 1998 and May 2001, respectively. He worked at DACOM Company located in Seoul, Korea, between 1995 and 1996 and at Nortel Networks in 2000. After working as a research professor at Kyungpook National University in 2001, he has been an assistant professor in the Department of Computer Science at KAIST since January 2002. His research interests are in congestion control, network performance evaluation, and Internet QoS.

DIGITAL AUDIOBROADCASTING

RAINER BAUER
Munich University of Technology (TUM)
Munich, Germany

1. INTRODUCTION

The history of broadcasting goes back to James Clerk Maxwell, who theoretically predicted electromagnetic radiation in 1861; and Heinrich Hertz, who experimentally verified their existence in 1887. The young Italian Guglielmo Marconi picked up the ideas of Hertz and began to rebuild and refine the Hertzian experiments and soon was able to carry out signaling over short distances in the garden of the family estate near Bologna. In the following years the equipment was continuously improved and transmission over long distances became possible. The first commercial application of radio transmission was point-to-point communication to ships, which was exclusively provided by Marconi's own company. Pushed by the promising possibilities of wireless communication the idea of broadcasting soon also came up. The first scheduled radio program was transmitted by a 100-W transmitter at a frequency around 900 kHz in Pittsburgh late in 1920.

The installation of more powerful transmitters and progress in receiver technology led to a rapidly increasing number of listeners. A milestone in broadcasting history was the invention of frequency modulation (FM) by Armstrong in the 1930s and the improvement in audio quality that came along with the new technology. Because FM needed higher transmission bandwidths, it was necessary to move to higher frequencies. While the first FM radio stations in the United States operated at frequencies around 40 MHz, today's FM radio spectrum is located in the internationally recognized VHF FM band from 88 to 108 MHz. Although the reach of the FM signals was below that of the former AM programs, due to the shorter wavelength of the FM band frequencies, broadcasters adopted the new technology after initial skepticism and the popularity of FM broadcasting grew rapidly after its introduction.

The next step toward increased perceived quality was the introduction of stereobroadcasting in the 1960s. Constant advances in audiobroadcasting technology resulted in today's high-quality audio reception with analog transmission technology. So, what is the reason for putting in a lot of time and effort into developing a new digital system?

In 1982 the compact disk (CD) was introduced and replaced the existing analog record technology within just a few years. The advantages of this new digital medium are constant high audio quality combined with robustness against mechanical impacts. The new technology also resulted in a new awareness of audio quality and the CD signal became a quality standard also for other audio services like broadcasting.

Using good analog FM equipment, the audio quality is fairly comparable to CD sound when the receiver is stationary. However, along with the development of broadcasting technology, the customs of radio listeners also changed. While at the beginning, almost all receivers were stationary, nowadays many people are listening to audiobroadcasting services in their cars, which creates a demand for high-quality radio reception in a mobile environment. This trend also reflects the demand for mobile communication services, which has experienced a dramatic boom.

Due to the character of the transmission channel, which leads to reflections from mountains, buildings, and cars, for example, in combination with a permanently changing environment caused by the moving receiver, a number of problems arise that cannot be handled in a satisfying way with existing analog systems. The problem here is termed multipath propagation and is illustrated in Fig. 1. The transmitted signal arrives at the receiver not only via the direct (line-of-sight) path but also as reflected and scattered components that correspond to different path delays and phase angles. This often results in severe interference and therefore signal distortion.

Another drawback is interference caused by transmission in neighboring frequency bands (adjacent-channel interference) or by transmission of different programs in the same frequency with insufficient spacial distance between the transmitters (cochannel interference).

The tremendous progresses in digital signal processing and microelectronics in the 1980s initiated a trend to supplement and even substitute existing analog systems with digital systems. Introduction of the compact disk was already mentioned above, but a change from analog

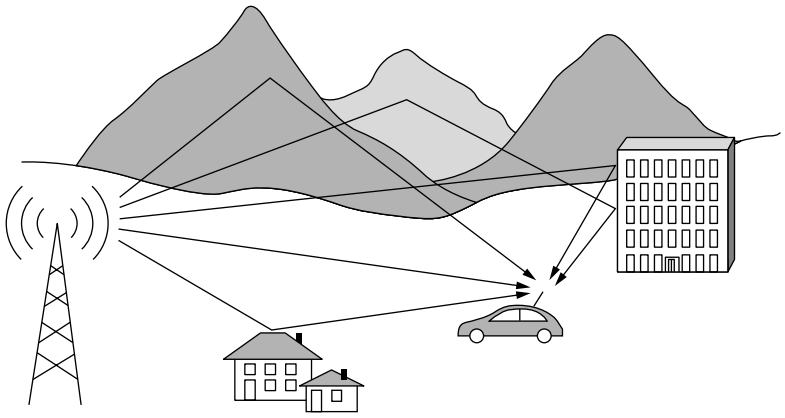

Figure 1. Scenario with multipath propagation.

to digital systems also took place in the field of personal communications. This was seen, for example, in the introduction of ISDN (Integrated Services Digital Network) in wireline communications and also in GSM (Global System for Mobile Communications) for personal mobile communications. The latter system caused a rapidly growing market for mobile communications systems and drove the development of new high-performance wireless communication techniques.

Several advantages of digital systems suggest the application of digital techniques also in broadcasting, which is still dominated by analog systems [1]. For instance, advanced digital receiver structures and transmission and detection methods are capable of eliminating the distortions caused by multipath propagation, which enables high-quality reception also in mobile environments.

To use the available frequency spectrum in an efficient way, the digitized audio signals can be compressed with powerful data reduction techniques to achieve a compression factor of up to 12 without perceptible degradation of audio quality compared to a CD signal.

Techniques such as channel coding to correct transmission errors are applicable only to digital signals. These methods allow an error free transmission even when errors occur on the transmission channel.

With advanced signal detection and channel coding techniques, a significantly lower signal to noise ratio is sufficient in producing a particular sound quality when compared to equivalent analog transmission systems. This results in lower transmission power and therefore reduced costs and also less "electromagnetic pollution," which has recently become a topic of increasing importance and relevance.

Another advantage of a digital broadcasting system is its flexibility. While conventional analog systems are restricted to audio transmission, a digital system can also provide other services besides audio transmission and is therefore open to trends and demands of the future. In combination with other digital services such as Internet or personal communications, a digital broadcasting technology further supports the convergence of information and communication techniques. Also there is a change of paradigm in the way we obtain information in everyday life. The growing importance of the Internet obliterates the boundaries between individual and mass communications. Broadcasting will have to face competition with other communication networks that have access to the consumer. To meet future demands, it is necessary to introduce digital broadcasting systems.

2. SYSTEM ASPECTS AND DIFFERENT APPROACHES

Besides technical aspects, the introduction of a digital audiobroadcasting system must also meet market issues. The transition from an analog to a digital system has to take place gradually. Users have to be convinced that digital audiobroadcasting has significant advantages compared to analog systems in order to bring themselves to buy new digital receivers instead of conventional analog ones. This can be obtained only by added value and new services. On the other hand, the situation of the broadcasters and network operators must be considered. Simultaneous transmission of digital and analog programs results in increasing costs that have to be covered. Standards have to be adopted to guarantee planning reliability to broadcasters, operators, and also manufacturers [2].

2.1. An Early Approach Starts Services Worldwide

An early approach to standardize a digital audiobroadcasting system was started in the 1980s by a European telecommunication consortium named Eureka. In 1992 the so-called Eureka-147 DAB system was recommended by the International Telecommunication Union (ITU) and became an ITU standard in 1994. The standard is aimed at terrestrial and satellite sound broadcasting to vehicular, portable and fixed receivers and is intended to replace the analog FM networks in the future. The European Telecommunications Standard Institute (ETSI) also adopted this standard in 1995 [3].

The terrestrial service uses a multicarrier modulation technique called coded orthogonal frequency-devision multiplex (COFDM), which is described later in this article along with other technical aspects of this system. With this multiplexing approach up to six high-quality audio programs (called an ensemble) are transmitted via closely spaced orthogonal carriers that allocate a total bandwidth of 1.536 MHz. The overall net data rate that can be transmitted in this ensemble is approximately 1.5 Mbps

(megabits per second) [4]. Although originally a sound broadcasting system was to be developed, the multiplex signal of Eureka-147 DAB is very flexible, allowing the transmission of various data services also. Because of the spreading in frequency by OFDM combined with channel coding and time interleaving, a reliable transmission can be guaranteed with this concept. A further advantage of the Eureka-147 system is the efficient use of radio spectrum by broadcasting in a single-frequency network (SFN). This means that one program is available at the same frequency across the whole coverage area of the network. In a conventional analog audiobroadcasting environment, each program is transmitted on a separate carrier (in FM broadcasting with a bandwidth of 300–400 kHz). If the network offers the same program outside the coverage area of a particular transmitter another frequency is usually used to avoid cochannel interference. On the other hand, adjacent channels within the coverage area of one transmitter are not used in order to reduce adjacent-channel interference. This leads to a complex network and requires a sophisticated frequency management, both of which can be avoided with a single-frequency network. The basic structures of a single-frequency network and a multiple frequency network are compared in Fig. 2. A further advantage of a single-frequency network is the simple installation of additional transmitters to fill gaps in the coverage.

To operate a system like Eureka-147 DAB dedicated frequency bands have to be reserved because it cannot coexist with an analog system in the same frequency band. In 1992 the World Administrative Radio Conference (WARC) reserved almost worldwide a 40-MHz wide portion (1452–1492 MHz) of the L band for this purpose. In several countries a part of the spectrum in the VHF band III (in Germany, 223–240 MHz) is also reserved for Eureka-147 DAB.

At present, the Eureka-147 DAB system is in operation or in pilot service in many countries worldwide [5].

2.2. A System for More Flexibility

The strategy to merge several programs into one broadband multiplex signal prior to transmission has several advantages with respect to the received signal quality. However, the ensemble format also shows drawbacks that aggravate the implementation of Eureka-147 DAB in certain countries. The broadcasting market in the United States for example is highly commercial with many independent private broadcasters. In this environment it would be almost impossible to settle on a joint transition scenario from analog to digital. Also, the reserved frequency spectrum in the L band is not available in the United States [6]. Therefore, a different system was considered by the U.S. broadcasting industry. The idea was that no additional frequency spectrum (which would cause additional costs, because spectrum is not assigned but auctioned off in the United States) should be necessary, and the broadcasters should remain independent from each other and be able to decide on their own when to switch from analog to digital. A concept that fulfills all these demands is in-band/on-channel (IBOC) digital audiobroadcasting. In this approach the digital signal is transmitted in the frequency portion to the left and the right of the analog spectrum, which is left free to avoid interference from nearby signals. The basic concept is shown in Fig. 3. The spectral position and power of the digital signal is designed to meet the requirements of the spectrum mask of the analog signal. The IBOC systems will be launched in an "hybrid IBOC" mode, where the digital signal is transmitted simultaneously to the analog one. When there is sufficient market penetration of the digital services, the analog programs can be switched off and the spectrum can be filled with a digital signal to obtain an all-digital IBOC system.

After the merger of USA Digital Radio (USADR) and Lucent Digital Radio (LDR) to iBiquity Digital Corp. there is currently a single developer of IBOC technology in the United States.

2.3. Digital Sound Broadcasting in Frequency Bands Below 30 MHz

The first radio programs in the 1920s were transmitted at frequencies around 900 kHz using analog amplitude modulation (AM). Although frequency modulation (FM), which was introduced in the late 1930s and operated at higher frequencies, allows a better audio quality, there are still many radio stations, particularly in the United States, that use the AM bands for audiobroadcasting. One advantage of these bands is the large coverage area that

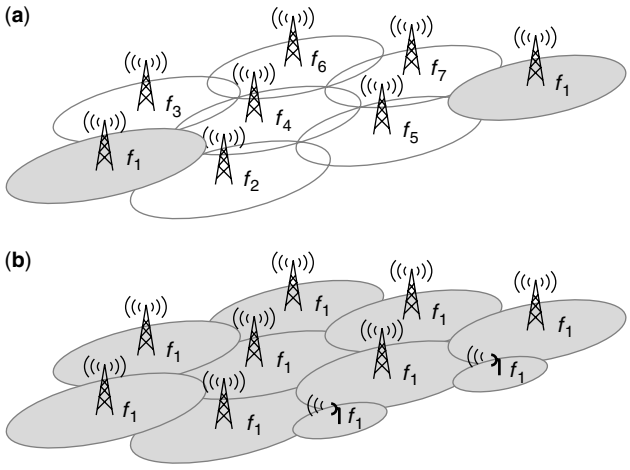

Figure 2. Conventional FM networks (**a**) and single-frequency network (**b**).

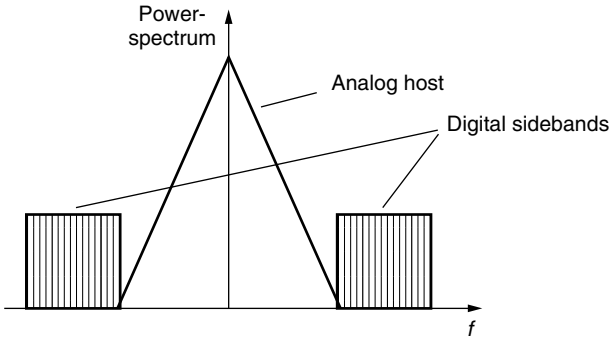

Figure 3. In-band/on-channel signaling.

can be obtained because of the propagation conditions of these frequencies. A major drawback, however, is the poor sound quality, due to the limited bandwidth available in these low-frequency bands.

On the other hand, the coverage properties still make this frequency band attractive for audiobroadcasting. With state-of-the-art audio compression technology and digital transmission methods, the sound quality can be increased to near FM quality.

In 1994 the European project (*Narrow Band Digital Broadcasting* (*NADIB*)) started to develop concepts for a digital system operating in the AM band. The international consortium Digital Radio Mondiale (DRM) [7], which was officially founded in 1998, began to develop an appropriate system. Together with a second approach proposed by iBiquity Digital Corp., the ITU finally gave a recommendation that encompasses both systems for digital sound broadcasting in the frequency bands below 30 MHz [8].

One major difference between both approaches is the strategy to deal with existing analog AM signals. While the DRM scheme is an all-digital approach that occupies all frequencies within the channels with a bandwidth of 9 or 10 kHz or multiples of these bandwidths, the iBiquity system applies the IBOC strategy described above for FM systems.

2.4. Mobile Satellite Digital Audio Radio Services (SDARS)

While the intention of terrestrial digital audio broadcasting technology is to replace existing analog radio in the AM and FM bands, new satellite platforms are emerging that are intended for mobile users. Previous satellite services such as ASTRA Digital (a proprietary standard of the satellite operator SES/ASTRA) or DVB-S, the satellite distribution channel of the European DVB (Digital Video Broadcasting) system, were designed to serve stationary users with directional satellite dishes. In 1999 the WorldSpace Corp. started its satellite service to provide digital high quality audio to emerging market regions such as Africa, Asia, and South and Central America [9]. Originally developed to serve portable receivers, the system is about to be expanded to mobile receivers as well.

Two systems that are targeting mobile users from the beginning are the two U.S. satellite systems operated by Sirius Satellite Radio Inc. and XM Satellite Radio Inc., which intended to launch their commercial service in 2001. Both systems are based on proprietary technology [10].

The three systems differ in the orbital configurations of their satellites. The complete WorldSpace network will consist of three geostationary satellites (each using three spot beams and serving one of the intended coverage areas Africa, parts of Asia, and South and Central America). The XM system uses only two geostationary satellites located to guarantee optimum coverage of the United States. A completely different approach was chosen for the Sirius system, where three satellites in a highly elliptical orbit rise and set over the coverage area every 16 h. The orbit enables the satellites to move across the coverage area at a high altitude (even higher than a geostationary orbit) and therefore also provide a high elevation angle. Two of the three satellites are always visible to provide sufficient diversity when a direct signal to one of the satellites is blocked.

To guarantee reception even in situations when the satellite signal is totally blocked, for example, in tunnels or in urban canyons, Sirius and XM use terrestrial repeaters that rebroadcast the signal.

One major advantage of a satellite system is the large coverage area. Regions with no or poor terrestrial broadcasting infrastructure can be easily supplied with high-quality audio services. On the other hand, it is difficult to provide locally oriented services with this approach.

2.5. Integrated Broadcasting Systems

Besides systems that are designed primarily to broadcast audio services, approaches emerge that provide a technical platform for general broadcasting services. One of these systems is the Japanese Integrated Services Digital Broadcasting (ISDB) approach, which covers satellite, cable, and terrestrial broadcasting as distribution channels. ISDB is intended to be a very flexible multimedia broadcasting concept that incorporates sound and television and data broadcasting in one system. The terrestrial component ISDB-T, which is based on OFDM transmission technology, will be available by 2003–2005. A second scheme that should be mentioned here is DVB-T, the terrestrial branch of the European digital video broadcasting (DVB) system, which is also capable of transmitting transparent services but is not optimized for mobile transmission.

2.6. Which Is the Best System?

To summarize the different approaches in sound broadcasting to mobile receivers, we have to consider the basic demands of the respective market (both customer and broadcaster aspects).

If the situation among the broadcasters is sufficiently homogeneous, which allows the combination of several individual programs to ensembles that are jointly transmitted in a multiplex, then the Eureka-147 system provides a framework for spectrally efficient nationwide digital audiobroadcasting. By adopting this system, a strategy for the transition from analog to digital that is supported by all parties involved must be mapped out.

A more flexible transition from analog to digital with no need for additional frequency bands is possible with the IBOC approach. Also, small local radio stations can be more easily considered using this approach.

However, if the strategy is to cover large areas with the same service, then satellite systems offer advantages over the terrestrial distribution channel.

3. THE EUREKA-147 DAB SYSTEM

Several existing and future systems have been summarized in the previous section. In this section we focus on Eureka-147 DAB as it was the first digital audiobroadcasting system in operational service.

Eureka-147 DAB is designed to be the successor of FM stereobroadcasting. It started as a proposal of a European consortium and is now in operational or pilot

service in countries around the world [5]. Although several alternative approaches are under consideration, right now Eureka-147 DAB is the first all-digital sound broadcasting system that has been in operation for years. When we refer to DAB below, we mean Eureka-147 DAB. Some features of the system are

- Data compression with MPEG-Audio layer 2 (MPEG — Moving Picture Experts Group) according to the standards ISO-MPEG 11172-3 and ISO-MPEG 1318-3 (for comparison with the well-known audio compression algorithm MP3, which is MPEG-Audio layer 3).
- Unequal error protection (UEP) is provided to the compressed audio data where different modes of protection are provided to meet the requirements of different transmission channels, namely, radiofrequency transmission for a variety of scenarios or cable transmission.
- The concept of (coded orthogonal frequency-devision multiplex (COFDM)) copes very well with the problem of multipath propagation, which is one of the major problems in mobile systems. Furthermore, this transmission scheme allows the operation of a single-frequency network (SFN).
- The DAB transmission signal carries a multiplex of several sound and data services. The overall bandwidth of one ensemble is 1.536 MHz and provides a net data rate of approximately 1.5 Mbps. The services can be combined very flexibly within one ensemble. Up to six high-quality audio programs or a mixture of audio and data services can be transmitted in one ensemble.

3.1. General Concept

The basic concept of signal generation in a DAB system is shown in Fig. 4. The input to the system may either be one or several audio programs or one or several data services together with information about the multiplex structure, service information, and so on. Audio and data services form the main service channel (MSC), while service and multiplex information are combined in the fast information channel (FIC). Every input branch undergoes a specific channel coding matched to the particular protection level required by the channel. Data compression is specified only for audio signals in the DAB standard. Data services are transparent and are transmitted in either a packet mode or a stream mode.

After additional time interleaving, which is skipped in Fig. 4, audio and data services form the MSC, which consists of a sequence of so-called common interleaved frames (CIFs) assembled by the main service multiplexer. The final transmission signal is generated in the transmission frame multiplexer, which combines the MSC and the FIC. Together with the preceding synchronization information, OFDM symbols are formed and passed to the transmitter.

In the following the main components of the block diagram (flowchart) in Fig. 4 are explained in more detail.

3.2. Audio Coding

Since the bit rate of a high-quality audio signal (e.g., a CD signal with 2×706 kbps) is too high for a spectral efficient transmission, audio coding according to the MPEG Audio layer 2 standard is applied. For a sampling frequency of 48 kHz the resulting bitstream complies with the ISO/IEC 11172-3 layer 2 format, while a sampling frequency of 24 kHz corresponds to ISO/IEC 13818-3 layer 2 LSF (low sampling frequency). The main idea behind the compression algorithms is utilization of the properties of human audio perception, which are based on spectral and temporal masking phenomena. The concept is shown in Fig. 5, where the sound pressure level is plotted as a function of frequency. The solid curve indicates the threshold in quiet, which is the sound pressure level of a pure tone that is barely audible in a quiet environment. The curve shows that a tone has to show a higher level

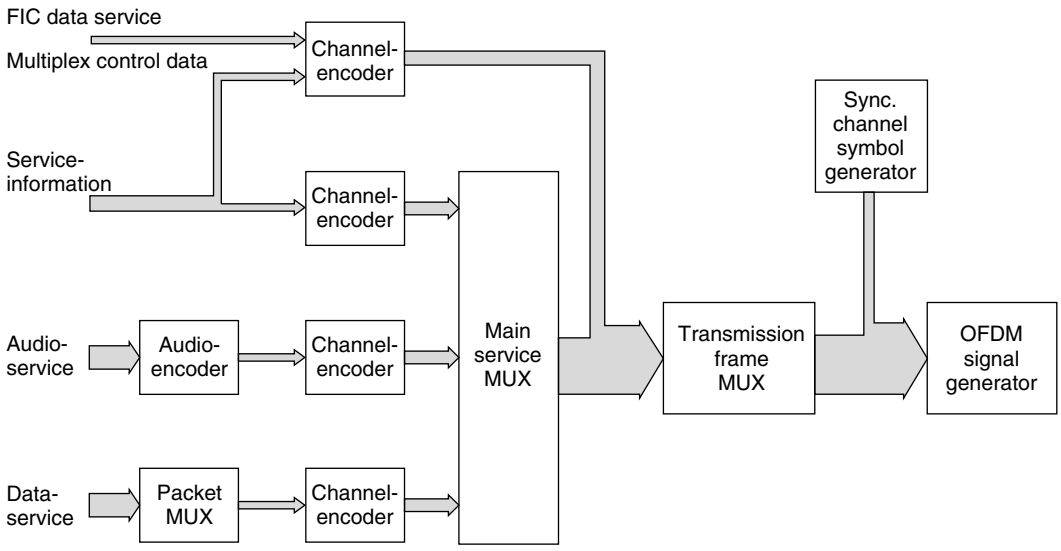

Figure 4. Generation of the transmission signal.

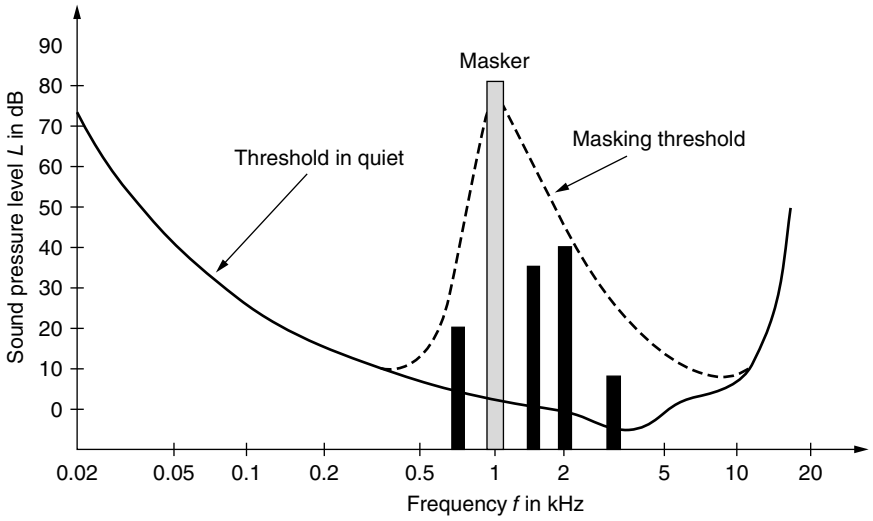

Figure 5. Example for masking.

at very low and very high frequencies to be perceivable than at medium frequencies around 3 kHz, where the human auditory system is very sensitive. Besides the threshold in quiet, each additional sound also creates a masking pattern that is also depicted in the figure. The shape of the pattern depends on the level and the frequency of the underlying sound. A general observation is that the slope of the masking pattern is steeper toward lower frequencies than in the opposite direction. All sound events that lie below this masking pattern (also indicated in Fig. 5) are not perceivable by the human ear and therefore do not have to be transmitted. Since a general audio signal consists of a more complex spectrum, the first step in audio coding is a transformation from the time domain into the frequency domain. Each frequency component creates a masking pattern by itself, and the masking pattern of the overall signal can be calculated by a superposition of the individual patterns. The signal is divided into frequency bands in the spectral domain, and each band is coded (quantized) separately in such a way that the quantization noise lies below the masking threshold in this band. By this technique the quantization noise can be shaped along the frequency axis, and the overall bit rate that is necessary to represent the signal can be reduced.

A simplified block diagram of the audio encoder is shown in Fig. 6. For processing, the sampled signal is divided into segments of length 24 or 48 ms, respectively. Each segment is then transformed from the time domain into the frequency domain by a filter bank with 32 subbands. In parallel, the masking threshold is calculated for each segment in a psychoacoustic model. The subband samples undergo a quantization process in which the number of quantization levels are controlled by the requirements given by the psychoacoustic model. Finally, the quantized samples together with the corresponding side information that is necessary to reconstruct the signal in the decoder are multiplexed into an audio frame. The frame also contains program-associated data (PAD).

The bit rates available for DAB are between 8 and 192 kbps for a monophonic channel. To achieve an audio quality that is comparable to CD quality, approximately 100 kbps are necessary per monochannel, which means a data reduction of a factor of ~7. Since the Eureka-147 DAB standard was fixed in the early 1990s, MPEG Audio layer 2 was chosen for audio coding because it combines good compression results with reasonable complexity.

With today's leading-edge audio compression algorithms such as MPEG2-AAC (advanced audiocoding) or the Lucent PAC (perceptual audiocoder) codec, compression gains of a factor of 12 can be realized without noticeable differences in a CD signal. The AAC codec, for example, is proposed for audiocoding in the Digital Radio Mondiale approach as well as in the Japanese ISDB system, while the PAC technology is applied in the Sirius and XM satellite services, for example.

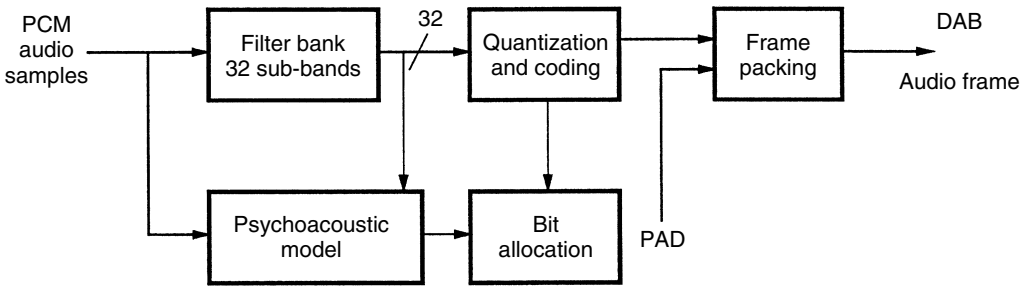

Figure 6. Simplified block diagram of an DAB audio encoder.

3.3. Channel Coding

Between the components for audioencoding and channel encoding an energy dispersal is performed by a pseudo random scrambling that reduces the probability of systematic regular bit patterns in the data stream.

The basic idea of channel coding is to add redundancy to a digital signal in such a way, that the redundancy can be exploited in the decoder to correct transmission errors. In DAB, a convolutional code with memory six and rate $\frac{1}{4}$ is applied. The encoder is depicted in Fig. 7. The code rate $\frac{1}{4}$ means that for every information bit that enters the encoder, 4 coded bits are produced. In the case of an audio signal not every part of the source coded audio frame has the same sensitivity to transmission errors. Very sensitive segments have to be protected by a strong code, while a weaker code can be applied to other parts. This concept, called unequal error protection (UEP), can easily be realized by a technique termed puncturing, which means that not every output bit of the convolutional encoder is transmitted. According to a defined rule, some of the bits are eliminated (punctured) prior to transmission. This technique is also shown in Fig. 7. A binary 1 in the puncturing pattern means that the corresponding bit at the output of the convolutional encoder is transmitted, while a binary 0 indicates that the bit is not transmitted (punctured). In the DAB specification, 24 of these puncturing patterns are defined, which allows a selection of code rates between $\frac{8}{9}$ and $\frac{8}{32}$. A code rate of $\frac{8}{9}$ means that for every 8 bits that enter the encoder, 9 bits are finally transmitted over the channel (depicted in the upper pattern in Fig. 7). On the other hand, with a code rate of $\frac{8}{32}$, all output bits are transmitted as indicated by the lower pattern in Fig. 7. To apply unequal error protection, the puncturing pattern can be changed within an audio frame. This is shown in Fig. 8. While header and side information is protected with the largest amount of redundancy, the scale factors are protected by a weaker code, and the subband samples finally have the least protection. The program-associated data (PAD) at the end of an audio frame are protected roughly by the same code rate as the scale factors. Besides the different protection classes within an audio frame, five protection levels are specified to meet the requirements of the intended transmission scenario. A cable transmission for example needs far less error protection than a very critical mobile multipath environment. Therefore, the DAB specifications contain 64 different protection profiles

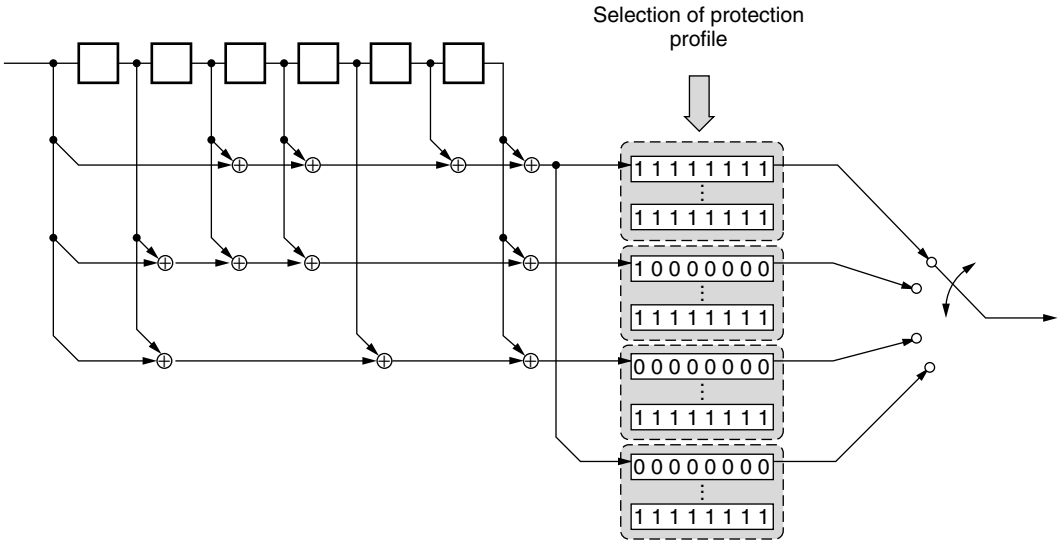

Figure 7. Channel encoder and puncturing.

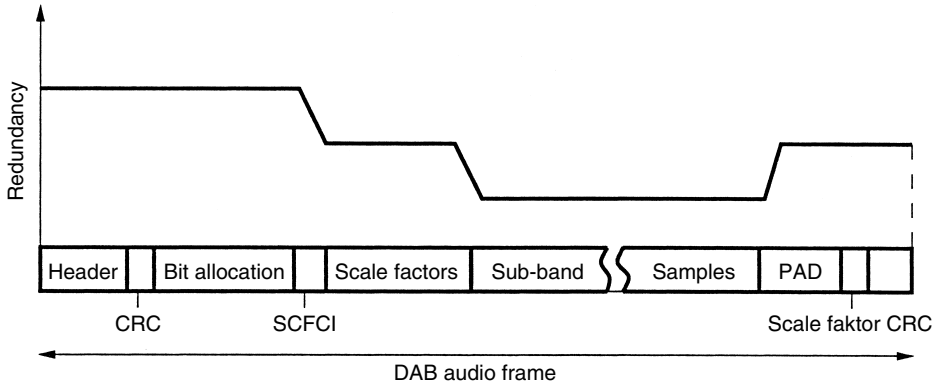

Figure 8. DAB audio frame with unequal error protection.

for different combinations of audio bit rate (32–384 kbps) and protection level.

3.4. Modulation and Transmission Format

As shown in Fig. 4, the channel coded data are multiplexed in the main service multiplexer. The structure of the frames that are finally transmitted across the air interface depends on the chosen transmission mode. DAB provides four different modes depending on the intended radiofrequency range. The duration of a transmission frame is either 24, 48, or 96 ms, and each frame consists of data from the fast information channel (FIC) and the main service channel (MSC) preceded by synchronization information.

The transmission scheme for DAB is orthogonal frequency-devision multiplex (OFDM), the motivation for which will be illustrated in a brief example.

A main problem of the mobile radio channel is multipath propagation. Let us consider a system that transmits at a symbol rate of $r = 1$ Msps (million symbols per second) (with QPSK modulation, this means a bit rate of 2 Mbps) on a single-carrier system. Hence, one symbol has a duration of $T_{sc} = 1\ \mu s$ (where subscript "sc" indicates single carrier), and the bandwidth of the system is $1/T_{sc} = 1$ MHz. We further assume a maximum channel delay τ_{max} of 80 μs. This means a difference in length between the direct path and the path with the largest delay of 24 km, which is a reasonable value for a terrestrial broadcasting channel. If we consider the relation between the symbol duration and the maximal path delay $\tau_{max}/T_{sc} = 80$, we see that this approach leads to heavy intersymbol interference since a received signal is still influenced by the 80 previously sent symbols. We can cope with this problem more easily if we do not transmit the datastream on a single carrier but multiplex the original datastream into N parallel steams (e.g., $N = 1000$) and modulate a separate carrier frequency with each individual stream. With the overall symbol rate given above, the symbol rate on each carrier is reduced to $r/N = 1000$ sps, which means a symbol duration of only $T_{mc} = 1$ ms (where subscript "mc" denotes multiple carriers). If we compare again the symbol duration with the maximal channel delay, a received symbol overlaps with only an 8% fraction of the previous symbol.

But what does this mean for the bandwidth that is necessary to transmit the large number of carriers? A very elegant way to minimize the carrier spacing without any interference between adjacent carriers is to use rectangular pulses on each subcarrier and space the resulting $\sin(x)/x$-type spectra by the inverse of the pulse (symbol) duration T_{mc}. This results in orthogonal carriers, and the overall bandwidth of the system with the parameters given above is $N \times 1/T_{mc} = 1000 \times 1\ \text{kHz} = 1\ \text{MHz}$, which is the same as for the single-carrier approach. This multicarrier approach with orthogonal subcarriers, called orthogonal frequency-devision multiplex (OFDM), is used as the transmission scheme in Eureka-147 DAB. Another advantage of OFDM is the simple generation of the transmission signal by an inverse discrete Fourier transform (IDFT), which can be implemented with low complexity using the fast fourier transform (FFT). Therefore, the modulation symbols of a transmission frame are mapped to the corresponding carriers before an IFFT generates the corresponding time-domain transmission signal. The individual carriers of the DAB signal are DQPSK-modulated, where the "D" stands for differential, meaning that the information is carried in the phase difference between two successive symbols rather than in the absolute phase value. This allows an information recovery at the receiver by just comparing the phases of two successive symbols. To initialize this process, the phase reference symbol has to be evaluated, which is located at the beginning of each transmission frame.

One essential feature of OFDM we did not mention yet is the guard interval. Since each overlapping of received symbols disturbs the orthogonality of the subcarriers and leads to a rapidly decreasing system performance, this effect has to be avoided. By introduction of a guard interval at the beginning of each OFDM symbol, this interference can be avoided. This guard interval is generated by periodically repeating the tail fraction of the OFDM symbol at the beginning of the same symbol. As long as the path delay is not longer than the guard interval, only data that belong to the actual symbol fall into the receiver window. By this technique all information of delayed path components contribute constructively to the received signal. This concept is sketched in Fig. 9.

The length of the guard interval specifies the maximal allowed path delay. In order to fix the parameters of an OFDM system, a tradeoff between two elementary properties of the mobile radio channel has to be made.

On one hand, the guard interval has to be sufficiently large to avoid interference due to multipath effects. This can be obtained by a large symbol duration. Because the carrier spacing is the inverse of the symbol duration, this results in a large number of closely spaced carriers within the intended bandwidth. On the other hand, a small carrier spacing means a high sensitivity to frequency shifts caused by the Doppler effect when the receiver is moving. This, in turn, depends on the used radiofrequency and the speed of the vehicle.

In Table 1 four sets of transmission parameters are given for the different scenarios (transmission modes). Mode I is suitable for terrestrial single frequency networks in the VHF frequency range. Mode II is suitable for smaller single-frequency networks or locally oriented conventional networks because of the rather small guard interval. Mode III has an even smaller guard interval and is designed for satellite transmission on frequencies up to 3 GHz where path delay is not the dominating problem. Mode IV is designed for single-frequency networks operating at frequencies higher than those of Mode I, and the parameters are in between those of Mode I and Mode II.

3.5. DAB Network

As mentioned before, DAB allows the operation of single-frequency networks. Several transmitters synchronously broadcast the same information on the same frequency. This becomes possible because of the OFDM transmission technique. For the receiver, it makes no difference whether

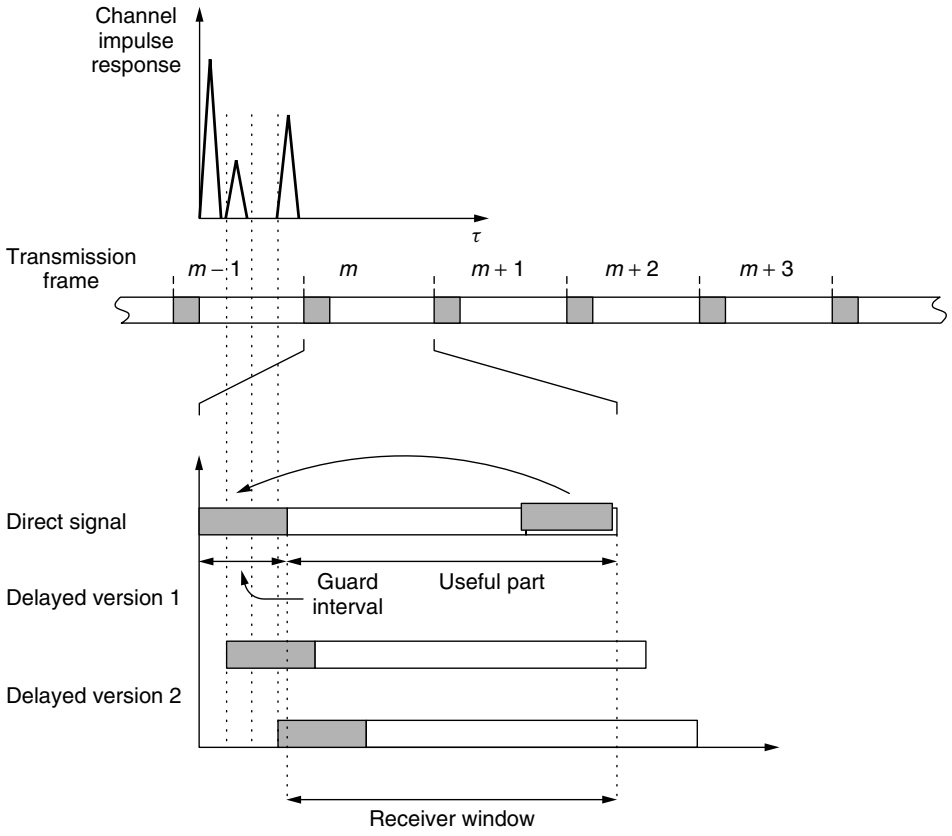

Figure 9. OFDM symbol in multipath environment.

Table 1. DAB Parameters for Transmission Modes I–IV [4]

Parameter	Mode I	Mode II	Mode III	Mode IV
Number of carriers	1536	384	192	768
Frame duration	96 ms	24 ms	24 ms	48 ms
Carrier spacing	1 kHz	4 kHz	8 kHz	2 kHz
Useful symbol duration (inverse carrier spacing)	1 ms	250 μs	125 μs	500 μs
Guard interval duration	246 μs	62 μs	31 μs	123 μs
Maximal transmitter separation	96 km	24 km	12 km	48 km
Frequency range for mobile transmission	≤375 MHz	≤1.5 GHz	≤3 GHz	≤1.5 GHz

the received signal components all come from the same transmitter or stem from different transmitters. Each component contributes constructively to the received signal as long as the path delays stay within the guard interval. Therefore, the maximal distance between the transmitters is determined by the length of the guard interval specified by the used transmission mode. To ensure synchronous transmission within the network, a time reference is necessary, which can be provided, for example, by the satellite-based Global Positioning System (GPS).

BIOGRAPHY

Rainer Bauer received his Dipl.-Ing. degree in electrical engineering and Dr.-Ing. degree from Munich University of Technology (TUM) in 1995 and 2002, respectively. Since 1995, he has been working at the Institute for Communications Engineering of TUM. His areas of interest are source-channel coding and decoding, as well as iterative decoding techniques and their application to wireless audio communications.

DIGITAL FILTERS

HANOCH LEV-ARI
Northeastern University
Boston, Massachusetts

1. INTRODUCTION

The omnipresence of noise and interference in communication systems makes it necessary to employ filtering to suppress the effects of such unwanted signal components. As the cost, size, and power consumption of digital hardware continue to drop, the superiority of digital filters over their analog counterparts in meeting the increasing demands of modern telecommunication equipment becomes evident in a wide range of applications. Moreover, the added flexibility of digital implementations makes adaptive digital filtering a preferred solution in situations where time-invariant filtering is found to be inadequate.

The design of linear time-invariant digital filters is by now a mature discipline, with methodological roots reaching back to the first half of the twentieth century. Digital filter design combines the power of modern computing with the fundamental contributions to the theory of optimized (analog) filter design, made by Chebyshev, Butterworth, Darlington, and Cauer. In contrast, the construction of adaptive digital filters is still an evolving area, although its roots can be traced back to the middle of the twentieth century, to the work of Kolmogorov, Wiener, Levinson, and Kalman on statistically optimal filtering. Adaptive filtering implementations became practical only after the early 1980s, with the introduction of dedicated digital signal processing hardware.

The practice of digital filter design and implementation relies on two fundamental factors: a well-developed mathematical theory of signals and systems and the availability of powerful digital signal processing hardware. The synergy between these two factors results in an ever-widening range of applications for digital filters, both fixed and adaptive.

1.1. Signals, Systems, and Filters

Signals are the key concept in telecommunications — they represent patterns of variation of physical quantities such as acceleration, velocity, pressure, and brightness. Communication systems transmit the information contained in a signal by converting the physical pattern of variation into its electronic analogue — hence the term "analog signal." *Systems* operate on signals to modify their shape. *Filters* are specialized systems, designed to achieve a particular type of signal shape modification. The relation between the signal that is applied to a filter and the resulting output signal is known as the *response* of the filter.

Most signals encountered in telecommunication systems are *one-dimensional* (1D), representing the variation of some physical quantity as a function of a single independent variable (usually time). Multidimensional signals are functions of several independent variables. For instance, a video signal is 3D, depending on both time and (x, y) location in the image plane. Multidimensional signals must be converted by scanning to a 1D format before transmission through a communication channel. For this reason, we shall focus here only on 1D signals that vary as a function of time.

Filters can be classified in terms of the operation they perform on the signal. Linear filters perform linear operations. Offline filters process signals after they have been acquired and stored in memory; online filters process signals instantaneously, as they evolve. The majority of filters used in telecommunication systems are online and linear. Since the input and output of an online filter are continuously varying functions of time, memory is required to store information about past values of the signal. Analog filters use capacitors and inductors as their memory elements, while digital filters rely on electronic registers.

1.2. Digital Signal Processing

Digital signal processing is concerned with the use of digital hardware to process digital representations of signals. In order to apply digital filters to real life (i.e., analog) signals, there is a need for an input interface, known as *analog-to-digital converter*, and an output interface, known as *digital-to-analog converter*. These involve *sampling* and *quantization*, both of which result in some loss of information. This loss can be reduced by increasing the speed and wordlength of a digital filter.

Digital filters have several advantages over their analog counterparts:

- *Programmability* — a time-invariant digital filter can be reprogrammed to change its configuration and response without modifying any hardware. An adaptive digital filter can be reprogrammed to change its response adaptation algorithm.
- *Flexibility* — digital filters can perform tasks that are difficult to implement with analog hardware, such as

large-scale long-term storage, linear phase response, and online response adaptation.

- *Accuracy and robustness* — the accuracy of digital filters depends mainly on the number of bits (wordlength) used, and is essentially independent of external factors such as temperature and age.
- *Reliability and security* — digital signals can be coded to overcome transmission errors, compressed to reduce their rate, and encrypted for security.
- *Cost / performance tradeoff* — the cost, size, and power consumption of digital hardware continue to drop, while its speed keeps increasing. As a result, a digital implementation often offers a better cost/performance trade-off than its analog counterpart.

Still, digital hardware is not entirely free from limitations, and the choice between digital and analog has to be made on a case-by-case basis.

1.3. Telecommunication Applications of Digital Filters

Among the many application areas of digital filters, we focus only on those applications that are directly related to communication systems. Our brief summary (Section 7) distinguishes between two main types of applications:

- *Time-invariant digital filters* — used as an alternative to analog filters in applications ranging from frequency-selective filtering and symbol detection in digital communication systems, through speech and image coding, to radar and sonar signal processing
- *Adaptive digital filters* — used in applications that require continuous adjustment of the filters response, such as channel equalization, echo cancellation in duplex communication systems, sidelobe cancellation and adaptive beamforming in antenna arrays, and linear predictive speech coding

2. FUNDAMENTALS OF DISCRETE-TIME SIGNALS AND SYSTEMS

2.1. Discrete-Time Signals

A *discrete-time signal* is a sequence of numbers (real or complex). As explained in the introduction (Section 1), such a sequence represents the variation of some physical quantity, such as voltage, pressure, brightness, and speed. Because discrete-time signals are often obtained by sampling of continuous-time signals, their elements are known as *samples*.

The samples of a discrete-time signal $x(n)$ are labeled by a discrete index n, which is an integer in the range $-\infty < n < \infty$. For instance, the signal

$$x(n) = \begin{cases} 2n+1 & 0 \le n \le 2 \\ 0 & \text{else} \end{cases}$$

consists of three nonzero samples preceded and followed by zero samples (Fig. 1).

Because signals represent physical quantities, they are subject to various constraints:

- A signal $x(\cdot)$ is called *bounded* if there exists a positive constant B such that $|x(n)| \le B$ for all n.

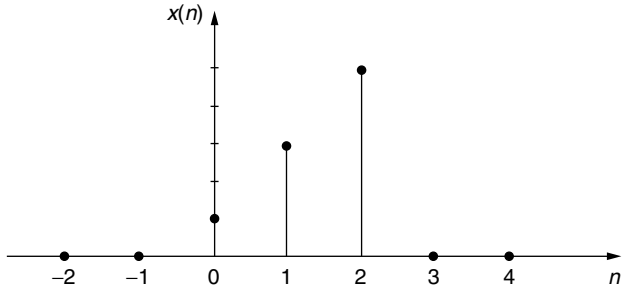

Figure 1. Graphical representation of a discrete-time signal.

- A signal $x(\cdot)$ is said to have *finite energy* if the infinite sum $\sum_{n=-\infty}^{\infty} |x(n)|^2$ converges to a finite value.
- A signal $x(\cdot)$ is said to have *finite average power* if the limit

$$\lim_{N\to\infty} \frac{1}{2N+1} \sum_{n=-N}^{N} |x(n)|^2$$

exists and is finite.

Here, and in the sequel, we use the shorthand notation $x(\cdot)$, which is equivalent to $\{x(n); -\infty < n < \infty\}$, to refer to the entire signal sequence, rather than to a particular sample. From a mathematical standpoint, a bounded signal has finite ℓ_∞ norm, while a finite-energy signal has finite ℓ_2 norm [2].

Certain elementary signal models are essential to the characterization and analysis of discrete-time systems. These include

- The discrete-time unit impulse, also known as the Krönecker delta:[1]

$$\delta(n) = \begin{cases} 1 & n = 0 \\ 0 & n \ne 0 \end{cases}$$

- The discrete-time unit step

$$u(n) = \begin{cases} 1 & n \ge 0 \\ 0 & n < 0 \end{cases}$$

- A two-sided sinusoid, $x(\cdot) = \{\cos 2\pi f_o n; -\infty < n < \infty\}$.
- A one-sided exponential, $a^n u(n)$. A decaying exponential is obtained by choosing $|a| < 1$; in this case the parameter a is known as a "forgetting factor" [3].

We observe that the discrete-time unit impulse $\delta(n)$ satisfies all three constraints — boundedness, finite energy, and finite power — while the discrete-time step $u(n)$ and the sinusoid $\cos 2\pi f_0 n$ are both bounded and have finite power, but infinite energy. Finally, the exponential $a^n u(n)$ satisfies all three constraints when $|a| < 1$, but it violates all three when $|a| > 1$. In general, every finite-energy

[1] The Krönecker delta should not be confused with the continuous-time impulse, namely, the Dirac delta function.

signal is bounded, and every bounded signal must have finite power:

$$\text{Finite energy} \Rightarrow \text{boundedness} \Rightarrow \text{finite power}$$

Also, since finite-energy signals have the property $\lim_{n\to\pm\infty} x(n) = 0$, they represent transient phenomena. Persistent phenomena, which do not decay with time, are represented by finite-power signals.

2.2. Discrete-Time Systems

A discrete-time system is a *mapping* namely, an operation performed on a discrete-time signal $x(\cdot)$ that produces another discrete-time signal $y(\cdot)$ (Fig. 2). The signal $x(\cdot)$ is called the *input* or *excitation* of the system, while $y(\cdot)$ is called the *output* or *response*.

Most synthetic (human-made) systems are *relaxed,* in the sense that a zero input [i.e., $x(n) = 0$ for all n] produces a zero output. Nonrelaxed systems, such as a wristwatch, rely on internally stored energy to produce an output without an input. In general every system can be decomposed into a *sum* of two components: a relaxed subsystem, which responds to the system input, and an autonomous subsystem, which is responsible for the zero-input response (Fig. 3). Since every analog and every digital filter is a relaxed system, we restrict the remainder of our discussion to relaxed systems only.

Relaxed systems can be classified according to certain input–output properties:

- A relaxed system is called *memoryless* or *static* if its output $y(n)$ at any given instant n depends only on the input sample $x(n)$ at the same time instant, and does not depend on any other input sample. Such a system can be implemented without using memory; it maps every input sample, as it becomes available, into a corresponding output sample.
- A relaxed system is called *dynamic* if its output $y(n)$ at any given instant n depends on past and/or future samples of the input signal $x(\cdot)$. This means that memory is required to store each input sample as it becomes available until its processing has been completed, and it is no more needed by the system. The number of input samples that need to be kept in memory at any given instant is known as the order of the system, and it is frequently used as a measure of system complexity.
- A relaxed system is called *causal* if its output $y(n)$ at any given instant n does not depend on future samples of the input $x(\cdot)$. In particular, every memoryless system is causal. Causality is a physical constraint, applying to systems in which n indicates (discretized) physical time.
- A relaxed system is called *time-invariant* if its response to the time-shifted input $x(n - n_o)$ is a similarly shifted output $y(n - n_o)$, for every input signal $x(\cdot)$ and for every integer n_o, positive or negative. In the context of (digital) filters, time-invariance is synonymous with fixed hardware, while time variation is an essential characteristic of adaptive filters.
- A relaxed system is called *stable* if its response to any bounded input signal $x(\cdot)$ is a bounded output signal $y(\cdot)$. This is known as bounded-input/bounded-output (BIBO) stability, to distinguish it from other definitions of system stability, such as internal (or Lyapunov) stability.
- A relaxed system is called *linear* if its response to the input $x(\cdot) = a_1x_1(\cdot) + a_2x_2(\cdot)$ is $y(\cdot) = a_1y_1(\cdot) + a_2y_2(\cdot)$ for any a_1, a_2 and any $x_1(\cdot), x_2(\cdot)$. Here $y_1(\cdot)$ (resp. $y_2(\cdot)$) is the system's response to the input $x_1(\cdot)$ [resp. $x_2(\cdot)$].

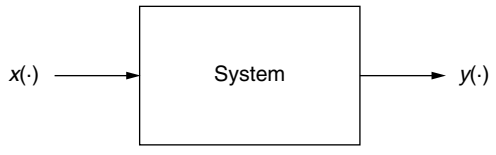

Figure 2. Block diagram representation of a discrete-time system.

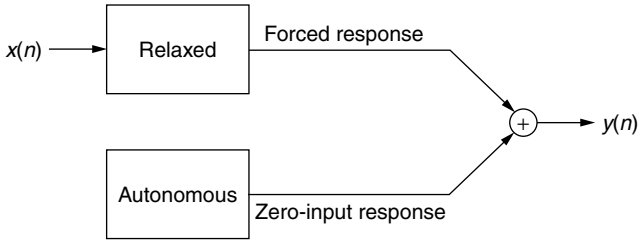

Figure 3. The decomposition of a nonrelaxed system.

As explained in the introduction, digital filters can be either fixed or adaptive. Fixed digital filters are time invariant and most often linear, while adaptive digital filters usually consist of a linear time-variant module and a nonlinear time-invariant module.

Our definitions of fundamental system properties make use of several basic building blocks of discrete-time systems in general, and digital filters in particular:

- *Unit-delay element* — delays a signal by one sample (Fig. 4).
- *Adder* — forms the sum of two signals, such that each output sample is obtained by adding the corresponding input samples (Fig. 5).
- *Signal scaler* — multiplies each sample of the input signal by a constant (Fig. 6). It is the discrete-time equivalent of an (wideband) amplifier.

These three basic building blocks — unit delay, addition, and signal scaling — are relaxed, linear, time-invariant,

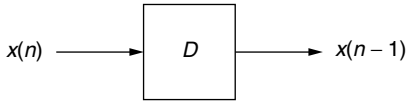

Figure 4. Block diagram representation of a unit-delay element.

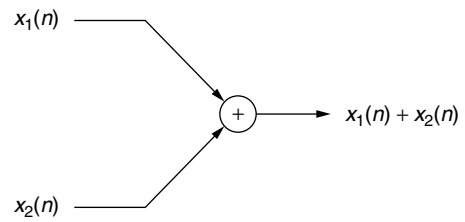

Figure 5. Block diagram representation of an adder.

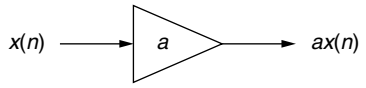

Figure 6. Block diagram representation of a signal scaler.

causal, and stable systems. In fact, every linear, time-invariant, and causal system can be implemented as a network of interconnected delays, scalers and adders (see Section 3.2). Notice that the adder and scaler are memoryless, while the unit delay is dynamic.

In reality, scalers are implemented using digital multipliers (Fig. 7). Multipliers can also be used to form the pointwise product of two signals (Fig. 8), and they serve as a fundamental building block in adaptive digital filters and other nonlinear systems.

2.3. Discrete-Time Sinusoidal Signals

A discrete-time signal of the form

$$x(n) = A\cos(2\pi f_0 n + \phi) \tag{1a}$$

is called *sinusoidal*. The *amplitude* A, *frequency* f_0, and *phase shift* ϕ are all real and, in addition

$$A > 0, \qquad 0 \le f_0 \le \tfrac{1}{2}, \qquad -\pi \le \phi \le \pi \tag{1b}$$

The *radial frequency* $\omega_0 = 2\pi f_0$ $(0 \le \omega_0 \le \pi)$ is often used as an alternative to f_0. The dimensions of f_0 are cycles per sample, and those of ω_0 are radians per sample.

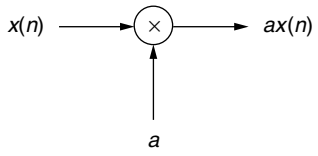

Figure 7. Implementing a signal scaler using a multiplier.

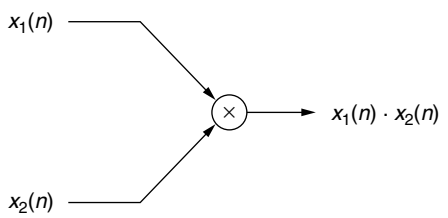

Figure 8. Block diagram representation of a signal multiplier.

The restriction imposed on the range of the frequency f_0 stands in sharp contrast to the continuous-time case, where sinusoids can have unlimited frequencies. However, in the discrete-time context this restriction is necessary in order to avoid *aliasing*.

Aliasing occurs because the two discrete-time sinusoidal signals

$$x_1(n) = \cos 2\pi f_1 n, \qquad x_2(n) = \cos 2\pi f_2 n$$

are indistinguishable when $f_1 - f_2$ is an integer. For instance, $\cos\left(\frac{3\pi}{2}n\right) = \cos\left(-\frac{\pi}{2}n\right)$, so that the frequency $f_1 = \frac{3}{4}$ cannot be distinguished from its *alias* $f_2 = -\frac{1}{4}$. From a mathematical standpoint, we observe that the sinusoidal signal of (1) is periodic in f_0 with a period of 1. In order to avoid ambiguity, we must therefore restrict f_0 to its fundamental (or principal) range $-\frac{1}{2} < f_0 \le \frac{1}{2}$. In addition, by using the symmetry property $\cos(-x) = \cos x$, we can avoid using negative frequencies altogether, which leads to the frequency range specified in Eq. (1b).

The constraint on f_0 is closely related to the well-known Nyquist condition: the range of frequencies allowed at the input of a sampler cannot exceed half the sampling rate. In particular, when the continuous-time sinusoid $\cos 2\pi f_0 t$ is sampled at a rate of F_s samples per second, the resulting sequence of samples forms a discrete-time sinusoid, $x(n) = \cos 2\pi f_0 n$, where $f_0 = f_0/F_s$. According to the Nyquist condition we must have $f_0 < F_s/2$ in order to avoid aliasing: the equivalent restriction on f_0 is $f_0 < \frac{1}{2}$. Anti-aliasing filters must be used to avoid the presence of aliased components in sampled signals.

2.4. Relaxed Linear Time-Invariant (LTI) Systems

The input–output characterization of relaxed discrete-time LTI systems relies on the notion of *impulse response*, namely the response of the system to the discrete-time unit impulse $\delta(\cdot)$ (Fig. 9).

The response of such a system to an arbitrary input $x(\cdot)$ is determined by a linear convolution between the input signal and the impulse response of the system:

$$y(n) = \sum_{k=-\infty}^{\infty} h(k)x(n-k) \tag{2}$$

This is usually expressed using the shorthand notation

$$y(\cdot) = h(\cdot) \circledast x(\cdot)$$

Thus, a relaxed LTI system is completely characterized by its impulse response. In particular, such a system is causal if, and only if

$$h(n) = 0 \quad \text{for} \quad n < 0$$

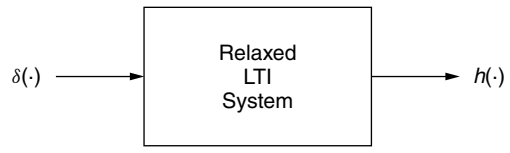

Figure 9. The impulse response of a relaxed LTI system.

As a result the convolution sum (2) for a causal system ranges only over $0 \le k < \infty$. Also, an LTI system is BIBO stable if, and only if

$$\sum_{k=-\infty}^{\infty} |h(k)| < \infty$$

The response of an LTI system to a sinusoidal input is of particular interest. The input signal $x(n) = \exp\{j\omega_0 n\}$ produces the output

$$y(n) = H(e^{j\omega_0})e^{j\omega_0 n} \equiv H(e^{j\omega_0})x(n) \tag{3a}$$

where

$$H(e^{j\omega}) = \sum_{k=-\infty}^{\infty} h(k)e^{-j\omega k} \tag{3b}$$

is known as the *frequency response* of the LTI system. We observe that the response to the complex sinusoid $x(n) = \exp\{j\omega_0 n\}$ is $H(e^{j\omega_0})x(n)$, namely, a scaled version of the input signal. From a mathematical standpoint, this means that complex sinusoids are eigenfunctions of LTI systems.

The infinite sum (3b) that defines the frequency response $H(e^{j\omega})$ converges for all ω if, and only if, $\sum_k |h(k)| < \infty$, which is also the necessary and sufficient conditions for BIBO stability. Thus, an unstable system does not have a frequency response — exciting it with a sinusoidal input produces an unbounded output signal. Unstable systems can be characterized by their response to exponentially decaying sinusoids, which leads us to the more general concept of a $\mathcal{Z}$ transform (see Section 3.1).

A real-life LTI system has a real-valued impulse response. The response of such a system to the real-valued sinusoid $x(n)\cos\omega_0 n$ is given by the real part of the response in (3)

$$y(n) = \mathrm{Re}\{H(e^{j\omega_0})e^{j\omega_0 n}\} = |H(e^{j\omega_0})|\cos[\omega_0 n + \theta(\omega_0)]$$

where $\theta(\omega_0) = \arg H(e^{j\omega_0})$. The effect of an LTI system on a real sinusoid is to scale its amplitude by $|H(e^{j\omega_0})|$, and to increase its phase by $\arg H(e^{j\omega_0})$. For this reason, $|H(e^{j\omega})|$ is known as the *magnitude response* of the system, and $\arg H(e^{j\omega})$ is known as its *phase response*.

3. TRANSFORM DOMAIN ANALYSIS OF SIGNALS AND SYSTEMS

Transform-domain analysis is a powerful technique for characterization and design of (fixed) digital filters. The role of the $\mathcal{Z}$ transform in the context of discrete-time signals and systems is similar to the role of the Laplace transform in the context of continuous-time signals and systems. In fact, the two are directly related via the process of sampling and reconstruction. Recall that interpolation, specifically the process of reconstructing a continuous-time signal from its samples, produces the continuous-time signal

$$x_r(t) = \sum_{n=-\infty}^{\infty} x(n)g(t - nT)$$

where $g(\cdot)$ is the impulse response of the interpolating filter and T is the sampling interval. The Laplace transform of this signal is

$$X_r(s) = \left[\sum_{n=-\infty}^{\infty} x(n)e^{-snT}\right] G(s)$$

namely, a product of the transfer function $G(s)$ of the interpolating filter with a transform-domain characterization of the discrete-time sequence of samples $x(\cdot)$. This observation motivates the introduction of the $\mathcal{Z}$ transform

$$X(z) = \sum_{n=-\infty}^{\infty} x(n)z^{-n} \tag{4}$$

so that $X_r(s) = G(s)X(z)|_{z=e^{sT}}$.

The $\mathcal{Z}$ transform converts difference equations into algebraic equations, which makes it possible to characterize every discrete-time LTI system in terms of the poles and zeros of its *transfer function*, namely, the $\mathcal{Z}$ transform of its impulse response. This is entirely analogous to the role played by the Laplace transform in the context of continuous-time LTI systems.

3.1. The $\mathcal{Z}$ Transform and the Discrete-Time Fourier Transform

From a mathematical standpoint, the $\mathcal{Z}$ transform (4) is the sum of two power series, viz., $X(z) = \sum_{n=-\infty}^{\infty} x(n)z^{-n} = X_+(z) + X_-(z)$, where

$$X_+(z) = \sum_{n=0}^{\infty} x(n)z^{-n}, \qquad X_-(z) = \sum_{n=-1}^{-\infty} x(n)z^{-n}$$

The $\mathcal{Z}$ transform $X(z)$ is said to exist only if both $X_+(z)$ and $X_-(z)$ converge absolutely and uniformly. This implies that the *region of convergence* (RoC) of $X(z)$ is $\{z; r < |z| < R\}$, where r is the radius of convergence of $X_+(z)$ and R is the radius of convergence of $X_-(z)$. Thus a $\mathcal{Z}$ transform exists if, and only if, $r < R$. When it does exist, it is an analytic function within its RoC.

The $\mathcal{Z}$ transform converts time-domain convolutions into transform-domain products. In particular, the input–output relation of a relaxed LTI system, specifically, $y(\cdot) = h(\cdot) \circledast x(\cdot)$ transforms into $Y(z) = H(z)X(z)$, where $X(z)$, $Y(z)$, and $H(z)$ are the $\mathcal{Z}$ transforms of $x(\cdot)$, $y(\cdot)$, and $h(\cdot)$, respectively. Thus, specifying the *transfer function*

$$H(z) = \sum_{k=-\infty}^{\infty} h(k)z^{-k}$$

along with its RoC provides the same information about the input–output behavior of a relaxed LTI system as the impulse response $h(\cdot)$. In particular

- The system is causal if, and only if, the RoC of $H(z)$ is of the form $|z| > r$ for some $r \ge 0$.
- The system is (BIBO) stable if, and only if, the unit circle is within the RoC of $H(z)$.

Thus the transfer function of a stable system is always well defined on the unit circle $\mathbf{T} = \{z; |z| = 1\}$, and we recognize $H(z)|_{z=e^{j\omega}}$ as the frequency response of the system [as defined in (3)]. More generally, if $x(\cdot)$ is a discrete-time sequence, whether a signal or an impulse response, such that $\sum_{n=-\infty}^{\infty} |x(n)| < \infty$, then the unit circle $\mathbf{T}$ is included in the RoC of the $\mathcal{Z}$ transform $X(z)$, and so $X(z)|_{z=e^{j\omega}}$ is well defined. The resulting function of ω, that is

$$X(e^{j\omega}) = \sum_{n=-\infty}^{\infty} x(n)e^{-j\omega n} \tag{5a}$$

is called the *discrete-time Fourier transform* (DTFT) of $x(\cdot)$.

From a mathematical standpoint, relation (5) is a complex Fourier series representation of the periodic function $X(e^{j\omega})$, and we recognize the samples $x(n)$ as the Fourier coefficients in this representation. The standard expression for Fourier coefficients

$$x(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} X(e^{j\omega})e^{j\omega n} d\omega \tag{5b}$$

is known as the *inverse DTFT*. The DTFT (5) converges absolutely (and uniformly) for ℓ_1 sequences, and the resulting limit is a continuous function of ω. The DTFT can be extended to other types of sequences by relaxing the notion of convergence of the infinite sum in (5a). For instance, the DTFT of ℓ_2 sequences is defined by requiring convergence in the $\mathcal{L}^2(\mathbf{T})$ norm, and the resulting limit is a square-integrable function on the unit circle $\mathbf{T}$. A further extension to ℓ_∞ sequences (= bounded signals) results in limits that are $\mathcal{L}^1(\mathbf{T})$ functions, and thus may contain impulsive components. For instance, the DTFT of the bounded signal $x(n) = e^{j\omega_0 n}$ is $X(e^{j\omega}) = 2\pi\delta(\omega - \omega_0)$, where $\delta(\cdot)$ is the Dirac delta function. The convergence of (5) in this case is defined only in the distribution sense. Also, notice that this signal has no $\mathcal{Z}$ transform.

3.2. Transfer Functions of Digital Filters

A fixed digital filter implements a realizable discrete-time linear time-invariant system. Realizability restricts us to causal systems with *rational transfer functions*

$$H(z) = \frac{b(z)}{a(z)} \tag{6a}$$

where $a(z)$ and $b(z)$ are finite-order polynomials in z^{-1}:

$$a(z) = 1 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_N z^{-N} \tag{6b}$$

$$b(z) = b_o + b_1 z^{-1} + b_2 z^{-2} + \cdots + b_M z^{-M} \tag{6c}$$

The roots of the numerator polynomial $b(z)$ are known as the *zeros* of the transfer function $H(z)$, and the roots of the denominator polynomial $a(z)$ are known as the *poles* of $H(z)$. A digital filter with $N = 0$ is known as a *finite-impulse response* (FIR) filter, while one with $N > 0$ is known as an *infinite-impulse response* (IIR) filter. In view of our earlier statements about causality and stability in terms of the region of convergence, it follows that a digital filter is stable if all its poles have magnitudes strictly less than unity. Thus, FIR filters are unconditionally stable, because all of their poles are at $z = 0$.

In view of (6), the input–output relation of a digital filter can be written as $a(z)Y(z) = b(z)X(z)$, which corresponds to a *difference equation* in the time domain

$$\begin{aligned} y(n) + a_1 y(n-1) + \cdots + a_N y(n-N) \\ = b_o x(n) + b_1 x(n-1) + \cdots + b_M x(n-M) \end{aligned} \tag{7}$$

The same input–output relation can also be represented by a block diagram, using multipliers (actually signal scalers), adders, and delay elements (Fig. 10). Such a block diagram representation is called a *realization* of the transfer function $H(z) = \dfrac{b(z)}{a(z)}$. Digital filter realizations are not unique: the one shown in Fig. 10 is known as the *direct form type 2* realization. Other realizations are described in Section 5.

A hardware implementation (i.e., a digital filter) is obtained by mapping the realization into a specific platform, such as a DSP chip or an ASIC (see Section 5). A software implementation is obtained by mapping the same realization into a computer program.

3.3. The Power Spectrum of a Discrete-Time Signal

The *power spectrum* of a finite-energy signal $x(\cdot)$ is defined as the square of the magnitude of its DTFT $X(e^{j\omega})$. Alternatively, it can be obtained by applying a DTFT to the *autocorrelation sequence*

$$C_{xx}(m) = \sum_{n=-\infty}^{\infty} x(n+m)x^*(n) = x(m) \circledast x^*(-m)$$

where the asterisk $(*)$ denotes complex conjugation. For finite-power signals the DTFT $X(e^{j\omega})$ may contain impulsive components, so that the square of its magnitude cannot be defined. Instead, the autocorrelation is defined in this case as

$$C_{xx}(m) = \lim_{N\to\infty} \frac{1}{2N+1} \sum_{n=-N}^{N} x(n+m)x^*(n)$$

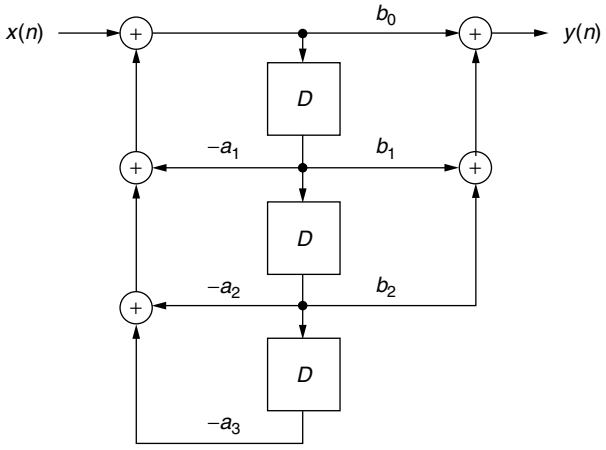

Figure 10. Direct-form type 2 realization of a digital filter with $M = 2$ and $N = 3$.

and the power spectrum is defined as the DTFT of the autocorrelation $C_{xx}(\cdot)$. Similarly, the autocorrelation of a random stationary signal is defined as

$$C_{xx}(m) = E\{x(n+m)x^*(n)\}$$

where $E\{\ \}$ denotes expectation (i.e., probabilistic mean). Thus, in all three cases the power spectrum is

$$S_{xx}(e^{j\omega}) = \sum_{m=-\infty}^{\infty} C_{xx}(m)e^{-j\omega m} \tag{8a}$$

and can be viewed as a restriction to the unit circle of the so-called *complex power spectrum*

$$S_{xx}(z) = \sum_{m=-\infty}^{\infty} C_{xx}(m)z^{-m} \tag{8b}$$

The complex power spectrum is used in the design of optimal (Wiener) filters (see Section 6.1).

Similarly, the cross-correlation of two signals is defined as

$$C_{yx}(m) = \begin{cases} \displaystyle\sum_{n=-\infty}^{\infty} y(n+m)x^*(n) \\ \qquad \text{finite-energy signals} \\ \displaystyle\lim_{N\to\infty} \frac{1}{2N+1} \sum_{n=-N}^{N} y(n+m)x^*(n) \\ \qquad \text{finite-power signals} \\ E\{y(n+m)x^*(n)\} \\ \qquad \text{jointly stationary random signals} \end{cases} \tag{9a}$$

and the (complex) cross spectrum is the transform of the cross-correlation:

$$S_{yx}(z) = \sum_{m=-\infty}^{\infty} C_{yx}(m)z^{-m} \tag{9b}$$

When $y(\cdot)$ is the response of a stable LTI system to the input $x(\cdot)$, then

$$S_{yx}(z) = H(z)S_{xx}(z) \tag{10}$$

where $H(z)$ is the transfer function of the system, and

$$S_{yy}(z) = H(z)S_{xx}\left[H\left(\frac{1}{z^*}\right)\right]^* \tag{11}$$

In particular, by using a unit-power white noise [i.e., one with $S_{xx}(z) = 1$] input, we find that

$$S_{yy}(z) = H(z)\left[H\left(\frac{1}{z^*}\right)\right]^* \tag{12}$$

This expression is called a *spectral factorization* of the complex power spectrum $S_{yy}(z)$ and the transfer function $H(z)$ is called a *spectral factor*.

4. DESIGN OF FREQUENCY-SELECTIVE DIGITAL FILTERS

The complete process of designing a digital filter consists of seven stages:

1. *Problem analysis* — determine what the filter is supposed to accomplish.
2. *Filter specification* — select a desired (ideal) frequency response for the filter, and decide how accurately it should be approximated.
3. *Filter design* — obtain the coefficients of a realizable transfer function $H(z)$ that approximates the desired frequency response within the specified tolerance.
4. *Filter realization* — determine how to construct the filter by interconnecting basic building blocks, such as delays, adders, and signal scalers (i.e., multipliers).
5. *Implementation choices* — select the specific hardware/software platform in which the building blocks will be implemented.
6. *Performance analysis* — use the physical parameters of the selected platform (accuracy, cost, speed, etc.) to evaluate the compliance of the selected implementation with the specification of the filter.
7. *Construction* — implement the specific choices made in the design and realization stages into the selected hardware/software platform.

In the problem analysis stage the designer uses specific information about the application to determine a desired frequency response, say, $D(\omega)$, for the filter. The desired magnitude response $|D(\omega)|$ is often a classical (ideal) frequency-selective prototype — lowpass, highpass, bandpass, or bandstop — except in specialized filter designs such as Hilbert transformers, differentiators, notch filters, or allpass filters. This means that $|D(\omega)|$ is piecewise constant, so that the frequency scale decomposes into a collection of bands. The desired phase response $\arg D(\omega)$ could be linear (exactly or approximately), minimum-phase, or unconstrained.

The designer must also define the set of parameters that determine the transfer function of the filter to be designed. First a choice has to be made between FIR and IIR, considering the following facts:

- Exact linear phase is possible only with FIR filters.
- FIR filters typically require more coefficients and delay elements than do comparable IIR filters, and therefore involve higher input–output delay and higher cost.
- Currently available design procedures for FIR filters can handle arbitrary desired responses (as opposed to ideal prototypes) better than IIR design procedures.
- Finite precision effects are sometimes more pronounced in IIR filters. However, such effects can be ameliorated by choosing an appropriate realization.
- Stability of IIR filters is harder to guarantee in adaptive filtering applications (but not in fixed filtering scenarios).

Additional constraints, such as an upper bound on the overall delay (e.g., for decision feedback equalization), or a requirement for maximum flatness at particular frequencies, serve to further reduce the number of independent parameters that determine the transfer function of the filter.

On completion of the problem analysis stage, the designer can proceed to formulate a specification and determine a transfer function that meets this specification, as described in the remainder of Section 4. The remaining stages of the design process (realization, implementation, performance analysis, and construction) are discussed in Section 5.

4.1. Filter Specification

Once the desired frequency response $D(\omega)$ has been determined along with a parametric characterization of the transfer function $H(z)$ of the designed filter, the next step is to select a measure of approximation quality and a tolerance level (i.e., the highest acceptable deviation from the desired response). The most commonly used measure is the weighted Chebyshev (or $\mathcal{L}^\infty$) norm

$$\max_\omega W(\omega)|H(e^{j\omega}) - D(\omega)|$$

where $W(\omega)$ is a nonnegative weighting function. Alternative measures include the weighted mean-square (or $\mathcal{L}^2$) norm

$$\int_{-\pi}^{\pi} W^2(\omega)|H(e^{j\omega}) - D(\omega)|^2 d\omega$$

and the truncated time-domain mean-square norm

$$\sum_{n=0}^{L} |h(n) - d(n)|^2$$

where $h(n)$ is the impulse response of the designed filter and $d(n)$ is the inverse DTFT of the desired frequency response $D(\omega)$.

The mean-square measures are useful mainly when the desired response $D(\omega)$ is arbitrary, since in this case optimization in the Chebyshev norm can be quite demanding. However, the approximation of ideal prototypes under the Chebyshev norm produces excellent results at a reasonable computational effort, which makes it the method of choice in this case.

The approximation of ideal prototypes is usually carried out under the *modified* Chebyshev norm

$$\max_\omega W(\omega)||H(e^{j\omega})| - |D(\omega)||$$

The elimination of phase information from the norm expression reflects the fact that in this case phase is either completely predetermined (for linear-phase FIR filters) or completely unconstrained (for IIR filters). Furthermore, the desired magnitude response is constant in each frequency band (e.g., unity in passbands and zero in stopbands), so it makes sense to select a weighting function $W(\omega)$ that is also constant in each frequency band. As a result, constraining the Chebyshev norm to a prescribed tolerance level is equivalent to providing a separate tolerance level for each frequency band, say

$$||H(e^{j\omega})| - D_i| \le \delta_i \quad \text{for all} \quad \omega \in B_i \tag{13}$$

where B_i is the range of frequencies for the ith band, D_i is the desired magnitude response in that band, and δ_i is the prescribed level of tolerance. For instance, the specification of a lowpass filter is

$$\begin{array}{lll} \text{Passband:} & 1 - \delta_p \le |H(e^{j\omega})| \le 1 + \delta_p & \text{for } |\omega| \le \omega_p \\ \text{Stopband:} & |H(e^{j\omega})| \le \delta_s & \text{for } \omega_p \le |\omega| \le \pi \end{array}$$

as illustrated by the template in Fig. 11. The magnitude response of the designed filter must fit within the unshaded area of the template. The tolerance δ_p characterizes *passband ripple*, while δ_s characterizes *stopband attenuation*.

4.2. Design of Linear-Phase FIR Filters

The transfer function of an FIR digital filter is given by (6) with $N = 0$, so that $a(z) = 1$ and $H(z) \equiv b(z) = \sum_{i=0}^{M} b_i z^{-i}$. The design problem is to determine the values of the coefficients $\{b_i\}$ so that the phase response is linear, and the magnitude response $|H(e^{j\omega})|$ approximates a specified $|D(\omega)|$. In order to ensure phase linearity, the coefficients $\{b_i\}$ must satisfy the symmetry constraint

$$b_{M-i} = sb_i \quad \text{for} \quad 0 \le i \le M, \quad \text{where} \quad s = \pm 1 \tag{14}$$

As a result, the frequency response satisfies the constraint $H^*(e^{j\omega}) = sH(e^{j\omega})e^{jM\omega}$, so that the phase response is indeed linear: $\arg H(e^{j\omega}) = (M\omega + s\pi)/2$. Another consequence of the symmetry constraint (14) is that the zero pattern of $H(z)$ is symmetric with respect to the unit circle: $H(z_o) = 0 \leftrightarrow H(1/z_o^*) = 0$.

The design of a linear-phase FIR filter is successfully completed when we have selected values for the filter coefficients $\{b_i\}$ such that (1) the symmetry constraint (14) is satisfied and (2) the magnitude tolerance constraints (13) are satisfied. A design is considered *optimal* when the order M of the filter $H(z)$ is as small as possible under the specified constraints. It is customary to specify the magnitude tolerances in decibels — for instance, a lowpass filter is characterized by

$$R_p = 20 \log \frac{1 + \delta_p}{1 - \delta_p}, \qquad A_s = 20 \log \frac{1}{\delta_s}$$

The most popular techniques for linear-phase FIR design are

- *Equiripple* — optimal in the weighted Chebyshev norm, uses the Remez exchange algorithm to optimize filter coefficients. The resulting magnitude response is equiripple in all frequency bands (as in Fig. 11). The weight for each band is set to be inversely proportional to the band tolerance. For instance, to design a lowpass filter with passband ripple $R_p = 1$ dB and stopband attenuation $A_s = 40$ dB, we

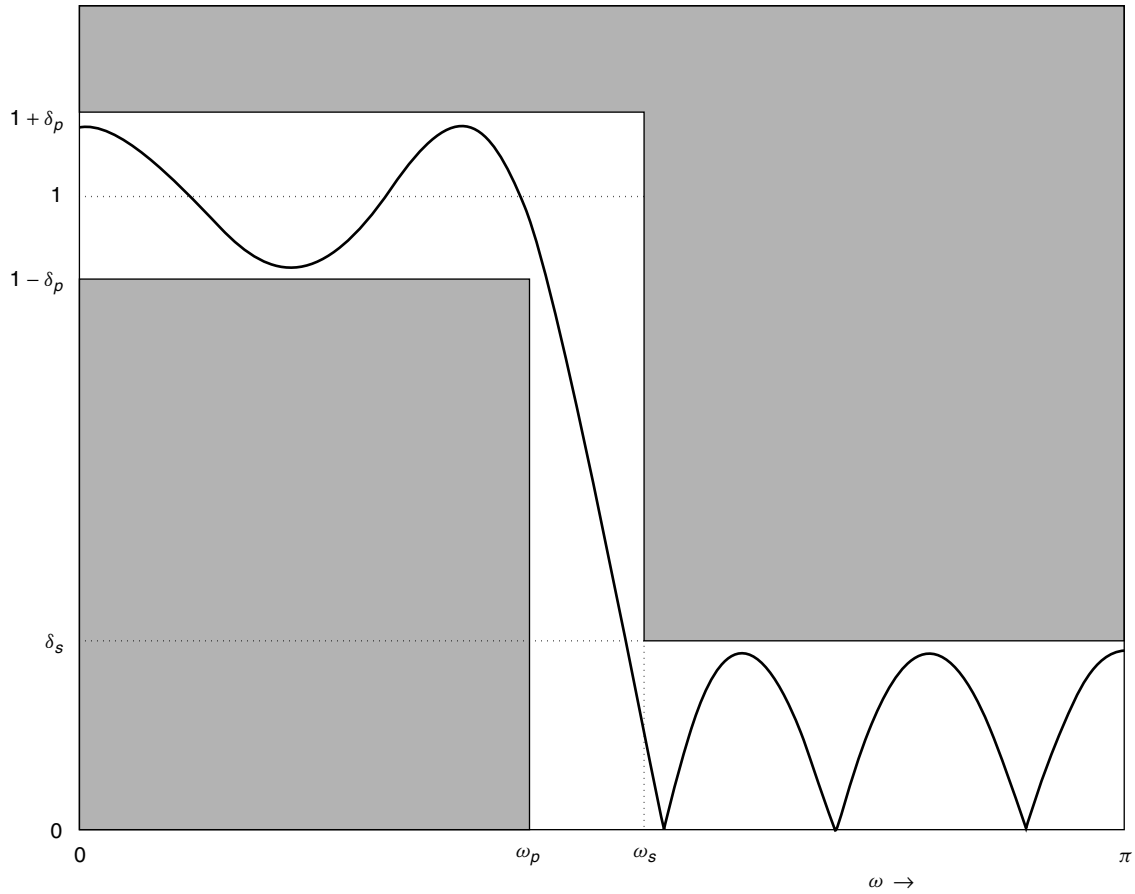

Figure 11. Specification for FIR lowpass filter design.

calculate first $\delta_p = 0.0575$ and $\delta_s = 0.01$ and then set $W_p = \delta_p^{-1} = 17.39$ and $W_s = \delta_s^{-1} = 100$. While, in principle, the Remez exchange algorithm can be applied to any desired magnitude response $|D(\omega)|$, most filter design packages (such a the *signal processing toolbox* in Matlab) accept only piecewise constant gain specifications.

- *Least squares* — optimal in the weighted mean-square norm, uses closed-form expressions for the optimal filter coefficients. As in the equiripple method, the weight for each band is set to be inversely proportional to the band tolerance. Because of the availability of a simple closed-form solution, the least-squares method is most frequently used to design filters with arbitrarily shaped magnitude responses.
- *Truncation and windowing* — optimal in the time-domain mean-square norm (when $L = M$) but not in any frequency-domain sense. The resulting filter usually has many more coefficients than the one designed by the equiripple method. The filter coefficients are obtained by (1) applying the inverse DTFT (5b) to the desired response $D(\omega)$ (which contains the appropriate linear phase term) to obtain the impulse response $d(n)$, and (2) multiplying this impulse response by a *window function* $w(n)$, which vanishes outside the range $0 \leq n \leq M$. The window function is selected to control the tradeoff between the passband attenuation of the filter, and the width of the transition band. The Kaiser window has a control parameter that allows continuous adjustment of this tradeoff. Other popular windows (e.g., Bartlett, Hamming, Von Hann, and Blackman) are not adjustable and offer a fixed tradeoff. The simplicity of the truncation and windowing method makes it particularly attractive in applications that require an arbitrarily shaped magnitude response (and possibly also an arbitrarily shaped phase response).

Specialized design methods are used to design nonstandard filters such as maximally flat or minimum-phase FIR filters, Nyquist filters, differentiators, Hilbert transformers, and notch filters [5,6].

4.3. IIR Filter Design

The transfer function of an IIR digital filter is given by (6) with $N > 0$, so that $H(z) = b(z)/a(z)$. The design problem is to determine the values of the coefficients $\{a_i\}$ and $\{b_i\}$ so that the magnitude response $|H(e^{j\omega})|$ approximates a specified $|D(\omega)|$, with no additional constraints on the phase response. The design of an IIR filter is successfully completed when we have selected values for the filter coefficients such that the magnitude tolerance constraints (13) are satisfied. A design is considered

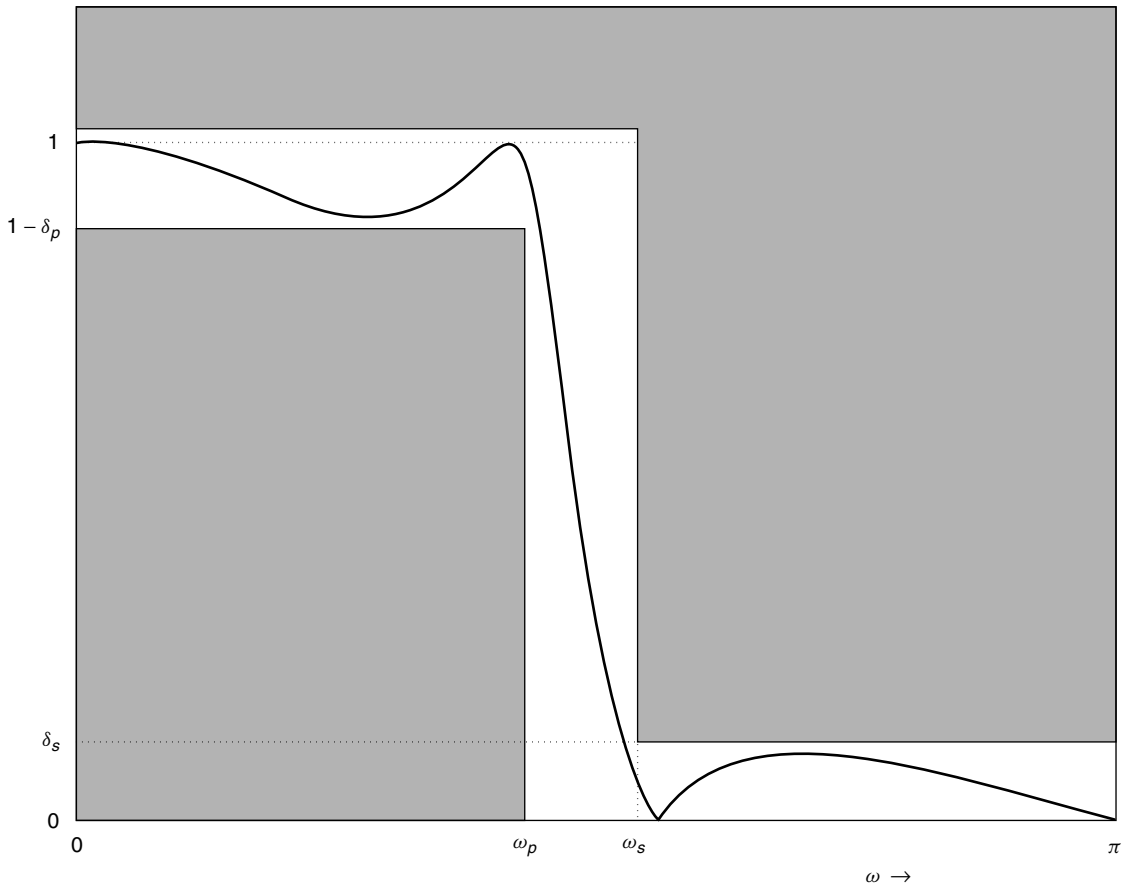

Figure 12. Specification for IIR lowpass filter design.

optimal when the filter order N is as small as possible under the specified constraints.

There exist a number of techniques for the design of IIR filters with an arbitrarily shaped $D(\omega)$, some based on the weighted (frequency-domain) $\mathcal{L}^2$ and $\mathcal{L}^\infty$ norms [5], and others on the truncated time-domain mean-square norm (with $L = M + N + 1$) [6]. Here we shall discuss only the design of classical (ideal) frequency-selective prototypes, which is the most common application for IIR digital filters. The most popular IIR design technique relies on a well-developed theory of analog filter design from closed-form (analytical) formulas. This means that the design of an IIR digital filter decomposes into three steps:

1. The specification of the desired classical frequency selective digital filter (lowpass, highpass, bandpass, or bandstop) is translated into a specification of an equivalent analog filter.
2. An analog filter $H_a(s)$ that meets the translated specification is obtained by (a) designing a lowpass analog filter $H_{\mathrm{LP}}(s)$ from closed-form formulas and (b) transforming $H_{\mathrm{LP}}(s)$ into a highpass, bandpass, or bandstop filter, as needed, by a complex variable mapping $s \rightarrow g(s)$, namely, $H_a(s) = H_{\mathrm{LP}}[g(s)]$.
3. The analog filter $H_a(s)$ is transformed into a digital filter $H(z)$ by (another) complex variable mapping.

The analog filter $H_{LP}(s)$ is one of four standard prototypes: Butterworth, Chebyshev type 1 or 2, or elliptic (also known as Chebyshev–Cauer). Since the magnitude response of such prototypes is always bounded by unity, the specification template has to be modified accordingly (see Fig. 12). As a result, the decibel scale characterization of tolerances for IIR design is also modified:

$$R_p = 20 \log \frac{1}{1-\delta_p}, \qquad A_s = 20 \log \frac{1}{\delta_s}$$

The variable transformation $s \rightarrow g(s)$ that converts the analog lowpass filter $H_{\mathrm{LP}}(s)$ into a highpass, bandpass, or bandstop filter $H_a(s)$ is described in Table 1. It involves $\Omega_{p,\mathrm{LP}}$, the passband edge frequency of the prototype $H_{\mathrm{LP}}(s)$,

Table 1. Frequency Transformations for Analog Filters

Type of Transformation	$g(s)$	Band-Edge Frequency of Target Filter
Lowpass to highpass	$\dfrac{\Omega_{p,\mathrm{LP}}\Omega_p}{s}$	Ω_p
Lowpass to bandpass	$\Omega_{p,\mathrm{LP}}\dfrac{s^2+\Omega_{p1}\Omega_{p2}}{s(\Omega_{p2}-\Omega_{p1})}$	Ω_{p1}, Ω_{p2}
Lowpass to bandstop	$\Omega_{p,\mathrm{LP}}\dfrac{s(\Omega_{p2}-\Omega_{p1})}{s^2+\Omega_{p1}\Omega_{p2}}$	Ω_{p1}, Ω_{p2}

as well as the passband edge frequencies of the target analog filter $H_a(s)$.

Several methods — including the impulse invariance, matched $\mathcal{Z}$, and bilinear transforms — can be used to map the analog transfer function $H_a(s)$, obtained in the second step of IIR design, into a digital transfer function $H(z)$. The most popular of these is the bilinear transform: the transfer function $H(z)$ is obtained from $H_a(s)$ by a variable substitution

$$H(z) = H_a\left(\alpha \frac{1 - z^{-1}}{1 + z^{-1}}\right) \tag{15a}$$

where α is an arbitrary constant. The resulting digital filter has the same degree N as the analog prototype $H_a(s)$ from which it is obtained. It also has the same frequency response, but with a warped frequency scale; as a result of the variable mapping (15a), we have

$$H(e^{j\omega}) = H_a(j\Omega)|_{\Omega=\alpha \tan(\omega/2)} \tag{15b}$$

Here we use Ω to denote the frequency scale of the analog filter $H_a(s)$ in order to distinguish it from the frequency scale ω of the digital filter $H(z)$. The frequency mapping $\Omega = \alpha \tan(\omega/2)$ governs the first step of the IIR design process — the translation of a given digital filter specification into an equivalent analog filter specification. While the tolerances R_p and A_s are left unaltered, all critical digital frequencies (such as ω_p and ω_s for a lowpass filter) are *prewarped* into the corresponding analog frequencies, using the relation

$$\Omega = \alpha \tan \frac{\omega}{2} \equiv \alpha \tan \pi f \tag{15c}$$

For instance, in order to design a lowpass digital filter with passband $|f| \le f_p = 0.2$ with ripple $R_p = 1$ dB and stopband $0.3 = f_s \le |f| \le 0.5$ with attenuation $A_s = 40$ dB, we need to design an analog filter with the same tolerances, but with passband $|\Omega| \le \Omega_p$ and stopband $|\Omega| \ge \Omega_s$, where

$$\Omega_p = \alpha \tan(0.2\pi), \qquad \Omega_s = \alpha \tan(0.3\pi)$$

Since the value of α is immaterial, the most common choice is $\alpha = 1$ (sometimes $\alpha = 2$ is used). The value of α used in the prewarping step must also be used in the last step when transforming the designed analog transfer function $H_a(s)$ into its digital equivalent $H(z)$ according to (15a).

Once the complete specification of the desired analog filter is available, we must select one of the four standard lowpass prototypes (Fig. 13):

- *Butterworth* — has a monotone decreasing passband and stopband magnitude response, which is maximally flat at $\Omega = 0$ and $\Omega = \infty$
- *Chebyshev 1* — has an equiripple passband magnitude response, and a monotone decreasing stopband response, which is maximally flat at $\Omega = \infty$
- *Chebyshev 2* — has a monotone decreasing passband magnitude response, which is maximally flat at $\Omega = 0$, and an equiripple stopband response
- *Elliptic* — has an equiripple magnitude response in both the passband and the stopband

All four prototypes have a maximum gain of unity, which is achieved either at the single frequency $\Omega = 0$ (for Butterworth and Chebyshev 2), or at several frequencies throughout the passband (for Chebyshev 1 and elliptic). When the Butterworth or Chebyshev 1 prototype is translated into its digital form, its numerator is proportional to $(1 + z^{-1})^N$. Thus only $N + 1$ multiplications are required to implement these two prototypes, in contrast to Chebyshev 2 and elliptic prototypes, which have nontrivial symmetric numerator polynomials, and thus require $N + \text{ceil}(N + 1/2)$ multiplications each.

As an example we present in Fig. 13 the magnitude response of the four distinct digital lowpass filters, designed from each of the standard analog prototypes to meet the specification $f_p = 0.23$, $f_s = 0.27$, $R_p = 1$ dB, and $A_s = 20$ dB. The order needed to meet this specification is 12 for the Butterworth, 5 for Chebyshev (both types), and 4 for the elliptic. Thus the corresponding implementation cost (=number of multipliers) is in this case 13 for Butterworth, 6 for Chebyshev 1, 11 for Chebyshev 2, and 9 for elliptic.

5. REALIZATION AND IMPLEMENTATION OF DIGITAL FILTERS

The preceding discussion of digital filters has concentrated solely on their input–output response. However, in order to build a digital filter, we must now direct our attention to the internal structure of the filter and its basic building blocks. The construction of a digital filter from a given (realizable) transfer function $H(z)$ usually consists of two stages:

- *Realization* — in this stage we construct a block diagram of the filter as a network of interconnected basic building blocks, such as unit delays, adders, and signal scalers (i.e., multipliers).
- *Implementation*–in this stage we map the filter realization into a specific hardware/software architecture, such as a general-purpose computer, a digital signal processing (DSP) chip, a field-programmable gate array (FPGA), or an application-specific integrated circuit (ASIC).

A realization provides an idealized characterization of the internal structure of a digital filter, in the sense that it ignores details such as number representation and timing. A given transfer function has infinitely many realizations, which differ in their performance, as explained in Section 5.3. The main distinguishing performance attributes are numerical accuracy and processing delay. These and other details must be addressed as part of the implementation stage, before we can actually put together a digital filter.

5.1. Realization of FIR Filters

FIR filters are always realized in the so-called transversal (also tapped-delay-line) form, which is a special case of the direct-form realization described in Section 3.2. Since

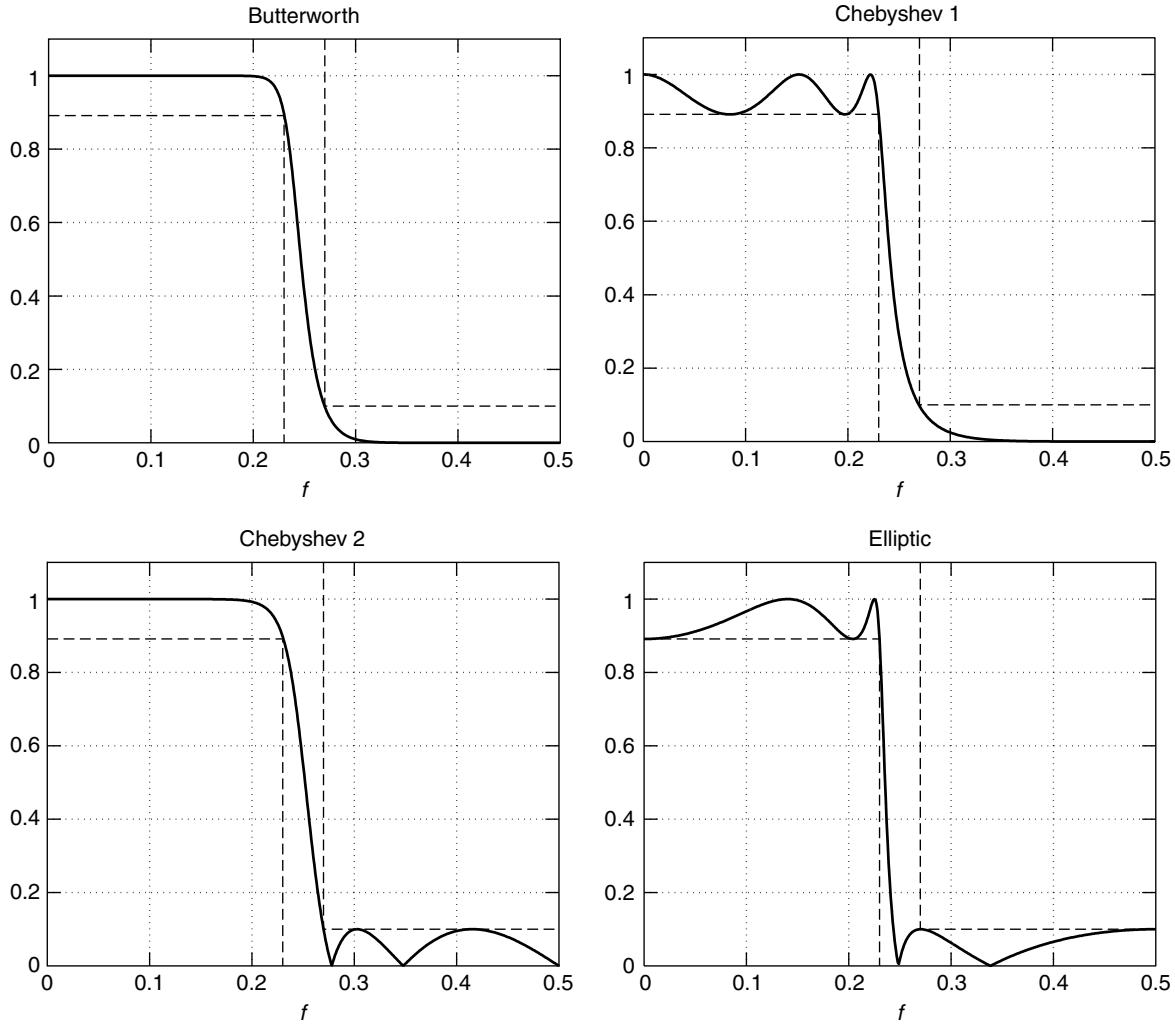

Figure 13. The four standard lowpass prototypes for IIR filter design.

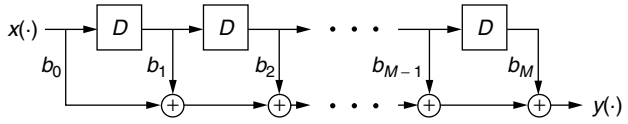

Figure 14. Transversal (direct-form) realization of an FIR digital filter.

$a(z) = 1$ for FIR filters, the direct form realization reduces to the configuration shown in Fig. 14.

The realization requires M delay elements, $M + 1$, multipliers and M adders. However, since FIR filters usually satisfy the symmetry constraint $b_i = \pm b_{M-i}$ in order to achieve linear phase, we can save about half of the number of multipliers.

5.2. Realization of IIR Filters

The transfer function of most practical IIR filters, such as those obtained from analog prototypes, have the same numerator and denominator degrees: $N \equiv \deg a(z) = \deg b(z) \equiv M$. Consequently, their direct-form realization requires N delay elements, $2N + 1$ multipliers, and N adders (see Fig. 10). We now describe two alternative realizations that require the same number of delays, multipliers, and adders as the direct-form realization.

The *parallel realization* of a rational transfer function $H(z)$ is obtained by using its partial fraction expansion

$$H(z) = A_0 + \sum_{j=1}^{N} \frac{A_j}{1 - p_j z^{-1}} \tag{16}$$

where p_j are the poles of $H(z)$ and where we assumed that (1) $M \leq N$ and (2) all poles are simple. Both assumptions hold for most practical filters, and in particular for those obtained from the standard analog prototypes.

Since the denominator polynomial $a(z)$ has real coefficients, its roots (i.e., the poles p_j) are either real or conjugate pairs. In order to avoid complex filter coefficients, the two terms representing a conjugate pair of poles are combined into a single second-order term:

$$\frac{A}{1 - p_0 z^{-1}} + \frac{A^*}{1 - p_0^* z^{-1}} = 2\frac{(\mathrm{Re}A) - (\mathrm{Re}p_0)z^{-1}}{1 - (2\mathrm{Re}p_0)z^{-1} + |p_0|^2 z^{-2}}$$

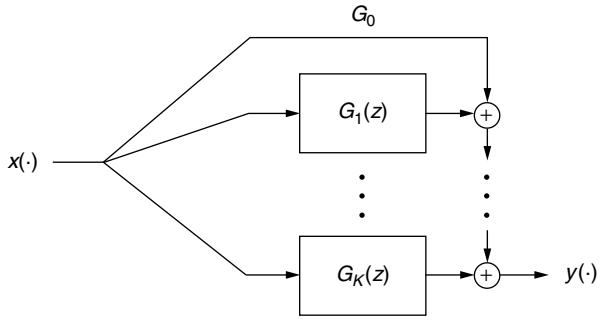

Figure 15. Parallel realization of an IIR digital filter.

Thus we obtain an additive decomposition

$$H(z) = A_0 + \sum_{k=1}^{K} G_k(z)$$

where each $G_k(z)$ is a strictly proper IIR filter or order 2 (for conjugate pairs of poles) or order 1 (for real poles). This results in a parallel connection of the subsystems $G_k(z)$ (Fig. 15). Finally, each individual $G_k(z)$ is realized in direct form.

The *cascade realization* is obtained by using the pole–zero factorization of the transfer function

$$H(z) \equiv \frac{b(z)}{a(z)} = b_0 \frac{\prod_{i=1}^{M} (1 - z_i z^{-1})}{\prod_{j=1}^{N} (1 - p_j z^{-1})} \tag{17}$$

where we recall again that the *zeros* z_i are the roots of the numerator polynomial $b(z)$ and the *poles* p_j are the roots of the denominator polynomial $a(z)$. Since these polynomials have real coefficients, their roots are either real or conjugate pairs. For each conjugate pair, the corresponding first-order factors are combined into a single second-order term:

$$(1 - z_0 z^{-1})(1 - z_0^* z^{-1}) = 1 - (2\mathrm{Re} z_0) z^{-1} + |z_0|^2 z^{-2}$$

Thus we obtain a multiplicative factorization

$$H(z) = \prod_{k=1}^{K} H_k(z) \tag{18}$$

where each $H_k(z)$ is a proper IIR filter or order 2 (for conjugate pairs of poles) or order 1 (for real poles). This results in a cascade connection of the subsystems $H_k(z)$ (Fig. 16). Again, each individual $H_k(z)$ is realized in direct form.

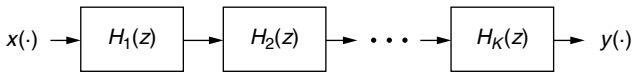

Figure 16. Cascade realization of an IIR digital filter.

There are multiple ways to form the factors $H_k(z)$ in (18), all requiring the same number of delays, multipliers, and adders as the direct-form realization. There are, however, differences in performance between these alternative factorizations, as explained in Section 5.3.

A unified algebraic framework for all possible realizations of a given finite-order transfer function $H(z)$ is provided by the theory of *factored state variable descriptions* (FSVD) [7]. The FSVD is a refinement of the well-known *state-space* description, which describes the relations between the input signal $x(\cdot)$, output signal $y(\cdot)$, and a state vector $s(n)$:

$$\begin{pmatrix} \mathbf{s}(n+1) \\ y(n) \end{pmatrix} = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} \mathbf{s}(n) \\ x(n) \end{pmatrix} \tag{19a}$$

The FSVD refines this characterization by specifying a multiplicative factorization

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \mathcal{F}_K \mathcal{F}_{K-1} \cdots \mathcal{F}_2 \mathcal{F}_1 \tag{19b}$$

that captures the decomposition of the realization into interconnected modules, as in the cascade or parallel realizations. Each $\mathcal{F}_k$ describes a single module, and each module is associated with a subset of the state vector $\mathbf{s}(n)$. The totality of all possible minimal realizations of a given $H(z)$ is captured by the notion of similarity transformations, combined with the added flexibility of factoring the (A, B, C, D) matrix as in (19b).

5.3. Implementation and Performance Attributes

The next stage in the design of a digital filter is *implementation*, that is, the mapping of a selected realization into a specific hardware/software architecture. Since a given transfer function has multiple implementations, which differ in their performance, the choice of a specific implementation should be based on objective performance criteria. Commonly used performance attributes for evaluating implementations include

- *Processing speed* — can be quantified in terms of two distinct attributes: (1) *throughput*, which is the number of input samples that can be processed by the digital filter in a unit of time, and (2) *input–output delay*, which is the duration between the instant a given input sample $x(n_o)$ is applied to the digital filter, and the instant the corresponding output sample $y(n_o)$ becomes available.
- *Numerical accuracy* — the level of error due to finite precision number representation.
- *Hardware cost* — the total number of each kind of basic building blocks, such as delays, multipliers, and adders.
- *Implementation effort* – the amount of work required to map a given realization into a specific hardware/software architecture. Structural attributes of the realization, such as modularity and/or regularity, contribute to the reduction of this effort.

The same attributes can be also used to evaluate the performance of realizations [6,7]. For instance, the direct realization of an IIR digital filter has much poorer numerical accuracy than does either the parallel or the cascade realizations. Similarly, the input–output delay of the parallel realization is somewhat shorter than that of the cascade or direct realizations. Such observations make it possible to optimize the selection of a realization, and to quantify the relative merits of alternative implementations.

6. OPTIMAL AND ADAPTIVE DIGITAL FILTERS

The desired response of classical frequency-selective filters is completely specified in terms of passbands, stopbands, and transition bands. In contrast, optimal filters use detailed information about the frequency content of the desired signal and the interference in achieving maximal suppression of the latter, along with minimal distortion of the former. Since the information needed to construct an optimal filter is typically not available a priori, it is usually estimated online from measurements of the available signals. When this process of frequency content estimation is carried out simultaneously with signal filtering, and the coefficients of the optimal filter are continuously updated to reflect the effect of new information, the resulting linear time-variant configuration is known as an *adaptive filter*.

Fixed frequency-selective filters are appropriate in applications where (1) the desired signal is restricted to known frequency bands (e.g., AM and FM radio, television, frequency-division multiplexing) or (2) the interfering signal is restricted to known frequency bands (e.g., stationary background in Doppler radar, fixed harmonic interference). On the other hand, in numerous applications the interference and the desired signal share the same frequency range, and thus cannot be separated by frequency selective filtering. Adaptive filters can successfully suppress interference in many such situations (see Section 7.2).

6.1. Optimal Digital Filters

Optimal filtering is traditionally formulated in a probabilistic setting, assuming that all signals of interest are *random*, and that their joint statistics are available. In particular, given the second-order moments of two discrete-time (zero-mean) random signals $x(\cdot)$ and $y(\cdot)$, the corresponding mean-square optimal filter, also known as a *Wiener filter*, is defined as the (unique) solution $h_{\text{opt}}(\cdot)$ of the quadratic minimization problem

$$\min_{h(\cdot)} E|y(n) - h(n) \circledast x(n)|^2 \tag{20}$$

where E denotes expectation. If $x(\cdot)$ and $y(\cdot)$ are jointly stationary, the Wiener filter $h_{\text{opt}}(\cdot)$ is time-invariant; otherwise it is a linear time-variant (LTV) filter. The Wiener filter can be applied in two distinct scenarios:

- *Linear mean-square estimation* — an unknown random signal $y(\cdot)$ can be estimated from observations of another random signal $x(\cdot)$. The corresponding estimate $\hat{y}(\cdot)$ is obtained by applying the observed signal $x(\cdot)$ to the input of the Wiener filter, so that $\hat{y}(\cdot) = h_{\text{opt}}(\cdot) \circledast x(\cdot)$.
- *System identification* — the impulse response of an unknown relaxed LTI system can be identified from observations of its input signal $x(\cdot)$ and output signal $y(\cdot)$. In fact, the optimal solution of the Wiener problem (20) coincides with the unknown system response, provided (1) the input signal $x(\cdot)$ is stationary, and is observed with no error and (2) the (additive) error in measuring the output signal $y(\cdot)$ is uncorrelated with $x(\cdot)$.

The unconstrained optimal solution of the Wiener problem (20) is a noncausal IIR filter, which is not realizable (see Section 3.2 for a discussion of realizability). In the case of jointly stationary $x(\cdot)$ and $y(\cdot)$ signals, realizable solutions are obtained by imposing additional constraints on the impulse response $h(\cdot)$ and/or the joint statistics of $x(\cdot), y(\cdot)$:

- When both the autospectrum $S_{xx}(z)$ and the cross-spectrum $S_{yx}(z)$ are rational functions, and the Wiener filter is required to be causal, the resulting Wiener filter is realizable; specifically, it is causal and rational.
- When $x(\cdot)$ and $y(\cdot)$ are characterized jointly by a state-space model, the resulting optimal filter can be described by a state-space model of the same order. This is the celebrated *Kalman filter*.
- Realizability can be enforced regardless of structural assumptions on the joint statistics of $x(\cdot)$ and $y(\cdot)$. In particular, we may constrain the impulse response in (20) to have finite length. This approach is common in adaptive filtering.

The classical Wiener filter is time-invariant, requiring an infinitely long prior record of $x(\cdot)$ samples, and thus is optimal only in steady state. In contrast, the Kalman filter is optimal at every time instant $n \geq 0$, requiring only the finite (but growing) signal record $\{x(k); 0 \leq k \leq n\}$. Consequently, the impulse response of the Kalman filter is time-variant and its length grows with n, asymptotically converging to the classical Wiener filter response. Finally, adaptive filters continuously adjust their estimates of the joint signal statistics, so the resulting filter response remains time-variant even in steady state, randomly fluctuating around the Wiener filter response.

6.2. Adaptive Digital Filters

In practice, the statistics used to construct an optimal filter must also be estimated from observed signal samples. Thus, the construction of an optimal filter consists of two stages:

- *Training Stage*. Finite-length records of the signals $x(\cdot)$ and $y(\cdot)$ are used to estimate the joint (first- and) second-order moments of these signals.

Subsequently, the estimated moments are used to construct a realizable optimal filter.

- *Filtering Stage*. The fixed optimal filter that was designed in the training stage is now applied to new samples of $x(\cdot)$ to produce the estimate $\hat{y}(\cdot)$.

Alternatively, we may opt to continue the training stage indefinitely; as new samples of $x(\cdot)$ and $y(\cdot)$ become available, the estimated statistics and the corresponding optimal filter coefficients are continuously updated. This approach gives rise to an adaptive filter configuration — a linear time-variant digital filter whose coefficients are adjusted according to continuously updated moment estimates (Fig. 17).

Since adaptive filtering requires ongoing measurement of both $x(\cdot)$ and $y(\cdot)$, it can be applied only in applications that involve the system identification interpretation of the Wiener filter. Thus, instead of applying $h_{\text{opt}}(\cdot)$ to $x(\cdot)$ to estimate an unknown signal $y(\cdot)$, adaptive filters rely on the explicit knowledge of both $x(\cdot)$ and $y(\cdot)$ to determine $h_{\text{opt}}(\cdot)$. Once this optimal filter response is available, it is used to suppress interference and extract desired signal components from $x(\cdot)$, $y(\cdot)$ (see Section 7.2).

The most common adaptive filters use a time-variant FIR configuration with continuously adjusting filter coefficients. Such filters take full advantage of the power of digital signal processing hardware because (1) the ongoing computation of signal statistics and optimal filter coefficients usually involves nonlinear operations that would be difficult to implement in analog hardware, and (2) modifications to the updating algorithms can be easily implemented by reprogramming. The most commonly used algorithms for updating the filter coefficients belong to the *least-mean-squares* (LMS) family and the *recursive least-squares* (RLS) family [3].

7. APPLICATIONS IN TELECOMMUNICATION SYSTEMS

Since the early 1980s, digital filtering has become a key component in a wide range in applications. We provide here a brief summary of the main telecommunication applications of digital filters, separated into two categories: (1) *time-invariant digital filters*, which are used to replace analog filters in previously known applications, and (2) *adaptive digital filters*, which enable new applications that were impossible to implement with analog hardware. A detailed discussion of numerous digital filtering applications can be found in the literature [1,4–6].

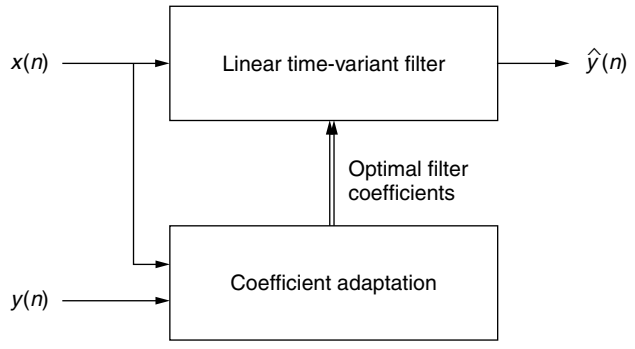

Figure 17. Adaptive filter configuration.

7.1. Time-Invariant Digital Filters

Ongoing improvements in the cost, size, speed, and power consumption of digital filters have made them an attractive alternative to analog filters in a variety of telecommunication applications that require a time-invariant filter response. The main types of such applications are:

- *Frequency-selective filters* — pass (or stop) prespecified frequency bands. Some examples include
  - RF-to-IF-to-baseband conversion in digital wireless systems
  - FDM multiplexing and demultiplexing
  - Subband decomposition for speech and image coding (e.g., MPEG)
  - Doppler radar moving-target indicator (MTI) to remove the nonmoving background
  - Digital spectrum analysis
- *Matched filters/correlators* — have an impulse response that matches a given waveform. Some examples include:
  - Matched filter for symbol detection in digital communication systems
  - Waveform-based multiplexing/demultiplexing (e.g., CDMA)
  - Front-end Doppler radar processing
- *Analog-to-digital and digital-to-analog conversion*
  - Oversampling converters (e.g., sigma–delta modulation)
  - Compact-disk recording and playing
- *Specialized filters* (such as)
  - Hilbert transformers
  - Timing recovery in digital communications (e.g., early–late gate synchronizer)

7.2. Adaptive Digital Filters

As explained in Section 6.2, adaptive filters implement the system identification scenario of the Wiener filter (Fig. 17), requiring two observed signals. Many applications use a variation of this configuration, known as the *adaptive interference canceler*, in which the received signal $y(\cdot)$ is a noisy version of an unknown desired signal $s(\cdot)$, and the so-called "reference signal" $x(\cdot)$ is a filtered version of the interference component of $y(\cdot)$ (Fig. 18).

Two assumptions must be satisfied in order for the adaptive filter to perform well as an interference canceler:

- *Lack of correlation* — the reference signal $x(\cdot)$ should be uncorrelated with the desired signal component of the received signal $y(\cdot)$.
- *FIR response* — the unknown system $H(z)$ should be FIR, and of a known order.

If these two assumptions are met, the estimated $\hat{H}(z)$ matches the true $H(z)$ perfectly, and the effect of

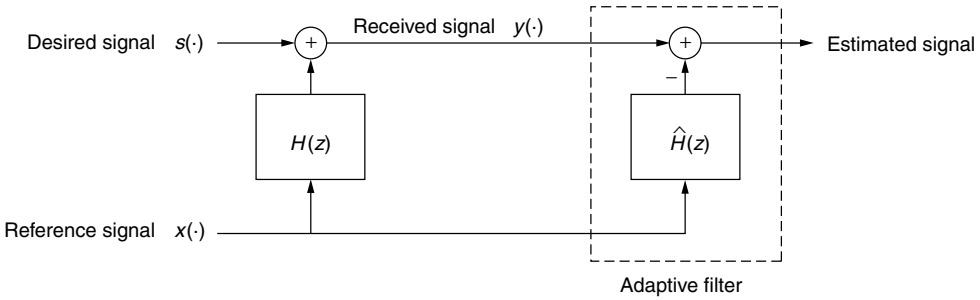

Figure 18. Adaptive interference canceller configuration.

interference is *completely cancelled*. In reality, both assumptions are met only approximately, so that only partial cancellation of the interference is achieved.

The interference cancelling configuration is useful in a variety of specific telecommunication applications, including

- *Echo cancellation* — used in duplex communication systems to suppress interference caused by signal leakage from the incoming far-end signal (the "reference signal" in Fig. 18) to the outgoing local signal (the "desired signal"). Such leakage is common in telephone lines (2W/4W converters), modems, teleconferencing systems and hands-off telephone units.
- *Decision feedback equalization* — used to reduce the effect of intersymbol interference (ISI) in a digital communication channel. Here the "reference signal" is the sequence of previously received symbols, which are assumed to be uncorrelated with the current symbol (the "desired signal"). In order for the equalizer to work correctly, the previously received symbols must be known without error. To meet this requirement, the equalizer alternates between a training phase and a tracking phase. In the training phase a prespecified "training sequence" of symbols is transmitted through the channel, and this information is used by the equalizer to determine the channel estimate $\hat{H}(z)$. In the tracking phase the equalizer uses detected previous symbols to track slow variations in the channel response: as long as the estimated response $\hat{H}(z)$ remains close to the true response $H(z)$, the cancellation of ISI is almost perfect, symbols are detected without error, and the correct "reference signal" is available to the equalizer. Since decision feedback equalization relies on previous symbols, it cannot reduce the ISI caused by the precursors of future symbols — this task is left to the feedforward equalizer.
- *Sidelobe cancellation* — used to modify the radiation pattern of a narrowbeam directional antenna (or antenna array), in order to reduce the effect of strong nearby interferers received through the sidelobes of the antenna. The "reference signal" in this case is obtained by adding an inexpensive omnidirectional antenna; if the interfering RF source is much closer than the source at which the main antenna is pointed, then the reference signal received by the omnidirectional antenna is dominated by the interference, and the lack-of-correlation assumption is (approximately) met.

The *adaptive beamformer* configuration, a variation of the sidelobe-canceling approach, is used to maintain the mainlobe of an antenna array pointed in a predetermined direction, while adaptively reducing the effect of undesired signals received through the sidelobes [3]. It can be used, for instance, to split the radiation pattern of a cellular base-station antenna into several narrow beams, each one tracking a different user.

Another common adaptive filtering configuration is the *adaptive linear predictor*, in which only one observed signal is available (Fig. 19). In this case the "reference signal" is simply a delayed version of the observed signal $y(\cdot)$, so that the Wiener problem (20) now becomes

$$\min_{h(\cdot)} E|y(n) - h(n) \circledast y(n-\Delta)|^2 \tag{21}$$

which is, a Δ-step-ahead linear prediction problem. In some applications the object of interest is the adaptively estimated linear predictor response $\hat{h}(\cdot)$, while in other applications it is the *predicted signal* $\hat{y}(n) = \hat{h}(n) \circledast y(n-\Delta)$, or the *residual signal* $y(n) - \hat{y}(n)$. Telecommunication applications of the linear predictor configuration include

- *Linear predictive coding* (LPC) — used for low-rate analog-to-digital conversion, and has become the standard speech coding method in GSM cellular systems. While the original LPC approach used only the linear predictor response $\hat{h}(\cdot)$ to represent the observed speech signal $y(\cdot)$, current LPC-based speech coders use, in addition, a compressed form of the residual signal $y(n) - \hat{y}(n)$ [6].
- *Adaptive notch filter* — used to suppress sinusoidal interference, such as narrowband jamming in spread-spectrum systems. Since spread-spectrum signals resemble broadband noise, which is almost completely unpredictable, while sinusoidal signals are

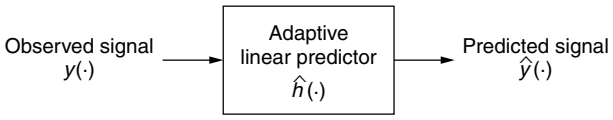

Figure 19. Adaptive linear predictor configuration.

perfectly predictable, the adaptive linear predictor response is almost entirely dominated by the sinusoidal component of the observed signal $y(\cdot)$. As a result, one can use the adaptive linear predictor configuration to suppress sinusoidal components or, with a minor modification, to enhance sinusoidal components.

- *Feedforward equalizer* — used to reduce the effect of ISI from precursors of future symbols. This is made possible by the fact that the adaptive linear predictor tends to render the equalized channel response minimum phase, thereby reducing the length of precursors. This minimum-phase property is an intrinsic characteristic of the MSE linear predictor defined by (21).

BIOGRAPHY

Hanoch Lev-Ari received the B.S. (summa cum laude) and the M.S. degrees in electrical engineering from the Technion, Israel Institute of Technology, Haifa, Israel in 1971 and 1976, respectively, and the Ph.D. degree in electrical engineering from Stanford University, Stanford, California, in 1984. During 1985 he held a joint appointment as an Adjunct Research Professor of Electrical Engineering with the Naval Postgraduate School, Monterey, California and as a Research Associate with the Information Systems Laboratory at Stanford. He stayed at Stanford as a Senior Research Associate until 1990. Since 1990 he has been an Associate Professor with the Department of Electrical and Computer Engineering at Northeastern University, Boston, Massachusetts. During 1994–1996 he was also the Director of the Communications and Digital Signal Processing (CDSP) Center at Northeastern University. Dr. Lev-Ari has over 100 journal and conference publications. He served as an Associate Editor of *Circuits, Systems and Signal Processing*, and of *Integration, the VLSI Journal*. His areas of interest include model-based spectrum analysis and estimation for nonstationary signals, scale-recursive (multirate) detection and estimation of random signals, Markov renewal models for nonstationary signals, and adaptive linear and nonlinear filtering techniques.

DIGITAL OPTICAL CORRELATION FOR FIBEROPTIC COMMUNICATION SYSTEMS

JOHN E. MCGEEHAN

University of Southern California
Optical Communications Laboratory
Los Angeles, California

1. INTRODUCTION

As bit rates continue to rise in the optical core of telecommunication networks [toward $\geq$40 Gbps (gigabits per second)], the potential inability of electronic signal processors to handle this increase is a force driving research in optical signal processing. Correlation, or matched filtering, is an important signal processing function. The purpose of a correlator is to compare an incoming signal with one that is "stored" in the correlator. At the appropriate sample time, a maximum autocorrelation peak will be produced if the input signal is an exact match to the stored one. This function is typically used to pick a desired signal out of noise, an essential requirement for radar and wireless CDMA systems. As telecommunication systems tend toward the use of optical fiber as the preferred transmission medium, optical CDMA networks are receiving greater attention and will require the use optical correlator implementations.

In present-day fiberoptic networks, data packets are converted to electrical form at each node to process their headers and make routing decisions. As routing tables grow in size, this is becoming a predominant source of network latency. The advent of optical correlation could enable packet headers to be read at the speed of light by simply passing the packets through a bank of correlators, each configured to match a different entry in the routing table. Simple decision logic could then configure a switch to route each packet according to which correlator produced a match. Thus, with the growing demand for all-optical networking functions, there is a strong push to develop practical and inexpensive optical correlators that can identify high-speed digital bit patterns on the fly and with minimal electronic control.

2. DIGITAL OPTICAL CORRELATION

The term "correlator" is typically used to describe a hardware implementation of a matched filter. Although there exist strict definitions for matched filters versus correlators, most hardware implementations that produce the same output as a matched filter, sampled at the peak autocorrelation value, are referred to as "correlators." The detailed theory of matched filters and correlation is presented in most textbooks on communication systems [1]. The aim here is to give a brief overview of the concepts that apply to the correlation of digital binary waveforms modulated onto optical carriers. This presents a unique case in that the data bits in an optical communication system are most commonly represented by the optical

power of the signal as opposed to a voltage as in electrical systems. Consequently, the digital waveforms consist of only positive values (a "unipolar" system), causing the correlation function of any two optical signals to be a completely nonnegative function. This creates some limitations for systems that transmit specially designed sets of codewords intended to have good autocorrelation properties; thus, a large autocorrelation peak when the incoming signal is synchronized with the receiver and matches the desired codeword and a low, ideally zero, level for all other codewords, for all possible shifts in time [2]. Sets of codewords with these properties are termed *orthogonal codes*. It is possible with optical phase modulation to achieve a bipolar system, but this requires a coherent receiver, which is far more complex to implement in optics than the standard direct intensity detection receivers.

Just as with electronics, prior to the development of high-speed digital signal processors, a common implementation of an optical correlator is the tapped-delay line. A basic implementation of an optical tapped-delay line is shown in Fig. 1a. The delay line is configured to match the correlation sequence 1101. Thus, the delay line requires four taps (one for each bit in the desired sequence), weighted by the factors 1, 1, 0 and 1, respectively. The weights are implemented by placing a switch in each path that is closed for weight = 1, and opened for weight = 0. The incoming optical bit stream is equally split among the four fiberoptic delay lines. Each successive delay line adds one additional bit of delay to the incoming signal before the lines are recombined, where the powers of the four signals are added together to yield the correlation output function. This function is sampled at the optimum time, T_s, and passed through a threshold detector that is set to detect a power level above 2 since the autocorrelation peak of 1101 with itself equals 3 (or more specifically, 3 times the power in each 1 bit). This threshold detection may be implemented either electronically or optically, although optical threshold detection is still a nascent research area requiring further development to become practical. Electronically, the output is detected with a photoreceiver and a simple decision circuit is used to compare the correlation output to the threshold value. The high-speed advantage of optics still prevails in this case since the correlation function is produced in the time it takes the signal to traverse the optical correlator, and the decision circuit only needs to be triggered at the sample-rate, which is often in the kilohertz–megahertz range, depending on the number of bits in each data packet or codeword. The mathematical function describing the tapped-delay-line correlator is

$$y(t) = \sum_{k=0}^{N-1} x(t - kT_{\text{bit}})h(kT_{\text{bit}}) \tag{1}$$

where N is the number of bits in the correlation sequence, T_{bit} is one bit period, $x(t - kT_{\text{bit}})$ is the input signal delayed by k bit times, and $h(kT_{\text{bit}})$ represents the k weights that multiply each of the k-bit delayed input signals. For a phase-modulated system, the same operation can be performed by replacing the switches with the appropriate optical phase shifters to match the desired codeword (e.g., $\pi\pi 0\pi$ instead of 1101). Figure 1b illustrates the delay-and-add operation of the correlator for the case when the three 4-bit words 1010, 1011, and 1101 are input to the correlator, where the second word is an exact match to the desired sequence. Since the correlation function for two 4-bit words is 7 bits long and the peak occurs during the fourth time slot, the correlation output is sampled every 4 bits and compared to a threshold as shown in Fig. 1c. As expected, the correlation output for the second word exceeds the threshold while the first and third samples produce no

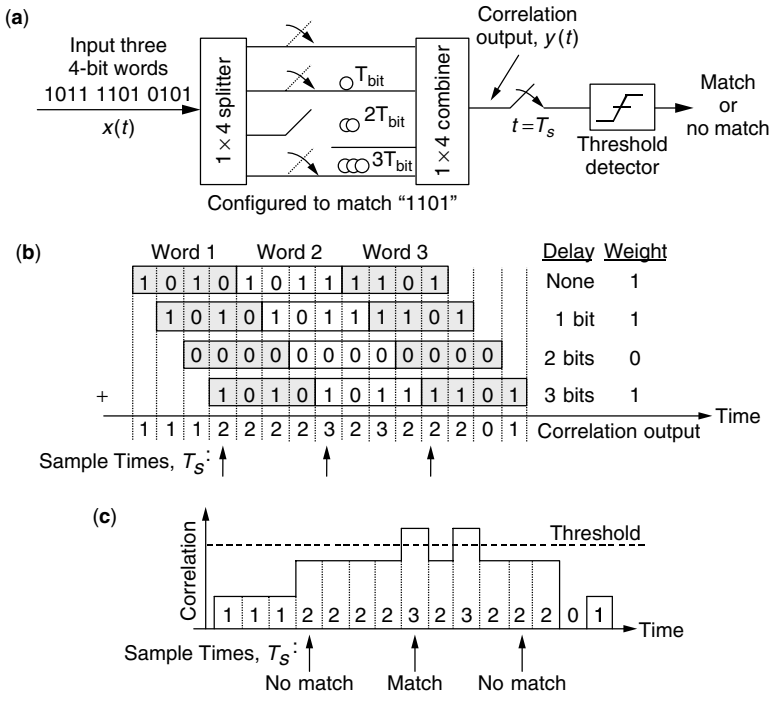

Figure 1. (**a**) A basic implementation of a fiberoptic tapped-delay-line correlator configured to produce an autocorrelation peak at the sample time, T_s, for the sequence 1101; (**b**) the weighted delay-and-add computation of the digital correlation output for three input words when correlated with the bit pattern 1101 (the three optimum sample times are labeled); (**c**) an intensity profile of the correlation output from this tapped-delay-line correlator. Only when the intensity is above the threshold at the sample time is a match signal produced.

matches. Note that for an input signal L bits long, the length of the correlation output will be $L + N - 1$ bits long.

It should also be noted that the correlator as shown will also produce a level 3 peak that is above the threshold at time T_s for a 1111 input, which is not the desired codeword. This is because the open switch in the third delay line, corresponding to the third correlation bit, does not care if the third bit is a 1 or a 0 since it does not pass any light. Thus, the correlator as shown is really configured to produce a match for the sequence $11x1$, where the x indicates a "don't care" bit that can either be 0 or 1. In many cases, such as in optical CDMA systems, the set of all possible codewords used in the system is specifically designed to always have a constant number of 1 bits so that this is not an issue. But, for cases in which the correlator must identify a completely unique sequence, the present correlator must be augmented with, for example, a second, parallel tapped-delay line that is configured in complement to the first one (the switches are closed for desired 0 bits and open otherwise), and produces a "match" signal when zero power is present at the sample time. Then, the incoming signal is uniquely identified only when both correlators produce a match. This configuration will be discussed later in further detail.

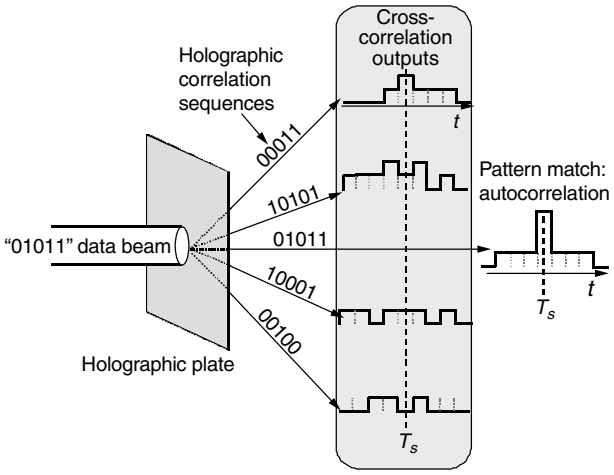

Figure 2. A collimated 01011 input beam in free space impinges on an optical angular multiplexed spectral holographic (AMSH) plate that is programmed to recognize five different correlation sequences. Each correlation sequence corresponds to a different scattering angle from the plate. Only the direction corresponding to a pattern match (01011) produces an intensity autocorrelation peak that will be above threshold at the sample time, while the rest produce cross-correlation outputs.

3. OPTICAL CORRELATOR IMPLEMENTATION

Digital optical correlators can be fabricated using free-space optics, fiber-based devices, and fiber-pigtailed crystals or semiconductors. Four varieties of optical correlators will be reviewed here, including (1) a free-space holographic correlator, (2) a fiberoptic correlator using separate fiber delay lines terminated with mirrors, (3) a single-fiber device with periodically spaced fiber Bragg gratings (FBGs) to provide time-delayed reflections, and (4) an optical phase-correlator implemented using FBGs. The first three of these correlators are explained assuming optical intensity-modulated correlation sequences. However, most can be modified to act as phase-coded correlators as well. No assumptions are made regarding any special data coding schemes.

One example of a free-space optical correlator employs spectral holography to create a correlating plate that is able to correlate an incoming bit stream with several correlation sequences simultaneously. The correlation sequences are encoded using an angular multiplexed spectral hologram (AMSH). The hologram acts upon the incoming modulated lightbeam to produce a correlation output [3]. The incoming bit pattern is spread out in the frequency domain using a grating, collimated by a lens and then sent through the AMSH plate, which is coded for a finite number of possible correlation patterns. The hologram is written using a 632.8-nm helium–neon laser and a photosensitive holographic plate and is designed to operate at signal wavelengths around 1550 nm (a standard fiberoptic communication wavelength). Each desired correlation sequence is written onto the holographic plate such that each pattern corresponds to a different diffraction angle. Figure 2 shows an input datastream of 01011 scattering off an AMSH plate. The correlation outputs corresponding to each correlation sequence are produced at different scattering angles at the output. As the number of correlation patterns increases, the difference between the output angles for each pattern decreases. At each diffraction angle, either an autocorrelation or cross-correlation output is produced, with the autocorrelation output appearing only at the diffraction angle corresponding to a matched correlation pattern, and cross-correlation outputs appearing at all other angles. A second grating can also be used to reroute any diffracted light back into an optical fiber for continued transmission. Otherwise, photodetectors may be placed at each diffraction angle to detect the correlation outputs. This free-space correlation method has a number of potential advantages over the fiber-based correlators that are detailed below, including the potential low size and cost associated with having one hologram that can correlate with many bit patterns simultaneously. However, further research is required on low-loss holographic materials at standard fiberoptic communication wavelengths, as the loss for the material used for this demonstration can exceed 80 dB due to high absorption at these frequencies.

To avoid the losses associated with exiting and reentering the fiber medium, a reconfigurable optical correlator that operates entirely within optical fibers is highly desirable for fiberoptic communication systems. In addition to the optical tapped-delay-line structure described in Fig. 1, a similar device may be constructed, except that each fiber branch is terminated with a fiber mirror (a metallic coating on the fiber end face), thereby providing a double pass through the delay lines and using the splitter also as a recombiner (see Fig. 3) [4]. The double pass requires that the relative delays be halved and an optical circulator must be added at the input to route the counterpropagating correlation output to the threshold detector. Aside from these differences, the operation of the correlator is identical to that described for Fig. 1. The

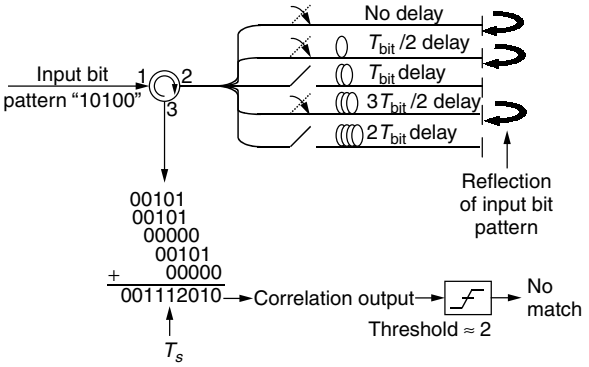

Figure 3. A fiberoptic delay line correlator in which each branch is terminated with a fiber mirror. The correlator is configured for the correlation sequence 11x1x, where the switches are closed to represent 1 bits and opened to indicate "don't care" bits, meaning that the peak of the output correlation function at time T_s will be the same regardless of whether the "don't care" bits are ones or zeros. The correlation output for an input pattern of 10100 is 001112010. The level 1 output at the sample time does not exceed the threshold and produces no match.

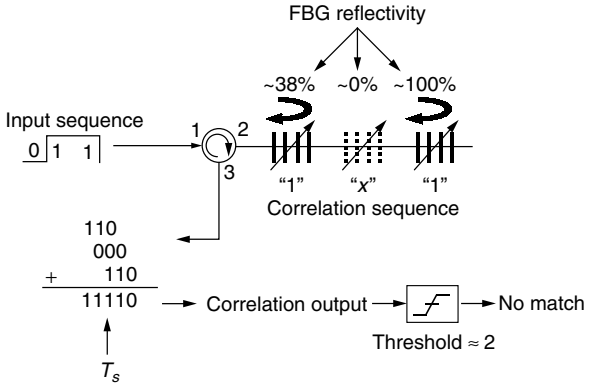

Figure 4. A fiber Bragg grating (FBG)–based optical correlator in which the correlation sequence is programmed by tuning the reflectivities of the gratings such that desired 1 bits reflect and "don't care" bits do not reflect. The cross-correlation output 11110 is the result of the correlation between the input sequence 011 and the programmed sequence 1x1. The output is sampled at time T_s and a threshold detector produces a "no match" decision.

fiber-mirror-based correlator shown in Fig. 3 is configured to recognize the correlation sequence 11010 (or more accurately, 11x1x, since the open switches represent "don't care" bits) by closing the first, second and fourth switches and setting the threshold just below a level 3. The figure shows the output cross-correlation function for the input sequence 10100, which will not produce a correlation peak above the threshold at the sample time.

A set of fiber Bragg gratings (FBGs) can also be used to construct an effective fiber-based optical correlator. An FBG is fabricated by creating a periodic variation in the fiber's index of refraction for a few millimeters to a centimeter of length along the fiber core [5]. Since optical fiber is photosensitive at ultraviolet frequencies, the grating can be written by illuminating the fiber from the side with the interference pattern of two ultraviolet laser beams. A conventional FBG acts as a reflective, wavelength-selective filter; that is, it reflects light at a particular wavelength that is determined by the spatial period of the index grating, and passes light at all other wavelengths. The bandwidth of the FBG filter depends largely on the magnitude of the index variation and is typically designed to be $<$100 GHz (0.8 nm) for communications applications. A nice feature of FBG filters is that the reflection spectrum can be adjusted by a few nanometers via heating or stretching of the grating. This allows one to alter the wavelength that the FBG reflects. The reflectivity of the grating is nearly 100% at the center of the reflected spectrum and falls off outside the grating bandwidth. By tuning the FBG so that the signal wavelength intersects with the rising or falling edge of the passband, the reflected energy at that wavelength will be reduced from 100% toward 0% as the grating's passband is tuned farther away.

Although it is possible to produce an optical correlator using FBGs to simply replace the fiber mirrors described above, the only advantage to this would be that the optical switches could be removed and the FBGs could simply be tuned *not* to reflect the incoming wavelength to represent the case of an open switch. However, the fact remains that this tapped-delay-line structure requires many separate branches of optical fiber, each precisely cut to provide delay differences as small as $\frac{1}{2}$ of a bit time, which is only 1 cm in fiber length at 10 Gbps. Using FBGs, a more compact, producible and manageable correlator can be produced [6]. The procedure for writing gratings into fibers makes it relatively simple to write several FBGs into a single fiber with precise control down to centimeter spacings (see Fig. 4). Using separate piezoelectric crystals or small heaters, each FBG can be independently stretched or heated to tune its reflection spectrum. Now the tapped-delay line may be implemented within a single piece of fiber, again with a circulator at the input to route the correlation output to the threshold detector. The FBG-based correlator shown in Fig. 4 is configured to recognize a bit pattern of 101 (or, more accurately, 1x1). This is accomplished by writing three gratings in a row, with center-to-center spacings equal to $\frac{1}{2}$ of a bit time in fiber so that the round-trip time between gratings corresponds to a 1-bit delay. The reflectivity of the third grating is ideally 100% since it is the last "mirror" in the series. The reflection spectrum of the second grating is tuned away from the incoming signal wavelength so that it will simply transmit the light and there will be no reflection for the $2T_{bit}$ delay. This is the equivalent of the "open switch" in the previous configuration. The first grating must then be tuned to only partially reflect the incoming light so that the remaining light can pass through to reflect off the third grating. The reflectivity of the first grating must be chosen carefully to guarantee that the pulses reflecting off the first grating have power equal to that of those that reflect off the third grating. In practice this can be determined by repeatedly sending a single pulse into the FBG array and observing the powers of the two, time-delayed output pulses on an oscilloscope (the two gratings will reflect the input pulse at different times, creating two pulses at the output). The first FBG can then be tuned until the two

pulses have equal power. The required reflectivities of the gratings in the array can also be calculated. Assume that there are n gratings in the array that represent 1 bits and therefore must provide some partial reflection of the incoming signal. Let the reflectivities of each grating be R_n (e.g., if $R_n = 0.4$, then the grating will reflect 40% of the incoming light and transmit the remaining 60% since $1 - R_n = 0.6$). Then the equation to determine the reflectivities needed to achieve equal output powers of all the time-delayed output pulses is

$$\frac{R_n}{(1-R_n)^2} = R_{n+1} \tag{2}$$

Thus, the reflectivity of the last grating in the array should be set equal to 1, and then the reflectivities of all the preceding gratings can be calculated using this recursive equation. For the case shown in Fig. 4, with $R_3 = 1$, we get $R_1 = (1 - R_1)$, which results in $R_1 = 38\%$. The cross-correlation output for the case of an input sequence of 011 is depicted in Fig. 4. Limitations of this method due to the increasing attenuation of the signal as it makes a double pass through the series of gratings will be discussed in the following section.

By replacing the switches or reflectivity-tuned FBGs in the previous configurations with phase shifters or phase-encoded FBGs, the fiber-based optical intensity correlators described above can be used as phase correlators instead [7]. The holographic correlator may also be adapted to correlate with phase-encoded signals. For these cases, the correlation sequences are a series of phase shifts such as $0\pi\pi00\pi0\pi$, for an 8-bit codeword. As long as the incoming codeword contains the same phase shifts, an autocorrelation peak will result. There are several methods of generating optical codewords containing such a series of phase shifts. One all-fiber method utilizes a single FBG, 4 cm long, with seven very thin wolfram wires (diameter = 25 μm) wrapped around the grating every 5 mm [8]. The 5 mm spacing provides a 50-ps round-trip delay, corresponding to 1 bit time at 20 Gbps, and the 7 wires mean that this correlator can recognize an 8-bit phase-encoded sequence. By passing a current through one of the wires, the FBG will be heated at only that point in the grating, causing the signal being reflected by the FBG to experience a phase shift at the time delay corresponding to the location of the wire. The heat-induced phase shift occurs because the index of refraction of the glass fiber is temperature-sensitive. Note that only point heating is desired here to induce the phase shifts — it is not the aim to shift the grating's reflection spectrum, which would occur if the entire grating were heated. This device may be used to both generate phase-encoded signals at the transmitter and to correlate with them at the receiver. The most common application of optical phase correlators is to construct optical CDMA encoders and decoders. One possible advantage of phase modulation over intensity modulation is the potential for multilevel coding. While intensity modulation coding primarily uses on/off keying (OOK), where a 1 bit is represented by the presence of light and a 0 bit by the absence of it, phase coding need not utilize phase shifts of only 0 and π. For example, another article demonstrated four-level encoding, using phase shifts of 0, $\pi/2$, π, and $3\pi/2$ [9].

This is merely a sampling of the available optical correlator designs, specifically concentrating on those that are easily compatible with fiberoptic telecommunication systems and provide easy-to-understand illustrations of optical correlators. However, many other novel correlator configurations have been developed in research labs. These include correlators based on semiconductor optical amplifiers (SOA) [10], erbium-doped fibers (EDFs) [11], optical loop mirrors [12], and nonlinear optical crystals [13].

4. IMPLEMENTATION CHALLENGES

While the previous section detailed some of the more common optical correlator structures, there are a number of roadblocks facing optical correlators that keep them from seeing wide use beyond research environments. However, a number of advances not only begin tackling these roadblocks but also aim to decrease the cost and increase the commercial viability of optical correlators.

A driving motivation for research in optical signal processing is the fact that electronics may at some point present a bottleneck in telecommunication networks. Optical signals in commercial networks currently carry data at 2.5 and 10 Gbps and in research environments, at 10, 40, and even 160 Gbps. At these higher speeds, either electronic circuits will be unable to efficiently process the data traffic, or it may actually become more economical to use optical alternatives. However, optical techniques also face significant hurdles in moving to 40 Gbps and beyond. In particular, optical correlators that rely on fiberoptic delays require greater fabrication precision as the bit rate rises. At 40 Gbps, a single bit time is 25 ps, corresponding to 0.5 cm of propagation in standard optical fiber. For the fiber-mirror-based correlator, the differences in length of the fiber branches must equal a $\frac{1}{2}$ of a bit time delay, or 2.5 mm — an impractically small length. The FBG-based correlator has an additional problem in that not only must the gratings have a center-to-center spacing of 2.5 mm at 40 Gbps, but the gratings themselves are often longer than 2.5 mm. While it is possible to make FBGs that are only 100s of micrometers long, the shorter length will make it difficult, but not impossible, to achieve a high-reflectivity grating with the appropriate bandwidth to reflect the higher data-rate signal. Furthermore, there must be some method to provide precise tuning of the closely spaced individual FBGs. One report [14] demonstrated a grating-based tapped-delay line correlator created from a single FBG. A periodically spaced series of thin-film metallic heaters were deposited on the surface of the FBG to effectively create several tunable FBGs from one long one. By passing individual currents through the heaters, the reflection spectrums for the portions of the FBG beneath the heaters are tuned away. Since the heaters can be deposited with essentially lithographic precision, this resolves the issue of how to precisely fabricate and tune very closely spaced FBGs. Of course, this technique will eventually be limited by how closely spaced the heaters can be before thermal crosstalk between neighboring elements becomes a significant problem. Spectral holography is perhaps one of the more promising techniques for higher bit rates, as it is currently

feasible (albeit expensive) to create holographic plates that can correlate with high-speed signals. However, the high absorption loss of current free-space holographic correlators at communication wavelengths remains a roadblock to any practical implementation.

Coherence effects can also present problems in optical correlators that utilize tapped-delay-line structures in which the light is split into several time-delayed replicas that are recombined at the correlator output. The coherence time of standard telecommunication lasers is typically tens of nanoseconds, corresponding to a coherence length in fiber of ~2 ms. When the differential time delay between two branches of the correlator is less than the coherence time of the laser (which is clearly the typical case), then the recombined signals will coherently interfere with each other, causing large power fluctuations in the correlation output function. This effect destroys the correlation output and must be mitigated or prevented in order to effectively operate the correlator. There are a number of ways that this problem can be solved. A polarization controller followed by a polarization beamsplitter (PBS) can be used at the input of each 1×2 optical splitter/combiner to ensure that the electric field polarizations between the two branches are orthogonal. This will prevent coherent interference of the recombined signals because orthogonally polarized lightbeams will not interfere with each other. Thus, for more than two branches, a tree structure of 1×2 splitters with polarization controllers and polarization beamsplitters can be used. Another, more manageable, solution is to somehow convert the coherent light into an incoherent signal before entering the correlator. One method of doing this uses cross-gain modulation in a semiconductor optical amplifier (SOA) to transfer the coherent data pattern onto incoherent light, which in this case is the amplified spontaneous emission light generated by the SOA [15].

An additional problem facing the grating-based correlator is the severe optical losses associated with multiple passes through the FBGs. This can so significantly limit the length of the correlation sequence that it can realistically correlate with before the power in the correlation output pulses are so low that they drop below the system noise floor. As explained before, the reflectivities of the gratings are determined by the need to equalize the pulses reflecting off of each grating representing a 1 bit, while recognizing that the pulses are attenuated with each pass through each grating. With four 1 bits in a correlation sequence, only ~65% of the incident light is present in the total correlation output. The rest is lost as a result of multiple reflections within the correlator, as the reflection off an internal grating can reflect again on the return trip and will no longer fall within the correlation time window. These multiple internal reflections do cause undesired replicas of the signal to add to the correlation output function, but they are so attenuated by the multiple reflections that they are not typically considered a significant impairment. As the number of 1 bits increases, the correlation sensitivity will decrease as more light is lost to these reflections. One method to mitigate this problem is to interleave the gratings between multiple fiber branches [6]. For the 4-bit sequence, two branches, each with two gratings, preceded by a splitter, can be used instead of a single row of gratings, thereby increasing the efficiency (assuming that all gratings are 1 bits) to ~75% of the incident light. This solution also alleviates the difficulty of spacing the gratings very closely together since only every other grating is on each branch, at the cost of introducing coherence effects that must be mitigated.

5. ADVANCED TOPICS

As wavelength-division-multiplexed (WDM) systems are becoming the standard in optical networks, it is becoming increasingly desirable to build modules that can act on multiple wavelength channels simultaneously. To this end, there is a growing interest in multiwavelength optical correlators. One study of a multiwavelength optical correlator uses sampled FBGs in a grating-based correlator structure. The reflection spectrum of a sampled FBG possesses multiple passbands so that it can filter several wavelength channels simultaneously [16]. When this type of FBG is stretched or heated, the entire reflection spectrum shifts, causing the reflectivity at each wavelength to experience the same variation. Thus, by replacing the standard FBGs with sampled FBGs in the correlator structure described previously, incoming signals on multiple wavelengths can simultaneously be correlated with a single correlation sequence. While it may still be necessary to demultiplex these channels prior to detection in order to check the correlation output for each channel, this technique still significantly reduces the number of components that would otherwise be required in a system that provided a separate correlator for each wavelength.

In Section 2, we mentioned that the conventional N-bit optical tapped-delay-line correlator cannot be configured to uniquely identify all 2^N possible bit patterns. This is because a 0 bit is represented by an open switch or a grating that is tuned not to reflect any light. This really means that these bit positions are considered "don't care" bits and the desired autocorrelation peak will result at the sample time whether the "don't care" bits are 1s or 0s. This is not an issue in optical CDMA systems, where the set of codewords can be specifically designed to maintain a constant number of 1 bits in each codeword. However, for applications that must be able to uniquely recognize any of the 2^N possible N-bit sequences, this situation will result in false-positive matches whenever a 1 is present where a 0 bit is desired. This is important for applications such as packet header or label recognition. A solution to this problem is to add a second correlator that is configured in complement to the first one and produces a "match" signal when *zero* power is present at the sample time. This is accomplished by placing a NOT gate at the output of the threshold detector which is set just above level zero. If the power goes above the threshold, this indicates that at least one 1 bit is present where a 0 is desired, and the NOT gate will convert the high output to a low one to indicate "no match" for this correlator. This correlator therefore correlates with the desired 0 bits in the sequence and is thus called a "zeros" correlator. Likewise, the originally described correlator is called a "ones" correlator. In the zeros correlator, the switches are closed for desired 0 bits

and open otherwise (or the FBGs reflect for desired 0 bits and are tuned away otherwise). Thus, the 1 bits are "don't care" bits in a zeros correlator. By combining the outputs of the ones and zeros correlators with an AND gate, the input sequence will only produce a final "match" signal when the input pattern uniquely matches the desired correlation sequence. An illustration of how the combination of a ones and a zeros correlator can avoid false positive matches is depicted in Fig. 5. The desired correlation sequence is 1001, meaning that the ones correlator is configured to match a 1xx1 pattern and the zeros correlator will produce a match for an $x00x$ pattern. In Fig. 5a, the incoming sequence is 1001, and so the ones and zeros correlators both produce "match" signals, resulting in a "match" signal at the output of the AND gate. In Fig. 5b, the input sequence is a 1101, causing the ones correlator to still produce a "match" signal (this would be a false-positive match if only this correlator were used). But the undesired 1 bit in the second time slot of the input sequence causes the power at the sample time in the zeros correlator to go above threshold, resulting in a "no match." The combination of the "match" and "no match" signals in the AND gate produce the correct "no match" result.

6. CONCLUSION

While optical correlators currently see limited commercial application, the frontier of all-optical networking is rapidly approaching, aided by the ever-increasing demand to transmit more bandwidth over the network core. This, in addition to the growing interest in optical CDMA networks, will push designers to develop producible optical correlators that can be dynamically adjusted to recognize very high bit-rate sequences. For applications such as header or label recognition, technologies that can implement huge arrays or banks of correlators to efficiently test the incoming signal against all possible bit sequences will be needed. Reaching these goals presents a significant engineering challenge, but research is continuing to make progress, and optical correlators, combined with the appropriate data coding techniques, offer great potential for bringing the ever-expanding field of optical signal processing to light.

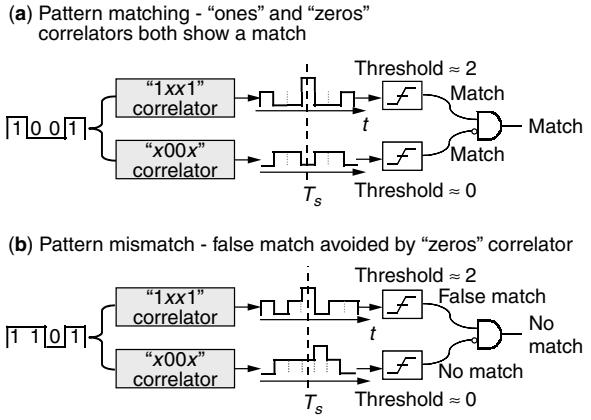

Figure 5. The concept of combining 1s and 0s correlators to uniquely recognize a bit sequence and avoid false-positive matches. The "ones" correlator tests for 1 bits in the correlation sequence and the "zeros" correlator tests for 0 bits. The correlators shown are configured to recognize a 1001 pattern when their outputs are combined in an AND gate. (**a**) The input pattern 1001 results in a match for both correlators, producing a final "match" decision at the output. (**b**) The input pattern 1101 results in a match for the "ones" correlators but a "no match" for the "zeros" correlator. The combination of these two outputs produces the correct "no match" decision at the output of the AND gate.

BIOGRAPHIES

John E. McGeehan received his B.S. and M.S. degrees in electrical engineering at the University of Southern California in Los Angeles in 1998 and 2001, respectively. He joined the Optical Communications Laboratory at the University of Southern California as a research assistant in 2001 and currently is working toward his doctorate. His research interests include the implementation of all-optical networking functions and optical signal processing as well as Raman amplification and signal monitoring. He is an author or co-author of nine technical papers.

Michelle C. Hauer received the B.S. degree in engineering physics from Loyola Marymount University, Los Angeles, California, in 1997. She currently is a research assistant in the Optical Fiber Communications Laboratory at the University of Southern California, Los Angeles, California, where she received the M.S.E.E. degree in 2000. Her doctoral research includes optical signal processing techniques for implementing all-optical networking functions. She is the author or co-author of more than 13 research papers. She is a member of the Tau Beta Pi, Eta Kappa Nu, and Sigma Pi Sigma academic honor societies in engineering, electrical engineering, and physics, respectively. She has also held a position as a systems engineer at Raytheon Company in El Segundo, California since 1997.

Alan Willner received his B.S. from Yeshiva University and his Ph.D. from Columbia University. He has worked at AT&T Bell Labs and Bellcore, and is Professor of Electrical Engineering at the University of Southern California. Professor Willner has received the following awards: the National Science Foundation (NSF) Presidential Faculty Fellows Award from the White House, the Packard Foundation Fellowship, the NSF National Young Investigator Award, the Optical Society of America (OSA) Fellow Award, the Fulbright Foundation Senior Scholars Award, the Institute of Electronic and Electrical Engineers (IEEE) Lasers and Electro-Optics Society (LEOS) Distinguished Traveling Lecturer Award, the USC/TRW Best Engineering Teacher Award, and the Armstrong Foundation Memorial Prize. His professional activities have included: editor-in-chief of the IEEE/OSA *Journal of Lightwave Technology*, editor-in-chief of the IEEE *Journal of Selected Topics in Quantum Electronics*, V.P. for Technical Affairs of the IEEE LEOS, Co-Chair of the OSA Science and Engineering Council, Elected Member of the IEEE LEOS Board of Governors, Program Co-Chair of the Conference on Lasers and Electro-Optics (CLEO), General Chair of the LEOS Annual Meeting Program, Program Co-Chair of the OSA Annual Meeting, OSA Photonics Division Chair,

General Co-Chair of the OSA Optical Amplifier Meeting, and Steering and Program Committee Member of the Conference on Optical Fiber Communications (OFC). Professor Willner has 325 publications, including one book.

DIGITAL PHASE MODULATION AND DEMODULATION

FUQIN XIONG
Cleveland State University
Cleveland, Ohio

1. INTRODUCTION

Digital signals or messages, such as binary 1 and 0, must be modulated onto a high-frequency carrier before they can be transmitted through some communication channels such as a coaxial cable or free space. The carrier is usually an electrical voltage signal such as a sine or cosine function of time t

$$s(t) = A\cos(2\pi f_c t + \theta)$$

where A is the amplitude, f_c is the carrier frequency, and θ is the initial phase. Each of them or a combination of them can be used to carry digital messages. The total phase $\Phi(t) = 2\pi f_c t + \theta$ can also be used to carry digital messages. The process that impresses a message onto a carrier by associating one or more parameters of the carrier with the message is called *modulation*; the process that extracts a message from a modulated carrier is called *demodulation*.

There are three basic digital modulation methods: amplitude shift keying (ASK), frequency shift keying (FSK), and phase shift keying (PSK). In ASK, data 1 and 0 are represented by the presence and absence of a burst of the carrier sine wave, respectively. The burst of the carrier that lasts a duration of a data period is called a *symbol*. The frequency and phase of the carrier are kept unchanged from symbol to symbol. In FSK, data 1 and 0 are represented by two different frequencies of the carrier, respectively. The amplitude and phase of the carrier are kept unchanged from symbol to symbol. In PSK, data 1 and 0 are represented by two different phases (e.g., 0 or π radians) of the carrier, respectively. The amplitude and frequency of the carrier are kept unchanged from symbol to symbol.

Modulation schemes are usually evaluated and compared using three criteria: *power efficiency, bandwidth efficiency, and system complexity*.

The bit error probability (P_b), or bit error rate (BER), as it is commonly called, of a modulation scheme is related to E_b/N_0, where E_b is the energy of the modulated carrier in a bit duration, and N_0 is the noise power spectral density. The *power efficiency* of a modulation scheme is defined as the required E_b/N_0 for a certain bit error probability (P_b), over an additive white Gaussian noise (AWGN) channel.

The *bandwidth efficiency* is defined as the number of bits per second that can be transmitted in one hertz (1 Hz) of system bandwidth. System bandwidth requirement depends on different criteria. Assuming the system uses

Nyquist (ideal rectangular) filtering at baseband, which has the minimum bandwidth required for intersymbol-interference (ISI)-free transmission of digital signals, then the bandwidth at baseband is $0.5R_s$, where R_s is the symbol rate, and the bandwidth at carrier frequency is $W = R_s$. Since $R_s = R_b/\log_2 M$, where R_b is the bit rate, for M-ary modulation, the bandwidth efficiency is

$$\eta_B = \frac{R_b}{W} = \log_2 M \quad \text{(bps/Hz) (Nyquist)}$$

This is called the Nyquist bandwidth efficiency. For modulation schemes that have power density spectral nulls such as the ones of PSK in Fig. 2, the bandwidth may be defined as the width of the main spectral lobe. Bandwidth efficiency based on this definition of bandwidth is called null-to-null bandwidth efficiency. If the spectrum of the modulated signal does not have nulls, null-to-null bandwidth no longer exists, as in the case of continuous-phase modulation (CPM). In this case, energy percentage bandwidth may be used as a definition. Usually 99% is used, even though other percentages (e.g., 90%, 95%) are also used. Bandwidth efficiency based on this definition of bandwidth is called percentage bandwidth efficiency.

System complexity refers to the circuit implementation of the modulator and demodulator. Associated with the system complexity is the cost of manufacturing, which is, of course, a major concern in choosing a modulation technique. Usually the demodulator is more complex than the modulator. A coherent demodulator is much more complex than a noncoherent demodulator since carrier recovery is required. For some demodulation methods, sophisticated algorithms, such as the Viterbi algorithm, are required. All these are basis for complexity comparison.

In comparison with ASK and FSK, PSK achieves better power efficiency and bandwidth efficiency. For example, in terms of power efficiency, binary PSK is 3 dB better than binary ASK and FSK at high signal-to-noise ratios, while BPSK is the same as BASK and better than BFSK in terms of bandwidth efficiency. Because of the advantages of PSK schemes, they are widely used in satellite communications, fixed terrestrial wireless communications, and wireless mobile communications.

A more complex, but more efficient PSK scheme is quadrature phase shift keying (QPSK), where the initial phase of the modulated carrier at the start of a symbol is any one of four evenly spaced values, say, $(0, \pi/2, \pi, 3\pi/2)$ or $(\pi/4, 3\pi/4, 5\pi/4, 7\pi/4)$. In QPSK, since there are four different phases, each symbol can represent two data bits. For example, 00, 01, 10, and 11 can be represented by $0, \pi/2, \pi$, and $3\pi/2$, respectively. In general, assuming that the PSK scheme has M initial phases, known as M-ary PSK or MPSK, the number of bits represented by a symbol is $n = \log_2 M$. Thus each 8-PSK symbol represents 3 bits, each 16-PSK symbol represents 4 bits, and so on.

As the order (M) of the PSK scheme is increased, the bandwidth efficiency is increased. In terms of null-to-null bandwidth, which is often used for PSK schemes, the efficiency is

$$\eta_B = \frac{R_b}{W} = \frac{R_b}{2R_s} = \frac{R_b}{2R_b/\log_2 M} = \frac{1}{2}\log_2 M$$

(bps/Hz) (null-to-null)

Thus the bandwidth efficiencies of BPSK, QPSK, 8-PSK, and 16-PSK are 0.5, 1, 1.5, and 2 bps/Hz.

Using the bandwidth efficiency, the bit rate that can be supported by a system bandwidth can be easily calculated. From above we have

$$R_b = \eta_B W$$

For example, for a satellite transponder that has a bandwidth of 36 MHz, assuming that Nyquist filtering is achieved in the system, the bit rate will be 36 Mbps for BPSK, 72 Mbps for QPSK, and so on. If null-to-null bandwidth is required in the system, the bit rate will be 18 Mbps for BPSK, 36 Mbps for QPSK, and so on. Practical systems may achieve bit rates somewhere between these two sets of values.

In this article, we first describe the commonly used class of PSK schemes, that is, MPSK. Then BPSK and QPSK are treated as special cases of MPSK. Next, differential PSK schemes are introduced, which are particularly useful in channels where coherent demodulation is difficult or impossible, such as fading channels. At the end of this article, advanced phase modulation schemes, such as offset QPSK (OQPSK), $\pi/4$-DQPSK, and continuous-phase modulation (CPM), including multi-h CPM, are briefly introduced. A future trend in phase modulation is in the direction of CPM and multi-h CPM.

2. PSK SCHEMES AND THEIR PERFORMANCE

2.1. Signal Waveforms

In PSK, binary data are grouped into n bits in a group, called n-tuples or symbols. There are $M = 2^n$ possible n-tuples. When each n-tuple is used to control the phase of the carrier for a period of T, *M-ary phase shift keying* (MPSK) is formed. The MPSK signal set is defined as

$$s_i(t) = A\cos(2\pi f_c t + \theta_i), \qquad 0 \le t \le T, \qquad i = 1, 2, \ldots, M \tag{1}$$

where A is the amplitude, f_c is the frequency of the carrier, and

$$\theta_i = \frac{(2i-1)\pi}{M}$$

are the (initial) phases of the signals. Note that θ_i are equally spaced. Each signal $s_i(t)$ is a burst of carrier of period T, called a *symbol waveform*. Each symbol waveform has a unique phase that corresponds to a n-tuple; or, in other words, each n-tuple is represented by a symbol waveform with a unique phase. When the PSK signal is transmitted and received, the demodulator detects the phase of each symbol. On the basis of phase information, the corresponding n-tuple is recovered. Except for the phase difference, the M symbol waveforms in MPSK have the same amplitude (A), the same frequency (f_c), and the same energy:

$$E = \int_0^T s_i^2(t)\,dt = \frac{A^2T}{2}, \qquad i = 1, 2, \ldots, M$$

The simplest PSK scheme is *binary phase shift keying* (BPSK), where binary data (1 and 0) are represented

by two symbols with different phases. This is the case when $M = 2$ in MPSK. Typically these two phases are 0 and π. Then the two symbols are $\pm A \cos 2\pi f_c t$, which are said to be *antipodal*.

If binary data are grouped into 2 bits per group, called dibits, there are four possible dibits: 00, 01, 10, and 11. If each dibit is used to control the phase of the carrier, then we have *quadrature phase shift keying* (QPSK). This is the case when $M = 4$ in MPSK. Typically, the initial signal phases are $\pi/4, 3\pi/4, 5\pi/4$, and $7\pi/4$. Each phase corresponds to a dibit. QPSK is the most often used scheme since its BER performance is the same while the bandwidth efficiency is doubled in comparison with BPSK, as will be seen shortly.

2.2. Signal Constellations

It is well known that sine-wave signals can be represented by phasors. The phasor's magnitude is the amplitude of the sine-wave signal; its angle with respect to the horizontal axis is the phase of the sine-wave signal. In a similar way, signals of modulation schemes, including PSK schemes, can be represented by phasors. The graph that shows the phasors of all symbols in a modulation scheme is called a signal constellation. It is a very convenient tool for visualizing and describing all symbols and their relationship in the modulation scheme. It is also a powerful tool for analyzing the performance of the modulation scheme.

The PSK waveform can be written as

$$s_i(t) = A \cos\theta_i \cos 2\pi f_c t - A \sin\theta_i \sin 2\pi f_c t \tag{2}$$
$$= s_{i1}\phi_1(t) + s_{i2}\phi_2(t), \qquad 0 \le t \le T, \qquad i = 1, 2, \ldots, M$$

where

$$\phi_1(t) = \sqrt{\frac{2}{T}} \cos 2\pi f_c t, \qquad 0 \le t \le T \tag{3}$$

$$\phi_2(t) = -\sqrt{\frac{2}{T}} \sin 2\pi f_c t, \qquad 0 \le t \le T \tag{4}$$

are two orthonormal basis functions and

$$s_{i1} = \int_0^T s_i(t)\phi_1(t)\,dt = \sqrt{E}\cos\theta_i \tag{5}$$

$$s_{i2} = \int_0^T s_i(t)\phi_2(t)\,dt = \sqrt{E}\sin\theta_i \tag{6}$$

are the projections of the signal onto the basis functions.

The phase is related with s_{i1} and s_{i2} as

$$\theta_i = \tan^{-1}\frac{s_{i2}}{s_{i1}}$$

Thus PSK signals can be graphically represented by a signal constellation in a two-dimensional coordinate system with the two orthonormal basis functions in Eqs. (5) and (6), $\phi_1(t)$ and $\phi_2(t)$, as its horizontal and vertical axes, respectively (Fig. 1). Each signal $s_i(t)$ is represented by a point (s_{i1}, s_{i2}), or a vector from the origin to this point, in the two coordinates. The polar coordinates of the signal are $(\sqrt{E}, \theta_i)$; that is, the signal vector's magnitude is $\sqrt{E}$ and its angle with respect to the horizontal axis is θ_i. The signal points are equally spaced on a circle of radius $\sqrt{E}$ and centered at the origin. The bits-signal mapping could be arbitrary provided that the mapping is one-to-one. However, a method called Gray coding is usually used in signal assignment in MPSK. Gray coding assigns n-tuples with only one-bit difference in two adjacent signals in the constellation. When an M-ary symbol error occurs because of the presence of noise, it is most likely that the signal is detected as the adjacent signal on the constellation; thus only one of the n input bits is in error. Figure 1 shows the constellations of BPSK, QPSK, and 8-PSK, where Gray coding is used for bit assignment.

2.3. Power Spectral Density

The *power spectral density* (PSD) of a signal shows the signal power distribution as a function of frequency. It provides very important information about the relative strength of the frequency components in the signal, which, in turn, determines the bandwidth requirement of the communication system.

The power spectral density of a bandpass signal, such as a PSK signal, is centered about its carrier frequency. Moving the center frequency down to zero, we obtain the baseband signal PSD, which completely characterizes the signal [1–3]. The baseband PSD expression of MPSK can be expressed as [3]

$$\Psi_{\tilde{s}}(f) = A^2 T \left(\frac{\sin \pi f T}{\pi f T}\right)^2 = A^2 n T_b \left(\frac{\sin \pi f n T_b}{\pi f n T_b}\right)^2 \tag{7}$$

where T_b is the bit duration, $n = \log_2 M$. Figure 2 shows the PSDs ($A = \sqrt{2}$ and $T_b = 1$ for unit bit energy: $E_b = 1$) for different values of M where the frequency axis is normalized to the bit rate (fT_b). From the figure we can see that the bandwidth decreases with M, or in other words, the bandwidth efficiency increases with M. The Nyquist bandwidth is

$$B_{\text{Nyquist}} = \frac{1}{nT_b} = \frac{R_b}{\log_2 M}$$

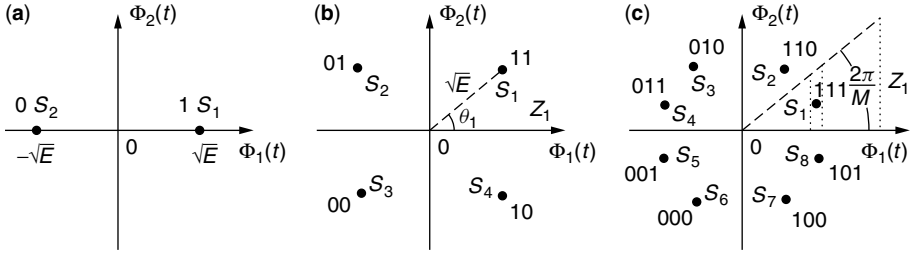

Figure 1. PSK constellations: (**a**) BPSK; (**b**) QPSK; (**c**) 8PSK.

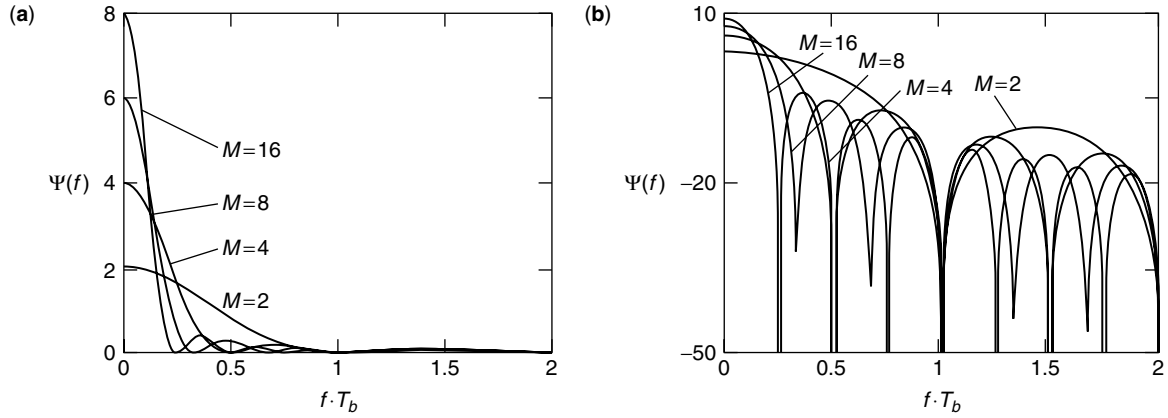

Figure 2. PSDs of MPSK: (**a**) linear; (**b**) logarithmic.

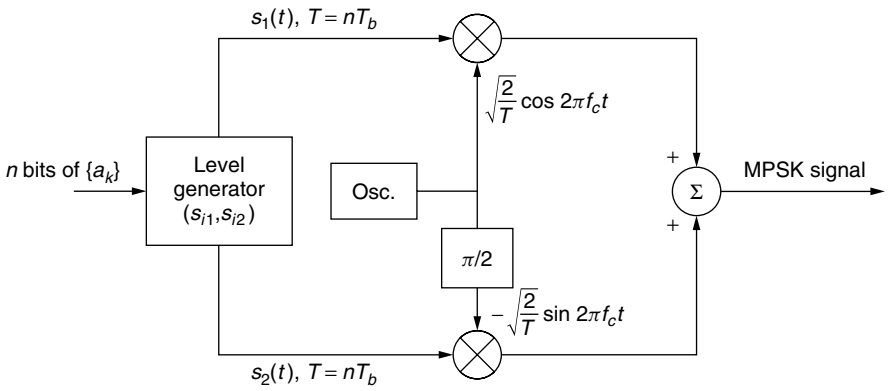

Figure 3. MPSK modulator (Osc. = oscillator). (From Ref. 3, copyright © 2000 Artech House.)

This translates to the Nyquist bandwidth efficiency of $\log_2 M$. The null-to-null bandwidth is

$$B_{null-to-null} = \frac{2}{nT_b} = \frac{2R_b}{\log_2 M}$$

This translates to a bandwidth efficiency of $0.5 \log_2 M$, which is half of that of the Nyquist bandwidth efficiency. Practical systems can achieve bandwidth efficiencies between these two values.

2.4. Modulator and Demodulator

Over the entire time axis, we can write MPSK signal as

$$s(t) = s_1(t)\sqrt{\frac{\pi}{2}} \cos 2\pi f_c t - s_2(t)\sqrt{\frac{\pi}{2}} \sin 2\pi f_c t, \quad -\infty < t < \infty \tag{8}$$

where

$$s_1(t) = \sqrt{E} \sum_{k=-\infty}^{\infty} \cos(\theta_k) p(t - kT) \tag{9}$$

$$s_2(t) = \sqrt{E} \sum_{k=-\infty}^{\infty} \sin(\theta_k) p(t - kT) \tag{10}$$

where θ_k is one of the M phases determined by the input binary n-tuple and $p(t)$ is the rectangular pulse with unit amplitude defined on $[0, T]$. Expression (8) requires that the carrier frequency be an integer multiple of the symbol timing so that the initial phase of the signal in any symbol period is θ_k.

Since MPSK signals are two-dimensional, for $M \geq 4$, the modulator can be implemented by a quadrature *modulator* (Fig. 3), where the upper branch is called the *in-phase channel* or *I channel*, and the lower branch is called the *quadrature channel* or the *Q channel*. The only difference for different values of M is the level generator. Each n-tuple of the input bits is used to control the level generator. It provides the I and Q channels the particular sign and level for a signal's horizontal and vertical coordinates, respectively.

Modern technology intends to use completely digital devices. In such an environment, MPSK signals are digitally synthesized and fed to a D/A (digital-to-analog) converter whose output is the desired phase-modulated signal.

The coherent demodulation of MPSK is shown in Fig. 4. The input to the *demodulator* is the received signal $r(t) = s_i(t) + n(t)$, where $n(t)$ is the additive white Gaussian noise (AWGN). There are two correlators, each consisting of a multiplier and an integrator. The carrier recovery (CR) block synchronizes the reference signals for the multipliers with the transmitted carrier in frequency and phase. This makes the demodulation

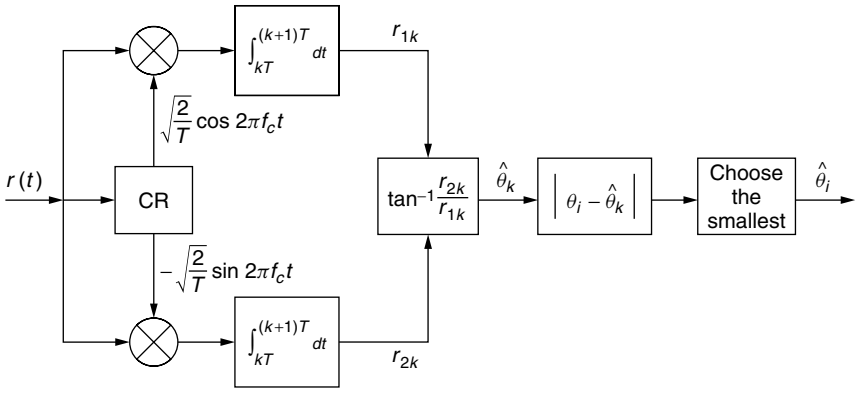

Figure 4. Coherent MPSK demodulator using two correlators. (From Ref. 3, copyright © 2000 Artech House.)

coherent and ensures the lowest bit error probability. The correlators correlate $r(t)$ with the two reference signals. Because of the orthogonality of the two components of the PSK signal, each correlator produces an output as follows:

$$r_1 = \int_0^T r(t)\phi_1(t)\,dt = \int_0^T [s(t) + n(t)]\phi_1(t)\,dt = s_{i1} + n_1$$

$$r_2 = \int_0^T r(t)\phi_2(t)\,dt = \int_0^T [s(t) + n(t)]\phi_2(t)\,dt = s_{i2} + n_2$$

where s_{i1} and s_{i2} are given as in Eqs. (5) and (6), respectively, and n_1 and n_2 are noise output. In Fig. 4 the subscript k indicates the kth symbol period.

Define

$$\widehat{\theta} \triangleq \tan^{-1}\frac{r_2}{r_1}$$

In the absence of noise, $\widehat{\theta} = \tan^{-1} r_2/r_1 = \tan^{-1} s_{i2}/s_{i1} = \theta_i$; that is, the PSK signal's phase information is completely recoverable in the absence of noise. With noise, $\widehat{\theta}$ will deviate from θ_i. To recover θ_i, the $\widehat{\theta}$ difference with all θ_i are compared and the θ_i that incurs the smallest $|\theta_i - \widehat{\theta}|$ is chosen.

The modulator and demodulator for BPSK and QPSK can be simplified from Figs. 3 and 4. For BPSK, since there is only I-channel component in the signal, the modulator is particularly simple: only the I channel is needed (Fig. 5a). The binary data (0,1) are mapped into (−1,1), which are represented by non-return-to-zero (NRZ) waveform $a(t)$, which is equivalent to Eq. (9). This NRZ waveform is multiplied with the carrier, and the result is the antipodal BPSK signal. The BPSK demodulator needs only one channel, too, as shown in Fig. 5b. In the absence of noise, the correlator output l is directly proportional to the data. Then l is compared with threshold zero, if $l \geq 0$ the data bit is 1; otherwise it is 0.

For QPSK, since it is equivalent to two parallel BPSK signals, the modulator can be simplified as shown in Fig. 6a, where $I(t)$ and $Q(t)$ are equivalent to Eqs. (9) and (10), respectively, except for a constant factor; the level generator is simply a serial-to-parallel converter. The demodulator is shown in Fig. 6b, which is simply a pair of two parallel BPSK demodulators.

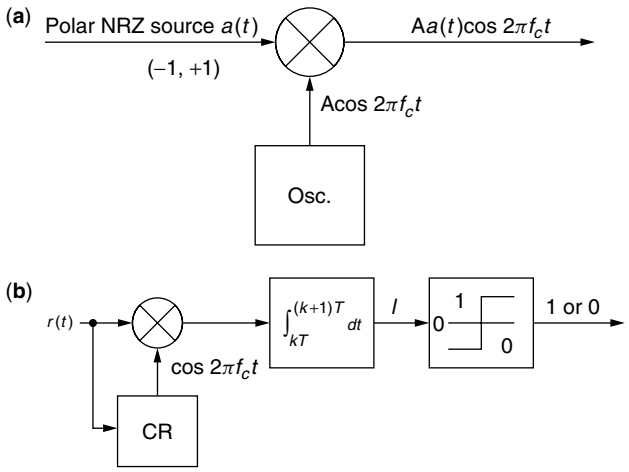

Figure 5. BPSK modulator (**a**); coherent BPSK demodulator (**b**). (From Ref. 3, copyright © 2000 Artech House.)

For $M > 4$, the general modulator and demodulator must be used.

2.5. Symbol and Bit Error Probability

In the demodulator shown in Fig. 4, a symbol error occurs when the estimated phase $\widehat{\theta}$ is such that the phase deviation $|\varphi| = |\widehat{\theta} - \theta_i| > \pi/M$ (see Fig. 1c). Thus the symbol error probability of MPSK is given by

$$P_s = 1 - \int_{-\pi/M}^{\pi/M} p(\varphi)\,d\varphi \tag{11}$$

It can be shown that $p(\varphi)$ is given by [3]

$$p(\varphi) = \frac{e^{-E/N_0}}{2\pi}\left\{1 + \sqrt{\frac{\pi E}{N_0}}(\cos\varphi)e^{(E/N_0)\cos^2\varphi} \times \left[1 + \operatorname{erf}\left(\sqrt{\frac{E}{N_0}}\cos\varphi\right)\right]\right\} \tag{12}$$

where

$$\operatorname{erf}(x) \triangleq \frac{2}{\sqrt{\pi}}\int_0^x e^{-u^2}\,du \tag{13}$$

is the error function.

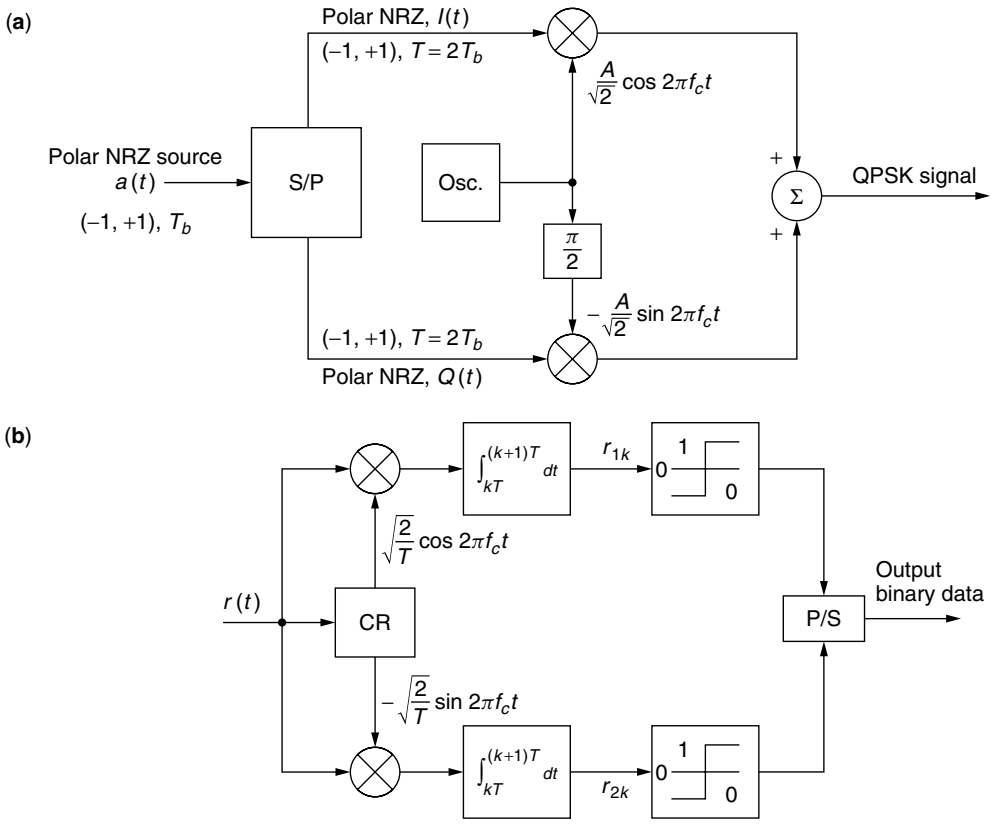

Figure 6. (**a**) QPSK modulator; (**b**) QPSK demodulator. (From Ref. 3, copyright © 2000 Artech House.)

When $M = 2$, (11) results in the formula for the symbol (and bit) error probability of BPSK:

$$P_s = P_b = Q\left(\sqrt{\frac{2E_b}{N_o}}\right) \qquad \text{(BPSK)} \tag{14}$$

where the E_b is the bit energy, which is also equal to the symbol energy E since a bit is represented by a symbol in BPSK, and

$$Q(x) = \int_x^\infty \frac{1}{\sqrt{2\pi}} e^{(-u^2/2)}\, du \tag{15}$$

is called the Q function.

When $M = 4$ [Eq. (11)] results in the formula for QPSK:

$$P_s = 2Q\left(\sqrt{\frac{2E_b}{N_0}}\right) - \left[Q\left(\sqrt{\frac{2E_b}{N_0}}\right)\right]^2 \tag{16}$$

Since the demodulator of QPSK is simply a pair of two parallel BPSK demodulators, the bit error probability is the same as that of BPSK:

$$P_b = Q\left(\sqrt{\frac{2E_b}{N_0}}\right) \qquad \text{(QPSK)} \tag{17}$$

Recall that QPSK's bandwidth efficiency is double that of BPSK. This makes QPSK a preferred choice over BPSK in many systems.

For $M > 4$, expression (11) cannot be evaluated in a closed form. However, the symbol error probability can be obtained by numerically integrating (11).

Figure 7 shows the graphs of P_s for $M = 2, 4, 8, 16$, and 32 given by the exact expression (11). Beyond $M = 4$, doubling the number of phases, or increasing the n-tuples represented by the phases by one bit, requires a substantial increase in E_b/N_0 [or signal-to-noise ratio (SNR)]. For example, at $P_s = 10^{-5}$, the SNR difference between $M = 4$ and $M = 8$ is approximately 4 dB, the difference between $M = 8$ and $M = 16$ is approximately 5 dB. For large values of M, doubling the number of phases requires an SNR increase of 6 dB to maintain the same performance.

For $E/N_0 \gg 1$, we can obtain an approximation of the P_s expression as

$$P_s \approx 2Q\left(\sqrt{\frac{2E}{N_0}} \sin\frac{\pi}{M}\right) \tag{18}$$

Note that only the high signal-to-noise ratio assumption is needed for the approximation. Therefore (18) is good for any values of M, even though it is not needed for $M = 2$ and 4 since precise formulas are available.

The bit error rate can be related to the symbol error rate by

$$P_b \approx \frac{P_s}{\log_2 M} \tag{19}$$

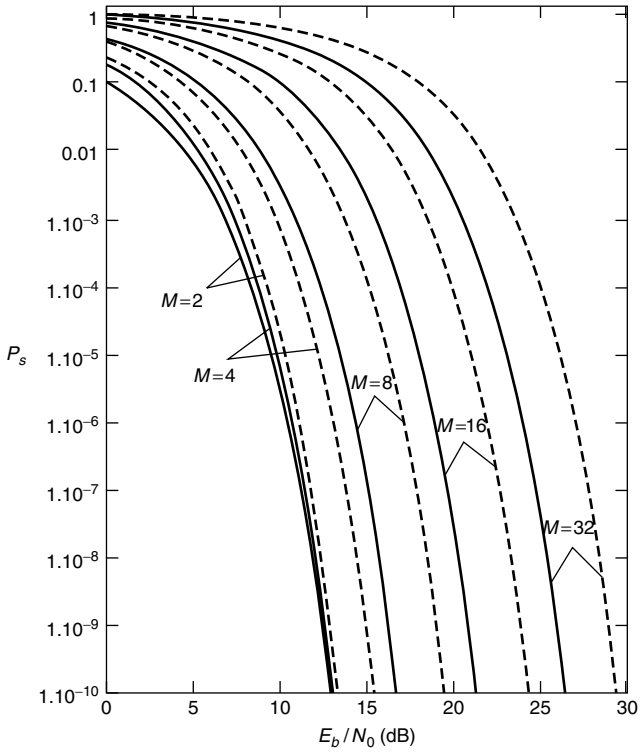

Figure 7. P_s of MPSK (solid lines) and DMPSK (dotted lines). (From Ref. 3, copyright © 2000 Artech House.)

for Gray-coded MPSK signals, since the most likely erroneous symbols are the adjacent signals that differ by only one bit.

Because of the substantial increase in SNR to maintain the same BER for larger M, higher-order PSK schemes beyond 8-PSK are not very often used. If further higher bandwidth efficiency is desired, quadrature amplitude modulation (QAM), which is a combination of phase and amplitude modulation, is a preferable choice over MPSK. For the same bandwidth efficiency, QAM delivers better power efficiency for $M > 4$ (see Section 8.7 of Ref. 3). However, QAM needs to preserve its amplitude through the transmitter stages. This can be difficult when nonlinear power amplifiers, such as traveling-wave-tube amplifiers (TWTAs) in satellite transponders, are used. QAM is widely used in telephone-line modems.

3. DIFFERENTIAL PSK SCHEMES

Differential encoding of a binary data sequence converts the original sequence into a new sequence of which each bit is determined by the difference of the current uncoded bit and the previous coded bit. Differential coding is needed in situations where coherent demodulation is difficult or phase ambiguity is a problem in carrier recovery. BPSK, QPSK, and MPSK all can be differentially coded.

3.1. Differential BPSK

We denote differentially encoded BPSK as *DEBPSK*. Figure 8a depicts the DEBPSK modulator. A DEBPSK signal can be coherently demodulated or differentially demodulated. We denote the modulation scheme that uses differential encoding and differential demodulation as *DBPSK*, which is sometimes simply called *DPSK*.

DBPSK does not require a coherent reference signal. Figure 8b shows a simple, but suboptimum, differential demodulator that uses the previous symbol as the reference for demodulating the current symbol. (This is commonly referred to as a *DPSK demodulator*. Another DPSK demodulator is the optimum differentially coherent demodulator. Differentially encoded PSK can also be coherently detected. These will be discussed shortly.) The front-end bandpass filter reduces the noise power but preserves the phase of the signal. The integrator can be replaced by a LPF (lowpass filter). The output of the integrator is

$$l = \int_{kT}^{(k+1)T} r(t)r(t-T)\,dt$$

In the absence of noise and other channel impairment

$$l = \int_{kT}^{(k+1)T} s_k(t)s_{k-1}(t)\,dt = \begin{cases} E_b & \text{if } s_k(t) = s_{k-1}(t) \\ -E_b & \text{if } s_k(t) = -s_{k-1}(t) \end{cases}$$

where $s_k(t)$ and $s_{k-1}(t)$ are the current and the previous symbols. The integrator output is positive if the current signal is the same as the previous one; otherwise the output is negative. This is to say that the demodulator makes decisions based on the difference between the two signals. Thus the information data must be encoded as the difference between adjacent signals, which is exactly what the differential encoding can accomplish. The encoding rule is

$$d_k = \overline{a_k \oplus d_{k-1}}$$

where $\oplus$ denotes modulo-2 addition. Inversely, we can recover a_k from d_k using

$$a_k = \overline{d_k \oplus d_{k-1}}$$

If d_k and d_{k-1} are the same, then they represent a 1 of a_k. If d_k and d_{k-1} are different, they represent a 0 of a_k.

The demodulator in Fig. 8 is suboptimum, since the reference signal is the previous symbol, which is noisy. The optimum noncoherent, or differentially coherent, demodulation of DEBPSK is given in Fig. 9. The derivation of this demodulator and its BER performance can be found in Ref. 3. Note that the demodulator of Fig. 9 does not require phase synchronization between the reference signals and the received signal. But it does require the reference frequency be the same as that of the received signal. Therefore the suboptimum receiver in Fig. 8b is more practical. Its error performance is slightly inferior to that of the optimum receiver.

The performance of the optimum receiver in Fig. 9 is given by

$$P_b = \frac{1}{2}e^{-E_b/N_0} \quad \text{(optimum DBPSK)} \tag{20}$$

The performance of the suboptimum receiver is given by Park [4]. It is shown that if an ideal narrowband IF

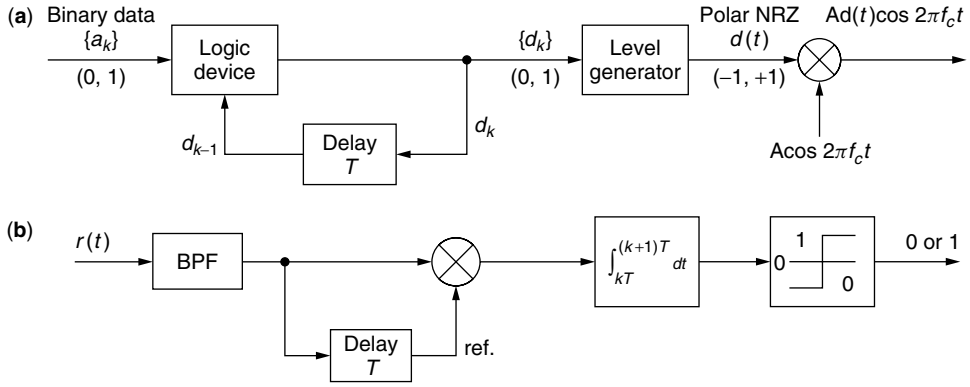

Figure 8. DBPSK modulator (**a**) and demodulator (**b**). (From Ref. 3, copyright © 2000 Artech House.)

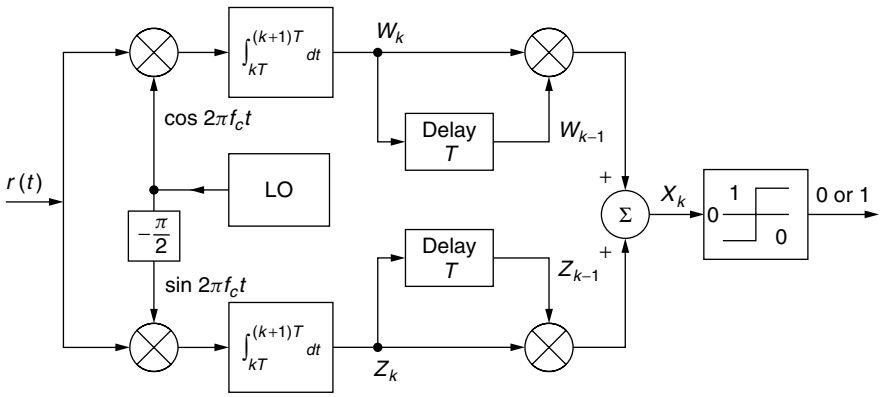

Figure 9. Optimum demodulator for DBPSK. (From Ref. 3, copyright © 2000 Artech House.)

(intermediate-frequency) filter with bandwidth W is placed before the correlator in Fig. 8b, the bit error probability is

$$P_b = \frac{1}{2}e^{-0.76E_b/N_0} \quad \text{for } W = \frac{0.5}{T} \quad \text{(suboptimum DBPSK)} \tag{21}$$

or

$$P_b = \frac{1}{2}e^{-0.8E_b/N_0} \quad \text{for } W = \frac{0.57}{T} \quad \text{(suboptimum DBPSK)} \tag{22}$$

which amounts to a loss of 1.2 and 1 dB, respectively, with respect to the optimum. If an ideal wideband IF filter is used, then

$$P_b \approx Q\left(\sqrt{\frac{E_b}{N_0}}\right) \quad \text{for } W > \frac{1}{T}$$
$$\approx \frac{1}{2\sqrt{\pi}\sqrt{E_b/2N_0}}e^{-E_b/2N_0}$$
$$\text{for } W > \frac{1}{T} \quad \text{(suboptimum DBPSK)} \tag{23}$$

The typical value of W is 1.5/T. If W is too large or too small, Eq. (23) does not hold [4]. The P_b for the wideband suboptimum receiver is about 2 dB worse than the optimum at high SNR. The bandwidth should be chosen as $0.57/T$ for the best performance. P_b curves of DBPSK are shown in Fig. 10.

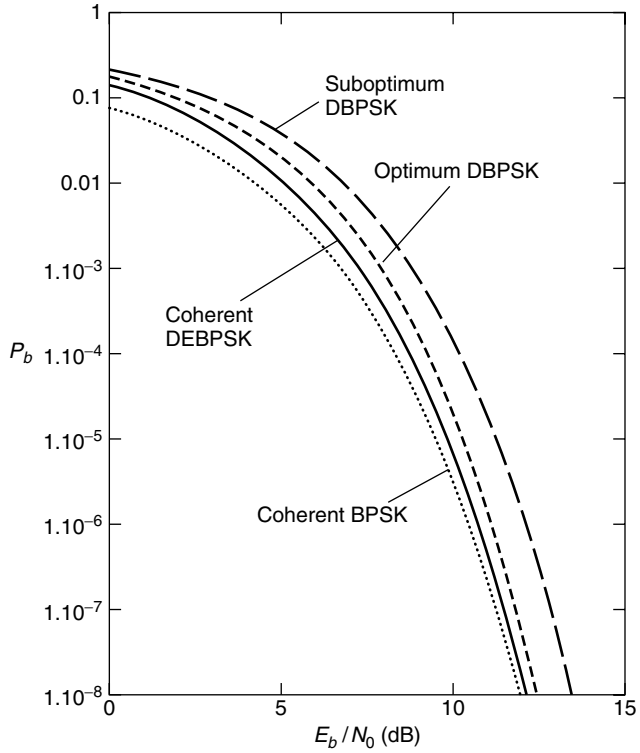

Figure 10. P_b of differential BPSK in comparison with coherent BPSK scheme. (From Ref. 3, copyright © 2000 Artech House.)

A differentially encoded BPSK signal can also be demodulated coherently (denoted as *DEBPSK*). It is used when the purpose of differential encoding is to eliminate phase ambiguity in the carrier recovery circuit for coherent PSK (see Section 4.10 of Ref. 3). This is rarely denoted by the acronym *DBPSK*. DBPSK refers to the scheme of differential encoding and differentially coherent demodulation as we have discussed above.

In the case of DEBPSK, the bit error probability (P_b) of the final decoded sequence $\{\widehat{a}_k\}$ is related to the bit error probability ($P_{b,d}$) of the demodulated encoded sequence $\{\widehat{d}_k\}$ by

$$P_b = 2P_{b,d}(1 - P_{b,d}) \tag{24}$$

(see Section 2.4.1 of Ref. 3). Substituting $P_{b,d}$ as in (14) into Eq. (24), we have

$$P_b = 2Q\left(\sqrt{\frac{2E_b}{N_0}}\right)\left[1 - Q\left(\sqrt{\frac{2E_b}{N_0}}\right)\right] \quad \text{(DEBPSK)} \tag{25}$$

for coherently detected differentially encoded PSK. For large SNR, this is just about 2 times that of coherent BPSK without differential encoding.

Finally we need to say a few words about the power spectral density of differentially encoded BPSK. Since the difference of differentially encoded BPSK from BPSK is differential encoding, which always produces an asymptotically equally likely data sequence (see Section 2.1 of Ref. 3), the PSD of the differentially encoded BPSK is the same as BPSK, in which we assume that its data sequence is equally likely. However, it is worthwhile to point out that if the data sequence is not equally likely, the PSD of the BPSK is not the one in Fig. 2, but the PSD of the differentially encoded PSK is still the one in Fig. 2.

3.2. Differential QPSK and MPSK

The principles of differential BPSK can be extended to MPSK, including QPSK. In *differential MPSK*, information bits are first differentially encoded. Then the encoded bits are used to modulate the carrier to produce the differentially encoded MPSK (DEMPSK) signal stream. In a DEMPSK signal stream, information is carried by the phase difference $\Delta\theta_i$ between two consecutive symbols. There are M different values of $\Delta\theta_i$; each represents an n-tuple ($n = \log_2 M$) of information bits.

In light of the modern digital technology, DEMPSK signals can be generated by digital frequency synthesis technique. A phase change from one symbol to the next is simply controlled by the n-tuple that is represented by the phase change. This technique is particularly suitable for large values of M.

Demodulation of DEMPSK signal is similar to that of differential BPSK [3]. The symbol error probability of the differentially coherent demodulator is approximated by

$$P_s \approx 2Q\left(\sqrt{\frac{2E}{N_0}}\sin\frac{\pi}{\sqrt{2}M}\right) \quad \text{(optimum DMPSK)} \tag{26}$$

for large SNR [6,7]. The exact curves are given as dotted lines in Fig. 7 together with those of coherent MPSK. Compared with coherent MPSK, asymptotically the DMPSK requires 3 dB more SNR to achieve the same error performance.

4. OTHER PSK SCHEMES

4.1. Offset QPSK

Offset QPSK (OQPSK) is devised to avoid the 180° phase shifts in QPSK [3,5]. OQPSK is essentially the same as QPSK except that the I- and Q-channel pulsetrains are staggered. The OQPSK signal can be written as

$$s(t) = \frac{A}{\sqrt{2}}I(t)\cos 2\pi f_c t - \frac{A}{\sqrt{2}}Q\left(t - \frac{T}{2}\right)\sin 2\pi f_c t, \quad -\infty < t < \infty \tag{27}$$

The modulator and the demodulator of OQPSK are basically identical to those of QPSK, except that an extra delay of $T/2$ seconds is inserted in the Q channel in the modulator and in the I channel in the demodulator.

Since OQPSK differs from QPSK only by a delay in the Q-channel signal, its power spectral density is the same as that of QPSK, and its error performance is also the same as that of QPSK.

In comparison to QPSK, OQPSK signals are less susceptible to spectral sidelobe restoration in satellite transmitters. In satellite transmitters, modulated signals must be band-limited by a bandpass filter in order to conform to out-of-band emission standards. The filtering degrades the constant-envelope property of QPSK, and the 180° phase shifts in QPSK cause the envelope to go to zero momentarily. When this signal is amplified by the final stage, usually a highly nonlinear power amplifier, the constant envelope will be restored. But at the same time the sidelobes will be restored. Note that arranging the bandpass filter after the power amplifier is not feasible since the bandwidth is very narrow compared with the carrier frequency. Hence the Q value of the filter must be extremely high such that it cannot be implemented by the current technology. In OQPSK, since the 180° phase shifts no longer exist, the sidelobe restoration is less severe.

4.2. π/4-DQPSK

Although OQPSK can reduce spectral restoration caused by a nonlinearity in the power amplifier, it cannot be differentially encoded and decoded. $\pi/4$-*DQPSK* is a scheme that not only has no 180° phase shifts like OQPSK but also can be differentially demodulated. These properties make it particularly suitable for mobile communications where differential demodulation can reduce the adversary effects of the fading channel. $\pi/4$-DQPSK has been adopted as the standard for the digital cellular telephone system in the United States and Japan.

$\pi/4$-DQPSK is a form of differential QPSK. The correspondence between data bits and symbol phase difference are shown as follows.

I_k Q_k	1 1	−1 1	−1 −1	1 −1
$\Delta\theta_k$	$\pi/4$	$3\pi/4$	$-3\pi/4$	$-\pi/4$

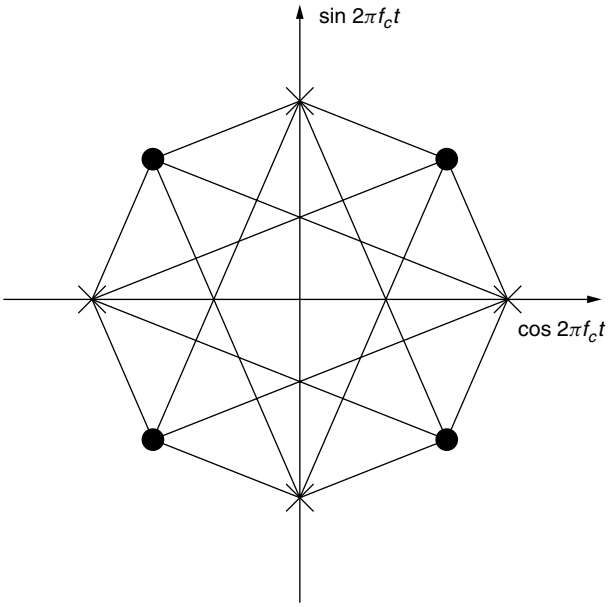

Figure 11. $\pi/4$-DQPSK signal constellation. (From Ref. 3, copyright © 2000 Artech House.)

We can see that the phase changes are confined to odd-number multiples of $\pi/4(45^\circ)$. There are no phase changes of 90° or 180°. In addition, information is carried by the phase changes $\Delta\theta_k$, not the absolute phase Φ_k. The signal constellation is shown in Fig. 11. The angle of a vector (or symbol) with respect to the positive direction of the horizontal axis is the symbol phase Φ_k. The symbols represented by $\bullet$ can become symbols represented only by $\times$, and vice versa. Transitions among themselves are not possible. The phase change from one symbol to the other is $\Delta\theta_k$.

Since information is carried by the phase changes $\Delta\theta_k$, differentially coherent demodulation can be used. However, coherent demodulation is desirable when higher power efficiency is required. There are four ways to demodulate a $\pi/4$-DQPSK signal: baseband differential detection, IF band differential detection, FM-discriminator detection, and coherent detection. The error probability of the $\pi/4$-DQPSK in the AWGN channel is about 2 dB inferior to that of coherent QPSK at high SNRs [3,8].

4.3. Continuous-Phase Modulation

The trend of phase modulation is shifting to *continuous-phase modulation* (CPM), which is a class of power- and bandwidth-efficient modulations. With proper choice of pulseshapes and other parameters, CPM schemes may achieve higher bandwidth and power efficiency than QPSK and higher-order MPSK schemes.

The CPM signal is defined by

$$s(t) = A\cos(2\pi f_c t + \Phi(t, \mathbf{a})), \quad -\infty \le t \le \infty \tag{28}$$

The signal amplitude is constant. Unlike signals of previously defined modulation schemes such as PSK, where signals are usually defined on a symbol interval, this signal is defined on the entire time axis. This is due to the continuous, time-varying phase $\Phi(t, \mathbf{a})$, which usually is influenced by more than one symbol. The transmitted M-ary symbol sequence $\mathbf{a} = \{a_k\}$ is embedded in the excess phase

$$\Phi(t, \mathbf{a}) = 2\pi h \sum_{k=-\infty}^{\infty} a_k q(t - kT) \tag{29}$$

with

$$q(t) = \int_{-\infty}^{t} g(\tau)\, d\tau \tag{30}$$

where $g(t)$ is a selected pulseshape. The M-ary data a_k may take any of the M values: $\pm 1, \pm 3, \ldots, \pm(M-1)$, where M usually is a power of 2. The phase is proportional to the parameter h which is called the modulation index. Phase function $q(t)$, together with modulation index h and input symbols a_k, determine how the phase changes with time. The derivative of $q(t)$ is function $g(t)$, which is the frequency shape pulse. The function $g(t)$ usually has a smooth pulseshape over a finite time interval $0 \le t \le LT$, and is zero outside. When $L = 1$, we have a full-response pulseshape since the entire pulse is in a symbol time T. When $L > 1$, we have a partial-response pulseshape since only part of the pulse is in a symbol time T.

The modulation index h can be any real number in principle. However, for development of practical maximum-likelihood CPM detectors, h should be chosen as a rational number.

Popular frequency shape pulses are the rectangular pulse, the raised-cosine pulse, and the Gaussian pulse. The well-known *Gaussian minimum shift keying* (GMSK) is a CPM scheme that uses the Gaussian frequency pulse:

$$g(t) = \frac{1}{2T}\left[Q\left(2\pi B_b \frac{t - \frac{T}{2}}{\sqrt{\ln 2}}\right) - Q\left(2\pi B_b \frac{t + \frac{T}{2}}{\sqrt{\ln 2}}\right)\right], \quad 0 \le B_b T \le 1 \tag{31}$$

where B_b is the 3-dB bandwidth of the premodulation Gaussian filter, which implements the Gaussian pulse effect [9]. GMSK is currently used in the U.S. cellular digital packet data system and the European GSM system.

If the modulation index h is made to change cyclically, then we obtain *multi-h CPM* (or MHPM); the phase is

$$\Phi(t, \mathbf{a}) = 2\pi \sum_{k=-\infty}^{\infty} h_k a_k q(t - kT) \tag{32}$$

where the index h_k cyclically changes from symbol to symbol with a period of K, but only one index is used during one symbol interval, that is, $h_1, h_2, \ldots, h_K, h_1, h_2, \ldots, h_K$, and so on. With proper choice of the index set and pulseshape, MHPM can be more power- and bandwidth-efficient than single-h CPM.

The major drawback of CPM and MHPM is the system complexity, especially the circuit complexity and the computational complexity of the demodulator, since optimum demodulation of CPM and MHPM requires complicated maximum-likelihood sequence estimation [3]. However, with the rapid advances in microelectronics and

digital signal processing power of the electronic devices, the practical implementation and use of CPM and MHPM is quickly emerging.

Significant contributions to CPM schemes, including signal design, spectral and error performance analysis were made by Sundberg, Aulin, Svensson, and Anderson, among other authors [10–13]. Excellent treatment of CPM up to 1986 can be found in the book by Anderson, et al. [13] or the article by Sundberg [10]. A relatively concise, but up-to-date, description of CPM and MHPM can be found in Ref. 3.

BIOGRAPHY

Fuqin Xiong received his B.S. and M.S. degrees in electronics engineering from Tsinghua University, Beijing, China, and a Ph.D. degree in electrical engineering from University of Manitoba, Winnipeg, Manitoba, Canada, in 1970, 1982, and 1989, respectively. He was a faculty member at the Department of Radio and Electronics in Tsinghua University from 1970 to 1984. He joined the Department of Electrical and Computer Engineering, Cleveland State University, Ohio, as an assistant professor in 1990, where he is currently a full professor and director of the Digital Communications. Research Laboratory. He was a visiting scholar at University of Manitoba in 1984–1985, visiting fellow at City University of Hong Kong, Kowloon, in spring 1997, and visiting professor at Tsinghua University in summer 1997. His areas of research are modulation and error control coding. He is the author of the best selling book *Digital Modulation Techniques*, published by Artech House, 2000. He is an active contributor of technical papers to various IEEE and IEE technical journals and IEEE conferences. He has been a reviewer for IEEE and IEE technical journals for years. He has been the principal investigator for several NASA sponsored research projects. He is a senior member of IEEE.

DISTRIBUTED INTELLIGENT NETWORKS

Iakovos S. Venieris

National Technical University of Athens
Athens, Greece

1. DEFINITION AND CHARACTERISTICS OF THE DISTRIBUTED INTELLIGENT NETWORK

The distributed intelligent network represents the next stage of the evolution of the intelligent network (IN) concept. The term corresponds to no specific technology or implementation but rather is used to refer, collectively, to a family of architectural approaches for the provisioning of telecommunication services that are characterized by: use of distributed, object oriented and, potentially, mobile code technologies, and a more open platform for service provisioning.

The intelligent network [1] first emerged around 1980 when value-added services that had previously been offered only on a private branch exchange basis involving mainly corporate users, first begun to be made available on the public network as well. The problem was that the only way that new services could be introduced using the infrastructure of the time required upgrading a large number of deployed telephone switches. In the first available programmable switches, services resided in the memory space of each switch and service view was therefore local. Thus, each installed service provided a number of additional features on the switch it was installed and so could be provided only for those telephone calls that were routed through that particular switch. A certain switch could have a number of services implemented in it, while others could have different sets or none. Also, there was no guarantee that the implementation of a service would behave in the same way, uniformly across switches coming from different vendors. This was the era of the "switch-based services."

New services therefore could not be provided nationwide simultaneously and often even when all involved switches had been upgraded, different service dialects existed as a result of the heterogeneity of the equipment and the unavoidable discrepancies between the implementation of the same service in switches provided by different vendors. These problems were further aggravated by the

need to guard against undesirable feature interaction problems: a process that even now cannot be automated or tackled with, in a systematic, algorithmic manner and usually involves manually checking through hundreds or even thousands of possible service feature combinations. Since this process had to also account for the different service dialects, each service that was added to the network increased the complexity in a combinatorial manner.

The result was that service introduction soon became so costly that new services could be provided only infrequently. The intelligent network idea sought to alleviate these problems. The key concept was to separate the resources (public telephony switches) from the logic that managed them. Once this was achieved, the logic could be installed in a central location called "service control point" and from there, operate on the switches under its control. Service introduction would consist simply in the installation of a new software component in the service control point and would therefore take effect immediately once this was completed and once involved switches were configured to recognize the new service prefixes. Once a switch identified an "intelligent network call," that is, a call prefixed with a number corresponding to an IN service (e.g., 0800 numbers), it would suspend call processing and request further instructions on how to proceed from the remotely located service or service logic program. No other logic therefore needed to be installed in the switches apart from a generic facility for recognizing such IN calls and participating in the interaction with the remotely located service logic programs. This interaction consisted of notifying the service logic programs of intelligent network calls or other important call events, receiving instructions from them, and putting these instructions into effect by issuing the appropriate signaling messages toward the terminals that requested the IN service or towards other resources involved in the provisioning of the service. Typical resources of the latter kind were intelligent peripherals and specialized resource functions where recorded service messages were and still are typically kept.

In order to implement a mechanism such as the one called for by the IN conception, three key artifacts are needed: (1) a finite state machine implementing an abstraction of the call resources of a public switch, (2) a remote centralized server where programs providing the algorithmic logic of a service are executed, and (3) a protocol for remote interaction between the switch and the service logic programs. Through this protocol (1) a limited aperture of visibility of the switch functionality — in terms of the said finite state machine — is presented to the service logic programs; and (2) hooks are provided allowing the latter to influence call processing in order to effect the desired behavior of any given service.

As noted above, prior to introduction of the intelligent network concept the last two of these three elements were not existent as service logic was embedded into every switch in order for a service to be provided. There was therefore no remote centralized server responsible for service execution and, hence, due to the locality of the interaction, no protocol needed to support the dialogue between the switch and the service logic program. Even the first of these three elements (the state machine abstracting call and connection processing operations in the switch) was not very formalized as switch-based services were using whatever nonstandardized programming handles a vendor's switch was exposing. This was, after all, why for a new service to be introduced, direct tampering with all affected switches was necessary, and in fact the implementation of the same service needed to be different in different switches. Also this accounted for the fact that, considering the heterogeneous nature of the switches comprising a certain operator's network, different service dialects were present, resulting in a nonuniform provision of a given service depending on the switch to which a subscriber was connected. Intelligent networks changed all that by defining a common abstraction for all switches and by centralizing service logic to a few (often one) easily administrated and managed servers. The abstraction of the switches was that of a state machine offering hooks for interest on certain call events to be registered, and supporting a protocol that allowed remote communication between the switches and the now centrally located service logic programs. It will be shown in the following paragraphs that this powerful and well-engineered abstraction is also vital in the distributed intelligent network.

2. THE NEED FOR DISTRIBUTED INTELLIGENT NETWORKS

The IN concept represents the most important evolution in telecommunications since the introduction of programmable switches that replaced the old electromechanic equipment. It allows for the introduction of new services, quickly, instantly, across large geographic areas, and at the cost of what is essentially a software development process as contrasted to the cost of directly integrating a new service in the switching matrix of each involved telephony center.

However, after 1998, a number of technical and socioeconomic developments have opened up new prospects and business opportunities and also have posed new demands, which traditional IN architectures seem able to accommodate only poorly: (1) use of mobile telephony became widespread, particularly in Europe and Japan; (2) the Internet came of age both in terms of the penetration it achieved and is projected to achieve, and also in terms of the business uses it is put to; and (3) deregulation seems to be the inevitable process globally setting network operators and carriers in fierce competition against each other. The import of the first two of these developments is that the public switched telephony network is no longer the only network used for voice communications. Cellular telephony networks and also telephony over the Internet are offering essentially the same services. Therefore, an architecture for service creation such as the IN that is entirely focused on the public telephony network falls short of providing the universal platform for service provisioning that one would ideally have wished: a single platform offering the same services over the wired, wireless and Internet components of a global integrated network for voice and data services. Deregulation, on the other hand, has two

primary effects; first, as noted above, it promotes competition between operators for market share making the introduction of new and appealing services a necessity for a carrier that wishes to stay in business. Since the basic service offered by any carrier is very much the same, a large amount of differentiation can be provided in the form of value-added or intelligent services that are appealing and useful to end users. The new telecommunications landscape is no longer homogenous but instead encompasses a variety of networks with different technologies and characteristics. The prospect for innovative services that focus not only on the telephone network but also Internet and mobile networks is immense. Particularly useful would be hybrid services that span network boundaries and involve heterogeneous media and access paradigms. Typical services belonging to this genre are "click to" services whereby a user can point to a hyperlink in his or hers browsers and as a result have a phone or fax (Facsimile) call being set up in the network. Also, media conversion services whereby a user who is not able to receive a certain, urgent email can have a phone call in his mobile terminal and listen to the contents of the mail using text to speech conversion. All these services cannot be offered by relying solely on an intelligent network. Other technologies and platforms would have to be combined and this would not result in a structured approach to service creation. Essentially, traditional intelligent networks cannot fulfill the new demands on rapid service creation and deployment in a converged Internet — telecommunications environment because the whole concept of this technology had at its focus the public telephony network and revolved around its protocols, mechanisms, and business models. Internet and cellular telephony, on the other hand, have their own protocols, infrastructure, and mechanisms, and these cannot be seamlessly incorporated into an architecture designed and optimized with a different network in mind. Furthermore, the business model envisaged by the traditional intelligent network is a closed one. It has to be said that the focus of the IN standardization was not to propose and enable new business models for telephony: only to expedite the cumbersome and costly process of manual switch upgrading that made introduction of new services uneconomical to the point of impeding the further growth of the industry. Intelligent network succeeded in solving this problem by removing the service intelligence from the switches and locating that intelligence in a few centralized points inside the network. However, the same organization continued to assume the role of the network operator or carrier and that of the service provider. Deregulation and the growth of Internet that adheres to a completely different business model necessitate the separation of these two roles and so require a technological basis that would support this new model. This is the problem that the next generation of the intelligent network technologies face.

The distributed intelligent network represents the next stage of the intelligent network evolution. The three main elements of the traditional intelligent network concept survive this evolution as could be inferred by the central role they have been shown to play in delivering services to the end users in the traditional IN context. Distributed IN is characterized by the use of distributed object technologies such as the Common Object Request Broker Architecture (CORBA), Java's Remote Method Invocation (RMI) or Microsoft's Distributed Component Object Model (DCOM) to support the switch — services interaction. In a traditional IN implementation, the Intelligent Network Application Protocol (INAP) information flows are conveyed by means of static, message-based, peer-to-peer protocols executed at each functional entity. The static nature of the functional entities and of the protocols they employ means that in turn the associations between them are topologically fixed. An IN architecture as defined in Ref. 2 is inherently centralized with a small set of service control points and a larger set of service switching points engaged with it in INAP dialogs. The service control points are usually the bottleneck of the entire architecture and their processing capacity and uptime in large extent determine the number of IN calls the entire architecture can handle effectively. Distributed object technologies can help alleviate that problem by making associations between functional entities less rigid. This is a by-product of the location transparencies that use of these technologies introduces in any context. More importantly, the fact that under these technologies the physical location of an entity's communicating peer is not manifested makes service provisioning much more open. This will be explained in more detail in later paragraphs. The remainder of this encyclopedia article is structured as follows: the distributed IN's conceptual model is introduced and juxtaposed with that of the traditional IN, typical distributed IN implementation issues are presented, and finally some emerging architectures that adhere to the same distributed IN principles are identified.

3. THE DISTRIBUTED INTELLIGENT FUNCTIONAL MODEL

According to the International Telecommunication Unions (ITU) standardization of IN, an intelligent network conceptual model is defined, layered in four planes depicting different views of the intelligent network architecture from the physical plane up to the service plane. Of these planes we will use as a means of comparing the IN architecture with that of distributed IN, the distributed functional plane. The distributed functional plane identifies the main functional entities that participate in the provision of any given IN service without regard to their location or mapping to physical elements of the network (the aggregation of functional entities to physical components is reflected in the physical plane). The functional models of IN and distributed IN are quite different in certain respects. First, a number of emerging distributed IN architectures like Parlay and JAIN (discussed later on) incorporate new functional entities to account for the new types of resources that can be found in a converged Internet — Telecommunications environment and which traditional IN models could not anticipate. Apart from that, a further difference emerges in the form of the more open environment for service provisioning, the distributed or remote-object interactions that characterize distributed IN and the potential use of mobile code technologies that can change the locality

of important components at runtime (and with this, the end points of control flows). Finally, the business model of distributed IN with its use of distributed object technologies explicitly enables and accommodates the separation between the roles of the network operator and the service provider.

Some of the abovementioned differences cannot be reflected in the distributed functional plane as defined in the IN's conceptual model as this is at a level of abstraction where such differences are hidden. Therefore, Fig. 1 compares the two technologies (traditional and distributed IN) by reflecting features of both their distributed and physical planes.

Figure 1a presents a limited view of the traditional IN conceptual model at the distributed and physical planes. A number of functional entities are there identified, of which the more central to this discussion will be the service creation environment function/service management function, the service control function, and the service switching function. Figure 1 also depicts a specialized resource function and an intelligent peripheral, which is were announcements are kept and digits corresponding to user's input are collected. The second part of Fig. 1 also depicts an abstract entity entitled "Internet/mobile resources," which represents functional entities present in distributed IN that correspond to resource types unique in the Internet or mobile networks components such as mail servers, media conversion servers or location servers.

Starting from the bottom up, the service switching function corresponds to the finite state machine reflecting the switch's call resources that the article drew attention to as being one of the main artifacts on which the whole IN concept is based. This functional entity is closely linked with the service control function, which is the place where service logic programs are executed. These are not depicted since they are thought of as incorporated with the latter. Finally, the service creation environment function and the service management function are the entities responsible for the creation of new service logic programs, and their subsequent injection and monitoring into the architecture and eventual withdrawal/superseding by other services or more up to date versions.

The INAP protocol is executed between the service switching and the service control functions that can be regarded as implementing a resource-listener-controller pattern. The service switching function is the resource that is monitored whereas the service control function is responsible for setting triggers corresponding to call events for which it registers an interest and also the controller that acts on these events when informed of their occurrence. A typical event for instance would be the detection of a digit pattern that should invoke an IN service (e.g., 0800). The service switching function undertakes the job of watching for these events and of suspending call processing when one is detected and delivering an event notification to the service control function for further instructions. This pattern is the same also in the distributed IN and can in fact also be identified in recent telecommunication architectures such as those articulated by the JAIN and Parlay groups.

The distributed IN conceptual model (Fig. 1b) differs by (1) explicitly enabling mobility of the service logic programs through the use of mobile code technologies and (2) replacing the message-based INAP protocol with distributed processing technologies like CORBA, RMI

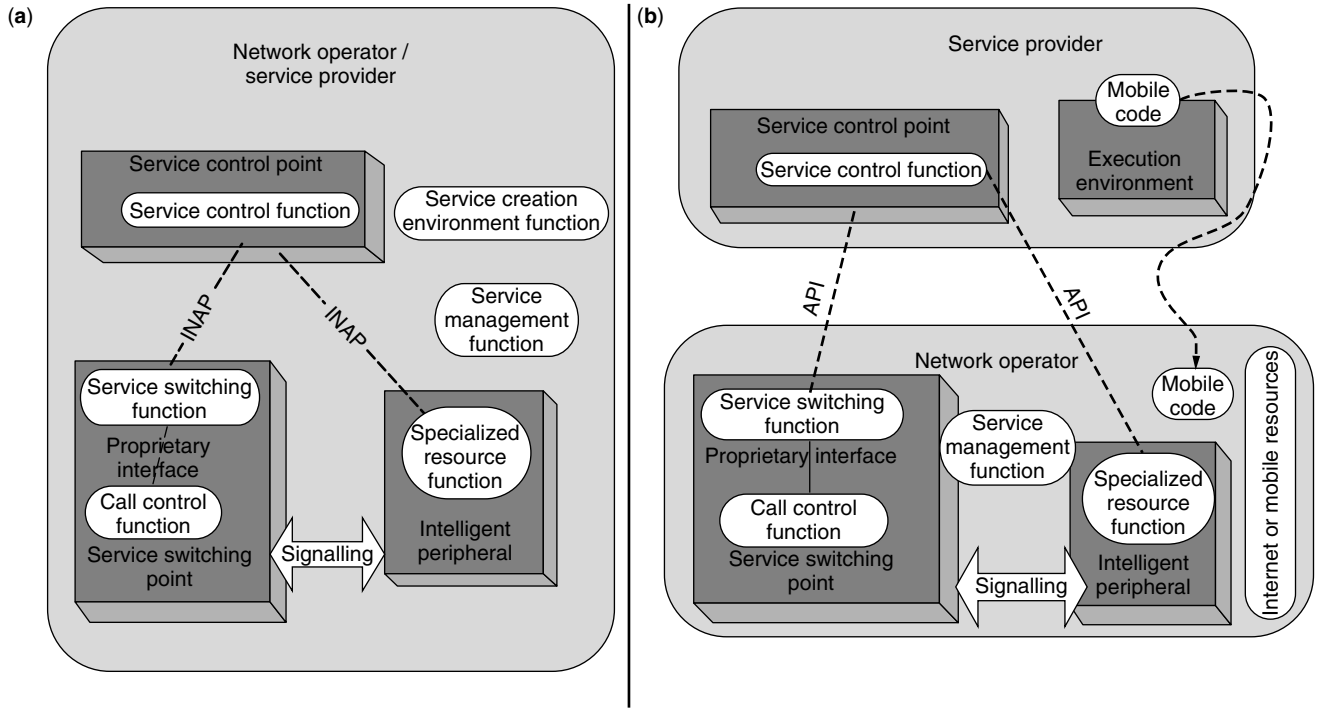

Figure 1. Traditional (**a**) and distributed (**b**) IN functional models.

or DCOM. It should be noted of course that both the traditional and the distributed IN conceptual models are populated by an additional number of functional entities which are not depicted in Fig. 1 nor enter this discussion for reasons of economy. Code mobility (often implemented using Java and/or some additional mobile code libraries) is used to allow service logic programs to reside not only in the service control function but also in the service switching function where an execution environment identical with the one that exists within the service control function can be found. Service logic programs in the form of mobile code components populate both execution environments and constitute the control part of IN service provisioning. From these execution environments, using distributed processing technologies, the switch resources, as exposed by the service switching function objects, are monitored and manipulated. This means that service logic programs in the distributed IN conceptual model are prime level entities and cannot be suitably depicted as pinned down inside the implementation of the service control function. In contrast to the functional plane of the IN conceptual model where the service control function and the service logic programs were one and the same, in the functional plane of the distributed IN conceptual model, the service control and also the service switching functions are containers (or execution environments) for service components capable of migrating to whichever environment is best suited to accommodate their execution. It is important to consider that this amount of flexibility would not be attainable were it not for the use of distributed processing technologies at the control plane. The defining characteristic of these technologies is that they abstract process, machine and network boundaries and provide to the programmer and the runtime instances of service code a view of the network as a generalized address space spanning conventional boundaries. In the same manner in which a program may hold a pointer to an object or function residing in the same local process, so it can, when distributed technologies are used, hold a pointer to an object located in a different process in the same machine, in a machine in the same local network, or in a machine located in a different network. Therefore the abstraction of a single memory space is supported and compiled code components can be mapped in an arbitrary way in processes and physical nodes without needing recompilation or rebooting of the system. This is a potent facility and it opens new capabilities which the distributed IN employs. It also has to be stated that the articulation of the traditional IN conceptual model, to an extent, anticipated a certain flexibility in the allocation of functional entities to physical ones according to the correspondences between the functional and the physical planes. This was however not materialized since the communication infrastructure used for the conveyance of the INAP information flows between the various entities of the system (and most importantly between the service switching and the service control entities) was the signaling system 7 network, which does not demonstrate the properties of a distributed processing environment. Therefore the full potential inherent in the abstract definition of the IN conceptual model was materialized only to a limited extent and mainly had to do with different configuration and aggregations of functional entities to the hardware nodes of the system. The interested reader should refer to Ref. 2 for a presentation of the various alternatives that are possible in an IN architecture. This leeway afforded to the network designer is something completely different from the ability of service logic programs to roam through the various execution environments of the system at runtime without requiring the system to suspend its operation and, under certain configuration options discussed in the following paragraph, in a manner completely automated and transparent even to the network management system.

4. ISSUES IN DISTRIBUTED IN IMPLEMENTATIONS

Given the considerations outlined above and the differences at the functional plane between traditional and distributed IN architectures, a number of approaches exist. Each of these approaches essentially answers a defining question in a different manner, and since for the most part they are orthogonal to each other, a large number of widely differing distributed IN implementations can be envisaged; all, however, share the same fundamental characteristics of increased flexibility and openness when compared with traditional IN.

The first point to examine is the set of considerations that govern the location of service logic programs inside the network. Attendant to it are the dynamics of their mobility. This is possible once employment of mobile code technologies is assumed. Service logic programs implemented as mobile components can migrate between execution environments dynamically. Considerations valid for incorporation in any given distribution algorithm are processing load, signaling load, and functionality. Given a number of execution environments present in the network's service switching and service control functions, each with its own characteristics, simple or elaborate load balancing mechanisms can be devised and implemented. These would allow service logic programs to locate themselves in such a way so that no individual execution environment's resources are strained beyond a certain point. Apparent tradeoffs exist with respect to complexity, time, and computing power spent in process or code migrations, which are in themselves costly procedures. This cost is reflected in terms of both time and processor load they temporarily create as they involve suspension or creation of new threads, allocation of objects in memory, and so on. These overheads, when also viewed in the light of the stringent performance and responsiveness demands that exist in a telecommunication system, should tilt the balance in favor of a simple and not very reactive load balancing algorithm that operates on ample time scales.

Processing load is not however the only kind of load to consider. Control load is another. Control load should not be confused with signaling load, which concerns protocol message exchanges between terminals and switches at various levels of the classic Five-layered telephony network architecture. Signaling load is for the most part transparent to the IN with the exception of those call events that invoke an IN service and for

which a service switching function has been asked to suspend call processing and wait for instructions from the service control function. Control load in this discussion is about the exchange of INAP information flows using the selected distributed processing technology between the service logic programs and the switching resources of the system. The location transparency provided by distributed technologies cannot clearly be interpreted to suggest that local or remote interactions take the same time. Therefore, when service logic programs are located in an execution environment closer to the switch they control, better performance can be expected. This means that, in general, the code distribution mechanism, should locate service logic programs at the proximity of the resources with which they are engaged if not at an execution environment collocated with those resources. There is, however, a tradeoff here between processing and control load. Because of the higher level of abstraction (method calls instead of messages) offered to service logic programs when distributed processing technologies are used, it is necessary that, under the hood, the respective middleware that is used to support this abstraction enters into some heavy processing. For every method call that is issued, it is necessary that each argument's transitive closure is calculated and then the whole structure is serialized into an array of bytes for subsequent transmission in the form of packets using the more primitive mechanisms offered by the network layer. On the recipient side, the reverse procedure should take place. This set of processes is known as marshaling/demarshaling and is known to be one of the most costly operations of distributed processing. Because of the processor intensive character of marshaling/demarshaling operations, it is possible that, under certain configurations, better performance is attained when the service logic program is located to a remote execution environment than to a local, strained, one. This in spite of the fact that the time necessary for the propagation of the serialized byte arrays in the form of packets from the invoking to the invoked party will be higher in the remote case. This interrelation between processing and control load means that no clear set of rules can be used to produce an algorithm that is efficient in all cases. The complex nature of the operations that take place in the higher software layers means that this is not an optimization problem amenable to be expressed and solved analytically or even by means of simulation, and therefore an implementor should opt for simple, heuristic designs, perhaps also using feedback or historic data. Another approach would be to rely on clusters of application servers into which service logic programs can be executed. Commercially available application servers enable process migration and can implement a fair amount of load balancing operations themselves, transparently to the programmer or the runtime instances of the service components.

The second point that can lead to differentiations in architecture design in distributed intelligent network is the question of who makes the abovementioned optimization and distribution decisions. There could be a central entity that periodically polls the various execution environments receiving historic processing and signal load data, runs an optimization algorithm and instructs a number of service logic programs to change their location in the network according to the results thus produced. The merit of this approach is that the optimization is networkwide and the distribution algorithm can take into account a full snapshot of the network's condition at any given instance of time when it is invoked. The disadvantage is the single point of failure and the cost of polling for the necessary data and issuing the necessary instructions. These communications could negatively affect traffic on the control network, depending, of course, on the frequency with which they are executed. A point to consider in this respect that can lead to more efficient implementations is whether networkwide optimization is necessary or whether locally executed optimizations could serve the same purpose with similar results and while projecting a much lower burden on the communication network. Indeed, it can be shown that it is highly unlikely for the purposes of any optimization to be necessary to instruct any given service logic program to migrate to an execution environment that is very remote to the one in which it was until that time executed. To see that this is the case, one can consider that a migration operation moving a service component to a very distant location will most likely result in an unacceptably higher propagation delay that would degrade the responsiveness of the corresponding resource–service logic link. Therefore locally carried optimizations could result in comparable performance benefits at a greatly reduced communication cost when compared to a networkwide optimization. Therefore, in each subnetwork an entity (migration manager) can be responsible for performing local optimizations and instructing service components to assume different configurations accordingly. Taking this notion to its logical conclusion, a further implementation option would be to have service logic programs as autonomous entities (mobile agents) that are responsible for managing their own lifecycle and proactively migrating to where they evaluate their optimal location to be. As before, considerations for deriving such an optimal location can be signaling or control load experienced at the execution environment where they were hosted but also, more appropriately in this case, the location of mobile users. Indeed, in this last scenario one can have a large population of service code components, each instantiated to serve a specific mobile (roaming) user. See Ref. 3 for a discussion of this approach. Service logic programs could then evaluate their optimal location in the network, also taking into consideration the physical location of the user they serve. This can, for instance, lead to migration operations triggered by the roaming of a mobile user. In this manner concepts like that of the virtual home environment for both terminal and personal mobility can be readily supported enabling one user to have access to the same portfolio of intelligent services irregardless of the network into which he/she is roaming and subject only to limitations posed by the presentation capabilities of the terminal devices he/she is using. Of course, the usefulness of autonomous service logic programs is not limited to the case of roaming or personal mobility

users, but this example provides an illustration of the amount of flexibility that becomes feasible when advanced software technologies such as distributed processing environments and mobile code are used in the context of an intelligent network architecture. Moreover, as more logic is implemented in the form of mobile code components, the supporting infrastructure can become much more generic, requiring fewer modifications and configuration changes and able to support different service paradigms. The generic character of the architecture means that stationary code components that require human individual or management intervention for their installation or modification are less likely to require tampering with, and that a greater part of the service logic can be deployed from a remote management station dynamically, at runtime, contributing to the robustness of the system and to an increased uptime. Naturally, the tradeoff is that making service logic programs more intelligent necessarily means increasing their size, straining both the memory resources of the execution environments into which they are executed and also requiring more time for their marshaling and demarshaling when they migrate from one functional entity to another. If their size exceeds a certain threshold, migration operations may become too costly and thus rarely triggered by the load balancing algorithm they implement, negating the advantages brought by their increased autonomy and making services more stationary and less responsive in changing network or usage conditions. Again, simpler solutions may be more appropriate and a designer should exercise caution in determining which logic will be implemented in the form of stationary code components, engraved in the infrastructure, and which will be deployed at runtime using mobile code.

Another major issue to consider in the implementation of a distributed intelligent network architecture is which distributed processing technology to use and how to support its interworking with the signaling system 7 network that interconnects the physical components hosting the functional entities in any intelligent network architecture. There are three main competing distributed technologies: CORBA, DCOM, and RMI. It is not the purpose of this article to examine or compare these three technologies, nor to identify their major strengths and weaknesses. However, for the purposes of an intelligent network implementation, CORBA is best suited because it is the only one of these three technologies to have interworking between it and the signaling system 7 network prescribed [4]. The alternative would be to bypass the native IN control network and install a private internet over which the traffic from DCOM or RMI could be conveyed. Since this is not a development that operators can be expected to implement quickly and for reasons of providing a solution that has the benefit of backward compatibility and also allows an evolutionary roadmap to be defined, CORBA should be the technology of choice in distributed IN implementations. A further reason is that CORBA, which is targeted more than the other two technologies for the telecommunications domain, has more advanced real time characteristics and is therefore better equipped to meet the demands of an operator. The interested reader is referred to Ref. 5 for an in-depth look of the implementation of a distributed IN architecture using CORBA.

5. A DISTRIBUTED IN ARCHITECTURE IN DETAIL

Figure 2 depicts a typical distributed IN implementation in more detail. The main components are (1) the network resources that provide the actual call control and media processing capabilities, (2) the remotely enabled distributed objects that wrap the functionality provided by the physical resources and expose it as a set of interfaces to the service layer, (3) the code components residing in the service layer that incorporate the business logic, and (4) the communication infrastructure that makes communication between the service logic programs and the network resources, via their wrappers, possible. Of course, in an actual architecture a lot more components would need to be identified, such as service management stations, and service creation systems. However, the purpose of the discussion presented here is to allow more insight, where appropriate, into the more technical aspects of a DIN implementation and not to provide a full and comprehensive description of a real system.

Notice, first, that terminals are not depicted in Fig. 2. This is because interaction with terminals at the signaling level is exactly the same as in the case of traditional IN. Signaling emitted by the terminals is used to trigger an IN session and signaling toward terminals or media resources of an IN system (like Intelligent peripherals or specialized resource functions) is used to carry out the execution of a service. However, service components do not directly perceive signaling as they interact with their peer entities on the network side by means of message- or method-based protocols. INAP is a typical method based protocol used at the control plane of IN and Parlay, JAIN, or a version of INAP based on remote application programming interfaces (APIs) are prime candidates for the control plane of distributed IN. In any case it is the responsibility of the network resources to examine signaling messages and initiate an IN session where appropriate, or, in the opposite direction, to receive the instructions sent to them by the service logic programs and issue the appropriate signaling messages to bring these instructions into effect. Therefore, since signaling is conceptually located 'below' the architecture presented in Fig. 2, it can safely be omitted in the discussion that follows. The reader who wishes to gain a fuller appreciation of the temporal relationships between the signaling and INAP messages that are issued in the course of the provisioning of an IN session can refer to Ref. 5.

Assuming a bottom–up approach, the first step would be to explore the programmability characteristics of the deployed equipment that forms the basis of a distributed IN architecture. We refer to deployed equipment as *distributed IN*, like IN before it, which has to be able to encompass and rely on equipment that is already deployed in the field if it is to succeed. Telecom operators have made huge investments in building their networks, and it would be uneconomical to replace all this equipment. At the very least, an evolutionary approach should

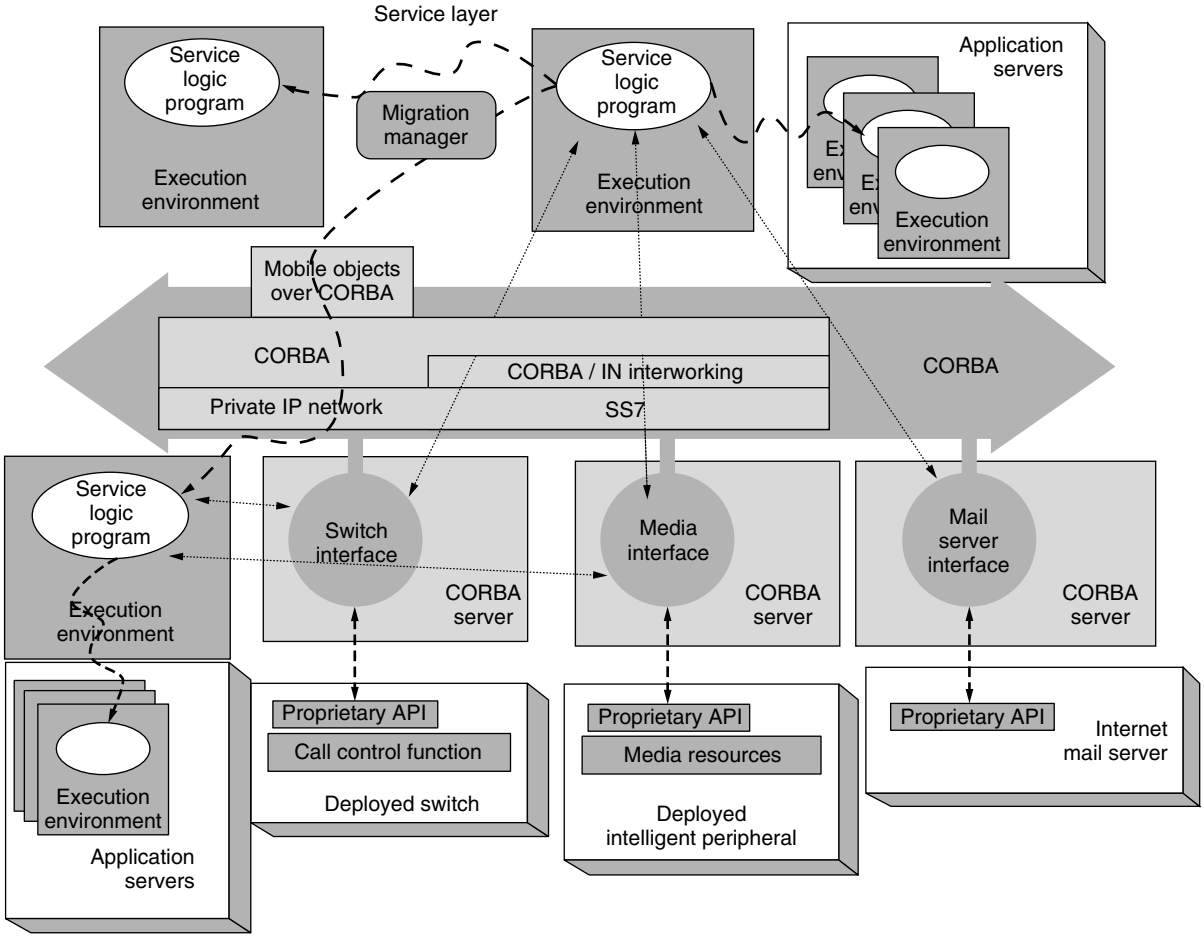

Figure 2. A distributed IN architecture in more detail.

be possible to implement where equipment would be replaced gradually over a period of years and the two technologies, IN and distributed IN, would coexist. It would be further advantageous if existing equipment could be seamlessly integrated into the new distributed intelligent network infrastructure. To address this issue we note that in general, network switches are not meant to be overly programmable. Certain proprietary APIs are always offered that provide an amount of control over how the switch responds to an incoming call, but there are few specifications defining standard interfaces that network switches should offer, and in any case there is much discrepancy between the equipment provided by different vendors. Of course, the IN itself could be regarded as a standard interface for network switches, but the purpose here is not to build the new distributed IN infrastructure over the already existing IN one. Rather, it is to build it on top of the same lower-level facilities and services that IN is using as part of its own implementation: and such lower-level facilities are accessible only to equipment vendors. An external integrator exploring the programmability features of a switch will be able to find standard interfaces only at the IN level, which, as we noted, is conceptually very elevated to be useful as the infrastructure of a distributed IN architecture (note, nevertheless, that Parlay, which is one of a group of emerging technologies that can fall under the "distributed" IN heading, also allows for an approach of using existing IN interfaces as an interim solution before it can be provided natively in switches as IN does). Below this level one, can find only proprietary APIs at different levels of abstraction.

It is therefore possible that a certain operation that a developer would wish to expose to the service components cannot be implemented because the programmability characteristics of the switch would not allow the programming of this behavior. Assuming however that the semantic gap between the operations that a network resource needs to make available for remote invocation and the programming facilities that are available for implementing these operations, can be bridged, generally accepted software engineering principles, object-oriented or otherwise could serve to provide the substrate of the distributed IN [6]. This substrate consists of set of remotely enable objects (CORBA objects "switch interface," "media interface," and "mail server interface" depicted in Fig. 2) that expose the facilities of the network resources they represent. Once this critical implementation phase has been carried out, subsequent implementation is entirely at the service layer. The "switch interface," "media

interface," and "mail server interface" objects are each responsible for exposing a remotely accessible facet of the functionality of the network resource they represent. Their implementation has then to mediate the method invocations it receives remotely, to the local proprietary API that each network resource natively provides. In the opposite direction, one has events that are detected by the network resources and have, ultimately, to reach the components residing in the service layer. This is accomplished by having the CORBA objects register themselves as listeners for these events. The process of registering an external object as a listener involves identifying the events to which it is interested and providing a callback function or remote pointer that will serve to convey the notification when an event satisfying the criteria is encountered. From that point on, the implementation of the CORBA object will itself convey the notification to the higher software layers. It is interesting to note that at this second stage the same pattern of listener and controller objects is also observed, with the exception that now the listener objects are the service logic programs or, in general, the service control logic in the network and the resource is the CORBA object itself. This observation is depicted at Fig. 3.

Through this wrapping of the native control interface to remote API-based ones two things are achieved: (1) the middleware objects residing at the CORBA servers in the middle tier of Fig. 3 can be used to implement standardized interfaces. As an example, Fig. 3 indicates INAP or Parlay API. INAP is, of course, a message-based protocol, but it is relatively straightforward to derive method — based interfaces from the original protocol specification and to express the protocol semantics in terms of method calls and argument passing instead of asynchronous exchange of messages and packets with their payloads described in Abstract Syntax Notation 1. In that sense, API-based versions of INAP can be used to implement the control plane of the distributed intelligent network, and so can, for that matter, emerging technologies such as Parlay and JAIN. The next section discusses such approaches.

6. EMERGING ARCHITECTURES

A number of architectures and most notably JAIN and Parlay have emerged that, although not classified under the caption of "distributed intelligent network," have nevertheless many similarities with it. Distributed intelligent networks make telecommunications service provisioning more open by resting on distributed object technologies and utilizing software technologies such as mobile code, which make the resulting implementation more flexible and responsive to varying network conditions. Parlay and JAIN move a step further toward this direction again by leveraging on CORBA, DCOM, or RMI to implement a yet more open service model that allows the execution of the services to be undertaken by actors different than the operator's organization, in their own premises closer to the corporate data they control and manipulate [7]. In particular, Parlay and JAIN use the same approach as in Ref. 5 of defining methods corresponding more or less to actual INAP information flows and of exposing a switch's (or, for that matter, any other network resident resources)

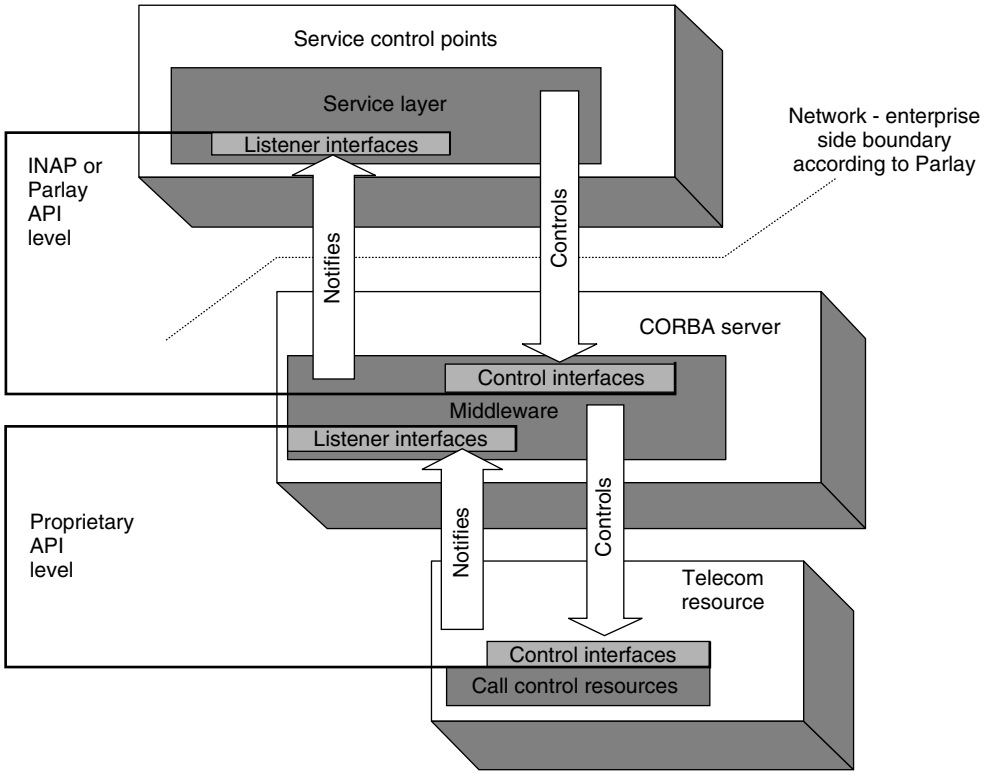

Figure 3. Parlay or other remote API implemented in middleware form over a native resource.

functionality to remotely located service code in the form of an interface of available methods. Moreover, a number of technologies such as the call processing language or telephony services expressing their interaction with the switch in the form of eXtensible Markup Language (XML) statements have appeared that can be used in the same manner as mobile code is used in a distributed IN environment. Service logic expressed in XML or Call Processing Language is inherently mobile in that it is not compiled code and can be interpreted by any appropriate execution environment or script engine. Such engines could then use INAP (message- or method-based) or Parlay and JAIN to interact with actually deployed equipment. Again, this approach enhances the open characteristics of the foreseen telecommunications environment by allowing even the service users themselves to code their services and injecting them into the network exactly in the same manner that mobile service components of the distributed IN where injected into the network. In either case, code mobility is exploited. In the call processing language or XML case, mobility accrues due to the interpreted or scripted nature of the code, in the distributed IN case, due to the semiinterpreted characteristics of the Java language and the Java virtual machine architecture. Service users could program their services themselves since the call processing language expresses telephony services logic at a very simple and abstract level relying on the actual execution engine for the translation of this logic to the appropriate set of INAP or Parlay commands. Alternatively, a graphical front end could be used where elementary building blocks are arranged in a two-dimensional canvas and then the appropriate call processing language or XML code is generated. This is not different from the service creation environments used in IN (both the traditional and the distributed ones), with the exception that such tools were very elaborate and expensive, requiring trained personnel to use them, whereas graphical front ends such as those described above can be simple and inexpensive as they need only produce a set of call processing language statements and not actual code.

7. CONCLUSIONS

The distributed intelligent network encompasses a wide range of architectures each adopting different implementation options and exhibiting different tradeoffs among the various properties that characterize such a system. The common elements in all such systems are the use of distributed processing technologies for the control plane (either INAP in the form of CORBA methods or Parlay/JAIN), mobile service code (Java components or interpreted call processing language or XML statements), and a more open service provisioning model (services executed at the premises of their users, directly managed and maintained or even coded by them).

Distributed IN thus represents the next stage in the evolution of traditional IN architectures that witnesses a new business model with the network operator concentrating on the role of the telecommunication infrastructure provider while more and more of the service provisioning role is assumed by external actors.

BIOGRAPHIES

Iakovos S. Venieris (venieris@cs.ntua.gr) was born in Naxos, Greece, in 1965. He received a Dipl.-Ing. from the University of Patras, Greece in 1988, and a Ph.D. from the National Technical University of Athens (NTUA), Greece, in 1990, all in electrical and computer engineering. In 1994 he became an assistant professor in the Electrical and Computer Engineering Department of NTUA where he is now an associate professor. His research interests are in the fields of broadband communications, Internet, mobile networks, intelligent networks, signaling, service creation and control, distributed processing, agents technology, and performance evaluation. He has over 150 publications in the above areas and has contributed to standardization bodies (ETSI, ITU-T, OMG, and IETF). He has participated in several European Union and national R&D projects. He is an associate editor of the *IEEE Communication Letters*, member of the editorial board of *Computer Communications* (Elsevier), and has been a guest editor for *IEEE Communications Magazine*. He is a reviewer for several journals and has been member of the technical program committee and session chairman of several international conferences. Dr. Venieris is the editor and coauthor of two international books on *Intelligent Broadband Networks* (Wiley 1998) and *Object oriented Software Technologies in Telecommunications* (Wiley 2000).

Dr. Ing. Menelaos Perdikeas (mperdikeas@semantix.gr) was born in Athens, Greece, in 1974 and received a Dipl.-Ing. in computer engineering and informatics (Summa Cum Laude) from the University of Patras, Greece, in 1997 and a Ph.D. in telecommunications engineering from the National Technical University of Athens in 2001. He has over 25 publications in international journals and conferences and has received a number of national and international distinctions, among which, the "D. Chorafas Award for Academic Achievement" for the year 2001. He is coauthor of the book *Object Oriented Software Technologies in Telecommunications* published by Wiley. His interests include intelligent network systems, service provisioning architectures using distributed object technologies, and the application of aspect-oriented programming methodologies and patterns in the development of telecommunications software. Dr. Perdikeas is among the founders of Semantix S. A., a Greek software company.

DIVERSITY IN COMMUNICATIONS

MOHSEN KAVEHRAD
Pennsylvania State University
University Park, Pennsylvania

1. INTRODUCTION

In designing a reliable communication link, the system must be planned around the chosen transmission medium referred to as the *channel*. The disturbances of the medium must be taken into account in the process of encoding the signal at the transmitting end, and in the process of extracting the message from the received waveform at the receiving end. Once a satisfactory characterization of the anticipated channel disturbances has been made, the message encoding chosen for transmission must be designed so that the disturbances will not damage the message beyond recognition at the receiving end. With a corrupted message at hand, the receiving system must be prepared to operate continuously in the presence of the disturbances and to take maximum advantage of the basic differences between the characteristics of messages and of disturbances.

In this article, we assume that the encoded form in which the message is to be transmitted has been selected, and that the encoded form has been translated into a radiofrequency (RF) or lightwave signal by an appropriate modulation technique, such as by varying some distinguishable parameter of a sinusoidal carrier in the RF or optical frequency spectrum. Improvements in system performance can be realized only through the utilization of appropriate corrective signal processing measures. Of primary interest here will be what is widely known as *diversity techniques* [1,2] as countermeasures for combating the effects of loss of received signal energy in parts or over its entire transmission bandwidth, termed as signal fading.

In many practical situations, one seeks economical ways of either transmitting and/or receiving signals in such a way that the signal is never completely lost as a result of transmission disturbances. This has been traditionally the case, in particular, in wireless communications. Ideally, one would like to find transmission methods that are negatively correlated in the sense that the loss of signal in one channel is offset by the guaranteed presence of signal in another channel. This can occur in some diversity systems, such as those that utilize antennas at different elevations in order to minimize the received signal loss of energy. Also, in Section 4.3 of this article the same scenario (negative correlation) applies. In a way, expert investment firms, claiming to provide a diversified portfolio to investors, try to do the same. They opt for capital investment from among those economy sectors whose mutual fund return values are to some degree negatively correlated or at least fluctuate, independently from one sector to another. Consequently, over a long time period, there will be a net gain associated with the diversified portfolio.

The principles of diversity combining have been known in the radio communication field for decades; the first experiments were reported in 1927 [1]. In diversity transmission techniques, one usually settles for fluctuations of signal transmissions over each channel that are more or less uncorrelated with those in other channels and the simultaneous loss of signal will occur rarely over a number of such channels. In order to make the probability of signal loss as low as possible, an effort is made to find many channels that are either statistically independent or negatively correlated. This may be performed over the dimensions of time, frequency and space in a wireless system. For this purpose, it is occasionally possible to use two different polarizations on the receiving antennas, or receivers at several different angles of arrival for the electromagnetic wavefront, or to place antennas in several different spatial locations (spatial diversity) or to transmit the signal over several widely separated carrier frequencies or at several widely separated times (time diversity). The term "diversity improvement" or "diversity gain" is commonly employed to describe the effectiveness of various diversity configurations. There is no standard definition for the effectiveness of diversity reception techniques. One common definition is based on the significance of diversity in reducing the fraction of the time in which the signal drops below an unusable level. Thus, one may define an *outage rate* at some specified level, usually with respect to the mean output noise level of the combiner of the diversity channel outputs. In the rest of this section, the problem of correlation among such multiport channels is discussed.

Assume that a number of terminal pairs are available for different output signals $y_i(t)$ from one or more input signals $x_j(t)$. When frequency (or time) diversity is used, there is no mathematical distinction between a set of multi-terminal-pair channels, each centered on the different carriers (or different times) and a single channel whose system function encompasses all frequencies (or all times) in use. In practice, since one may use physically different receivers, the use of separate system functions to characterize the outputs from each receiver is useful. If space diversity is used, one may be concerned with the system function that depends on the spatial position as a continuous variable.

The cross-correlation function between the outputs of two diversity channels when the channels are both excited by the same signal $x_j(t)$ is fully determined by a complete knowledge of the system functions for each channel alone. In view of the random nature of the channels, the most that can be done to provide this knowledge in practice is to determine the joint statistical properties of the channels.

The signal diversity techniques mentioned above do not all lead to independent results. One must, therefore, recognize those diversity techniques that are dependent in order to avoid trying to "squeeze blood out of a bone." For example, one cannot apply both frequency *and* time diversity to the same channel in any wide sense. In fact one might argue that complete distinction between frequency and time diversity may be wholly artificial, since the signal designer usually has a given time–bandwidth product available that can be exploited in conjunction with the channel characteristics. Another pair of diversity channels that are not necessarily independent of each other are distinguished as angular diversity and space diversity channels. Consider an array of n isotropic antennas that are spaced a sufficient distance apart so that the mutual impedances between antennas can be ignored. If the transmission characteristics of the medium are measured between the transmitting-antenna terminals and the terminals of each of the n receiving antennas, then n channel system functions will result, each of which is associated with one of the spatially dispersed antennas. If the antenna outputs are added through a phase-shifting network, the resultant array will have a receiving pattern that can be adjusted by changing the phase shifting network to exhibit preferences for a variety of different angles of arrival. The problem of combining the outputs of the array through appropriate phase shifters, in order to achieve major lobes that are directed at favorable angles of arrival would be considered a problem in angular diversity, while the problem of combining the outputs of the elements in order to obtain a resultant signal whose qualities are superior to those of the individual outputs is normally considered as the problem of space diversity combining, yet both can lead to the same end result. Signal diversity techniques and methods of combining signals from a number of such channels are discussed in the next section.

2. DIVERSITY AND COMBINING TECHNIQUES

Diversity is defined here as a general technique that utilizes two or more copies of a signal with varying degrees of disturbance to achieve, by a selection or a combination scheme, a consistently higher degree of message recovery performance than is achievable from any one of the individual copies, separately. Although diversity is commonly understood to aim at improving the reliability of reception of signals that are subject to fading in the presence of random noise, the significance of the term will be extended here to cover conceptually related techniques that are intended for other channel disturbances.

The first problem in diversity is the procurement of the "diverse" copies of the disturbed signal, or, if only one copy is available, the operation on this copy to generate additional "diversified" copies. When the signal is disturbed by a combination of multiplicative and additive disturbances, as in the case of fading in the presence of additive random noise, the transmission medium can be tapped for a permanently available supply of diversity copies in any desired numbers.

Propagation media are generally time-varying in character, and this causes transmitted signals to fluctuate randomly with time. These fluctuations are usually of three types:

1. Rapid fluctuations, or fluctuations in the instantaneous signal strength, whose cause can be traced to interference among two or more slowly varying copies of the signal arriving via different paths. This may conveniently be called *multipath fading*. If the multiple paths are resolved by the receiver [2], fading is called *frequency-selective*. Otherwise, it is called *single-path* (flat) *fading*. This type of fading often leads to a complete loss of the message during time intervals that are long even when compared with the slowest components of the message. It is observed, however, that if widely spaced receiving antennas are used to pick up the same signal, then the instantaneous fluctuations in signal-to-noise ratio (SNR) at any one of the receiving sites is almost completely independent of the instantaneous fluctuations experienced at the other sites. In other words, at times when the signal at one of the locations is observed to fade to a very low level, the same signal at some other sufficiently distant site may very well be at a much higher level compared to its own ambient noise. This type of variation is also referred to as *macrodiversity*. Signals received at widely spaced time intervals or widely spaced frequencies also show almost completely independent patterns of instantaneous fading behavior. Nearly uncorrelated multipath fading has also been observed with signal waves differing only in polarization. It will be evident that by appropriate selection or combining techniques, it should be possible to obtain from such a diversity of signals a better or more reliable reception of the desired message than is possible from processing only one of the signals all the time.

2. The instantaneous fluctuations in signal strength occur about a mean value of signal amplitude that changes relatively so slowly that its values must be compared at instants separated by minutes to hours before any significant differences can be perceived. These changes in short-term (or "hourly") mean signal amplitude are usually attributable to changes in the attenuation in the medium that the signals will experience in transit between two relatively small geographic or space locations. No significant random spatial variations in the received mean signal amplitude are usually perceived in receiving localities that could be utilized for diversity protection against this attenuation fading or, as sometimes called, "fading by shadowing". However, it is possible to combat this type of fading by a feedback operation in which the receiver informs the transmitter about the level of the received mean signal amplitude, thus "instructing" it to radiate an adequate amount of power. But the usual practice is to anticipate the greatest attenuation to be expected at the design stage and counteract it by appropriate antenna design and adequate transmitter power.

3. Another type of attenuation fading is much slower than that just described. The "hourly" mean signal levels are different from day to day, just as they are from hour to hour in any single day. The mean signal level over one

day changes from day to day and from month to month. The mean signal level for a period of one month changes from month to month and from season to season, and then there are yearly variations, and so on. As in the case of the "hourly" fluctuations in paragraph 2, the long-term fluctuations are generally caused by changes in the constitution of the transmission medium, but the scale and duration of these changes for the long-term fluctuations are vastly greater than those for the "hourly" changes. Diversity techniques per se are ineffective here.

In addition to the instantaneous-signal diversity that can be achieved by seeking two or more separate channels between the transmitting and receiving antennas, certain types of useful diversity can also be achieved by appropriate design of the patterns of two or more receiving antennas placed essentially in the same location (microdiversity), or by operations in the receiver on only one of the available replicas of a disturbed signal. The usefulness of "receiver diversity" of a disturbed signal will be demonstrated in examples of the next section. The application discussed in Section 4.1 demonstrates the use of diversity (under certain circumstances) from a delayed replica of the desired signal arriving via a different path of multiple fading paths. The latter is referred to as *multipath diversity*, where the same message arrives at distinct arrival times at a receiver equipped to resolve the multipath into a number of distinct paths [3] with different path lengths. The example presented in Section 4.2 shows application of diversity for the case in which the interference from some other undesired signal source is the cause of signal distortion.

The second problem in diversity is the question of how to utilize the available disturbed copies of the signal in order to achieve the least possible loss of information in extracting the desired message. The techniques that have thus far been developed can be classified into (1) switching, (2) combining, and (3) a combination of switching and combining. These operations can be carried out either on the noisy modulated carriers (predetection) or on the noisy, extracted modulations that carry the message specifications (postdetection). In any case, if K suitable noisy waveforms described by $f_1(t), f_2(t), \ldots, f_k(t)$ are available, let the kth function be weighted by the factor a_k, and consider the sum

$$f(t) = \sum_{k=1}^{K} a_k f_k(t) \tag{1}$$

In the switching techniques only one of the a_k values is different from zero at any given time. In one of these techniques, called *scanning diversity*, the available waveforms are tried one at a time, in a fixed sequence, until one is found whose quality exceeds a preset threshold. That one is then delivered for further processing in order to extract the desired message, until its quality falls below the preset threshold as a result of fading. It is then dropped and the next one that meets the threshold requirement in the fixed sequence is chosen. In scanning diversity, the signal chosen is often not the best one available. A technique that examines the K available signals simultaneously and selects only the best one for delivery is conceptually (although not always practically) preferable. Such a technique is referred to as *optimal selection diversity*.

In the combining techniques, all the available noisy waveforms, good and poor, are utilized simultaneously as indicated in Eq. (1); the a_k values are all nonzero all the time. Of all the possible choices of nonzero a_k values, only two are of principal interest. First, on the assumption that there is no a priori knowledge or design that suggests that some of the $f_k(t)$ values will always be poorer than the others, all the available copies are weighted equally in the summation of Eq. (1) irrespective of the fluctuations in quality that will be experienced. Thus, equal mean values of signal level and equal RMS (root-mean-square) values of noise being assumed, the choice $a_1 = a_2 = \cdots = a_k$ is made, and the technique is known as *equal-weight* or *equal-gain combining*. The second possible choice of nonzero weighting factors that is of wide interest is one in which a_k depends upon the quality of $f_k(t)$ and during any short time interval the a_k values are adjusted automatically to yield the maximum SNR for the sum $f(t)$. This is known as *maximal ratio combining*.

In the alternate switching–combining technique a number of the a_k values up to $K - 1$ can be zero during certain time intervals because some of the available signals are dropped when they become markedly noisier than the others. This approach is based on the fact that the performance of an equal-gain combiner will approximate that of the maximal ratio combiner as long as the SNRs of the various channels are nearly equal. But if any of the SNRs become significantly inferior to the others, the overall SNR can be kept closer to the maximum ratio obtainable if the inferior signals are dropped out of the sum $f(t)$.

Over a single-path fading channel, implementation of selection combining does not require any knowledge about the channel, that is, no channel state information (CSI) is necessary at the receiver, other than that needed for coherent carrier recovery, if that is employed. The receiver simply selects the diversity branch that offers the maximum SNR. For equal-gain combining some CSI estimation can be helpful in improving the combiner performance. For example, in a multipath diversity receiver, the maximum delay spread of a multipath fading channel, which is indicative of the channel memory length, can guide the integration time in equal-gain combining, such that the combiner can collect the dispersed signal energy more effectively and perhaps avoid collecting noise over low signal energy time intervals [4]. Maximal ratio combining (MRC) performs optimally, when CSI estimates on both channel phase and multiplicative path attenuation coefficient are available to the combiner. MRC, by using these estimates and proper weighting of the received signal on each branch, yields the maximum SNR ratio for the sum $f(t)$, compared to the selection and equal-gain combining. In the MRC case, diversity branches that bear a strong signal are accentuated and those that carry weak signals are suppressed such that the total sum $f(t)$ will yield the maximum SNR [2]. This is similar to the philosophy that in a free-market society, by making the rich richer, the society as a whole is better off, perhaps because of

increased productivity. Needless to say, in a society as such, laws and justice must also protect the welfare of the needy in order to bring social stability.

Where there is rich scattering, for all multipath fading cases, a RAKE receiver [5] can yield MRC performance. A simplified equal-gain combiner can also be used in some cases, achieving a somewhat lesser diversity gain [4]. However, in digital transmission, if the channel maximum delay spread exceeds the duration of an information bit, intersymbol interference is introduced which needs to be dealt with.

2.1. Statistical Characterization of Fading

For analytical purposes, combined time and frequency, three-dimensional presentations of recordings of fading signals envelopes are obtained through elaborate measurements. These are usually treated as describing a random variable whose statistical properties are determined from fraction-of-time distributions and are hence intimately related to the duration of the interval of observation. The probability distribution functions of such random variables can be considered to characterize a type of stochastic process for which ergodicity theorem applies. According to this theorem, time and distribution averages of random variables described by fraction-of-time distributions are one and the same thing, and they can be used interchangeably depending on expediency.

It is important to note here that although the rate at which the envelope of a received carrier fluctuates may often appear to be high, it is usually quite slow in comparison with the slowest expected variations in the message waveform. In other words, the envelope of the carrier is usually approximately constant when observed over intervals of time that extend over the duration of the longest message element, or over a few periods of the lowest-frequency component in the message spectrum. On the timescale of the fading envelope, such time intervals are then too short for any significant changes in the envelope to occur but not so short that the details of the message waveform are perceived in averaging over the interval. The probability distribution of a fading envelope is usually determined from samples of short time duration, and the results are presented in histograms. Such histograms are invariably compared with simple mathematical curves such as the Rayleigh density and distribution functions or some other functions whose shapes resemble the appearance of the experimental presentations. The fit of the experimental distributions to the Rayleigh distribution is most often excellent for long-range SHF and UHF tropospheric transmission, quite often so for short-range UHF and for ionospheric scatter and reflection of VHF and HF. Accordingly, the Rayleigh fading model is almost always assumed in theoretical treatments, although it is well known that serious deviations from it arise in some situations. According to this model, if a sinusoid of frequency ω_c is radiated at the transmitting end, it will reach a receiver in the form:

$$R(t) = X(t)\cos[\omega_c t + \phi(t)] \tag{2}$$

where $X(t)$ is a slowly fluctuating envelope (or instantaneous amplitude) whose possible values have a probability density function (PDF)

$$p(X) = \frac{2X}{x^2}\exp\left[-\frac{X^2}{x^2}\right] \qquad \text{for} \qquad X \geq 0$$
$$= 0 \qquad \text{otherwise} \tag{3}$$

where x^2 is the mean-square value of X during the small time interval discussed earlier.

No explicit assumptions are usually made concerning the phase $\phi(t)$ beyond the fact that its fluctuations, like those of $X(t)$, are slow compared to the slowest expected variations in the message waveform. But one possible and sometimes convenient assumption to make is that $\phi(t)$ fluctuates in a random manner and can assume all values between 0 and 2π in accordance with the probability density function:

$$p(\phi) = \frac{1}{2\pi} \qquad \text{for} \quad 0 \leq \phi \leq 2\pi$$
$$= 0 \qquad \text{otherwise} \tag{4}$$

The convenience that results from the assumption of a uniformly distributed phase is due to the fact that $R(t)$ of Eq. (2) can now be viewed as a sample function of a narrowband Gaussian process with zero mean and variance $\frac{x^2}{2}$. One may envision, over a multipath channel, many unresolved scattered rays combine in order to give rise to a Gaussian envelope, $R(t)$.

A Rayleigh PDF, as presented, has a single maximum that tends to occur around small values of the random variable X. Thus, in transmitting a binary modulated signal over a Rayleigh fading channel and receiving the signal in additive white Gaussian noise (AWGN), the average bit error rate (BER) for the detected bits tends to be inversely proportional to the receiver SNR, as shown in Fig. 1. This is shown for several binary modulation techniques. This is quite a slow decrease compared to the same, transmitted over an AWGN channel that only suffers with additive white Gaussian noise. For the latter, the BER drops as a function of SNR, exponentially. Naturally, the Rayleigh fading channel model demands significantly higher transmitted power for delivering the bits as reliably as over an AWGN channel. Now, consider use of diversity combining in transmitting a binary modulated signal over a Rayleigh fading channel when the signal is received in AWGN. The average BER for the detected bits now tends to decrease inversely as a function of SNR raised to the power of diversity order, L, as shown in Fig. 2. This is quite a remarkable improvement. In a way, diversity combining process modifies the Rayleigh PDF to look more like a truncated Gaussian PDF, as the order of diversity increases. Thus, loosely speaking, the performance in BER versus SNR for binary transmission over a Rayleigh fading channel starts to resemble that of transmission over an AWGN channel when diversity combining is employed.

Another case of interest in transmission over fading channels is when the received signal in AWGN has a strong deterministic (nonrandom) component. This will contribute to moving the received signal mean away from the region of small signals to a range of rather large

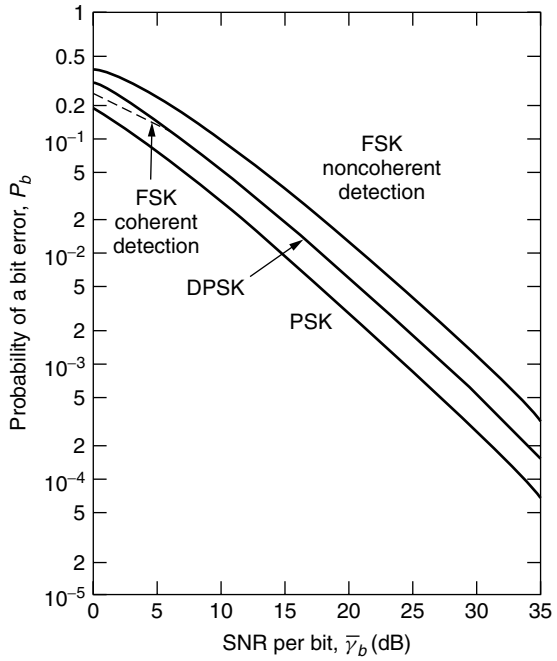

Figure 1. Performance of binary signaling on a Rayleigh fading channel (from Proakis [2]).

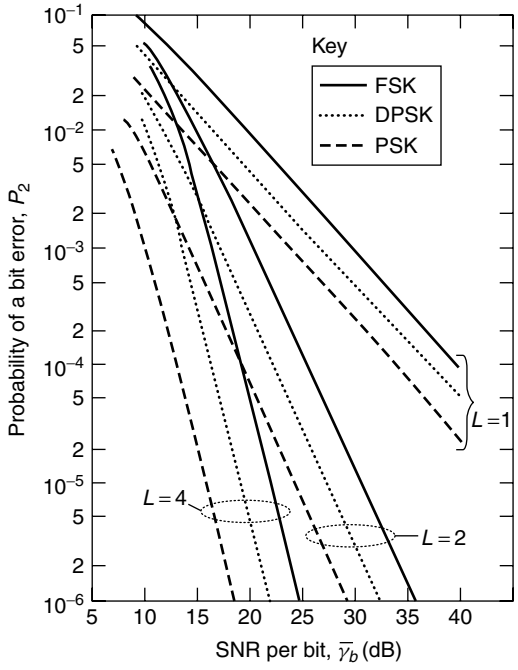

Figure 2. Performance of binary signals with diversity (from Proakis [2]).

signal values. Statistically, the Rayleigh PDF is modified to a Rice PDF [2] that is much milder in the manner by which it affects the transmitted signal. Transmission over a short (∼3 km) line-of-sight microwave channel is often subject to Rice fading. Finally, another PDF that is frequently used to describe the statistical fluctuations of signals received from a multipath fading channel is the Nakagami m distribution [2]. The parameter m is defined as the ratio of moments, called the *fading figure*. By setting $m = 1$, the Nakagami PDF reduces to a Rayleigh PDF. As m increases to values above $m = 1$, transmission performance over a Nakagami channel improves. In a way, this is similar to what happens on a Rice channel. That is, receiver is provided with a stronger signal average, as m increases above the $m = 1$ value.

3. DIVERSITY THROUGH CHANNEL CODING WITH INTERLEAVING

In general, time and/or frequency diversity techniques may be viewed as a form of trivial repetition (block) coding of the information signal. The combining techniques can then be considered as soft-decision decoding of the trivial repetition codes. Intelligent (nontrivial) coding in conjunction with interleaving provides an efficient method of achieving diversity on a fading channel, as emphasized, for example, by chase [6]. The amount of diversity provided by a code is directly related to the code minimum distance, $d_{\min}$. With soft-decision decoding, the order of diversity is increased by a factor of $d_{\min}$, whereas, if hard-decision decoding is employed, the order of diversity is increased by a factor of $\frac{d_{\min}}{2}$. Note that, although coding in conjunction with interleaving can be an effective tool in achieving diversity on a fading channel, it cannot help the signal quality received through a single stationary antenna located in a deep-fade null. The interleaving will not be helpful, since in practice, the interleaving depth cannot be indefinite.

In the next section, we present some examples illustrating the benefits of diversity combining in various communications applications.

4. APPLICATION EXAMPLES

Three examples, illustrating benefits of diversity techniques in practical communications systems, are presented in this section.

4.1. Wideband Code-Division-Multiple-Access Using Direct-Sequence Spread-Spectrum (DSSS) Communications

One application [4] treats a wireless cellular scenario. This represents the up and downstream transmission mode, from user to base station (BS) and from the base to user, of a wireless local-area network (LAN) with a star architecture. Each user has a unique DSSS code and a correlator exists for each user in a channel bank structure at the base station. The output of the bank of correlators is fed to the usual BS circuitry and call setup is handled using standard BS features. Average power control is used in this system to avoid the classical near/far problem. In wireless LAN we have a severe multipath fading problem. It is really a classical Rayleigh multipath, fading channel scenario. The role of asynchronous transmission is clear — a user transmits at random. The signal arrives at the correlator bank and is detected, along with interfering signals. Because the broad bandwidth of a DSSS signal can indeed exceed the channel coherence band (this is the channel band over which all frequency components of the transmitted signal are treated in a correlated

manner), there is inherent diversity in transmission that can be exploited as multipath diversity [3] by a correlation receiver. The psuedonoise (PN) sequences used as direct sequence spreading codes in this application are indeed trivial repeat codes. By exclusive-OR addition of a PN sequence to a data bit, the narrowband of data is spread out to the level of the wide bandwidth of PN sequence. A correlation receiver that knows and has available the matching PN sequence, through a correlation operation, generates correlation function peaks representing the narrowband information bits with a correlation function base, in time, twice the size of a square PN sequence pulse, called a *PN chip*. In this application, the correlator, or matched-filter output, will be a number of resolved replicas of the same transmitted information bit, displayed by several correlation peaks. The number of correlation peaks representing the same information bit corresponds to the diversity order, in this application. Many orders of diversity can be achieved this way.

The replicas obtained this way may now be presented to a combiner for diversity gain. A simple equal gain combiner has been adopted [4] that is by far simpler in implementation than a RAKE receiver [5]. The multipath diversity exploitation in conjunction with multiantenna space diversity [7] establishes a foundation for joint space and time coding.

4.2. Indoor Wireless Infrared (IR) Communications

The purpose of using infrared wireless communication systems in an indoor environment is to eliminate wiring. Utilization of IR radiation to enable wireless communication has been widely studied and remote-control units used at homes introduce the most primitive applications of this type of wireless systems. A major advantage of an IR system over an RF system is the absence of electromagnetic wave interference. Consequently, IR systems are not subject to spectral regulations as RF systems are. Infrared radiation, as a medium for short-range indoor communications, offers unique features compared to radio. Wireless infrared systems offer an inherent spatial diversity, making multipath fading much less of a problem. It is known that the dimension of the coherence area of a fully scattered light field is roughly of the order of its wavelength [8].

This is due to the fact that the receive aperture diameter of a photodiode by far exceeds the wavelength of an infrared waveform. Therefore, the random path phase of a fading channel is averaged over the photo-receiver surface. Hence, the signal strength fluctuations that are caused by phase cancellations in the RF domain are nonexistent in the optical domain. An optical receiver actually receives a large number (hundreds of thousands) of independent signal elements at different locations on the receiving aperture of the photodiode. This in fact provides spatial diversity, which is very similar to employing multiple, geographically separated antennae in an RF fading environment. In summary, because of the inherent diversity channels, the frequency-selective fading effect at the optical carrier frequency level is not a problem in an IR system.

Since infrared transmission systems use an optical medium for data transmission, they have an inherent potential for achieving a very high capacity level. However, in order to make this feasible, the communication system design has to offer solutions to the problems associated with IR propagation in a noisy environment. Various link designs may be employed in indoor wireless infrared communication systems. The classification is based on the degree of directionality and existence of a line-of-sight path between a transmitter and a receiver. In one configuration, instead of transmitting one wide beam, multi-beam transmitters are utilized [9]. These emit multiple narrow beams of equal intensity, illuminating multiple small areas (often called *diffusing spots*) on a reflecting surface. Each beam aims in a prespecified direction. Such a transmitting scheme produces multiple-line-of-sight (as seen by the receiver) diffusing spots, all of equal power, on an extended reflecting surface, such as a ceiling of a room. Each diffusing spot in this arrangement may be considered as a secondary line-of-sight light source having a Lambertian illumination pattern [10]. Compared to other configurations, this has the advantage of creating a regular grid of diffusing spots on the ceiling, thus distributing the optical signal as uniformly as possible within the communication cell as shown in Fig. 3. A direction diversity (also known as angle diversity) receiver that utilizes multiple receiving elements, with each element pointed at a different direction, is used, in order to provide a diversity scheme for optimal rejection of ambient noise power from sunlight or incandescent light, for example, and to substantially reduce the deleterious effects of time dispersion via multiple arrivals of reflecting light rays, causing intersymbol interference in digital transmission. The composite receiver consists of several narrow field-of-view (FoV) elements replacing a single element wide-FoV receiver. The receiver consists of more than one element in order to cover several diffusing spots, thus ensuring uninterrupted communication in case some of the transmitter beams are blocked. Additionally, a multiple-element receiver provides diversity, thus allowing combining of the output signals from different receiver elements, using optimum combining methods. An increased system complexity is the price that one has to pay to escape from restrictions of line-of-sight links, retaining the potential for a high capacity wireless communication system.

For indoor/outdoor wireless transmission systems, use of multiple antennas at both transmit and receive sides to achieve spatial diversity at RF has gained a significant amount of attention. This is motivated by the lack of

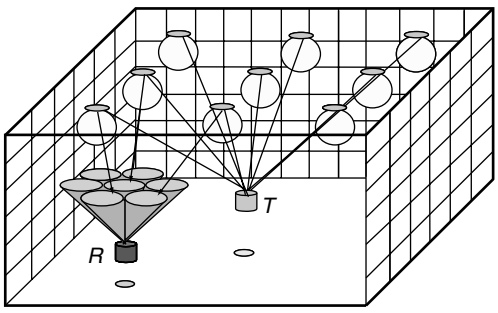

Figure 3. Multispot diffusing configuration (T — transmitter; R — receiver).

available bandwidth at the low-frequency end of the radio spectrum. The approach, in a way, is similar to the IR system described earlier. The capacity increase and spatial multiplexing for high-data-rate transmissions via multiple transmit antennas have been illustrated in Ref. 11. Earlier, transmission of orthogonally-polarized transmitted digitally modulated RF waveforms was introduced to achieve capacity increase over multipath fading channels of point-to-point high-data-rate digital radio routes [12].

4.3. Polarization-Insensitive Fiberoptic Communications

In a coherent optical receiver, receiving a modulated lightwave on a single-mode fiber, the polarization state of the received optical signal must be matched with that of the receiver local laser source signal. A mismatch reduces (perhaps drastically) the received signal strength. Unless the polarization states of the light fields are controlled carefully, receiver performance degradation is unavoidable. The problem encountered here is very similar to the flat fading on a single-path fading channel. Occasionally, the entire band of the received signal is severely attenuated. In an earlier study [13] we examined a polarization-insensitive receiver for binary frequency shift keying (FSK) transmission with discriminator demodulation. The polarization-state-insensitive discriminator receiver is shown in Fig. 4. The two branches carry horizontally and vertically polarized optical beams obtained through a polarization beamsplitter. The information-carrying optical beams are subsequently heterodyne demodulated down to FSK-modulated IF signals and are received by the discriminators for demodulation. The demodulated baseband signals are then combined; thereby a polarization-independent signal is obtained. This is yet another example of diversity combining of equal-gain type.

5. CONCLUDING REMARKS

Given proper operating condition of the equipment, the reliability of a communication system is basically determined by the properties of the signal at the receiving end. We have concentrated in this article on diversity and the effects it may have upon the signal reliability. It is established that "diversification" offers a gain in reliable signal detection. However, a wireless channel offers endless possibilities over a multiplicity of dimensions. Diversity is only one way of introducing a long-term average gain into the detection process. More recently, the availability of low-cost and powerful processors and the development of good channel estimation methods have rejuvenated an interest in adaptive transmission rate techniques with feedback. This new way of thinking is termed *opportunistic communication*, whereby dynamic rate and power allocation may be performed over the dimensions of time, frequency, and space in a wireless system. In a fading (scattering) environment, the channel can be strong sometimes, somewhere, and *opportunistic* schemes can choose to transmit in only those channel states. Obviously, some channel state information is required for an opportunistic communication approach to be successful. Otherwise, it becomes like shooting in the dark. This is in some respects similar to building a financial investment portfolio of stocks, based on some "insider's" information. Clearly, it results in more gain compared to traditional methods of building a diversified portfolio of stocks, based on long-term published trends. Similarly, one would expect a great loss, if the "insider's" information turned out to be wrong. Consequently, opportunistic communications based on wrong channel states will result in a great loss in the wireless network capacity. *Thus, in those wireless applications where reliable channel states may easily be obtained, it is possible to achieve enormous capacities, at a moderate realization complexity*.

BIOGRAPHY

Mohsen Kavehrad received his B.Sc. degree in electronics from Tehran Polytechnic, Iran, 1973, his M.Sc. degree from Worcester Polytechnic in Massachusetts, 1975, and his Ph.D. degree from Polytechnic University (Brooklyn Polytechnic), Brooklyn, New York, November 1977 in electrical engineering. Between 1978 and 1989, he worked on telecommunications problems for Fairchild Industries, GTE (Satellite and Labs.), and AT&T Bell Laboratories. In 1989, he joined the University of Ottawa, Canada, EE Department, as a full professor. Since January 1997, he has been with The Pennsylvania State University EE Department as W. L. Weiss Chair Professor and founding director of the Center for Information and Communications Technology Research. He is an IEEE fellow for his contributions to wireless communications and optical networking. He received three Bell Labs awards for his contributions to wireless communications, the 1991 TRIO feedback award for a patent on an optical interconnect, 2001 IEEE VTS Neal Shepherd Best Paper Award, 5 IEEE Lasers and Electro-Optics Society Best Paper Awards between 1991–95 and a Canada NSERC Ph.D.-thesis award in 1995, with his graduate students for contributions to wireless systems and optical networks. He has over 250 published papers, several book chapters, books, and patents in these areas. His current research interests are in wireless communications and optical networks.

1. INTRODUCTION

1.1. Outline

Discrete multitone (DMT) modulation as well as orthogonal frequency-division multiplex (OFDM) belong to the category of multicarrier schemes. The early ideas go back to the late 1960s and early 1970s [e.g., 1,2]. With the development of fast digital signal processors, the attraction of these techniques increased [e.g., 3–5] and advanced developments have been carried out [e.g., 6,7]. Meanwhile, DMT was introduced as a standard for digital communications on twisted-pair cables [digital subscriber line (DSL)] [8].

The basic idea of multicarrier modulation is to partition a high-rate datastream into a large number of low-rate data signals that are modulated onto different carrier frequencies and are transmitted simultaneously over parallel subchannels. Because of the partition of the datastream, the data rate on each subchannel is much lower than for the original signal. As low-rate signals are much less susceptible to channel impairments, the reception and reconstruction of the subchannel signals at the receiver side is simplified significantly. However, all subchannels have to be received in parallel and have to be processed simultaneously — a requirement that can be met in an economic way only with digital signal processing. Because of the large number of carriers, the subchannel signals can be well adapted to the channel characteristics. As a consequence, multicarrier schemes like DMT offer the ability to maximize the data throughput over frequency-selective channels, such as the telephone subscriber line.

As multicarrier modulation like DMT or OFDM can be interpreted as a further development of frequency-division multiplexing (FDM) [4], we begin with the explanation of the classical FDM principles.

1.2. Frequency-Division Multiplexing (FDM)

With FDM the available bandwidth of the transmission medium is separated into a number of frequency bands in order to transmit various signals simultaneously on the same medium. The principal block diagram is given in Fig. 1. Each band-limited baseband signal $x_\nu(t)$ is modulated onto a carrier $\cos(\omega_\nu t)$ with carrier frequency ω_ν, $\nu = 0, 1, \ldots, N-1$.

The received FDM signal is first bandpass (BP)-filtered with center frequency ω_μ, multiplied by $\cos(\omega_\mu t)$ and then lowpass (LP)-filtered to obtain the demodulated signal $\hat{x}_\mu(t)$.

The FDM signal at the transmitter output is

$$s(t) = \sum_{\nu=0}^{N-1} x_\nu(t)\cos(\omega_\nu t) \tag{1}$$

For the spectra of the transmitter signals, we have

$$s(t) \leftrightarrow S(\omega) \tag{2}$$

$$x_\nu(t)\cos(\omega_\nu t) \leftrightarrow \tfrac{1}{2}X_\nu(\omega-\omega_\nu) + \tfrac{1}{2}X_\nu(\omega+\omega_\nu) \tag{3}$$

$$s(t) \leftrightarrow S(\omega) = \frac{1}{2}\sum_{\nu=0}^{N-1} X_\nu(\omega-\omega_\nu) + X_\nu(\omega+\omega_\nu) \tag{4}$$

The term $S(\omega)$ is shown in Fig. 2 for the simplified case that all $X_\nu(\omega)$ are real-valued. In conventional FDM systems, the frequencies ω_ν have to be chosen in such a way that the spectra of the modulated signals do not overlap. If all baseband signals $X_\nu(\omega)$ have the same

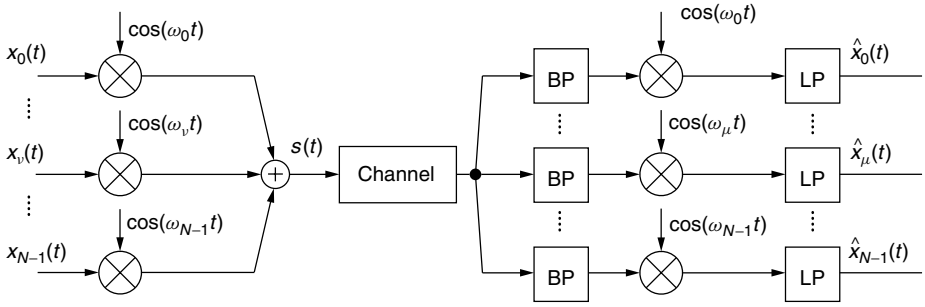

Figure 1. Analog frequency division multiplexing. The baseband signals $x_0(t), \ldots, x_{N-1}(t)$ are modulated on different carriers.

bandwidth, the carrier frequencies are normally chosen equidistantly. However, the FDM system described above wastes valuable bandwidth because (1) some space must be available for the transition between the passband and the stopband of each bandpass filter in Fig. 1; and (2), if $s(t)$ is real, $S(\omega)$ is conjugated symmetric, that is, $S(-\omega) = S^*(\omega)$, where * denotes the conjugate complex operation. As a consequence, the bandwidth of $S(\omega)$ is twice as required theoretically.

The second drawback can be solved by quadrature amplitude modulation (QAM) [9]. With QAM, two independent baseband signals are modulated onto a sine and a cosine carrier with the same frequency ω_ν which gives an unsymmetric spectrum. As a result the spectral efficiency is doubled.

The first drawback of FDM can be overcome by multicarrier modulation, such as by DMT, which allows for a certain overlap between the spectra illustrated in Fig. 2. Of course, spectral overlap in general could lead to nontolerable distortions. So the conditions for this overlap have to be carefully established in order to recover the signal perfectly at the receiver side. This will be done in the next section.

2. MULTICARRIER BASICS

2.1. Block Diagram and Elementary Impulses

Following the ideas outlined in the previous section and applying discrete-time signals $X_\nu[k]$ at the input leads us to the block diagram in Fig. 3.

The impulse modulator translates the sequence $\{\ldots, X_\nu[0], X_\nu[1], \ldots\}$ into a continuous-time function

$$x_\nu(t) = T_S \sum_{k=-\infty}^{\infty} X_\nu[k] \cdot \delta(t - kT_S), \quad \nu = 0, 1, \ldots, N-1 \tag{5}$$

where T_S is the symbol interval, $\delta(t)$ is the Dirac impulse and $\delta[k]$ is the unit impulse with

$$\delta[k] = \begin{cases} 1 & \text{for} \quad k = 0 \\ 0 & \text{for} \quad k \neq 0 \end{cases} \tag{6}$$

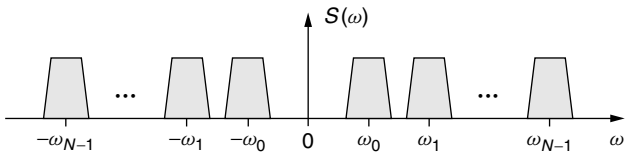

Figure 2. Spectrum $S(\omega)$ of the FDM signal $s(t)$.

The output signal $s(t)$ of the multicarrier transmitter is given by

$$s(t) = T_S \sum_{\nu=0}^{N-1} e^{j\omega_\nu t} \sum_{k=-\infty}^{\infty} X_\nu[k] g(t - kT_S) \tag{7}$$

where $g(t)$ is the impulse response of the impulse shaping filter. The carrier frequencies ω_ν are chosen as integer multiples of the carrier spacing $\Delta\omega$:

$$\omega_\nu = \nu \cdot \Delta\omega, \quad \nu = 0, 1, \ldots, N-1 \tag{8}$$

All practical multicarrier systems are realized with digital signal processing. Nevertheless, we will use the analog model of Fig. 3 in this section, because the analysis can be done more conveniently and the understanding of the principles of multicarrier modulation is easy. Section 3.1 deals with the digital implementation.

The output signal $s(t)$ can be either real or complex. If complex, $s(t)$ can be considered as the complex envelope and the channel is the equivalent baseband channel. As will be shown in Section 3.2 , DMT modulation provides a real-valued output signal $s(t)$. Nevertheless, the following derivations hold for both cases.

The receiver input signal $w(t)$ is demodulated and filtered by the receiver filters with impulse response $h(t)$, resulting in the signal $y_\mu(t)$, $\mu \in \{0, \ldots, N-1\}$. Sampling this signals at the time instants $t = kT_S$ gives the discrete-time output $Y_\mu[k]$. The signal after filtering is given by

$$\begin{aligned} y_\mu(t) &= (w(t)e^{-j\omega_\mu t}) \star h(t) \\ &= \int_{-\infty}^{\infty} w(\tau) e^{-j\omega_\mu \tau} h(t - \tau) d\tau, \quad \mu = 0, \ldots, N-1 \end{aligned} \tag{9}$$

where $\star$ denotes the convolution operation. For the moment, we assume an ideal channel. Thus $w(t) = s(t)$ and we get from (9) with (7) and (8)

$$\begin{aligned} y_\mu(t) = T_S \int_{-\infty}^{\infty} \Bigg(&\sum_{\nu=0}^{N-1} e^{j(\nu-\mu)\Delta\omega\tau} \\ &\times \sum_{k=-\infty}^{\infty} X_\nu[k] g(\tau - kT_S) h(t - \tau) \Bigg) d\tau \end{aligned} \tag{10}$$

Sampling $y_\mu(t)$ at $t = kT_S$ yields the output signal

$$\begin{aligned} Y_\mu[k] = y_\mu(kT_S) = \int_{-\infty}^{\infty} \Bigg(&\sum_{\nu=0}^{N-1} e^{j(\nu-\mu)\Delta\omega\tau} \\ &\times \sum_{l=-\infty}^{\infty} X_\nu[l] g(\tau - lT_S) h(kT_S - \tau) \Bigg) d\tau \end{aligned} \tag{11}$$

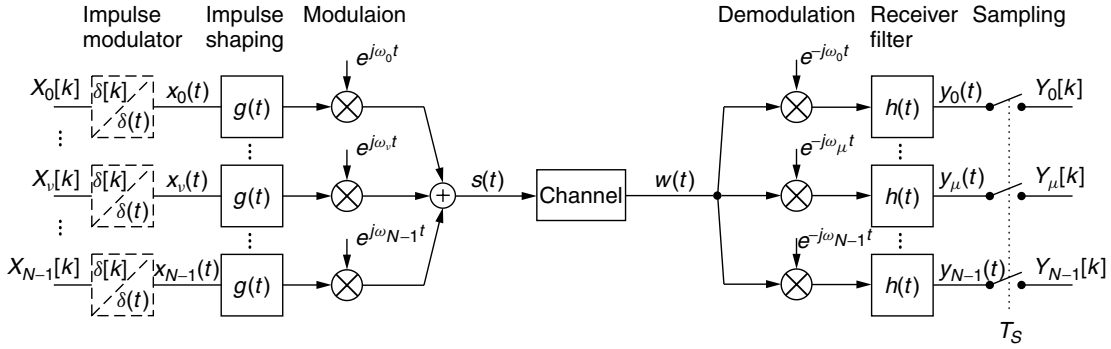

Figure 3. Block diagram of a general multicarrier system.

Now, the target is to recover the sequences $X_\nu[k]$ at the receiver side without distortion. As the given system is linear, we can restrict our analysis to the evaluation of the response to one single transmitted symbol on one subcarrier. We can then make use of the superposition theorem for the general case of arbitrary input sequences. Basically, two types of interference can be seen from Eq. (11):

1. *Intersymbol interference* (ISI), in which a symbol sent at time instant k on subcarrier μ has impact on previous or following samples $y_\mu(lT_S)$ with $l \neq k$.
2. *Intercarrier interference* (ICI), which is the result of crosstalking between different subchannels at time instants kT_S.

Without loss of generality we assume that the system model in Fig. 3 has zero delay, i.e., the filters $g(t)$, $h(t)$ are not causal. We sent one unit impulse $\delta[k]$ at the time $k = 0$ on subcarrier ν:

$$X_i[k] = \delta[\nu - i]\delta[k] \tag{12}$$

The received signal $y_\mu(t)$ is free of any interference at the sampling instants kT_S, if

$$Y_\mu[k] = \delta[\nu - \mu]\delta[k] \tag{13}$$

To gain further insight into the nature of ISI and ICI, we take a closer look at the received signals before they are being sampled. A unit impulse $X_\nu[k] = \delta[k]$ on carrier ν yields the transmitter output signal

$$s(t) = T_S\, g(t) e^{j\nu\Delta\omega t} \tag{14}$$

which is also the input signal $w(t)$ as we assume an ideal channel. We now define the elementary impulse $r_{\nu,\mu}(t)$ as the response $y_\mu(t)$ to the receiver input signal of Eq. (14).

$$\begin{aligned} r_{\nu,\mu}(t) &= T_S \left(g(t)e^{j(\nu-\mu)\Delta\omega t}\right) \star h(t) \\ &= T_S \int_{-\infty}^{\infty} g(\tau) e^{j(\nu-\mu)\Delta\omega\tau} h(t-\tau)\, d\tau \end{aligned} \tag{15}$$

Obviously, $r_{\nu,\mu}(t)$ depends only on the difference $d = \nu - \mu$. Thus we get

$$r_d(t) = T_S(g(t)e^{jd\Delta\omega t}) \star h(t) \tag{16}$$

We can now formulate the condition for zero interference as

$$r_d(kT_S) = \delta[d]\delta[k] \tag{17}$$

This can be interpreted as a more general form of the first Nyquist criterion because it forces not only zero intersymbol interference but also zero intercarrier interference [10,11]. If we set $d = 0$, Eq. (17) simplifies to the Nyquist criterion for single-carrier systems. In the context of multicarrier systems and filterbanks, (17) is also often called an *orthogonality condition* or a *criterion for perfect reconstruction*.

For DMT systems without guard interval $g(t) = h(t)$ holds and they are rectangular with duration T_S. The purpose of the guard interval will be explained in the next section. With the carrier spacing

$$\Delta\omega = \frac{2\pi}{T_S}, \tag{18}$$

we obtain from Eq. (16) the elementary impulses

$$r_0(t) = \begin{cases} 1 - \dfrac{|t|}{T_S} & |t| \leq T_S \\ 0 & \text{elsewhere} \end{cases} \tag{19}$$

$$r_d(t) = \begin{cases} \dfrac{\operatorname{sgn}(t)(-1)^d}{j2\pi d} \left(1 - e^{jd(2\pi/T_S)t}\right) & \text{for } |t| \leq T_S \\ 0 & \text{elsewhere} \end{cases} \quad d \neq 0 \tag{20}$$

These functions are shown in Fig. 4a and give us some insight into the nature of intersymbol and intercarrier interference. We clearly see that the sampling instants $t = kT_S$ do not contribute to any interference. As the elementary impulses are not always zero between the sampling instants, they cause quite some crosstalk between the subchannels. The oscillation of the crosstalk is increased with the distance d between transmitter and receiver subchannel, whereas their amplitude is decreasing proportional to $1/d$.

The impact of interference can also be seen from Fig. 4b, where the eye diagram of the real part of $y_\mu(t)$ is shown for a 16-QAM on $N = 256$ subcarriers; that is, the real and imaginary parts of the symbols $X_\nu[k]$ are taken at random out of the set $\{\pm 1, \pm 3\}$ and are modulated on all subcarriers.

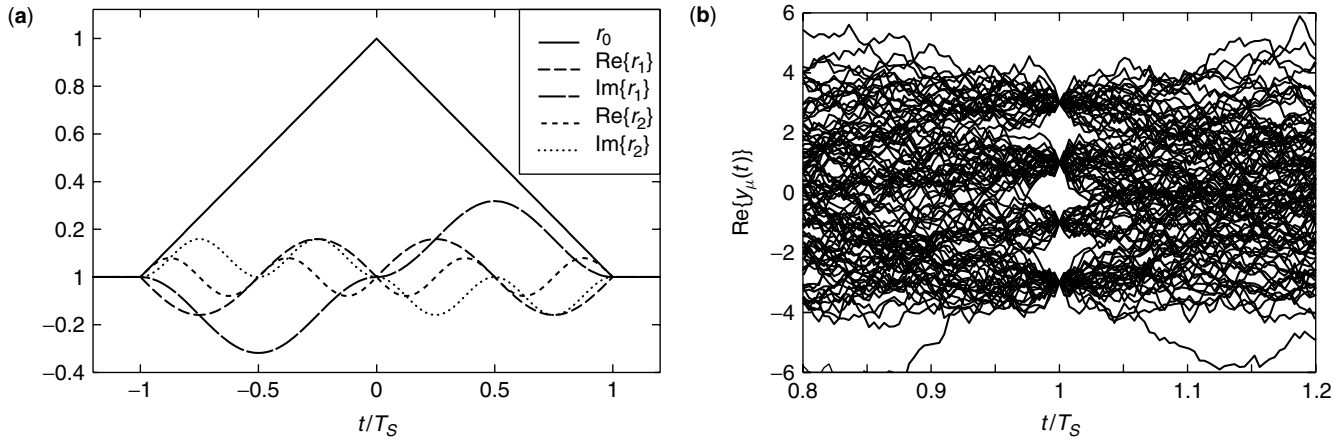

Figure 4. (**a**) Elementary impulses $r_d(t)$ of a multicarrier system with rectangular impulse shapes; (**b**) eye diagram of real part of $y_\mu(t)$ for 16-QAM and $N = 256$ carriers.

Obviously, even with an ideal channel the horizontal eye opening tends to zero, requiring very small sampling jitter and making a correct detection of the transmitted symbols extremely difficult.

2.2. Introduction of a Guard Interval

An effective solution to increase the horizontal eye opening is the introduction of a guard interval. It is introduced by choosing different impulse responses $g(t) \neq h(t)$ at transmitter and receiver. The duration of the guard interval is given as

$$T_G = T_S - T_u \geq 0 \tag{21}$$

where T_S and T_u denote the length of the impulse response of the transmitter and the receiver filter $g(t)$ and $h(t)$, respectively. Both impulse responses are rectangular and symmetric to $t = 0$.

In contrast to (18), the carrier spacing is now

$$\Delta\omega = \frac{2\pi}{T_u} \tag{22}$$

For the elementary impulses follows

$$r_0(t) = \begin{cases} \dfrac{-|t| + T_S - T_G/2}{T_S - T_G} & \text{for} \quad \dfrac{T_G}{2} < |t| < T_S - \dfrac{T_G}{2} \\ 1 & \text{for} \quad |t| < \dfrac{T_G}{2} \\ 0 & \text{for} \quad |t| > T_S - \dfrac{T_G}{2} \end{cases} \tag{23}$$

$$r_d(t) = \left\{ \begin{array}{ll} \dfrac{\text{sgn}(t)(-1)^d}{j2\pi d} \left(e^{j\text{sgn}(t)\, d\pi (T_G/T_u)}\right. & \text{for } \dfrac{T_G}{2} < |t| \\ \left. - e^{jd(2\pi/T_u)t}\right) & < T_S - \dfrac{T_G}{2} \\ 0 & \text{elsewhere} \end{array} \right\} d \neq 0 \tag{24}$$

As can be seen from Fig. 5, there are flat regions around the sampling instants $t = kT_S$, $k = 0, \pm 1, \ldots$ which prevent any interference. In many multicarrier systems, DMT as well as OFDM, the guard interval is chosen as $T_G/T_u = \frac{1}{16}, \ldots, \frac{1}{4}$. In Fig. 5b the eye diagram for a DMT system with guard interval is shown. Obviously, the horizontal eye opening is now increased

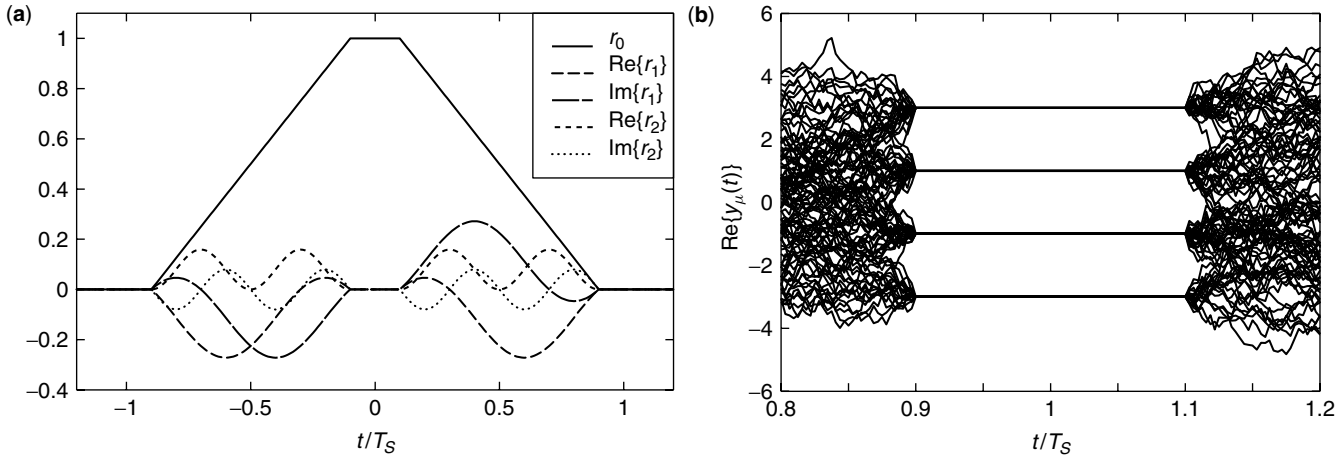

Figure 5. (**a**) Elementary impulses $r_d(t)$ with guard interval $T_G = T_u/4$; (**b**) eye diagram of real part of $y_\mu(t)$ for 16-QAM and $N = 256$ carriers and $T_G = T_u/4$.

and is as long as the guard interval. Therefore, the impact of timing jitter and interference is reduced considerably. However, DMT and OFDM systems are much more sensitive to timing jitter than are single-carrier systems [12].

During the guard interval period T_G, no information can be transmitted. Thus, the spectral efficiency is reduced by a factor T_G/T_S.

3. PRINCIPLES OF DISCRETE MULTITONE MODULATION

3.1. Implementation with Digital Signal Processing

While the continuous-time model in Fig. 3 is valuable for the analysis, the implementation of DMT systems is exclusively done using digital signal processing. Sampling the continuous-time signals in Fig. 3 with the sampling period T_A leads to the discrete-time or digital DMT system in Fig. 6.

The impulse modulators are replaced by upsamplers. They insert $N_S - 1$ zero samples between each incoming symbol $X_\nu[k]$. Thus $T_S = N_S \cdot T_A$ holds. We define

$$T_S = N_S \cdot T_A, \quad T_G = G \cdot T_A, \quad T_u = N \cdot T_A \tag{25}$$

From (21) follows

$$N_S = G + N \tag{26}$$

where G denotes the number of guard samples. For the complex carriers in Fig. 3, we obtain the following with Eqs. (8), (22), and (25) and $t = nT_A$:

$$\exp(j\omega_\nu n T_A) = \exp\left(j\frac{2\pi}{N}\nu n\right) = w^{-\nu n} \quad \text{with}$$
$$w = \exp\left(-j\frac{2\pi}{N}\right) \tag{27}$$

Of course, we have to ask whether the sampling theorem is fulfilled. As $g(t)$ and $h(t)$ are rectangular, and thus have infinite bandwidth, the sampling theorem is not met, at least not exactly. Consequently, the digital system in Fig. 6 is not an exact representation of the continuous-time system of Fig. 3. Nevertheless it is a reasonable approximation, and the concept of the elementary impulses and the generalized Nyquist criterion can be used similarly. We now adopt causal discrete-time filters:

$$g[n] = \begin{cases} \dfrac{1}{\sqrt{N}} & \text{for } n = 0, \ldots, N_S - 1 \\ 0 & \text{elsewhere} \end{cases} \tag{28}$$

The output signal of the transmitter in Fig. 6 can be written as

$$s[n] = \sum_{\nu=0}^{N-1} w^{-\nu n} \sum_{k=-\infty}^{\infty} X_\nu[k] g[n - kN_S] \tag{29}$$

We introduce the operator div for integer divisions as $n \operatorname{div} N_S = \lfloor n/N_S \rfloor$, where $\lfloor\ \rfloor$ indicates rounding toward the nearest smaller integer. With (28) we get from (29)

$$s[n] = \frac{1}{\sqrt{N}} \sum_{\nu=0}^{N-1} X_\nu[n \operatorname{div} N_S] \cdot w^{-\nu n} \tag{30}$$

Here we recognize the expression for the discrete Fourier transform (DFT; IDFT = inverse DFT) pair:

$$\text{DFT: } X_m = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} x_n w^{nm} \quad \text{IDFT: } x_n = \frac{1}{\sqrt{N}} \sum_{m=0}^{N-1} X_m w^{-nm} \tag{31}$$

Thus, we identify the input signals $X_0[k], \ldots, X_{N-1}[k]$ as a block with index k and define the blockwise IDFT:

$$x_i[k] = \frac{1}{\sqrt{N}} \sum_{\nu=0}^{N-1} X_\nu[k] \cdot w^{-i\nu} \tag{32}$$

which allows us to express (30) as

$$s[n] = x_{n \bmod N}[n \operatorname{div} N_S] \tag{33}$$

For each block k of N input samples, $N_S = N + G$ output samples are produced. The first block $k = 0$ produces the output sequence

$$\{s[0], \ldots, s[N_S - 1]\} = \{x_0[0], \ldots, x_{N-1}[0], x_0[0], \ldots, x_{G-1}[0]\}$$

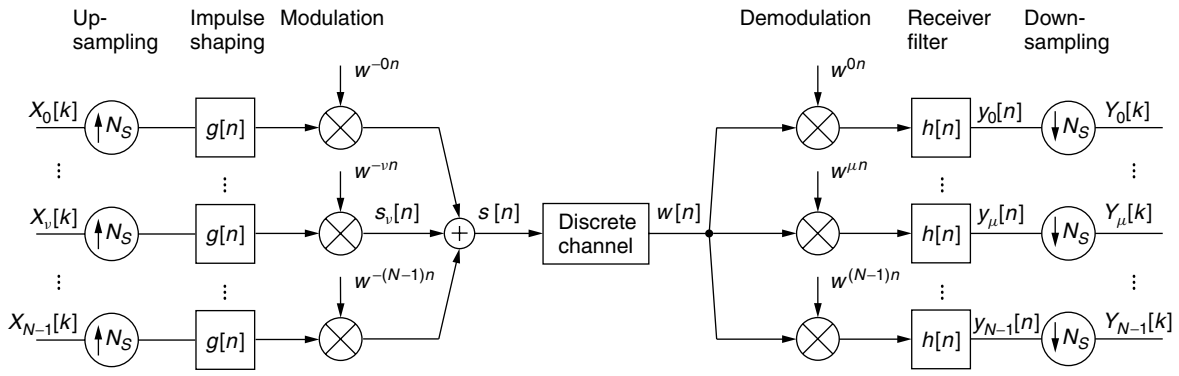

Figure 6. Transmitter and receiver for digital multicarrier transmission.

while the second block ($k = 1$) yields the output

$$\{s[N_S], \ldots, s[2N_S - 1]\}$$
$$= \{x_G[1], \ldots, x_{N-1}[1], x_0[1], \ldots, x_{2G-1}[1]\}$$

We recognize that each output block contains the symbols $x_0[k], \ldots, x_{N-1}[k]$ plus G additionally samples taken out of the same set. The calculation of $s[n]$ applying a blockwise IDFT is illustrated in Fig. 7, where a block of N input symbols is first IDFT-transformed and then parallel–serial-converted. The commutator puts out N_S symbols for each block by turning more than one revolution, resting after each block in a different position. Thus, although each block contains all transformed symbols, the ordering and the subset of doubled samples vary. To overcome this inconvenience and to facilitate the block processing at the receiver side, practically all DMT systems compute a block of N samples by inverse DFT processing and insert the additional samples at the beginning of the block. Therefore the guard interval is also called *cyclic prefix* (CP). Thus, a DMT block for index k will be ordered as follows:

$$\underbrace{x_{N-G}[k], x_{N-G+1}[k], \ldots, x_{N-1}[k]}_{G \text{ samples, cyclic prefix}}, \underbrace{x_0[k], x_1[k], \ldots, x_{N-1}[k]}_{N \text{ data samples}} \tag{34}$$

Thus, we can express the transmitter signal after insertion of the CP as

$$\tilde{x}[n] = x_{n \bmod N_S}[n \operatorname{div} N_S] \tag{35}$$

The discrete-time output signal with block processing is denoted as $\tilde{x}[n]$ in order to distinguish it from $s[n]$. At this point, the mathematical notation seems to be a little bit more tedious than in Eq. (30), but (32) and (35) describe the signals for independent block processing, which simplifies the operations in the transmitter and especially in the receiver considerably. Later we will derive a compact matrix notation that operates blockwise, taking advantage of the block independence.

3.2. Real-Valued Output Signal for Baseband Transmission

Because the DMT signal is transmitted over baseband channels, we must ensure that the output signal $\tilde{x}[n]$ and thus $x_i[k]$ are real-valued. Therefore we have to decompose $x_i[k]$ of (32) into real and imaginary parts

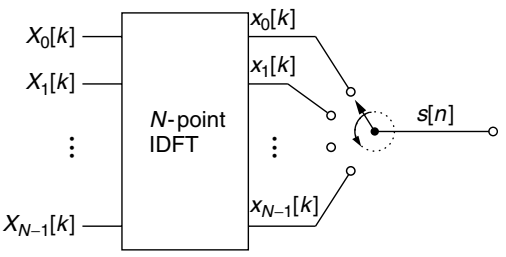

Figure 7. Inverse IDFT with parallel–serial conversion.

and set the latter to zero. After some calculations, this provides the following conditions on the input sequences $X_\nu[k]$:

$$X_0, X_{N/2} \in \mathcal{R} \tag{36}$$

$$X_\nu = X^*_{N-\nu}, \qquad \nu = 1, \ldots, \frac{N}{2} - 1 \tag{37}$$

Consequently, we get from (32) with $X_\nu[k] = X'_\nu[k] + jX''_\nu[k]$

$$x_i[k] = \frac{1}{\sqrt{N}} \left(X_0[k] + (-1)^i X_{N/2}[k] + 2 \times \sum_{\nu=1}^{\frac{N}{2}-1} X'_\nu[k] \cos\left(\frac{2\pi}{N} i\nu\right) - X''_\nu[k] \sin\left(\frac{2\pi}{N} i\nu\right) \right) \tag{38}$$

To simplify the transmitter scheme, we can choose $\tilde{X}_0 = X_0 + jX_{N/2}$ as indicated in Fig. 8. For practical implementations, this is of minor importance as usually X_0 and $X_{N/2}$ are set to zero. The reason will be discussed in Section 3.3.

It is convenient to interpret the DMT signal in (38) as a sum of $N/2$ QAM carriers where $X_\nu[k]$ modulates the νth carrier.

The detailed block diagram of a DMT transmitter as realized in practice is depicted in Fig. 8. The parallel–serial conversion and the insertion of the guard interval is symbolized by the commutator which inserts at the beginning of each block G guard samples, copied form the end of the block. A digital-to-analog converter (DAC) provides the continuous-time output $\tilde{x}(t)$. We clearly see that the guard interval adds some overhead to the signal and reduces the total data throughput by a factor $\eta = G/N_S$. Therefore, the length G of the cyclic prefix is normally chosen much smaller than the size N of the inverse DFT. We will see in Section 3.5 that the cyclic prefix allows for a rather simple equalizer.

Figure 9 depicts the corresponding DMT receiver. After analog-to-digital conversion and synchronization, the signal $\tilde{y}[n]$ is serial–parallel converted. Out of the N_S symbols of one block, the G guard samples are discarded and the remaining N symbols are fed into a DFT. Note that synchronization and timing estimation are essential receiver functions to produce reliable estimates of the transmitted data at the receiver. There have been many proposals for synchronization with DMT modulation, such as that by Pollet and Peeters [13].

Another major item to be considered with DMT modulation is the large peak-to-average power ratio (PAPR) of the output signal $\tilde{x}[n]$. Thus, a wide input range of the DAC is required. Furthermore, large PAPR can cause severe nonlinear effects in a subsequent power amplifier. The PAPR should be considered particularly for multicarrier modulation with a large numbers of subcarriers, because this ratio increases with the number of subcarriers. In order to reduce the

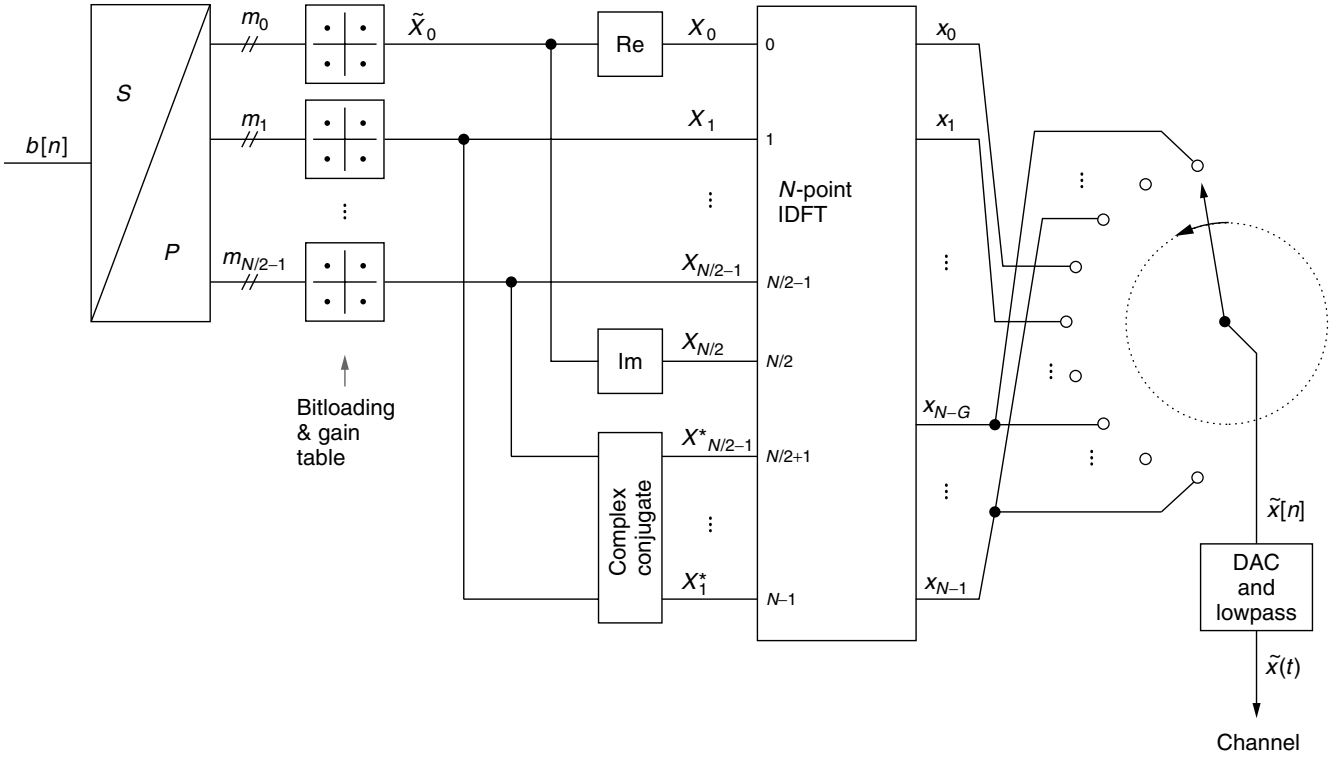

Figure 8. DMT transmitter.

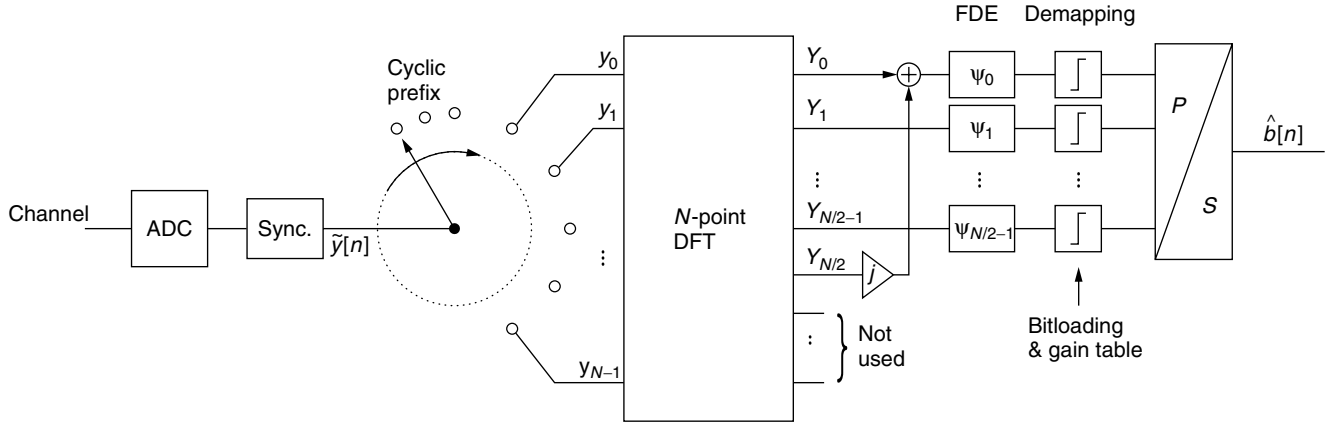

Figure 9. DMT receiver.

PAPR, several techniques have been proposed, such as "selective mapping" and "partial transmit sequence" approaches [14].

3.3. Spectral Properties

We calculate the spectrum of the output signal $s[n]$ in Fig. 6 for one modulated subchannel, namely, the input signal is given by (12). This gives

$$s[n] = g[n] \cdot w^{-\nu n} \leftrightarrow S(\omega) = \sum_{n=-\infty}^{\infty} g[n] \cdot w^{-\nu n} \cdot e^{-j\omega n T_A} \quad (39)$$

From Eqs. (22) and (25) we obtain $T_A = 2\pi/(N\Delta\omega)$. Together with (28), it follows from (39) that

$$S(\omega) = \frac{1}{\sqrt{N}} \begin{cases} \dfrac{1 - w^{(\omega/\Delta\omega - \nu)N_S}}{1 - w^{(\omega/\Delta\omega - \nu)}} & \text{for } \dfrac{\omega}{\Delta\omega} \neq \nu \\ N_S & \text{for } \dfrac{\omega}{\Delta\omega} = \nu \end{cases} \quad (40)$$

In order to obtain a real-valued output signal, according to (37), we have to sent a unit impulse on subchannel $N - \nu$, too. In Fig. 10a the magnitude of the spectrum is depicted for the case that subcarrier ν is modulated. The spectrum is quite similar to a $\sin(\omega)/\omega$-function. However,

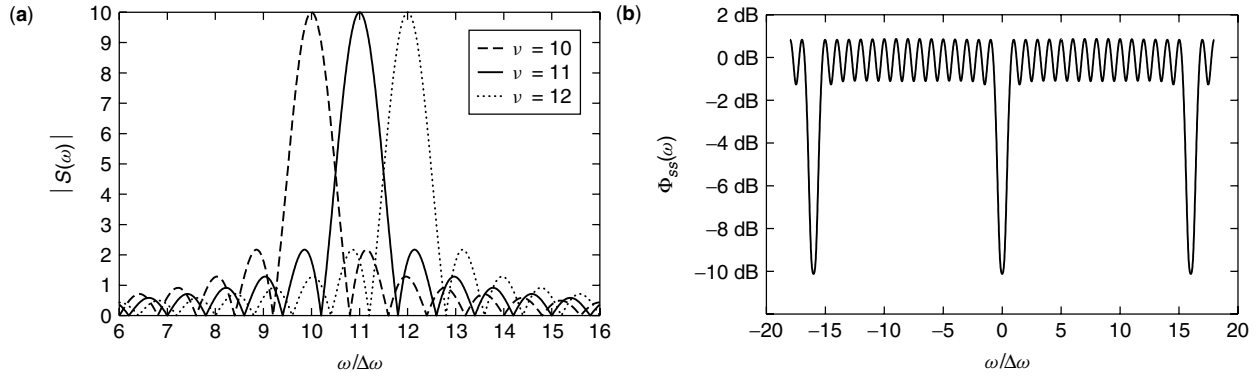

Figure 10. (**a**) Magnitude response $|S(\omega)|$ for modulated carrier ν, $G = N/8$; (**b**) power spectral density $\Phi_{ss}(\omega)$ for $N = 32$, $G = 4$. The ripple increases with the duration of the guard interval.

as Fig. 6 is a discrete-time system, $S(\omega)$ is periodic with $\omega_A = N \cdot \Delta\omega$. Note that the spectrum of a single subcarrier with carrier frequency $\nu\Delta\omega$ does *not* have zero crossings at $\omega = (\nu \pm m)\Delta\omega$, $m = 1, 2, \ldots$ if a guard interval with length $G > 0$ is used.

In order to calculate the power spectral density (PSD) of a DMT signal, we now consider stochastic input sequences $X_\nu[k]$ that are uncorrelated, have zero mean and variances σ_ν^2. Then the PSD of the output signal $s_\nu[n]$ of modulator ν in Fig. 6 becomes

$$\Phi_{s_\nu s_\nu}(\omega) = \frac{\sigma_\nu^2}{N_S} \cdot |G(\omega)|^2, \qquad \text{with}$$

$$G(\omega) = \sum_{n=-\infty}^{\infty} g[n] e^{-j\omega n T_A} = \frac{1}{\sqrt{N}} \frac{1 - w^{\frac{\omega}{\Delta\omega} N_S}}{1 - w^{\frac{\omega}{\Delta\omega}}} \tag{41}$$

From this it follows the total PSD of the transmitter

$$\Phi_{ss}(\omega) = \frac{1}{N_S} \sum_{\substack{\nu=-15 \\ \nu \neq 0}}^{15} \sigma_\nu^2 \cdot |G(\omega - \nu\Delta\omega)|^2 \tag{42}$$

which is depicted in Fig. 10b for a system with $N = 32$. All carriers are modulated with equal power $\sigma_\nu^2 = 1$, except for carriers $\nu = 0$ and $\nu = N/2$. Because of (37), the subcarriers $\nu = 17, \ldots, 31$[1] are modulated with the complex conjugate of the sequences $X_1[k], \ldots, X_{15}[k]$. Note that we can approximately add the PSD of all sequences $s_\nu[n]$ despite their pairwise correlation because their spectra overlap to only a very small extent. As the antialiasing lowpass in the DAC has a cutoff frequency of $\omega_A/2$ [15], the carriers in this frequency region cannot be modulated; therefore, at least the carrier at $\nu = N/2$ remains unused. The carrier at $\nu = 0$ is seldom used, either, because most channels do not support a DC component.

[1] Because of the periodicity of $\Phi_{ss}(\omega)$ this is equivalent to modulate the subcarriers $\nu = -15, \ldots, -1$.

3.4. System Description with Matrix Notation

We have seen that the transmitter processes the data blockwise, resulting in simple implementation without the need of saving data from previous blocks. We now consider how this block independence can be extended to the receiver when including the channel. Figure 11 shows a block diagram for the complete DMT transmission system. For the moment we focus on the signal only and consider the influence of the noise later. The receiver input signal is then given by

$$\tilde{y}[n] = \tilde{x}[n] \star c[n] = \sum_{m=-\infty}^{\infty} \tilde{x}[m]\, c[n-m] \tag{43}$$

The discrete-time channel impulse response $c[n]$ includes the influences of DAC and ADC (digital-to-analog and analog-to-digital conversion), respectively. We assume that the channel can be described by a finite-length

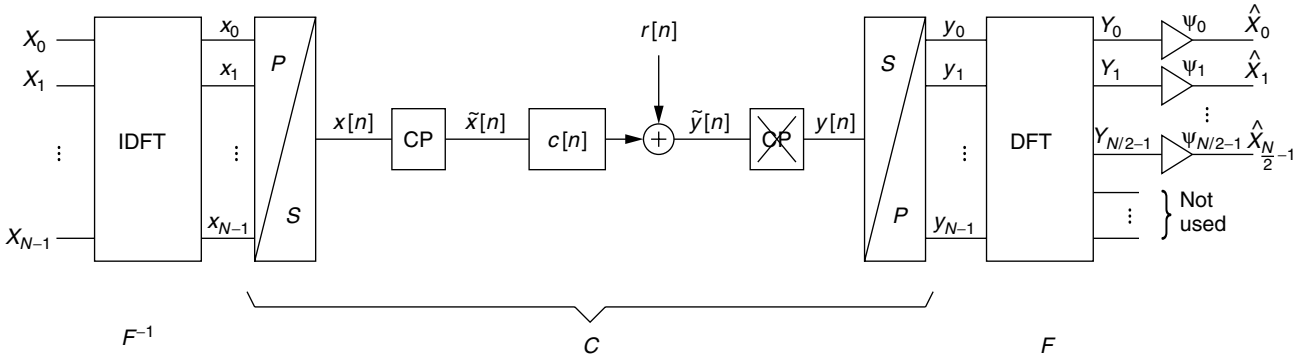

Figure 11. Discrete-time model of a DMT transmission system.

impulse response $c[n]$ with $L+1$ samples $c[0], \ldots, c[L]$. From (43) we conclude that for independence of the received blocks, it must hold that

$$L \leq G \tag{44}$$

Thus, the cyclic prefix must be at least as long as the length of the channel impulse response. If this condition is satisfied, we can adopt a vector notation for the block data:

$$\mathbf{x} = \begin{pmatrix} x_0 \\ x_1 \\ \vdots \\ x_{N-1} \end{pmatrix}, \quad \tilde{\mathbf{x}} = \begin{pmatrix} x_{N-G} \\ \vdots \\ x_{N-1} \\ x_0 \\ \vdots \\ x_{N-1} \end{pmatrix}, \quad \tilde{\mathbf{y}} = \begin{pmatrix} \tilde{y}_0 \\ \vdots \\ \tilde{y}_{G-1} \\ \tilde{y}_G \\ \vdots \\ \tilde{y}_{N+G-1} \end{pmatrix},$$

$$\mathbf{y} = \begin{pmatrix} y_0 \\ y_1 \\ \vdots \\ y_{N-1} \end{pmatrix} = \begin{pmatrix} \tilde{y}_G \\ \tilde{y}_{G+1} \\ \vdots \\ \tilde{y}_{N+G-1} \end{pmatrix} \tag{45}$$

where $\mathbf{y}$ is the input signal after removal of the cyclic prefix. It can be expressed as

$$\mathbf{y} = \begin{pmatrix} c[G] & c[G-1] & \cdots & c[0] & 0 & \cdots & 0 \\ 0 & c[G] & c[G-1] & \cdots & c[0] & \cdots & 0 \\ \cdots & & & & & \cdots & \\ 0 & 0 & \cdots & c[G] & c[G-1] & \cdots & c[0] \end{pmatrix} \cdot \tilde{\mathbf{x}} \tag{46}$$

or

$$\begin{pmatrix} y_0 \\ y_1 \\ \vdots \\ y_{G-1} \\ y_G \\ y_{G+1} \\ \vdots \\ y_{N-1} \end{pmatrix} = \underbrace{\begin{pmatrix} c[0] & 0 & \cdots & 0 & c[G] & \cdots & c[2] & c[1] \\ c[1] & c[0] & 0 & \cdots & 0 & c[G] & \cdots & c[2] \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ c[G-1] & \cdots & \cdots & c[0] & 0 & \cdots & 0 & c[G] \\ c[G] & c[G-1] & \cdots & \cdots & c[0] & 0 & \cdots & 0 \\ 0 & c[G] & c[G-1] & \cdots & \cdots & c[0] & 0 & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & \cdots & \cdots & c[G] & \cdots & \cdots & c[1] & c[0] \end{pmatrix}}_{\mathbf{C}} \times \begin{pmatrix} x_0 \\ x_1 \\ \vdots \\ x_{G-1} \\ x_G \\ x_{G+1} \\ \vdots \\ x_{N-1} \end{pmatrix} \tag{47}$$

The latter expression is preferred as it directly relates the signals $\mathbf{x}$ and $\mathbf{y}$ and transforms the effect of the guard interval insertion and removal into the channel matrix $\mathbf{C}$. The matrix equation (47) represents the circular convolution, which is equivalent to multiplication in the frequency domain [15]:

$$y[n] = x[n] \otimes c[n] = \sum_{m=0}^{N-1} x[m] \cdot c[(n-m) \bmod N] \tag{48}$$

From this point of view, the cyclic prefix transforms the linear convolution (43) into a circular convolution. The matrix $\mathbf{C}$ is a circulant matrix whose eigenvalues λ_μ and eigenvectors $\boldsymbol{\vartheta}_\mu$ are given by

$$\lambda_\mu = \sum_{n=0}^{N-1} c[n] w^{\mu n}, \quad \boldsymbol{\vartheta}_\mu = \frac{1}{\sqrt{N}} \begin{pmatrix} w^{-0} \\ w^{-\mu} \\ w^{-2\mu} \\ \vdots \\ w^{-(N-1)\mu} \end{pmatrix},$$

$$\mu = 0, \ldots, N-1 \tag{49}$$

This can be easily verified by checking the equation $\mathbf{C}\boldsymbol{\vartheta}_\mu = \lambda_\mu \boldsymbol{\vartheta}_\mu$. We identify the inverse DFT matrix as

$$\mathbf{F^{-1}} = (\boldsymbol{\vartheta_0}, \boldsymbol{\vartheta_1}, \ldots, \boldsymbol{\vartheta_{N-1}}) \tag{50}$$

This means that the eigenvectors of the channel matrix $\mathbf{C}$ are the columns of the inverse DFT matrix. As a consequence, we can diagonalize the channel matrix by multiplying with the IDFT and its inverse, the DFT matrix $\mathbf{F}$

$$\mathbf{FCF^{-1}} = \boldsymbol{\Lambda} \qquad \text{where } \boldsymbol{\Lambda} = \operatorname{diag}(\lambda_\mu) \tag{51}$$

With $\mathbf{X} = (X_0[k], \ldots, X_{N-1}[k])^T$ and $\mathbf{Y} = (Y_0[k], \ldots, Y_{N-1}[k])^T$ we can write

$$\mathbf{x} = \mathbf{F^{-1}X}, \qquad \mathbf{y} = \mathbf{Cx} = \mathbf{CF^{-1}X}, \qquad \mathbf{Y} = \mathbf{Fy} = \mathbf{FCF^{-1}X} \tag{52}$$

We can now describe the input-output-relation of the whole transmission system of Fig. 11 with a single diagonal matrix: $\mathbf{Y} = \boldsymbol{\Lambda}\mathbf{X}$, or $Y_\mu[k] = \lambda_\mu \cdot X_\mu[k]$. The result shows that due to the cyclic prefix the parallel subchannels are independent, and perfect reconstruction can be realized by a simple one-tap equalizer with tap weight ψ_μ per subchannel located at the output of the receiver DFT as shown in Fig. 11. As equalization is done after the DFT, this equalizer is usually referred to as a *frequency-domain equalizer* (FDE).

Following from Eq. (49), we can interpret the eigenvalues λ_μ of the channel matrix as the DFT of the channel impulse response. If we define

$$C(\omega) = \sum_{n=0}^{N-1} c[n] \cdot e^{-j\omega n T_A} \tag{53}$$

as the discrete-time Fourier transform of $c[n]$, we see that the eigenvalues are just the values of the channel transfer function at the frequencies $\omega_\mu = \mu \cdot \Delta\omega$:

$$\lambda_\mu = C(\omega_\mu) \tag{54}$$

Because DMT is a baseband transmission scheme, the channel impulse response $c[n]$ is real-valued and therefore its spectrum shows hermitian symmetry:

$$\lambda_0, \lambda_{N/2} \in \mathcal{R}; \qquad \lambda_\mu = \lambda^*_{N-\mu} \qquad \text{for } \mu = 1, \ldots, N/2-1 \tag{55}$$

Let us summarize the results. We have shown that the insertion of the cyclic prefix translates the linear convolution (43) into a circular convolution (48) that corresponds to a multiplication in frequency domain, as long as the impulse response of the channel is not longer than the guard interval. If the guard interval is sufficiently large, no interblock and no intercarrier interference occur and each subchannel signal is weighted only by the channel transfer function at the subchannel frequency. If the channel impulse response $c[n]$ exceeds the guard interval, the described features of DMT are not valid anymore. To overcome this problem, $c[n]$ can be compressed by a so-called time-domain equalizer (TDE) to the length of the guard interval. The TDE will be applied before the guard interval is removed at the receiver [e.g., 16–18].

3.5. Frequency-Domain Equalization (FDE)

The output signal of the DFT at the receiver in Fig. 11 is given by

$$Y_\mu[k] = \lambda_\mu \cdot X_\mu[k] + q_\mu[k] \tag{56}$$

where $q_\mu[k]$ represents the noise introduced on the subchannel after DFT processing. For many practical channels, the noise $r[n]$ on the channel will be Gaussian but not white. Therefore, the power of $q_\mu[k]$ will depend on the subchannel. If N is chosen sufficiently large, the subchannel bandwidth is very small and thus the noise in each subchannel will be approximately white with variance $\sigma^2_{q,\mu}$. Further, the noise is uncorrelated with the noise on any other subchannel [5]. The equalizer coefficients ψ_μ can be derived with or without considering the noise term in Eq. (56). If the signal-to-noise ratio (SNR) is high, we approximately neglect the noise and find the optimal FDE parameters as $\psi_\mu = 1/\lambda_\mu$. With $\hat{X}_\mu[k] = \psi_\mu Y_\mu[k]$ follows $\hat{X}_\mu[k] = X_\mu[k] + q_\mu[k]/\lambda_\mu$ for the reconstructed signal at the receiver. The SNR at the output of the μ-th subchannel is then given by

$$\mathrm{SNR}_\mu = \frac{E\{|X_\mu|^2\}}{E\{|\hat{X}_\mu - X_\mu|^2\}} = \frac{\sigma^2_\mu \cdot |\lambda_\mu|^2}{\sigma^2_{q,\mu}} \tag{57}$$

where $\sigma^2_\mu = E\{|X_\mu[k]|^2\}$ is the signal power of the μth input signal at the transmitter.

However, the SNR per subchannel can be improved by considering the noise in the derivation of the equalizer coefficients ψ_μ. Considering the AWGN (additive white Gaussian noise) in the subchannels, we calculate the equalizer coefficients by minimizing the mean-square error (MSE) $E\{|\hat{X}_\mu - X_\mu|^2\}$ which can be written with $\psi_\mu = \psi'_\mu + j\psi''_\mu$ and $\lambda_\mu = \lambda'_\mu + j\lambda''_\mu$ as

$$\begin{aligned} E\{|\hat{X}_\mu - X_\mu|^2\} = {} & (\psi'^2_\mu + \psi''^2_\mu)(|\lambda_\mu|^2\sigma^2_\mu + \sigma^2_{q,\mu}) \\ & - 2\sigma^2_\mu(\psi'_\mu\lambda'_\mu - \psi''_\mu\lambda''_\mu) + \sigma^2_\mu \end{aligned} \tag{58}$$

For minimization of the MSE, we set the gradient of (58) to zero:

$$\frac{\partial}{\partial \psi'_\mu} E\{|\hat{X}_\mu - X_\mu|^2\} = 0 \quad \frac{\partial}{\partial \psi''_\mu} E\{|\hat{X}_\mu - X_\mu|^2\} = 0 \tag{59}$$

which results in

$$\begin{aligned} \psi'_\mu = \frac{\lambda'_\mu}{|\lambda_\mu|^2 + \sigma^2_{q,\mu}/\sigma^2_\mu}, \; \psi''_\mu = \frac{-\lambda''_\mu}{|\lambda_\mu|^2 + \sigma^2_{q,\mu}/\sigma^2_\mu} \\ \Rightarrow \psi_\mu = \frac{\lambda^*_\mu}{|\lambda_\mu|^2 + \sigma^2_{q,\mu}/\sigma^2_\mu} \end{aligned} \tag{60}$$

The subchannel SNR can be calculated as

$$\mathrm{SNR}_\mu = \frac{E\{|X_\mu|^2\}}{E\{|\hat{X}_\mu - X_\mu|^2\}} = \frac{\sigma^2_\mu \cdot |\lambda_\mu|^2}{\sigma^2_{q,\mu}} + 1 \tag{61}$$

which gives a better performance than the first case, especially for low SNR.

It is this amazingly simple equalization with a one-tap equalizer per subchannel that makes DMT so popular for the transmission over frequency-selective channels like the telephone subscriber line.

4. CHANNEL CAPACITY AND BIT LOADING

The channel capacity [19], or the maximum error-free bitrate, of an ideal AWGN channel is given by

$$R_{\max} = \frac{\omega_B}{2\pi} \cdot \log_2\left(1 + \frac{\sigma^2_y}{\sigma^2_r}\right) \tag{62}$$

where $\omega_B = N \cdot \Delta\omega$ is the total channel bandwidth, σ^2_y is the received signal power, and σ^2_r is the noise power. The capacity of subchannel μ with very small bandwidth $\Delta\omega$ is then

$$R_\mu = \frac{\Delta\omega}{2\pi} \cdot \log_2\left(1 + \frac{\Delta\omega\Phi_{xx}(\omega_\mu)|C(\omega_\mu)|^2}{\Delta\omega\Phi_{rr}(\omega_\mu)}\right) \tag{63}$$

where $\Phi_{xx}(\omega)$ denotes the power spectral density (PSD) of the transmitter signal $\tilde{x}[n]$, $C(\omega)$ is the channel transfer function in (53) and $\Phi_{rr}(\omega)$ is the PSD of the (colored) noise $r[n]$. The total capacity of all subchannels is

$$R = \frac{\Delta\omega}{2\pi} \cdot \sum_{\mu=0}^{N-1} \log_2\left(1 + \frac{\Phi_{xx}(\omega_\mu)|C(\omega_\mu)|^2}{\Phi_{rr}(\omega_\mu)}\right) \tag{64}$$

In the limit for $\Delta\omega \to 0$ with $\Delta\omega \cdot N = \omega_B = \text{const.}$ we get

$$R = \frac{1}{2\pi}\int_0^{\omega_B} \log_2\left(1 + \frac{\Phi_{xx}(\omega)|C(\omega)|^2}{\Phi_{rr}(\omega)}\right) d\omega \tag{65}$$

We now want to maximize the channel capacity R, subject to the constraint that the transmitter power is limited:

$$\frac{1}{2\pi}\int_0^{\omega_B} \Phi_{xx}(\omega)d\omega = P_t \tag{66}$$

Thus, we search for a function $\Phi_{xx}(\omega)$ that maximizes Eq. (65) subject to the constraint (66). This can be

accomplished by calculus of variations [20]. Therefore we set up the Lagrange function

$$L(\Phi_{xx}, \omega) = \log_2\left(1 + \Phi_{xx}(\omega)\frac{|C(\omega)|^2}{\Phi_{rr}(\omega)}\right) + \lambda \cdot \Phi_{xx}(\omega) \quad (67)$$

which must fulfill the Euler–Lagrange equation

$$\frac{\partial L}{\partial \Phi_{xx}} = \frac{d}{d\omega}\frac{\partial L}{\partial \Phi'_{xx}}, \quad \text{where } \Phi'_{xx} = \frac{d\Phi_{xx}}{d\omega} \quad (68)$$

This requires that $\Phi_{xx}(\omega) + \Phi_{rr}(\omega)/|C(\omega)|^2 = \Phi_0 = \text{const}$. Thus,

$$\Phi_{xx}(\omega) = \begin{cases} \Phi_0 - \Phi_{rr}(\omega)/|C(\omega)|^2 & \text{for } |\omega| < \omega_B \\ 0 & \text{elsewhere} \end{cases} \quad (69)$$

This represents the "water-filling solution." We can interpret $\Phi_{rr}(\omega)/|C(\omega)|^2$ as the bottom of a bowl in which we fill an amount of water corresponding to P_t. The water will distribute in a way that the depth represents the wanted function $\Phi_{xx}(\omega)$, as illustrated in Fig. 12.

The optimum solution according to (69) can be achieved by appropriately adjusting the constellation sizes and the gain factors for the bit-to-symbol mapping for each carrier.

In practice, when the bit rate assignments are constrained to be integer, the "water-filling solution" has to be modified. There have been extensive studies on the allocation of power and data rate to the subchannels, known as *bitloading algorithms* [21–24]. In the following, the connection between the channel characteristics and bitloading is presented for an asymmetric digital subscriber line (ADSL) system.

5. APPLICATIONS OF DMT

The DMT modulation scheme has been selected as standard for ADSL [8], a technique for providing high-speed data services over the existing copper-based telephone network infrastructure. Typically, these phone lines consist of unshielded twisted-pair (UTP) wire, which share the same cable with multiple other pairs. Hence, the performance of ADSL transmission depends on the noise environment and cable loss [25]. When lines are bound together in a cable, they produce crosstalk from one pair to another, at levels that increase with frequency and the number of crosstalking pairs or disturbers. For this reason, crosstalk is one of the major noise sources. Additional disturbances are given by impulse noise and possibly radiofrequency interferers. Beside that, line attenuation increases with frequency and distance. A modulation scheme that is well suited for the wide variations in the ADSL channel characteristics is provided by DMT. In particular, rate adaption is quite simple for DMT modulation to optimize the ADSL system transmission. Some aspects of an ADSL system are regarded in the remainder of this section.

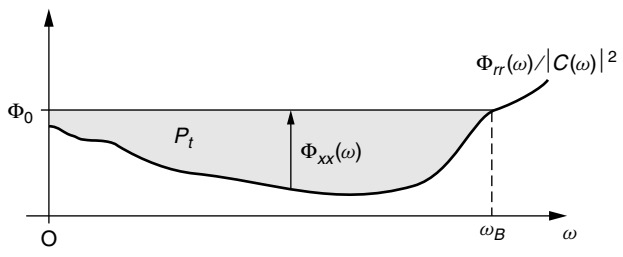

Figure 12. Optimum water-filling solution.

The parameter of the DMT modulation scheme for downstream transmission are determined by the ADSL standard [8] as follows:

- FFT size of $N = 512$. Consequently, excluding the two carriers at $\nu = 0$ and $\nu = N/2$, 255 usable parallel subchannels result.
- Sampling rate $f_A = 1/T_A = 2.208$ MHz.
- Guard interval length $G = 32 = N/16$.
- Adaptive bitloading with a maximum number of $m_{\max} = 15$ bits per subcarrier (tone).
- A flat transmit power spectral density of about -40 dBm/Hz (dBm = decibels per milliwatt). As the spectrum ranges up to $f_A/2 = 1.104$ MHz, the total transmit power is about 20 dBm.

The achievable data throughput depends on the bit allocation that is established during initialization of the modem and is given by

$$R = \frac{1}{T_S}\sum_{\nu=1}^{N/2-1} m_\nu \quad (70)$$

where m_ν denotes the number of bits modulated on the νth subcarrier. The frequency spacing $\Delta f = \Delta\omega/2\pi$ between subcarriers is given by

$$\Delta f = \frac{f_A}{N} = 4.3125 \text{ kHz} \quad (71)$$

As ADSL services share the same line with the plain old telephone service (POTS), a set of splitter filters (POTS splitter) at the customer premises and the network node separate the different frequency bands. Usually, POTS signals occupy bandwidths of up to 4 kHz. To allow a smooth and inexpensive analog filter for signal separation, ADSL services can use a frequency range from 25 kHz up to 1.1 MHz.

Figure 13a shows the variation of the SNR in the DMT subchannels at the receiver for a subscriber line of 3 km length and 0.4 mm wire diameter. DMT modems for ADSL with rate adaption measure the SNR per subchannel during an initialization period.

Of course, the POTS splitter in an ADSL system essentially removes all signals below 25 kHz. Thus, the first few channels cannot carry any data, as can be seen in Fig. 13b, which shows the bitloading corresponding to the SNR of Fig. 13a. A minimum bitload of 2 bits per carrier is stipulated in the standard. The total bit rate is about 4 Mbps. Further, attenuation can be severe at the upper end of the ADSL frequency band. As a consequence, SNR is low and the adaptive bitloading algorithm allocates fewer bits per carrier.

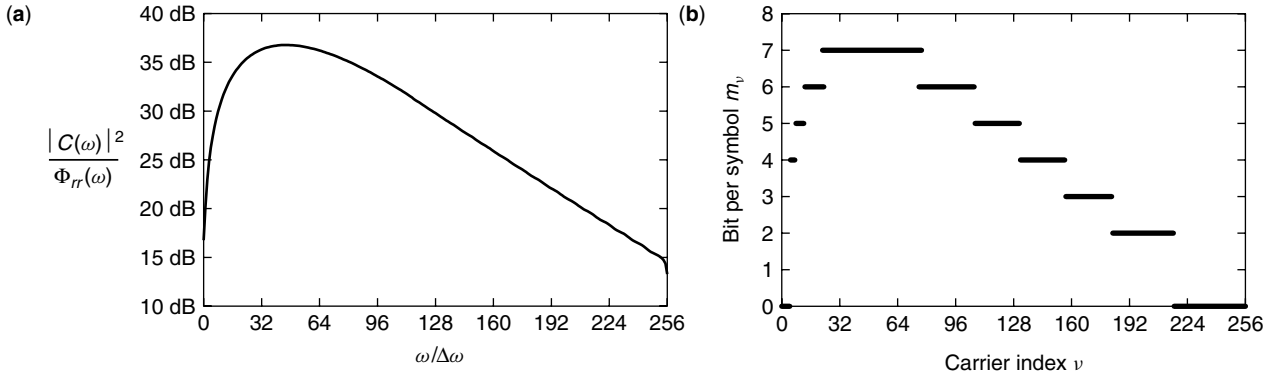

Figure 13. (**a**) SNR in the DMT subchannels at the receiver for a subscriber line of 3 km length and 0.4-mm wire diameter for an asymmetric digital subscriber line (ADSL); (**b**) adaptive bitloading for DMT modulation for transmission over a subscriber line 3 km length and 0.4 mm diameter.

BIOGRAPHIES

Romed Schur received his Dipl.-Ing. degree in electrical engineering and information technology from the University of Stuttgart, Germany, in 1997. He joined the Institute for Telecommunications at the University of Stuttgart as a research and teaching assistant in 1997 and is currently working toward his Ph.D. His interests include multicarrier modulation, xDSL transmission, as well as filterbanks and their applications to communication.

Stephan Pfletschinger studied electrical engineering and information technology at the University of Stuttgart, Germany, and received the Dipl.-Ing. degree with distinction in 1997. Since then he has been with the Institute of Telecommunications at the University of Stuttgart as a teaching and research assistant and is working toward his Ph.D. His research interests include multicarrier modulation and cable TV networks.

Joachim Speidel studied electrical engineering and information technology at the University of Stuttgart, Germany, and received his Dipl.-Ing. and Dr.-Ing. degree in 1975 and 1980, respectively, all with summa cum laude. From 1980 to 1992 he worked for Philips Communications (today Lucent Technologies Bell Labs Innovations) in the field of digital communications, ISDN, and video coding. During his industry career he has held various positions in R&D, as a member of technical staff, laboratory head, and finally as vice president. Since autumn 1992 he has been full professor at the University of Stuttgart and Director of the Institute of Telecommunications. His research areas are digital multimedia communications in mobile, optical, and electrical networks with emphasis on systems, modulation, source and channel coding.

1. INTRODUCTION

Ring networks are well known and widely used in today's Synchronous Optical Network (SONET) or Synchronous Digital Hierarchy (SDH) transport networks [1]. They are attractive because they offer reliable and cost-efficient transport. In combination with dense wavelength-division multiplexing (DWDM), ring networks provide high capacity and transparent transport for a variety of client signals. Compared to a star and bus topology, the ring topology provides two diverse routes between any two network nodes. Ring network topologies are therefore often used in combination with protection schemes for increased reliability. Additionally, network management, operation and node design are less complex in rings than in mesh topologies.

DWDM is the key technology to provide high transmission capacity by transmitting many optical channels simultaneously over the same optical fiber. Each channel uses a dedicated optical wavelength (or, equivalently, color or frequency) [2]. Multiplexing in the frequency domain has been used for many decades in the communication industry, including radio or TV broadcast, where several channels are multiplexed and transmitted over the air or cable. The information signals are modulated at the transmitter side on carrier signals of different frequencies (wavelengths), where they are then combined for transmission over the same medium. At the receiver side, the channels are selected and separated using bandpass filters. More recent advances in optical technology allow for the separation of densely spaced optical channels in the spectrum. Consequently, more than 80 optical channels can be transmitted over the same fiber, with each channel transporting payload signals of $\geq$2.5 Gbps (gigabits per second). In combination with optical amplification of multiplexed signals, DWDM technology provides cost-efficient high-capacity long-haul (several 100 km) transport systems. Because of its analog nature, DWDM transport is agnostic to the frame format and bit rate (within a certain range) of the payload signals. Therefore, it is ideal in supporting the transportation of various high–speed data and telecommunication network services, such as Ethernet, SONET, or SDH.

These advantages fit the demands of modern communication networks. Service providers are facing the merging of telecommunication and data networks and a rapid increase in traffic flow, driven mainly by Internet applications. The level of transmission quality is standardized in the network operation business, or, commonly agreed. There are few possibilities to achieve competitive advantages for network operators. But these differences, namely, better reliability of service or flexibility of service provisioning, have a major influence on the market position. This explains why the transportation of telecommunication and data traffic is a typical volume market [3, p. 288]. As a default strategy in volume markets, it is the primary goal to provide highest data throughput at the most competitive price in order to maximize market share. As a secondary goal, network operators tend to provide flexibility and reliability as competitive differentiators. DWDM ring networks fulfill these basic market demands in an almost ideal way.

In the following sections, we will approach DWDM ring networks from three different viewpoints:

- *The Network Architecture Viewpoint*. DWDM ring networks are an integral part of the worldwide communication network infrastructure. The network design and the architecture have to meet certain rules in order to provide interoperability and keep the network structured, reliable, and manageable. The DWDM ring network architecture, the network layers, and specific constrains of DWDM ring networks will be discussed in Section 2. We will also take a look at protection schemes, which are an important feature of ring networks.
- *The Network Node Viewpoint*. Optical add/drop multiplexers (OADMs) are the dominant type of network elements in DWDM ring networks. The ring features will be defined mainly by the OADM

functionality. The basic OADM concept and its functionality is discussed in Section 3.

- *The Component Viewpoint*. Different component technologies can be deployed to realize the OADM functionality. It is the goal of system suppliers, to utilize those components that minimize the cost involved in purchasing and assembling these components and maximize the functionality of the OADM and DWDM ring network. State-of-the-art technologies and new component concepts are presented in Section 4.

2. DWDM RING NETWORK ARCHITECTURE

2.1. Basic Architecture

The basic ring architecture is independent of transport technologies such as SONET, SDH, or DWDM. Two-fiber rings (Fig. 1, *left*) use a single fiber pair; one fiber for each traffic direction between any two adjacent ring nodes. Four-fiber rings (Fig. 1, *right*) use two fiber pairs between each of the nodes. The second fiber pair is dedicated to protection or low priority traffic. It allows for enhanced protection schemes as discussed in Section 2.4.

The optical channels are added and dropped by the OADM nodes. Signal processing is performed mainly in the optical domain using wavelength-division multiplexing and optical amplification techniques. All-optical processing provides transparent and cost-efficient transport of multiwavelength signals. However, it has some constraints:

- *Wavelength Blocking*. In order to establish an optical path, either the wavelength of this path has to be available in all spans between both terminating add/drop nodes or the wavelength has to be converted in intermediate nodes along the path. Otherwise, wavelength blocking occurs. It results in lower utilization of the ring resources. It can be minimized, but not avoided completely by careful and farsighted network planning and wavelength management. It has been shown that the positive effects of wavelength conversion in intermediate nodes are limited [4].
- *"Signal Quality Supervision."* As today's services are mainly digital, the bit error ratio (BER) is the preferred quality-of-service information. All-optical performance supervision does not provide a parameter that directly corresponds to the BER of the signal.
- *Optical Transparency Length*. This is the maximum distance that can be crossed by an optical channel. The transparency length is limited by optical signal impairments, such as attenuation of optical signal power (loss), dispersion, and nonlinear effects. It depends on the data rate transported by the optical channels, the ring capacity, the quality of the optical components, and the type of fiber (e.g., standard single-mode fiber, dispersion shifted fiber). For 10-Gbps signals, transparency lengths of 300 km can be achieved with reasonable effort. This makes DWDM ring networks most attractive for metropolitan-area networks (MAN; $\leq$80 km ring circumference) and regional area networks ($\leq$300 km ring circumference).

2.2. Transparent Networks and Opaque Networks

If the optical transparency length is exceeded, full regeneration of the signal, including reamplification, reshaping, and retiming (3R regeneration) is necessary. With 3R regeneration however, the transport capability is restricted to certain bit rates and signal formats. In this case, the ring is called opaque. Specific digital processing equipment must be available for each format that shall be transported. Furthermore, 3R regeneration is very costly. The typical opaque DWDM ring topology uses all-optical processing within the ring. 3R regeneration is only performed at the tributary interfaces where the signals enter and exit the ring (i.e., at the add/drop locations). This decouples the optical path design in the ring from any client signal characteristic. Furthermore, it provides digital signal quality supervision the add/drop traffic. Support of different signal formats is still possible by using the appropriate tributary interface cards without the need for reconfiguration at intermediate ring nodes.

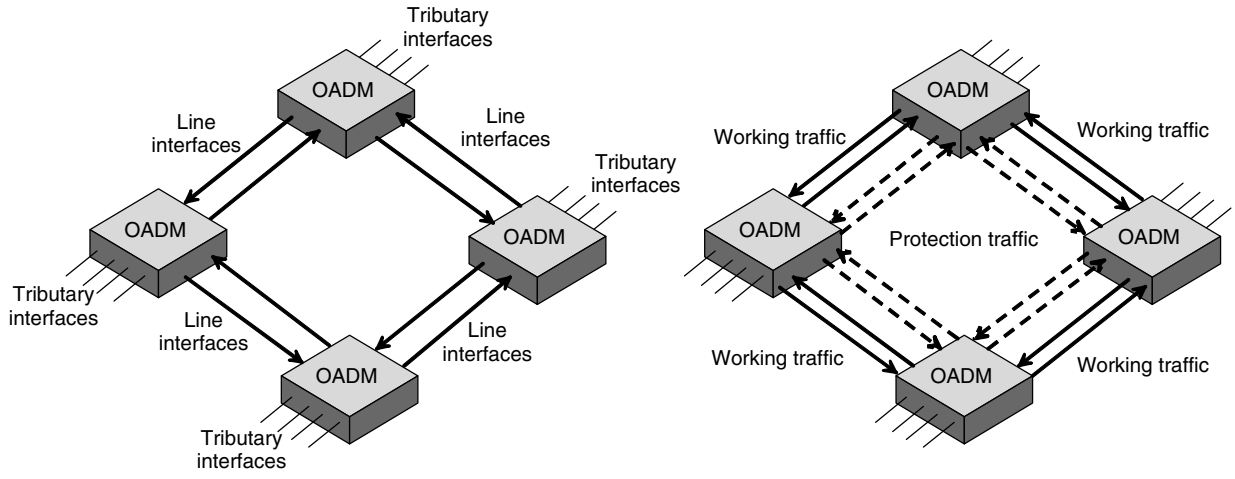

Figure 1. Basic ring architectures: *left*, two-fiber ring; *right*, four-fiber ring.

2.3. Optical-Layer Networks

The International Telecommunication Union (ITU) has standardized the architecture of the Optical Transport Network (OTN) in its recommendation ITU-T G.872 [5]. G.872 defines three optical layer networks: the optical transmission section (OTS) layer, the optical multiplex section (OMS) layer, and the optical channel (OCh) layer network. Figure 2 shows the mapping of these layer networks on a DWDM ring network.

- The OTS represents the DWDM signal transmitted between two nodes (OADM) and/or optical line amplifiers (OLA). Intermediate optical line amplifiers can be used to amplify the signal in cases of long distances between two adjacent nodes.
- The OMS represents the DWDM signal between two adjacent nodes.
- The OCh represents a single optical channel between the 3R regeneration points. For the case of the typical opaque ring architecture, the OCh is terminated at the tributary interfaces of the OADM nodes.

Supervision and management functions are defined for each network layer. Overhead that supports these functions is transported on an optical supervisory channel, which uses a dedicated wavelength for transmission between the nodes. ITU-T G.872 defines also two digital layer networks for a seamless integration of optical and digital processing. These digital layers, the optical channel transport unit (OTU) and the optical channel data unit (ODU) are further described in ITU–T recommendation G.709 [6]. They provide the following three functions: digital signal supervision, time division multiplexing for the aggregation of lower bit rate signals, and forward error correction (FEC) [7]. FEC allows for extending the optical transparency length for a given signal quality.

2.4. Protection

Ring networks support protection switching ideally, since there are always two alternate paths between any two ring nodes. Ring protection schemes are already defined for SONET and SDH [1,8]. Similar concepts can be applied to DWDM ring networks.

$1+1$ *optical channel* (*OCh*) *protection* is the most simple ring protection scheme. It belongs to the class of "dedicated protection," as it uses a dedicated protection connection for each working connection. At the add ring node, the traffic is bridged (branched) to both the working connection and the protection connection. The drop ring nodes select between the two connections based on the quality of the received signals. As a result, $1+1$ OCh protected connections always consume one wavelength per transmission direction in the entire ring, whereas unprotected connections use this wavelength on the shortest path between the terminating nodes only. The utilization of the ring capacity for working traffic can maximally reach 50%.

Optical multiplex section bidirectional self-healing ring (*OMS-BSHR*) belongs to the class of "shared protection," as it shares the protection connection between several working connections. BSHR is also known in SONET as bidirectional line switched ring (BLSR) [9]. OMS-BSHR can be used in both two- and four-fiber rings. In case of a two-fiber BSHR (Fig. 3), One-half of the wavelength channels are used for the working connections; the other half are used for protection. In order to avoid wavelength converters at the protection switches, working and protection wavelengths of opposite directions should be the same (flipped wavelength assignment). For example, in a DWDM ring of N wavelength channels, the wavelengths 1 to $N/2$ (lower band) are used for working connections whereas the wavelengths $N/2+1$ to N (upper band) are used for protection connections. This working

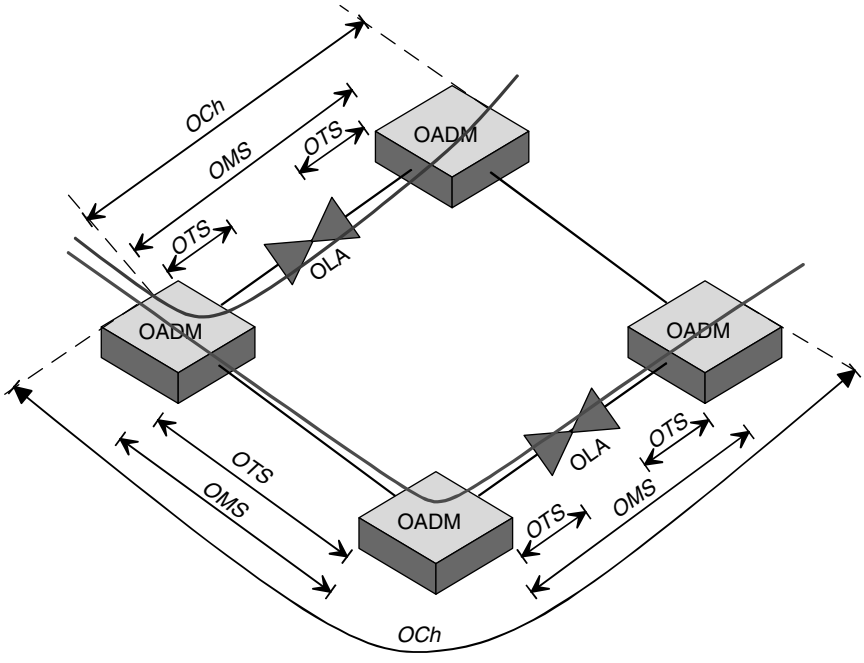

Figure 2. Optical-layer networks.

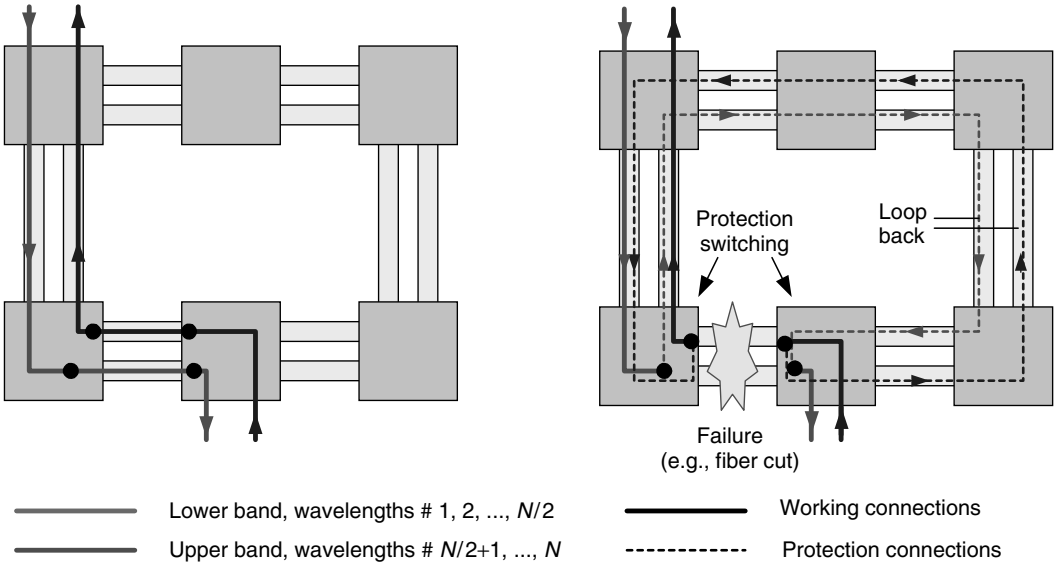

Figure 3. Two-fiber OMS-BSHR: *left*, normal operation; *right*, protection case.

and protection traffic runs in a clockwise direction. In the counter clockwise direction, the wavelengths $N/2+1$ to N are used for working connections and the wavelengths 1 to $N/2$ are used for protection. In case of a failure, the two nodes adjacent to the failure location perform ring protection switching (Fig. 3, *right*). They bridge and select the clockwise working connection to and from the counter clockwise protection connection and vise versa. The whole working traffic that passed the failure location is now looped back to the other direction of the ring.

In a four-fiber BSHR, dedicated fibers for working traffic and protection traffic are used. By this, four-fiber BSHR rings provide twice the capacity than the two-fiber BSHR rings. In addition to the ring protection of the two-fiber BSHR, the four-fiber BSHR can perform span protection. This provides protection against failures of the working fiber pair between two adjacent nodes. An "automatic protection switching" (APS) protocol is necessary for the coordination of the bridge and switch actions and for the use of the shared protection connection. Unlike in $1+1$ OCh protecting the utilization of the ring capacity for working traffic is always exactly 50%. A disadvantage of OMS-BSHR are the long pathlengths that are possible due to the loop back in the protection case. In order not to exceed the transparency length in a case of protection, the ring circumference is reduced.

The *bidirectional optical channel shared protection ring* (*OCh-SPR*) avoids the loop back problem of the OMS-BSHR. Here, ring protection is performed by the add and drop nodes of the optical channel. The add nodes switch the add channels to the working or protection connection. The drop nodes select the working or protection channels directly (Fig. 4).

OCh-SPR can be used in both the two- and four-fiber rings. An automatic protection switching protocol is required for the coordination of the bridge and switch actions; as well as, for the use of the shared protection connection. In an OCh-SPR, protection switches for each optical channel are needed, while the OMS-BSHR allows the use of a protection switch for all working/protection connections in common.

A general issue of shared protection schemes in all-optical networks is the restricted supervision capability of inactive protection connections. Failures of protection connections that are not illuminated can be detected only after activation. Usually, activation occurs due to a protection situation. In that case, the detection of failures in the protection connection comes too late. Furthermore, the dynamic activation/deactivation of protection channels on a span has an influence on the other channels of the span. It will result in bit errors for these channels if not carefully performed.

2.5. Single-Fiber Bidirectional Transmission

DWDM allows bidirectional signal transmission over a single fiber by using different wavelengths for the two signal directions. This allows for building two-fiber ring architectures by only using a single fiber between the ring nodes. It also allows for four-fiber architectures with two physical fibers. However, the two-fiber OMS-BSHR and OCh-SPR protection schemes with their sophisticated wavelength assignment are not supported.

3. OADM NODE ARCHITECTURE

The network functionalities described in the previous section are realized in the optical add/drop multiplexers. The OADM node architecture and functionality is described below.

3.1. Basic OADM Architecture

An OADM consists of three basic modules as shown in Fig. 5:

- The *DWDM line interfaces*, which physically process the ring traffic

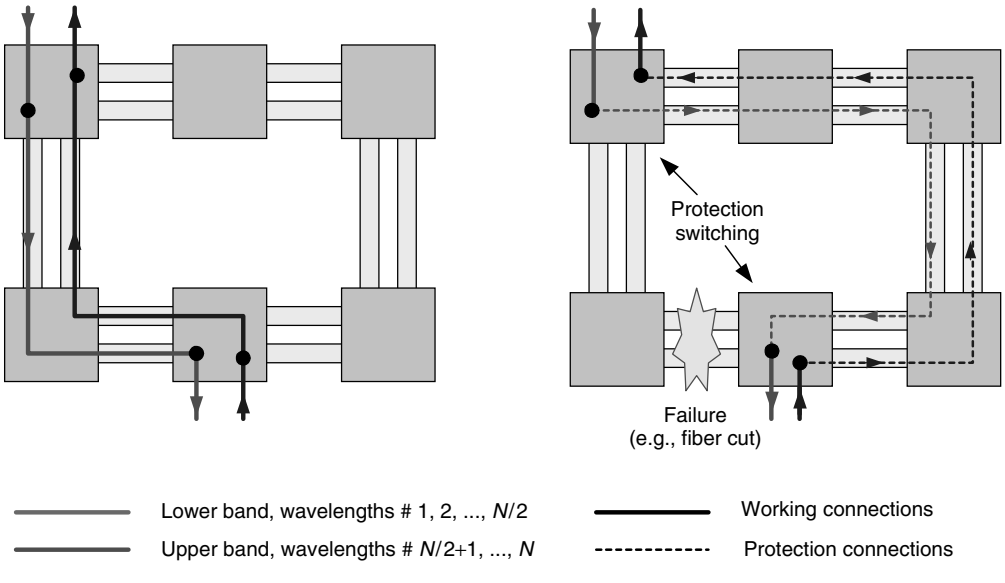

Figure 4. Two-fiber OCh shared protection: *left*, normal operation; *right*, protection case.

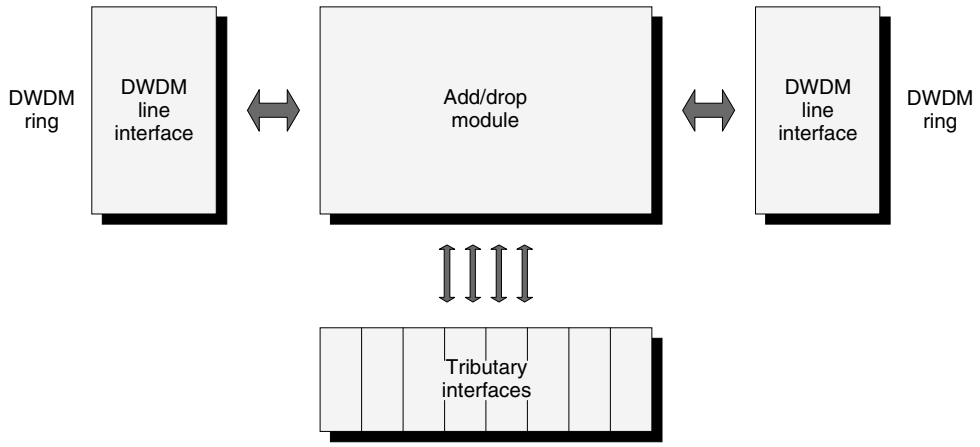

Figure 5. Basic OADM architecture.

- The *add/drop module*, which performs both through connections and the add/drop function for the optical channels
- The *tributary interfaces*, which physically process the add/drop channels

The detailed functionality of these modules depends on the OADM features.

3.2. Characteristic OADM Features

This section describes the most important features of the OADM nodes.

3.2.1. Add/Drop Capacity. The add/drop capacity is defined as the relationship between the capacity of the tributary interfaces and the capacity of both line interfaces. In an extreme case, the entire traffic entering the OADM from both sides of the ring must be dropped. Therefore, an add/drop multiplexer is considered to have 100% add/drop capacity if the capacity of the tributary interfaces equals the capacity of both line interfaces. For instance, an OADM of 100% add/drop capacity in an 80-channel DWDM ring provides 160 channels at its tributary interfaces. Designing an OADM for an appropriate add/drop capacity is an efficient approach in minimizing cost and complexity.

3.2.2. Flexibility. The selection of add/drop channels in an OADM can either be remotely configurable for channels that require frequent reconfiguration (dynamic), or it can be performed manually for "long term" connections (static). Furthermore, channels that will never be dropped can be passed through directly from one line interface to the other without add/drop capabilities (express channels). Other important OADM features are

- *Transparency* or *opacity* as discussed in Section 2.2.
- *Wavelength conversion* capability as discussed in Sections 2.

- *Protection switching* features as discussed in Section 2.4.
- *Signal supervision* capabilities can be based on optical parameters only, such as optical power and optical signal-to-noise ratio (OSNR). Additionally, in opaque rings, signal supervision can be based on bit error ratio monitoring.

3.3. The DWDM Line Interfaces

The main functionality of the DWDM line interfaces includes, primarily the compensation for physical degradation of the DWDM signal during transmission and secondarily the supervision of the DWDM signal. There are three major categories of degradation: (1) loss of optical signal power due to attenuation, (2) dispersion of the impulse shape of high-speed optical signals, and (3) impulse distortion or neighbor channel crosstalk due to nonlinear fiber-optical effects. To overcome these degradations, optical amplifiers and dispersion compensation components may be used. For metropolitan applications, moderate-gain amplifiers can be used to reduce the nonlinear fiber-optical effects, since the node distance is relatively short. Design approaches are mentioned in the references [2,10]. In the line interfaces, signal supervision is based on optical parameters (e.g., optical power, OSNR).

3.4. The Add/Drop Module

The add/drop module performs the following major functions:

- It configures the add/drop of up to 100% of the ring traffic.
- It converts the wavelengths of the add/drop and the through signals (optional).
- It protects the traffic on the OMS or OCh level (optional).

3.4.1. Optical Channel Groups. Optical channels can be classified as dynamic, static, or express traffic. In order to minimize the hardware complexity, in other words installation costs, traffic classes are assigned to optical channel groups accordingly. The optical channel groups are processed according to their specific characteristics. Figure 6 illustrates the group separation (classes) of DWDM traffic by group multiplexer and demultiplexer components. The groups are processed within the add/drop module using different techniques. Methods for defining groups and related component technologies are discussed in Section 4 based on technological boundary conditions.

For dynamic traffic, wavelength routing technologies, such as remotely controlled optical switching fabrics or tunable filters, are used. For static traffic, *manual configuration* via distribution frames (patch panels) is employed. Wavelength routing necessitates higher installation costs than manual configuration. However, it enables the reduction of operational costs due to automation. Operational costs can become prohibitive for manual configuration if frequent reconfiguration is necessary. A cost-optimal OADM processes part of the traffic via distribution frames and the other part via wavelength routing techniques. Hence, the use of costly components is focused on cases where they benefit most [11]. Designing an OADM for a specific add/drop capacity is very efficient especially in the wavelength routing part of the add/drop module. Figure 7 shows a possible architecture of a wavelength routing add/drop matrix.

The add/drop process of the dynamic traffic can be performed in two stages: the add/drop stage and the distribution stage. In order to perform wavelength conversion, wavelength converter arrays (WCA) can be used in addition. The add/drop stage is the only requirement. The distribution stage and the wavelength converters are optional.

The *add/drop-stage* filters the drop channels out of the DWDM signal and adds new channels to the ring. Single optical channels are typically processed. But it is also possible to add or to drop optical channel groups to

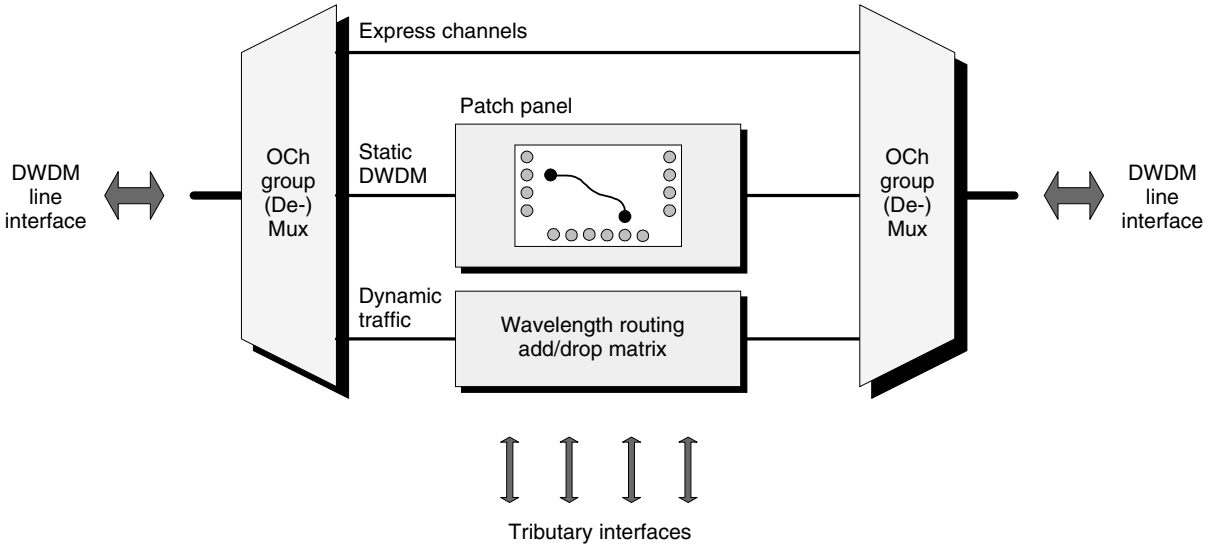

Figure 6. Add/drop module — processing according to traffic characteristics.

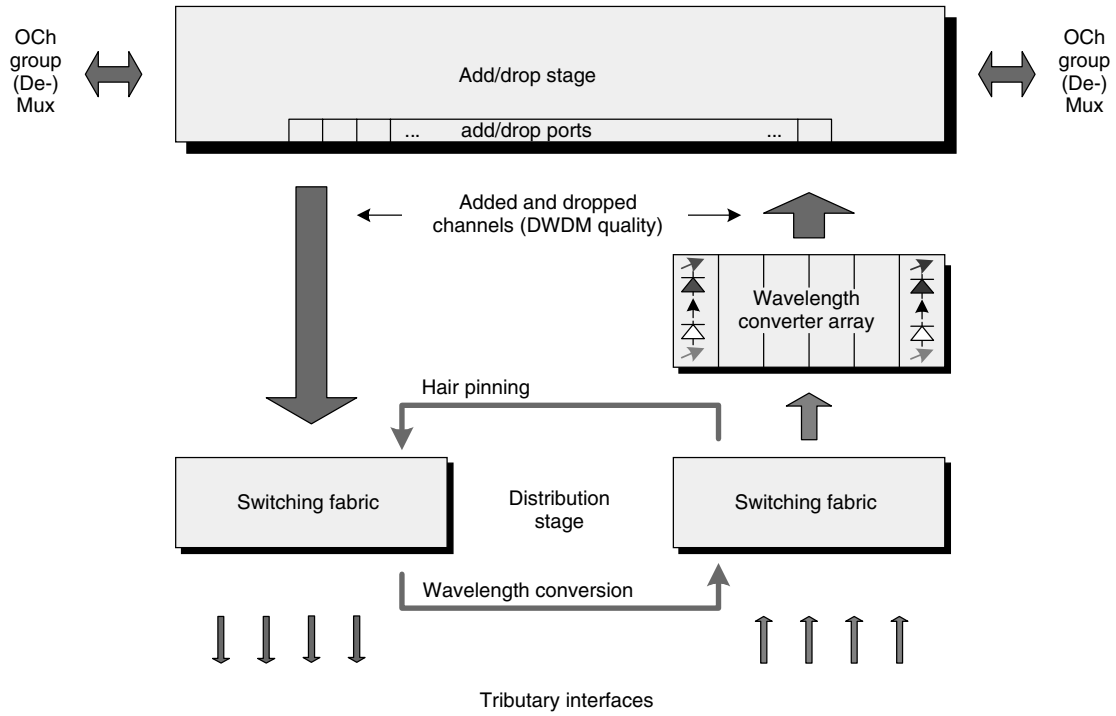

Figure 7. Wavelength routing add/drop matrix (two-stage).

a single port. Various technologies for realizing add/drop stages will be discussed in Section 4.2.

The *wavelength converter array* can be used for wavelength assignment of add channels from the tributary interfaces and for wavelength conversion of through channels. Technologies are discussed in Sections 4.3 and 4.4.

The distribution stage performs the following functions:

1. *Assignment of Channels to Specific Tributary Interfaces*. Not every tributary signal must be connected to the ring at anytime. There may be "part-time" leased lines that share the same wavelength channel such as one at business hours other one at nighttime or at weekends. For example, one customer uses the wavelength channel at the distribution stage connects tributary signals to specific add channels for insertion into the ring. For extraction, it connects them to specific drop channels.
2. *Wavelength Conversion for the Through Channels*. Dropped channels can be reinserted on another wavelength via the link "wavelength conversion" in Fig. 7. A WCA is required for this application.
3. *Hairpinning*. In some applications, add/drop multiplexers are used to route signals between tributary interfaces. This function is known as "hairpinning." It can be realized by the connection as shown in Fig. 7.
4. *Flexible Wavelength Assignment for the Add Channels*. Besides wavelength conversion, the WCA can be used to assign a specific wavelength to an incoming tributary signal. The distribution stage allows for flexible assignment of tributary signals to a WCA element of a specific wavelength. This function can be part of the tributary interfaces as well.

Techniques of switching fabrics to perform these functions are mentioned in Section 4.3.

3.5. The Tributary Interfaces

The tributary interfaces prepare the incoming signals for transmission over the DWDM ring. Incoming signals do not necessarily have DWDM quality. Furthermore, they monitor the quality of the incoming and outgoing tributary signals. It is a strong customer requirement to support a large variety of signal formats and data rates as tributary signals. In the simplest case the tributary signal is directly forwarded to the add/drop module (transparent OADM). In this case, the incoming optical signal must have the correct wavelength to fit into the DWDM line signal; otherwise, the signal has to enter the ring via wavelength converters, either as part of the tributary interface or via the WCA of the add/drop module. The simplest way of signal supervision is monitoring the optical power (loss of signal) of the incoming and outgoing tributary signals. A more advanced approach in the optical domain is the measurement of the optical signal-to-noise ratio. If digital signal quality supervision (i.e., bit error ratio measurement) is needed, 3R regeneration has to be performed. This normally requires client signal-specific processing using dedicated tributary ports for different client formats, such as SONET or Gigabit Ethernet.

4. OADM COMPONENTS

This section focuses on component technologies of the add/drop module and the tributary interfaces.

4.1. Group Filters and Multiplexer/Demultiplexer Components

A multiplexer/demultiplexer in the sense of a WDM component is a device that provides one optical fiber port for DWDM signals and multiple fiber ports for optical channels or channel groups. These multiplexers/demultiplexers are passive components that work in both directions. They can be used for either separating DWDM signals or for combining optical channels to one DWDM signal. Group filters and WDM multiplexers/demultiplexers are basically the same type of component. They just have different optical filter characteristics. A WDM multiplexer/demultiplexer combines or separates single optical channels whereas a group filter combines or separates optical channel groups. Figure 8 shows three basic realizations of wavelength multiplexer/demultiplexer filters.

A basic advantage of block channel groups as opposed to interleaved optical channel groups is the stronger suppression of neighbor group signals. Nevertheless, we will see in Section 4.2 that there are applications in which interleaved channel groups support the overall system performance better than channel blocks. Static multiplexer/demultiplexer filters are usually based on technologies such as multilayer dielectric thin-film filter (TFF), fixed fiber bragg grating (FBG), diffraction grating, arrayed waveguide grating (AWG), cascaded Mach–Zehnder interferometer, and Fabry–Perot interferometer. A detailed discussion of these technologies is given in Section 3.3 of Ref. 2. Interleaver filter technologies are described in Refs. 12 and 13.

4.2. Add/Drop Filter Technologies

Figure 9 shows two popular realization concepts of add/drop filters: (*left*) wavelength multiplexer/demultiplexer — optical switch combination and (*right*) tunable filter cascade — circulator/coupler combination.

The multiplexer/demultiplexer–optical switch solution usually demultiplexes the entire DWDM signal and provides single optical channels via switches at each add/drop port. The tunable filter cascade (Fig. 9, *right*) provides exactly the same functionality. The incoming DWDM signal is forwarded clockwise to the tunable filter cascade by a circulator. The tunable filters reflect selected channels. All other channels pass the filter cascade. The reflected channels travel back to the circulator to be forwarded to the drop port, again in a clockwise motion [14]. For adding optical channels, either a coupler

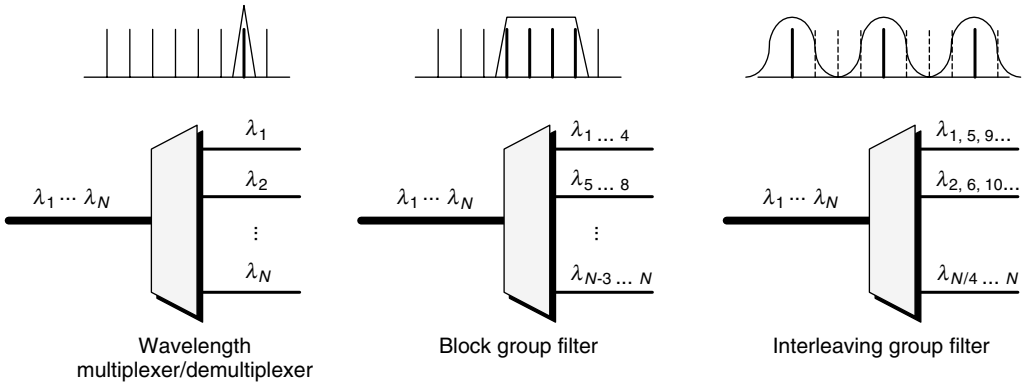

Figure 8. Static wavelength multiplexer/demultiplexer filters.

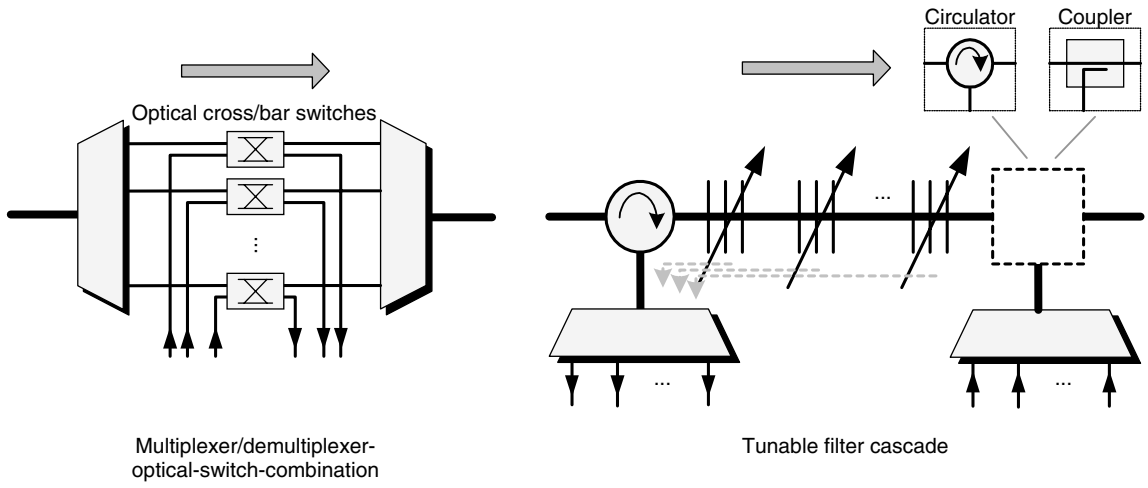

Figure 9. Add/drop filter technologies.

or a circulator can be used. A coupler provides better isolation between the add ports and the drop ports. It is also the least expensive approach. On the other hand, circulators allow for a lower transmission loss. Here, the advantage of interleaved channel groups becomes evident: the bandwidth requirements for tunable filters are lower. In tunable filter cascades, the reconfiguration process can affect uninvolved traffic. For example, if a filter is tuned from wavelength 1 to wavelength 4, it passes the wavelengths 2 and 3. Therefore, traffic running on these channels is affected by the retuning process and thus may render it unusable. The influence of the dispersion of the tunable filters is strong compared to the multiplexer/demultiplexer–optical switch solution. This is another drawback of tunable filter cascades. If tunable filters are tuned to a neutral park position between two densely spaced channels, these channels can be degraded by the dispersion of the filter. This design issue can be overcome by using interleaved channel groups. Wider spacing between the channels lowers the bandwidth requirements for the filters, and thus resulting in a lower dispersion. The basic advantage of tunable add/drop filters is the lower number of internal fiber connections and splices. However, because of the typical characteristics of fiber gratings (e.g., cladding modes), this application is limited to small and medium size channel groups. A more detailed comparison of both concepts is given in Ref. 15.

4.3. Optical Switching Fabrics

Optical switching fabrics provide cross–connection functionality. They are the technology of choice in distribution stages of optical add/drop multiplexers (see Fig. 7). From the viewpoint of OADM optical signal processing, we can distinguish between protection switching and wavelength routing applications.

Protection switching requires switching times of a few milliseconds. Switching times up to hundreds of milliseconds are sufficient for wavelength routing applications. For protection switching and wavelength routing applications, electromechanical, thermooptic, electrooptic, and acoustooptic switches can be used, see Ref. 2, Section 3.7 and Ref. 16, Chap. 10. Today, among the electromechanical switches, the MEMS technology (microelectromechanical system) is seen as the most promising technology in providing high port counts. Switches of more than 100×100 ports have been realized.

Tunable filters, as discussed in Section 4.2, are also an alternative technology to switching fabrics in order to realize cross–connection functionality. Optical circuits using tunable filters and circulators have been presented by Chen and Lee [17].

4.4. Wavelength Converter Technologies

Today, wavelength conversion is performed by O/E/O (optical/electrical/optical) conversion using photodiodes and tunable or fixed-wavelength lasers that are either modulated externally or internally (directly). Tunable lasers allow for covering a wide range of wavelengths and to minimize the number of wavelength converters that are needed. An overview about tunable laser technology is given in Ref. 18. The optical receiver and transmitter components can be connected via analog electrical amplifiers allowing for the transmission of any signal format up to a certain bit rate. If 3R regeneration is performed (digital signal processing between receiver and transmitter), a further limitation to certain signal formats may apply. In future transparent systems, the use of all-optical wavelength converters is expected. All-optical wavelength converters make use of nonlinear optical effects such as cross-gain modulation (CGM), cross phase modulation (XPM) or four-wave mixing (FWM). These effects are treated in detail in Ref. 19, Section 2.7. Semiconductor optical amplifiers (SOA) are the preferred active medium as they exhibit strong nonlinearity, wide gain bandwidth and easy integration. As a pump source, unmodulated lasers are used. Tunable pump lasers provide the capability of tunable all-optical wavelength converters.

5. SUMMARY

DWDM ring networks provide high capacity, high flexibility (multiservice integration), and high reliability (protection) at low operational costs to the operators of metropolitan and regional networks. Because of the simple ring topology, the network management is relatively less complex. The ring functions are determined mainly by the optical add/drop multiplexers. The DWDM line interface mainly determines the maximum ring circumference that can be achieved. An add/drop module, that provides manual routing capabilities, allows for low installation costs. But if frequent reconfiguration is necessary, operational costs can become prohibitive. For this type of traffic, wavelength routing capabilities that provide remotely controlled dynamic routing should be implemented. The technologies of choice for wavelength routing are integrated optical switching fabrics such as MEMS and tunable filters.

DWDM networks can either be transparent or opaque. In the transparent realization, no electronic traffic processing occurs within the ring. The transport is independent of the data format. In opaque networks, for quality-of-service supervision and management reasons, digital (electronic) processing is performed at the borders of the DWDM ring network. The transport in opaque networks may be limited to certain data formats.

The business success of network operation is driven mainly by an overall cost minimization by selling data transport in high volume. This is a general rule in markets that are characterized by low differentiation possibilities and high impact of small differences (volume markets). In the network operation business, differentiation is possible by better reliability, availability and flexibility. Therefore, DWDM ring networks are ideal in paving the way for the business success of metropolitan and regional network operators.

BIOGRAPHIES

Detlef Stoll received a Dipl.-Ing. degree (M.S.) in communication engineering in 1988 from the University of

Hannover, Germany, and a Ph.D. degree in electrical engineering in 1993 from the University of Paderborn, Germany. The subject of his Ph.D. thesis was the derivation of an integrated model for the calculation of the nonlinear transmission in single-mode optical fibers including all linear and nonlinear effects. He joined the Information & Communication Networks Division of the Siemens Corporation in 1994 as a research & development engineer. At Siemens, he worked on the advance development of broadband radio access networks and on the development of SONET/SDH systems. From 1998 to 2000 he led the advance development of a Wavelength Routing Metropolitan DWDM Ring Network for a multi-vendor field trial. Since 2000 he is managing the development of optical network solutions at Optisphere Networks, Inc. located in Boca Raton, Florida. Dr. Stoll has filed approximately 20 patents and published numerous articles in the field of optical networks and forward error correction techniques. His areas of interest are linear and nonlinear systems and wavelength routing networks.

Juergen Heiles received a Dipl.-Ing. (FH) degree in electrical engineering from the University of Rhineland-Palatinate, Koblenz, Germany, in 1986. He joined the Public Networks Division of the Siemens Corporation, Munich, Germany, in 1986 as a research & development engineer of satellite communication systems and, later on, fiber optic communication systems. Since 1998 he has been responsible for the standardization activities of the Siemens Business Unit Optical Networks. He participates in the ITU, T1, OIF and IETF on SONET/SDH, OTN, ASON, and GMPLS and is editor or coauthor of several standard documents. Juergen Heiles has over 15 years of experience in the design, development, and system engineering of optical communication systems starting from PDH systems over the first SONET/SDH systems to today's DWDM networks. He holds three patents in the areas of digital signal processing for optical communication systems. His areas of interest are network architectures and the functional modeling of optical networks.

Jimin Xie received a B.S. degree in electronics in 1986 from the Institute of Technology in Nanjing, China, and an M.S. degree in radio communications in 1988 from the Ecole Superieure d'Electricite in Paris, France, and a Ph.D. degree in opto-electronics in 1993 from the Université Paris-Sud, France. He worked on submarine soliton transmission systems for Alcatel in France from 1993 to 1995. In 1996, he worked at JDS Uniphase as a group leader in the Strategy and Research Department in Ottawa, Canada. At JDSU, he worked on the design and development of passive DWDM components, such as interleaver filters, DWDM filters, OADM modules, polarization detectors and controllers, dispersion compensators, gain flatteners, optical switches, etc. Dr. Xie has filed 12 patents in the field of optical components. Since 2001, he has been the manager of the Optical Technologies department at Optisphere Networks, Inc. located in Boca Raton, Florida. He participates in the OIF standardization activities for Siemens. His areas of interest are the new technologies of components and modules for optical networks.

E

EXTREMELY LOW FREQUENCY (ELF) ELECTROMAGNETIC WAVE PROPAGATION

Steven Cummer
Duke University
Durham, North Carolina

1. INTRODUCTION

Extremely low frequency (ELF) electromagnetic waves are currently the lowest frequency waves used routinely for wireless communication. The IEEE standard radio frequency spectrum defines the ELF band from 3 Hz to 3 kHz [1], although the acronym ELF is often used somewhat loosely with band limits near these official boundaries. Because of the low frequencies involved, the bandwidth available for ELF communication is very small, and the data rate of correspondingly low. Existing ELF communications systems with signal frequencies between 40 and 80 Hz transmit only a few bits per minute [2]. Despite this severe limitation, ELF waves have many unique and desirable properties because of their low frequencies. These properties enable communication under conditions where higher frequencies are simply not usable. Like all electromagnetic waves excited on the ground in the HF (3–30 MHz) and lower bands, ELF waves are strongly reflected by the ground and by the Earth's ionosphere, the electrically conducting portion of the atmosphere above roughly 60 km altitude [3]. The ground and ionosphere bound a spherical region commonly referred to as the *earth–ionosphere* waveguide in which ELF and VLF (very low frequency, 3–30 kHz) propagate. The combination of strongly reflecting boundaries and long ELF wavelengths (3000 km at 100 Hz) enables ELF waves to propagate extremely long distances with minimal attenuation. Measured ELF attenuation rates (defined as the signal attenuation rate in excess of the unavoidable geometric spreading of the wave energy) are typically only ~1 dB per 1000 km at 70–80 Hz [4–6]. The signal from a single ELF transmitter can, in fact, be received almost everywhere on the surface of the planet, even though only a few watts of power are radiated by existing ELF systems. Because the wavelength at ELF is so long, ELF antennas are very inefficient and it takes a very large antenna (wires tens of kilometers long) to radiate just a few watts of ELF energy. This makes ELF transmitters rather large and expensive. Only two ELF transmitters currently operate in the world, one in the United States and one in Russia. Besides their global propagation, the value of ELF waves results from their ability to penetrate effectively through electrically conducting materials, such as seawater and rock, that higher frequency waves cannot penetrate. These properties make ELF waves indispensable for applications that require long-distance propagation and penetration through conducting materials, such as communication with submarines [7]. Unlike many other radiobands, there are strong natural sources of ELF electromagnetic waves. The strongest of these in most locations on the earth is lightning, but at high latitudes natural emissions from processes in the magnetosphere (the highest portions of the earth's atmosphere) can also be strong. There are a variety of scientific and geophysical applications that rely on either natural or man-made ELF waves, including subsurface geologic exploration [8], ionospheric remote sensing [9], and lightning remote sensing [10].

2. THE NATURE OF ELF PROPAGATION

Communication system performance analysis and most geophysical applications require accurate, quantitative models of ELF propagation. Because the ELF fields are confined to a region comparable to or smaller than a wavelength, phenomena in ELF transmission and propagation are substantially different from those at higher frequencies. But before delving too deeply into the relevant mathematics, a qualitative description will give substantial insight into the physics of ELF transmission, propagation, and reception.

2.1. Transmission

A fundamental limit on essentially all antennas that radiate electromagnetic waves is that, for maximum efficiency, their physical size must be a significant fraction of the wavelength of the radiated energy [11]. At ELF, this is a major practical hurdle because of the tremendously long wavelengths (3000 km at 100 Hz) of the radiated waves. Any practical ELF transmission system will be very small relative to the radiated wavelength. Very large and very carefully located systems are required to radiate ELF energy with sufficient power for communication purposes, and even then the antenna will still be very inefficient.

Multikilometer vertical antennas are not currently practical. Thus a long horizontal wire with buried ends forms the aboveground portion of existing ELF antennas. The aboveground wire is effectively one half of a magnetic loop antenna, with the other half formed by the currents closing below ground through the earth, as shown in Fig. 1. The equivalent depth d_{eq} of the closing current with frequency ω over a homogeneous ground of conductivity σ_g is [12]

$$d_{\mathrm{eq}} = (\omega\sigma_g\mu_0)^{-1/2} = 2^{-1/2}\delta \tag{1}$$

where δ is the skin depth [13] of the fields in the conducting ground. A grounded horizontal wire antenna of length l is thus equivalent to an electrically small magnetic loop of area $2^{-1/2}\delta l$. This effective antenna area, which is linearly related to the radiated field strength, is inversely proportional to the ground conductivity. This implies that a poorly conducting ground forces a deeper closing current and therefore increases the efficiency of the antenna. This general effect is opposite that for vertically oriented

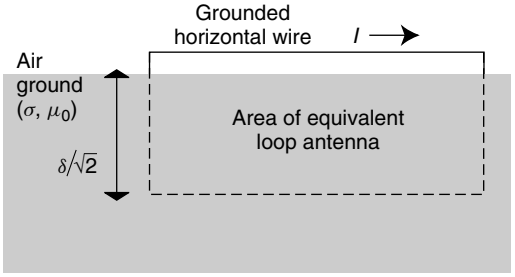

Figure 1. Typical implementation of an ELF antenna. By grounding the ends of a long, current-carrying horizontal wire, the current is forced to close through the ground at a significant depth if the ground is poorly conducting. This forms a physically large loop antenna. The U.S. Navy ELF transmitter antenna is many tens of kilometers long above ground and has an effective current closure depth of 2.6 km.

antennas, in which a good conducting ground serves to improve the radiation efficiency. Horizontal ELF antennas thus require placement over as poorly conducting ground as possible for maximum efficiency.

The U.S. Navy ELF transmitter, which transmits at frequencies between 70 and 80 Hz and is described in some detail by Friedman [2], is distributed in multiple wire antennas in Wisconsin and Michigan. This is one of only a few locations in the United States with relatively low ground conductivity; the measured conductivity is $\sim 2.4 \times 10^4$ S/m (siemens per meter) [14], giving an effective loop depth of 2.6 km. Individual horizontal wires in the antenna system range from 45 to 90 km in length. Despite their physical length, the antennas are still very short compared to the radiated wavelength, and their radiation resistance is very low. The antennas in the ELF system are driven with nearly 1 MW of total power to force 200–300 A of current through them, but the total radiated power from the two-site system is between only 2 and 8 W [15]. Such a small radiated power is still sufficient to cover the globe with a receivable ELF signal at submarine depths.

A similar 82-Hz Russian ELF transmitter became operational in the early 1990s [16]. This antenna consists of multiple 60-km wires on the Kola Peninsula in northwestern Russia. This system radiates slightly more power than does the U.S. version because of lower ground conductivity in its location.

Interestingly, lightning is a stronger radiator of ELF electromagnetic waves than are controlled artificial (human-made) sources. Cloud-to-ground lightning return strokes have typical vertical channel lengths of 5–10 km and contain current pulses that last for hundreds of microseconds with peak currents of tens of kiloamperes. An average lightning stroke radiates a peak power of 10 GW in electromagnetic waves, approximately 1% of which is spread throughout the ELF band [17]. This peak power lasts only for the duration of a lightning stroke, on the order of one millisecond. But the sum of the electromagnetic fields generated by lightning discharges over the entire globe creates a significant ELF noise background [18] that must be overcome in communications applications.

2.2. Propagation

ELF electromagnetic waves propagate along the earth's surface in a manner significantly different from waves in an unbounded medium. The main difference is that waves are bounded above and below by very efficient reflectors of electromagnetic waves. The lower boundary is either earth or water, both of which are very good electrical conductors at ELF. The atmosphere is also electrically conducting, very poorly at low altitudes but with a conductivity that increases exponentially up to ~100 km altitude, above which it continues to increase in a more complicated manner. The region above ~60 km, where the atmosphere is significantly conducting, is called the *ionosphere*. In general, the effect of electrical conductivity on electromagnetic waves is frequency-dependent; the lower the frequency, the greater the effect. The ionospheric conductivity affects ELF waves significantly above ~50–70 km, depending on the precise frequency. Higher-frequency waves can penetrate much higher, but ELF waves are strongly reflected at approximately this altitude. ELF waves are thus confined between the ground and the ionosphere, which are separated by a distance on the order of or much smaller than an ELF wavelength. This spherical shell waveguide, a section of which is shown in Fig. 2, is commonly referred to as the *earth–ionosphere waveguide*.

Because ELF electromagnetic waves are almost completely confined to this small (compared to a wavelength) region, their energy attenuates with distance from the transmitter more slowly than do higher-frequency waves. As a result of two-dimensional energy spreading, the electromagnetic fields decay with distance as $r^{-1/2}$ (producing a r^{-1} power decay), with a slight modification for long propagation distances over the spherical earth. Experimental measurements have shown that the additional attenuation with distance of ELF radiowaves due to losses or incomplete reflection in the ground or ionosphere is typically only 1 dB per 1000 km at 70–80 Hz [4–6]. In general, this attenuation through losses increases with increasing frequency. Because of their low attenuation, ELF waves can be received worldwide from a single transmitter. It is this global reach that makes ELF waves so useful in a variety of applications discussed below.

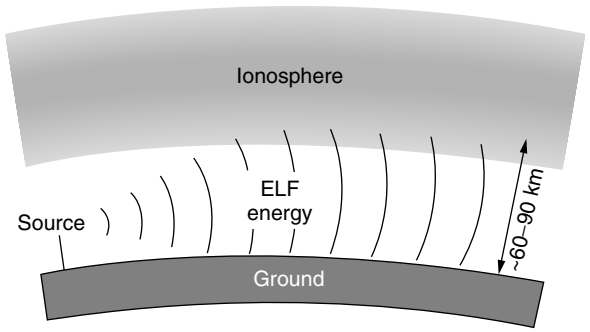

Figure 2. Qualitative ELF electromagnetic wave propagation. The ground and ionosphere (above ~60 km) are good electrical conductors that reflect ELF energy, forming the earth–ionosphere waveguide.

The low attenuation of ELF waves propagating on the surface of a sphere also produces a number of interesting propagation effects. As an ELF receiver approaches the point on the earth directly opposite the transmitter (the antipode), the signals arriving from all angles are comparable in amplitude, and therefore all contribute to the electromagnetic fields. This leads to so-called antipodal focusing, which has been theoretically investigated [12,19,20] but was experimentally verified only in 1998 [16].

At frequencies low enough that the attenuation of a fully around-the-world signal is not too severe, the multi-round-trip signals self-interfere, producing cavity resonances of the earth–ionosphere shell. These resonances are commonly called the *Schumann resonances*, after W. O. Schumann who first predicted them theoretically [21]. They can often be observed as peaks in the broadband background ELF fields in an electromagnetically quiet location and are generated primarily by steady lightning activity around the globe [22]. The frequencies of the first three resonances are approximately 8, 14, and 20 Hz [22], and in a low-noise location they can be observed up to at least 7 orders [16].

Wave propagation in the earth–ionosphere waveguide, like that in a simple parallel-plate waveguide, can be very compactly described mathematically by a sum of discrete waveguide modes that propagate independently within the boundaries. The mathematical details of the mode theory of waveguide propagation are discussed in later sections. An important consequence of this theory is that frequencies with a wavelength greater than half the waveguide height can propagate in only a single mode. For the earth–ionosphere waveguide, propagation is single mode at frequencies less than approximately 1.5–2.0 kHz, depending on the specific ionospheric conditions. This suggests a propagation-based definition of ELF, which is sometimes used in the scientific literature, as the frequencies that propagate with only a single mode in the earth–ionosphere waveguide (i.e., $f \lesssim 2$ kHz) and those for which multiple paths around the earth are not important except near the antipode (i.e., $f \gtrsim 50$ Hz, above Schumann resonance frequencies).

2.3. Reception

Receiving or detecting ELF electromagnetic waves is substantially simpler than transmitting them. Because of the long wavelength at ELF, any practical receiving antenna will be electrically small and the fields will be spatially uniform over the receiving antenna aperture. An ELF receiving antenna is thus usually made from either straight wires or loops as long or as large as possible. Both of these configurations are used as ELF receiving antennas in communication and scientific applications [12].

Again, because of the long wavelength and low transmitted field strength, the maximum practical length possible for an electric wire antenna and the maximum area and number of turns for a magnetic loop antenna are normally preferred to receive the maximum possible signal. How to deploy an antenna as big as possible is often an engineering challenge, as demonstrated by the issues involved in towing a long wire behind a moving submarine to act as an ELF antenna [23].

Designing an antenna preamplifier for an ELF system is also not trivial, especially if precise signal amplitude calibration is needed. Because the output reactance of an electrically short wire antenna is very large, the preamplifier in such a system must have a very high input impedance [12]. And even though the output impedance of a small loop antenna is very small, system noise issues usually force a design involving a stepup voltage transformer and a low-input-impedance preamplifier [24]. Another practical difficulty with ELF receivers is that in many locations, electromagnetic fields from power lines (60 Hz and harmonics in the United States, 50 Hz and harmonics in Europe and Japan) are much stronger than the desired signal. Narrowband ELF receivers must carefully filter this noise, while ELF broadband receivers, usually used for scientific purposes, need to be located far from civilization to minimize the power line noise.

The frequencies of ELF and VLF electromagnetic waves happen to overlap with the frequencies of audible acoustic waves. By simply connecting the output of an ELF sensor directly to a loudspeaker, one can "listen" to the ELF and VLF electromagnetic environment. Besides single-frequency signals from ELF transmitters and short, broadband pulses radiated by lightning, one might hear more exotic ELF emissions such as whistlers [25], which are discussed below, and chorus [26].

3. APPLICATIONS OF ELF WAVES

The unique properties of ELF electromagnetic waves propagating between the earth and the ionosphere, specifically their low attenuation with distance and their relatively deep penetration into conducting materials, make them valuable in a variety of communication and scientific applications discussed below.

3.1. Submarine Communication

The primary task of existing ELF communications systems is communication with distant submerged submarines. The ability to send information to a very distant submarine (thousands of kilometers away) without requiring it to surface (and therefore disclose its position) or even rise to a depth where its wake may be detectable on the surface is of substantial military importance. The chief difficulty in this, however, is in transmitting electromagnetic waves into highly conducting seawater. The amplitude of electromagnetic waves propagating in an electrically conducting material decays exponentially with distance. The distance over which waves attenuate by a factor of e^{-1} is commonly referred to as the "skin depth." This attenuation makes signal penetration beyond a few skin depths into any material essentially impossible. For an electromagnetic wave with angular frequency ω propagating in a material with conductivity σ and permittivity ε, if $\sigma/\omega\varepsilon \gg 1$, then the skin depth δ is very closely approximated by

$$\delta = \left(\frac{2}{\omega\sigma\mu_0}\right)^{-1/2} \tag{2}$$

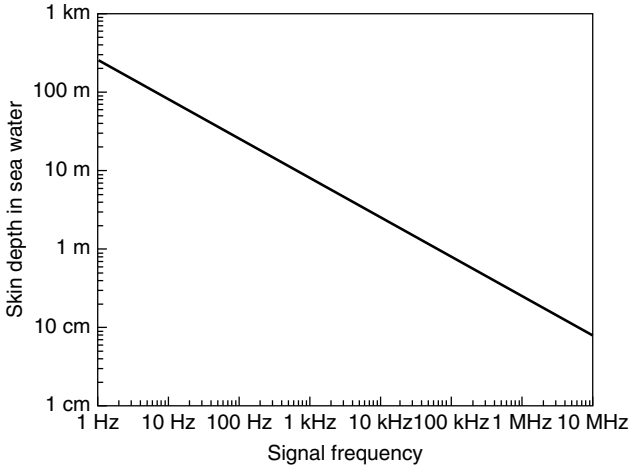

Figure 3. Skin depth (e^{-1} decay depth) of an electromagnetic wave in seawater versus frequency. Only ELF wave frequencies less than ~1 kHz can penetrate sufficiently into seawater to enable communication with submerged submarines.

This expression is usually valid in even weakly conductive materials at ELF because of the low frequency. Figure 3 shows the skin depth in seawater ($\sigma = 4$ S/m, $\varepsilon = 81\varepsilon_0$) as a function of frequency. Only ELF signals below approximately 1 kHz penetrate deeply enough to be practically useful for sending signals to submarines at a depth where they are not detectable from the surface. Because of the very low rate of data transmission on ELF (only a few bits per minute on existing systems [2]), ELF signals from transmitters are used primarily as "bell ringers" to notify the submarine to rise in order to receive more detailed information on a higher frequency. The second signal is often transmitted at ~20 kHz, a frequency low enough to/enable the submarine to remain submerged to receive the signal, using one of a number of military VLF transmitters. Submarine communication at VLF and ELF is only one-way because a transmitting system at these low frequencies is too large to install on a submarine. If higher-rate or two-way communication is needed, the submarine must extend an antenna above water to receive or transmit a signal. Because this can render the submarine detectable by radar, one-way ELF and VLF communication is often the preferred means of communication.

The same low attenuation through conducting materials that makes ELF useful for submarine communications makes it useful for communication in underground mines, where it has been used in some applications [27].

3.2. Global Communication and Navigation

Before satellites were available to relay HF and higher-frequency radio signals long distances over the horizon, global wireless communications and navigation systems depended on very long-distance coverage from a small number of transmitters. ELF and VLF signals provide a very straightforward way to do this. Besides communicating with submarines, VLF transmitters provide a one-way communication link with other military operations. These global VLF links provide a robust and jam-resistant alternative to much higher-data-rate, satellite-based communications. In the event of a global catastrophe, ordinary wireless long-distance communication channels may not be available; satellites may be disabled, and the ionosphere may be so strongly perturbed that HF signals are too strongly attenuated to be useful for long-distance communication. Even under these extreme conditions, ELF and VLF signals are still expected to propagate with low attenuation.

A VLF-based navigation system, called Omega [28], operated from 1955 until 1997. This system of eight transmitters distributed around the world and operating between 10 and 14 kHz provided global positioning accuracy to approximately 2 km. The receiver location was derived from phase differences between signals received simultaneously from multiple Omega transmitters. The satellite-based Global Positioning System (GPS) is a substantially more accurate system, leading to the decommission of the Omega system.

3.3. Geophysical Exploration

The ability of ELF electromagnetic waves to penetrate conducting materials such as rock enables their use in geophysical exploration. A standard subsurface geophysical exploration tool called *magnetotellurics* [8] relies on the fact that ELF and VLF fields on the surface of the ground are influenced by the subsurface properties because of this deep penetration. The specific source of the observed ELF and VLF fields does not matter, provided it is sufficiently far away. Both natural and artificial wave sources are commonly used. Whatever the source, the ratio of perpendicular horizontal components of the electric and magnetic field is a specific function of the subsurface electrical properties [8]. Measurements of this ratio as a function of frequency and position can be inverted into a subsurface geological map, often revealing key subsurface features such as hydrocarbon and ore-bearing deposits [29].

3.4. Scientific Applications

ELF electromagnetic waves are also used in a variety of scientific applications. Natural ELF and VLF emissions from lightning can be used very effectively for remotely sensing the ionosphere [30–32]. The lower ionosphere (~60–150 km) is one of the most inaccessible regions of the atmosphere; it is too low for satellites and too high for airplanes or balloons to probe directly, and higher-frequency incoherent scatter radar [33] used to study the higher-altitude ionosphere seldom returns a useful signal from the lower regions [34]. Because ELF and VLF waves are strongly reflected by the lower ionosphere (~60–150 km) as they propagate, they can very effectively be used to probe the lower ionosphere. And lightning is a very convenient broadband and high power source for such remote sensing.

The ELF radiation from lightning also provides a means for remotely sensing the characteristics of the source lightning discharge itself. Because this energy travels so far with minimal attenuation, a single ELF magnetic or electric field sensor can detect strong lightning discharges many thousands of kilometers away. By modeling the

propagation of the ELF signal (techniques for this are described in the later sections of this article), important parameters describing the current and charge transfer in the lightning can be quantitatively measured [10]. Applications of this technique for lightning remote sensing have led to discoveries about the strength of certain lightning processes [35] and have helped us understand the kind of lightning responsible for a variety of the most recently discovered effects in the mesosphere from strong lightning [36].

A specific kind of natural ELF–VLF electromagnetic emission led to the discovery in the 1950s that near-earth space is not empty but rather filled with ionized gas, or plasma. A portion of the ELF and VLF electromagnetic wave energy launched by lightning discharges escapes the ionosphere and, under certain conditions, propagates along magnetic field lines from one hemisphere of earth to the other. These signals are called "whistlers" because when the signal is played on a loudspeaker, the sound is a frequency-descending, whistling tone that lasts around a second. Thorough reviews of the whistler phenomenon can be found in Refs. 25 and 37. L. Storey, in groundbreaking research, identified lightning as the source of whistlers and realized that the slow decrease in frequency with time in the signal could be explained if the ELF–VLF waves propagated over a long, high-altitude path through an ionized medium [38]. The presence of plasma in most of near-earth space was later confirmed with direct measurements from satellites. The study of natural ELF waves remains an area of active research, including emissions observable on the ground at high latitudes [26,39] and emissions observed directly in space on satellites [e.g., 40] and rockets [e.g., 41].

An interesting modern ELF-related research area is ionospheric heating. A high-power HF electromagnetic wave launched upward into the ionosphere can nonlinearly interact with the medium and modify the electrical characteristics of the ionosphere [42,43]. By modulating the HF wave at a frequency in the ELF band, and by doing so at high latitudes where strong ionospheric electric currents routinely flow [44], these ionospheric currents can be modulated, forming a high-altitude ELF antenna [45]. The ELF signals launched by this novel antenna could be used for any of the applications discussed above. Currently, a major research project, the High-frequency Auroral Active Research Program (HAARP), is devoted to developing such a system in Alaska [46].

4. MATHEMATICAL MODELING OF ELF PROPAGATION

Accurate mathematical modeling of ELF propagation is needed for many of the applications described in the previous sections. It is also complicated because of the influence of the inhomogeneous and anisotropic ionosphere on the propagation. Some of the best-known researchers in electromagnetic theory (most notably J. Wait and K. Budden) worked on and solved the problem of ELF and VLF propagation in the earth–ionosphere waveguide. This work is described in many scientific articles [e.g., 47–51] and technical reports [e.g., 52,53], and is also conveniently and thoroughly summarized in a few books [19,20,54]. The approaches taken by these researchers are fundamentally similar but treat the ionospheric boundary in different ways. A solution for a simplified ELF propagation problem that provides significant insight into subionospheric ELF propagation is summarized below, followed by a treatment with minimal approximations that is capable of more accurate propagation predictions.

4.1. Simplified Waveguide Boundaries

To understand the basic principles of ELF propagation, we first consider a simplified version of the problem. Consider a vertically oriented time-harmonic short electric dipole source at a height $z = z_s$ between two flat, perfectly conducting plates separated by a distance h, as shown in Fig. 4. This simple approximation gives substantial insight into the ELF propagation problem, which is harder to see in more exact treatments of the problem. This simplified problem is, in fact, a reasonably accurate representation of the true problem because at ELF the ionosphere and ground are very good electrical conductors. The main factors neglected in this treatment are the curvature of the earth and the complicated reflection from and losses generated in a realistic ionosphere.

Wait [19] solved this problem analytically and showed that the vertical electric field produced by this short electric dipole source, as a function of height z and distance r from the source, is given by

$$E_z(r,z) = \frac{\mu_0 \omega I\, dl}{4h} \sum_{n=0}^{\infty} \delta_n S_n^2 H_0^{(2)}(kS_n r) \times \cos(kC_n Z_0) \cos(kC_n z) \tag{3}$$

where $\omega = 2\pi \times$ source frequency
$k = \omega/c$
$Idl =$ source current $\times$ dipole length
$\delta_0 = \frac{1}{2}$, $\delta_n = 1$, $n \geq 1$
$C_n = n\lambda/2h =$ cosine of the eigenangle θ_n of the nth waveguide mode
$S_n = (1 - C_n^2)^{1/2} =$ sine of the eigenangle θ_n of the nth waveguide mode
$H_0^{(2)} =$ Hankel function of zero order and second kind

If $|kS_n/r| \gg 1$, the Hankel function can be replaced by its asymptotic expansion $H_0^{(2)}(kS_n r) =$

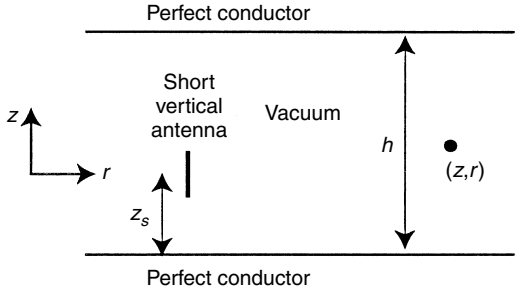

Figure 4. A simplified version of the earth–ionosphere waveguide propagation problem. A slab of free space containing a vertical antenna is bounded above and below by perfectly conducting planes.

$(2/(\pi k S_n r))^{1/2} \exp[-i(kS_n r - \pi/4)]$. This substitution, often referred to as the *far-field approximation*, is generally valid for distances more than one wavelength from the source. In this form, it is easy to see that the electric field decays with distance as $r^{-1/2}$, as it should because the propagation is confined by the waveguide to two dimensions.

This solution shows that the fields inside the perfectly conducting waveguide are the sum of the fields in an infinite number of independently propagating waveguide modes, each of which corresponds to a specific plane-wave angle θ_n of incidence on the waveguide boundaries. Each mode propagates with a different phase velocity $v_p = c/\sin(\theta_n)$, and the fields at a distance are simply the sum of the fields in each mode. This concept of waveguide modes is very general for wave propagation in bounded structures [54] and applies to light propagation in optical fibers [55], acoustic propagation in the ocean [56], and many other scenarios. A physical interpretation of the eigenangle of a waveguide mode is that the modal eigenangles are the set of incidence angles on the boundaries for which a plane wave reflected once each from the upper and lower boundaries is in phase with the incident (nonreflected) plane wave.

The summation in Eq. (3) is over an infinite number of modes. However, the equation for C_n shows that for any frequency there is a mode order $n_{\max}$ above which C_n is greater than unity. For modes of order greater than $n_{\max}$, S_n is purely imaginary, and the mode fields exponentially decay, rather than propagate, with increasing distance from the source. Such modes are called *evanescent* and, because of their exponential decay, do not contribute significantly to the total field except very close to the source. Equivalently, for a fixed mode of order n, there is a frequency below which the mode is evanescent. This frequency is called the *cutoff frequency* of the mode, which in this case is given by $f_{cn} = nc/2h$. Because at any frequency the number of propagating waves is finite, the summation can be terminated at $n_{\max}$ to a very good approximation to compute the fields beyond a significant fraction of a wavelength from the source.

The number of propagating modes $n_{\max}$ is a function of frequency. As frequency decreases, so does the number of modes required to describe the propagation of the energy. This is demonstrated in Fig. 5 with a calculation using Eq. (3). We assume a waveguide upper boundary height of 80 km, representative of the earth–ionosphere waveguide at night, and the source and receiver are on the lower boundary of the waveguide ($z = 0$). The two curves in the figure show the vertical electric field as a function of distance from a 1-A/m vertical electric dipole source at 200 Hz and 10 kHz. The difference between them is obvious and has a clear physical interpretation. At $f = 200$ Hz, only one waveguide mode propagates; all others are evanescent. This one mode is called the *transverse electromagnetic* (TEM) mode because it contains only E_z and H_ϕ fields that point transverse to the propagation direction. Thus at 200 Hz, the field decays with distance smoothly as $r^{-1/2}$ from this single mode. This represents classic, single-mode ELF propagation. But at $f = 10$ kHz, six modes propagate, each with a different phase velocity. The relative phase of these modes changes rapidly with distance, which produces a very complicated field variation with distance, as shown. The six modes interfere constructively where the amplitude is a local maximum, and interfere destructively where the amplitude is a local minimum. This complicated field pattern with distance is very typical of multimode propagation, which occurs at VLF in the earth–ionosphere waveguide. The overall amplitude difference between the two curves results from the fixed antenna length used in this calculation, which is electrically shorter (and therefore less efficient) at lower frequencies. Interesting practical issues arise in multimode propagation. The presence of deep nulls means that at certain locations and under certain waveguide conditions, the received signal level can be very low even for high transmitted power. Predicting signal coverage from military VLF transmitters and finding the locations of these nulls was one of the original motivations behind modeling the ELF–VLF propagation problem as accurately as possible.

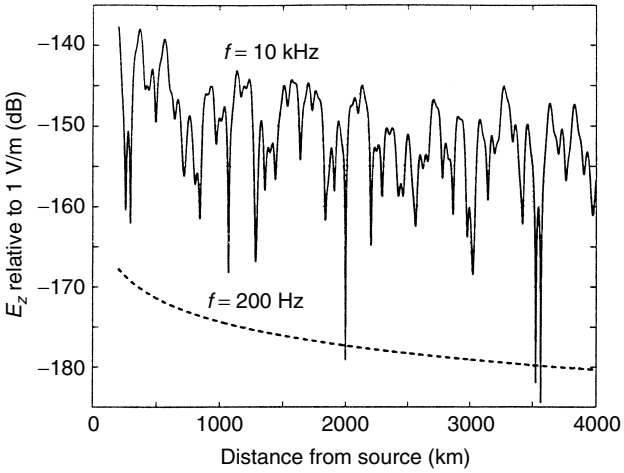

Figure 5. Vertical electric field strength versus distance from a 1-A/m electric dipole source, assuming perfectly conducting earth–ionosphere waveguide boundaries separated by 80 km, and calculated using Eq. (3). At $f = 200$ Hz, only one mode propagates, and the total field decays simply as $r^{-1/2}$. At $f = 10$ kHz, 6 modes propagate with different phase velocities. Even though the fields in each mode decay as $r^{-1/2}$, the mutual interference of all 6 modes creates the very complicated amplitude variation with distance shown here.

Equation (3) is valid for a source at any frequency. However, for frequencies high enough that the wavelength is much smaller than h, the number of propagating modes $n_{\max}$ is so great that the mode-based formulation becomes difficult to use in calculations. Ray theory [57], in which the fields at a distance are described by a sum of discrete rays that each undergo a different number of reflections from the ground and ionosphere, becomes a much more practical and compact representation of the fields at a distance. For propagation in the earth–ionosphere waveguide, this mode theory/ray theory boundary occurs around 50 kHz. At VLF and ELF frequencies, the mode theory description of the fields can very efficiently describe the propagation of the wave energy because only a few modes are propagating (i.e., are not evanescent).

There are other electromagnetic field components produced by this vertical dipole source. In the case of perfectly conducting boundaries, H_ϕ and E_r are nonzero, and expressions for these components can be found directly from the solution for E_z [19]. In general, all the field components in a single mode vary sinusoidally with altitude; thus the altitude variation of the fields is also quite complicated in the case of multimode propagation. The fields produced by a horizontal electric dipole, such as the ELF antenna described above for submarine signaling, are a similar modal series containing different field components [19].

4.2. Realistic Waveguide Boundaries

While the perfectly conducting boundary approximation demonstrates the fundamental characteristics of ELF propagation, it is rarely accurate enough for quantitatively correct simulations of earth–ionosphere waveguide propagation. The real ionosphere is not a sharp interface like that assumed above, but is a smoothly varying waveguide boundary. Nor is it a simple electrical conductor as assumed; it is a magnetized cold plasma with complicated electromagnetic properties. The key ionospheric parameters for electromagnetic wave propagation and reflection are the concentration of free electrons and ions (electron and ion density), the rate of collisions for electrons and ions with other atmospheric molecules (collision frequencies), and the strength and direction of Earth's magnetic field. Figure 6 shows representative altitude profiles of electron and ion density for midday and midnight and profiles of electron and ion collision frequencies. The index of refraction of a cold plasma like the ionosphere is a complicated function of all of these parameters [58], in which is therefore difficult to handle in analytic calculations. Also, in general, the ground is not a perfect conductor and may even be composed of layers with different electromagnetic properties, such as an ice sheet on top of ordinary ground. These realistic boundaries cannot be treated as homogeneous and sharp.

Both Budden [49] and Wait [19] derived solutions for the earth–ionosphere waveguide problem with arbitrary boundaries. Their solutions are fundamentally similar, with slight differences in the derivation and how certain complexities, such as the curved earth, are treated. We follow Wait's treatment below.

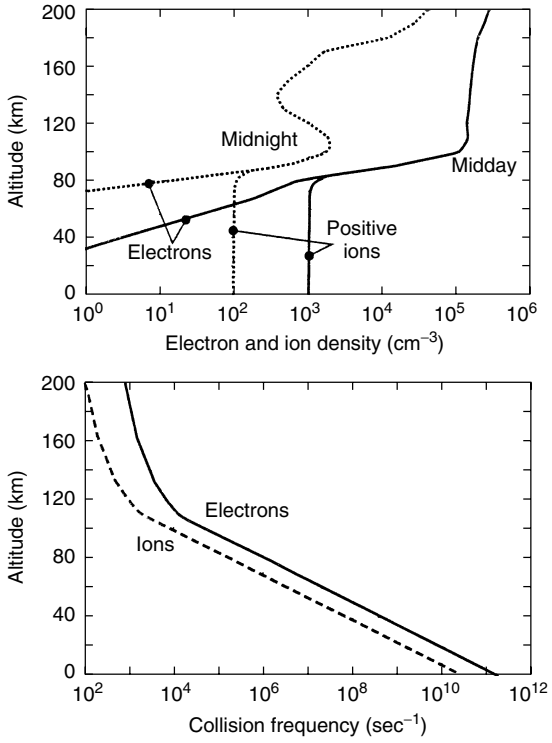

Figure 6. Representative midday and midnight ionospheric electron density, ion density, and collision frequency profiles. Negative ions are also present where needed to maintain charge neutrality.

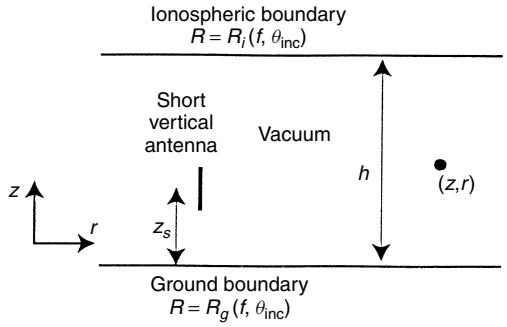

Figure 7. A generalized version of the earth–ionosphere waveguide propagation problem. A slab of free space containing a vertical antenna is bounded above and below by completely arbitrary reflecting boundaries.

4.2.1. Propagation Modeling with General Boundaries. We again consider propagation inside a free-space region between two boundaries separated by a distance h. Now, however, the boundaries at $z = 0$ and $z = h$ are completely general and are described only by their plane-wave reflection coefficients, as shown in Fig. 7. These reflection coefficients are functions of incidence angle, incident polarization, and frequency. This important generalization makes the following formulation applicable to essentially any two-dimensional planar waveguide, regardless of size or bounding material.

Ordinarily, the electromagnetic fields can be separated into transverse electric (TE) and transverse magnetic (TM) groups that propagate independently in a two-dimensional waveguide. However, since the ionosphere is a magnetized plasma and thus is anisotropic, these field groups are coupled at the upper boundary and an incident TE or TM wave produces both TE and TM reflections. Purely TE or TM fields do not exist in the earth–ionosphere waveguide. The coupling between the fields means that the reflection coefficient from the upper boundary is not a scalar quantity but is rather a 2×2 matrix, where each matrix element is one of the four different reflection coefficients for a specific incident and reflected polarization. The lower boundary of the earth–ionosphere waveguide is the ground, which is generally isotropic so that the cross-polarized reflection coefficients in the ground reflection matrix are zero.

With this in mind, we define $\mathbf{R}_I$, the reflection matrix of the ionosphere at altitude $z = h$, and $\mathbf{R}_G$, the reflection matrix of the ground at $z = 0$, as

$$\mathbf{R}_I(\theta) = \begin{bmatrix} {}_{\parallel}R^i_{\parallel} & {}_{\parallel}R^i_{\perp} \\ {}_{\perp}R^i_{\parallel} & {}_{\perp}R^i_{\perp} \end{bmatrix} \mathbf{R}_G(\theta) = \begin{bmatrix} {}_{\parallel}R^g_{\parallel} & 0 \\ 0 & {}_{\perp}R^g_{\perp} \end{bmatrix} \tag{4}$$

These reflection coefficients are implicitly functions of the angle of incidence and the frequency. The left subscript on the matrix elements denotes the incident wave polarization (parallel or perpendicular to the plane of incidence containing the wavevector and the boundary normal), and the right subscript denotes the reflected polarization.

By using the plane-wave spectrum representation of the fields from a short vertical electric dipole, by postulating a particular solution form in the presence of the waveguide, and by enforcing continuity of the tangential field components between the free-space and boundary regions, Wait [19] shows that the fields in the waveguide, in terms of the electric and magnetic Hertz vectors $\mathbf{U}$ and $\mathbf{V}$ are given by the complex contour integral

$$\begin{bmatrix} U_z \\ V_z \end{bmatrix} = -\frac{kIdl}{8\pi\omega\varepsilon_0} \int_\Gamma \mathbf{F}(C) \begin{bmatrix} 1 \\ 0 \end{bmatrix} H_0^{(2)}(kSr)dC \tag{5}$$

with

$$\mathbf{F}(C) = \frac{\begin{matrix}(\exp ikCz + \mathbf{R}_G(C)\exp -ikCz) \\ (\exp ikCh + \mathbf{R}_I(C)\exp -ikCh)\end{matrix}}{\begin{matrix}\exp ikCh(1 - \mathbf{R}_G(C) \\ \mathbf{R}_I(C)\exp -2ikCh)\end{matrix}}, \tag{6}$$

where C and S are the cosine and sine of the complex angle of incidence θ of the wave on the upper and lower boundaries, respectively, as was the case for the simplified boundaries discussed above. The symbols in Eqs. (5) and (6) are consistent with those in Eq. (3). The integrand contains poles where

$$\det(1 - \mathbf{R}_G(C)\mathbf{R}_I(C)\exp -2ikCh) = 0 \tag{7}$$

and thus the integral can be evaluated as a residue series [59]. Equation (7), commonly referred to as the *mode condition*, requires that one eigenvalue of the net reflection coefficient $\mathbf{R}_G\mathbf{R}_I \exp -2ikCh$ be unity. This is equivalent to stating that the plane wave at the given incidence angle reflected once each from the upper and lower boundaries must be in phase with and equal in amplitude to the incident plane wave. In this way, the fields in the waveguide can be thought of as the sum of contributions from the angular spectrum of plane waves at angles for which propagation in the waveguide is self-reinforcing. Each angle of incidence θ_n that satisfies the mode condition is referred to as an *eigenangle* and defines a waveguide mode at the frequency ω under consideration. Budden [49] solved the same problem in a slightly different way by summing the fields produced by an infinite number of sources, each corresponding to a different multiply reflected plane wave in the waveguide. Wait's and Budden's solutions are essentially identical.

From Eqs. (5)–(7), an explicit expression for the Hertz vectors in the free-space region between the two boundaries is given by

$$\begin{bmatrix} U_z \\ V_z \end{bmatrix} = \frac{ikIdl}{4\omega\varepsilon_0} \sum_n \frac{\exp 2ikC_nh}{\partial\Delta/\partial C\Big|_{\theta=\theta_n}} \times \begin{bmatrix} (\exp 2ikC_nh - {}_{\perp}R^g_{\perp\perp}R^i_{\perp})f_p^1(z) \\ i_{\parallel}R^g_{\parallel\parallel}R^i_{\perp}f_p^2(z) \end{bmatrix} H_0^2(kS_nr) \tag{8}$$

where $\Delta(C) = \det(\exp 2ikCh - \mathbf{R}_G\mathbf{R}_I)$. The actual electric and magnetic fields are easily derived from these Hertz vector components [19].

Each term in (8) has a physical interpretation. The leading constant is a source term that depends on the current–moment Idl of the vertical dipole source. The first term in the summation is commonly referred to as the *excitation function* for a particular mode at a given frequency, and it quantifies the efficiency with which that mode is excited by a vertical dipole on the ground. The 2×1 matrix in the summation describes the field variation with altitude, and the functions f_p^1 and f_p^2 are defined explicitly by Wait [19]. The $H_0^2(kS_nr)$ term describes the propagation of a cylindrically expanding wave, which exists because the expansion in the vertical direction is limited by the waveguide boundaries so that the mode fields spread only horizontally. For distances where $kS_nr \gtrsim 1$, we can approximate $H_0^2(kS_nr) \approx \left(\frac{2}{\pi kS_nr}\right)^{1/2} \exp[-i(kS_nr - \pi/4)]$, which more explicitly shows the $r^{-1/2}$ cylindrical spreading. In this approximation, it is also clear that each mode propagates as $\exp[-i(kS_nr)]$. The sine of the modal eigenangle thus contains all the information about the phase velocity and attenuation rate of the mode. Because the boundaries are lossy in the earth–ionosphere waveguide (due to both absorption in the boundaries and energy leakage out of the waveguide from imperfect reflection), the eigenangles and thus S_n are necessarily complex.

As was the case for the simplified, perfectly conducting waveguide, the summation in Eq. (8) is over an infinite number of modes. In practice, however, it can be limited only to the modes that contribute significantly to the fields at a distance r from the source. All modes are at least somewhat lossy with realistic waveguide boundaries, but there generally is a sharp transition between low loss and very high loss at the cutoff frequency of each mode. Often for long distances at ELF and VLF, only a few low-attenuation modes or even just one contribute significantly to the fields, leading to a very compact and efficient calculation. For very short distances, however, even highly attenuated modes can contribute to the fields and mode theory becomes less efficient and more difficult to implement.

Two factors have been neglected in this analysis of ELF propagation with realistic boundaries. One is the curvature of the earth. Treating the curvature exactly substantially increases the complexity of the modeling [19], but relatively simple corrections to Eqs. (7) and (8) can account for this curvature fairly accurately.

By introducing an artificial perturbation to the index of refraction of the free-space region between the ground and ionosphere to the flat-earth problem [19,49], the ground curvature can be handled correctly. At lower VLF ($\lesssim$5 kHz) and ELF, the flat-earth mode condition in Eq. (7) is accurate, and this correction is not needed [19]. The curved boundaries also affect the geometric decay of the fields with distance. Simply replacing the $r^{-1/2}$ term in Eq. (8) with the factor $[a \sin(r/a)]^{-1/2}$, where a is the radius of the earth, properly accounts for energy spreading over a spherical boundary [49,19].

Antipodal effects are also neglected in the analysis presented above. When the receiver approaches the antipode of the transmitter, signals that propagate around the earth in directions other than the direct great circle path are comparable in amplitude to the direct signal and thus interfere. As discussed above, this effect is most significant at ELF and has been studied theoretically [12,19,20]. Experimental results from 1998 compare favorably with predictions[16].

4.2.2. Practical Implementation. The general equations describing mode-based ELF and VLF propagation are complicated because of the complexity of the physical boundaries of the earth–ionosphere waveguide. The most difficult part of implementing calculations in Eq. (8) with realistic boundaries is solving Eq. (7) to find the modal eigenangles for a general boundary. When the reflection matrixes cannot be described analytically, such as for an arbitrary ionospheric profile, an iterative numerical procedure is needed to find the set of eigenangles that satisfy the mode condition. Such a numerical model and code was developed over a number of years by the Naval Electronics Laboratory Center (NELC), which later became the Naval Ocean Systems Center (NOSC) and is now the Space and Naval Warfare Systems Center (SSC). The details of this model are described in a series of papers [51,60] and technical reports [53,61,62]. The end result was a model called long wave propagation capability (LWPC) that calculates the eigenangles for an arbitrary ionospheric profile and arbitrary but uniform ground, and then calculates the total field at a given distance from the source. This model includes the modifications to the mode condition [Eq. (7)] and the field equation [Eq. (8)] to account for propagation over a curved earth, and it also includes the capability of accounting for sharp inhomogeneities in the ionosphere along the direction of propagation. The technique used for this calculates mode conversion coefficients at the two sides of the sharp inhomogeneity [63,64].

Using the nighttime ionospheric profiles in Fig. 6 and ground parameters representative of propagation over land ($\varepsilon_r = 15$, $\sigma = 10^{-3}$), we have used the LWPC model to calculate the vertical electric field versus distance from a 1 A m vertical electric dipole source for source frequencies of 200 Hz and 10 kHz. The results, shown in Fig. 8, are directly comparable to the simplified model results in Fig. 5. While qualitatively similar, there are significant differences. Again, the overall amplitude difference between the 200-Hz and 10-kHz signals relates to our use of a fixed antenna length in the simulation. At ELF (200 Hz), there is again only one propagating mode

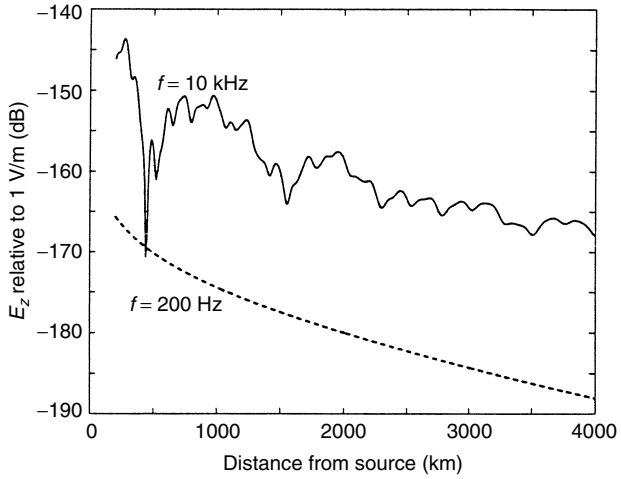

Figure 8. Model ELF and VLF calculations using LWPC with the ionospheric profiles shown in Fig. 6. At $f = 200$ Hz, only one mode propagates, and the total field decays slightly faster than $r^{-1/2}$ because of the lossy waveguide boundaries. At $f = 10$ kHz, more modes propagate and produce a more complicated amplitude variation with distance. Because the boundaries are lossy, however, the total signal is dominated by only a few modes, resulting in a simpler amplitude variation than the lossless waveguide results in Fig. 5.

that gives a smooth amplitude variation with distance. For the realistic ionosphere, however, the field attenuates faster than $r^{-1/2}$ with distance because energy is lost in the imperfectly conducting boundaries as well as through geometric spreading. At VLF (10 kHz), the amplitude varies considerably with distance, which is again a consequence of multimode propagation at the higher frequency. These variations are much less severe than in the calculation with perfectly conducting boundaries. This is also a consequence of the lossy boundaries. Certain modes are lossier than others, and these decay more rapidly with distance, so that fewer propagating modes contribute significantly to the fields at a given distance. If the calculation were extended for longer distances, there would be a point beyond which one mode dominates the fields, and the amplitude variation would become smooth. This does not happen for perfectly conducting boundaries because all modes decay with distance at the same rate. Measurements of VLF signal strength with distance made from aircraft have shown that this model can very accurately predict the variation of signal with distance, provided the correct ionosphere is used in the simulation [65].

4.3. Analytic Approximations

Analytic approximations have been developed for ELF propagation that are more realistic than the overly simplified perfectly conducting parallel-plate waveguide but that are much less complicated than the exact approach. One of the most widely used and most accurate approximations for ELF propagation was developed by Greifinger and Greifinger [66]. They recognized that because ELF wavelengths are so long, only a few key characteristics of the ionospheric altitude profile strongly

influence the characteristics of ELF propagation. These approximate solutions apply only to single-mode, ELF propagation and thus to frequencies less than 1 kHz, and are most accurate at frequencies less than a few hundred hertz.

By making a few key approximations but still accounting for the anisotropy of the ionosphere, Greifinger and Greifinger [66] show that the sine of the eigenangle of the single ELF propagating mode S_0 is approximated by

$$S_0 \approx \left(\frac{h_1(h_1 + i\pi\zeta_1)}{(h_0 - \zeta_0 i\pi/2)(h_1 + \zeta_1 i\pi/2)} \right)^{1/2} \tag{9}$$

The parameter h_0 is the altitude at which the parallel ionospheric conductivity $\sigma_\parallel(h_0) = \omega\varepsilon_0$, and ζ_0 is the parallel conductivity scale height at the altitude h_0. The parameter h_1 is a higher altitude at which $4\mu_0\omega\sigma_H(h_1)\zeta_1^2 = 1$, where ζ_1 is the Hall conductivity scale height at the altitude h_1. The parallel and Hall conductivities are functions of the ionospheric electron and ion densities, collision frequencies, and magnetic field [67] and are straightforward to calculate. With this expression for S_0, the vertical electric field at ground level radiated by a vertical electric dipole is then given by [68]

$$E_z(r, 0) = \frac{\mu_0\omega Idl}{4(h_0 - i\pi\zeta_0/2)} S_0^2 H_0^{(2)}(kS_0 r) \tag{10}$$

Equations (9) and (10) give a simple, noniterative method for calculating the ELF propagation characteristics under a realistic ionosphere. This method was compared with LWPC calculations at 50 and 100 Hz and was found to be very accurate [66]. To demonstrate, we consider 200 Hz ELF propagation under the ionospheric profiles shown in Fig. 6. After calculating the associated parallel and Hall conductivity profiles, we find for this ionosphere that $h_0 = 55$ km, $\zeta_0 = 2.5$ km, $h_1 = 74$ km, and $\zeta_1 = 7.2$ km. Plugging these numbers into Eqs. (9) and (10), the vertical electric field strength versus distance from a 1-A/m source at 200 Hz is as shown in Fig. 9. The approximate method in this section is very close to the full-wave, LWPC calculation, as shown; only the modal attenuation rate is slightly underestimated. The approximate method is also much closer to the full-wave calculations than is the perfectly conducting waveguide approximation, which, because it is lossless, drastically underestimates the modal attenuation. For realistic nighttime ionospheres, there is often complicated attenuation behavior as a function of ELF frequency because of sharp ionospheric gradients between 100 and 150 km [9] that is not be captured by this approximate method. Nevertheless, this method can accurately predict ELF field strength for realistic ionospheres and is much simpler to implement than a more exact, full-wave calculation.

4.4. Finite-Difference Methods

A completely different approach to modeling ELF propagation that has been used applies full-wave finite-difference simulations [69] to model the electromagnetic fields everywhere in the computational domain [32,70]. This brute-force but versatile approach has become usable only relatively recently because of the computing power available on modest platforms. This method is based on decomposing the volume of interest into a finite grid of discrete points at which all electromagnetic field components are computed. As a general rule, the spacing between grid points must be significantly smaller than one wavelength in order to accurately model the fields. This makes finite-difference methods well suited to low-frequency ELF and VLF propagation propagation problems in which the wavelength is quite long and the usual computational domain is a relatively small number of wavelengths in size. A major advantage of this method is that arbitrary lateral inhomogeneities, such as smooth or sharp changes in the ionospheric profile along the propagation direction, can be introduced without any increase in model complexity. Also, because the model complexity depends only on the size of the computational domain, short propagation paths are significantly easier to model than long paths. The opposite is true for mode-theory-based calculations, in which long paths are simpler because fewer modes contribute to the total fields. Mode theory and finite-difference methods are thus rather complementary. Finite-difference methods can easily handle arbitrary inhomogeneities and work especially well over short distances, while mode theory calculations can be very efficient, especially over long distances. Most importantly, the mode theory formulation of the problem also provides essential physical insight into the ELF propagation problem.

BIOGRAPHY

Steven A. Cummer is an assistant professor of the Department of Electrical and Computer Engineering at Duke University Durham, North Carolina. He received his B.S., M.S., and Ph.D. degrees in electrical engineering from Stanford University, California, in 1991, 1993, and 1997, respectively. He spent two years at NASA Goddard Space Flight Center in Greenbelt, Maryland, as an National Research Council postdoctoral research associate, and joined Duke University in 1999. He received a National Science Foundation CAREER award

in 2000 and a Presidential Early Career Award for Scientists and Engineers (PECASE) in 2001. His current research is in a variety of problems in ionospheric and space physics, emphasizing electromagnetic modeling and remote sensing using ground-based and satellite instruments.

1. INTRODUCTION

Since its introduction in the late 1970s as a general iterative procedure for producing maximum-likelihood estimates in cases a direct approach is computationally or analytically intractable, the expectation-maximization (EM) algorithm has been used with increasing frequency in a wide variety of application areas. Perhaps not surprisingly, one of the areas that has seen an almost explosive use of the algorithm since the early 1990s is telecommunications. In this article we describe some of the varied uses of the EM algorithm that appeared in the literature in the area of telecommunications since its introduction and include some new results on the algorithm that have not appeared elsewhere in the literature.

The expectation-maximization (EM) algorithm was introduced in its general form by Dempster et al. in 1977 [1]. Previous to that time a number of authors had in fact proposed versions of the EM algorithm for particular applications (see, e.g., Ref. 4), but it was [1] that established the algorithm (in fact, as argued by some, a "procedure", rather than an algorithm) as a general tool for producing maximum-likelihood (ML) estimates in

situations where the observed data can be viewed as "incomplete" in some sense. In addition to introducing the EM algorithm as a general tool for ML estimation, Dempster et al. [1] also dealt with the important issue of convergence, which was further studied and refined by the work of Wu [5].

Following the publication of [1], the research community experienced an almost explosive use of the EM algorithm in a wide variety of applications beyond the statistics area in which it was introduced. Early application areas for the EM algorithm outside its native area of statistics include genetics, image processing, and, in particular, positron emission tomography (PET) [6,7], (an excellent treatment of the application of the EM algorithm to the PET problem can be found in Snyder and Miller [8]). In the late 1980s there followed an increasing number of applications of the EM algorithm in the signal processing area, including in speech recognition, neural networks, and noise cancellation. Admittedly somewhat arbitrarily, we will not cite references here in the signal processing area, with the exception of one that had significant implications in the area of communications: the paper by Feder and Weistein [9]. This paper will be described in somewhat more detail later, and it is important in the area of telecommunications in that it dealt with the problem of processing a received signal that is the superposition of a number of (not individually observable) received signals. Clearly, this framework applies to a large number of telecommunications problems, including multiuser detection and detection in multipath environments. The reader can find other references (not a complete list) on the use of the EM algorithm in the signal processing (and other areas) in the tutorial paper by Moon [10]. For a general introduction to the EM algorithm and its applications in the statistics area, the reader is urged to read the original paper of Dempster et al. [1], as well as a book published in 1997 [11] on the algorithm. The appearance of a book on the EM algorithm is perhaps the best indication of its widespread use and appeal.

As mentioned above, in this manuscript we are interested in a somewhat narrow application area for the EM algorithm, that of telecommunications. Clearly, the boundaries between signal processing and telecommunications are not always well defined and in presenting the material below some seemingly arbitrary decisions were made: Only techniques that deal with some aspect of data transmission are included.

In Section 2 and for completeness we first give a brief introduction of the EM algorithm. In Section 3 we present a summary of some of the main published results on the application of the EM algorithm to telecommunications. Section 4 contains some recent results on the EM algorithm, and Section 5 concludes.

2. THE ESSENTIAL EM ALGORITHM

Let $\mathbf{b} \in \mathcal{B}$ be a set of parameters to be estimated from some observed data $\mathbf{y} \in \mathcal{Y}$. Then the ML estimate $\widehat{\mathbf{b}}$ of $\mathbf{b}$ is a solution to

$$\widehat{\mathbf{b}} = \arg \max_{\mathbf{b} \in \mathcal{B}} g(\mathbf{y} \mid \mathbf{b}) \tag{1}$$

where $g(\mathbf{y} \mid \mathbf{b})$ is the conditional density of the data given the parameter vector to be estimated. In many cases a simple explicit expression for this conditional density does not exist, or is hard to obtain. In other cases such an expression may be available, but it is one that does not lend itself to efficient maximization over the set of parameters. In such situations, the expectation–maximization algorithm may provide a solution, albeit iterative (and possibly numerical), to the ML estimation problem.

The EM-based solution proceeds as follows. Suppose that instead of the data $\mathbf{y}$ actually available one had data $\mathbf{x} \in \mathcal{X}$ from which $\mathbf{y}$ could be obtained through a many-to-one mapping $\mathbf{x} \rightarrow \mathbf{y}(\mathbf{x})$, and such that their knowledge makes the estimation problem easy (for example, the conditional density $f(\mathbf{x} \mid \mathbf{b})$ is easily obtained.) In the EM terminology, the two sets of data $\mathbf{y}$ and $\mathbf{x}$ are referred to as the incomplete and complete data, respectively.

The EM algorithm makes use of the loglikelihood function for the complete data in a two-step iterative procedure that under some conditions converges to the ML estimate given in (1) [1,5]. At each step of the EM iteration, the likelihood function can be shown to be nondecreasing [1,5]; if it is also bounded (which is mostly the case in practice), then the algorithm converges. The two-step procedure at the ith iteration is

1. *E step*: Compute $Q(\mathbf{b} \mid \mathbf{b}^i) \equiv E[\log f(\mathbf{x} \mid \mathbf{b}) \mid \mathbf{y}, \mathbf{b}^i]$.
2. *M step*: Solve $\mathbf{b}^{i+1} = \arg \max_{\mathbf{b} \in \mathcal{B}} Q(\mathbf{b} \mid \mathbf{b}^i)$.

Here $\mathbf{b}^i$ is the parameter vector estimate at the ith iteration. The two steps of the iteration are referred to as the expectation (E step) and maximization (M step) steps, respectively. Note that in the absence of the data $\mathbf{x}$, which makes $\log f(\mathbf{x} \mid \mathbf{b})$ a random variable, the algorithm maximizes its conditional expectation instead, given the incomplete data and the most recent estimate of the parameter vector to be estimated.

As mentioned earlier, the EM algorithm has been shown [1,5] to result in a monotonically nondecreasing loglikelihood. Thus, if the loglikelihood is bounded (which is the case in most practical systems), then the algorithm converges. Under some conditions, the stationary point coincides with the ML estimate.

3. AN OVERVIEW OF APPLICATIONS TO TELECOMMUNICATIONS

In this section we provide a brief overview on the use of the EM algorithm in the telecommunications area.

3.1. Parameter Estimation from Superimposed Signals

One of the earliest uses of the EM algorithm with strong direct implications in communications appeared in 1988 [9]. Feder and Weinstein [9] look at the problem of parameter estimation from a received signal, $y(t)$ (it can be a vector in general), which is a superposition of a number of signals plus Gaussian noise:

$$y(t) = \sum_{k=1}^{K} s_k(t; \theta_k) + n(t) \tag{2}$$

For simplicity in illustrating the basic idea, we will assume that $y(t)$, $n(t)$, and each $\theta_k, k = 1, 2, \ldots, K$ are scalar (Feder and Weinstein [9] handle the more general case of vectors); the objective is to estimate the parameters $\theta_k, k = 1, 2, \ldots, K$ from the data $y(t)$ observed over a T-second interval. It is assumed that the $s_k(t; \theta_k)$ are known signals given the corresponding parameters θ_k, and $n(t)$ is white Gaussian noise with $\sigma^2 = E[|n(t)|^2]$. Clearly, if instead of the superimposed data $y(t)$ one had available the individual components of $y(t)$, the problem of estimating the θ_k would become much simpler since there would be no coupling between the parameters to be estimated. Thus, the complete data $\mathbf{x}(t)$ are chosen to be a decomposition of $y(t)$: $\mathbf{x}(t) = [x_1(t), x_2(t), \ldots, x_K(t)]'$ (where the prime sign $'$ means transpose) where

$$x_k(t) = s_k(t; \theta_k) + n_k(t), \quad k = 1, 2, \ldots, K \tag{3}$$

$$\sum_{k=1}^{K} n_k(t) = n(t) \tag{4}$$

and, thus

$$y(t) = \sum_{k=1}^{K} x_k(t)$$

The $n_k(t)$ are assumed statistically independent (for analytic convenience) and have corresponding variances $\beta_k \sigma^2$, where it is assume that $\beta_k \geq 0$ and

$$\sum_{k=1}^{K} \beta_k = 1$$

Then the E step of the EM algorithm yields [9]

$$Q(\boldsymbol{\theta} \mid \hat{\boldsymbol{\theta}}) = -\sum_{k=1}^{K} \frac{1}{\beta_k} \int_T \left| \hat{x}_k(t) - s_k(t; \theta_k) \right|^2 dt \tag{5}$$

where

$$\hat{x}_k(t) = s_k(t; \hat{\theta}_k) + \beta_k \left[y(t) - \sum_{i=1}^{K} s_i(t; \hat{\theta}_i) \right] \tag{6}$$

and $\hat{\theta}_i, i = 1, 2, \ldots, K$ are the most recent estimates. At the M step, maximization of (5) with respect to the parameter vector $\boldsymbol{\theta}$ corresponds to minimizing each term in the sum in (5) with respect to the corresponding individual parameter. Thus, the desired decoupling.

Feder and Weinstein [9] went on to apply the general results presented above to the problems of estimating the multipath delays and to the problem of multiple source location. No modulation was present in the received signals, but, as mentioned above, the technique is quite general and has over the years been used in a number of applications in telecommunications. Direct applications of the results in Ref. 9 to the problem of multiuser detection can be found in Refs. 12–16.

3.2. The Multiuser Channel

In Ref. 17, also published in 1988, Poor uses the EM algorithm to estimate the amplitudes of the user signals in a multiuser environment, in the presence of modulation. In this application, the modulation symbols (binary-valued) are treated as "nuisance" parameters. The complete data are chosen as the received (incomplete) data along with the binary modulation symbols over an observation window. The E step of the EM iteration involves the computation of conditional expectations of the binary-valued symbols, which results in "soft" data estimates in the form of hyperbolic tangents. At convergence, the algorithm yields the amplitude estimates and on slicing the soft-data estimates, also estimates of the binary modulation symbols (although no optimality can be claimed). Follow-up work that relates to Ref. 17 can be found in Refs. 18–21, in which the emphasis is not on amplitude estimation (amplitudes are assumed known) but on K-user multiuser detection. In Refs. 18, 20, and 21 the complete data are taken to be the received (baud rate) matched-filter samples along with the binary modulation symbols of $(K - 1)$ users, treated as interference in detecting a particular user. In addition to the application of the standard EM algorithm, the authors in Refs. 18, 20, and 21 also study the use of the space-alternating generalized EM (SAGE) algorithm [22,23], a variant of the EM algorithm that has better convergence properties and may simplify the maximization step. Other work in the area of spread-spectrum research that uses the SAGE algorithm in jointly detecting a single user in the presence of amplitude, phase, and time-delay uncertainties has also been presented [24,25].

3.3. Channel Estimation

In Refs. 26 and 27, the authors deal with detection in an impulsive noise channel, modeled as a class A mixture. In these papers the role of the EM algorithm is not directly in detection itself, but rather in estimating the triplet of parameters of the (Gaussian) mixture model, namely, the variances of the nominal and contaminant distributions and the probability of being under one or the other distribution. The estimate of the mixture model is then used (as if it were perfect) to select the nonlinearity to be used for detection. This particular application of the EM algorithm to estimate the Gaussian mixture model is one of its original and most typical uses. Follow-up (but more in-depth) work on the use of the EM algorithm to estimating class A noise parameters can be found in Ref. 28. Further follow-up work on the problem of detection in impulsive noise can be found in Refs. 29 and 30. As in Refs. 26 and 27, the authors in Refs. 29 and 30 use the EM algorithm to estimate parameters in the impulsive noise model, which are then used for detection in a spread-spectrum, coded environment. In Ref. 31 the EM algorithm is used to estimate the noise parameters in a spatial diversity reception system when the noise is modeled as a mixture of Gaussian distributions. Also in a spatial diversity environment, Baroso et al. [32] apply the EM algorithm to estimate blindly the multiuser array channel transfer function. Data detection in the paper is considered separately.

The EM algorithm has also been used for channel estimation under discrete signaling. In a symposium paper [33] and in a follow-up journal paper [34], Vallet

and Kaleh study the use of the EM algorithm for channel estimation modeled as having a finite impulse response, for both linear and nonlinear channels. In this work, the modulation symbols are considered as the "nuisance" parameters and the authors pose the problem as one of estimating the channel parameters. At convergence, symbol detection can be performed as well. Other work on the use of the EM algorithm to channel estimation/equalization in the presence of data modulation can be found in the literature [12,35–37]. Zamiri-Jafarian and Pasupathy present an algorithm for channel estimation, motivated by the EM algorithm, that is recursive in time.

3.4. The Unsynchronized Channel

In 1989 a paper dealing (for the first time) with sequence estimation using the EM algorithm appeared [38] with a follow-up journal paper appearing in 1991 [39]. In Refs. 38 and 39 the received data are "incomplete" in estimating the transmitted sequence because time synchronization is absent. The complete data in the paper were defined as the baud rate (nonsynchronized) matched-filter samples along with the correct timing phase. The E step of the algorithm was evaluated numerically, and the M step trivially corresponded to symbol-by-symbol detection in the absence of coding. The algorithm converged within 2–4 iterations, depending on the signal-to-noise ratio (SNR). The fast convergence of the algorithm can be attributed to the fact that the parameters to be estimated came from a discrete set. Follow-up work using the EM algorithm for the time unsynchronized channel appeared in 1994 and 1995 [40–42]. In one of Kaleh's papers [40], which in fact uses the Baum–Welch algorithm [4], a predecessor to EM, instead of posing the problem as sequence estimation in the presence of timing offset, the author poses the problem as one of estimating the timing offset (and additive noise variance) in the presence of random modulation. At convergence, symbol estimates can also be obtained. In Ref. 42, in addition to the absence of time synchronization, the authors assume an unknown amplitude. In the paper the authors use the SAGE algorithm [22] to perform sequence estimation.

3.5. The Random Phase Channel

Similar to Refs. 38 and 39, in a 1990 paper [43] the authors consider sequence estimation in the presence of random phase offset, for both uncoded and trellis-coded systems. We provide a brief description of the results here.

Let $\mathbf{s} = (s_1, s_2, \ldots, s_N)$ be the vector containing the complex modulation symbols, $\mathbf{D}$ be a diagonal matrix with the elements of $\mathbf{s}$ as diagonal elements, and θ be the phase offset over the observation window. Then the received (incomplete) data vector $\mathbf{r}$ can be expressed as

$$\mathbf{r} = \mathbf{D}e^{j\theta} + \mathbf{N} \tag{7}$$

where $\mathbf{N}$ is a zero mean, i.i.d., complex, Gaussian noise vector. The parameter vector to be estimated is the modulation sequence $\mathbf{s}$. Let the complete data $\mathbf{x}$ consist of the incomplete data $\mathbf{r}$ along with knowledge of the random phase vector θ, namely, $\mathbf{x} = (\mathbf{r}, \theta)$. Assuming PSK modulation (the case of QAM can also be handled easily), the E step of the algorithm at the ith iteration yields

$$Q(\mathbf{s} \mid \mathbf{s}^i) = \Re\{\mathbf{r}^\dagger \mathbf{s} \cdot (\mathbf{r}^\dagger \mathbf{s}^i)^*\} \tag{8}$$

For the maximization step of the EM algorithm, we distinguish between coded and uncoded transmission. Observe from (8) that in the absence of coding, maximizing $Q(\mathbf{s} \mid \mathbf{s}^i)$ with respect to sequences $\mathbf{s}$ is equivalent to maximizing each individual term in the sum, specifically, making symbol-by-symbol decisions. When trellis coding is used, the maximization over all trellis sequences can be done efficiently using the Viterbi algorithm. Follow-up work on sequence estimation under phase offset can be found in the literature [44–47]. The use of the EM algorithm for phase synchronization in OFDM systems has also been studied [48].

3.6. The Fading Channel

Sequence estimation for fading channels using the EM algorithm was first studied in 1993 [49], with follow-up work a bit later [45,47,50]. Here the authors look at the problem as one of sequence estimation, where the random fading are the unwanted parameters. A brief summary of the EM formulation as presented in the references cited above is given below.

Let $\mathbf{D}$, $\mathbf{s}$, and $\mathbf{N}$ be as defined above and $\mathbf{a}$ be the complex fading process modeled as a zero-mean, Gaussian vector with independent real and imaginary parts having covariance matrix $\mathbf{Q}$. Then the received data $\mathbf{r}$ are

$$\mathbf{r} = \mathbf{D}\mathbf{a} + \mathbf{N} \tag{9}$$

Let the complete data $\mathbf{x}$ be the incomplete data $\mathbf{r}$ along with the random fading vector $\mathbf{a}$: $\mathbf{x} = (\mathbf{r}, \mathbf{a})$. Then, for PSK signaling, the expectation step of the EM algorithm yields

$$Q(\mathbf{s} \mid \mathbf{s}^i) = \Re[\mathbf{r}^\dagger \mathbf{D}\hat{\mathbf{a}}_i] \tag{10}$$

where

$$\hat{\mathbf{a}}_i = E[\mathbf{a} \mid \mathbf{r}, \mathbf{s}^i] = \mathbf{Q}\left[\mathbf{Q} + \frac{\mathbf{I}}{\mathrm{SNR}}\right]^{-1} (\mathbf{D}^i)^* \mathbf{r} \tag{11}$$

When the fading is static over a number of symbols, the expectation step of the algorithm becomes $Q(\mathbf{s} \mid \mathbf{s}^i) = \Re[\mathbf{r}^\dagger \mathbf{s}\hat{a}_i]$, where $\hat{a}_i = \mathbf{r}\mathbf{s}^{i\dagger}$. Again, the maximization step can be done easily and corresponds to symbol-by-symbol detection in the uncoded case, or Viterbi decoding in the trellis-coded case.

Other work on the use of the EM algorithm for sequence estimation in multipath/fading channels can be found in the literature [51–57]. In Refs. 54 and 55 the authors introduce an approximate sequence estimation algorithm motivated by the EM algorithm.

3.7. The Interference Channel

In addition to the multiuser interference channel, a number of papers applying the EM algorithm to sequence estimation in interference and/or to interference

suppression have appeared in the literature more recently. These include Refs. 58–62. An application to sequence estimation [60] is briefly presented below.

Let

$$r(t) = S(t;\mathbf{a}) + J(t) + n(t) \tag{12}$$

be the received data, where $S(t;\mathbf{a})$, $0 \le t < T$, is the transmitted signal (assuming some arbitrary modulation) corresponding to a sequence of M information symbols $\mathbf{a}$. $J(t)$ models the interference, and $n(t)$ is zero-mean, white, Gaussian noise having spectral density $N_0/2$. For generality, we will not specify the form of the signal part, $S(t;\mathbf{a})$, but special cases of interest include direct-sequence spread-spectrum (DSSS) and multicarrier spread-spectrum (MCSS) applications.

Let the complete data be the received data $r(t)$ along with the interference $J(t)$ (which is arbitrary at this point). Application of the EM algorithm yields the following expectation step ($\mathbf{a}^k$ is the sequence estimate at the kth iteration and $\langle\cdot,\cdot\rangle$ denotes inner product):

$$Q(\mathbf{a} \mid \mathbf{a}^k) = \langle r(t) - \hat{J}^k(t), S(t;\mathbf{a})\rangle \tag{13}$$

$$\hat{J}^k(t) = E[J(t) \mid \{r(\tau) : 0 \le \tau \le T\}, \mathbf{a}^k] \tag{14}$$

These expressions are quite general and can be applied to arbitrary interference models, provided the conditional mean estimates (CMEs) in (14) can be computed. For a vector-space interference model

$$J(t) = \sum_{j=1}^{N} g_j \phi_j(t) \tag{15}$$

where $\{\phi_1(t), \phi_2(t), \ldots, \phi_N(t)\}$ is an orthonormal basis set and $g_j, j = 1, 2, \ldots, N$ are zero-mean, uncorrelated random variables having corresponding variances λ_j, we have

$$\hat{J}^k(t) = \sum_{i=1}^{N} \hat{g}_i^k \phi_i(t) \tag{16}$$

where

$$\hat{g}_i^k = \left(1 + \frac{N_0}{2\lambda_i}\right)^{-1} \langle r(t) - S(t;\mathbf{a}^k), \phi_i(t)\rangle$$

4. SOME RESULTS ON APPLICATION OF THE EM ALGORITHM

We present briefly next some more recent results on the use of the EM algorithm in telecommunications.

4.1. Decoding of Spacetime-Coded Systems

The results presented here are a brief summary of those reported in Ref. 63. We consider a mobile radio system where the transmitter is equipped with N transmit antennas and the mobile receiver is equipped with M receive antennas. Data blocks of length L are encoded by a spacetime encoder. After serial-to-parallel conversion, the coded symbol stream is divided into N substreams, each of which is transmitted via one transmit antenna simultaneously. The transmitted code block can be written in matrix form as

$$\mathbf{D} = \begin{pmatrix} d_1^{(1)} & d_2^{(1)} & \ldots & d_N^{(1)} \\ d_1^{(2)} & d_2^{(2)} & \ldots & d_N^{(2)} \\ \vdots & \vdots & \ddots & \vdots \\ d_1^{(L)} & d_2^{(L)} & \ldots & d_N^{(L)} \end{pmatrix} \tag{17}$$

where the superscript in $d_n^{(l)}$ represents time index and the subscript is the space index. In other words, $d_n^{(l)}$ is the complex symbol transmitted by the nth antenna during the lth symbol time. We denote the row vectors of $\mathbf{D}$ by $\mathbf{D}^{(l)}$.

Assuming quasistatic fading (the nonstatic case has been handled as well), let

$$\mathbf{\Gamma}_j = (\,\gamma_{1j} \quad \gamma_{2j} \quad \cdots \quad \gamma_{Nj}\,)^T, j = 1, 2, \ldots, M$$

be the fading vector whose components γ_{ij} are the fading coefficients in the channel connecting the ith transmit antenna to the jth receive antenna, for $i = 1, 2, \ldots, N$. The γ_{ij} are assumed independent. Then the received data at the jth receive antenna are

$$\mathbf{Y}_j = \mathbf{D}\mathbf{\Gamma}_j + \mathcal{N}_j, j = 1, 2, \ldots, M$$

Defining the complete data as $\{\mathbf{Y}_j, \mathbf{\Gamma}_j\}_{j=1}^M$, the E step of the EM algorithm at the kth iteration yields

$$\mathbf{Q}(\mathbf{D} \mid \mathbf{D}^k) = \sum_{l=1}^{L}\sum_{j=1}^{M}\left[\Re(\overline{y_j^{(l)}}\mathbf{D}^{(l)}\hat{\mathbf{\Gamma}}_j^k) - \frac{1}{2}\mathbf{D}^{(l)}(\hat{\mathbf{\Omega}}_j)^k(\mathbf{D}^{(l)})^*\right] \tag{18}$$

$$\hat{\mathbf{\Gamma}}_j^k = \left((\mathbf{D}^k)^*\mathbf{D}^k + \frac{\mathbf{I}}{\mathrm{SNR}}\right)^{-1}(\mathbf{D}^k)^*\mathbf{Y}_j \tag{19}$$

$$\hat{\mathbf{\Omega}}_j^k = \mathbf{I} - \left((\mathbf{D}^k)^*\mathbf{D}^k + \frac{\mathbf{I}}{\mathrm{SNR}}\right)^{-1}(\mathbf{D}^k)^*\mathbf{D}^k + \hat{\mathbf{\Gamma}}_j^k(\hat{\mathbf{\Gamma}}_j^k)^* \tag{20}$$

and the M step

$$\mathbf{D}^{k+1} = \arg\max_{\mathbf{D}} \sum_{l=1}^{L}\sum_{j=1}^{M}\left[\Re(\overline{y_j^{(l)}}\mathbf{D}^{(l)}\hat{\mathbf{\Gamma}}_j^k) - \frac{1}{2}\mathbf{D}^{(l)}\hat{\mathbf{\Omega}}_j^k(\mathbf{D}^{(l)})^*\right] \tag{21}$$

For the spacetime codes designed in Ref. 64, the Viterbi algorithm can be used to efficiently perform the required maximization. Simulation results are shown in Fig. 1 for the 8-state code over QPSK introduced in Ref. 64.

Other work using the EM algorithm in the spacetime area can be found in Ref. 65. This paper uses again Feder and Weistein's results [9] in a multitransmit antenna, multipath environment in conjunction with orthogonal frequency-division multiplexing (OFDM).

4.2. SNR Estimation

Estimation of the SNR and the received signal energy is an important function in digital communications. We present

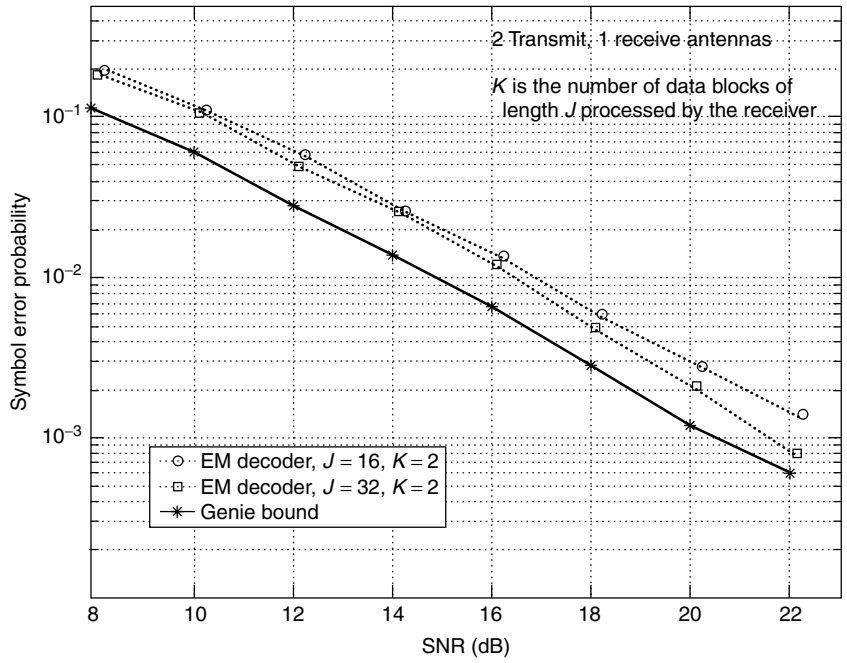

Figure 1. Symbol error probability of the "genie" and EM-based decoders as a function of block length: $N = 2$, $M = 1$, 8-state space-time code, quasistatic fading.

here an application of the EM algorithm to this problem. This is a summary of results from Ref. 66.

Let the received data be

$$r_k = \sqrt{E}d_k + \sqrt{v}n_k, k = 1, 2, \ldots, N$$

where E is the received signal energy; v is the additive noise variance; the n_k are zero-mean, unit-variance, i.i.d. Gaussian; and the d_k are binary modulation symbols (the more general case is handled as well) with $d_k \in \{1, -1\}$. We are interested in estimating the vector $\boldsymbol{\theta} = (E, v)$ from the received (incomplete) data vector $\mathbf{r}$ using the EM algorithm. Let the complete data be $\mathbf{x} = (\mathbf{r}, \mathbf{d})$. Then the E step of the EM algorithm yields

$$Q(\boldsymbol{\theta} \mid \boldsymbol{\theta}^i) = -N\ln(v) - \frac{1}{v}\sum_{k=1}^{N} r_k^2 - \frac{N \cdot E}{v} + \frac{2\sqrt{E}}{v} \cdot \sum_{k=1}^{N} r_k \hat{d}_k^i \tag{22}$$

where

$$\hat{d}_k^i = E\left[d_k \mid \mathbf{r}, \boldsymbol{\theta}^i\right] = \tanh\left(\frac{\sqrt{E^i}}{v^i} r_k\right) \tag{23}$$

Taking derivatives w.r.t. (with respect to) E and v, the M step of the EM algorithm yields the following recursions:

$$\hat{E}^{i+1} = \left(\frac{B^i}{N}\right)^2 \tag{24}$$

$$\hat{v}^{i+1} = \frac{A}{N} - \hat{E}^{i+1} \tag{25}$$

$$\hat{\mathrm{SNR}}^{i+1} = \frac{\hat{E}^{i+1}}{\hat{v}^{i+1}} \tag{26}$$

where

$$A = \sum_{k=1}^{N} r_k^2 \tag{27}$$

$$B^i = \sum_{k=1}^{N} r_k \tanh\left(\frac{\sqrt{E^i}}{v^i} r_k\right) \tag{28}$$

Figure 2 shows results on the bias and mean-square error in estimating the SNR and the received signal energy for the EM algorithm and a popular high-SNR approximation to the ML estimator (the true ML estimator is much too complex to implement).

4.3. On the (Non) Convergence of the EM Algorithm for Discrete Parameters

For continuous parameter estimation, under continuity and weak regularity conditions, stationary points of the EM algorithm have to be stationary points of the loglikelihood function [e.g., 11]. On the other hand, any fixed point can be a convergence point of the discrete EM algorithm even though the likelihood of such a point can be lower than the likelihood of a neighboring discrete point. In this subsection we summarize some results on the (non)convergence of the discrete EM algorithm presented in Ref. 67.

Let $\mathbf{a}$ be a M-dimensional discrete parameter with values in $\mathcal{A}$. It is assumed that, along with the discrete EM algorithm, a companion continuous EM algorithm

$$\mathbf{a}_c^{k+1} = \arg\max_{\mathbf{a} \in \mathcal{C}^{\mathbf{M}}} Q(\mathbf{a} \mid \mathbf{a}^k) \tag{29}$$

where $\mathcal{C}^M$ is the M-dimensional complex space, is well defined. The companion continuous EM mapping is the map $\mathbf{M}_c : \mathbf{a}^k \to \mathbf{a}_c^{k+1}$, for $\mathbf{a}_c^{k+1} \in \mathcal{C}^M$. The Jacobian of the continuous EM mapping $\mathbf{M}_c(\mathbf{a})$ is denoted with $\mathbf{J}_c(\mathbf{a})$, and the Hessian of its corresponding objective function $Q(\mathbf{a} \mid \mathbf{a}^k)$ is denoted with $\mathbf{H}^Q(\mathbf{a})$.

Computationally "inexpensive" maximization of the objective function $Q(\mathbf{a} \mid \mathbf{a}^k)$ over $\mathcal{A}$ can be obtained for

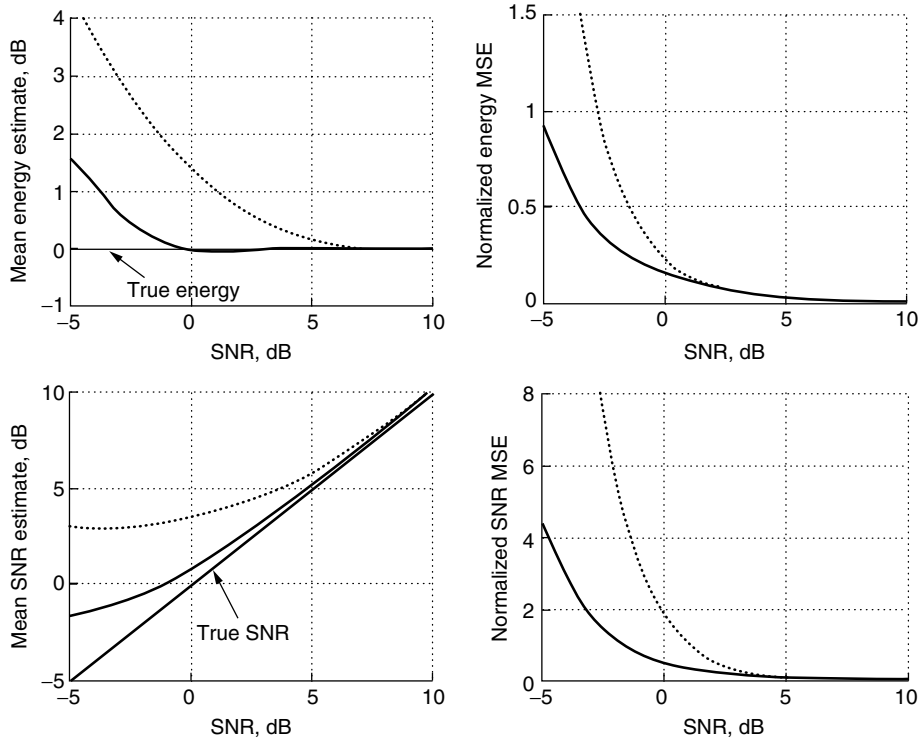

Figure 2. Comparison between the EM and high SNR ML approximation (dashed lines) for sequence length $N = 50$.

some special structures. The particular case of interest is the quadratic form

$$Q(\mathbf{a} \mid \mathbf{a}^k) = -\tfrac{1}{2}\|\mathbf{a} - \mathbf{a}_c^{k+1}\|^2 \tag{30}$$

for which the discrete maximization in the *M step* can be obtained on a parameter-by-parameter basis. Equation (30) implies that $\mathbf{a}^{k+1}$ is the discrete point closest to the continuous maximizer of $Q(\mathbf{a} \mid \mathbf{a}^k)$ over $\mathcal{C}^M$, $\mathbf{a}_c^{k+1}$. Note that $\mathbf{a}_c^{k+1}$ is (implicitly) a function of the previous iterate $\mathbf{a}^k$. As a special case of (30), $\mathbf{a}^{k+1} = \text{sign}[\mathbf{a}_c^{k+1}]$ for QPSK signaling, namely, for $a_{d,i} \triangleq [\mathbf{a}]_i \in \{\pm 1 \pm j\}$. Clearly, not only is the objective function (30) quadratic but, additionally, its Hessian is $\mathbf{H}^Q(\mathbf{a}) = -\mathbf{I}$. It is important to note that (30) holds for all the sequence estimation problems described in this overview [see Refs. 8, 10, and 13 for a linear modulation $S(t; \mathbf{a})$] except for (18), where the objective function is quadratic in the unknown symbol sequence $\{d_j^{(l)}\}$ but the Hessian is not $-\mathbf{I}$ in the general case. The arguments given below can easily be generalized for a nonidentity Hessian matrix.

Let $d_{\min}$ denote half the minimum Euclidean distance between any two discrete points from $\mathcal{A}$:

$$d_{\min} = \tfrac{1}{2} \min_{\mathbf{a}_1, \mathbf{a}_2 \in \mathcal{A}} \|\mathbf{a}_1 - \mathbf{a}_2\|. \tag{31}$$

$d_{\min} = 1$ for uncoded binary antipodal signaling. Let $\hat{\mathbf{a}}_c$ be a fixed point of the companion continuous EM algorithm (29). One of the authors [67] has been shown, based on the first two terms of the Taylor expansion of $\mathbf{M}_c(\mathbf{a})$ in a neighborhood $U(\hat{\mathbf{a}}_c)$ of $\hat{\mathbf{a}}_c$, that all $\mathbf{a} \in \mathcal{A} \cap U(\hat{\mathbf{a}}_c)$ such that

$$\|\hat{\mathbf{a}}_c - \mathbf{a}\| < \frac{d_{\min}}{1 - \hat{\lambda}_{\min}} \tag{32}$$

where $\hat{\lambda}_{\min} \triangleq \lambda_{\min}[\mathbf{J}_c(\hat{\mathbf{a}}_c)]$ is the minimum eigenvalue of the Jacobian matrix $\mathbf{J}_c(\hat{\mathbf{a}}_c)$, are stationary points of the discrete EM algorithm. Inequality (32) follows from the fact that the eigenvalues of $\mathbf{J}_c(\hat{\mathbf{a}}_c)$ are nonnegative and smaller than one (see lemma in Ref. 2). It defines a ball of radius $r^{nc} = d_{\min}/(1 - \hat{\lambda}_{\min})$ centered at a fixed point of the companion continuous EM algorithm $\hat{\mathbf{a}}_c$.

Parameter $\hat{\lambda}_{\min}$ is, in the general case, a function of the received signal. As shown by Meng and Rubin [3] (see also Ref. 11), $\mathbf{J}_c(\hat{\mathbf{a}}_c)$ and, consequently, its eigenvalues can be estimated in a reliable manner using a continuous EM algorithm. Furthermore, when the complete data of the EM algorithm are chosen in such a way that $\mathbf{H}^Q(\hat{\mathbf{a}}_c) = -\mathbf{I}$ as in (30), then matrices $\mathbf{J}_c(\hat{\mathbf{a}}_c)$ and the Hessian of the loglikelihood function, $\mathbf{H}^l(\hat{\mathbf{a}}_c)$, have the same eigenvectors. Their eigenvalues have the following relationship: $1 - \lambda_i[\mathbf{J}_c(\hat{\mathbf{a}}_c)] = \lambda_i[-\mathbf{H}^l(\hat{\mathbf{a}}_c)]$, for all i. Thus

$$r^{nc} = \frac{d_{\min}}{\lambda_{\max}[-\mathbf{H}^l(\hat{\mathbf{a}}_c)]}$$

The term $(1 - \hat{\lambda}_{\min})$ is the largest eigenvalue of the matrix $\mathbf{I} - \mathbf{J}_c(\hat{\mathbf{a}}_c)$, often referred to as the *iteration matrix* in the optimization literature [e.g., 11], since it determines the convergence iteration steps in the neighborhood $U(\hat{\mathbf{a}}_c)$. Its smallest eigenvalue is a typical measure of convergence speed of the continuous EM algorithm since it measures the convergence step along the slowest direction. Its largest eigenvalue determines the convergence step along the fastest direction. Thus, we can say that the nonconvergence radius is determined by (it is in fact inversely proportional to) the largest convergence step of the companion continuous EM algorithm.

An important implication of (32) is that $\hat{\lambda}_{\min} = 0$ is sufficient for the nonconvergence ball to hold at most one discrete stationary point. Sequence estimation, in the presence of interference when $\hat{\lambda}_{\min} = 0$ or when this identity can be forced using rank-reduction principles, has been analyzed in Ref. 67 and in part in Ref. 70, and is presented briefly next.

In the following, the received signal model given in (12) with a linear modulation

$$S(t;\mathbf{a}) = \sum_{m=0}^{M-1} a_n h(t - mT) \tag{33}$$

where pulses $\{h(t - mT), m \in [0, M-1]\}$ are orthonormal, is assumed.

For this problem, a reduced nonconvergence ball radius has been derived [67] without having to resort to the Taylor expansion of $\mathbf{M}_c(\mathbf{a})$. The reduced nonconvergence radius is a function of only $d_{\min}$ and the statistics of noise and interference. In the special case when $N = M$ and $\text{span}\{h(t - nT), n \in [0, N-1]\} = \text{span}\{\phi_n(t), n \in [0, N-1]\}$, where $\phi_n(t)$ are defined in (15), the reduced radius and r^{nc} are equal. Both are

$$r^{nc} = \left[1 + \frac{\tilde{\lambda}_{\min}}{N_0}\right] d_{\min} \tag{34}$$

where $\tilde{\lambda}_{\min} = \min_j\{\lambda_j\}$; λ_j is the variance of the coefficient g_j in (15). For example, let's assume $M = N = 2$, interference energy $J = \lambda_1 + \lambda_2 = 2\lambda_1 = 2\tilde{\lambda}_{\min}$, binary antipodal signaling with $d_{\min} = 1$, and noise and signal realizations such that $\hat{\mathbf{a}}_c \approx \mathbf{0}$ (see Ref. 67 for details). Then, if $J/N_0 > 2\sqrt{2} - 2$ all possible discrete points in $\mathcal{A}$ will be found inside the convergence ball whose radius is given by (34). Consequently, the discrete EM algorithm will generate a sequence of identical estimates $\mathbf{a}^k = \mathbf{a}^0$ for any k and any initial point $\mathbf{a}^0 \in \mathcal{A}$.

Next, we provide symbol error rate results for a binary communications example where $N > M$ and $\text{span}\{h(t - mT),\ m \in [0, M-1]\} \subset \text{span}\{\phi_n(t),\ n \in [0, N-1]\}$ holds. Figure 3 demonstrates that, in the case of an interference process whose full spectrum covers the spectrum of the useful signal, one could significantly increase the convergence probability of the EM algorithm using a rank-reduction approach. Two second-order Gaussian processes uniformly positioned in frequency within the signal spectra are used to model interference using $N > M$ eigenfunctions. The EM algorithm obtained by modeling the interference with $P < M < N$ largest eigenfunctions $\phi_n(t)$, and thus forcing $\hat{\lambda}_{\min} = 0$ in (32), is compared to the performance of the EM algorithm that uses the full-rank model. It can be observed that the reduced-rank EM algorithm has little degradation, whereas the full-rank EM algorithm does not converge and has a catastrophic performance for large SNR.

4.4. Detection in Fading Channels with Highly Correlated Multipath Components

Here we study another example where the convergence of the discrete EM algorithm can be stymied by a large nonconvergence ball.

We assume a continuous-time L-path Rayleigh fading channel model:

$$\begin{aligned} r_1(t) &= \sum_{k=1}^{K}\sum_{l=1}^{L} \alpha_{l,k,1} S(t - \tau_{l,k,1}; \mathbf{a}_k) + n_1(t) \\ &\vdots \\ r_{N_a}(t) &= \sum_{k=1}^{K}\sum_{l=1}^{L} \alpha_{l,k,N_a} S(t - \tau_{l,k,N_a}; \mathbf{a}_k) + n_{N_a}(t) \end{aligned} \tag{35}$$

Here N_a is the number of receive antennas and K is the number of users; $\mathbf{a}_k$ is the vector of N symbols of

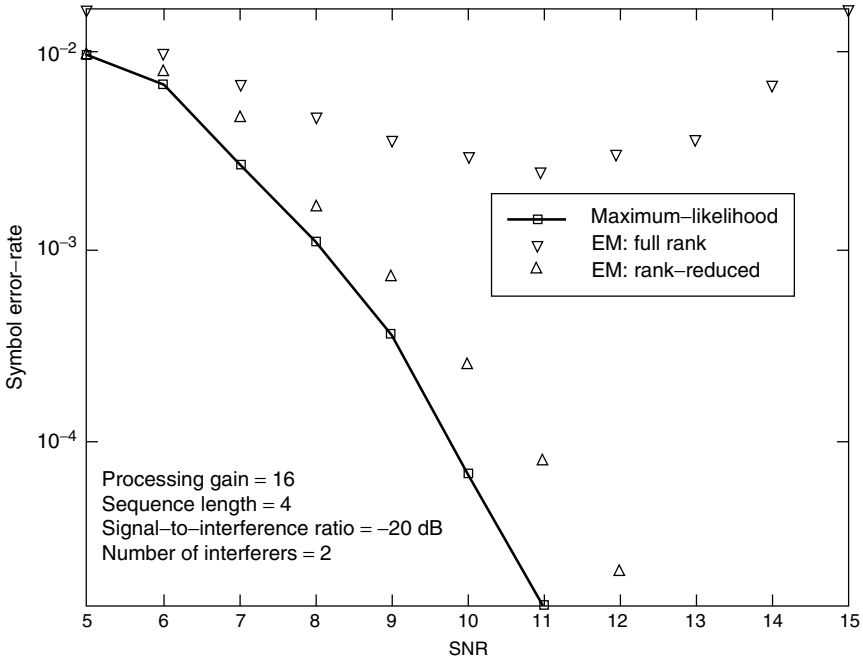

Figure 3. Comparison of ML, reduced-rank EM, and full-rank EM receivers for two second-order Gaussian interferers.

user k; $\alpha_{l,k,i}$ are zero-mean, complex circular Gaussian random variables of respective variances $\gamma_{l,k,i}$ and $\tau_{l,k,i}$ are (assumed known) path delays. We group the fading coefficients, $\alpha_{l,k,i}$, for each i into a vector $\boldsymbol{\alpha}_i$ such that $\alpha_{l,k,i} = [\boldsymbol{\alpha}_i]_{l+L\cdot(k-1)}$ is the $l + L\cdot(k-1)$th element of the vector $\boldsymbol{\alpha}_i$. The covariance matrix of $\boldsymbol{\alpha}_i$ is $\boldsymbol{\Gamma}_i$. P_s of the transmitted symbols are assumed to be known pilot symbols that allow for ambiguity resolution (67). The signal is assumed to have the following form:

$$S(t;\mathbf{a}_k) = \sum_{n=1}^{N} a_{n,k} h(t - nT)$$

where $h(t)$ is the known signaling pulse (assumed common for simplicity) modulated by the transmitted symbol sequence $\mathbf{a}$ of length N. Pulses $h(t - iT)$ are typically orthogonal to avoid ISI for frequency nonselective channels. The vector of time-delayed modulated signals is $\mathbf{s}_i(t;\mathbf{a}) = [S(t-\tau_{1,1,i};\mathbf{a}_1), S(t-\tau_{2,1,i};\mathbf{a}_1), \ldots, S(t-\tau_{L,K,i};\mathbf{a}_K)]^T$, where $\mathbf{a}$ is a NK-dimensional vector of user symbols such that its subvector of length K $[\mathbf{a}]_{(k-1)\cdot N+1}^{k\cdot N}$ is the vector of N symbols of user k.

For simplicity the receiver antennas are assumed to be sufficiently separated so that any $\boldsymbol{\alpha}_i$ and $\boldsymbol{\alpha}_j$ for $i \neq j$ are independent. $\mathbf{G}_i(\mathbf{a}) = \langle \mathbf{s}_i(t;\mathbf{a}), \mathbf{s}_i^H(t;\mathbf{a})\rangle$ is the Gramian of $\mathbf{s}_i(t;\mathbf{a})$ in the L_2 space.

An EM solution is nontrivially based on the EM solution for superimposed signals introduced by Feder and Weinstein described in Section 3.1 (see, also Refs. 53 and 69). The complete data vector includes not only the path plus noise components but also the fading vectors $\boldsymbol{\alpha}_i$, as

$$(\mathbf{x}, \boldsymbol{\alpha}) \triangleq ([\mathbf{x}_1, \ldots, \mathbf{x}_{N_A}], \boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_{N_a}) \tag{36}$$

$$\triangleq (\{x_{1,1,1}(t), \ldots, x_{L,K,N_a}(t), \quad t \in [T_i, \ldots, T_f]\}, \boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_{N_a}) \tag{37}$$

where $x_{l,k,i}(t) \triangleq \alpha_{l,k,i} S(t - \tau_{l,k,i};\mathbf{a}_k) + n_{l,k,i}(t)\cdot n_{l,k,i}(t)$ is a complex zero-mean AWGN process with variance $\beta_{l,k}N_0$ such that $E\{n_{l,k,i}(t) n^*_{j,m,i}(t)\} = 0$ for all $l \neq j$ and $k \neq m$ and $n_i(t) = \sum_{l=1}^{L}\sum_{k=1}^{K} n_{l,k,i}(t)$. Clearly, $\beta_{l,k}$ has to satisfy the constraint $\sum_{l=1}^{L}\sum_{k=1}^{K}\beta_{l,k} = 1$. In the following, $\beta_{l,k} \equiv 1/(KL)$.

The terms $x_{l,k,i}(t)$ are mutually independent given the data sequence $\mathbf{a}$ and the fading vectors $\boldsymbol{\alpha}_i$, and the EM objective function, in the case of orthogonal signaling, can be represented in the following manner:

$$Q(\mathbf{a} \mid \mathbf{a}^m) = \sum_{k=1}^{K}\sum_{n=1}^{N}\left[\Re\left\{a_{n,k}\sum_{i=1}^{N_a}\sum_{l=1}^{L}\beta_{l,k}\hat{z}_{l,n,k,i}(\mathbf{a}^m)\right\} - \frac{1}{2}|a_{n,k}|^2\sum_{i=1}^{N_a}\sum_{l=1}^{L}\beta_{l,k}\hat{\rho}_{ll,kk,i}(\mathbf{a}^m)\right] \tag{38}$$

Here $\hat{z}_{l,n,k,i}(\mathbf{a}^m) = \langle \hat{\chi}_{l,k,i}(t;\mathbf{a}^m), h(t - \tau_{l,k,i} - nT)\rangle$ is the sampled pulse-matched filter response to signal path component estimates $\hat{\chi}_{l,k,i}(t;\mathbf{a}^m)$.

The E step requires estimation of the phase and amplitude compensated signal path components

$$\hat{\chi}_{l,k,i}(t;\mathbf{a}^m) = E\{\alpha^*_{l,k,i}x_{l,k,i}(t) \mid \{r_i(t); t \in [T_i, \ldots, T_f]\}, \mathbf{a}^m\}$$
$$= \hat{\rho}_{ll,kk,i}(\mathbf{a}^m)S(t - \tau_{l,k,i};\mathbf{a}^m) + \beta_{l,k}\left[\hat{\alpha}^*_{l,k,i}(\mathbf{a}^m)r_i(t) - \sum_{q=1}^{K}\sum_{j=1}^{L}\hat{\rho}_{lj,kq,i}(\mathbf{a}^m)S(t - \tau_{j,q,i};\mathbf{a}^m)\right]$$

Signal path components are estimated by successive refinement. The refinement attempts to find those component estimates that explain the received signal with a smallest measurement error. $\hat{\alpha}_{l,k,i}(\mathbf{a}^m)$ and $\hat{\rho}_{lj,kq,i}(\mathbf{a}^m)$ are, respectively, the conditional mean estimates of the complex coefficients

$$\hat{\alpha}_{l,k,i}(\mathbf{a}^m) = E\{\alpha_{l,k,i} \mid \{r_i(t); t \in [T_i, \ldots, T_f]\}, \mathbf{a}^m\}$$
$$= [(N_0\boldsymbol{\Gamma}_i^{-1} + \mathbf{G}_i(\mathbf{a}^m))^{-1}\langle \mathbf{s}_i(t;\mathbf{a}^m), r_i^H(t)\rangle]_l$$

and their cross-correlations

$$\hat{\rho}_{lj,kq,i}(\mathbf{a}^m) = E\{\alpha^*_{l,k,i}\alpha_{j,q,i} \mid \{r_i(t); t \in [T_i, \ldots, T_f]\}, \mathbf{a}^m\}$$
$$= \left[\left(\boldsymbol{\Gamma}_i^{-1} + \frac{\mathbf{G}_i(\mathbf{a}^m)}{N_0}\right)^{-1} + \hat{\boldsymbol{\alpha}}_i(\mathbf{a}^m)\hat{\boldsymbol{\alpha}}_i^H(\mathbf{a}^m)\right]_{l+(k-1)L, j+(q-1)L} \tag{39}$$

The M step of the companion continuous EM algorithm can be expressed in closed form as

$$\hat{a}^{m+1}_{cu,n,k} = \frac{\sum_{i=1}^{N_a}\sum_{l=1}^{L}\beta_{l,k}\hat{z}_{l,n,k,i}(\mathbf{a}^m)}{\sum_{i=1}^{N_a}\sum_{l=1}^{L}\beta_{l,k}\hat{\rho}_{ll,kk,i}(\mathbf{a}^m)}, (n,k) \in \overline{\mathcal{J}}_{ps}$$
$$\hat{a}^{m+1}_{cu,n,k} = a^k_n, (n,k) \in \mathcal{J}_{ps} \tag{40}$$

where $\mathcal{J}_{ps}$ are index pairs corresponding to pilot symbols and

$$\overline{\mathcal{J}}_{ps} = \{(1,1), \ldots, (K,N)\}\backslash\mathcal{J}_{ps}$$

It combines in an optimal manner the phase/amplitude-compensated signal path components estimated in the E step. In this way, it achieves multipath diversity combining.

The M step of the (discrete) EM algorithm requires quantization, for example, taking the sign of the components of $\mathbf{a}^{m+1}_{cu}$, in case of binary signaling.

The number of fixed points (and, consequently, convergence to the ML estimate) of the discrete EM algorithm is a function of the path Gramian matrices $\mathbf{G}_i(\mathbf{a})$ whose structure defines the size of the nonconvergence ball. For highly correlated paths the nonconvergence ball will be so large that we need to use other detection methods.

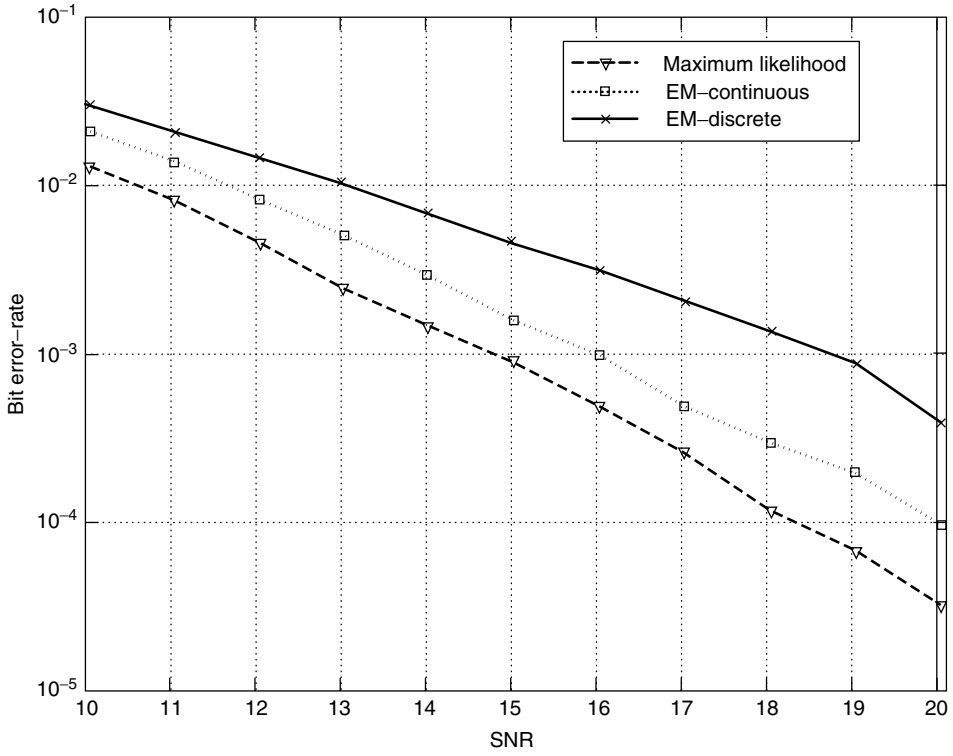

Figure 4. Performance comparison for highly correlated path components.

An alternative approach to detection termed *generalized decorrelator* (see, e.g., Refs. 18, 53, 68, and 69) allows the continuous EM algorithm to converge and quantizes the continuous maximizer. For uncoded BPSK signaling we have

$$\hat{\mathbf{a}}_c = \text{sign}[\mathbf{a}_c^{\infty}]$$

In the following example, the delays are $\tau_l/T \in \{0, \frac{1}{3}, \frac{4}{3}\}$. The number of antennas is 1, processing gain is equal to 3, the sequence length is 6 and the pilot symbol block length is 3. The paths are fading independently and their variance is $1/L$. The last two signal path components are highly correlated because of their integer symbol delay. Cross-correlation to the first component is also high as a result of the small processing gain. This particular case is detrimental to receivers that are based on the decorrelation between signal path components. The generalized decorrelator (continuous EM algorithm), as can be seen in Fig. 4, achieves a performance within 1.5–2 dB of the optimal. It manages diversity combining even for this particularly difficult situation. On the other hand, the discrete EM algorithm has a loss of 1–3 dB relative to the continuous EM detector.

5. CONCLUSION

We have provided a short overview of the use of the EM algorithm in telecommunications. Clearly, the EM algorithm has established itself as a generic tool in the design of telecommunication systems. If current work using it in various problems is any indication, the algorithm will get even more attention in the future.

BIOGRAPHIES

Costas N. Georghiades received his B.E. degree, with distinction, from the American University of Beirut in 1980, and his M.S. and D.Sc. degrees from Washington University in 1983 and 1985, respectively, all in electrical engineering. Since 1985, he has been with the Electrical Engineering Department at Texas A&M University, where he is a professor and holder of the J.W. Runyon, Jr. Endowed Professorship. He currently serves as director of the Telecommunications and Signal Processing Group in the department. Over the years he served in editorial positions with the *IEEE Transactions on Communications*, the *IEEE Transactions on Information Theory*, the *IEEE Journal on Selected Areas in Communications* and the *IEEE Communications Letters*. Dr. Georghiades is a fellow of the IEEE. His general interests are in the application of information and estimation theories to the study of communication systems, with particular interest in optimum receiver design, wireless communication, and optical systems.

Predrag Spasojevic received the Diploma of Engineering degree from the School of Electrical Engineering, University of Sarajevo, in 1990; and his M.S. and Ph.D. degrees in electrical engineering from Texas A&M University, College Station, Texas, in 1992 and 1999, respectively. From 2000 to 2001 he has been with WINLAB, Rutgers University, where he is currently an assistant professor in the Department of Electrical & Computer Engineering. His research interests are in the general areas of communication theory and signal processing.

FADING CHANNELS

ALEXANDRA DUEL-HALLEN
North Carolina State University
Raleigh, North Carolina

1. INTRODUCTION

Radio communication channels include shortwave ionospheric radiocommunication in the 3–30-MHz frequency band (HF), tropospheric scatter (beyond-the-horizon) radio communications in the 300–3000 MHz frequency band (UHF) and 3000–30,000-MHz frequency band (SHF), and ionospheric forward scatter in the 30–300-MHz frequency band (VHF) [1,2]. These channels usually exhibit *multipath propagation* that results from *reflection, diffraction* and *scattering* of the transmitted signal. Multipath propagation and *Doppler effects* due to the motion of the transmitter and/or receiver give rise to *multipath fading* channel characterization. The fading signal is characterized in terms of *large-scale* and *small-scale* fading.

The large-scale fading model describes the average received signal power as a function of the distance between the transmitter and the receiver. Statistical variation around this mean (on the order of 6–10 dB) resulting from *shadowing* of the signal due to large obstructions is also included in the model of large-scale fading. Large-scale fading describes the variation of the received power over large areas and is useful in estimating radio coverage of the transmitter. The large scale fading model is determined by averaging the received power over many wavelengths (e.g., 1–10 m for cellular and PCS frequencies of 1–2 GHz) [3].

The small-scale fading model describes the instantaneous variation of the received power over a few wavelengths. This variation can result in dramatic loss of power on the order of 40 dB. It is due to superposition of several reflected or scattered components coming from different directions. Figure 1 depicts small-scale fading and slower large-scale fading for a mobile radiocommunication system. The figure illustrates that small-scale variation is averaged out in the large-scale fading model.

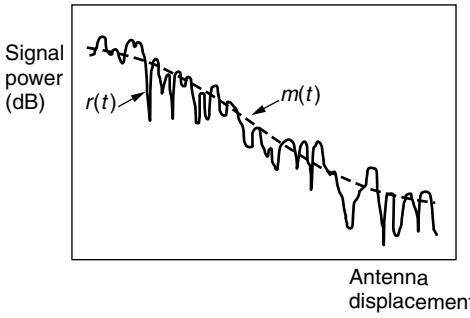

Figure 1. Large- and small-scale fading (reprinted from Ref. 2 © IEEE).

In Section 2, we review the large-scale fading models. Sections 3–5 describe small-scale fading. Multipath fading channels are characterized in Section 3. Section 4 describes useful fading models. Performance analysis for flat fading channels and diversity combining approaches are described in Section 5.

2. LARGE-SCALE FADING

Propagation path loss $L_s(d)$ is defined as the ratio of the transmitted power to the received power in a radiofrequency (RF) channel. In a free-space model, the propagation path loss is proportional to d^2, where d is the distance between the transmitter and the receiver. When the receiving antenna is isotropic, this loss is given by [2]

$$L_s(d) = \left(\frac{4\pi d}{\lambda}\right)^2 \tag{1}$$

where λ is the wavelength of the RF signal. In the mobile radio channel, the average path loss is usually more severe due to obstructions and is inversely proportional to d^n, where $2 \le n \le 6$. The average path loss is given by [2,3]

$$L_{\text{av}}(d)\ (\text{dB}) = L_s(d_0) + 10n \log_{10} \frac{d}{d_0} \tag{2}$$

where d_0 is the close-in reference distance. This distance corresponds to a point located in the far field of the antenna. For large cells, it is usually assumed to be 1 km, whereas for smaller cells and indoor environments, the values of 100 m and 1 m, respectively, are used. The value of the exponent n depends on the frequency, antenna heights, and propagation conditions. For example, in urban area cellular radio, n takes on values from 2.7 to 3.5; in building line-of-sight conditions, $1.6 \le n \le 1.8$; whereas in obstructed in building environments, $n = 4$–6 [3].

The actual path loss in a particular location can deviate significantly from its average value (2) due to *shadowing* of the signal by large obstructions. Measurements show that this variation is approximately *lognormally* distributed. Thus, the path loss is represented by the random variable

$$L_p(d)\ (\text{dB}) = L_{\text{av}}(d)\ (\text{dB}) + X_\sigma \tag{3}$$

where X_σ has Gaussian distribution (when expressed in decibels) with mean zero and standard deviation σ (also in decibels). Note that average path loss (2) corresponds to a straight line with slope $10n$ (dB) per decade when plotted on log–log scale. Thus, in practice, the values of n and σ are determined using linear regression to minimize the difference between the actual measurements (over various locations and distances between the transmitter and receiver) and the estimated average path loss in the mean-squared-error (MSE) sense. Figure 2 illustrates the actual measured data and the estimated average path loss for several transmitter-receiver separation values.

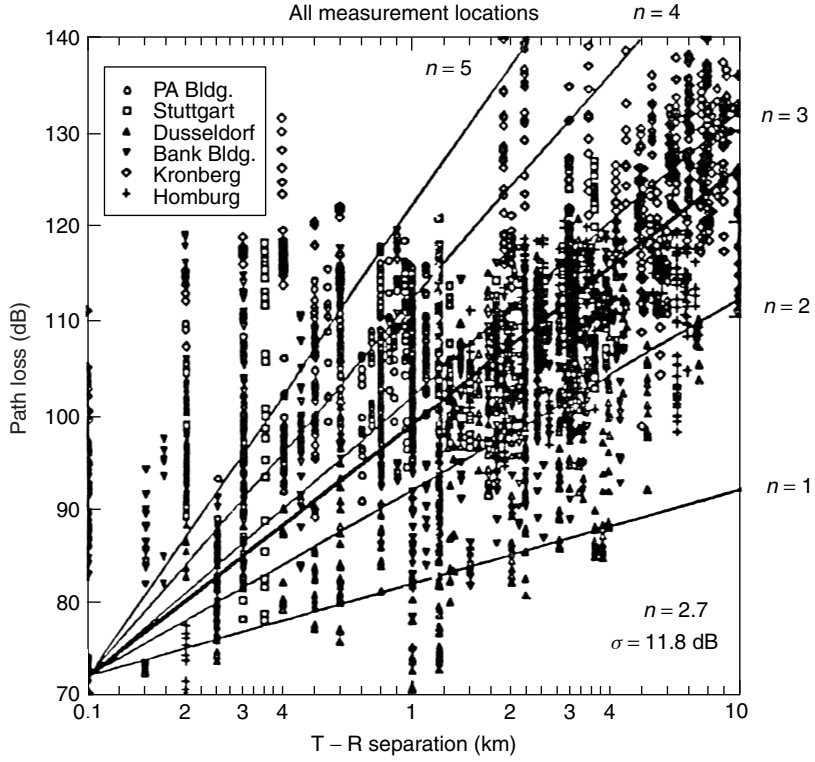

Figure 2. Scatterplot of measured data and corresponding MMSE path loss model for many cities in Germany. For these data, $n = 2.7$ and $\sigma = 11.8$ dB (reprinted from Ref. 15, © IEEE).

References 1–7 describe appropriate models and approaches to measurement and estimation of propagation path loss for various wireless channels and provide additional useful references on this subject. The rest of this article is devoted to characterization, modeling, and performance analysis of small-scale fading.

3. CHARACTERIZATION OF FADING MULTIPATH CHANNELS

A signal transmitted through a wireless channel arrives at its destination along a number of different paths (referred to as *multipath propagation*) as illustrated in Fig. 3. Multipath causes interference between *reflected or scattered* transmitter signal components. As the receiver moves through this *interference pattern*, a typical fading signal results as illustrated in Fig. 4. If an unmodulated carrier at the frequency f_c is transmitted over a fading channel, the complex envelope (the *equivalent lowpass signal*) [1] of the received fading signal is given by

$$c(t) = \sum_{n=1}^{N} A_n e^{j(2\pi f_n t + 2\pi f_c \tau_n + \phi_n)} \tag{4}$$

where N is the number of scatterers, and for the nth scatterer, A_n is the *amplitude*, f_n is the *Doppler frequency shift*, τ_n is the *excess propagation delay* (relative to the arrival of the first path), and ϕ_n is the phase. The *Doppler frequency shift* is given by [3]

$$f_n = f_c \frac{v}{c} \cos\theta = f_{dm} \cos\theta \tag{5}$$

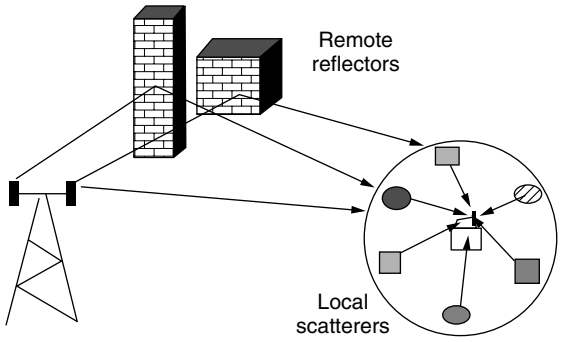

Figure 3. Typical mobile radio environment.

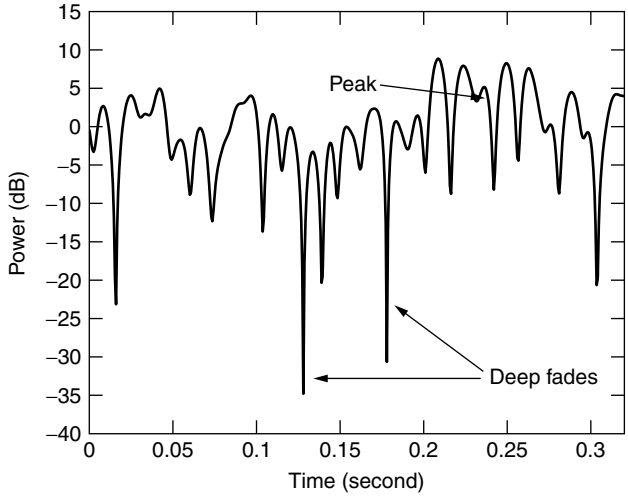

Figure 4. A typical fading signal (provided by Ericsson Inc.).

where v is the vehicle speed (assumed constant), c is the speed of light, θ is the incident radiowave angle with respect to the motion of the mobile, and f_{dm} is the *maximum Doppler frequency shift*.

The parameters A_n, f_n, τ_n, and ϕ_n are very *slowly time-variant,* and can be viewed as fixed on the timescale of a few milliseconds. Thus, the signal in (4) is a superposition of complex sinusoids with approximately constant amplitudes, frequencies, and phases, and varies in time as the mobile moves through the interference pattern. The superposition of terms in (4) can result in destructive or constructive interference, causing deep fades or peaks in the received signal, respectively, as illustrated in Fig. 4. The power of the fading signal can change dramatically, by as much as 30–40 dB. This variation can be conveniently modeled by characterizing $c(t)$ as a *stationary random process*. This statistical characterization is useful for describing time dispersion and fading rapidity of multipath fading channels [1–9].

3.1. Statistical Characterization

If we assume that the complex envelope of the transmitted signal is $s_l(t)$, the equivalent baseband signal received at the output of the fading channel is

$$r(t) = \int_{-\infty}^{\infty} c(\tau, t) s_l(t - \tau)\, d\tau \tag{6}$$

where the time-variant impulse response $c(\tau, t)$ is the response of the channel at time t to the impulse applied at time $t - \tau$ [1]. (In practice, additive Gaussian noise is also present at the output of the channel.) Expression (6) can be viewed as the superposition of delayed and attenuated copies of the transmitted signal $s_l(t)$, where the delays are given by τ_n and the corresponding complex gains have amplitudes A_n [see (4)] and time-variant phases [determined from the phase terms in (4)].

For each delay τ, the response $c(\tau, t)$ is modeled as a *wide-sense stationary* stochastic process. Typically, the random processes $c(\tau_1, t)$ and $c(\tau_2, t)$ are uncorrelated for $\tau_1 \neq \tau_2$ since different multipath components contribute to these signals (this is called *uncorrelated scattering*). For fixed delay τ, the autocorrelation function of the impulse response is defined as [1]

$$\phi_c(\tau; \Delta t) = \tfrac{1}{2} E[c^*(\tau, t) c(\tau, t + \Delta t)] \tag{7}$$

The power of $c(\tau, t)$ as a function of the delay τ is

$$\phi_c(\tau; 0) \equiv \phi_c(\tau) \tag{8}$$

This is called *multipath intensity profile* or *power delay profile* and is determined from measurements [1,3]. A "worst case" multipath intensity profile for an urban channel is shown in Fig. 5. The range of values of τ where $\phi_c(\tau)$ is nonnegligible is called the *multipath spread* of the channel and denoted as T_m. The values of multipath spread vary greatly depending on the terrain. For urban and suburban areas, typical values of multipath spread are from 1 to 10 μs, whereas in rural mountainous area, the multipath spreads are much greater with values from 10 to 30 μs [1]. The *mean excess delay* and *RMS delay spread* σ_τ are defined as the mean and the standard deviation of the excess delay, respectively, and can be determined from the multipath intensity profile [2,3]. Typical RMS delay spreads are on the order of one microsecond for urban outdoor channels, hundreds of nanoseconds for suburban channels, and tens of nanoseconds for indoor channels [3].

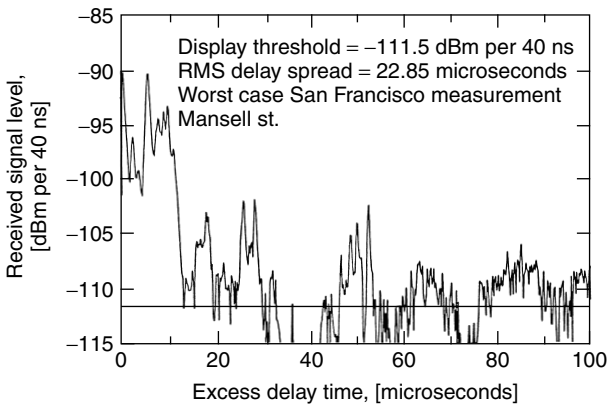

Figure 5. Measured multipath power delay profiles: from a 900-MHz cellular system in San Francisco (reprinted from Ref. 16, © IEEE).

The Fourier transform of the channel response $c(\tau, t)$ is the time-variant channel transfer function $C(f; t)$. It is also modeled as a wide-sense stationary random process. The correlation

$$\phi_c(\Delta f; \Delta t) = \tfrac{1}{2} E[C^*(f; t) C(f + \Delta f; t + \Delta t)] \tag{9}$$

is called the *spaced-frequency spaced-time autocorrelation function*. It is the Fourier transform of the autocorrelation function $\phi_c(\tau; \Delta t)$ in (7) [1]. It can be shown that this function can be factored into a product of time-domain and frequency-domain correlation functions. The latter is the *spaced-frequency correlation function* $\phi_c(\Delta f; 0) \equiv \phi_c(\Delta f)$ and is the Fourier transform of the multipath intensity profile $\phi_c(\tau)$ in (8) [1].

The complex envelope of the response $C(f; t)$ is specified by (4) with f viewed as the frequency of the unmodulated input carrier. Consider input frequency separation Δf. In the expressions for $C(f; t)$ and $C(f + \Delta f; t)$, the multipath components corresponding to the Doppler shift f_n have phase separation $\Delta\phi_n = 2\pi \Delta f \tau_n$. As Δf increases, these phase shifts result in decreased correlation between fading responses associated with two frequencies [10]. The *coherence bandwidth* $(\Delta f)_c$ provides a measure of this correlation. If the frequency separation is less than $(\Delta f)_c$, the signals $C(f; t)$ and $C(f + \Delta f; t)$ are strongly correlated, and thus fade similarly. The coherence bandwidth is inversely proportional to the multipath spread. However, the exact relationship between the coherence bandwidth and the multipath spread depends on the underlying meaning of the strong correlation of fading signals at different frequencies and varies depending on the channel model [2,3]. For example, if $|\phi_c(\Delta f)|$ is required to remain above 0.9, the corresponding coherence bandwidth is defined as $(\Delta f)_c \approx 1/(50\sigma_\tau)$, where σ_τ is the RMS delay

spread. When the frequency correlation is allowed to decrease to 0.5, greater coherence bandwidth $(\Delta f)_c \approx 1/(5\sigma_\tau)$ results.

The time variation of the channel response $c(\tau, t)$ due to the Doppler shift can be statistically characterized using the *spaced-time correlation function* determined from (9) as

$$\phi_c(0; \Delta t) \equiv \phi_c(\Delta t) \tag{10}$$

or its Fourier transform $S_c(\lambda)$ [1]. The function $S_c(\lambda)$ is called the *Doppler power spectrum* of the channel. As the maximum Doppler shift increases, the channel variation becomes more rapid [see (4)], and $S_c(\lambda)$ widens, resulting in *spectral broadening* at the receiver. The shape of the autocorrelation function depends on channel characteristics. For example, the popular Rayleigh fading channel discussed in Section 4 has the autocorrelation function

$$\phi_c(\Delta t) = J_0(2\pi f_{dm} \Delta t) \tag{11}$$

where $J_0(.)$ is the zero-order Bessel function of the first kind [11]. The Doppler power spectrum for this channel is given by

$$S_c(\lambda) = \frac{1}{\pi f_{dm}} \left[1 - \left(\frac{f}{f_{dm}} \right)^2 \right]^{1/2}, \quad |f| \le f_{dm} \tag{12}$$

These functions are plotted in Fig. 6.

Time variation of the fading channel is characterized in terms of the *Doppler spread* and the *coherence time*. The Doppler spread B_d is defined as the range of frequencies over which the Doppler power spectrum is essentially nonzero. For example, in (12), $B_d = 2f_{dm}$. The coherence time $(\Delta t)_c$ measures the time interval over which the time variation is not significant, or the samples of the fading signal are strongly correlated when their time separation is less than the coherence time, although different interpretations are used [3]. The Doppler spread and the coherence time are inversely proportional to one another. A popular rule of thumb is $(\Delta t)_c = 0.423/f_{dm}$. This definition implies that if the time separation is greater than the coherence time, the signals will be affected differently by the channel.

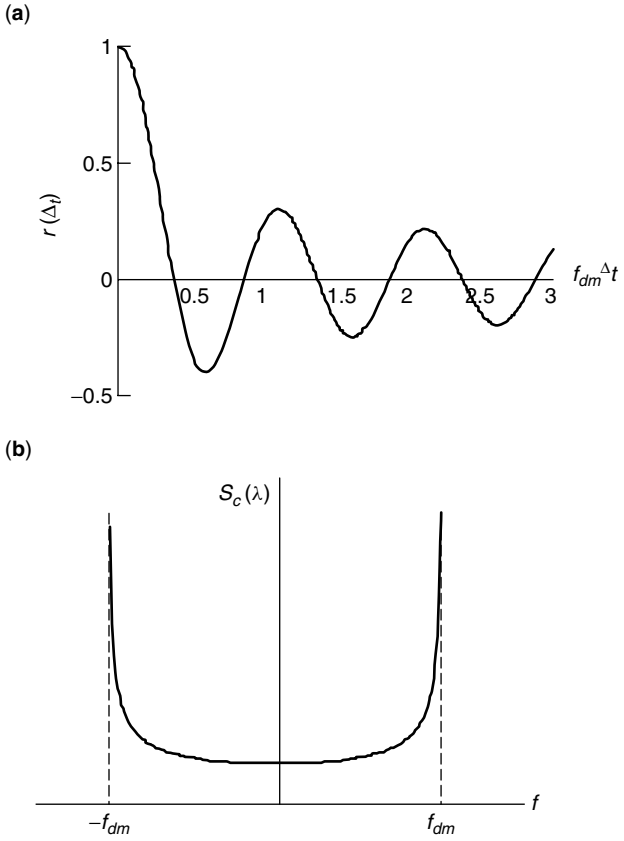

Figure 6. (**a**) The spaced-time autocorrelation function of the Rayleigh fading channel; (**b**) the Doppler power spectrum of the Rayleigh fading channel.

3.2. Relationship Between Signal Characteristics and the Fading Channel Model

Consider a linear communication system that transmits data at the symbol rate $1/T$ and employs a pulseshape with the complex envelope $s_l(t)$ and the frequency response $S_l(f)$ [1]. Assume that the bandwidth W of the transmitted signal is approximately $1/T$. The resulting output signal is characterized in terms of the response of the channel to this pulseshape as in (6), and the frequency response of the output signal is given by $C(f; t)\, S_l(f)$. The relationship between the symbol interval (or bandwidth W) and the statistical fading-channel parameters defined above dictate the choice of the underlying channel model used in analyzing performance of wireless communication systems.

First, consider the *multipath channel characterization* and *signal dispersion*. Suppose that the symbol interval is much larger than the multipath spread of the channel, $T \gg T_m$. Then all multipath components arrive at the receiver within a small fraction of the symbol interval. In this case, the coherence bandwidth significantly exceeds the bandwidth of the signal, $W \ll (\Delta f)_c$. Thus, all spectral components are affected by the channel similarly. Also, there is no *multipath-induced intersymbol interference* (ISI) in this case. This channel is modeled as complex time-varying attenuation $c(t)$ (4) [also given by $C(0; t)$], so the complex envelope of the received signal is $r(t) = c(t)\, s_l(t)$. It is called *frequency-nonselective*, or *flat fading* channel. These channels primarily occur in *narrowband* transmission systems.

If the symbol interval is smaller the multipath spread of the channel, $T < T_m$, or equivalently, the coherence bandwidth is smaller than the signal bandwidth, $W > (\Delta f)_c$, the channel becomes *frequency-selective* (it is also sometimes called the *multipath fading channel*). A common rule of thumb is that the channel is frequency-selective if $T < 10\sigma_\tau$, and flat fading if $T \ge 10\sigma_\tau$, where σ_τ is the RMS delay spread [3] With this definition of a frequency-selective channel, spectral components of the transmitted signal separated by the coherence bandwidth fade differently, resulting in frequency diversity, as discussed in Section 5. On the other hand, frequency

selectivity also causes dispersion, or ISI, since delayed versions of the transmitted signal arrive at the receiver much later (relative to the symbol interval) than components associated with small delays. This channel is often modeled using several fading rays with different excess multipath delays

$$c(t) = c_1(t)\delta(t-\tau_1) + c_2(t)\delta(t-\tau_2) + \cdots + c_L(t)\delta(t-\tau_L) \tag{13}$$

where the components $c_l(t), l = 1, \ldots, L$ are uncorrelated flat fading (e.g., Rayleigh distributed) random variables. The powers associated with these rays are determined by the multipath intensity profile (8).

Now, consider *rapidity*, or *time variation* of the fading channel. The channel is considered *slowly varying* if the channel response changes much slower than the symbol rate. In this case, the symbol interval is much smaller than the coherence time, $T \ll (\Delta t)_c$, or the signal bandwidth significantly exceeds the Doppler spread, $W \gg B_d$. If the symbol interval is comparable to or greater than the coherence time, (or the coherence bandwidth is similar to or exceeds the signal bandwidth), the channel is *fast-fading*. While most mobile radio, or PCS, channels are slowly fading, as the velocity of the mobile and the carrier frequency increase, the channel becomes *rapidly time-varying* since the Doppler shift increases [see (5)]. This rapid time variation results in time selectivity (which can be exploited as time diversity), but degrades reliability of detection and channel estimation [12–14].

4. FADING-CHANNEL MODELS

The *complex Gaussian distribution* is often used to model the equivalent lowpass flat-fading channel. This model is justified since superposition of many scattered components approximates a Gaussian distribution by the central-limit theorem. Even if the number of components in (5) is modest, experiments show that the Gaussian model is often appropriate. The *Rayleigh fading* process models fading channels without strong *line of sight* (LoS). Define $c(t) = c_I(t) + jc_Q(t)$, where the in-phase (real) and quadrature (imaginary) components are independent and identically distributed (i.i.d.) zero-mean stationary real Gaussian processes with variances σ^2. The average power of this process is $\frac{1}{2}E[c^*(t)c(t)] = \sigma^2$. The amplitude of this process has a Rayleigh distribution with the probability density function (PDF):

$$p_R(r) = \frac{r}{\sigma^2}\exp\left(-\frac{r^2}{2\sigma^2}\right) \tag{14}$$

and the phase is uniformly distributed:

$$p_\theta(\theta) = \frac{1}{2\pi},\ |\theta| \le \pi \tag{15}$$

The Rayleigh distribution is a special case of the *Nakagami-m* distribution that provides a more flexible model of the statistics of the fading channel. The PDF of the amplitude of the Nakagami-m distribution is [1]

$$p_R(r) = \frac{2}{\Gamma(m)}\left(\frac{m}{\Omega}\right)^m r^{2m-1}\exp\left(-\frac{mr^2}{\Omega}\right) \tag{16}$$

where $\Gamma(.)$ is the Gamma function [11], $\Omega = E(R^2)$ and the parameter m is the *fading figure* given by $m = \Omega^2/E[(R^2-\Omega)^2]$, $m \ge 1/2$. While the *Rayleigh* distribution uses a single parameter $E(R^2) = 2\sigma^2$ to match the fading statistics, the Nakagami-m distribution depends on two parameters, $E(R^2)$ and m. For $m = 1$ the density (16) reduces to Rayleigh distribution. For $\frac{1}{2} \le m < 1$, the tail of the Nakagami-m PDF decays slower than for Rayleigh fading, whereas for $m > 1$, the decay is faster. As a result, the Nakagami-m distribution can model fading conditions that are either more or less severe than Rayleigh fading. The Nakagami-m PDF for different values of m is illustrated in Fig. 7.

The Rayleigh distribution models a complex fading channel with zero mean that is appropriate for channels without the line-of-sight (LoS) propagation. When strong nonfading, or specular, components, such as LoS propagation paths, are present, a DC component needs to be added to random multipath, resulting in *Ricean* distribution. The pdf of the amplitude of Ricean fading is given by

$$p_R(r) = \frac{r}{\sigma^2}\exp -\left(\frac{r^2+s^2}{2\sigma^2}\right) I_0\left(\frac{rs}{\sigma^2}\right), \qquad r \ge 0 \tag{17}$$

where s is the peak amplitude of the dominant nonfading component and $I_0(.)$ is the modified Bessel function of the first kind and zero order [11]. The *Ricean factor K*

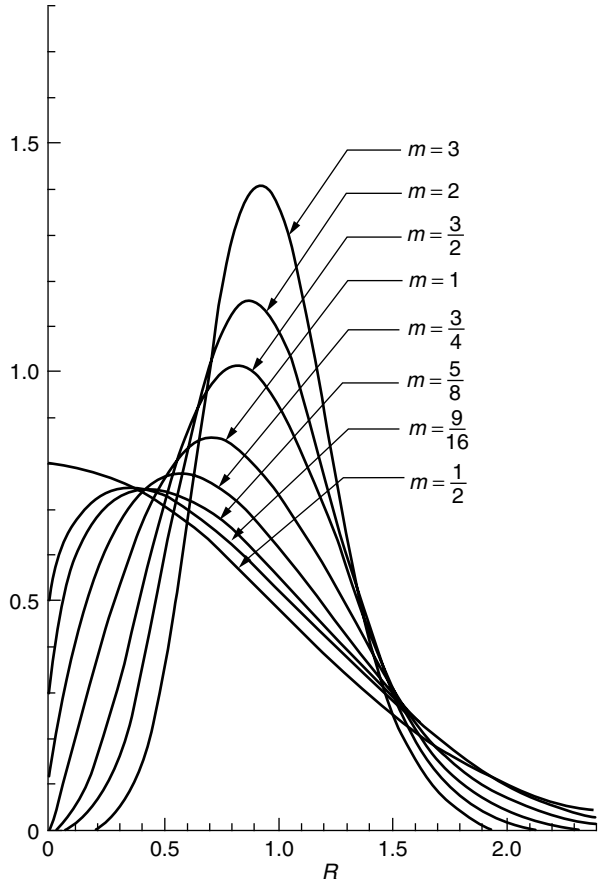

Figure 7. The PDF for the Nakagami-m distribution, shown with $\Omega = 1$, where m is the fading figure (reprinted from Ref. 17).

specifies the ratio of the deterministic signal power and the variance of the multipath:

$$K = 10 \log_{10} \left(\frac{s^2}{2\sigma^2} \right) \text{ (dB)} \tag{18}$$

As $s \to 0$ ($K \to -\infty$), the power of the dominant path diminishes, and the Ricean PDF converges to the Rayleigh PDF. Examples of Ricean fading and other LoS channels include airplane to ground communication links and microwave radio channels [1].

As an alternative to modeling the Rayleigh fading as a complex Gaussian process, one can instead approximate the channel by summing a set of complex sinusoids as in (4). The number of sinusoids in the set must be large enough so that the PDF of the resulting envelope provides an accurate approximation to the Rayleigh PDF. The Jakes model is a popular simulation method based on this principle [10]. The signal generated by the model is

$$c(t) = \sqrt{\frac{2}{N}} \sum_{n=1}^{N} e^{j(\omega_d t \cos \alpha_n + \phi_n)} \tag{19}$$

where N is the total number of plane waves arriving at uniformly spaced angles α_n as shown in Fig. 8. The $c(t)$ can be further represented as

$$c(t) = \frac{E_0}{\sqrt{2N_0 + 1}} (c_1(t) + j c_Q(t))$$

$$c_I(t) = 2 \sum_{n=1}^{N_0} \cos \phi_n \cos \omega_n t + \sqrt{2} \cos \phi_N \cos \omega_m t$$

$$c_Q(t) = 2 \sum_{n=1}^{N_0} \sin \phi_n \cos \omega_n t + \sqrt{2} \sin \phi_N \cos \omega_m t$$

where $N_0 = \frac{1}{2}[(N/2) - 1)$, $\omega_m = 2\pi f_{dm}$, and $\omega_n = \omega_m \cos(2\pi n/N)$. In the Jakes model, the parameter $N_0 + 1$ is often referred as the *number of oscillators* and N is termed the *number of scatterers*. The Jakes model with as few as nine oscillators ($N_0 = 8$, and $N = 34$) closely approximates the Rayleigh fading distribution (14,15).

When a multipath fading channel with impulse response (13) needs to be modeled, the Jakes model can be extended to produce several uncorrelated fading components using the same set of oscillators [10]. The autocorrelation function and the Doppler spectrum of the signals generated by the Jakes model are characterized by Eqs. (11) and (12), respectively, and are shown in Fig. 6. This statistical characterization is appropriate for many channels where the reflectors are distributed uniformly around the mobile (*isotropic* scattering). Several other approaches to simulating Rayleigh fading channels based on *Clarke and Gans fading models* are described by Rappaport [3]. Moreover, *physical models* are useful [e.g., when the variation of amplitudes, frequencies, and phases in (4) is important to model as in *long-range fading prediction*] and *autoregressive* (*Gauss–Markov*) models are often utilized to approximate fading statistics in fading estimation algorithms since they result in rational spectral characterization [12,13].

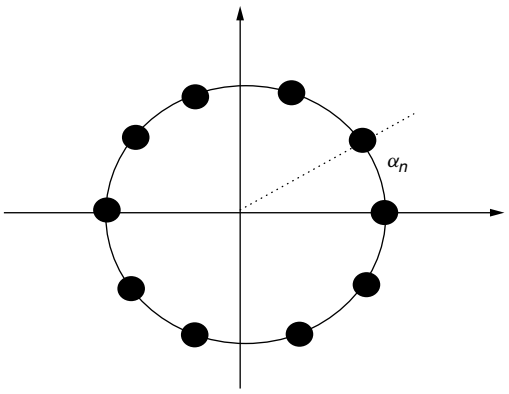

Figure 8. The Jakes model with $N = 10$ scatterers ($N_0 = 2$, 3 oscillators).

5. DIVERSITY TECHNIQUES AND PERFORMANCE ANALYSIS

5.1. Performance Analysis for Flat Fading Channels

Fading channels undergo dramatic changes in received power due to multipath and Doppler effects. When communication signals are transmitted over these channels, the bit error rate (BER) varies as a function of the signal-to-noise ratio (SNR) and is significantly degraded relative to the BER for the additive white Gaussian noise (AWGN) channel with the same average SNR. Consider the following example of transmission of binary phase-shift-keyed (BPSK) signal over the flat Rayleigh fading channel. At the output of the matched filter and sampler at the bit rate $1/T_b$ (where T_b is the bit interval), the complex envelope of the received signal is

$$r_k = c_k b_k + z_k \tag{20}$$

where c_k are the samples of the fading signal $c(t)$, b_k is the i.i.d. information sequence that takes on values $\{+1, -1\}$, and z_k is the i.i.d. complex white Gaussian noise sequence with the variance $\frac{1}{2}E[|z_k|^2] = N_0$. Since the channel is assumed to be stationary, we omit the subscript k in subsequent derivations. The equivalent passband energy is normalized as $E_b = \frac{1}{2}$, so the instantaneous SNR at the receiver is given by

$$\gamma = \frac{|c|^2}{2N_0} \tag{21}$$

Assume without loss of generality that the average power of the fading signal $E[|c_k|^2] = 1$. Then the average SNR per bit

$$\Gamma = \frac{1}{2N_0} \tag{22}$$

Suppose coherent detection of the BPSK signal is performed, and signal phase is estimated perfectly at the receiver. (This assumption is difficult to satisfy in practice for rapidly varying fading channels [12,13], so the analysis below represents a lower bound on the achievable performance.) The BER for each value of the instantaneous

SNR (21) can be computed from the BER expression for the AWGN channel [1]:

$$\text{BER}\ (\gamma) = Q[(2\gamma)^{1/2}] \tag{23}$$

where the Q function $Q(x) = 1/(2\pi)^{1/2} \int_{-\infty}^{x} \exp(-y^2/2)\, dy$. To evaluate average BER for the Rayleigh fading channel, the BER (23) has to be averaged over the distribution of the instantaneous SNR:

$$\text{BER} = \int_0^{\infty} Q[(2\gamma)^{1/2}] p(\gamma)\, d\gamma \tag{24}$$

Since $|c|$ is *Rayleigh* distributed, the instantaneous SNR γ has a *chi-square* distribution with the PDF $p(\gamma) = 1/\Gamma \exp(-\gamma/\Gamma)$, $\gamma \geq 0$. When this density is substituted in (24), the resulting BER for binary BPSK over flat Rayleigh fading channel is

$$\text{BER} = \frac{1}{2}\left[1 - \left(\frac{\Gamma}{1+\Gamma}\right)^{1/2}\right] \tag{25}$$

The BER for other fading distributions (e.g., Ricean or Nakagami-m) can be obtained similarly by averaging the BER for AWGN (23) over the fading statistics as in (24). Figure 9 illustrates performance of BPSK over a Nakagami-m fading channel for different values of m. Observe that as m increases, the fading becomes less severe, and the BER approaches that of the AWGN channel. Rayleigh fading ($m = 1$) results in significant SNR loss relative to the nonfading channel. In fact, for large SNR, the BER in (25) behaves asymptotically as $\frac{1}{4}\Gamma$, whereas the BER decreases exponentially with SNR for AWGN. The error rates of other modulation methods [e.g., coherent and noncoherent frequency shift keying (FSK), differential PSK (DPSK)] also *decrease only inversely with SNR*, causing very large power consumption.

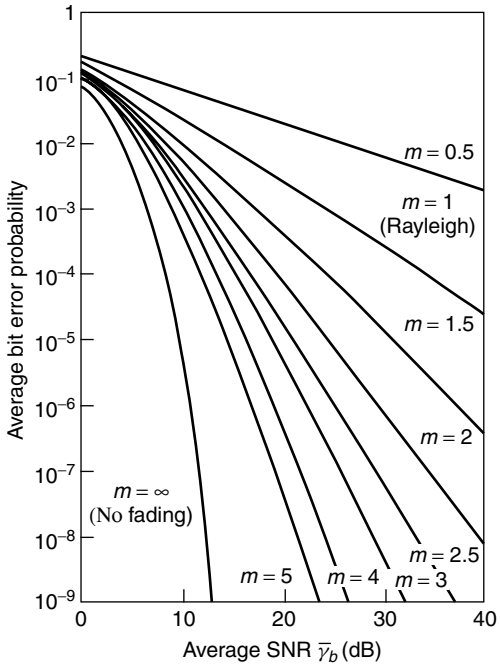

Figure 9. Average error probability for two-phase PSK with Nakagami fading (reprinted from Ref. 1).

5.2. Diversity Techniques

The poor performance of flat fading channels is due to the presence of deep fades in the received signal (Fig. 4) when the received SNR is much lower than the average SNR value. *Diversity techniques* help to combat fading by sending replicas of transmitted data over several uncorrelated (or partially correlated) fading channels. Since these channels are unlikely to go through a deep fade at the same time, higher average received SNR results when the outputs of the diversity branches are combined. Many diversity techniques are used in practice.

In *space*, or *antenna diversity* systems, several antenna elements are placed at the transmitter and/or receiver and separated sufficiently far apart to achieve desired degree of independence. (Note that the correlation function in space is analogous to that in time [10]. Typically, antenna separations of about $\lambda/2$ at the mobile station and several λ at the base station are required to achieve significant antenna decorrelation, where λ is the wavelength.)

Time diversity relies on transmitting the same information in several time slots that are separated by the coherence time $(\Delta t)_c$. Time diversity is utilized in coded systems by interleaving the outputs of the encoder.

Frequency diversity can be employed when the transmitter bandwidth is larger than the coherence bandwidth of the channel, and several fully or partially uncorrelated fading components can be resolved. The number of such uncorrelated components is determined by the ratio $W/(\Delta f)_c$ [1]. In PSK or quadrature-amplitude-modulated (QAM) systems, the transmitter bandwidth is approximately $1/T$. Because of the narrow transmission bandwidth, these channels are often frequency-nonselective. When frequency selectivity is present, it usually causes ISI since the multipath delay is significant relative to the symbol interval. Thus, *equalizers* are used to mitigate the ISI and to obtain the diversity benefit [1,12–14]. On the other hand, *direct-sequence spread-spectrum* (DSSS) systems employ waveforms with the transmission bandwidth that is much larger than the symbol rate $1/T$, and thus enjoy significant frequency diversity. DSSS signals are designed to achieve approximate orthogonality of multipath-induced components, thus eliminating the need for equalizers. Frequency diversity combining in these systems is achieved using a *RAKE correlator* [1].

In addition to the diversity techniques mentioned above, *angle of arrival* and *polarization* diversity are utilized in practice. Different diversity methods are often combined to maximize diversity gain at the receiver. To illustrate the effect of diversity on the performance of communication systems in fading channels, consider the following simple example. Suppose the transmitted BPSK symbol b_k is sent over L independent Rayleigh fading channels (we suppress the time index k below). The received equivalent lowpass samples are

$$r^i = c^i b + z^i, \qquad i = 1, \ldots, L \tag{26}$$

where c^i are i.i.d. complex Gaussian random variables with variances $E[|c^i|^2] = 1/L$ [this scaling allows us to compare performance directly with a system without diversity in (20)], b is the BPSK symbol as in Eq. (20), and z^i are i.i.d. complex Gaussian noise samples with $\frac{1}{2}E[|z_k|^2] = N_0$. Thus, the average SNR *per channel* (*diversity branch*) is $\Gamma_c = \Gamma/L$, where Γ is the SNR per bit.

There are several options for combining L diversity branches. For example, the branch with the highest instantaneous SNR can be chosen resulting in *selection diversity*. Alternatively, *equal gain combining* is a technique where all branches are weighted equally and cophased [3]. The maximum diversity benefit is obtained using *maximum ratio combining* (MRC) (this is also the most complex method). In MRC, the outputs r^i are weighted by the corresponding channel gains, cophased, and summed producing the decision variable (the input to the BPSK threshold detector):

$$U = (c^1) * r^1 + (c^2) * r^2 + \cdots + (c^L) * r^L$$

Note that if a signal undergoes a deep fade, it carries weaker weight than a stronger signal with higher instantaneous power. It can be shown that for large SNR, the BER for this method is approximately [1]

$$\text{BER} \approx \left(\frac{1}{(4\Gamma_c)}\right)^L \binom{2L-1}{L} \tag{27}$$

This BER of MRC for BPSK is illustrated in Fig. 10 for different values of L (binary PSK curve). The figure also shows performance of two less complex combining methods used with orthogonal FSK (*square-law combining*) and DPSK. The latter two techniques are noncoherent (i.e., do not require amplitude or phase estimation). From Eq. (27) and Fig. 10 we observe that the *BER for all methods decreases inversely with the Lth power of the SNR*. Thus, diversity significantly reduces power consumption in fading channels.

In addition to diversity, *adaptive transmission* is an effective tool in overcoming the effects of fading. The idea is to adjust the transmitted signal (power, rate, etc.) to fading conditions to optimize average power and bandwidth requirements. Many advances in the area of communication over fading channels, and additional sources are cited in Refs. 12 and 13.

6. SUMMARY

The fading signal was characterized in terms of large-scale and small-scale fading. The large-scale fading models that describe the average and statistical variation of the received signal power were presented. The small-scale fading channel was characterized statistically in terms of its time-variant impulse response. Time and frequency-domain interpretation was provided to describe signal dispersion and fading rapidity, and it was shown how the transmitted signal affects the choice of the fading channel model. Several statistical models of fading channels were presented, and simulation techniques were discussed. Finally, performance limitations of fading channels were revealed, and fading mitigation methods using diversity techniques were reviewed.

BIOGRAPHY

Alexandra Duel-Hallen received the B.S. degree in Mathematics from Case Western Reserve University in 1982, the M.S. degree in Computer, Information and Control Engineering from the University of Michigan in 1983, and a Ph.D. in Electrical Engineering from Cornell University in 1987. During 1987–1990 she was a Visiting Assistant Professor at the School of Electrical Engineering, Cornell University, Ithaca, New York. In 1990–1992, she was with the Mathematical Sciences Research Center, AT&T Bell Laboratories, Murray Hill, New Jersey. She is an Associate Professor at the Department of Electrical and Computer Engineering at North Carolina State University, Raleigh, North Carolina, which she joined in January 1993. From 1990 to 1996, Dr. Duel-Hallen was Editor for Communication Theory for the *IEEE Transactions on Communications*. During 2000–2002, she has served as Guest Editor of two Special Issues on Multiuser Detection for the *IEEE Journal on Selected Areas in Communications*. Dr. Duel-Hallen's current research interests are in wireless and multiuser communications. Her 1993 paper was selected for the IEEE Communications Society 50th Anniversary Journal Collection as one of 41 key papers in physical and link layer areas, 1952–2002.
