1. INTRODUCTION

The majority of communications applications, from cellular telephone conversations to credit card transactions, assume the availability of a reliable network. At this level, data are expected to traverse the network and to arrive intact at their destination. The physical systems that compose a network, on the other hand, are subjected to a wide range of problems, ranging from signal distortion to component failures. Similarly, the software that supports the high-level semantic interface often contains unknown bugs and other latent reliability problems. Redundancy underlies all approaches to fault tolerance. Definitive definitions for all concepts and terms related to reliability, and, more broadly, dependability, can be found in the book by Anderson et al. [1].

Designing any system to tolerate faults first requires the selection of a fault model, a set of possible failure scenarios along with an understanding of the frequency, duration, and impact of each scenario. A simple fault model merely lists the set of faults to be considered; the decision regarding inclusion in the set is based on a combination of expected frequency, impact on the system, and feasibility or cost of providing protection. Most reliable network designs address the failure of any single component, and some designs tolerate multiple failures. In contrast, few attempt to handle the adversarial conditions that might occur in a terrorist attack, and cataclysmic events are almost never addressed at any scale larger than a city.

The temporal characteristics of faults vary widely, but can be roughly categorized as permanent, intermittent, or transient. Failures that prevent a component from functioning until repaired or replaced, such as the destruction of a network fiber by a backhoe, are considered permanent. Failures that allow a component to function properly some of the time are called *intermittent*. Damaged connectors and electrical components sometimes produce intermittent faults, operating correctly until mechanical vibrations or thermal variations cause a failure, and recovering when conditions change again. The last category, transient

faults, is usually the easiest to handle. Transient faults range from changes in the contents of computer memory due to cosmic rays, or bit errors due to thermal noise in a demodulator, and are typically infrequent and unpredictable. The difference between an intermittent fault and a transient fault is sometimes solely one of frequency; for transient faults, a combination of error-correcting codes and data retransmission usually provides adequate protection.

Redundancy takes two forms, spatial and temporal. *Spatial redundancy* replicates the components or data in a system. Transmission over multiple paths through a network and the use of error correction codes are examples of spatial redundancy. Temporal redundancy underlies automatic repeat request (ARQ) algorithms, such as the sliding-window abstraction used to support reliable transmission in the Internet's Transmission Control Protocol (TCP). A reliable network typically provides both spatial and temporal redundancy to tolerate faults with differing temporal persistence. Spatial redundancy is necessary to overcome permanent failures in physical components, while temporal redundancy requires fewer resources and is thus preferable when dealing with transient errors.

Beyond the selection of a fault model, several additional problems must be considered in the design of a fault-tolerant system. A system must be capable of detecting each fault in the model, and must be able to isolate each fault from the functioning portion of the system in a manner that prevents faulty behavior from spreading. As a fault detection mechanism may detect more than one possible fault, a system must also address the process of fault diagnosis (or localization), which narrows the set of possible faults and allows more efficient fault isolation techniques to be employed. An error identified by a system need not necessarily be narrowed down to a single possible fault, but a smaller set of possibilities usually allows a more efficient strategy for recovery.

Fault isolation boundaries are usually designed to provide fail-stop behavior for the desired fault model. The term *fail stop* implies that incorrect behavior does not propagate across the fault isolation boundary; instead, failed components cease to produce any signals. Fail stop does not imply self-diagnosis; components adjacent to a failed component may diagnose the failure and deliberately ignore any signals from the failed component, but the physical system design must allow such a decision. In a router, for example, the interconnect between cards controlling individual links must provide electrical isolation to support fail-stop behavior for failed cards. A bus-based computer interconnect does not allow for fail stop, as nothing can prevent a failed card from driving the bus lines inappropriately. In modern, high-end servers, such buses have been replaced by switched networks with broadcast capability in order to enable such isolation. The eradication of similar phenomena in the move from shared to switched Ethernets in the mid-1990s was one of the main administrative advantages of the change, as failed hosts are much less likely to render a switched network unusable by flooding it with continuous traffic.

Two models of network service have dominated research and commercial networking. The first is the telephony network, or more generally a network in which quasipermanent routes called *circuits* deliver fixed data capacity from one point to another. In digital telephony, a voice circuit requires 64 kbps (kilobits per second); a single lightpath in a wavelength-division-multiplexed (WDM) optical network may deliver up to 40 Gbps, but is conceptually similar to the circuit used to carry a phonecall. The second network service model is the packet-switched data network, which evolved from the early ARPANET and NSFNET projects into the modern Internet. Packet-switched networks seldom provide strong guarantees on delivered data rate or maximum delay, but are typically more efficient than circuit-oriented designs, which must base guaranteed agreements on worst-case traffic load scenarios.

For the purposes of our discussion, the key difference between these two models lies in the fact that applications using packet-switched networks can generally tolerate more serious service disruptions than can those based on circuit-switched networks. The latter class of applications may assume that data rate, delay, and jitter guarantees provided by the network will be honored even when failures occur, whereas minor disruptions may occur even in normal circumstances on packet-switched networks because of fluctuations in traffic patterns and loads. Fault tolerance issues are thus addressed in markedly different ways in the two types of networks. In packet-switched networks like the Internet, users currently tolerate restoration times of minutes [2,3], whereas fault tolerance for circuit-switched networks can be considered a component of quality of service (QoS) [4,5], and is typically achieved in milliseconds, or, at worst, seconds.

The majority of this article focuses on fault tolerance issues in high-speed backbone networks, such as wide-area networks (WANs) and metropolitan-area networks (MANs). Such networks are predominantly circuit-based and carry heavy traffic loads. As even a short downtime may cause substantial data loss, rapid recovery from failure is important, and these networks require high levels of reliability. Backbone networks generally are implemented using optical transmission and, conversely, fault tolerance in optical networks is typically considered in the context of backbone networks [6,7]. In these networks, a failure may arise because a communications link is disconnected or a network node becomes incapacitated. Failures may occur in military networks under attack [8], as well as in public networks, in which failures, albeit rare, can be extremely disruptive [9, Chap. 8].

The next section provides an overview of fault detection mechanisms and the basic strategies available for recovery from network component failures. Sections 3 and 4 build on these basics to illustrate recovery schemes for high-speed backbone networks. Sections 5 and 6 examine simple and more complex topologies and discuss the relationship between topology and recovery. Section 5 highlights ring topologies, as they are a key architectural component of high-speed networks. Section 6 extends the concepts developed for rings by overlaying logical ring topologies over physical mesh topologies. We also discuss

some link- and node-based reliability schemes that are specifically tailored to mesh networks. Although the text focuses on approaches to fault tolerance in high-speed backbone networks, many of the principles also apply to other types of networks. In Section 7, we move away from circuit-switched networks and examine fault tolerance for packet-switched networks, and in particular the Internet. Finally, Section 8 discusses reliability issues for local-area networks (LANs).

2. FAILURE DETECTION AND RECOVERY

A wide variety of approaches have been employed for detection of network failures. In electronic networks with binary voltage encodings (e.g., RS-232), two nonzero voltages are chosen for signaling. A voltage of zero thus implies a dead line or terminal. Similarly, electronic networks based on carrier modulation infer failures from the absence of a carrier. Shared segments such as Ethernet have been more problematic, as individual nodes cannot be expected to drive the segment continuously. In such networks, many failures must be detected by higher levels in the protocol stack, as discussed later in this section.

The capacity of optical links makes physical monitoring a particularly important problem, and many techniques have been explored and used in practice. Optical encoding schemes generally rely on on/off keying; that is, the presence of light provides one signal, and its absence provides a second. With single-wavelength optics, information must be incorporated into the channel itself. One approach is to monitor time-averaged signal power, using an encoding scheme that results in a predictable distribution of ON and OFF frequencies. A second approach utilizes overhead bits in the channel, allowing bit error rate (BER) sampling at the expense of restricting the data format used by higher levels of the protocol stack. A third approach employs a sideband to carry a pilot tone. These approaches are complementary, and can be used in tandem.

A WDM system typically applies the single-wavelength techniques just mentioned to each wavelength, but the possibility of exploiting the multiplexing to reduce the cost of failure detection has given rise to new techniques. A single wavelength, for example, can be allocated to provide accurate estimates of BER along a link. Unfortunately, this approach may fail to detect frequency-dependent signal degradation. Pairing of monitoring wavelengths with data wavelengths reduces the likelihood of missing a frequency-dependent failure, but is too inefficient for most networks.

The approaches discussed so far have dealt with failure detection at the link level. With circuit-switched networks, the receiver on any given path can directly monitor accumulated effects along the entire path. The techniques discussed for a single wavelength can also be employed for a full path with optically transparent networks. With networks that perform optoelectronic conversion at each node, only in-band information is retained along the length of the path and overhead in the data format is typically necessary for failure detection. Path-based approaches are advantageous in the sense that they may cover a broader set of possible failures. They get to the root of the problem; something went wrong getting from the sender to the receiver. Link-based approaches, however, make fault localization simpler, an important benefit in finding and repairing problems in the network. In practice, most backbone networks use a combination of link and path detection techniques to obtain both benefits.

Additional fault tolerance is often included in higher levels of a network protocol stack. Most protocols used for data networking (as opposed to telephony), for example, include some redundancy coding for the purposes of error detection. Typically, feedback from these layers is not provided to the physical layer, although some exceptions do exist in LANs, such as the use of periodic packet transmissions and inference of failures when no packet arrives (see Section 8 for more detail). Instead, the error detection schemes allow the network to tolerate transient errors through temporal redundancy, namely, retransmission. Voice channels and other redundant forms of data also utilize error correction or other error tolerance techniques in some cases. A telephone circuit crossing an asynchronous transfer mode (ATM) network may lose an occasional cell to a cyclic redundancy check (CRC) failure. In such a case, the cell is discarded, and the voice signal regenerated by interpolation from adjacent cells. This interpolation suffices to make a single cell loss undetectable to humans; thus, as long as the transient errors occur infrequently, no loss is noticed by the people using the circuit.

The choice of failure detection methods used in a backbone network is intertwined with the choice of strategies for restoring circuits that pass through a failed element of the network. Path monitoring, for example, does not readily provide information for failure localization. Correlated failures between paths may help to localize failures, but typically a more careful investigation must be initiated to find the problem. Path monitoring also requires that failure information propagate to the endpoints of the path, delaying detection. Link monitoring allows more rapid and local response to failures, but does not require such an approach. Instead, failure information can be propagated to the ends of each path crossing a link, while the localized failure information is retained for initiating repairs and for dynamic construction of future paths. At the algorithmic level, circuit rerouting schemes can be broadly split into path-based and link- or node-based approaches.

Prompted by the increasing reliance on high-speed communications and the requirement that these communications be robust to failure, backbone networks have generally adopted self-healing strategies to automatically restore functionality. The study of self-healing networks is often classified according to the following three criteria [e.g., 10,11]: (1) the use of link (line) rerouting versus path (or end-to-end) rerouting, (2) the use of centralized computation versus distributed computation, and (3) the use of precomputed versus dynamically computed routes. A succinct comparison of the different options can be found in the book by Wu [12, pp. 291–294] and the paper by Johnson et al. [13]. For path recovery, when a failure leaves a node disconnected from the primary route, a backup route, which may or may not share nodes and links with the primary route, is used. *Link rerouting* usually refers

to the replacement of a link by links connecting the two end nodes of the failed link. When the rerouting is precomputed, the method is generally termed *protection*. Thus, *path protection* refers to precomputed recovery applied to connections following a particular path across a network. *Link or node protection* refers to precomputed recovery of all the traffic across a failed link or node, respectively. Figure 1 illustrates path and link rerouting. Protection routes are precomputed at a single location, and are thus centralized, although some distributed reconfiguration of optical switches may be necessary before traffic is restored. Restoration techniques, on the other hand, can rely on distributed signaling between nodes or on allocation of a new path by a central manager.

3. PATH-BASED SCHEMES

Protection schemes, in which recovery routes are preplanned, generally offer better recovery speeds than restoration approaches, which search for new routes dynamically in response to a failure and generally involve software processing [14,15]. The *Synchronous Optical* NET*work* (SONET) specification, for example, requires that recovery time with protection approaches be under 60 ms. Recovery can be achieved in tens of milliseconds using optomechanical add/drop multiplexers [16,17], and in a few microseconds using acoustooptical switches [18,19]. In contrast, dynamic distributed restoration using digital cross-connect systems (DCSs) for ATM or SONET [20–23] typically targets a 2-s recovery-time goal [17,24,25]. Dynamic centralized path restoration for SONET [26] may even take minutes [24,27]. The performance of several algorithms has been reviewed [28,29]. Restoration typically requires less protection capacity, however.

In this section, we focus on path protection, as the majority of current backbone networks utilize such techniques. Path protection trades longer recovery times for reduced capacity requirements relative to the link-based approaches discussed in the next section. These tradeoffs are discussed in more depth elsewhere [30–32]. Path protection involves finding, for each circuit, a backup route (or path). Figure 2 shows two primary routes and their corresponding backup routes. For each circuit, the two routes do not overlap on any links, implying that no single link failure can affect both a primary route and its backup.

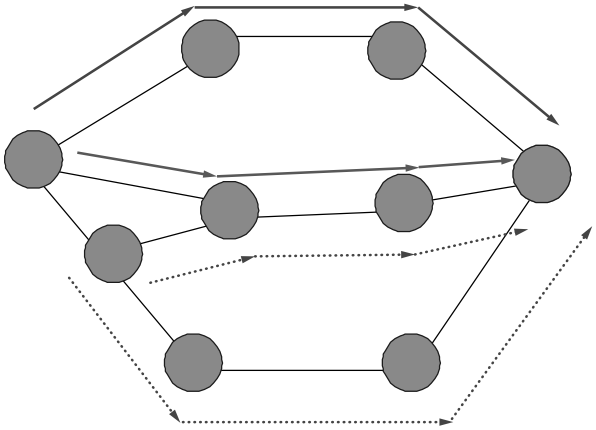

Figure 2. Path protection and associated bandwidth sharing on the backup.

Path protection can itself be divided into several categories: one-plus-one (written $1+1$), one-for-one (written $1:1$), and one-for-N ($1:N$). In the first case, all data are sent along two routes simultaneously, a primary and a backup. The two routes are link-disjoint for tolerance to link failures, or node-disjoint (excluding source and destination) for tolerance to node failures. The receiver monitors incoming traffic on the primary route; when a component along the primary route fails, the receiver switches to the backup signal. The backup route is typically the longer of the two, ensuring that no data are lost because of a single failure. Because both primary and backup routes carry live traffic, the $1+1$ approach is sometimes referred to as *live backup*. Recovery using live backup is extremely fast, as it is based on a local decision by a single node. Protection capacity requirements are high, however, as the backup channel cannot be shared among connections.

The other two approaches, together known as *event-triggered backup*, require less network capacity devoted to protection than does live backup. The penalty is loss of some data when a failure occurs as well as slower restoration times relative to live backup. With event-triggered backup, the backup path is activated only after a failure is detected. As with live backup, the receiver monitors the primary path, but rather than acting locally when it detects a failure, the receiver notifies the sender that a failure has occurred on the primary path, at

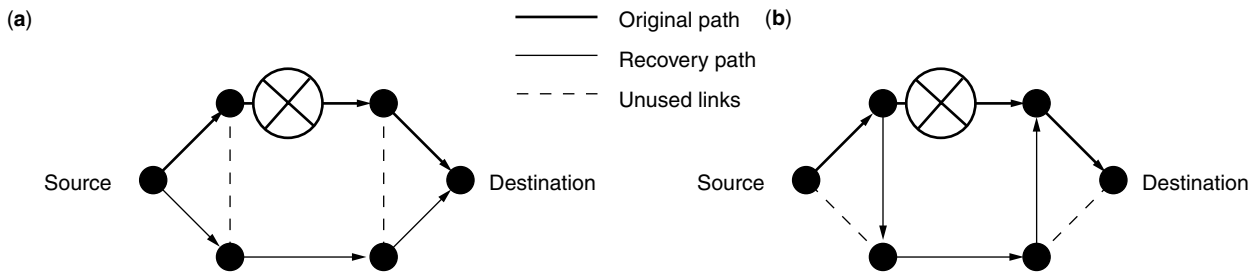

Figure 1. Path (**a**) and link (**b**) rerouting; the failure is marked with an ⊗.

which point the sender begins sending traffic on the backup path. All data transmitted or in flight between the time of the failure and the sender switching over to the backup route are lost. With $1:1$ protection, optical cross-connects are preconfigured for a particular route. Sharing and reuse of the backup route is therefore somewhat restricted. With $1:N$ protection, backup resources can be shared between any set of circuits for which the primary routes do not have resources in common, as illustrated by the two circuits in Fig. 2. Two primary routes passing through a single link, for example, cannot share backup resources; if that link should fail, only one of the two routes could be recovered. The need to configure optical cross-connects along the backup route adds further delay to restoration time and increases data loss with $1:N$ protection, but sharing of backup resources reduces protection capacity requirements by roughly 15–30% relative to $1+1$ protection in an all-optical network. Traffic grooming, in which traffic can be assigned to wavelengths in granularities smaller than those of whole wavelengths, can allow for much more effective sharing.

All forms of protection require adequate spatial redundancy in the network topology to allow advance selection of two disjoint routes for each circuit. For link (or node) protection, this requirement translates to a need for two-edge (-vertex)-redundant graphs; in other words, a graph must remain completely connected after removal of any single edge (vertex, along with all adjacent edges). For path protection, the same condition suffices, as shown by Menger's theorem [33,34], which states that, given a two-edge (-vertex)-redundant graph, two edge- (-vertex)-disjoint routes can be found between any two vertices in the graph. A variety of schemes based on Menger's theorem have been proposed, such as subnetwork connection protection (SNCP) and variations thereof [35–40], which establish two paths between every pair of nodes. However, Menger's theorem is only the starting point for designing a recovery algorithm, which must also consider rules for routing and reserving spare capacity. Path protection over arbitrary redundant networks can also be performed with trees, for example, which are more bandwidth-efficient for multicast traffic [41,42].

With ATM, path rerouting performed by the private network node interface (PNNI) tears down virtual circuit (VC) connections after a failure, forcing the source node to establish a new end-to-end route. Backup virtual paths (VPs) can be predetermined [43] or selected jointly by the end nodes [44]. Source routing, which is used by ATM PNNI, can be preplanned [45] or partially preplanned [46].

4. LINK- AND NODE-BASED SCHEMES

As with path rerouting, methods commonly employed for link and node rerouting in high-speed networks can be divided into protection and restoration, although some hybrid schemes do exist [23]. The two types offer a tradeoff between adaptive use of backup (or "spare") capacity and speed of restoration [25,46]. Dynamic restoration typically involves a search for a free path using backup capacity [47–49] through broadcasting of help messages [13,20,22,24,25,28]. The performance of several algorithms has also been discussed [28,29]. Overheads due to message passing and software processing render dynamic processing slow. For dynamic link restoration using digital cross-connect systems, a 2-s restoration time is a common goal for SONET [17,20–22,24,25]. Preplanned methods, or link protection, depend mostly on lookup tables and switches or add/drop multiplexers. For all-optical networks, switches may operate in a matter of microseconds or nanoseconds and propagation delay dominates switching time.

Link and node protection can be viewed as a compromise between live and event-triggered path protection. Although not as capacity-efficient as $1:N$ path protection [32,44], link protection is more efficient than live path backup, as backup capacity is shared between links. All traffic carried by a failed link or node is recovered independent of the circuits or end-to-end routes associated with the traffic. In particular, the two nodes adjacent to the failure initiate recovery, and only nodes local to the failure typically take part in the process. Backup is not live, but triggered by a failure. Overviews of the different types of protection and restoration methods and comparison of the tradeoffs among them can be found elsewhere in the literature [15,30,50–52].

The fact that link and node protection are performed independently of the particular traffic being carried does provide an additional benefit. In particular, these approaches are independent of traffic patterns, and can be preplanned once to support arbitrary dynamic traffic loads. Path protection does not provide this feature; new protection capacity may be necessary to support additional circuits, and routes chosen without knowledge of the entire traffic load, as is necessary when allocating routes online, are often suboptimal. This benefit makes link and node restoration particularly attractive at lower layers, at which network management at any given point in the network may not be aware of the origination and destination, or of the format [24] of all the traffic being carried at that location.

Link rerouting in ATM usually involves a choice of new routes by nodes adjacent to the failure [53,54].

5. RINGS

Rings have emerged as one of the most important architectural building blocks for backbone networks in the MAN and WAN arenas. While ring networks can support both path-based and link- or node-based schemes for reliability, rings merit a separate discussion because of the practical importance and special properties of ring architecture.

Rings are the most common means of implementing both path and link protection in SONET, which is the dominant protocol in backbone networks. The building blocks of SONET networks are generally self-healing rings (SHRs) and diversity protection (DP) [12,16,19,24,55–64]. SHRs are unidirectional path-switched rings (UPSRs) or bidirectional line-switched rings (BLSRs), while DP refers to physical redundancy in which a spare link (node) is assigned to one or several links (nodes) [12, pp. 315–322].

In SONET, path protection is usually performed by a UPSR, as illustrated by Fig. 3a, in which a route in the

clockwise direction is replaced by a route in the counterclockwise direction in response to a failure. Link rerouting is performed in a SONET BLSR using a technique known as *loopback*, in which traffic is sent back in the direction from which it came. Figure 3b illustrates this operation, in which a route in the clockwise direction is looped back (redirected) onto a counterclockwise route at the node adjacent to the failure. After traveling around the entire ring to the other end of the failed link, the route is looped back again away from the failed link, rejoining the original route. Note that, with the exception of the failed link, the final backup route includes all of the original route. The waste of bandwidth due to traversing both directions on a single link, known as *backhauling*, can be eliminated by looping back at points other than the failure location [65,66]. In case of failure of a node on a BLSR, the failure is handled in a manner similar to that for a link failure. The failure of a node is equivalent to the failure of a metalink consisting of the node and the two links adjacent to it. The only difference is that network management must be able to purge any traffic directed to the failed node from the network.

Loopback operations can be performed on entire fibers or on individual wavelengths. With fiber-based loopback, all traffic carried by a fiber is backed by another fiber, regardless of how many wavelengths are involved. If traffic is allowed in both directions in a network, fiber-based loopback relies on four fibers, as illustrated in Fig. 4. In WDM-based loopback, restoration is performed in a wavelength-by-wavelength basis.

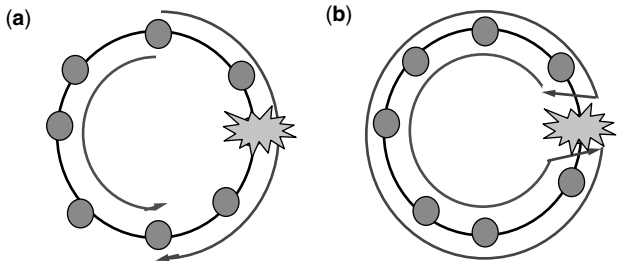

Figure 3. Path protection and node protection in a ring: (**a**) UPSR — automatic path switching; (**b**) BLSR — link/node rerouting.

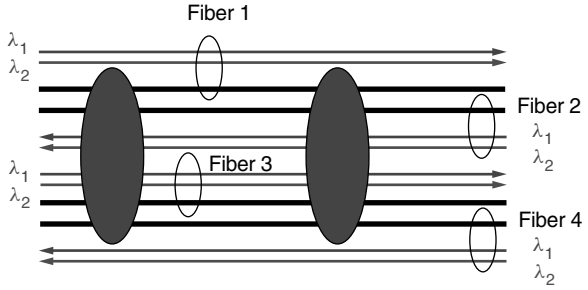

Figure 4. Four-fiber system with fiber-based loopback. Primary traffic is carried by fiber 1 and fiber 2. Backup is provided by fiber 3 for fiber 1 and by fiber 4 for fiber 2.

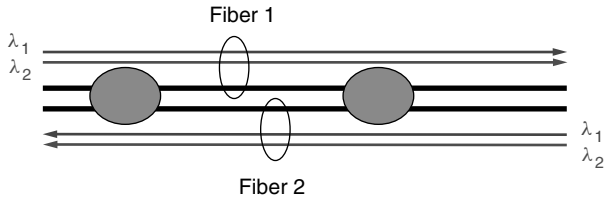

Figure 5. Two-fiber WDM-based loopback. Primary traffic is carried by fiber 1 on λ_1 and by fiber 2 on λ_2. Backup is provided by on λ_1 on fiber 2 for λ_1 on fiber 1. λ_2 on fiber 2 is backed up by λ_2 on fiber 1.

WDM-based loopback requires at least two fibers. Figure 5 illustrates WDM-based loopback. A two-fiber counterpropagating WDM system can be used for WDM-based loopback, even if traffic is allowed in both directions. Note that WDM loopback as shown in Fig. 5 does not require any change of wavelength; traffic initially carried by λ_1 is backed up by the same wavelength. Obviating the need for wavelength changing is economical and efficient in WDM networks. One could, of course, back up traffic from λ_1 on fiber 1 onto λ_2 on fiber 2, if there were advantages to such wavelength changing, for instance in terms of wavelength assignment for certain traffic patterns. We can easily extend the model to a system with more fibers, as long as the backup for a certain wavelength on a certain fiber is provided by some wavelength on another fiber. Moreover, we may change the fiber and/or wavelengths from one fiber section to another. For instance, the backup to λ_1 on fiber 1 may be λ_1 on fiber 2 on a two-fiber section and λ_2 on fiber 3 on another section with four fibers. Note, also, that we could elect not to back up λ_1 on fiber 1 and instead use λ_1 on fiber 1 for primary traffic. The extension to systems with more fibers, interwavelength backups and backups among fiber sections can be readily done.

The finer granularity of WDM-based recovery systems provides several advantages over fiber-based systems. First, if fibers carry at most half of their total capacity, only two fibers rather than four are necessary to provide recovery. Thus, a user need only lease two fibers, rather than paying for unused bandwidth over four fibers. On existing four-fiber systems, fibers could be leased by pairs rather than fours, allowing two leases of two fibers each for a single four-fiber system. The second advantage is that, in fiber based-systems, certain wavelengths may be selectively given restoration capability. For instance, half the wavelengths on a fiber may be assigned protection, while the rest may have no protection. Different wavelengths may thus afford different levels of restoration QoS, which can be reflected in pricing. In fiber-based restoration, all the traffic carried by a fiber is restored via another fiber. If each fiber is less than half full, WDM-based loopback can help avoid the use of counterpropagating wavelengths on the same fiber. Counterpropagating wavelengths on the same fiber are intended to enable duplex operation in situations that require a full fiber's worth of capacity in each direction and that have scarce fiber resources. However, counterpropagation on the same fiber is onerous and reduces the number of wavelengths that a fiber can carry with respect to unidirectional propagation. WDM-based loopback may make using two unidirectional

fibers preferable to using two counterpropagating fibers, for which one fiber is a backup for the other.

When more than one ring is required, rings must be interconnected. In SONET, the usual method to handle nodes shared between rings is called *matched nodes*. Figure 6 shows matched nodes under normal operating conditions. Consider traffic moving from ring 1 to ring 2; traffic in the reverse direction is handled similarly. Under normal operation, matched node 1 is responsible for all interring communications. Matched node 1 houses an add/drop multiplexer (ADM) that performs a drop and continue operation. The drop and continue operation consists of duplicating all traffic through matched node 1 and transmitting it to matched node 2. Thus, matched node 2 has a live backup of all the traffic arriving to matched node 1, and mirrors the operation of matched node 1. However, under normal operating conditions, ring 2 disregards the output from matched node 2. Failure of any node other than the primary matched node is handled by a single ring in a standalone manner. Failure of the secondary matched node treats intraring and interring traffic differently. Note that, depending on the failure mode of the primary matched node, the failure may be seen by both rings or by a single ring. Indeed, failures may occur only on access cards interfacing with one or the other ring, or a wholesale failure may be detected by both rings. Loopback is performed on all the rings that see the failure. Intraring traffic is recovered within the ring wherein it lies, and interring traffic is handled by the second node. How to extend matched nodes to cases other than simple extensions of the topology shown in Fig. 6 is generally unknown. For instance, the case in which a node is shared by more than one ring is difficult. Similarly, the case in which two adjacent rings share links without duplication of resources, as shown in Fig. 8, is complicated in the case of shared nodes.

Many schemes besides SONET exist or have been proposed to enable ring-based networks, usually using optical fiber as the medium. The proprietary protocol Fiber Distributed Data Interface (FDDI) [67–69] is such a scheme. Both FDDI and IEEE 802.5 control access to the ring by passing an electronic token from node to node. Only the node with the token is allowed to transmit. Multiple ring topologies may be interconnected through a hub [70], or rings may coexist in a logically interconnected fashion over a single physical ring [71–73], or rings may be arranged hierarchically [70,74,75].

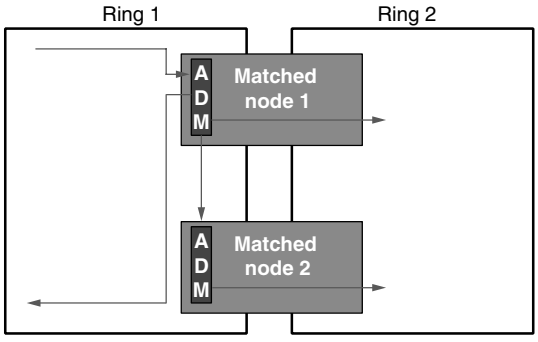

Figure 6. Matched nodes.

The IEEE 802.17 Resilient Packet Ring (RPR) Working Group has been set up to investigate the use, mainly at the MAN, of an optical ring architecture coupled with a packet-based MAC. The purpose of this project is to combine the robustness of rings with a flexible MAC that is well suited to current optical access applications [76].

6. MESH NETWORKS

In this section, we expand our exploration of topologies to redundant meshes. Restricting a network to use only DP and SHRs is a constraint that has cost implications for building and expanding networks [63]; see Stoer's book [34] for an overview of the design of topologies under certain reliability constraints. Ring-based architectures may be more expensive than meshes [63,77], and as nodes are added, or networks are interconnected, ring-based structures may be difficult to preserve, thus limiting their scalability [12,63,78]. However, rings are not necessary to construct fault-tolerant networks [79,80]. Mesh-based topologies can also provide redundancy [34,78,81]. Even if we constrain ourselves to always use ring-based architectures, such architectures may not easily bear changes and additions as the network grows. For instance, adding a new node, connected to its two nearest node neighbors, will preserve mesh structure, but may not preserve ring structure. Our arguments indicate that, for reasons of cost and extensibility, mesh-based architectures are more promising than interconnected rings.

Algorithmic approaches to general mesh restoration are often difficult, however, and implementations can be substantially more complex. To address this problem, many techniques attempt to find rings within the meshes. Overlays using rings are obtained by placing cycles atop existing mesh networks. Each such cycle creates a ring. Service protection or restoration is then generally obtained on each ring as though it were a physical ring. Covering mesh topologies with rings is a means of providing both mesh topologies and distributed, ring-based restoration. Numerous approaches ensure link restorability by finding covers of rings for networks. Many of these techniques have been proposed in the context of backbone networks in order to enable recovery over mesh topologies.

One such approach is to cover nodes in the network by rings [56]. In this manner, a portion of links are covered by rings. If primary routings are restricted to the covered links, link restoration can be effected on each ring in the same manner as in a traditional SHR, by routing backup traffic around the ring in the opposite direction to the primary traffic. Using such an approach, the uncovered links can be used to carry unprotected traffic; that is, traffic that may not be restored if the link that carries it fails. However, under some conditions it may not be possible to cover all nodes with a single ring, or the length of the resulting may be undesirable. A large ring forces long routes for many connections. Such long routes have several drawbacks, both from the point of view of routing (reduced wavelength-assignment efficiency) and from the point of view of communications (excessive jitter).

To allow every link to carry protected traffic, other ring-based approaches ensure that every link is covered by a

ring. One approach to selecting such covers is to cover a network with rings so that every link is part of at least one ring [82]. Several issues arise concerning the overlap and interconnection of such rings. Many of these issues are similar to issues encountered in SONET network deployment. The two main issues are management of links logically included in two rings and node management for ring interconnection.

The first issue concerns the case in which a single link is located on two rings. If that link bears a sufficient number of fibers or wavelengths, the two rings can be operated independently over that link, as shown in Fig. 7. However, the resources available to the overlay network may require sharing the resources over that link. Figure 8 shows such a network, in which only a single wavelength is available to the overlay network. In such a case, the logical fibers must be physically routed through available physical fibers, with network management acting to ensure that conflicts are avoided on the shared span. Such operations incur significant overhead.

The second issue relates to node interconnection among rings. Minimizing the amount of fiber required to obtain redundancy using ring covers is equivalent to finding the minimum cycle cover of a graph, an NP-complete problem [83,84], although bounds on the total length of the cycle cover may be found [85].

A more recent approach to ring covers, intended to overcome the difficulties of previous approaches, is to cover every link with exactly two rings, each with two fibers. The ability to perform loopback style restoration over any link in mesh topologies was first introduced in the late 1990s [86,87], using certain types of ring covers. In particular, Ellinas et al. [86] consider link failure restoration in optical networks with arbitrary two-link redundant arbitrary mesh topologies and bidirectional links. The approach is an application of the double-cycle ring cover [88–90], which selects cycles in such a way that each edge is covered by two cycles. For planar graphs, the problem can be solved in polynomial time; for nonplanar graphs, it is conjectured that double-cycle covers exist, and a counterexample must have certain properties unlikely to occur in network graphs [91]. Cycles can be used as rings to perform restoration. Each cycle corresponds to either a primary or a secondary two-fiber ring. Let us consider a link covered by two rings, rings 1 and 2. If we assign a direction to ring 1 and the opposite direction to ring 2, ring-based recovery using the double-cycle cover uses ring 2 to back up ring 1. This recovery technique is similar to recovery in conventional SHRs, except that the two rings that form four-fiber SHRs are no longer collocated over their entire lengths. In the case of four fiber systems, with two fibers in the same direction per ring, we have fiber-based recovery, because fibers are backed up by fibers. Extending this notion to WDM-based loopback, each ring is both primary for certain wavelengths and secondary for the remaining wavelengths. For simplicity, let us again consider just two wavelengths. Figure 9 shows that we cannot assign primary and secondary wavelengths in such a way that a wavelength is secondary or primary over a whole ring.

The use of double-cycle covers can also lead to asymmetric restoration times for a bidirectional connection. In particular, the links and nodes used to recover traffic crossing a link often depend on the direction of the traffic, with each direction being recovered by a separate cycle. The two directions on a link thus have different restoration times and timing jitter, which can lead to

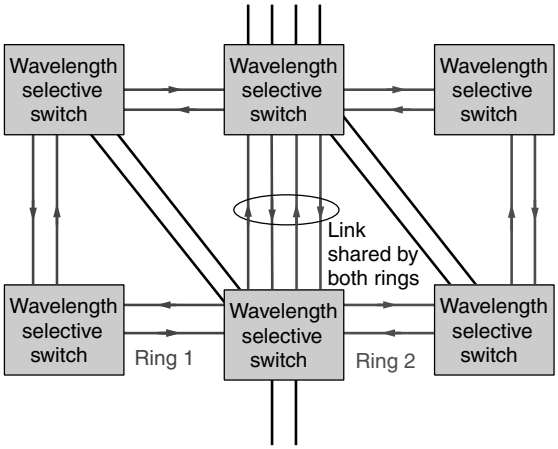

Figure 7. Two rings traversing separate resources over the same link.

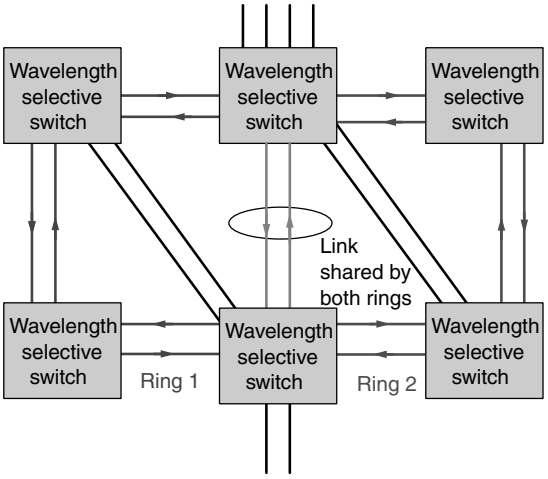

Figure 8. Two rings traversing shared resources over the same link.

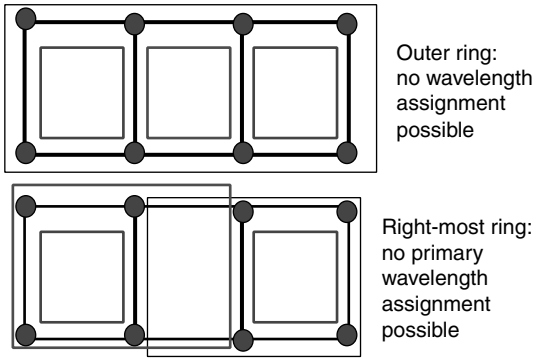

Figure 9. Example showing the problems of applying double cycle covers to wavelength recovery.

problems for bidirectional connections. In contrast, both SHRs and generalized loopback (discussed later in the section) avoid these problems by protecting bidirectional traffic with unique, bidirectional restoration paths.

Cycle covers work well for link failures, but have drawback for recovery from node failures, particularly when failures occur at nodes that are shared by one than one link. While node recovery can be effected with double-cycle ring covers, such restoration requires cumbersome hopping among rings. Moreover, if a link or node is added to a network, the cover of cycles can change significantly, limiting the scalability of double cycle covers. These drawbacks are a general property of ring embeddings, and are already found in SONET networks.

In order to avoid the limitations of ring covers, an approach using preconfigured protection cycles, or p-cycles, is given by Grover and Stamatelakis [92]. A *p-cycle* is a cycle on a redundant mesh network. Links on the p-cycle are recovered by using the p-cycle as a conventional BLSR. Links not on the p-cycle are recovered by selecting, along the p-cycle, a path connecting the nodes at either end of the failed link. Some difficulty arises from the fact that several p-cycles may be required to cover a network, making management among p-cycles necessary. A single p-cycle may be insufficient because a Hamiltonian circuit might not exist, even in a two-connected graph. Even finding p-cycles that cover a large number of nodes may be difficult. Some results [93–95] and conjectures [96,97] exist concerning the length of maximal cycles in two-connected graphs. The p-cycle approach is in effect a hybrid ring approach, which mixes link protection (for links not on the p-cycle) with ring recovery (for links on the p-cycle).

Another approach to link restoration on mesh networks, which we term generalized loopback, was first presented in 1999 [98]. The principle behind generalized loopback is to select a directed graph, called the *primary graph*, such that another directed graph, called the *secondary*, can be used to carry backup traffic for any link failure in the primary. Construction of a primary involves selection of a single direction for each link in the network. Loopback then occurs along the secondary graph in a manner akin to SONET BLSR. Figure 10 demonstrates generalized loopback for a simple network. In the figure, only two fibers per link are shown — one primary fiber and its corresponding secondary fiber. When the link $[Y, X]$ fails, traffic from the primary digraph floods onto the secondary digraph starting at Y. The secondary digraph carries this backup traffic from one endpoint of the failed node to the other endpoint, possibly along multiple paths. When traffic reaches X (along the first successful path), it is again placed on the primary fiber, as though no failure had occurred. Unnecessary backup paths are subsequently torn down. The fact that multiple paths may exist for restoration allows us to reclaim some arcs (fibers) from secondary digraphs to carry additional traffic. The capacity efficiency obtained in this manner is, for typical networks, in the order of 20% over methods, such as double-cycle cover, that require half of the network capacity to be devoted to recovery.

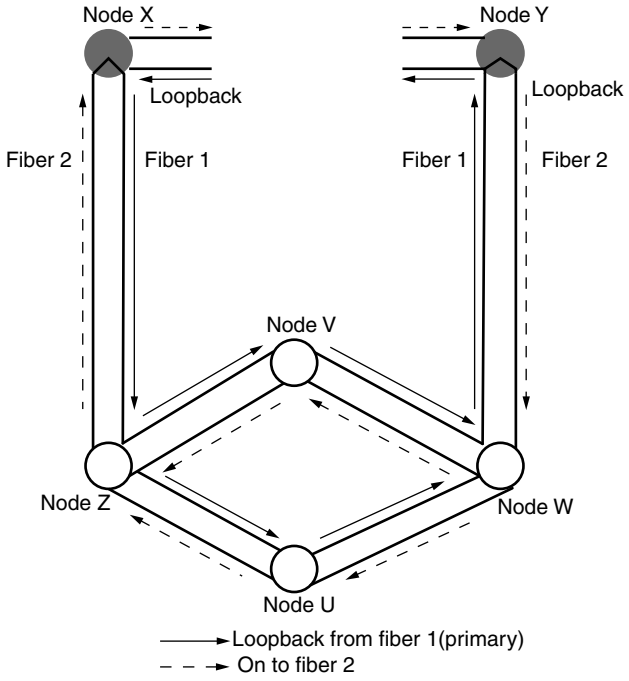

Figure 10. Generalized loopback.

7. PACKET-BASED APPROACHES

This section looks more closely at techniques particular to packet-based networks, giving more details for the failure detection techniques mentioned in Section 2 and the recovery schemes used when failures are detected. Some packet-based networks, such as FDDI, are based on ring topologies and use failure detection and recovery techniques nearly identical to those described in previous sections. For packet networks built with redundant mesh topologies, the approach is substantially different.

One protocol of particular interest and importance was developed in the mid-1980s [99] to allow redundant interconnection of LANs for reliability while avoiding problems of infinite routing loops. The model, known as an extended LAN, uses bridges to connect LANs and to forward traffic between LANs as necessary. The bridges cooperate in a distributed fashion to select a minimum spanning tree (MST) from the full-connectivity graph. All traffic is then routed along the MST, preventing cycles. Periodic configuration messages are sent from the root of the tree and forwarded over all LANs. Failure detection then relies on timeout mechanisms — if a bridge fails to hear the configuration message on any LAN to which it is attached, it acts to find a new route from the spanning tree to that LAN. The simplest method is to restart the search entirely, but some optimizations are possible.

The MST approach serves its purpose, allowing redundant topologies in packet-switched networks without allowing for routing loops. However, restricting traffic to flow along a tree can severely limit the capacity of the extended LAN, and can force traffic between two LANs that are close in the original mesh to follow a long path through the tree, consuming some of the capacity of many other LANs in the process.

Autonet, developed in the early 1990s, solved this problem to some extent by allowing the use of all links in the network [100]. Routing cycles and deadlocks in Autonet were prevented through the use of up*/down* (read "up star, down star," and alluding to regular expressions) routes. With this approach, all routers are assigned a unique number, and packets between two hosts in the network must follow a route that moves in a monotone sequence upward followed by a monotone sequence downward before exiting the network. Any route obeying this constraint can be used. Consider a cycle or self-cycle in routes, and label each link in the cycle as either up or down, depending on the identifiers assigned to the routers at the end of the link. Obviously, a cycle must contain both up and down links, and in particular must contain a two-link section with the first link down and the second up. No route can legally follow both links in this section, however, implying that deadlocks are impossible; thus, all up*/down* routes are mutually deadlock-free. Autonet relied on timeouts built into the switch hardware for detection of failed links and nodes, but was otherwise quite similar to the extended LAN approach in terms of reliability.

Since the early 1990s, many vendors of packet-based networks have recognized the importance of redundancy, and have introduced hardware and software support for combining physical channels into single logical channels between high-end switches. While this approach may seem fairly natural in a packet-based network, in which utilization is already based on statistical multiplexing of the links, some complexities must be addressed. These complexities arise from an assumption by higher-level protocols, in particular the Transmission Control Protocol (TCP), which packets sent through a network arrive in order of transmission. Use of multiple physical routes to carry packets from a single TCP connection often violates this assumption, causing TCP's congestion control mechanisms to drastically cut bandwidth. To address this issue, link aggregation schemes try to restrict individual TCP connections to specific links, and rely on the availability of many connections to provide good load balancing and capacity benefits from aggregation. Failure detection, as with Autonet, is generally handled in hardware, and results in routing reorganization. Unlike many backbone networks, the capacity of most packet-switched networks degrades in the presence of failures, encouraging network architects and managers to operate in somewhat risky modes in which inadequate capacity remains available after certain failures. This phenomenon can be observed even in high-end packet-based systems, including some SAN's backing bank operations.

In the wide area, fault tolerance in packet-switched networks relies on a combination of physical layer notification and rerouting by higher-level routing protocols. The Border Gateway Protocol (BGP) [101], a peer protocol to the Internet Protocol (IP), defines the rules for advertising and selecting routes to networks in the Internet. More specifically, it defines a homogeneous set of rules for interactions between *autonomous systems* (ASs), networks controlled by a single administrative entity. With each AS, administrators are free to select whatever routing protocol suits their fancy, but AS's must interact with each other in a standard way, as defined by BGP. BGP explicitly propagates failure information in the form of withdrawn routes, which cancel previously advertised routes to specific networks.

From the point of view of recovery in the context of optical backbone networks, the overhead required for packet-based systems depends critically on what functionalities are implemented in the optical domain. Restoration, in which, after a failure, excess bandwidth is claimed for the purpose of providing alternate routes to traffic around a failure, is challenging in the optical domain, since it requires operating on the whole datastream and possibly separating packets from a stream. In order to avoid packet-level operations, flow switching on a stream-by-stream basis, for instance using multiprotocol label switching (MPLS), is a promising alternative. Such stream-based operations are more amenable to optical processing. For recovery, stream-based processing reduces roughly to circuit-based recovery.

Packet-switched approaches for optical access seek to perform some subset of the functionalities of traditional opto-electronic packet-based networks optically [102]. These functionalities may be header recognition, buffering, packet insertion, packet reading, packet retrieval, and rate conversion. Performing such operations in the optical domain is challenging and no consensus has emerged regarding implementation. However, certain general statements can be made. Operations, such as buffering a stream, that involve significant timing issues or that introduce loss and distortion on the datastream, tend to be challenging. Replicating a stream, for instance, can be done using passive optical splitters and is therefore relatively straightforward. Merging streams, on the other hand, is challenging because of timing issues. The most challenging operations are the ones performed at the packet level. Again, different levels of difficulty arise. Reading signals from an optical datastream is possible by removing a fraction of the signal power and operating on that fraction. Retrieving a packet (reading the packet and removing it from the stream) is difficult because it involves performing an operation on the whole stream, as well as timing, phase, and polarization issues. Thus, operations such as packet-switching are also challenging because of issues of timing and speed of optical switches. Thus, fully optical packet-switched systems replicating the entire operations of electronic systems are still distant.

8. HIGH-SPEED LANS

The vast majority of the proposed architectures for LANs consist of star topologies or of networks built from combinations of star topologies, in which some type of switch, router, or other type of hub, is placed in the center of a topology and each node is directly connected to the hub [103]. The emergent 10 Gb/s standard (IEEE 802.3ae) for LANs and MANs also allows for optical stars and trees. From the point of reliability, stars present many weaknesses. In particular, a failure at the hub may entail failure of the whole network. However, other failures may occur even without outright failure of the hub. If the hub passively broadcasts, total failure of the hub is unlikely.

However, many partial failure scenarios exist: amplifier failures; port connection failures, at the access nodes or at the hub; transmitter or receiver failures at access nodes, for instance, because of laser failures; or cabling failures in the fiber itself. Such failures entail the failure of one or more arms of the star.

The center of a star topology is inherently a single point of failure, making complete replication of the system necessary to support recovery. Operation of a fully redundant system is difficult, however, as illustrated by existing reliable networks based on star topologies. Many enterprise networks and storage area networks (SANs), for example, are built as stars.

Such systems typically use single-wavelength optical connections rather than WDM, and rely on electronic switching. Enterprise networks are usually based on Gigabit Ethernet (GigE), while SAN's are based on Fibre Channel (FC). Network interface cards (NIC's), housing both a receiver and a transmitter, are optically connected to an electronic switch. The switch is closer to a traditional router than to the passive broadcast hubs or wavelength-selective switches discussed in the context of star-based WDM LANs. For such networks, redundancy is obtained by full duplication of all resources, as shown in Fig. 11.

In addition to replication, the two switches must be connected. Consider the case of failure of the primary NIC in server 1. Server 1 communicates via the secondary switch. Requiring other servers also to communicate via the secondary switch is undesirable. Indeed, although we show just two servers, such networks typically have many servers connected to them and reconfiguring so many connections simultaneously is difficult. Moreover, there is some delay involved in creating new connections through switch 2 owing to initialization overheads. To avoid reconfiguration at all servers, all servers other than server 1 continue to communicate with the primary switch and the two switches communicate with each other via the interswitch connection.

In the context of optical networks, an interswitch connection translates into connection between two hubs. In order to manage such an interhub connection, the hub needs to be equipped with far greater capabilities than simple optical broadcasting. Thus, it would appear that optical star dedicated networks will be difficult to deploy and that the means of providing robustness available in traditional star topologies cannot be easily extended to optical access networks.

The star topology for LAN's connected to a backbone is not limited to optical applications. Such an architecture has been proposed, for instance, for the Integrated Services LAN (ISLAN) defined by IEEE 802.9 using unshielded twisted pair.

While stars and topologies built from stars dominate in the LANs, LANs are also built using bus schemes. Bus schemes allow nodes to place and retrieve traffic using a shared medium. Figure 12 shows a folded bus and a dual bus. In a folded bus, a single bus, originating at a head end, serves all nodes. Typically, nodes use the bus first as a collection bus, onto which they place traffic (in the left-to-right direction in Fig. 12a). The last node folds back the bus to make it travel in the right-to-left direction. In the right-to-left direction, nodes collect traffic placed onto the bus. The traffic may be read only or read and removed. In the dual-bus architecture, two buses are used, each with its own headend. Folded and dual buses are simple options for LANs and certain types of MANs. In particular, they offer an effective way of sharing bandwidth among several users and are therefore attractive to allow nodes to access optical bandwidth, whether for a full fiber, a few wavelengths, or a single wavelength.

Folded and dual buses suffer from reliability drawbacks. Figure 13 shows a folded bus and a dual bus after a failure. Partial recovery can be effected by creating a bus on either side of the failure. For a dual-bus architecture, the node immediately upstream of the failure needs to be

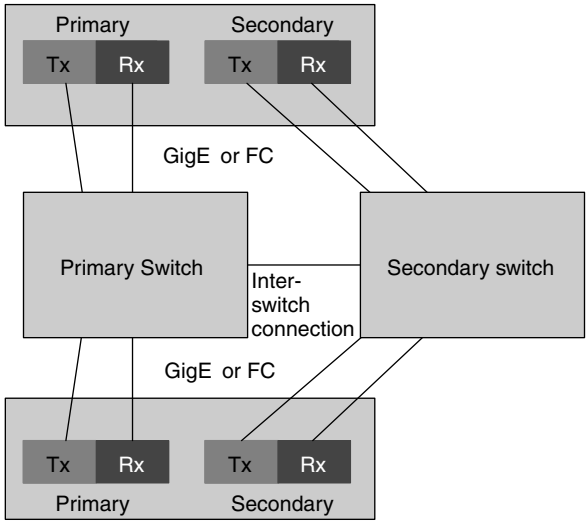

Figure 11. Redundant architecture in an enterprise network or LAN using traditional star topologies.

able to fold the bus. In order to reestablish full connectivity after a failure, the end nodes of the original buses must be able to connect outside the original buses to transmit traffic that was destined to traverse the cut.

BIOGRAPHY

Muriel Medard is an Assistant Professor in the Electrical Engineering and Computer Science (EECS) at MIT and a member of the Laboratory for Information and Decision Systems. She was previously an Assistant Professor at the Electrical and Computer Engineering Department and a member of the Coordinated Science Laboratory at the University of Illinois Urbana — Champaign. From 1995 to 1998 she was a Staff Member at MIT Lincoln Laboratory in the Optical Communications and the Advanced Networking Groups. Professor Medard received B.S. degrees in EECS and Mathematics in 1989, a B.S. degree in Humanities in 1990, a M.S. degree in Electrical Engineering 1991, and a Sc.D. degree in Electrical Engineering in 1995, all from the Massachusetts Institute of Technology (MIT), Cambridge. Medard's research interests are in the areas of reliable communications, particularly for optical and wireless networks. She received a 2001 NSF Career award. She was awarded the IEEE Leon K. Kirchmayer Prize Paper Award 2002 for her paper, "The effect upon channel capacity in wireless communications of perfect and imperfect knowledge of the channel."

NETWORK SECURITY

ROLF OPPLIGER
eSECURITY Technologies
Rolf Oppliger
Bern, Switzerland

1. INTRODUCTION

According to Shirey [1], the term *computer network* (or *network*) refers to, "a collection of host computers together with the subnetwork or internetwork through which they can exchange data." Many different technologies and communication protocols can be used (and are in use) to build and operate computer networks. Examples include the IEEE 802 family of protocols for local area networking, the Point-to-Point Protocol (PPP) for dialup networking, and the TCP/IP protocol suite for internetworking.[1]

Almost all contemporary networking technologies and communication protocols are highly complex and have not been designed with security in mind. Consequently, they

[1] The acronym TCP/IP refers to an entire suite of communications protocols that center around the Transmission Control Protocol (TCP) and the Internet Protocol (IP). The emerging use of TCP/IP networking has led to a global system of interconnected hosts and networks that is commonly referred to as the Internet.

are inherently vulnerable and exposed to a variety of threats and corresponding attacks. To make things worse, there are a number of reasons why networked computer systems are inherently more vulnerable and exposed to threats and corresponding attacks than their standalone counterparts:

- More points exist from where an attack can be launched. Note that a computer system that is inaccessible or unconnectable to users cannot be attacked. Consequently, by adding more network connections (i.e., network connectivity) for legitimate users, more possibilities to attack the system are automatically added, as well.
- The physical perimeter of a networked computer system is artificially extended by having it connect to a computer network. This extension typically leads beyond what is actually controllable by a system administrator.
- Networked computer systems typically run software that is inherently more complex and error-prone. There are many network software packages that have a long bug record and that are known to be "buggy" accordingly (e.g., the UNIX sendmail daemon). More often than not, intruders learn about these bugs before system administrators do. To make things worse, intruders must know and be able to exploit one single bug, whereas system administrators must know and be able to fix all of them. Consequently, the workload between system administrators and potential intruders is asymmetrically distributed.

In essence, the aim of network security is to provide the technologies, mechanisms, and services that are required and can be used to protect the computational and networking resources against accidental and/or intentional threats. Mainly because of the importance of computer networks in daily life, network security is a hot topic today.

This article provides an overview and discussion about the current state -of- the -art and future perspectives in network security in general, and Internet security in particular. As such, it is organized as follows. Possible threats and attacks against computer networks and distributed systems are overviewed and briefly discussed in Section 2. The OSI security architecture is introduced in Section 3. The architecture provides a useful terminology that is applicable to a wide range of networking technologies and corresponding communication protocols. As a case study, Internet security is further addressed in Section 4. Finally, conclusions are drawn and an outlook is given in Section 5. Some parts of this article are taken from Ref. 2. Readers may refer to this reference book to get some further information about network security in general, and Internet security in particular.

2. THREATS AND ATTACKS

A threat refers to "a potential for violation of security, which exists when there is a circumstance, capability, action, or event that could breach security and cause harm [1]. That is, a threat is a possible danger that might exploit a vulnerability." A threat can be either accidental (e.g., caused by a natural disaster) or intentional (e.g., an attack). In the sequel, we focus only on intentional threats and corresponding attacks that may be launched either by legitimate users (i.e., insiders) or — more importantly — outside attackers (i.e., outsiders). All statistical investigations reveal (or confirm) the fact that most attacks are launched by insiders rather than outsiders. This is because insiders generally have more knowledge and possibilities to attack computer systems that store, process or transmit valuable information assets.

Again referring to Shirey [1], an attack is "an assault on system security that derives from an intelligent threat, i.e., an intelligent act that is a deliberate attempt (especially in the sense of a method or technique) to evade security services and violate the security policy of a system." There are many attacks that can be launched against computer networks and the systems they interconnect. Most attacks are due to vulnerabilities in the underlying network operating systems. In fact, the complexity of contemporary network operating systems makes it possible and very likely that we will see an increasingly large number of network-based and software-driven attacks in the future. What we experience today with macro viruses and network worms is only the tip of an iceberg.

With regard to telecommunications, it is common to distinguish between passive and active attacks:

- A *passive attack* attempts to learn or make use of information but does not affect system or network resources.
- An *active attack* attempts to alter system or network resources and affect their operation.

Passive and active attacks are typically combined to more effectively invade a computing or networking environment. For example, a passive wiretapping attack can be used to eavesdrop on authentication information that is transmitted in the clear (e.g., a username and password), whereas this information can later be used to masquerade another user and to actively attack the corresponding computer system. Passive and active attacks are further explored next.

2.1. Passive Attacks

As mentioned above, a passive attacker attempts to learn or make use of information but does not affect system or network resources. As such, a passive attack primarily threatens the confidentiality of data being transmitted. This data may include anything, including, for example, confidential electronic mail messages or usernames and passwords transmitted in the clear. In fact, the cleartext transmission of authentication information is the single most important vulnerability in computer networks today.

In regard to the intruder's opportunities to interpret and extract the information that is encoded in the transmitted data, it is common to distinguish between passive wiretapping and traffic analysis attacks:

- In a *passive wiretapping* attack, the intruder is able to interpret and extract the information that is encoded in the transmitted data. For example, if two parties communicate unencrypted, a passive wiretapper is trivially able to extract all information that is encoded in the data.
- In a *traffic analysis* attack, the intruder is not able to interpret and extract the information that the transmitted data encodes (because, e.g., the information is encrypted for transmission). Instead, *traffic analysis* refers to the inference of information from the observation of external traffic characteristics. For example, if an attacker observes that two companies — one financially strong, the other financially weak — begin to trade a large number of encrypted messages, he/she may infer that they are discussing a merger. Many other examples occur in military environments.

The feasibility of a passive attack primarily depends on the physical transmission media in use and their physical accessibility to potential intruders. For example, mobile communications is inherently easy to tap, whereas metallic transmission media at least require some sort of physical access. Lightwave conductors also can be tapped, but this is technically more challenging and expensive. Also note that the use of concentrating and multiplexing techniques, in general, makes it more difficult to passively attack data in transmission. Because of these difficulties, it is more likely that computer networks are passively attacked at the edge (e.g., local-area network segments that are connected to a wide-area network) than in its core or backbone.

It is, however, also important to note that a passive attacker does not necessarily have to tap a physical communications line. Most network interfaces can operate in a so-called promiscuous mode. In this mode, they are able to capture all frames transmitted on the local area network segment they are connected to, rather than just the frames addressed to the computer systems of which they are part. This capability has many useful purposes for network analysis, testing, and debugging (e.g., by utilities such as etherfind and tcpdump in the case of the UNIX operating system). Unfortunately, the capability also can be used by attackers to snoop on all traffic on a particular network segment. Several software packages are available for monitoring network traffic, primarily for the purpose of network management. These software packages are dual-use, meaning they can, for example, be effective in eavesdropping and capturing email messages or usernames and passwords as they are transmitted over shared media and communication lines.

A number of technologies can be used to protect a network environment against passive wiretapping attacks. For example, switched networks are more difficult to wiretap (because data are not broadcast and sent to all potential recipients). Consequently, the use of switched networks in the local area has had a very positive effect on the possibility to passively attack computer networks. Also, a few tools attempt to detect network interfaces that operate in promiscuous mode. For example, a tool named AntiSniff[2] implements a number of tricks to do so. One trick is to send an Ethernet frame with an invalid MAC address to a system and to encapsulate an Internet Control Message Protocol (ICMP) request packet with a valid IP header in the Ethernet frame (ICMP is the control protocol that complements IP). If the targeted system has a network interface that operates in promiscuous mode, it will grab the frame from the Ethernet segment decapsulate it and properly forward it to the local IP module. The IP module, in turn, will decapsulate and receive the ICMP echo request and eventually return a corresponding ICMP response. As a consequence, the targeted system reacts on something it should not have reacted (i.e., because of the invalid MAC address it should not have received the ICMP request in the first place). Obviously, it is simple to hide a network interface that operates in a promiscuous mode simply by not responding to ICMP requests that are encapsulated in Ethernet frames with invalid MAC addresses. What we are going to see in the future is that tools that can be used to passively wiretap network segments and tools that try to detect these tools play "hide and seek" on network segments. Last but not least, the use of data encryption is both effective and efficient against passive wiretapping attacks. In fact, it is the preferred technology and the technology of choice for network practitioners.

Contrary to passive wiretapping attacks, protection against traffic analyses is much more complicated and requires more sophisticated security technologies. Note that the use of encryption techniques does not protect against traffic analysis attacks. In fact, there are only a few technologies readily available to protect against traffic analysis attacks. Exemplary technologies include traffic padding (as discussed later) and a few privacy-enhancing technologies (PETs), such as onion routing (not addressed in this article). There is a lot of room for further research and development in this area.

2.2. Active Attacks

As mentioned above, an active attacker attempts to alter system or network resources and affect their operation. Consequently, an active attack primarily threatens the integrity or availability of data being transmitted. What this basically means is that the attacker can modify, extend, delete, or replay data units that are transmitted in computer networks and distributed systems.

The underlying reason why most active attacks are possible and fairly easy to launch in computer networks and distributed systems is that the data units that are sent and received are seldom protected in terms of authenticity and integrity. Examples of such data units include Ethernet frames, IP packets, User Datagram Protocol (UDP) datagrams, and Transmission Control Protocol (TCP) segments. Consequently, it is simple to do such things as flooding a recipient and cause a "denial of service" or "degradation of service," spoofing the source of data units or the identity of somebody else, or taking over and "hijacking" established network connections. Active attacks are very powerful and it is possible and very likely that we

[2] *http://www.securitysoftwaretech.com/antisniff/*.

will see many other active attacks being discovered and published in the future.

A number of technologies can be used to protect against some active attacks. Most of these technologies use cryptographic techniques to protect the authenticity and integrity of data units that are transmitted. There are, however, also a number of active attacks that are hard to protect against. Examples include denial-of-service and degradation-of-service attacks, as well as their distributed counterparts (i.e., distributed denial-of-service and degradation-of-service attacks). Similar to the real world, protection against this kind of attacks is very difficult to achieve in the digital world of computer networks. How would you, for example, protect your mailbox in the real world against somebody who fills it up with empty paper sheets? There seems to be no simple answer to this question, and the problem is difficult to address in either the real or digital world. In the digital world the problem is even more worrisome, simply because the corresponding attacks are much simpler (and less expensive) to launch. There are, for example, many tools that automatically fill up the mailboxes of particular victims.

3. OSI SECURITY ARCHITECTURE

According to Shirey [1], a *security architecture* refers to "a plan and set of principles that describe (a) the security services that a system is required to provide to meet the needs of its users, (b) the system elements required to implement the services, and (c) the performance levels required in the elements to deal with the threat environment." As such, a security architecture is the result of applying good principles of systems engineering and addresses issues related to physical security, computer security, communication security, organizational security (e.g., administrative and personnel security), and legal security. This is complicated and difficult to achieve, but it is very important. More often than not, systems and applications are designed, implemented and deployed without having an appropriate security architecture in mind.[3]

To extend the field of application of the reference model for open systems interconnection (OSI), the ISO/IEC JTC1 appended a security architecture as part two of ISO/IEC 7498 in the late 1980s [3]. The OSI security architecture is still valid and in use today. It provides a general description of security services and related security mechanisms, which may be provided by a computer network, and defines the positions within the OSI reference model where the services and mechanisms may be provided. Since its publication, the OSI security architecture has turned out to be a primary reference for network security professionals. In 1991, the ITU-T adopted the OSI security architecture in its recommendation X.800 [4] and the Privacy and Security Research Group (PSRG) of the Internet Research Task Force (IRTF) adopted the OSI security architecture in a corresponding Internet security architecture[4] in the early 1990s. In essence, ISO/IEC 7498-2, ITU-T X.800, and the Internet security architecture describe the same security architecture, and in this article we use the term OSI security architecture to collectively refer to all of them.

In short, the OSI security architecture provides a general description of security services and related security mechanisms and discusses their interrelationships. It also shows how the security services map onto a given network architecture and briefly discusses their appropriate placement within the OSI reference model. Having the abovementioned definition of a security architecture in mind, it is obvious that the OSI security architecture does not conform to it. In fact, the OSI security architecture rather refers to a (terminological) framework and a general description of security services and related security mechanisms than to a full-fledged security architecture. Nevertheless, we use it in this article to serve as a starting point for subsequent discussions.

3.1. Security Services

The OSI security architecture distinguishes among five complementary classes of security services. These classes comprise authentication, access control, data confidentiality, data integrity, and nonrepudiation services. Just as layers define functionality in the OSI reference model, so do security services in the OSI security architecture define various security objectives and aspects relevant for computer networks and distributed systems.

- *Authentication services* provide for the authentication of communicating peers or data origins:
  - A *peer entity authentication service* provides the ability to verify that a peer entity in an association is the one it claims to be. In particular, a peer entity authentication service provides assurance that an entity is not attempting to masquerade or perform an unauthorized replay of some previous association. Peer entity authentication is typically performed either during a connection establishment phase or, occasionally, during a data transfer phase.
  - A *data origin authentication service* allows the sources of data received to be verified to be as claimed. A data origin authentication service, however, cannot provide protection against the duplication or modification of data units. In this case, a data integrity service must be used in conjunction with a data origin authentication service. Data origin authentication is typically provided during a data transfer phase.

  Authentication services are important because they are a prerequisite for proper authorization, access control, and accountability. *Authorization* refers to the process of granting rights, which includes the granting of access based on access rights. Access control refers to the process of enforcing access rights, and accountability to the property that ensures that the actions of a principal may be traced uniquely to this particular principal.

[3] Refer to *http://www.esecurity.ch/security_architectures.pdf* for a white paper that describes the role and importance of having an appropriate security architecture.

[4] This work has been abandoned.

- *Access control services* provide for the protection of system or network resources against unauthorized use. As mentioned above, access control services are often closely tied to authentication services; For instance, a user or a process acting on a user's behalf must be properly authenticated before an access control service can effectively mediate access to system resources. In general, access control services are the most commonly used services in both computer and communication security.
- *Data confidentiality* refers to the property that information is not made available or disclosed to unauthorized individuals, entities, or processes. Thus, *data confidentiality services* provide for the protection of data from unauthorized disclosure:
  - A *connection confidentiality service* provides confidentiality of all data transmitted in a connection.
  - A *connectionless confidentiality service* provides confidentiality of single data units.
  - A *selective field confidentiality service* provides confidentiality of only certain fields within the data during a connection or in a single data unit.
  - A *traffic flow confidentiality service* provides protection of information that may otherwise be compromised or indirectly derived from a traffic analysis.

  The provision of a traffic flow confidentiality service requires fundamentally different security mechanisms than the other data confidentiality services.
- *Data integrity* refers to the property that information is not altered or destroyed in some unauthorized way. Thus, *data integrity services* provide protection of data from unauthorized modifications:
  - A *connection integrity service with recovery* provides integrity of data in a connection. The loss of integrity is recovered, if possible.
  - A *connection integrity service without recovery* provides integrity of data in a connection. In this case, however, the loss of integrity is not recovered.
  - A *selected field connection integrity service* provides integrity of specific fields within the data during a connection.
  - A *connectionless integrity service* provides integrity of single data units.
  - A *selected field connectionless integrity service* provides integrity of specific fields within single data units.

  Note that on a connection, the use of a peer entity authentication service at the start of the connection and a connection integrity service during the connection can jointly provide for the corroboration of the source of all data units transferred on the connection, the integrity of those data units, and may additionally provide for the detection of duplication of data units, for example, by using sequence numbers.
- *Nonrepudiation services* prevent one of the entities involved in a communication from later denying having participated in all or part of the communication. Consequently, they have to provide some sort of protection against the originator of a message or action denying that he/she has originated the message or the action, as well as against the recipient of a message denying having received the message. Consequently, there are two non-repudiation services to be distinguished:
  - A *nonrepudiation service with proof of origin* provides the recipient of a message with a proof of origin.
  - A *nonrepudiation service with proof of delivery* provides the sender of a message with a proof of delivery.

  Nonrepudiation services are becoming increasingly important in the context of electronic commerce (e-commerce) on the Internet [5]. For example, a non-repudiation service with proof of delivery may be important for secure messaging (in addition to any secure messaging scheme that employs digital envelopes and digital signatures). The corresponding service is sometimes also referred to as "certified mail." Certified mail is certainly a missing piece for the more professional use electronic mail.

The security services mentioned in the OSI security architecture can be complemented by anonymity or pseudonymity services. These services are not addressed in this article. Sometimes, the availability of anonymity or pseudonymity services directly contradicts the availability of other security services, such as authentication and access control services.

In either case, a security service can be implemented by one or several security mechanisms. The security mechanisms that are addressed in the OSI security architecture are briefly overviewed next.

3.2. Security Mechanisms

The OSI security architecture distinguishes between specific security mechanisms and pervasive security mechanisms.

3.2.1. Specific Security Mechanisms. The OSI security architecture enumerates the following eight specific security mechanisms:

- *Encipherment*, which refers to the application of cryptographic techniques to encrypt data and to transform it in a form that is not intelligible by an outsider (i.e., somebody not knowing a particular cryptographic key). As such, encipherment can be directly used to protect the confidentiality of data units and traffic flow information or indirectly to support or complement other security mechanisms. Many algorithms and standards can be used for encipherment. Examples include secret key cryptosystems, such as the Data Encryption Standard (DES) and the Advanced Encryption Standard (AES), and public key cryptosystems, such as RSA and ElGamal.

- *Digital signature mechanisms*, which can be used to provide an electronic analog of handwritten signatures for electronic documents. Like handwritten signatures, digital signatures must not be forgeable; a recipient must be able to verify it, and the signer must not be able to repudiate it later. But unlike handwritten signatures, digital signatures incorporate the data (or the hash of the data) that are signed. Different data therefore result in different signatures even if the signatory is unchanged. As of this writing, many countries have or are about the put in place laws for electronic or digital signatures (e.g., the U.S. Electronic Signatures in Global and National Commerce Act). In addition, there are many algorithms and standards that can be used for digital signatures. Examples include RSA, ElGamal, and the Digital Signature Standard (DSS).
- *Access control mechanisms*, which use the authenticated identities of principals, information about these principals, or capabilities to determine and enforce access rights and privileges. If a principal attempts to use an unauthorized resource, or an authorized resource with an improper type of access, the access control function (e.g., the reference monitor) must reject the attempt and may additionally report the incident for the purposes of generating an alarm and recording it as part of a security audit trail. Access control mechanisms and the distinction between discretionary access control (DAC) and mandatory access control (MAC) have been extensively discussed in the computer security literature. They are usually described in terms of subjects, objects, and access rights. A subject is an entity that can access objects. It can be a host, a user, or an application. An object is a resource to which access should be controlled and can range from a single data field in a file to a large program. Access rights specify the level of authority for a subject to access an object, so access rights are defined for each subject/object pair. Examples of UNIX access rights include read, write, and execute. More recently, the idea of role-based access controls (RBACs) has been proposed and adopted by operating system and application software developers.
- *Data integrity mechanisms*, which are used to protect the integrity of either single data units and fields within these data units or sequences of data units and fields within these sequences. Note that data integrity mechanisms, in general, do not protect against replay attacks that work by recording and replaying previously sent messages. Also, protecting the integrity of a sequence of data units and fields within these data units generally requires some form of explicit ordering, such as sequence numbering, timestamping, or cryptographic chaining.
- *Authentication exchange mechanisms*, which are used to verify the claimed identities of principals. In accordance with ITU-T recommendation X.509, the term "strong," is used to refer to an authentication exchange mechanism that uses cryptographic techniques to protect the messages that are exchanged, whereas the term "weak" is used to refer to an authentication exchange mechanism that does not do so. In general, weak authentication exchange mechanisms are vulnerable to passive wiretapping and replay attacks, and the widespread use of weak authentication exchange mechanisms is the single most important vulnerability of contemporary computer networks and distributed systems.
- *Traffic padding mechanisms*, which are used to protect against traffic analysis attacks. Traffic padding refers to the generation of spurious instances of communication, spurious data units, and spurious data within data units. The aim is not to reveal if data that are being transmitted actually represent and encode information. Consequently, traffic padding mechanisms can only be effective if they are protected by some sort of a data confidentiality service. Furthermore, traffic padding is effective in leased lines or circuit-switched networks. It is not particularly useful in packet-switched data networks, such as TCP/IP networks and the Internet.
- *Routing control mechanisms*, which can be used to choose either dynamically or by prearrangement specific routes for data transmission. Communicating systems may, on detection of persistent passive or active attacks, wish to instruct the network service provider to establish a connection via a different route. Similarly, data carrying certain security labels may be forbidden by a security policy to pass through certain networks or links.
- Notarization mechanisms, which can be used to assure certain properties of the data communicated between two or more entities, such as its integrity, origin, time, or destination. The assurance is provided by a trusted third party (TTP) in a testifiable manner.

There are many products that implement specific security mechanisms to provide one (or several) security service(s).

3.2.2. Pervasive Security Mechanisms. Pervasive security mechanisms are not specific to any particular security service and are in general directly related to the level of security required. Some of these mechanisms can also be regarded as aspects of security management. The OSI security architecture enumerates the following five pervasive security mechanisms.

- The general concept of *trusted functionality* can be used to either extend the scope or to establish the effectiveness of other security mechanisms. Any functionality that directly provides, or provides access to, security mechanisms should be trustworthy.
- System resources may have *security labels* associated with them, for example, to indicate sensitivity levels. It is often necessary to convey the appropriate security label with data in transit. A security label may be additional data associated with the data transferred or may be implicit (e.g., implied by the use of a specific key to encipher data or implied by the context of the data such as the source address or route).

- Security-relevant *event detection* can be used to detect apparent violations of security.
- A *security audit* refers to an independent review and examination of system records and activities to test for adequacy of system controls, to ensure compliance with established policy and operational procedures, to detect breaches in security, and to recommend any indicated changes in control, policy, and procedures. Consequently, a *security audit trail* refers to data collected and potentially used to facilitate a security audit.
- *Security recovery* deals with requests from mechanisms such as event handling and management functions, and takes recovery actions as the result of applying a set of rules.

The OSI security architecture can be used to discuss the security properties of any computer network. In the following section, it is used to discuss Internet security as a case study. Similar discussions could be held for any other networking technology, such as wireless networks (e.g., GSM, GPRS, and UMTS networks).

4. CASE STUDY: INTERNET SECURITY

Today, the Internet is omnipresent and issues related to network security are best illustrated using the Internet as a working example for an international information infrastructure. In the past, we have seen many network-based attacks, such as password sniffing, IP spoofing and sequence number guessing, session hijacking, flooding, and other distributed denial of service attacks, as well as exploitations of well-known design limitations and software bugs. In addition, the use and wide deployment of executable content, such as that provided by Java applets and ActiveX controls, for example, have provided new possibilities to attack hosts and entire sites.

There are basically three areas related to Internet security: access control, communication security, and intrusion detection and response. These areas are reviewed next.

4.1. Access Control

In days of old, brick walls were built between buildings in apartment complexes so that if a fire broke out, it would not spread from one building to another. Quite naturally, these walls were called *firewalls*. Today, when a private TCP/IP network (i.e., a corporate intranet) is connected to a public TCP/IP network (e.g., the Internet), its users are usually enabled to communicate with the outside world. At the same time, however, the outside world can interact with the private network and its computer systems. In this situation, an intermediate system can be plugged between the private network and the public network to establish a controlled link, and to erect a security wall or perimeter. The aim of the intermediate system is to protect the private network from network-based attacks that originate from the outside world, and to provide a single choke point where security (i.e., access control) and audit can be imposed. Note that all traffic in and out of the private network can be enforced to pass through this single, narrow choke point. Also note that this point provides a good place to collect information about system and network use and misuse. As a single point of access, the intermediate system can record what occurs between the private network and the outside world. Quite intuitively, these intermediate systems are called *firewall systems*, or *firewalls* in short.

In essence, a firewall system represents a blockade between a privately owned and protected network, which is assumed to be secure and trusted, and another network, typically a public network or the Internet, which is assumed to be nonsecure and untrusted. The purpose of the firewall is to prevent unwanted and unauthorized communications into or out of the protected network. Therefore, it is necessary to define what the terms "unwanted" and "unauthorized" actually mean. This is a policy issue and the importance of an explicitly specified network security or firewall policy is not readily understood today.

In addition to the physical firewall analogy mentioned above, there are many other analogies that may help to better understand and motivate for the use of firewalls. Examples include the tollbooth on a bridge, the ticket booth at a movie theater, the checkout line at a supermarket, the border of a country, and the fact that apartments are usually locked at the entrance and not necessarily at each door. These analogies illustrate the fact that it sometimes makes a lot of sense to aggregate security functions at a single point. A firewall is conceptually similar to locking the doors of a house or employing a doorperson. The objective is to ensure that only properly authenticated and authorized people are able to physically enter the house. Unfortunately, this protection is not foolproof and can be defeated with enough effort. The basic idea is to make the effort too big for an average burglar, causing the burglar to eventually go away and find another, typically more vulnerable, house. However, just in case the burglar does not go away and somehow manages to enter the house, we usually lock up our valuable goods in a safe. According to this analogy, the use of a firewall may not always be sufficient, especially in high-security environments in which we live these days.

Roughly speaking, a firewall is a collection of hardware, software, and policy that is placed between two networks to control data traffic from one network to the other (and vice versa). There are several technologies that can be used to build firewall systems. Examples include (static or dynamic) packet filters, circuit-level gateways (e.g., SOCKS servers), and application-level gateways (i.e., proxy servers). These technologies are usually combined in either a dual-homed firewall or screened subnet firewall configuration with one or several demilitarized zones (DMZs). You may refer to Ref. 2 for an overview and discussion of firewall configurations. In either case, a network security or firewall policy must specify what protocols and services are authorized to traverse the firewall. Typically, a firewall implements a policy that does not restrict outbound connections, but that requires inbound connection to be strongly authenticated by a corresponding application-level gateway. Strong authentication can

be based on one-time password systems, such as SecurID or S/Key, or challenge–response mechanisms.

Today, the market for firewalls is mature and the corresponding products start to differentiate themselves through the provision of additional functionality, such as network address translation (NAT), content screening (e.g., virus scanning), virtual private networking, and intrusion detection. As such, firewalls are likely to stay in corporate environments to provide basic access control and complementary security services to intranet systems.

4.2. Communication Security

According to Shirey [1], the term *communication security* refers to "measures that implement and assure security services in a communication system, particularly those that provide data confidentiality and data integrity and that authenticate communicating entities." The term is usually understood to include cryptographic algorithms and key management methods and processes, devices that implement them, and the lifecycle management of keying material and devices. For all practical purposes, key management is the Achilles heel of any communication security system, and it is certainly the point where an attacker would start with.

Several (cryptographic) security protocols have been developed, proposed, implemented, and partly deployed on the Internet:

- On the *network access layer*, several layer 2 tunneling protocols are in use. Examples include the Point-to-Point Tunneling Protocol (PPTP) and the Layer 2 Tunneling Protocol (L2TP). L2TP is often secured with IPsec as discussed next.
- On the *Internet layer*, several layer 3 tunneling protocols are in use. Most importantly, the IETF (IP security) IPSEC WG has developed and standardized an IPsec protocol with a corresponding key management protocol called Internet Key Exchange (IKE). The IPsec and IKE protocols are in widespread use for virtual private networking. Most firewalls implement the protocols to interconnect network segments or mobile systems.
- On the *transport layer*, several (cryptographic) security protocols layered on top of TCP are in widespread use. Examples include the Secure Sockets Layer (SSL) and the Transport Layer Security (TLS) protocols. These protocols are sometimes also referred to as "session layer security protocols." Unfortunately, there is currently no widely deployed transport layer security protocol layered on top of UDP. This is unfortunate, because SSL/TLS does not provide a solution for UDP-based applications and application protocols.
- On the *application layer*, there are a number of (cryptographic) security protocols that are either integrated into specific applications and application protocols or provide a standardized application programming interface (API). The first class leads to security-enhanced application protocols, such as secure Telnet and secure FTP, whereas the second class leads to authentication and key distribution systems, such as Kerberos. With its use in UNIX and Microsoft operating systems (e.g., Windows 2000 and Windows XP), Kerberos is the most widely deployed authentication and key distribution system in use today.

Above the application layer, there are a few (cryptographic) security protocols that can be used to cryptographically protect messages before they are actually transmitted in computer networks. Examples include Pretty Good Privacy (PGP) and Secure MIME (S/MIME). Another possibility is to use the eXtended Markup Language (XML) with its security features that are currently being standardized by the World Wide Web Consortium (W3C).

Given this variety of (cryptographic) security protocols for the various layers in the Internet model, one may ask what protocol is best or which layer that is best suited to provide security services for Internet applications and users. Unfortunately, both questions are difficult to address and may require different answers for different security services. For example, data confidentiality services can be provided at lower layers, whereas nonrepudiation services are more likely to be provided at higher layers. In either case, the end-to-end argument applies [6]. Roughly speaking, the end-to-end argument states that the function in question (e.g., a security function) can completely and correctly be implemented only with the knowledge of the application standing at the endpoints of the communications system. Therefore, providing that function as a feature of the communications system itself is not possible (sometimes an incomplete version of the function provided by the communications system may be useful as a performance enhancement). This argument should always be kept in mind when network providers argue that security functions can easily be outsourced.

4.3. Intrusion Detection and Response

An *intrusion* refers to a sequence of related actions by a malicious adversary that results in the occurrence of unauthorized security threats to a target computing or networking domain. Similarly, the term *intrusion detection* refers to the process of identifying and responding to intrusions. This process is not an easy one. Nevertheless, there is an increasingly large number of tools that can be used to automate intrusion detection. The tools are commonly referred to as *intrusion detection systems* (IDSs). Although the research community has been actively designing, developing, and testing IDSs for more than a decade, corresponding products have received wider commercial interest only relatively recently. Furthermore, the IETF has chartered an Intrusion Detection Exchange Format (IDWG) WG "to define data formats and exchange procedures for sharing information of interest to intrusion detection and response systems, and to management systems which may need to interact with them."

There are basically two technologies that can be used to implement IDSs: attack signature recognition and anomaly detection.

1. Using *attack signature recognition*, an IDS uses a database with known attack patterns (also known as attack signatures) and an engine that uses this database to detect and recognize attacks. The database can either be local or remote. In either case, the quality of the IDS is as good as the database and its attack patterns as well as the engine that makes use of this database. The situation is similar and quite comparable to the antivirus software (i.e., the database must be updated on a regular basis).
2. Using *anomaly detection*, an IDS uses a database with a formal representation of "normal" (or "normal-looking") user activities and an engine that makes use of this database to detect and recognize attacks. For example, if a user almost always starts up his/her email user agent after having successfully logged onto a system, the IDS's engine may get suspicious if this user starts a Telnet session to a trusted host first. The reason for this activity may be an attacker misusing the account to gain illegitimate access to a remote system. Again, the database can either be local or remote, and the quality of the IDS is as good as the database and its statistical material.

Obviously, it is possible and useful to combine both technologies in a single IDS. The design of IDSs is a new and very active area of research and development. Many technologies that had originally been developed under the umbrella of artificial intelligence (AI) are being reused and applied to the problem of how to reliably detect intrusions. Exemplary technologies include knowledge-based systems, expert systems, neural networks, and fuzzy logic. In fact, some of these technologies have experienced a revival in the field of intrusion detection.

Once an intrusion is detected, it is important to respond in appropriate ways. Therefore, large organizations usually establish and maintain an incidence response team (IRT). For smaller organizations, it is usually more efficient to outsource this task to a commercially operating IRT.

5. CONCLUSIONS AND OUTLOOK

Network security is a hot topic today. Like many other topics related to IT security, network security has many aspects and the OSI security architecture may serve as a primary reference to structure them. In this article, we introduced the OSI security architecture and elaborated on the current state-of-the-art and future perspectives of network security in general, and Internet security in particular. More specifically, we looked into three areas that are particularly important for Internet security: access control, communication security, and intrusion detection and response.

The network security industry has shifted away from an industry that focused primarily on the use of preventive security technologies to an industry that also takes into account the importance of detective and reactive security technologies (under the term "detection and response"). The major argument for this paradigm shift is the insight that preventive security technologies are not complete in the sense that they will always leave vulnerabilities that are still exploitable by attackers, and that administrators must know how to detect attacks and counteract on them. Consequently, detection and response is equally important to prevention and an increasingly large number of companies are providing (security) monitoring services to their customers [7]. The importance of detection and response is likely to continue in the future and we will see many companies starting to specialize in this particular field.

BIOGRAPHY

Rolf Oppliger studied computer science, mathematics, and economics at the University of Berne, Switzerland, where he received M.Sc. and Ph.D. degrees in computer science in 1991 and 1993, respectively. In 1999, he received the Venia legendi for computer science from the University of Zürich, Switzerland. The focus of his professional activities is information technology (IT) security in general, and network security in particular. He has authored nine books, including, for example, the second editions of *Internet and Intranet Security* (Artech House, 2002) and *Security Technologies for the World Wide Web* (Artech House, 2003), frequently speaks at security-related conferences, and regularly publishes papers and articles in scientific magazines and journals. He's the founder and owner of eSECURITY Technologies Rolf Oppliger (www.esecurity.ch), Gümligen, Switzerland works for the Swiss Federal Strategy Unit, Bern, Switzerland, for Information Technology (FSUIT), teaches at the University of Zürich, and serves as editor for the Artech House Computer Security Series and the Swiss digma magazine for data law and information security. He's a member of the Association for Computing Machinery (ACM), the IEEE Computer Society, and served as vice chair of the IFIP TC 11 working group on network security.

NETWORK TRAFFIC MANAGEMENT

SONIA FAHMY
Purdue University
West Lafayette, Indiana

1. INTRODUCTION

Communication networks have experienced tremendous growth in size, complexity, and heterogeneity since the late 1980s. With the surging popularity of many diverse Internet applications and the increase in content distribution, a "tragedy of the commons" situation has arisen where access must be controlled and congestion must be avoided. Internet traffic can be classified according to the application generating it. A representative list of applications includes video, voice, image, and data in conversational, messaging, distribution, and retrieval modes. These applications are either inelastic (real time), which require end-to-end delay bounds, or elastic, which can wait for data to arrive. Real-time applications can be further subdivided into those that are intolerant to delay, and those that are more tolerant, called *delay-adaptive*. This chapter surveys the required network traffic management building blocks for both types of application traffic. We begin by discussing traffic management objectives and components, and then devote a section for each of these components. We also include a number of case studies that illustrate how these traffic management components can be used to compose services for Internet applications.

1.1. Traffic Management Objectives

Traffic management aims at delivering a negotiated quality of service (QoS) to applications and at controlling congestion. This implies that critical or real-time application traffic may be given better service at network nodes than less critical traffic. In addition, congestion must be controlled to avoid the performance degradation and congestion collapse that occur when network buffers overflow and packets are lost. The network load should not increase beyond a certain optimal operating point, commonly known as the "knee" of the delay throughput curves. This is the point beyond which increasing the load level on the network results in a dramatic increase in end-to-end delay, caused by network congestion and retransmissions. Therefore, the objectives of network traffic management include

1. *Fairness*. Traffic sources should be treated according to some fairness criteria, such as (weighted) max–min fairness (with or without minimum guarantees) [8,42,48], or proportional fairness, which can be tied to pricing through appropriate utility functions [21,52]. *Max–min fairness* gives equal (or weighted) shares to sources sharing a common bottleneck. This means that the share of the constrained (min) sources is maximized, and excess resources are distributed equally among unconstrained sources. Given a configuration with n contending sources, suppose that the ith source is allocated a bandwidth x_i. The allocation vector $\{x_1, x_2, \ldots, x_n\}$ is feasible if all link load levels are less than or equal to 100%. Given an allocation vector, the source with the smallest allocation is, in some sense, the "unhappiest source." We find the feasible vectors that give the maximum allocation to this unhappiest source (thus maximizing the minimum source, or max–min). Then, we remove this "unhappiest source" and reduce the problem to that of the remaining $n - 1$ sources operating on a network with reduced link capacities. We repeat this process until all sources have been allocated the maximum that they can obtain.
2. *Efficient Resource Utilization*. The available resources, such as network buffers, network link bandwidths, processing capabilities, proxy servers, should be efficiently utilized.
3. *Bounded Queuing Delay*. Queuing delay should be small to guarantee low end-to-end delay according to application QoS requirements, and to ensure buffers do not overflow and cause excessive packet loss. Guarantees made to an application can be either deterministic (given for all packets), or statistical. Statistical guarantees can be made in steady state or over specific intervals of time, for instance, over no more than $x\%$ of time intervals will have more than $y\%$ of the packet delays exceed 5 ms.
4. *Stability*. The transmission rates of the sources should not unnecessarily fluctuate in steady state.
5. *Fast Transient Response*. Traffic sources should react rapidly to changing network conditions, such as sudden congestion. Performance should be acceptable even when there is no steady state. Thus, traffic management operations should be robust.
6. *Simplicity*. "Occam's Razor" dictates that entities are not to be multiplied beyond necessity. Traffic management algorithms should have reasonable time and space complexity. This includes scaling to large numbers of users.

Note that traffic management and congestion avoidance are dynamic problems. Static solutions such as increasing buffer size, bandwidth and processing power [43–46], namely, overprovisioning, do not sufficiently address dynamic application needs, especially when some traffic sources are not well behaved.

1.2. Traffic Management Building Blocks

Network traffic management has witnessed a flurry of research activity, especially since the late 1970s. We will use the terms *microflow*, *connection*, and *session* to denote a data stream identified by fields in the Internet Protocol (IP) and the Transmission Control Protocol (TCP) or User Datagram Protocol (UDP) headers, such as source and destination address, protocol identifier, and source and destination ports. The datastream may be unicast (point-to-point), multicast (point-to-multipoint, or multipoint-to-multipoint) from a sending application to a set of receiving applications. We will use *flow* to denote either a microflow or an aggregate of microflows (a macroflow). We will use *end system* to denote a sender,

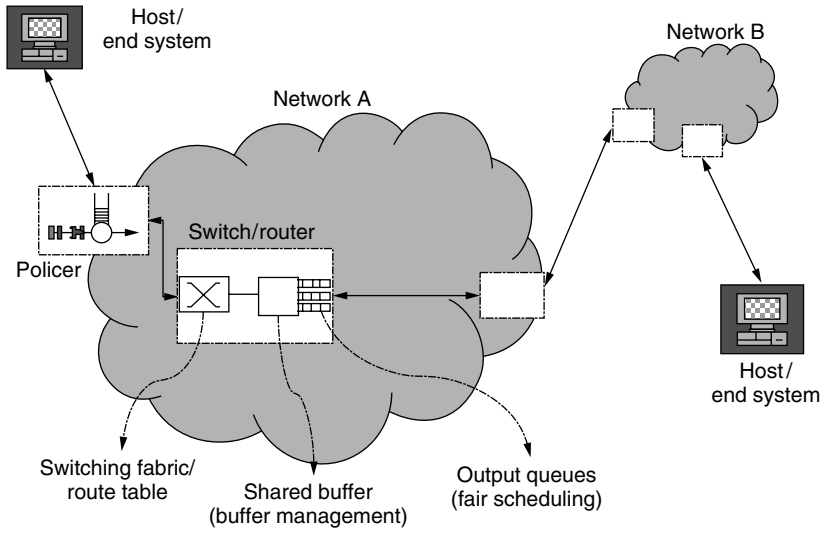

Figure 1. A network can use shaping or policing at the edge, and buffer management and scheduling at core routers and switches to meet guarantees. In combination with constrained routing, admission and policy control, and resource reservation, QoS is provided. Feedback-based congestion control is used to adapt to network conditions.

a receiver, or an edge router. An edge router can be an *ingress* router if it is at the entrance of a domain (with respect to a particular flow or connection); or an *egress* router if it is at the exit of a domain.

Figure 1 illustrates the traffic management components. Constrained routing, connection admission control, policy control, and resource reservations (not shown) are required to ensure that sufficient resources exist for QoS guarantees to be met. Once this is done, traffic shaping and policing, scheduling, and buffer management are required to control resource usage and provide QoS, as shown in the figure. Finally, traffic monitoring and feedback control are important to avoid congestion collapse in computer networks.

An interesting point to note is that the traffic management components bear some similarities to traffic management on transportation highways. For example, an analogy can be drawn between traffic shaping and stoplights that control traffic merging onto a highway on-ramp. Network traffic policing is also analogous to traffic patrol cars that stop speeding vehicles. Packet scheduling resembles several lanes merging onto one lane, or stop signs or lights that control traffic proceeding through an intersection. Buffer management is, in some sense, similar to traffic exiting the highway through various offramps. Finally, constrained routing and congestion control are in some sense similar to listening to traffic reports on your radio and deciding on alternative routes (constrained routing), or deciding not to leave your home yet, if critical highways are congested (congestion control).

The traffic management components in data networks are summarized in Table 1. Admission and policy control, resource reservation and constrained routing are typically performed at a coarse timescale, such as the connection setup time and during renegotiation. Thus we will refer to them as *session-level* (or *connection-level*) operations. Congestion control is invoked as a reaction to network state, and hence the response to network state is on the order of a burst or a round-trip time (time to send a packet from the source to the destination and time to receive feedback back to the source). The remaining traffic management components, namely, traffic shaping, policing, scheduling and buffer management, are performed at the packet level at network switches and routers. Other operations, such as capacity planning and pricing [18,58], operate on timescales on the order of connections, days, or even weeks, and we do not include those in our discussion.

As listed in the fourth column of Table 1, some of the traffic management mechanisms operate at end systems (sources or edge routers) such as traffic shaping; some operate at network switches or routers such as buffer management; and some require both end systems and network switches to cooperate such congestion control using explicit feedback from the network. Congestion control is a closed-loop form of control, while the other operations are typically open-loop, although they may sometimes use measurement to perform better decisions. In the case studies (Section 6), we will see how these building blocks are used in the Internet integrated (IntServ) and differentiated (DiffServ) services, in asynchronous transfer mode (ATM), and with traffic engineering (TE) for label-switched paths.

2. CONSTRAINT-BASED ROUTING

Several routing algorithms that base path selection decisions on policy or quality of service (QoS) have been proposed for the Internet since the mid 1990s. Constraint-based routing usually considers flow aggregates (also known as *macroflows* or *trunks*), rather than individual micro-flows (e.g., a single HTTP connection). Routing constraints may be imposed by administrative policies (Section 2.1), or by the application QoS requirements (Section 2.2).

2.1. Policy Routing

Policy-based routing chooses paths conformant to administrative rules and service agreements. With policy-based routing schemes, the administrators can base routing decisions not only on the destination location but also on factors such as the applications, the protocols used, the size of packets, or the identity of end systems. As the Internet

Table 1. Traffic Management Components and Their Timescales

Timescale	Component	Definition	Location	Open/Closed-Loop
Session level	Admission control	Determines if a new connection/flow requirements can be met without affecting existing connections	Routers/end systems	Open/measured
	Policy control	Determines if a new connection/flow has the administrative permissions to be admitted	Routers/end systems	Open
	Resource Reservation	Sets up resource reservations in network nodes for an admitted connection/flow	Routers/end systems	Open/measured
	Constrained routing	Selects a path based on requirements that are either administrative-oriented (policy-based routing) or service-oriented (QoS routing)	Routers/end systems	Open/measured
Round-trip time (burst level)	Congestion control	Controls the input load to the optimal operating point	End systems with or without router assistance	Closed
Packet level	Traffic shaping	Delays selected packets to smooth bursty traffic	End systems	Open
	Traffic policing	Drops selected packets to conform to a traffic profile	End systems	Open
	Packet scheduling	Determines which packet to transmit next onto the output link	Routers/end systems	Open
	Buffer management	Determines which packets to admit into a buffer	Routers/end systems	Open

continues to grow and diverse Internet services are offered, more stringent administrative constraints can ensure adequate service provisioning and safety from malicious users attempting to obtain services that do not conform to their service agreements or profiles without paying for such services. Policy-based routing can also provide cost savings, load balancing, and basic QoS. Policy constraints are applied before the application of the required QoS constraints (Section 2.2). Policy constraints may be exchanged by the routing protocols while updating route information, or simply provided manually during network configuration. In the latter case, the main problem that may occur is policy rule conflicts.

2.2. QoS Routing

QoS routing can be defined as "a routing mechanism under which paths for flows are determined based on some knowledge of resource availability in the network as well as the QoS requirement of flows" [20]. As most deployed Internet routing strategies are developed for the best-effort model, they are sometimes unsuitable for emerging real-time application requirements. QoS routing extends the best-effort paradigm by finding alternate routes for forwarding flows that cannot be admitted on the shortest existing path. Unlike connectionless best-effort schemes, QoS routing is connection-oriented with resource reservation. QoS routing, however, determines a path only from a source to a destination and does not reserve any resources on that path [80]. A resource reservation technique such as RSVP (Section 6.1) or ATM UNI must then be employed to reserve the required resources. After a path is found and resources are reserved, all packets of the QoS flow must be forwarded through that path. This means that the path must be fixed throughout the lifetime of the flow. This is called "route pinning."

QoS routing dynamically determines feasible paths that also optimize resource usage. Many factors affect the performance of QoS routing solutions, including the particular QoS routing scheme used, the accuracy of information that the QoS routing scheme uses, the network topology, and the network traffic characteristics [63]. A key problem that arises with QoS routing is tractability. Optimizing a path for two or more quality metrics is intractable if the quality metrics are independent and allowed to take real or unbounded integer values [64]. If all metrics except one take bounded integer values, or if all the metrics except one take unbounded integer values but the maximum constraints are bounded, then the problem can be solved in polynomial time [2]. More recent studies show the possibility of performing QoS routing with inaccurate information without suffering significant loss in performance. It was also shown that applying aggregation techniques for scalability does not always negatively impact performance.

3. ADMISSION CONTROL

The Internet protocol (IP) currently supports a best effort service, where no delay or loss guarantees are provided. This service is adequate for non-time-critical applications, or time critical applications under light-load conditions. Under highly overloaded conditions,

however, buffer overflows and queuing delays cause the real-time communication quality to quickly degrade. To support real time applications, a new service model was designed [12]. In this model, both real-time and non-real-time applications share the same infrastructure, thus benefiting from statistical multiplexing gains.

Applications specify their traffic characteristics and their quality of service requirements. Admission control is employed to determine whether these requirements can be met. If they can be met, reservations are made, as discussed in Section 5. Using different classification, policing, shaping, scheduling, and buffer management rules, different applications are serviced with different priorities to ensure that the quality of service requirements are met.

Therefore, admission control is the process where, given the current set of connections and the *traffic characteristics* of a new connection, a decision can be made on whether it is possible to meet the new connection *quality of service requirements*, without jeopardizing the performance of existing connections. Traffic characteristics are commonly described by traffic descriptors. These typically include a subset of the following components: a peak rate, an average rate, and the maximum burst size, that can be enforced by a token bucket or leaky bucket (described in Section 7). For example, in ATM networks the generic cell rate algorithm (GCRA) is used to enforce the peak rate (PCR/CDVT) and average (sustained) rate (SCR/BT) parameters, and the maximum burst size (MBS). QoS requirements are negotiated by the source with the network and used to define the expected quality of service provided by the network. The parameters typically include a maximum delay, delay variation (jitter) and packet loss ratio. For each service, the network guarantees the negotiated QoS parameters if the end system complies with the negotiated traffic contract. For noncompliant traffic, the network need not maintain the QoS objective.

Note that existing connections are accounted for in the admission control algorithm in several possible ways. The declared traffic characteristics of existing connections can be used in the QoS computations. Alternatively, measurement-based admission control (MBAC) can be used, where the new connection declared traffic characteristics are combined with the *measured* traffic characteristics of existing connections, in order to compute whether the QoS would be acceptable to the new connection [49]. This, however, assumes that past measurements are sufficiently correlated with future behavior, which may not always hold. More recently, endpoint admission control has been proposed, where the hosts (the endpoints) probe the network to detect the level of congestion. The host admits a new flow only if the level of congestion is sufficiently low [15].

4. POLICY CONTROL

It is important to firmly control which users are allowed to reserve resources, and how much resources they can reserve. Network managers and service providers must be able to monitor, control, and enforce use of network resources and services based on policies derived from criteria such as the identity of users and applications, traffic or bandwidth requirements, security considerations, or time of day or week. Figure 2 depicts the typical policy control architecture (standardized for the Internet). In this model, a protocol called *Common Open Policy Service* (COPS) is used for policy rule exchange between a policy server [referred to as a *policy decision point* (PDP)] and a network device [referred to as a *policy enforcement point* (PEP)] [11]. The *Lightweight Directory Access Protocol* (LDAP) is used for policy rule retrieval from a policy repository. A policy repository is a server dedicated to the storage and retrieval of policy rules. The Policy Management Console is the coordinator of the entire policy management process.

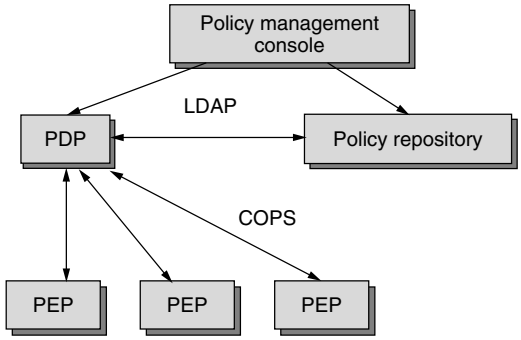

Figure 2. LDAP is used to retrieve the rules from the policy server, and COPS exchanges policy rules among the PDP and PEPs.

5. RESOURCE RESERVATION

A resource reservation protocol is the means by which applications communicate their requirements to the network in an efficient and robust manner. Applications that receive real-time traffic inform the network of their needs, while applications that send real-time traffic inform the receivers and network about their traffic characteristics. The reservation protocol is a "signaling" protocol (a term originating from telephone networks) that installs and maintains reservation state information at each router along the path of a stream. The reservation protocol does not provide any network service; it can be viewed as a "switch state establishment protocol," rather than just a resource reservation protocol. The protocol transfers reservation data as opaque data — it can also transport policy control and traffic control messages.

Resource reservation protocols interact with the *admission control process* to determine whether sufficient resources are available to make the reservation, and the *policy control process* to determine whether the user has permission to make the reservation. If the reservation process gets an acceptance indication from both the admission control and policy control processes, it sends the appropriate parameter values to the packet classifier and packet scheduler. The *packet classifier* determines the QoS class of packets according to the requirements, and the *packet scheduler* (Section 8) and *buffer manager* (Section 9) manage various queues to guarantee the required quality of service. For example, to guarantee the bandwidth and

delay characteristics reserved, a fair packet scheduling scheme can be employed. Fair scheduling isolates datastreams and gives each stream a percentage of the bandwidth on a link. This percentage can be varied by applying weights derived from the reservations [30].

In ATM networks, the User-Network Interface (UNI) protocol establishes resource reservations. In the integrated services framework, the RSVP protocol is used, as discussed in Section 6.1.

6. EXAMPLE ARCHITECTURES

Before we discuss the packet-level and burst-level traffic management components, we will look at four architectures to see how the connection-level building blocks are composed to provide various services.

6.1. Integrated Services and RSVP

An example of a multiservice network is the integrated services framework, which requires resources to be reserved a priori for a given traffic *microflow*. The integrated services framework maps the three application types (delay-intolerant, delay-adaptive, and elastic) onto three service categories: the guaranteed service for delay intolerant applications, the controlled load service for delay adaptive applications, and the currently available best-effort service for elastic applications. The guaranteed service gives firm bounds on the throughput and delay, while the controlled load service tries to approximate the performance of an unloaded packet network [12,81].

Figure 3 illustrates the components of an integrated services router. The Resource Reservation Protocol (RSVP) [13] is the signaling protocol adopted to establish resource reservations state for both unicast and multicast connections. An RSVP sender uses the PATH message to communicate with receiver(s) informing them of microflow characteristics. RSVP provides receiver-initiated reservation of resources, using different reservation *styles* to fit a variety of applications. RSVP receivers periodically alert networks to their interest in a data microflow, using RESV messages that contain the source IP address of the requester and the destination IP address, usually coupled with microflow details. The network then allocates

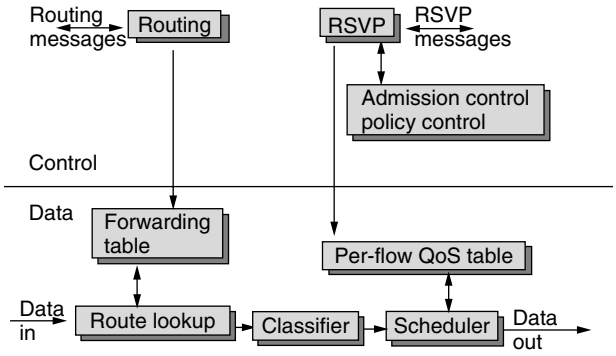

Figure 3. A router with QoS (integrated services) capabilities. RSVP interfaces with admission and policy control, and stores reservation information in a QoS table that is consulted when forwarding a flow.

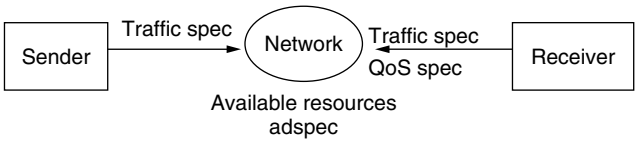

Figure 4. The RSVP sender announces its traffic specifications, and the receiver announces its QoS requirements. The network available resources are checked to see the requested QoS for this traffic can be supported.

the required bandwidth and defines priorities, as shown in Fig. 4. RSVP decouples the packet classification and scheduling from the reservation operation, transporting the messages from the source and destination as opaque data. Periodic renewal of state (soft state) allows networks to be self-correcting despite routing changes and loss of service. This enables routers to understand their current topologies and interfaces, as well as the amount of network bandwidth currently supported.

An RSVP reservation request consists of a **FlowSpec**, specifying the desired QoS, as well as a **FilterSpec**, defining the flow to receive the desired QoS. The FlowSpec is used to set parameters in the packet scheduler, while the FilterSpec is used in the packet classifier. The FlowSpec in a reservation request will generally include a service class and two sets of numeric parameters: (1) an **RSpec** (R for "reserve") that defines the desired QoS, and (2) a **TSpec** (T for "traffic") that describes the data flow. The basic FilterSpec format defined in the present RSVP specification has a very restricted form: sender IP address, and optionally the UDP/TCP source port number.

The main problem with the integrated services model has been its scalability, especially in large public IP networks, which may potentially have millions of concurrent microflows. RSVP exhibits overhead in terms of state, bandwidth, and computation required for each microflow. One of the solutions proposed to this problem is the aggregation of flows, and the simplification of core router state and computation, used in the differentiated services framework.

6.2. Differentiated Services

The differentiated services (DiffServ) framework provides a scalable architecture for Internet service differentiation [9,19]. The main DiffServ design principles are the separation of policy from mechanisms, and pushing complexity to the network domain boundaries, as illustrated in Fig. 5. For a customer to receive DiffServ from its Internet Service Provider (ISP), the customer should have a *service-level agreement* (SLA) agreed on with the ISP. Bandwidth brokers (BBs) [54,62] perform coarse-grained long-term admission and policy control and configure the edge (ingress and egress) routers.

DiffServ core routers are only responsible for forwarding based on the classification performed at the edge. The Differentiated Services Code Point (DSCP) (contained in the IP header DSFIELD/ToS) [61] is used to indicate the forwarding treatment a packet should receive (Fig. 5). DiffServ standardizes a number of per hop behaviors (PHBs) employed in the core routers, including a PHB, expedited

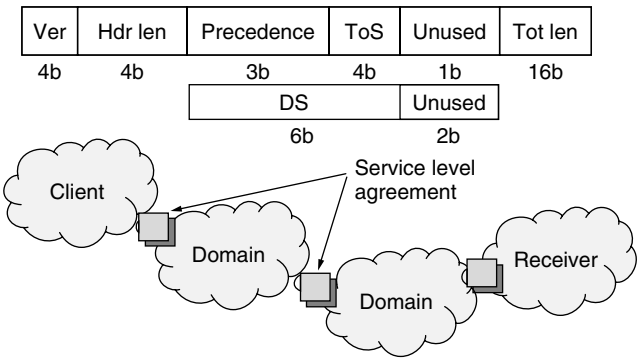

Figure 5. Differentiated Services networks use marking at the edge routers according to bilateral service level agreements, and simple forwarding in the core according to the 6 DS bits in the IP header.

forwarding (EF), and a PHB group, assured forwarding (AF) [37,41]. EF provides a low loss low delay service by employing strict admission control procedures. AF provides a set of better than best effort services for more bursty traffic, by using a number of levels of services, that use multiple queues and multiple drop priorities per queue.

6.3. Asynchronous Transfer Mode (ATM) Networks

Asynchronous transfer mode (ATM) networks were proposed to transport a wide variety of traffic, such as voice, video, and data, in a seamless manner. ATM transports data in fixed size 53 byte-long packets, called *cells*. End systems must set up virtual channel connections (VCCs) of appropriate service categories prior to transmitting information. Service categories are a small number of general ways to provide QoS, which are appropriate for different classes of applications. ATM service categories distinguish real-time from non-real-time services, and provide simple and complex solutions for each case. The added mechanisms in the more complex categories are justified by providing a benefit or economy to a significant subset of the applications [33].

ATM provides six service categories: constant bit rate (CBR), real-time variable bit rate (rt-VBR), non real-time variable bit rate (nrt-VBR), available bit rate (ABR), guaranteed frame rate (GFR), and unspecified bit rate (UBR) [32]. The *constant-bit-rate* (CBR) service category guarantees a constant rate called the *peak cell rate* (PCR). The network guarantees that all cells emitted by the source that conform to this PCR are transferred by the network at PCR. The *real-time variable-bit-rate* (VBR-rt) class is characterized by PCR, sustained cell rate (SCR), and maximum burst size (MBS), which control the bursty nature of traffic. The network attempts to deliver cells of these classes within fixed bounds of cell transfer delay (max-CTD) and cell delay variation (peak-to-peak CDV). *Non-real-time VBR* sources are also specified by PCR, SCR, and MBS, but the network does not specify the CTD and CDV parameters for VBR-nrt.

The *available-bit-rate* (ABR) service category is specified by a PCR as well as a minimum cell rate (MCR), which is guaranteed by the network. Excess bandwidth is shared in a fair manner by the network. We discuss ABR further in Section 10.5. The *unspecified bit rate* (UBR) does not support any service guarantees. UBR VCs are not required to conform to any traffic contract. PCR, however, may be enforced by the network. Switches are not required to perform any congestion control for UBR VCs. When queues become full, switches simply drop cells from UBR connections. Some improvements to UBR, known as UBR+, have been proposed. The *guaranteed-frame-rate* (GFR) service category is an enhancement of UBR that guarantees a minimum rate at the frame level. GFR is different from ABR because it does not use feedback control. The GFR class is intended to be a simple enhancement of UBR that guarantees some minimum rate to application frames.

6.4. Multiprotocol Label Switching

Multiprotocol label switching (MPLS) [73] uses fixed length labels, attached to packets at the ingress router. Forwarding decisions are based entirely on these labels in the interior routers of the MPLS path, as illustrated in Fig. 6. MPLS has made constraint-based routing a viable approach in IP networks [5,6]. Constraint-based routing can reduce manual configuration and intervention required for realization of traffic engineering objectives [6]. The traffic engineer can use administratively configured routes to perform optimizations. This enables a new routing paradigm with special properties, such as being resource-reservation-aware and demand-driven, to be merged with current Internet Gateway routing Protocols (IGPs), such as the Open Shortest Path First (OSPF), or the Intermediate System-Intermediate System (IS-IS) protocols. A constraint-based routing process incorporated in layer 3 and its interaction with MPLS and the current Internet Gateway Protocols (IGPs) is shown in Fig. 7. Constraint-based routing requires schemes for exchanging state information among processes, maintaining this state information, interaction with the current IGP protocols, and accommodating the adaptivity and survivability requirements of MPLS traffic trunks (aggregates of traffic flows) [20].

6.5. Interoperability Among Different Architectures

When QoS networks are deployed, typically only edge networks would be RSVP-enabled, and the core transit network would be DiffServ-enabled, use ATM, or use MPLS with constraint-based routing. In this scenario

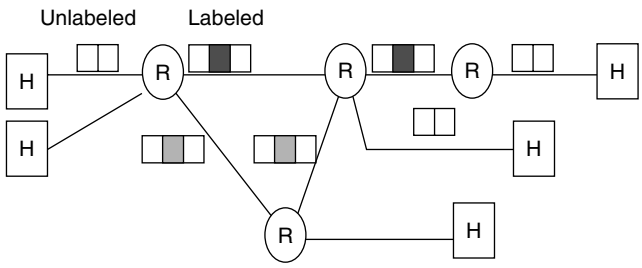

Figure 6. In MPLS, labels are attached to packets and used to perform switching decisions, until the labels are removed. Labels can also be nested.

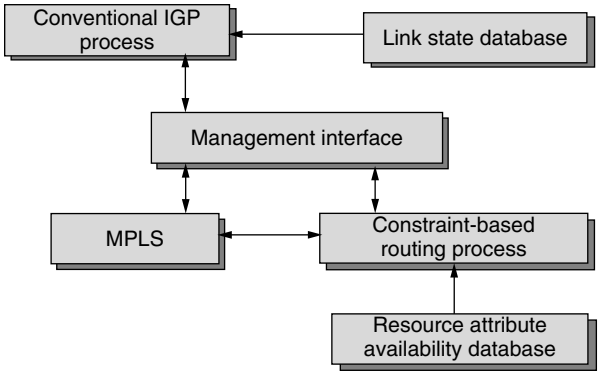

Figure 7. The constraint-based routing process interfaces with MPLS and resource databases.

the RSVP networks (at the edges) may be considered as customers of the transit DiffServ/ATM/MPLS network. The edge routers (at the edge of RSVP and DiffServ networks, for example) would be both RSVP- and DiffServ-capable. RSVP signaling messages are carried transparently through the DiffServ network; only the RSVP-enabled networks process RSVP messages. The DSCP marking can be done either at the host itself or at an intermediate router. RSVP reservations have to be converted into appropriate DiffServ PHBs for achieving end-to-end QoS. MPLS [73] may also be used for establishing label switched paths and trunks based on traffic engineering parameters, as discussed in Section 6.4.

7. POLICING AND SHAPING

In addition to the connection-level operations we have discussed so far, some traffic management operations must be performed for every packet. The end systems and edge routers are responsible for sending data that conforms to a negotiated traffic contract. As previously discussed, a traffic contract typically specifies the average rate, peak rate, and maximum burst size of a traffic flow. An incoming packet is checked against a traffic meter, and a decision is made on whether it is conforming (in profile) or non-conforming (out of profile). The shaping and policing functions (sometimes called usage parameter control (UPC)) have four possible choices when a packet is out of profile:

- *Dropping*. The nonconforming packet can be dropped to ensure that the traffic entering the network conforms to the contract, that is, that traffic is *policed* according to the profile.
- *Marking* (*Tagging*). The nonconforming packet can be marked as a low-priority packet by setting one or more bits in the packet header. In ATM, this is done by setting the value of the cell loss priority (CLP) bit in the ATM header to 1. In DiffServ networks, the DSCP is marked to reflect one of three priority levels, as discussed below. During congestion, the network may choose to discard low-priority packets in preference to high priority packets.
- *Buffering*. The nonconforming packet may be buffered and sent at a later time when it becomes conforming to the contract. This *traffic shaping* function reduces the traffic variation and burstiness and makes traffic smooth. It also provides an upper bound for the rate at which the flow traffic is admitted into the network, thus aiding in computing QoS bounds and buffer requirements [22,23].
- *No Action*. The nonconforming packet may be allowed into the network without any changes. This is typically an undesirable solution because it can cause congestion in the interior of the network.

The leaky-bucket and the token bucket algorithms have been designed for shaping and policing traffic. Partridge [69] describes the *leaky-bucket algorithm*, which was based on ideas discussed by Turner in 1986. The leaky bucket buffers incoming packets in a "bucket" that "leaks" at a certain rate. The algorithm has two input parameters: (1) the depth (size) of the bucket, b, and (2) the rate at which packets are drained out of the bucket, r. The generic cell rate algorithm (GCRA) [32] that is used in ATM is a variation of the leaky bucket.

Whereas the leaky bucket is filled with incoming packets and transmits them (if any are present) at a fixed rate (for shaping), the token bucket indicates whether traffic can be transmitted based on the availability of tokens. Tokens are added to the bucket at a fixed rate r, and can accumulate only up to the bucket depth b (where b controls the maximum burst size). The appropriate number of tokens are consumed when traffic is transmitted. Traffic may be allowed to be sent *in a burst* as long as a sufficient number of tokens is available in the bucket. This is the primary difference between a leaky bucket and a token bucket — a leaky bucket additionally controls the drain rate. Combinations of both are typically used to control the peak rate, average rate, and maximum burst size, according to the service provided.

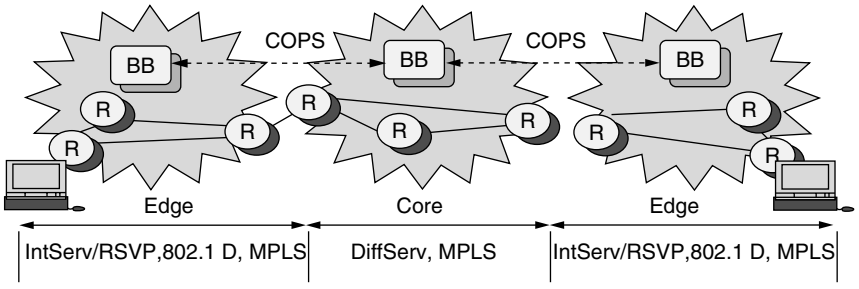

Figure 8. Networks with MPLS label-switched paths, ATM, or QoS (e.g., IntServ/RSVP or DiffServ) capabilities can interoperate. Bandwidth brokers (BBs) use the COPS protocol to exchange policy information among different domains.

For example, in the ATM variable-bit-rate (VBR) service, leaky buckets are used to control the peak rate, PCR, with tolerance CDVT, and to control the sustained (average) rate, SCR, with tolerance BT. The maximum burst size is limited to MBS. In DiffServ networks, the edge router contains meters, markers, droppers, and shapers, collectively referred to as *traffic conditioning functions*. A traffic conditioner may re-mark a traffic stream or discard or shape packets to alter the temporal characteristics of the stream and bring it into compliance with a traffic profile specified by the network administrator. As shown in Fig. 9, incoming traffic passes through a classifier, which is used to select a class for each traffic flow. The meter measures and sorts the classified packets into precedence (priority) levels. The decision (marking, shaping, or dropping) is based on the measurement result.

DiffServ-assured forwarding provides up to three drop precedences for each queue, as depicted in Fig. 10. Assume that the drop precedences are DP0 (green), DP1 (yellow) and DP2 (red), where DP0 means lower precedence to drop, and DP2 means higher (similar to colors in traffic stoplights). A three-color-marker (TCM) is used to mark packets with one of these three precedences. The DSCP is set to one of 3 values according to the DP. Traffic conditioners may also be TCP-aware and choose to protect "critical" TCP packets by marking them as DP0 [35].

8. SCHEDULING

Another packet-level traffic management function is packet scheduling. At every router or switch output port, a *scheduling discipline* must be used decide which packet to transmit next onto the output link (and onto the next hop). Scheduling is important because it resolves contention for a shared resource (the output link) and determines whether real-time applications can be given performance guarantees. Packet scheduling services different queues with different priorities to ensure that the quality of service requirements are met (recall Fig. 10). Multiple queues are needed because if packets from all flows share the same buffer using first-in first-out (FIFO) queuing, it is impossible to isolate packets from various flows. The degree of aggregation (how many microflows share a queue) determine the guarantees that can be made, as well as the state and time complexity of the scheduling discipline.

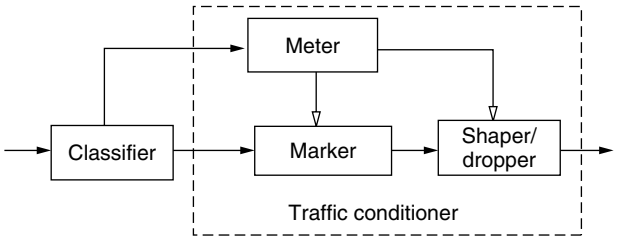

Figure 9. An edge router typically includes a classifier, a meter, a marker, a shaper, and a dropper.

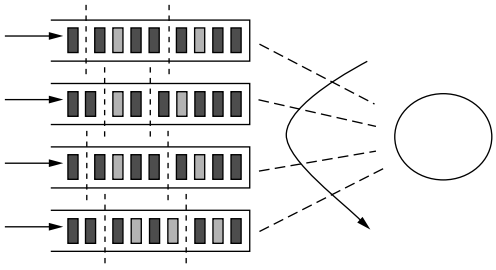

Figure 10. The assured forwarding service queues packets into four queues, with three drop precedences (denoted by three colors) per queue.

Scheduling disciplines aim at (1) meeting performance bounds for guaranteed services, including bandwidth, delay, delay variation (jitter), and loss; (2) providing some level of fairness and protection among flows; (3) being easily integrated with admission control algorithms; and (4) having low state and time complexity. A tradeoff among these goals must be achieved.

Scheduling algorithms may be work-conserving or non-work-conserving. A work-conserving scheduler is idle only when there is no packet awaiting service. Non-work-conserving schedulers may choose to be idle even if they have packets awaiting service, in order to make outgoing traffic more predictable and reduce delay variation (jitter). The best-known work-conserving scheduling discipline is the *generalized processor sharing* (GPS) discipline [67,68]. GPS serves packets as if they are in separate logical queues, servicing an infinitesimally small amount of data from each nonempty queue in turn. This intuitively resembles a *bit-by-bit* round-robin service. Connections can also be assigned weights and can be serviced in proportion to their weights. GPS cannot be directly implemented, but can be emulated as a weighted round robin or deficit round robin [36,75]. Deficit round robin can handle variable packet sizes without having to know the mean packet size of each connection in advance.

Weighted fair queuing (WFQ) approximates *packet-by-packet* GPS [7,24,82]. WFQ computes the time a packet would complete service in a GPS regime, and services packets in the order of these finishing times. A number of variants of WFQ have been developed, including self-clocked fair queuing (SCFQ), virtual clock (VC), and worst-case fair weighted fair queuing (WF^2Q). Other scheduling algorithms include delay and jitter earliest due date (EDD) and stop-and-go. The state overhead of scheduling algorithms can be alleviated if packets carry more information, as in the core-stateless fair queuing approach [77,78].

9. BUFFER MANAGEMENT

In most routers, packets are admitted into the router buffer as long as buffer space is still available. When the buffer is full, incoming packets have to be dropped — which is what is commonly referred to as the "drop tail" policy, since packets are dropped from the tail of the queue. This is the simplest policy to implement. Alternatively, packets may be dropped from the front of the queue, or from random locations within the queue. Such "pushout" mechanisms are typically more expensive.

Partial packet discard (PPD) schemes were first proposed to drop remaining segments, such as ATM cells of

an IP packet, if other segments of the packet have already been dropped. The intuition behind this is that the receiver will anyway discard segments of a packet if the complete packet cannot be reassembled. Therefore, these partial packets should not consume network resources (e.g., bandwidth) on the path between the router where a segment of the packet is discarded, and the receiver. Early packet discard (EPD) [72] has been proposed to extend this notion to drop complete packets when the buffer reaches a certain occupancy, say, 90%, in order to save the remaining capacity for partial segments of admitted packets.

Active queue management (AQM) in routers was later proposed to improve application goodput and response times by detecting congestion *early* and improving fairness among various flows. The main goal of AQM is to drop/mark packets before buffer overflow, in order to (1) give early warning to sources, (2) avoid synchronization among TCP congestion control phases of different flows (TCP congestion control is discussed in Section 10), (3) avoid bias against bursty connections, and (4) punish misbehaving sources.

Active queue management gained significant attention in the early 1990s with the design of the random early detection (RED) algorithm [29]. RED maintains a long-term average of the queue length (buffer occupancy) of a router using a lowpass filter. If this average queue length falls below a certain minimum threshold, all packets are admitted into the queue, as depicted in Fig. 11a. If the average queue length exceeds a certain maximum threshold, all incoming packets are dropped. When the queue length lies between the minimum and maximum thresholds, incoming packets are dropped/marked with a linearly increasing probability up to a maximum drop probability value, p_{max}. RED includes an option known as the "gentle" variant (Fig. 11b). With gentle RED, the packet drop probability varies linearly from p_{max} to 1 as the average queue size varies from th_{max} to twice th_{max}.

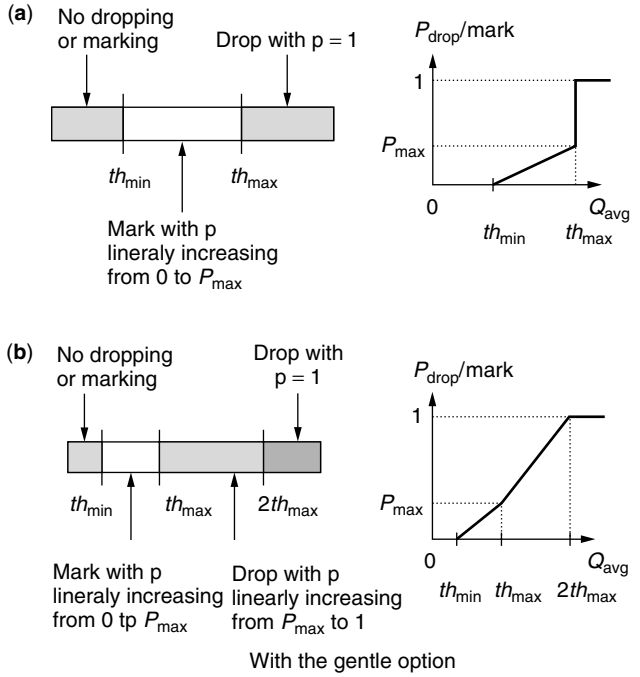

Figure 11. Random early detection (RED) probabilistically drops/marks packets based on average queue length without (**a**) and with (**b**) "gentle" option.

A number of RED variants have appeared, including flow-RED (FRED) [57], stabilized RED (SRED) [65], and BLUE [27]. Although FRED performs best among all RED variants, FRED maintains counts of the buffer occupancies for each flow in order to make better packet admission decisions. This provides the best isolation among flows, especially in the presence of misbehaving flows that send at high rates. However, maintaining per flow packet counts implies that FRED implementation complexity is higher than the other variants. Algorithms for the ATM guaranteed frame rate (GFR) service are also very similar in spirit to FRED. More recently, a number of other algorithms, including random early marking (REM) [4], adaptive virtual queue (AVQ) [55], and the proportional integrator (PI) controller [39], have been proposed. Although RED and these algorithms improve performance over simple drop-tail queues, it is difficult to configure their parameters, and some are complex to implement, so they are still under study.

If the network architecture supports marking packets with different drop precedence values, buffer management algorithms can provide differential drop. For example, in differentiated services networks, within each assured service queue, discrimination among packets can be performed using various mechanisms. The RIO (RED with IN and OUT) algorithm distinguishes between two types of packets, IN and OUT of profile, using two RED instances [19]. Each RED instance is configured with min_{th}, max_{th}, and P_{max} (recall Fig. 11a). Suppose the parameters for the IN profile packets are min_{in}, max_{in}, and P_{max_in}, and for the OUT-of-profile packets are min_{out}, max_{out}, and P_{max_out}. To drop OUT packets earlier than IN packets, min_{out} is chosen to be smaller than min_{in}. The router drops OUT packets more aggressively by setting P_{max_out} higher than P_{max_in}. To realize three drop precedences (red, yellow, and green), three REDs can be used.

10. CONGESTION CONTROL

In addition to connection-level and packet-level traffic management operations, network feedback can be used to control congestion at the burst level. This section discusses how closed-loop feedback operates, using the congestion control algorithms in TCP/IP and ATM networks as case studies.

10.1. TCP Congestion Control

In the year 2000, almost 90% of the Internet traffic used the TCP protocol, although multimedia traffic, especially RTP [74] and RTSP, have been slowly increasing. When congestion collapse was first experienced in the Internet in the 1980s [40,44,48], an investigation resulted into the design of new congestion control algorithms, now an essential part of the TCP protocol. Every TCP connection starts off in the "slow start" phase [40]. The slow-start algorithm uses a variable called *congestion window* (*cwnd*). The sender can only send the minimum of *cwnd* and

the receiver advertised window which we call *rwnd* (for receiver flow control). Slow start tries to reach equilibrium by opening up the window very quickly. The sender initially sets *cwnd* to 1 (or 2) and sending one segment. For each acknowledgment (ACK) the sender receives, *cwnd* is increased by one segment. Increasing by one for every ACK results in exponential increase of *cwnd* over round trips, as shown in Fig. 12. In this sense, the name "slow start" is a misnomer.

TCP uses another variable *ssthresh*, the slow-start threshold, to ensure *cwnd* does not increase exponentially forever. Conceptually, *ssthresh* indicates the "right" window size depending on current network load. The slow-start phase continues as long as *cwnd* is less than *ssthresh*. As soon as *cwnd* crosses *ssthresh*, TCP goes into "congestion avoidance." In the congestion avoidance phase, for each ACK received, *cwnd* is increased by 1/*cwnd* segments. This is *approximately* equivalent to increasing the *cwnd* by one segment in one round trip (an *additive* increase), if every segment (or every other segment) is acknowledged by the destination.

TCP maintains an estimate of the round-trip time (RTT), which is the time it takes for the segment to travel from the sender to the receiver plus the time it takes for the ACK (and/or any data) to travel from the receiver to the sender. The *retransmit timeout* (RTO) maintains the value of the time to wait for an ACK after sending a segment before assuming congestion, timing out and retransmitting the segment. When the TCP sender times out, it assumes the network is congested, and sets *ssthresh* to max(2, min(*cwnd*/2, *rwnd*)) segments, *cwnd* to one, and goes to slow start [1]. The halving of *ssthresh* is a *multiplicative* decrease. The *additive-increase multiplicative-decrease* (AIMD) system has been shown to be stable [17]. This basic version of TCP is called "TCP Tahoe."

10.2. TCP Flavors

Several variations on TCP congestion control have been designed, including TCP Reno [26], New-Reno [38], selective acknowledgments (SACK) [60], and forward acknowledgments (FACK) [59], to recover rapidly from one or multiple segment losses, detected through *duplicate* or *selective* acknowledgments, instead of only through timeouts as with the basic TCP (Tahoe). Other algorithms, such as TCP Vegas [14], use changes in round-trip time estimates, rather than packet loss, to adjust the TCP congestion window. Several TCP variations for wireless networks have also been proposed to operate in environments where bandwidth is limited, bandwidth may be asymmetric, and error rate is high. Because of possibly high error rates, losses are no longer assumed to be due to congestion in these proposals.

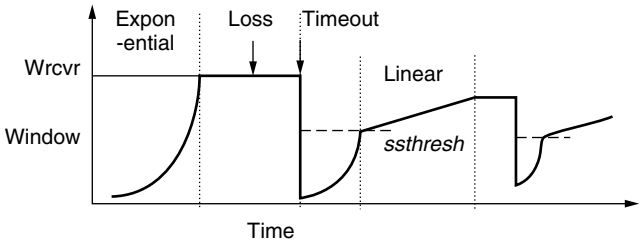

Figure 12. The TCP congestion window grows with ACKs and shrinks when packet loss is detected.

10.3. TCP-Friendly Rate Control

Clever techniques to discover the bottleneck bandwidth and control the source rate accordingly were designed in the early 1990s, including packet pair techniques [53]. Other techniques (proposed for congestion control at the application layer for both unicast and multicast) were used in the Internet Video Service [10], which uses network feedback obtained through the Real Time Control Protocol (RTCP) [74] to control the rate of sources in a video application. More recently, several researchers have investigated how applications can control their transmission *rates* (rather than *windows*) such that it approximates the behavior of TCP. This allows applications running on top of UDP (that do not require reliability) to coexist with TCP connections without starving the TCP connections. Different formulae have been developed that compute the precise "TCP-friendly" application rate. This rate is a function of the connection round trip time, and the frequency of packet loss indications perceived by the connection [66]. Example TCP-friendly protocols include the RAP protocol [71], and TCP-friendly rate control (TFRC) [31].

10.4. Explicit Congestion Indication

As discussed earlier, TCP assumes congestion when it times out waiting for an ACK, or it received duplicate or selective ACKs. This is *implicit feedback* from the network. The *explicit* congestion notification (ECN) option for TCP connections [28,70] allows active queue management mechanisms such as RED to probabilistically mark (rather than drop) packets when the average queue length lies between the two RED thresholds. This is only allowed if both the sender and receiver are ECN-capable (determined at connection setup time). In this case, the receiver echoes back to the sender the fact that some of its packets were marked, so the sender knows that the network is approaching a congested state (Fig. 13). The sender should therefore reduce its congestion window as if the packet was dropped, but need not reduce it drastically as long as it preserves TCP behavior in the long term [56]. The main advantages of ECN are that TCP does not have to wait for a timeout and some packet drops can be avoided.

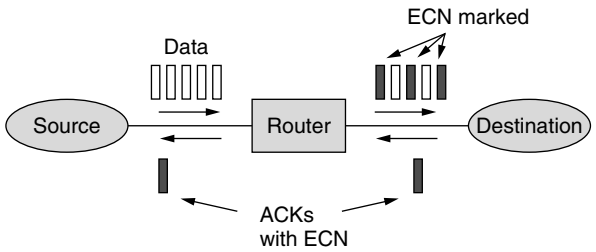

Figure 13. When congestion is incipient, AQM routers mark the ECN bit in TCP packets. The ECN bit is then marked in the ACK packets returning to the sender.

10.5. Explicit Rate Feedback

Instead of using only one bit for explicit feedback, the network can inform the sources of the precise rates they should transmit at. The ATM ABR service (designed before the ECN mechanism was proposed) allows the network to divide the available bandwidth fairly and efficiently among active sources. The ABR traffic management model is (1) "rate-based" because the sources transmit at a specified "rate," rater than using a window; (2) "closed-loop" because, unlike CBR and VBR, there is continuous feedback of control information to the source throughout the connection lifetime; and (3) "end-to-end" because control cells travel from the source to the destination and back to the source [47]. The key attractive features of the ATM ABR service are that it (1) gives sources low cell loss guarantees, (2) minimizes queuing delay, (3) provides possibly nonzero minimum rate guarantees, (4) utilizes bandwidth and buffers efficiently, and (5) gives the contending sources fair shares of the available resources.

The components of the ABR traffic management framework are shown in Fig. 14. To obtain network feedback, the sources send resource management (RM) cells every $Nrm - 1$ (Nrm is a parameter with default value 32) data cells. Destinations simply return these RM cells back to the sources. The RM cells contain the source rate, and several fields that can be used by the network to provide feedback to the sources. These fields are: the explicit rate (ER), the congestion indication (CI) flag and the no increase (NI) flag. The ER field indicates the rate that the network can support for this connection at that particular instant. The ER field is initialized at the source to a rate no greater than the PCR, and the CI and NI flags are usually reset. Each switch on the path *reduces* the ER field to the maximum rate it can support, and sets CI or NI if necessary. When a source receives a returning RM cell, it computes its allowed cell rate (ACR) using its current ACR value, the CI and NI flags, and the ER field of the RM cell [47].

Several algorithms have been developed to compute the ER feedback to be indicated by the network switches to the sources in RM cells [3,16,50,51,76]. The "explicit rate indication for congestion avoidance+" (ERICA+) algorithm [51] computes weighted max–min fair rates (with minimum guarantees) that result in high link utilization and small queuing delay in the network. The algorithm uses the measured load in the forward direction to provide feedback in the reverse direction. The rate is computed as a function of the connection load, the total load, the available capacity, the previous maximum allocation, the normalized weights, and the minimum guarantee. ABR queues can thus be pushed to the edge of a domain [34,79]. Extensions for supporting point-to-multipoint and multipoint-to-point connections are also provided [25].

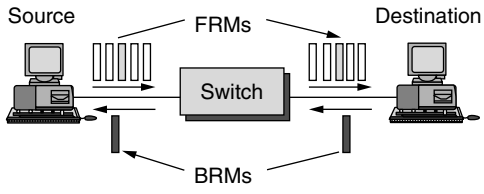

Figure 14. Resource management (RM) cells are sent every Nrm cells in the forward direction, and backward RM cells return to the source with explicit rate information.

BIOGRAPHY

Sonia Fahmy received her PhD degree at the Ohio State University in August 1999. Since then, she has been an Assistant Professor at the Computer Science Department at Purdue University. She has been very active in the Traffic Management working group of the ATM Forum, and has participated in several IETF working groups. Her work is published in over 40 journal and conference papers, and several ATM Forum contributions. She is a member of the ACM, IEEE, Phi Kappa Phi, Sigma Xi, and Upsilon Pi Epsilon, and is listed in the *International Who's Who in Information Technology*. She received the Schlumberger Foundation Technical Merit Award in 2000 and 2001. She has served on the program committees of several conferences, including IEEE INFOCOM, ICNP, and ICC; and co-chaired the SPIE Conference on Scalability and Traffic Control in IP Networks. Her research interests span several areas in the design and evaluation of network architectures and protocols. She is currently investigating multipoint communication, congestion control, and wireless networks. Please see *http://www.cs.purdue.edu/homes/fahmy/* for more information.

NETWORK TRAFFIC MODELING

Campinas, Brazil

1. INTRODUCTION

Traffic, that is, data being transmitted, is what telecommunication networks are built to carry. The fascinating and unprecedented "Internet revolution" has led to an ever increasing need for larger amounts of data to be transmitted, as well as fast increasing expectations in terms of the diversity and quality of the transmitted data. Modern networks are expected to accommodate a very heterogeneous traffic mix, including traditional telephone calls, data services, World Wide Web browsing, and video or other multimedia information. In this context, network designers and telecommunication engineers are called on to design, control, and manage networks of increasing transmission speed (bandwidth), size, and complexity. Any effort in network design, control, or management requires decisions and optimization actions that in turn require accurate prediction of the performance of the system under design or control. This is why the science and "art" of traffic modeling has been playing a crucial role in the area of communication network design and operation [7].

The amount of traffic per unit time arriving at a network access point, the number of Internet access requests in an hour or the traffic *workload* through an Internet provider's nodes (routers or switches) is a real physical quantity, even though it consists of bits and bytes and *not* of atoms or molecules. This physical quantity is highly variable with time and space, and appears irregular or, *random*. Furthermore, network traffic usually exhibits visual clusters of activity separated by less active intervals, what is described in the telecommunications lingo, as *bursty* behavior. In order to predict the performance of networks carrying this variable and diverse traffic, researchers and telecommunication engineers utilize analysis (closed-form mathematics), numeric approximations, computer simulation, experimentation with real systems (in the laboratory or in the field), and heuristic or ad hoc projections based on past experience. All of these require, to a great or less degree, some representation or abstraction of *real-life* network traffic, that is, traffic "models."

Traffic modeling has a theoretical/analytic aspect, whereby suitable stochastic models are devised in the mathematical sense, and attributed to different types of data sources and network types. Each model has a number of parameters that determine specific aspects such as mean value, higher moments, autocorrelation function, and marginal density. Such models include [1]

- Renewal models
- Markov and semi-Markov processes
- Autoregressive processes (AR, ARMA, and ARIMA)
- Specially invented processes like Transform-Expand-Sample (TES), SRP, DAR and other
- Long-range dependent, self-similar and multifractal processes

There are also key *computational* and statistical aspects to traffic modeling: After deciding on or hypothesizing about a model (or model family) in the abstract, particular values have to be chosen for the parameters of the model. This usually means performing *matching* or *fitting* where parameter values are estimated statistically from the measured traffic data. Depending on the number of parameters involved, the type of model, and the nature of the data, this task may be far from straightforward and quite time-consuming. The moments to be estimated also depend on the type of network and traffic source, and represent an assumption in themselves. Typical traffic sources include

- Voice, very important for its dominant presence in telephone networks
- Video, especially digital, compressed video (e.g., MPEG)
- Data applications such as FTP, TELNET, SMTP, HTTP
- Traffic in local area and campus networks (LAN and MAN)
- Aggregated traffic on network "trunks" over wide-area networks (WANs)

In this article, we present the most common stochastic processes used for traffic modeling, in Section 2. Such processes can be used either to model the aggregate traffic of several sources (flows, connections, calls) on a network link or can be used to model individual sources, such as the stream generated by a phonecall. Models for specific sources are introduced in Section 3. Some special aspects of traffic modeling related to network performance, namely the concepts of *effective bandwidths* and *envelope processes* are discussed briefly in Section 4. Finally, conclusions and some current open and challenging issues are discussed in Section 5.

2. TRAFFIC MODELS

2.1. General Background

Traffic modeling starts usually by a researcher or telecom engineer collecting samples of traffic during a period of time ("traffic traces") from a specific source and/or at a specific point in the network (e.g., access point, router port, or transmission link). Before stochastic modeling is applied, care must be taken to remove *determinism* and identifying the "residual uncertainty" [16] so that what remains to be modeled is truly stochastic in nature, and *stationary* (i.e., does not have fundamental properties that change with time of the day or month). At a second step, the data are analyzed and a stochastic model is proposed so that a realization of the stochastic process matches the

data trace. A theoretical traffic model has to be checked against several data traces before one can be confident of its accuracy. In what follows, we present stochastic processes commonly used to describe traffic streams.

Network traffic can be *simple* or *compound*. Simple traffic corresponds to single arrivals of discrete data entities (e.g., "packets") and is typically described as a *point process* [9], that is, a sequence of arrival instants $T_1, T_2, \ldots, T_n, \ldots$, with $T_0 = 0$. Point processes can be described equivalently by counting processes and interarrival-time processes. A counting process $\{N(t)\}_{t=0}^{\infty}$ is a continuous-time, nonnegative integer-valued stochastic process, where $N(t)$ is the number of traffic arrivals in the interval $(0, t]$. An interarrival time process is a real-valued random sequence $\{A_n\}_{n=1}^{\infty}$, where $A_n = T_n - T_{n-1}$ is the length of the time interval separating the n-th arrival from the previous one.

Compound traffic consists of *batch arrivals*, that is, multiple units possibly arriving simultaneously at an instant T_n. In the case of compound traffic, we also need to know the real-valued random sequence $\{B_n\}_{n=1}^{\infty}$, where B_n is the (random) number of units in the batch.

In some cases, it is more appropriate or convenient to assume that time is *slotted*, which leads to *discrete-time* traffic models. This means that arrivals may take place only at integer times T_n and interarrival periods are also integer-valued. Furthermore, there are cases where the natural structure of the traffic is such that interarrival times are deterministic or periodic, with only the amount of arriving *workload* changing from arrival to arrival (e.g., compressed video "frames", arriving every $\frac{1}{30}$th of a second).

A simple way to represent a stochastic process is to give the moments of the process — particularly the first and the second moments, which are called the mean, variance, and autocovariance functions. The mean function of the process is defined by $\mu_t = E(X_t)$. The variance function of the process is defined by $\sigma_t^2 = E[(x_t - \mu_t)^2]$, and the autocovariance function between X_{t_1} and X_{t_2} is defined by $\gamma(t_1, t_2) = E[(X_{t_1} - \mu_{t_1})(X_{t_2} - \mu_{t_2})]$.

Another topic that is very relevant in traffic modeling is that of traffic "burstiness." Burstiness is present in a traffic process if the interarrival times process $\{A_n\}$ tends to give rise to runs for several short interarrival times followed by relatively long ones. With typical network traffic exhibiting patterns and bursts that coexist over many magnitudes of time scales (from minutes to hours to days) come the notion of timescale invariance. *Timescale* refers to the change or immunity to change of the process structure on scaling of the time axis. A process $\{X_t\}$ can be defined as scaling invariant if for some $\alpha \in [a, b]$ the process is equal in distribution to its scaled version $\{X_{\alpha t}\}$. If a traffic is not scale-invariant then when studying its behavior as time scales increase, it will show that the bursts and random fluctuations degenerate toward a white noise, nonbursty type of traffic.

The marginal distribution of a process $\{X_t\}$ captures the steady-state first-order distribution of X and is considered the primary characteristic in describing network traffic. Assuming that the process is wide-sense stationary (WSS), the marginal distribution becomes invariant to time and is then defined by the one-dimensional probability density function (PDF): $f_X(x) = f_{X_t}(x) = \frac{d}{dx} Pr[X_t \leq x]$. The PDF describes the probability that the data will assume a value within some given range at any instant of time.

The autocorrelation function of a process $\{X_t\}$ captures the second order measurement of the process and it is used as a supplement to the marginal distribution. The autocorrelation function for network traffic describes the general dependence of the values at another time. Assuming the process is WSS, then the autocorrelation between the data values at times t and $t + k$ is defined as follows:

$$\rho(k) = \frac{E[X_t X_{t+k}] - (E[X_t])^2}{E[(X_t - E[X_t])^2]}$$

where k is called the "lag," the difference or distance between timepoints under consideration. If the autocorrelation function $\rho(k)$ of $\{X_k\}$ is equal to zero for all values of $k \neq 0$, then $\{X_k\}$ is of the *renewal* type. Markov and other *short-range dependent* (SRD) models have a correlation structure that is characterized by an *exponential* decay, which leads to $\sum_k \rho(k) < \infty$.

On the other hand, many real traffic traces exhibit *long-range dependence* (LRD) and can be modeled by self-similar and multifractal models later in this article. For these processes, the autocorrelation function decays slowly (say, polynomially instead of exponentially) in a way that makes the autocorrelation nonsummable: $\sum_k \rho(k) \to \infty$ [23].

2.2. Short-Range Dependent Models

2.2.1. Renewal Models. Renewal models have been used for a long time because of their simplicity and tractability. For this type of traffic, the interarrival times are independent and identically distributed (i.i.d.), with an arbitrary distribution. The major modeling drawback of renewal processes is that the autocorrelation function of A_n is *zero* except for lag $n = 0$. Hence, renewal models seldom capture the behavior of high-speed network traffic in an accurate manner.

Within the renewal family, *Poisson* models are the oldest and most widely used, having been historically closely linked to traditional telephony and the work of A. K. Erlang. A Poisson process is a renewal process with *exponentially* distributed interarrival times with rate λ: $P[A_n \leq t] = 1 - e^{-\lambda t}$. It is also a counting process with $P[N(t) = n] = \frac{(\lambda t)^n e^{-\lambda t}}{n!}$, and independent numbers of arrivals in disjoint intervals. Poisson processes are very appealing due to their attractive memoryless and aggregation properties.

2.2.2. Markov Models. Unlike renewal traffic models, Markov and Markov renewal traffic models [1,7] introduce dependence into the random sequence A_n. Consequently, they can potentially capture traffic burstiness, due to nonzero autocorrelations of A_n. Consider a Markov process $M = \{M(t)\}_{t=0}^{\infty}$ with a discrete state space, where M behaves as follows. It stays in state i for an exponentially distributed holding time that depends on i alone; it then jumps to state j with probability p_{ij}, such that the matrix

$P = [p_{ij}]$ is a probability matrix. In a simple Markov traffic model, each jump of the Markov process corresponds to an arrival, so interarrival times are exponentially distributed, and their rate parameter depends on the state from which the jump occurred. Arrivals may be single, a batch of units or a continuous quantity.

Markov-modulated models constitute another important class of traffic models. Let $M = \{M(t)\}_{t=0}^{\infty}$ be a continuous-time Markov process, with state space of $1, 2, \ldots, m$. Now assume that while M is in state k, the probability law of traffic arrivals is completely determined by k. Thus, the probability law for arrivals is *modulated* by the state of M. The modulating process can be more complicated than a Markov process (so the holding times need not be restricted to exponential random variables), but such models are far less analytically tractable.

The most commonly used Markov modulated model is the *Markov modulated Poisson process* (MMPP) model, which combines a modulating (Markov) process with a modulated Poisson process. In this case, while in state k of M, arrivals occur according to a Poisson process of rate k. As a simple example, consider a 2-state MMPP model, where one state is an ON state with a positive Poisson rate, and the other is an OFF state with a rate of zero. Such models have been widely used to model voice traffic sources.

A semi-Markov process is a generalization of Markov processes, that allows the holding time to follow an arbitrary probability distribution. This destroys the Markov property since times are not exponentially distributed, however it allows for more general models of traffic. When values from a semi-Markov chain are generated, the next state is chosen first, followed by a value for the holding time. If the holding times are ignored, then the sequence of states will be a discrete time Markov chain, referred to as an *embedded* Markov chain.

2.2.3. Autoregressive Models. The autoregressive model of order p, AR(p), is a process $\{X_t\}$ whose current value is expressed as a finite linear combination of previous values of the process plus a white-noise process ε_t: $X_t = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \cdots + \phi_p X_{t-p} + \varepsilon_t$ where ϕ_i are constants and X_{t-i} are past values of the process at time $t - i$. The recursive form of this model makes it a popular modeling candidate as it makes it straightforward to *generate* an autocorrelated traffic sequence, such as variable-bit-rate (VBR) video traffic [1,7]. However, autoregressive models cannot simultaneously match the empirical marginal distribution of arbitrary traffic such as video.

Another model of the same family is the autoregressive moving-average model of order (p, q), denoted by ARMA (p, q): $X_t = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \cdots + \phi_p X_{t-p} + \varepsilon_t - \theta_1 \varepsilon_{t-1} - \theta_2 \varepsilon_{t-2} - \cdots - \theta_q \varepsilon_{t-q}$. Because of the larger number of parameters, ARMA models are more flexible than AR models and can be used in more cases. However, estimation of its parameters is more involved.

2.2.4. Transform–Expand–Sample (TES). Transform–expand–sample (TES) models represent another important class of models appropriate for modeling autocorrelated traffic streams. This family of models aims to capture *both* autocorrelation and *marginal distribution* of the empirical traffic trace; in fact, it was historically the first traffic model explicitly devised to accomplish exactly this dual purpose and specifically for network traffic data. TES models capture stationary, correlated time series and also allow one to generate synthetic streams of real-looking traffic streams to drive simulations of networks [7].

TES models include two types of TES processes: TES$^+$ and TES$^-$. TES$^+$ produces sequences with positive autocorrelation at lag 1, while TES$^-$ produces negative autocorrelation at lag 1. The TES$^+$ process is more suitable for modeling network traffic. To define the TES$^+$ process, we first introduce a modulo 1 operation. The modulo 1 of a real number x, denoted by $\langle x \rangle$, is defined as $\langle x \rangle = x - \lfloor x \rfloor$, where $\lfloor x \rfloor$ is the maximum integer less than x. The recursive construction of the background TES$^+$ process is defined by

$$U_n^+ = \begin{cases} U_0^+ & n = 0 \\ \langle U_{n-1}^+ + V_n \rangle & n > 0 \end{cases}$$

where $\{V_n\}$ is a sequence of IID random variables referred to as *innovations* and U_0^+ is uniformly distributed on $[0, 1)$ and independent of $\{V_n\}$. The resulting sequence $\{U_n^+\}$ has a $[0, 1)$ uniform marginal distribution, and autocorrelation function determined by the probability density function $f_V(t)$ of V_n. The choice of $f_V(t)$ determines the correlation structure of the resulting process. From this background sequence the output process of the model referred to as the foreground sequence, $\{X_n^+\}$ is created by "distorting" each U_n^+ by $X_n^+ = F^{-1}(U_n^+)$, where F is the marginal distribution of the empirical data [9].

2.2.5. Other Short-Range Dependent Models. Another interesting model is the *spatial renewal process* (SRP), which efficiently models processes exhibiting arbitrary marginal distribution and aperiodically decaying autocorrelation (see the paper by Taralp et al. [20] and references cited therein).

A *discrete autoregressive model* of order p, denoted as DAR(p), generates a stationary sequence of discrete random variables with an arbitrary probability distribution and with an autocorrelation structure similar to that of an AR(p). DAR(1) is a special case of DAR(p) process; it has a smaller number of parameters than do general Markov chains, simpler parameter estimation, and can match arbitrary distributions. Moreover, the analytic queuing performance is tractable (see paper by Adas [1] and references cited therein).

2.3. Long-Range Dependent and Self-Similar Traffic Models

Measurements and statistical analysis of real traces performed during the 1990s revealed that traffic exhibits large irregularities (*burstiness*) both in terms of extreme variability of traffic intensities as well as persistent autocorrelation. Network traffic often looks extremely irregular at different timescales [12,17], and such extreme behavior is not exhibited by the traditional Poisson traffic, which smoothes out when aggregated at coarser timescales. If traffic were to follow a Poisson or Markov arrival process, it would have a characteristic burst length that would tend to be smoothed by averaging over a long enough timescale. Instead, measurements of real traffic indicate consistently

that significant traffic burstiness is present on a wide range of timescales.

This behavior is reminiscent of and has been modeled according to *self-similar* processes. Self-similar or *fractal* modeling has been used in a number of research areas such as hydrology, financial mathematics, telecommunications, and chaotic dynamics [4,24]. Internet traffic, and more generally broadband network traffic, is an area where fractal modeling has become popular more recently. Such modeling has also been related to the observation of ON–OFF traffic with "heavy-tailed" distribution [23].

2.3.1. Heavy-Tailed ON–OFF Models. The fractal nature of network traffic is consistent with and predicted by the behavior of the individual connections that produce the aggregate traffic stream. In WAN traffic, individual connections correspond to "sessions," where a session starts at a random point in time, generates packets or bytes for some time and then stops transmitting. On the other hand, in LAN traffic, individual connections correspond to an individual source–destination pair. Individual connections are generally described using simple traffic models such as ON–OFF sources.

Traditional ON–OFF models assume finite variance distributions for the duration of the ON and the OFF periods. The aggregation of a large number of such processes results in processes with very small correlations. On the other hand, a positive random variable Y is called "heavy-tailed with tail index α," if it satisfies: $P[Y > y] = 1 - F(y) \approx cy^{-\alpha}, y \to \infty, 0 < \alpha < 2$, where $C > 0$ is a finite constant independent of y. This distribution has infinite variance. Furthermore, if $1 < \alpha < 2$, then it has a finite mean. The superposition of many such sources was shown to produce aggregate traffic that exhibits long-range dependence and even self-similarity [12,22].

2.3.2. Monofractal Models. Self-similarity in a process indicates that some aspect of the process is *invariant* under scale-changing transformations, such as "zooming" in or out. In network traffic, this is observed when traffic becomes bursty, exhibiting significant variability, on many or all timescales. The appeal and modeling convenience of self-similar processes lies in the fact that the degree of self-similarity of a series can be expressed using only one parameter. The *Hurst* parameter, H, describes the speed of decay of the series autocorrelation function. For self-similar series the value of H is between 0.5 and 1. The degree of self-similarity increases as the Hurst parameter approaches unity.

A process $\{X_k\}$ whose autocorrelation function, $\rho(k)$, takes the form $\rho(k) \approx ck^{-\beta}, 0 < \beta < 1$, for large k and a constant $c > 0$, is said to be *long-range dependent*. This implies that the autocorrelation function decays slowly and is not summable, thus $\sum_k \rho(k) \to \infty$. Figure 1 shows the autocorrelation as a function of time for streams with different H values. Note that for streams with greater H the autocorrelation decays more slowly as a function of time.

In the case of traffic traces, self-similarity is used in the distributional sense: when viewed at varying

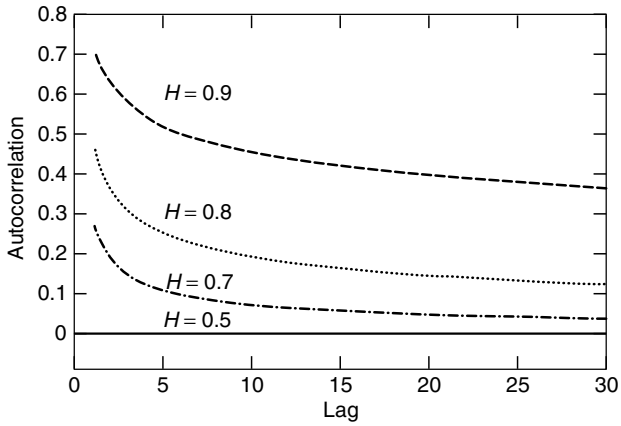

Figure 1. The autocorrelation as a function of time for different values of H.

scales, the object's distribution remains unchanged. Equivalence in distribution between X and Y is denoted by $X \stackrel{d}{=} Y$. We provide in the following certain common definitions of self-similar traffic processes, following Tsybakov and Georganas [22]. Let $X = \{X_t : t = 1, 2, 3, \ldots\}$ be a second-order stationary sequence with mean $\mu = E[X_t]$, variance $\sigma^2 = \text{var}(X_t)$, and autocorrelation function $r(k) = \dfrac{E[(X_{t+k} - \mu)(X_t - \mu)]}{\sigma^2}$. Let $X^{(m)}(t) = \frac{1}{m}(X_{tm-m+1} + \cdots + X_{tm}), m = 1, 2, 3, \ldots$, be the corresponding aggregated sequence with level of aggregation m, obtained by dividing the original sequence X into nonoverlapping blocks of size m and averaging over each block. The index t labels the block. For each $m = 1, 2, 3, \ldots$ let $\mathbf{X}^{(m)} = \{X^{(m)}(k) : k = 1, 2, 3, \ldots\}$ denote the averaged process with autocorrelation function $r^{(m)}(k)$.

- A process X is called *exactly second-order self-similar* with parameter $H = 1 - (\frac{\beta}{2}), 0 < \beta < 1$ if its correlation coefficient is $r(k) = \frac{1}{2}[(k+1)^{2-\beta} - 2k^{2-\beta} + (k-1)^{2-\beta}], k = 1, 2, 3, \ldots$.
- A strict-sense stationary process X is called *strictly self-similar* with parameter $H = 1 - (\frac{\beta}{2}), 0 < \beta < 1$, if $X \stackrel{d}{=} m^{1-H}X^{(m)}$. If X is strictly self-similar, then it is also exactly second-order self-similar. The opposite is not true, except for Gaussian processes.
- A process X is called asymptotically second-order self-similar with parameter $H = 1 - (\frac{\beta}{2}), 0 < \beta < 1$, if $\lim_{m\to\infty} r^{(m)}(k) = \frac{1}{2}\delta^2(k^{2-\beta}), k = 1, 2, 3, \ldots$ where $\delta^2(f(x)) = f(x + \frac{1}{2}) - f(x - \frac{1}{2})$.
- A strict-sense stationary process X is called strictly asymptotically self-similar if $X^{(m)} \stackrel{d}{=} X, m \to \infty$. Note that a strictly asymptotically self-similar process is not necessarily asymptotically second-order self-similar.

2.3.3. Fractal Gaussian Noise and Fractal Brownian Motion. The fractal Brownian motion (FBM) is a self-similar process with Gaussian stationary increments [14]. The increment process is called *fractal Gaussian noise*, and its autocorrelation function is invariant under aggregation and is given by $r(k) = 1/2[|k+1|^{2H} - 2|k|^{2H} + |k-1|^{2H}]$.

The FBM process accurately models Ethernet, ATM, and FDDI traffic, as well as video sources. The aggregate of ON–OFF sources with heavy tails tends to an FBM.

The analysis of a queuing system with FBM input is quite challenging. However, it becomes manageable if the fractal Brownian traffic [15] process is used instead. The fractal Brownian traffic is defined as the fluid input in time interval $(s, t]$, and is given by $A(s,t) = m(t-s) + \sigma(Z_t - Z_s)$ where m is the mean input rate, σ^2 is the variance of traffic in a given time unit, and Z_x is a normalized fractal Brownian motion, defined as a centered Gaussian process with stationary increments and variance $E[Z_t^2] = t^{2H}$.

2.3.4. Distorted Gaussian. The distorted Gaussian (DGauss) model begins with a Gaussian process with a given autocorrelation structure and maps it into an appropriate marginal distribution. Examples of this popular traffic generation technique include the autoregressive-to-anything process [20] and the self-similar traffic model [8].

Many techniques exist to generate Gaussian time series (Gaussian in the marginal distribution) with a wide range of autocorrelation decay characteristics. A background Gaussian process Z_k is imparted with an autocorrelation structure $\rho'(t)$ and is run through a fitting function $X_k = F_X^{-1}(F_N(Z_k))$ to map its values into an appropriate distribution. Because of the background–foreground transformations, precompensation is applied to the background autocorrelation ρ' such that the resulting output autocorrelation ρ matches the desired specification [8].

2.3.5. Fractal Lévy Motion. Laskin et al. [11] introduced a teletraffic model that takes into account, in addition to the Hurst parameter $H \in [\frac{1}{2}, 1)$, the Lévy parameter $\alpha \in (1,2]$. This was the so-called *fractional Lévy motion* (fLm), mentioned by Mandelbrot [14]. Two important subclasses of Lévy motion exist: (1) the well-known ordinary Lévy motion (oLm), an α-stable process (distributed in the sense of P. Lévy) with independent increments, which is a generalization of the ordinary Brownian motion (the Wiener process); and (2) the fractional Lévy motion, a self-similar and stable distributed process, which generalizes the fractional Brownian motion (fBm), has stationary increments and an infinite "span of interdependence."

Several self-similar stable motions have been proposed for traffic modeling. These processes combine, in a natural way, both scaling behavior and extreme local irregularity.

2.4. Multifractal Models

Historically following self-similar models, researchers have been studying also the possibility of modeling network traffic with *multifractal* processes (see book by Park and Willinger [16] and references cited within). It appears that even though measured network traffic is consistent with asymptotic self-similarity, it also exhibits small timescaling features that differ from those observed over larger time scale. This small timescaling behavior has been related to communication protocol-specific mechanisms and end-to-end congestion control algorithms that operate at those small timescales (less than a few hundred milliseconds). Modeling network traffic with multifractals has the potential of capturing the observed scaling phenomena at large as well as small timescales and thus to naturally extend and improve the original self-similar models of measured traffic.

To quantify the local variations of traffic at a particular point in time t_0, let $Y = \{Y(t), 0 < t < 1\}$ denote the traffic rate process representing the total number of packets or bytes sent over a link in an interval $[t_0, t_0 + t]$. The traffic has a *local scaling component* $\alpha(t_0)$ at time t_0 if the traffic rate process behaves like $t^{\alpha(t_0)}$ as $t \to 0$. In this context, $\alpha(t_0) > 1$ relates to instants with low intensity levels or small local variations, and $\alpha(t_0) < 1$ is found in regions with high level of burstiness or local irregularities.

If $\alpha(t_0)$ is constant for all t_0, then the traffic is *monofractal*. Equivalently, if $\alpha(t_0) = H$ for all t_0, then the traffic is exactly self-similar, with Hurst parameter H. On the other hand, if $\alpha(t_0)$ is not constant and varies with time, the traffic is *multifractal*.

The multifractal appearance of WAN traffic is attributed to the existence of certain multiplicative mechanisms in the background. Multifractal processes are well modeled using multiplicative processes or "conservative cascades." The latter are a fragmentation mechanism, which preserves the mass of the initial set (or does so in the expected value sense). The generator of the cascade is called the fragmentation rule and the mathematical construct that describes the way mass is being redistributed is called the limiting object or multifractal. Modern data networks together with their protocols and controls can be viewed as specifying the mechanisms and rules of a process that fragments units of information at one layer in the networking hierarchy into smaller units at the next layer, and so on.

Multifractal processes are a generalization of self-similar processes. Hence, self-similar processes are also multifractal, but the reverse is not always true. This leads to the important modeling question: Which of the two types of models is more appropriate in a given case? A method for distinguishing between the two models has been proposed [19]. Their conclusion was that traffic traces from environments were well modeled using self-similar models and that more sophisticated models such as multifractals were not needed. On the other hand, in WAN environments, there were cases where self-similar models were not deemed adequate and where multifractal models appeared to be more appropriate.

2.5. Fluid Traffic Models

In fluid traffic modeling, individual units such as packets, are not explicitly modeled. Instead, traffic is viewed as a "stream of fluid" arriving at a certain *rate* that may be changing. Fluid models can simplify analysis due to their lower "resolution" or level of detail. More importantly, fluid models can make network simulation much more efficient, since the computer representation of the fluid traffic requires much fewer "events" (e.g., rate changes) that need to be tracked.

In modern high-speed networks such as asynchronous transfer mode (ATM) networks, the size of individual packets is often fixed and very small (e.g., 53 bytes), relative to the total transmission speed and aggregate volume of

information being transmitted (e.g., hundreds of megabits or gigabits per second). Therefore fluid modeling may be appropriate in such cases and, in general, whenever individual packets can be regarded as effectively insignificant with respect to the total traffic. The validity of this approximation depends heavily on the timescale involved as well as the point of interest inside the network (e.g., access points versus large routers in the middle of the network).

Fluid models [9] typically assume that sources are bursty, commonly of the ON–OFF type. In the OFF state, there is *no* traffic arriving, while in the ON state traffic arrives at a constant rate. To maintain analytic tractability, the durations of ON an OFF periods are assumed exponentially distributed and mutually independent (i.e., they form an alternating renewal process).

3. SOURCE MODELS

In this section, the modeling of different type of traffic sources is discussed. The flow generated by some network sources are regulated by the stack of protocols used in the network. Such type of sources is called *elastic sources*. Sources whose flow do not depend on network protocol are called *streaming sources*. First, streaming multimedia sources are introduced, followed by the modeling of elastic sources. This section concludes with a general characterization of traffic streams, called *effective bandwidth*.

3.1. Data

Datastreams were traditionally modeled by Poisson processes. The rationality behind it was that the superposition of several independent renewal processes tends to a Poisson process.

The nature of traffic changes as new applications becomes a significant part of the network traffic. SMTP, email, TELNET, and FTP were responsible for most of the traffic in pre-Web time. As the use of Web services became predominant, Internet traffic began to present new patterns. Most of today is network traffic is based on the Transmission Control Protocol (TCP). Internet traffic observed at long timescales exhibits self-similarity. However, at long timescales, typically shorter than a round–trip time, Internet traffic presents high variability. At short timescales, Internet traffic marginal distribution is non-Gaussian and the scaling exponent of the variance is smaller than the asymptotic exponent. In other words, at short timescales, Internet traffic exhibits multifractal scaling, with different moments of the traffic showing scaling described by distinct exponents. However, at long timescales it can be modeled as self-similar [4,5]. Such behavior is originated by the complex interaction between network protocols that governs the network flow and TCP sources.

3.2. Voice

The packetstream from a voice source can be characterized by an ON–OFF model; Thus, during silent periods no packet is generated and during "talkspurt" periods, packets are generated either at exponentially distributed intervals or at constant intervals depending whether compression algorithms are used. The residence time in each state is exponentially distributed.

A popular approach to analyze a multiplexer fed by several ON–OFF sources is to use Markov modulated processes to mimic the superposition process. The arrival rates and the transition probabilities of the underlying Markov chain are defined in a way that certain statistics of the Markov modulated process have the same numerical value of the corresponding statistics of the superposition process. The advantage of adopting a 2-state process is to keep the complexity of both the matching procedure and the queuing solution low. In a 2-state MMPP (Fig. 2) there are only four parameters to be determined: the arrival rate and the sojourn time in each state. Several procedures are available to set these four parameters. Most of procedures consider 2 superstates: the underloaded and the overloaded states [18]. In the overload state, the packet generation rate (due to the number of source in state ON)

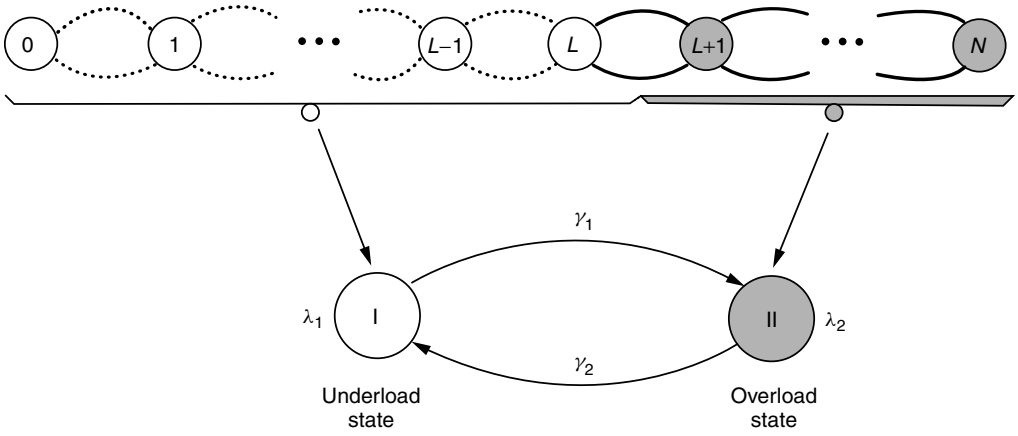

Figure 2. Modeling the superposition of voice sources as a 2-state MMPP. The states of the original Markov chain represent the number of sources in state ON and the arrival rate, in the nth state is n times the arrival rate in state ON. The superstates of the 2-state MMPP correspond to underload overload periods depending on whether the aggregated arrival rate surpasses the channel capacity.

exceeds the server capacity, whereas in the underload state it is below the server capacity.

3.3. Video

The bit rate of a videostream depends not only on the coding algorithm but also on the level of activity of a scene. Whenever there is a scene change, a new scene has to be encoded, generating a high number of bits to be transmitted, and, consequently high bit rates.

The MPEG coding scheme is widely used for several types of applications. MPEG streams consist of a series of frames. In MPEG-2, there are three types of frames: intracoded (I), predictive (P), and bidirectional (B). A periodic sequence of I, B, P frames is called *group of pictures* (GOP). An MPEG transmission consists of one GOP after the other. Typically I frames will have more bits than P and B frames, and B frames will have the least number of bits. The size of I frames can be approximated by a Normal distribution, whereas the size of B and P frames can be approximated either by a gamma or by a lognormal distribution. Figure 3 illustrates the bit rate profile of a typical videostream. The high peaks correspond to scene changes, whereas the low peaks correspond to the activity within a scene.

Video traffic exhibits long-range dependencies [2,8]. The repetitive pattern of GOPs introduces strong periodic components in the autocorrelation function (ACF). Video streams are usually modeled either by a fractal Brownian motion process or by a fractal ARIMA (0,d,0) process, which are LRD processes. However, some researchers advocate that, for finite buffer, long-term correlation have minor impact on queuing performance, and, therefore, Markovian models should be used, since only short term correlations impact the performance. The discrete first-order autoregressive model, DAR(1), is a popular Markovian process used for video modeling. Actually, Markovian models give rise to ACF of the form $\rho(k) \sim e^{-\beta k} (\beta > 0)$, whereas an LRD process exhibits ACF of the form $\rho(k) \sim k^{-\beta} = e^{-\beta \log^k} (\beta > 0)$ [10]. In fact, the performance of fractal models may be overly sensitive to the buffer size, and, consequently, may underestimate the actual performance. On the other hand, Markovian models provide good performance under heavy loads; however, they perform poorly under light loads [10].

3.4. Elastic Sources

The amount of data an application can pump into the network is often regulated by the network protocols and their congestion control mechanisms, which probe the available bandwidth to determine the amount of data that can be transmitted. Traffic sources whose transmission rate depend on network congestion status are called *elastic sources*. Examples of elastic sources are the available bit rate service (ABR) in ATM networks and the Transmission Control Protocol (TCP), largely deployed in the Internet.

TCP congestion control mechanism is a window-based one. Segments, or "packets" in TCP language, are transmitted and acknowledgments from the receiver are expected. Each segment has a sequence number, set at the sending end. Acknowledgments specify the sequence number of the acknowledged segment. Acknowledgments are cumulative; an acknowledgment notifies the transmitter that all the segments with a lower sequence number were properly received. The time from sending a packet to receiving its acknowledgment is called round–trip time (RTT). TCP controls a connection rate by limiting the number of transmitted-but-yet-to-be-acknowledged segments. In the beginning, the window size is set to one. Every time an acknowledgment is received, that is, at every RTT, the window size is doubled, and the window grows up to a threshold. After this threshold, the window is incremented by one segment.

Whenever an acknowledgment fails to arrive after a predefined interval, a timeout event occurs and the threshold is set to one-half the current congestion window and the congestion window is set to one. If the transmitter receives three consecutive acknowledgments for the same segment, it is assumed that the next segment was lost and the window is set to one-half its current value.

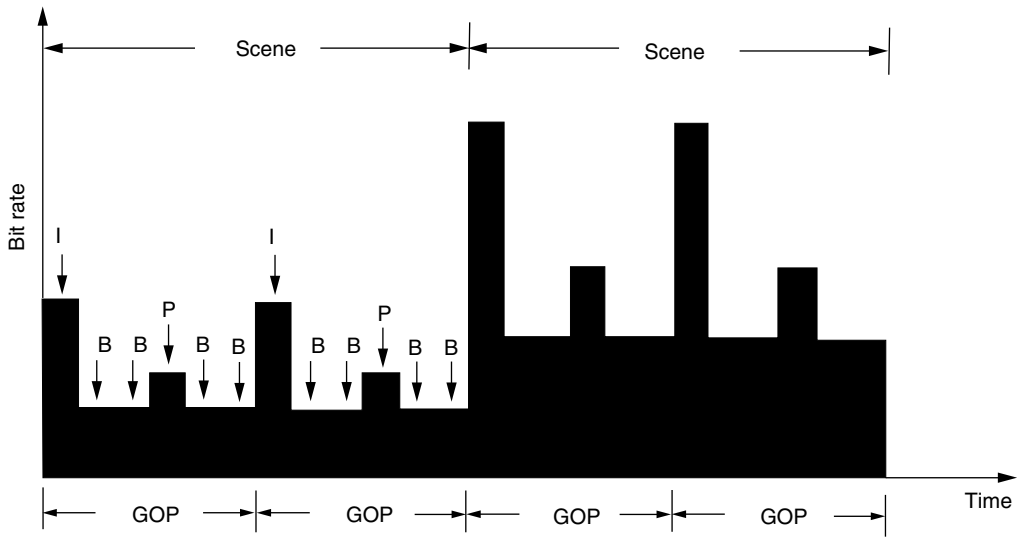

Figure 3. Bit rate of a video transmission.

The evolution of the window size between loss events can be analyzed in order to determine a TCP connection throughput, that is, the amount of data a TCP connection pumps into the network per unit of time by observing the window size evolution between loss events. The distribution of interloss periods as well as the distribution of the type of the loss event should be factored into this computation.

4. EFFECTIVE BANDWIDTHS AND ENVELOPE PROCESSES

Most communications services are subject to performance constraints designed to guarantee a minimal quality of service (QoS). Consider a general traffic stream offered to a deterministic server, and assume that some prescribed parameterized performance constraints are required to hold. The effective bandwidth of the traffic stream corresponds to the minimal deterministic service rate, required to meet these constraints. Queuing-oriented performance constraints include bounds on such statistics as queuing delay quantiles or averages, server utilization, and overflow probabilities. The effective-bandwidth concept serves as a compromise between two alternative bandwidth allocation schemes, representing a pessimistic and an optimistic outlook. The strict one allocates bandwidth based on the stream peak rate, seeking to eliminate losses, whereas the lenient one allocates bandwidth based on the stream average rate, merely seeking to guarantee stability.

Let us formally define effective bandwidth, Let $X[0,t]$ be the workload that arrived during time interval $[0,t]$ for a traffic stream. Effective bandwidth of the traffic stream is defined as $\alpha(s) = \lim_{t\to\infty} \frac{1}{st} \log E(e^{sX[0,t]})$, which is a function of $s > 0$, the so-called space parameter. In the effective bandwidth theory, s is the asymptotic exponential decay rate of queue size distribution tail probability with respect to queue size; that is, when the service rate is $\alpha(s)$, the queue size distribution tail probability with respect to queue size is $P(Q > B) \approx \exp(-sB)$, where Q denotes the queue size. This is why s is called the *space parameter*.

The notion of effective bandwidth provides a useful tool for studying resource requirements of telecommunications services and the impact of different management schemes on network performance. Estimates of effective bandwidths are called *empirical effective bandwidths*, while the analytic form are called *analytic effective bandwidths*.

4.1. Envelope Processes

An envelope process is a function which provides a bound for the amount of work generated in a traffic stream during a certain time interval. If $A(t_2 - t_1)$ is the amount of bits generated during the interval $t_2 - t_1$, then $\hat{A}(t)$ is an envelope process for $A(t)$ if and only if $\hat{A}(t_2 - t_1) > A(t_2 - t_1)$, for any $t_2 > t_1$. For any traffic stream, $A(t)$, there is a whole family of possible envelope processes; however, the lowest bound is the one of interest. Envelope processes are useful tools since, in general, they require a small number of parameters — that is, they are a *parsimonious* way of representing a stochastic process. However, dimensioning based on envelope processes may overestimate the required resources. Moreover, envelope processes are not appropriate for the study of phenomena at the cell timescale, such as cell discarding.

Network services can be either deterministic or statistical. Accordingly, deterministic and stochastic envelope processes are defined. A deterministic envelope process is a strict upper bound on the amount of work arriving during an interval for a traffic stream. A commonly used envelope process is $\int_0^t A(t) < \rho t + \sigma$, where ρ is the source mean arrival rate and σ is the maximum amount of work allowed in a burst [3]. $\rho t + \sigma$ is a model for the output of a leaky bucket regulator where ρ is the leaky rate and σ the bucket size.

In a stochastic envelope process, the amount of work generated in a certain interval may surpass a deterministic bound with a certain probability value. An accurate stochastic envelope process for a fractal Brownian motion process is $\rho t + k\sigma t^H$, where ρ is the mean arrival rate, σ is the standard deviation, and H is the Hurst parameter [6]. Note that the amount of work is not a linear function of time, it has a t^H which takes into account long periods of arrivals.

5. CONCLUSIONS

The aim of traffic modeling is to provide network designers with simple means to predict the network load, and consequently, the network performance. Since the early days of telephony networking, engineers have been engaged in understanding the nature of network traffic, and its impact on quality of service provisioning. Traffic models mimic the traffic patterns observed in real networks. The suitability of a traffic model is related to the degree of accuracy of the conclusions that can be drawn from studies using such a model. Therefore, there is no unique model for a certain type of traffic, but models with different degrees of accuracy.

With the advent of integrated networks, Poisson models for traffic streams were replaced by more sophisticated short range dependent models which considered the correlation pattern besides the mean arrival rate. By 1993, the seminal work of Leland et al. [12] demonstrated the fractal nature of LAN traffic. Several other works followed showing that other types of traffic such as video traffic were also fractal. Recent studies have shown that Internet traffic is not precisely fractal at small timescales, but can be represented well as fractal at larger timescales. The understanding of the impact of multifractality on network performance is still an open problem.

Traffic patterns are influenced by several factors such as the nature of file size, human think time, protocol fragmentation, and congestion control mechanisms. New challenging problems in traffic modeling will certainly exist when multimedia applications become a significant part of the whole network traffic.

BIOGRAPHIES

Mihail (Mike) Devetsikiotis was born in Thessaloniki, Greece. He received the Dipl. Ing. degree in Electrical Engineering from the Aristotle University of Thessaloniki, Greece, in 1988, and the M.Sc. and Ph.D. degrees in

Electrical Engineering from North Carolina State University, Raleigh, in 1990 and 1993, respectively. As a student, he received scholarships from the National Scholarship Foundation of Greece, the National Technical Chamber of Greece, and the Phi Kappa Phi Academic Achievement Award for a Doctoral Candidate at North Carolina State University. He is a member of the IEEE, INFORMS, and the honor societies of Eta Kappa Nu, Sigma Xi, and Phi Kappa Phi. In 1993 he joined the Broadband Networks Laboratory at Carleton University, as a Post-Doctoral Fellow and Research Associate. He later became an Adjunct Professor in the Department of Systems and Computer Engineering at Carleton University in 1995, an Assistant Professor in 1996, and an Associate Professor in 1999. Dr. Devetsikiotis joined the Department of Electrical and Computer Engineering at North Carolina State University as an Associate Professor, in 2000. He has served as an officer of the IEEE Communications Society Technical Committee on Communication Systems Integration and Modeling, and as Associate Editor of the journal *ACM Transactions on Modeling and Computer Simulation*.

Nelson Fonseca received his Electrical Engineer (1984) and M.Sc. in Computer Science (1987) degrees from The Pontificial Catholic University at Rio de Janeiro, Brazil, and the M.Sc. (1993) and Ph.D. (1994) degrees in Computer Engineering from The University of Southern California in Los Angeles. Since 1995 he has been affiliated to the Institute of Computing of the State University of Campinas, Brazil, where is currently an Associate Professor.

He is the recipient of Elsevier Editor of the Year 2000, of the 1994 USC International Book award, and of the Brazilian Computing Society First Thesis and Dissertations award. Mr. Fonseca is listed in Marqui's *Who's Who in the World* and *Who's Who in Science and Engineering*.

He served as Editor-in-Chief for the *IEEE Global Communications Newsletter* (1999–2002). He is an Editor for *Computer Networks*, an Editor for the *IEEE Transactions on Multimedia*, an Associate Technical Editor for the *IEEE Communications Magazine*, and an Editor for the *Brazilian Journal on Telecommunications*.

Dr. Fonseca was the chairman of the 7th IEEE Workshop on Computer-Aided Modeling, Analysis and Design of Communications Networks and Links (CAMAD'98), Vice-Chairman of IEEE GLOBECOM99 Symposium on Multimedia Services and Technology Issues, Vice-Chairman of CAMAD'2000, and Vice-Chairman of the International Teletraffic Congress'17, 2001.

1. INTRODUCTION

Conventional (serial) computers have a processing unit that executes instructions one after the other, *sequentially*, at a rate that could be as high as 1 billion instructions per second. The way the human brain processes information seems, however, to be quite different. The brain has about 100 billion processing units, called *neurons*, that are highly interconnected. A neuron typically is connected to more than 1,000 other neurons, giving rise to more than 100 trillion connections. Even if only 0.1% of them are active at any given time, and each connection functions as a very slow processor performing one computation every 5 milliseconds, the brain can deliver *in parallel* 100 trillion operations per second (100 Teraops)! Exploiting vast amounts of low-level parallelism may explain why the human brain can perform high-level perceptual tasks, such as visual pattern recognition, speech understanding and so on, very efficiently even though its pattern-searching capabilities are very modest compared with today's fast computers.

Should we try to build computers that work like the human brain? Should we try to imitate closely what we know from biology? These questions have been long debated in the scientific and engineering community. At the one end, *computational neuroscientists* tell us that accurate modeling of the neuronal interactions will illuminate how the brain operates. At the other end, engineers, who are mostly interested in building intelligent machines, tell us that it may be sufficient to draw from the principles that led to successful designs in biology without trying to approximate the biological systems very closely. So starting from the same inquiry, the highly interdisciplinary field of *neural networks* (NN), or *neurocomputing*, has emerged and moved outward in several different directions, and it continues to evolve.

Artificial neural networks (ANNs) are highly interconnected distributed information processing architectures that are built by connecting many simple processing unit models. They come in many different flavors, but all are characterized by their ability to *learn*, that is, to adapt their behavior and structure to capture and form a representation of the process that generates information in the environment where they operate. It is typical to select first an appropriate NN model; then adequately *train* it, using data representative of the underlying environment; and finally present to it novel (unseen) data and let the network extract useful information, a process called *generalization*, or *recall*. Neural networks have become a mainstream information technology and are no longer considered exotic techniques. They are commonly used in data analysis (time series, forecasting, compression, etc.), in studying systems behavior (system identification, adaptive control, chaotic behavior etc.), and in modeling stochastic processes (for uncertainty characterization, pattern classification etc). Neural network solutions have been tried on all types of scientific and engineering problems, ranging from signal and image processing, communications, and intelligent multimedia systems, to data mining, credit card fraud detection, economic forecasting, modeling of ecological systems and detecting patterns in gene expression microarrays, and so on.

This article is organized as follows: In Section 2, we introduce basic knowledge NNs such as the structure of commonly used processing elements, a review of popular network architectures, and associated learning rules. In Section 3, we discuss why different NN architectures have found so many applications in communications by selecting some well-known subareas and discussing representative cases of their use.

2. BASIC NEURAL NETWORKS THEORY

2.1. The Neuron Node

Let us start by considering a simplified view of a bipolar biological neuron. At the "center" of the neuron there is the cell body, or *soma*, that contains the cell *nucleus*. One or more *dendrites* are connected to the nucleus. They are so called because they structurally resemble the branches of a tree. Dendrites form the receiving end of the nerve cell, and their role is to sense activity at their neighborhood and generate a proportional amount of electrical impulses that are sent toward the cell body. A long signal transmission line, called an *axon*, is emanating at the cell body and carries the accumulated activity (action potentials) away from the soma toward other neurons. At the other end of the axon there are *synaptic terminals*. There, the transmitted signal is translated to signals sensed by the dendrites of neighboring neurons through an electrochemical interface process called a *synapse*. A typical cortical neuron may have a few thousand synapses for receiving input, and its axon may have a thousand or so synaptic terminals for propagating activity to other neurons' dendrites.

The communication operations of the simplified neuron model can be summarized as follows: Signals (impulse trains) arrive at the various input synapses. Some signals are stronger than others and some synapses are less receptive than others, due to causes such as fatigue, exposure to chemical agents, and so on. So, as induced signals travel toward the cell body, they effectively are "weighted" (i.e., they are not all deemed equally important). The induced activity is integrated over time and if it exceeds a threshold, the neuron "fires" (produces an output). The generated output signal is transmitted along the axon and may induce signals at the dendrites of other neurons in the proximity.

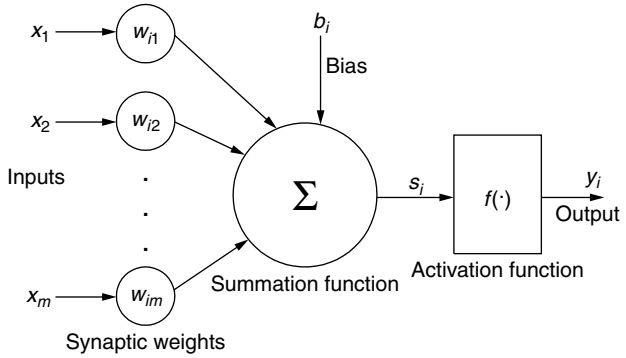

Figure 1. The basic neural network node model.

A neuron node, or *processing element* (PE), of an ANN is a simplistic model that mimics the sequence of the actions described above (see also Fig. 1). Each input $x_k, k = 1, 2, \ldots, m$, to PE_i is first multiplied by the corresponding *synaptic weight*, w_{ik}, that models the strength of the synapse between neurons k an i. Then all weighted inputs are summed. A node specific *bias*, or forcing term, b_i, is also added to the partial sum, providing an additional mechanism to influence node i directly and not through the outputs of other neurons. The *induced local field* s_i becomes the input of an *activation function* $f(\cdot)$ that determines the output y_i of the node. The whole processing can be described by the following two simple equations:

$$s_i = \sum_{k=1}^{m} w_{ik} x_k + b_i \tag{1}$$

$$y_i = f(s_i) \tag{2}$$

The activation, or *transfer function* $f(\cdot)$ usually is nonlinear and limits the range of the values of the neuronal output y_i. Among the most widely used functional forms are those shown in Fig. 2. The hard delimiter (left-most panel) produces a binary, 0 or 1, output when the induced local field has a negative value or positive value, respectively. The transition from level 0 to level 1 is gradual when using a linear ramp-like function (middle panel). Perhaps the most commonly used activation function is the *sigmoidal*

$$f(x) = \frac{1}{1 + e^{-ax}} \tag{3}$$

(see right-most panel). As a increases, the sigmoidal nonlinearity behaves like a hard delimiter. When a -1, $+1$, *antipodal* hard delimiter is used, the neuron node is also usually referred to as a *perceptron*.

2.2. Neural Network Architectures

As with biological NNs, individual neurons are not very useful when working in isolation. Neuron units are usually organized in layers. In a *feedforward* NN, the outputs of the nodes in one layer become inputs to the nodes of the next layer. This is shown in Fig. 3, where circles depict neuron units and arcs represent weighted connections among them. The network is *fully connected* because the output of a node feeds into every node of the next layer

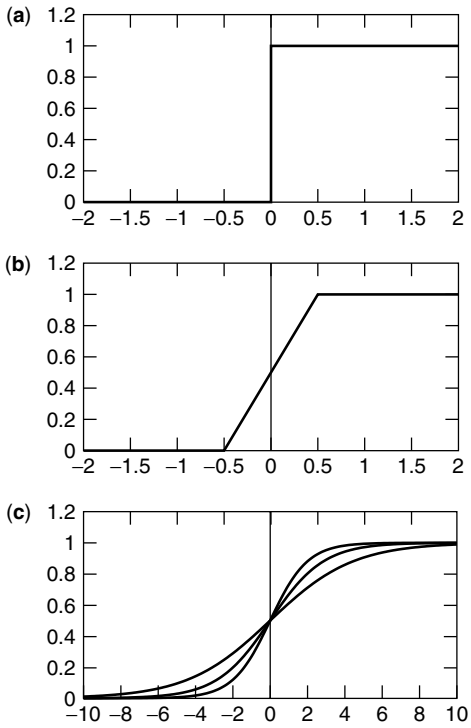

Figure 2. Neural network node activation functions. From left to right: (**a**) hard delimiter; (**b**) piecewise linear; (**c**) sigmoidal; it approaches the hard delimiter as a increases.

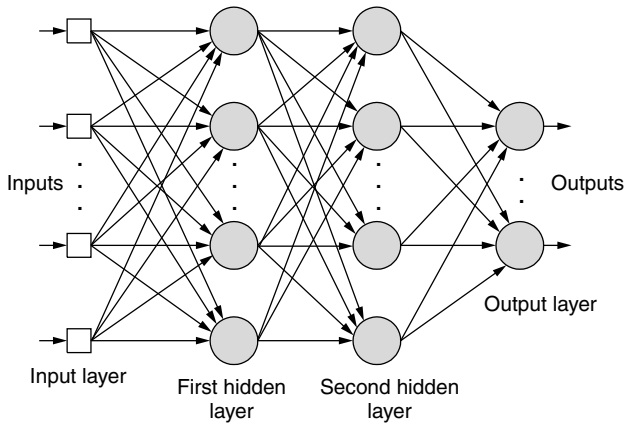

Figure 3. The multilayer feedforward neural network architecture.

via a weighted connection. It has one input layer, two *hidden* layers, and one output layer. The input layer is where the network receives stimuli from the environment, and the output layer is where it returns its response. The middle layers are called "hidden" because their nodes are not directly accessible from outside the network.

If the output of a neuron may become an input to itself, or to other neurons of the same or previous layers, the resulting architecture is called a *feedback*, or *recurrent*, NN. A single layer, fully recurrent NN with four nodes is shown in Fig. 4, where a small box denotes a synaptic weight. Each PE receives a weighted input from the output of every node, including itself, and from an external bias.

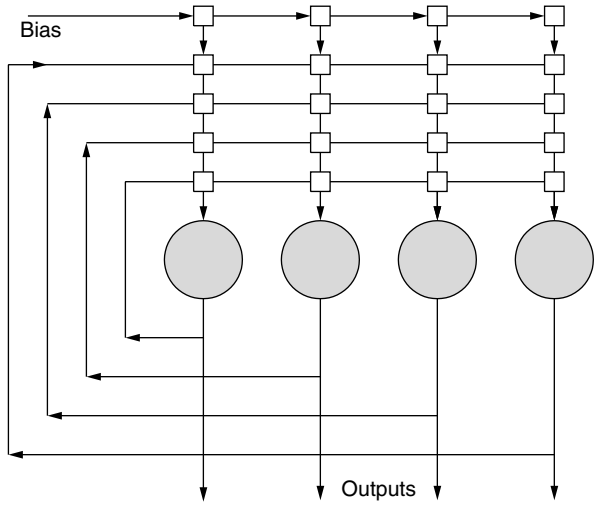

Figure 4. A single layer fully recurrent neural network architecture.

All weighted inputs are accumulated to produce the neuron activation that is passed through a nonlinear thresholding transfer function to produce the new output, as shown in Fig. 1.

Hopfield neural networks (HNNs) [1,2], are single-layer recurrent networks that can collectively provide good solutions to difficult optimization problems. A connection between two neuron processors (analog amplifiers) in established through a conductance weight T_{ij}, which transforms the voltage outputs of neuron unit j to a current input for neuron unit i. Externally supplied bias currents I_i are also feeding into every neuron processor.

It has been shown [3] that in the case of symmetric weight connections ($T_{ij} = T_{ji}$), the equations of motion for the activation of the HNN neurons always lead to convergence to a stable state, in which the output voltages of all the neurons remain constant. In addition, when the diagonal weights (T_{ii}) are zero and the width of the neuron amplifier gain curve is narrow, (i.e., the nonlinear activation function $f(\cdot)$ approaches the antipodal thresholding function), the stable states of a network with N neuron units are the *local* minima of the quadratic *energy function*

$$E = -\frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N} T_{ij}V_iV_j - \sum_{i=1}^{N} V_iI_i \tag{4}$$

If the small boxes in Fig. 4 represent conductance weights that meet the conditions discussed, the recurrent NN shown in the figure becomes an HNN with $N = 4$ neuron processors.

2.3. Learning and Generalization

2.3.1. Supervised Learning. Neural network learning amounts to adjusting the synaptic weights periodically and until an appropriate cost function is sufficiently minimized. There are two categories of learning methods. In *supervised* learning, also called "training with a teacher," it is assumed that a desired response $\mathbf{d}$ is provided for every input vector $\mathbf{x}$ in a training set $\mathcal{X}$. For every pair $(\mathbf{x}, \mathbf{d}) \in \mathcal{X}$ the network output $\mathbf{y}$ is compared to $\mathbf{d}$ and the difference (error) vector $\mathbf{e} = \mathbf{d} - \mathbf{y}$ is used to determine how the network weights will get updated, as suggested by the block diagram in Fig. 5 (a).

Supervised learning can be used to train a neural network to act as a *pattern classifier*. Let us assume for simplicity that the network input patterns (vectors) belong to one of two possible classes, C_1 or C_2. Then it suffices to use only one neuron in the output layer; its desired output can be $+1$ if it is known that the pattern belongs to class C_1, or -1 if the pattern belongs to class C_2. By adding more neurons in the output layer, neural classifiers that can discriminate among more than two categories can be built.

Supervised learning can also be used in the more general *pattern association* context. If the input and desirable output patterns are identical, the network is trained to act as an *associative memory*. After adequate training, when the network is presented with an unseen input pattern, it is expected to *recall* the learned pattern that most closely resembles the input. In general, input vectors can be n-dimensional and desirable output vectors m-dimensional, with $m \neq n$.

An example of a weight updating rule used in supervised learning is the so-called *delta rule*, or *Windrow-Hoff* rule. It states that the amount of weight adjustment of synapse k to neuron i, Δw_{ik}, should be proportional to the product of the observed error e_i and the input signal to

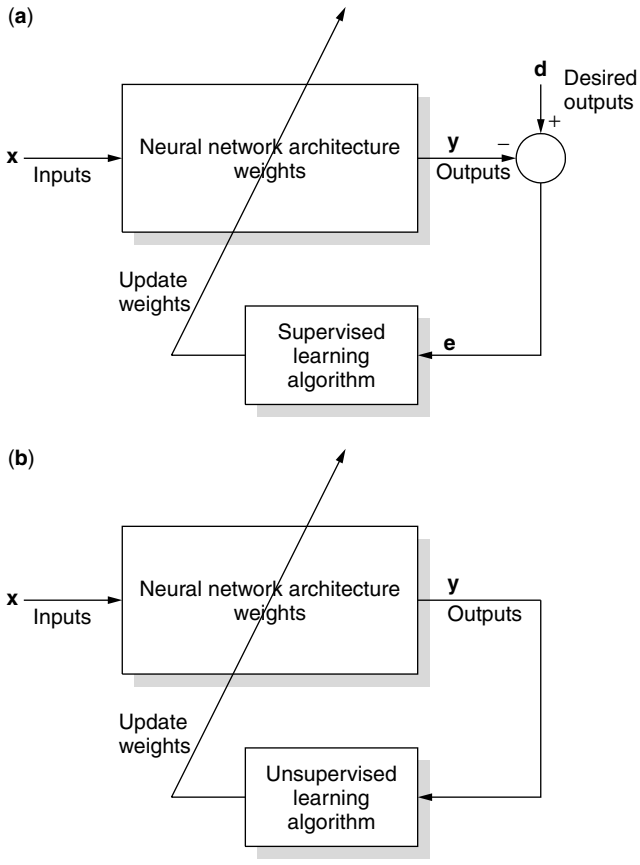

Figure 5. Learning methods: (**a**) supervised training; (**b**) unsupervised training.

neuron i from neuron k, that is

$$\Delta w_{ik} = \alpha e_i x_k \tag{5}$$

Constant α controls the *learning rate* and usually is a small number between 0 and 1. Therefore, after the presentation of input pattern n, the updated weight becomes

$$w_{ik}(n+1) = w_{ik}(n) + \Delta w_{ik}(n) \tag{6}$$

Note that the delta rule uses only information local to neuron i in updating its synaptic weights. However, it does assume that the error term is accessible (i.e., that a desired output d_i is provided for every neuron). It has been shown that if the input vectors in a training set can be separated by a linear hyperplane into two classes, this hyperplane (decision boundary) can be determined by using the weights, upon convergence, of a single layer perceptron trained using correction-based learning.

The error term is directly accessible only for the neurons in the output layer L of a multilayer perceptron (MLP). However, an elegant generalization of the delta rule has been derived that allows the supervised training of MLPs. It is widely known as the *back-propagation algorithm* [4,5] and works as follows. First, the network weights are initialized and an input pattern $\mathbf{x}(n)$ is presented to the input layer. The pattern propagates forward to produce output $\mathbf{y}(n)$ in the output layer L. The network error for pattern n can be defined as

$$E(n) = \frac{1}{2}\sum_{i \in L} e_i^2(n) \tag{7}$$

Adjusting the weight to minimize the total average error $E = 1/N \sum_n E(n)$ leads to a generalized delta rule

$$\Delta w_{ik}(n) = \alpha \delta_i(n) x_k(n) \tag{8}$$

where $\delta_i(n) = \dfrac{\partial E(n)}{\partial s_i}$ is the *local gradient* of the network error for pattern n with respect to neuron i. If neuron i is at the output layer L, this quantity is directly proportional to the error $e_i(n)$. On the other hand, if neuron i is at some level $l < L$, $\delta_i^l(n)$ is proportional to the sum of the $w_{ji}\delta_j^{l+1}(n)$ terms, taken over all neurons j in layer $l+1$ that are connected to neuron i in layer l. So the back-propagation algorithm starts from the output layer L, where vector δ^L is computed directly using the measured error vector $\mathbf{e}$ and is used to update the synaptic weights from layer $L-1$ to layer L. Then these weights and δ^L are used to compute δ^{L-1} and update the synaptic weights from layer $L-2$ to layer $L-1$, and so on. So the error correction propagates backward, toward the input layer, and the weights connecting neurons in two successive layers can be updated in parallel using only localized processing.

Supervised learning methods have been used extensively in communication applications such as channel modeling and identification, adaptive equalization, and so on, as is discussed in more detail in Section 3.

2.3.2. Unsupervised Learning. As with biological neurons, an ANN may have to learn without a "teacher" (i.e., without using a prelabeled training data set). In *unsupervised learning*, as input patterns are presented one after the other, the network should be able to build a meaningful representation of their distribution. Furthermore, it should detect changes in the important characteristics of this distribution and react by adapting its parameters accordingly, as suggested by the block diagram in Fig. 5 (b).

To *self-organize* the network relies on local processing rules that over time help it discover important features in the input patterns and track how they change. A stable representation eventually emerges, for example, a clustering or a topological map arrangement, that models quite well the input patterns' distribution.

Self-organization requires some form of competition, possibly followed by cooperation among neurons in the neighborhood of the winner. In *competitive learning*, neurons start competing when a new pattern is presented to the network. The neuron that is most excited is usually declared the "winner." Neurons in the winner's neighborhood are then cooperating and update their weights according to a local learning rule. For example, in the case of Kohonen's *self-organizing map* (SOM) [5,6], if neuron i wins in the competition for representing pattern $\mathbf{x}(n)$, only neurons j in its topological neighborhood (same region in the lattice of neurons) are allowed to update their weights according to the rule

$$\Delta \mathbf{w}_j(n) = \alpha h_{ji}(n)(\mathbf{x}(n) - \mathbf{w}_j(n)) \tag{9}$$

where function $h_{ji}(n)$ is defined over the winner's neighborhood and its value decreases as the distance of neuron j from the winner neuron i increases. Furthermore, the domain of $h_{ji}(n)$ may shrink over time. In essence, Kohonen's learning rule "moves" toward the input pattern vector, the weight vectors of neurons located in the winner's neighborhood.

A similar situation arises when training *radial basis functions* (RBF) [5,7]. RBFs are three-layer feedforward NNs. The first layer is used to input patterns; every neuron k in the middle (hidden) layer receives the input pattern vector $\mathbf{x}$ and produces an output based on a Caussian bell-shape nonlinear activation function

$$\phi_k(\mathbf{x}, \mathbf{c}_k) = \exp\left(-\frac{1}{2\sigma_k^2}\|\mathbf{x} - \mathbf{c}_k\|^2\right) \tag{10}$$

where $\mathbf{c}_k$ is the *center* associated with the kth neuron. Finally, each neuron j in the output layer is computing a different linear combination of the hidden layer neuron outputs, that is

$$y_j = \sum_k w_{jk}\phi_k(\mathbf{x}, \mathbf{c}_k) \tag{11}$$

A combination of unsupervised and supervised training can be used for RBF networks. The hidden neuron centers may be updated in an unsupervised manner as follows:

$$\Delta \mathbf{c}^* = \beta\,(\mathbf{x}(n) - \mathbf{c}^*) \tag{12}$$

where $\mathbf{c}^*$ is the center of the winning neuron [i.e., the one at smallest distance from the input pattern $\mathbf{x}(n)$]. The weights $\{w_{jk}\}$ may then be updated using error correction supervised learning

$$\Delta w_{jk} = \alpha\,(d_j(n) - y_j(n))\,\phi_k(\mathbf{x}, \mathbf{c}_k) \tag{13}$$

where $d_j(n)$, $y_j(n)$ are the desired and actual response of output layer neuron j to input pattern $\mathbf{x}(n)$ in the training set $\mathcal{X}$.

Unsupervised training is also used extensively in communication applications, such as coding and decoding, vector quantization, neural receiver structures, and blind equalization, to mention a few.

3. NEURAL NETWORK APPLICATIONS TO COMMUNICATIONS

Neural network techniques have traditionally been employed in solving complex problems where a conventional approach has not demonstrated satisfactory performance or has failed to adequately capture the underlying data-generation process. Although they often do improve the performance substantially, it sometimes is hard to understand the decisions they make and explain how these performance gains come about. This has been a point of criticism to the "black box" use of NNs. However, as the field matures and a clear link to Bayesian statistics is established [8], analyzing systematically and explaining how complex networks form successful representations is becoming more and more possible.

In the limited space of this article, we do not intend to provide a comprehensive survey of the numerous applications that NNs have found in communications. We will rather select a few well-known problems in communications and discuss some indicative neurocomputing solutions proposed for them. The selection of the problems to be discussed does not imply that they are more important than others. For a comprehensive review of the literature, the interested reader is referred to the recent article [9] and the edited collections of papers in Refs. 10 and 11.

3.1. Channel Modeling and Identification

Various feedforward neural network architectures, including the multilayer perceptrons and radial basis functions, are *universal approximators* [12,13]. This important property ensures that a neural network of appropriate size can approximate arbitrarily well any continuous nonlinear mapping from an n- to an to m-dimensional space, where $m \neq n$.

Communication channels often exhibit nonlinear, slowly time-varying behavior. So it is natural that NN techniques have been tried for the modeling and identification of communication channels that are used in receiver design, performance evaluation, and so on. Typical examples include satellite channels identification [14] and the modeling of nonlinear time-varying fading channels [15]. In this context, neural networks, with a moderate number of weights (free parameters) that can be updated in parallel, have been shown to provide an attractive alternative to classical nonlinear system identification methods, such as those based on Volterra series [16].

3.2. Channel Equalization

The demand for very high-speed transmission of information over physical communication channels has been constantly increasing over the past 20 years. Communication channels are usually modeled as linear filters having a low-pass frequency response. If the filter characteristics are imperfect, the channel distorts the transmitted signal in both amplitude and delay, causing what is known as *intersymbol interference* (ISI) [17]. As a result of this linear distortion, the transmitted symbols are spread and overlapped over successive time intervals. In addition to noise and linear distortion, the transmitted symbols are subject to other *nonlinear* impairments arising from the modulation/demodulation process, crosstalk interference, the use of amplifiers and converters, and the nature of the channel itself. All the signal processing techniques used at the receiver's end to combat the introduced channel distortion and recover the transmitted symbols are referred to as *adaptive equalization* schemes.

Adaptive equalization is characterized in general by the structure of the equalizer, the adaptation algorithm, and the use or not of training sequences [17]. Linear equalization employs a linear filter, usually with a finite impulse response (FIR) or lattice structure. A recursive least squares (RLS) algorithm or a stochastic gradient algorithm, such as the least mean squares (LMS), is used to optimize a performance index. However, when the channel has a deep spectral null in its bandwidth, linear equalization performs poorly because the equalizer places a highgain at the frequency of the null, thus enhancing the additive noise at this frequency band [17]. Decision feedback (DFE), in conjunction with a linear filter equalizer, can be employed to overcome this limitation. Although DFE and other methods, such as the maximum likelihood (ML) sequence detection [18], are nonlinear, the nonlinearity usually lies in the way the transmitted sequence is recovered at the receiver with the channel model being linear. If nonlinear channel distortion is too severe to ignore, the aforementioned algorithms suffer from a severe performance degradation. Among the many techniques that have been proposed to address the nonlinear channel equalization problem are those in Refs. 19–21, which rely on the Volterra series expansion of the nonlinear channel.

The authors in Ref. 22 have used an MLP feedforward NN structure for the equalization of linear and nonlinear channels. The network is trained to approximate the correct mapping from delayed channel outputs to originally transmitted symbols. It is demonstrated that significant performance improvements can be achieved. A functional-link NN-based DFE equalizer that exceeds the bit error rate performance of conventional DFE equalizers was reported in Ref. 23. For two-dimensional signaling, such as quadrature amplitude modulation (QAM) or phase shift keying (PSK) [17], NNs that can process complex numbers are needed. The authors in Ref. 24 have designed equalizers based on complex-valued radial basis functions and have shown that they can approximate well the decisions

of the optimal Bayesian equalizer. Combining in a loop a DFE equalizer and a self-organizing features map is discussed in Ref. 25. An interesting two-stage equalization strategy is proposed where the DFE compensates for dynamic linear distortions and the SOM compensates for nonlinear ones.

Fully recurrent neural networks (RNNs) have been used in Ref. 26 for both trained adaptation and blind equalization of linear and nonlinear communication channels. Since RNNs essentially model nonlinear infinite memory filters, they can accurately realize with a relatively small number of parameters the inverse of finite memory systems, and thus compensate effectively for the channel-introduced interferences. Their performance is shown to exceed that of traditional equalization algorithms and feedforward NN schemes, especially in the presence of spectral nulls and/or severe nonlinearities. Furthermore, due to the small number of neurons involved, the computational cost of their training may, in practice, be much smaller than that of the MLP-based equalizers of similar performance.

Blind equalization is a particularly useful and difficult type of equalization when training sequences are undesirable or not unfeasible, as, for example, in the case of multipoint communication networks and strategic communications. In the absence of a training sequence, the only knowledge about the transmitted signal is the constellation from which the symbols are drawn. A novel RNN training approach was introduced in Ref. 26 for the blind equalization of nonlinear channels using only a partial set of statistics of the transmitted signal. It is shown that simple RNN structures can equalize linear and nonlinear channels better than the traditional constant modulus algorithm.

3.3. CDMA Multiuser Detection

Code division multiple access (CDMA) is a spectrum-efficient method for the simultaneous transmission of digital information sent by multiple users over a shared communication channel. The spectral efficiency, as well as the antijamming and other attractive properties, make CDMA spread-spectrum techniques useful in a number of communication technologies, including mobile telephony and satellite communications. The wide bandwidth that spread-spectrum CDMA techniques employ enables them to exploit powerful low-rate error-correction coding to further enhance performance. The major limitation of the CDMA techniques however, is the so-called *near–far* problem. When the power of the signals transmitted by the users becomes very dissimilar, the conventional matched-filter detector exhibits severe performance degradation, so more complicated detectors have to be employed.

The optimum centralized demodulation of the information sent simultaneously by several users through a shared Gaussian multiple access channel is a very important problem arising in multipoint-to-point digital communication networks such as radio networks, local area networks, uplink satellite channels, uplink cellular communications, and so on. In CDMA, each transmitter modulates a different signature signal waveform, which is known to the receiver. At the receiver, the incoming signal is the sum of the signals transmitted by each individual user. To demodulate the received signal, we need to suppress the inherent channel noise, often modeled as an additive Gaussian process, and the multiple access interference (MAI).

It has been shown by Verdu et al. [27,28] that for the Gaussian channel, *optimal CDMA multiuser detection* (OMD) can be formulated as the solution of a quadratic integer programming problem that involves the sampled outputs of a bank of filters matched to the signature waveforms of the transmitting users as well as the cross-correlations of them. In Ref. 29, it is proved that, in both the *synchronous* and the *asynchronous* transmission cases, OMD is a computationally expensive problem for which polynomial time solutions most likely do not exist (NP-hard). Therefore, research efforts have concentrated on the development of suboptimal receivers that exhibit good near–far resistance properties, have low computational complexity, and achieve bit-error-rate (BER) performance that is comparable to that of the optimal receiver. Among the many suboptimal multiuser detectors proposed in the literature, we mention the *decorrelating detector* [28], which is linear in nature and complexity and achieves near-optimal performance, assuming that the users' signals form a linearly independent set and the spreading codes of all users are known. Another suboptimal detector is the *multistage detector* (MSD) [30], which relies on improving each stage's estimate by subtracting the estimate of the MAI obtained by the previous stage.

Feedforward NN-based multiuser detectors were first proposed in Refs. 31 and 32. While their performance is shown to be very good for a very small number of synchronous or asynchronous users, their hardware complexity (number of neurons and training time) appears to be *exponential* in the number of users, as conjectured in Ref. 31. Furthermore, it is only empirically possible to determine the number of neurons in the hidden layer as the number of users increases.

The well-known ability of HNNs to provide fast suboptimal solutions to hard combinatorial optimization problems has been exploited to implement efficiently the CDMA OMD in Ref. 33. Starting from the observation that the OMD problem's objective function can be put in the quadratic format of equation (4), an HNN multiuser detector is derived that is proven to be a generalization of the multistage detector. The HNN-based detector has been evaluated via extensive simulations and has been found to outperform the CD by orders of magnitude, exceed the performance of the MSD, and approach the performance of the OMD. Furthermore, the HNN-based detector has a hardware complexity (number of neurons) that is *linear* in the number of users K and does not require any training. Since it can be implemented directly using analog VLSI hardware, its computational cost per symbol is practically constant irrespective of the number of users.

However, as the number of simultaneous users increases, all NN-based receivers may become impractical. To address this severe limitation, a hybrid digital signal preprocessing–NN CDMA multiuser detection scheme was proposed in Ref. 34. An investigation on the nature of the local minima of the OMD's objective function led to the formulation of a computationally efficient digital

signal preprocessing stage that recursively reduces the size of the search space over which the original large-size OMD optimization problem has to be solved. After preprocessing, the remaining optimization problem has the same structure as the OMD but is much smaller and can be solved by an HNN implementable directly in hardware. The lesson learned is that combining conventional DSP with NN methods is worth considering because it often leads to optimized and practical solutions.

3.4. Networking Applications

Multimedia teleconferencing, video-on-demand, and distant learning are only a few examples of emerging applications that require high-speed communications. Each such application presents to the underlying network infrastructure different traffic characteristics and quality of service (QoS) requirements. An intelligent network should efficiently broker among applications with time-varying profiles to meet their short-term requirements while also maximizing the delivered long-term throughput.

The *asynchronous transfer mode* (ATM) is a widely accepted backbone networking technology due to its provisions for QoS delivery. ATM has builtin proactive and reactive mechanisms for effectively managing network resources (e.g., buffer space, etc.) according to traffic profiles and QoS requirements. By using them, it is possible to statistically time multiplex among sources with different burstiness and bit rate characteristics (e.g., voice, data, video) as they compete for the available bandwidth. It is not surprising that NNs, with their learning from examples, adaptation, and prediction capabilities, are among the artificial intelligence methods that have been employed extensively in this context.

The proactive mechanism that decides if a new call can be accepted given the current state of the network is termed *call admission control* (CAC). The integration of adaptive CAC and link capacity control for multimedia traffic over ATM is discussed in Refs. 35 and 36. Neural networks are trained to estimate the cell loss rate from link capacity and observed traffic. The link capacity assignment is then optimized according to the estimated cell loss rate. The application of NNs to the selective admission of a set of calls from a number of inhomogeneous call classes with differing rate and traffic variability characteristics is discussed in Ref. 37.

A good example of adaptive network traffic management is the dynamic allocation of video transmission bandwidth by taking into account the rate of scene changes. In Ref. 38 it is shown that it is feasible to predict scene changes online by employing low-complexity time-delay NNs and use these predictions in dynamic bandwidth allocation for the efficient transmission of real-time video traffic over ATM networks. Furthermore, in Ref. 39 a system consisting of pipelined recurrent NN models, where each RNN has a small number of neurons, is shown to be able to accurately predict the future behavior of MPEG video traffic, based on the ability of each RNN module to learn from previous traffic measurements. The system was used to guide control actions in real time and to prevent excess network loading.

An important task of adaptive network management is to ensure that applications honor their commitments and to respond if they violate their "contract" with the network. During call progress, the same parameters used for call admission may be utilized by a reactive network *policing* mechanism to ensure that the user's traffic remains within the prenegotiated values. A network policing architecture consisting of two interconnected NNs is introduced in Ref. 40. The first NN is trained to learn the probability density function (pdf) of the nonviolating traffic profile of the application. The second NN is trained to capture the characteristics of the pdf of the actual traffic as the call progresses. If the two distribution profiles start deviating considerably, an error signal is generated and used to "reshape" the accepted traffic [41]. The results show that this policing method can efficiently detect and properly react to peak and mean traffic violations. In Ref. 42 a closed loop, end-to-end, broadband network traffic control system is presented that employs different NN architectures for traffic characterization, call admission control, traffic policing, and congestion control.

3.5. Other Communications Applications

Other telecommunication areas where NNs have been used include, but are not limited to: cellular and mobile communications [43,44], mobile phone and credit card fraud detection [45,46], intelligent switching and routing [47,48], scheduling problems in radio networks [48,49], and so on. A large collections of application-related papers can be found in books [10,11].

Neural networks have also been extensively utilized in diverse application domains that are related to communications, such as electronic commerce over the Internet [50], modeling agents behavior [51], automatic language identification [52], text-independent speaker verification [53], character recognition and document analysis [54], image vector quantization [55], signal processing [56], and pattern recognition [8].

4. THE FUTURE?

The highly interdisciplinary field of NNs has always been an area where engineers, statisticians, neuroscientists, and cognitive scientists meet and interact. It is this cross-fertilization of ideas that has rejuvenated NN research over the past 10 years. At the one end, the field has established new links with areas of advanced statistics and machine learning, such as independent component analysis [57], support vector machines [58], graphical models [59], and so on. Coupled with developments in computational neuroscience and digital communications, these advances may soon lead to breakthroughs in novel fields such as that of *neurotechnology*, which promises the use of information technology to substitute for lost functionality in the human nervous system [60].

BIOGRAPHY

Elias S. Manolakos is leading the Parallel Processing and Architectures research group of the Communications

and Digital Signal Processing (CDSP) Center, a world-class Center for Research and Graduate Studies of the Electrical and Computer Engineering Department at Northeastern University, Boston, Massachusetts, where he is currently an associate professor. His research interests are in parallel and distributed computing; embedded systems; pattern recognition; neural networks; and applications in signal processing, communication, and biocomputing. He has served on the editorial boards of the *IEEE Transactions of Signal Processing, IEEE Computing in Science and Engineering, Journal of VLSI Signal Processing, IEEE Letters*, among others Manolakos has participated in the organization of several conferences and has chaired the technical program of the IEEE International Workshop on Signal Processing Systems Design and Implementation (SiPS, 1998) and the IEEE International Workshop in Neural Networks for Signal Processing (NNSP, 1995). He has authored or coauthored with his students more than 70 referenced publications and has coedited three books. He is a senior member of the IEEE and an elected advisory board member of the IEEE Signal Processing Society's Technical Committee on Neural Networks for Signal Processing.

NONLINEAR EFFECTS IN OPTICAL FIBERS

ANDREW R. CHRAPLYVY

Holmdel, New Jersey

1. NONLINEAR EFFECTS IN OPTICAL FIBERS

The field of nonlinear optics in silica optical fibers originated in the late 1960s–early 1970s [1]. Initially nonlinear effects in single-mode silica fibers were laboratory curiosities requiring powerful lasers for their observation. The

discovery of erbium-doped fiber amplifiers for the 1.5-μm wavelength region [2,3] fundamentally altered the lightwave communication landscape by ushering in the era of wavelength-division multiplexing (WDM) and elevating optical nonlinearities to a primary systems consideration.

Before the early 1990s long-haul high-speed digital lightwave systems typically transmitted one wavelength channel on each optical fiber. These signals required frequent (every 40–50 km) 3R regeneration (reamplify, retime, reshape) that was accomplished using optoelectronic regenerators. In principle many information channels, each at a separate wavelength, could be transmitted over a single fiber. This is known as *wavelength-division multiplexing* (WDM). However, at each regenerator site the WDM channels must be optically demultiplexed, individually regenerated, and then optically multiplexed onto the next fiber span. For a large number of channels, this is prohibitively expensive. The advent of erbium-doped fiber amplifiers, which provide broadband optical gain in the wavelength region of minimum loss of silica fibers (1.55 μm), eliminated this problem. The broad amplifier gain bandwidth (~35 nm) allows simultaneous amplification of many WDM channels, thereby eliminating the need for demultiplexing at each repeater site. By replacing 3R regenerators with optical amplifiers, the distance between optoelectronic signal regeneration was increased from about 50 km to hundreds or even thousands of kilometers. However these major benefits of amplifiers increase the effects of optical nonlinearities. WDM increases the optical power propagating through fibers, and replacing regenerators with amplifiers increases the distances between signal regeneration. Increased optical powers and longer interaction lengths magnify the effects of nonlinearities. In WDM systems with several tens of channels propagating several hundreds of kilometers between regenerator sites various optical nonlinearities can be easily observed even though the power in the individual wavelength channels is on the order of 1 mW.

A number of nonlinearities in silica fibers can impact amplified lightwave systems [4]. They fall into two general categories. Stimulated scattering such as stimulated Brillouin scattering and stimulated Raman scattering are interactions between optical signals and acoustic or molecular vibrations in the fiber. Although both processes can produce exponential optical gain, they are qualitatively very different and affect lightwave systems in different ways. The second category of nonlinearities arises from modulation of the refractive index of silica by intensity changes in the signal. This gives rise to nonlinearities such as *self-phase modulation*, whereby an optical signal alters its own phase and spectrum; *cross-phase modulation* in WDM systems, where one optical signal affects the phases and spectra of all other optical signals and vice versa; and *four-photon mixing*, whereby WDM signals interact to produce mixing sidebands (as in intermodulation distortion).

1.1. Stimulated Scattering

1.1.1. Stimulated Brillouin Scattering. *Stimulated Brillouin scattering* (SBS) is the interaction between light and acoustic waves. In optical fibers SBS has the lowest threshold power of all the nonlinearities [5]. Light scatters from acoustic phonons and is downshifted in frequency. The magnitude of the downshift depends on the scattering angle (varying from a zero-frequency shift for forward scattering to a maximum frequency shift in the backward direction). In single-mode silica fibers the only frequency-shifted scattered light that continues to be guided is backward-propagating light. The Brillouin shift for backward scattering in silica is about 11 GHz. This backscattered light experiences exponential gain due to the forward-propagating light. System impairment occurs when the backscattered light level becomes comparable to the signal power and begins to deplete the signal. For typical fibers the threshold power for this process is ~10 mW for single fiber spans and correspondingly lower for concatenated amplified spans. However, optical amplifiers usually have optical isolators (otherwise long amplified systems could easily optically oscillate), which prevent backward SBS light from propagating through multiple fiber spans. Consequently the SBS impairment in amplified systems occurs at the same power levels as in regenerated systems. In addition, SBS impairments are not exacerbated in WDM systems, because each signal channel interacts with acoustic phonons having slightly different frequencies. Thus the nonlinearities accumulate individually for each channel. However, some systems will require individual signal powers greater than 10 mW. For example, to overcome fiber attenuation in extremely long single-span systems, higher signal powers, which may exceed the SBS threshold, are required.

Although SBS has the lowest threshold of all the fiber nonlinearities, it is also the easiest nonlinearity to counteract because of the lifetime of the acoustic phonons that give rise SBS. The phonon lifetime in silica fibers is about 15 ns, which corresponds to an optical linewidth of about 20 MHz. Optical sources with linewidths greater than 20 MHz will experience reduced SBS. Typical laser diodes have linewidths less than 10 MHz, but dithering the laser injection current can artificially broaden the effective linewidths because it causes a dithering of the optical frequency of the signal. The SBS gain is then reduced by the ratio of the magnitude of the frequency dither divided by 20 MHz. It is easy to increase the SBS threshold by an order of magnitude simply by dithering the diode laser frequency over a 200-MHz range. Typically this corresponds to a dither current of about 0.2 mA. The dithering technique is now an industrywide standard whenever SBS is a nuisance.

1.1.2. Stimulated Raman Scattering. *Stimulated Raman scattering* (SRS) in optical fibers is the interaction between light and the vibrational modes of silica molecules in the core of the fiber. Although both SRS and SBS are examples of stimulated scattering, there are a number of key differences between the two nonlinearities. Unlike SBS, SRS is an extremely broadband effect. The Raman transitions in silica glass are very broad and overlap into a continuous-gain curve such as that shown in Fig. 1. Note that the peak SRS gain occurs at a frequency about 15 THz lower than the input signal. Unlike SBS, SRS occurs in both forward and backward directions. Isolators at amplifier sites will not diminish forward SRS, and the effect accumulates with the number of amplified fiber spans.

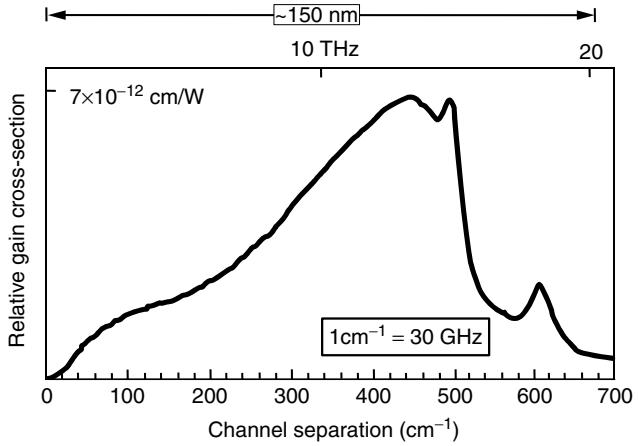

Figure 1. The relative SRS gain coefficient for fused-silica fibers at 1.5 μm.

In single-channel systems some of the spontaneously scattered Raman-shifted light, having amplitude given by the Raman gain curve in Fig. 1, will be guided in the core of the fiber in the forward direction. The copropagating signal light will amplify this scattered light. Because the peak SRS gain is over two orders of magnitude smaller than the peak SBS gain, significantly higher optical powers are required to exceed the SRS threshold for a single channel. The SRS threshold for single fiber spans is over 1 W and manifests itself by exponential amplification of wavelengths near the peak of the Raman gain curve about 15 THz lower in frequency than the signal. In amplified systems one might expect that the threshold is 1 W divided by the number of spans. However, the optical gain bandwidth of an erbium amplifier is roughly 4 times smaller than the bandwidth of the SRS gain profile. Consequently, only Raman light generated within the amplifier gain profile will propagate through the amplified chain of fibers. Since the SRS gain profile is roughly triangular, the peak Raman gain at 30 nm is roughly $\frac{1}{4}$th that of the maximum gain. It follows that in the worst case, the SRS threshold for an amplified chain will be about 4 W divided by the number of amplified spans between regenerators. SRS can be easily suppressed in single-channel amplified systems by periodically inserting optical bandpass filters that pass the signal and reject most of the SRS spectrum.

It is in WDM systems that SRS can be particularly vexing. Because the SRS gain is so broad, WDM channels will be coupled to each other for channels spaced up to 20 THz (150 nm). The short-wavelength channels will act as Raman pumps for long-wavelength channels [6,7]. The long-wavelength channels will be amplified at the expense of the short-wavelength channels, which will be attenuated. Impairments from such interactions will occur at powers much lower than 1 W. For example, for two channels separated by 15 THz (110 nm), unacceptable system degradations will occur at 50 mW in a single fiber span. For multiple channels and multiple spans the threshold powers for degradation will be proportionately smaller. Ultimately, SRS limits the number WDM channels that can be transmitted through single-mode fibers. The number of channels is inversely proportional to the overall transmission distance. Thus far the discussion is based on the assumption of continuous-wave (CW) power at all the signal wavelengths. However, digital systems typically transmit binary information in which a pulse of light represents a logical "one" (called a "mark") and absence of optical power represents a logical "zero" (called a "space"). A space can neither experience Raman gain from shorter wavelengths nor produce Raman gain for longer-wavelength signals. Only marks can be amplified or depleted by SRS, and the amount of gain or depletion will depend on the presence of marks in other channels. Since the occurrence of marks is a random process the amount of amplification or depletion for marks in a particular channel will vary from mark to mark. This is called *pattern-dependent SRS*. Marks with pattern-dependent amplitudes give rise to intersymbol interference (ISI), one of several types of degradations in digital systems. Pattern-dependent SRS is somewhat ameliorated by two effects: modulation statistics and chromatic dispersion. In a binary bit stream the probability of occurrence of marks and spaces is $\frac{1}{2}$. In a WDM system with many channels the occurrence of marks and spaces at a particular instant in time is a random variable. As the number of WDM channels increases, the pattern dependent variation of SRS decreases. This averaging effect is further increased due to chromatic dispersion; specifically, different wavelengths in an optical fiber propagate with different group velocities. Consequently a particular bit in a given channel "samples" multiple time slots (bits) of neighboring channels as it propagates through the fiber. This further diminishes pattern dependent SRS effects. Ultimately this leads to a very efficient method to combat SRS. Filters placed periodically along the fiber (conveniently located within the optical amplifiers themselves) with the inverse filter profile of the SRS gain curve in Fig. 1 can almost completely undo the effects of SRS; specifically, slightly more attenuation is provided to the long-wavelength channels than to the short-wavelength channels. This method of combating SRS is now routinely used in long WDM systems consisting of many channels.

In the early days of WDM systems, optical nonlinearities were viewed as detrimental phenomena that needed to be mitigated. With time clever applications of fiber nonlinearities have led to useful optical devices. An important example is the use of SRS to provide optical gain for the WDM signals. Injecting pump light of the appropriate wavelength(s) into a fiber can turn the fiber into a stimulated Raman amplifier; thus the transmission medium is also an amplification medium. In fact, systems can be designed so that the amount of optical gain produced by SRS exactly compensates the intrinsic attenuation of the transmission fiber. Such a system no longer requires discrete amplifiers every 80–100 km but requires only periodic injection of pump light. The noise figures of Raman-amplified systems are typically several decibels lower than the noise figures of conventional systems amplified by discrete amplifiers. Typically pump light is injected in the backward direction relative to the signals but there are examples of both counter and copropagating Raman pumping.

1.2. Nonlinear Refractive Index

The refractive indices of many optical materials are weakly intensity-dependent ($n = n_0 + n_2 I$). The intensity-dependent refractive index, n_2, of silica has a value of 2.6×10^{-20} m^2/W. Although the n_2 of silica is extremely small (many semiconductor materials have values of n_2 orders of magnitude larger than those of silica), in long amplified systems or in certain WDM systems the effects of the nonlinear refractive index can be quite prominent.

1.2.1. Self-Phase Modulation. *Self-phase modulation* (SPM) describes the effect of a pulse on its own phase [8]. The edge of an optical pulse represents a time-varying intensity. A time-varying intensity in a medium with an intensity-dependent refractive index will produce a time-varying refractive index, which, in turn, produces a time-varying phase that corresponds to a spectral broadening (Fig. 2). Therefore one of the consequences of the nonlinear refractive index of silica is that the spectral width of signal pulses will gradually increase as they propagate in a fiber. For example, a 1-mW pulse would exhibit a twofold broadening after propagating several thousand kilometers in an amplified system. However, a 10-mW pulse will experience the same spectral broadening in 10 times less interaction length.

Spectral broadening can degrade systems in several ways. In a densely spaced WDM system SPM can broaden the signals so that adjacent channels begin to partially overlap spectrally. This leads to optical crosstalk. Spectral broadening can also lead to pulseshape deformation. Because of the nonlinear refractive index, the peak of a pulse accumulates phase more quickly than the wings. This results in stretching of the wavelength on the leading edge of the pulse and compression on the trailing edge. Thus the trailing edge of a pulse acquires a blue shift and the leading edge acquires a red shift (Fig. 3). Recall that most fibers have finite chromatic dispersion. Thus two edges of a pulse will propagate at different speeds. In fibers

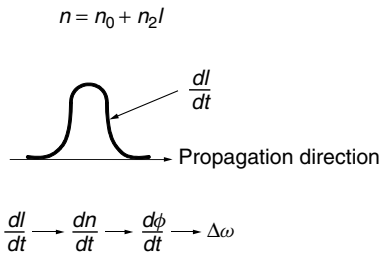

Figure 2. Source of spectral broadening due to nonlinear refractive index.

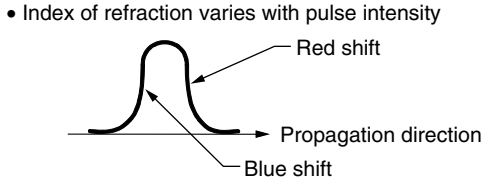

Figure 3. Effect of SPM on leading and trailing edges of a pulse.

with normal chromatic dispersion (red propagates faster than blue) the pulse will begin to temporally broaden. With sufficient temporal broadening pulses will begin to overlap neighboring time slots and interfere with neighboring bits. Bit errors can occur when a mark spreads into a neighboring space. In fibers with anomalous dispersion (blue propagates faster than red) the pulses initially become narrower in time. Ultimately the two edges pass through the center of the pulse, and with further propagation, the pulse will temporally broaden and bit errors will occur when pulses overlap neighboring time slots. System degradations due to the combined effects of SPM and chromatic dispersion are now mitigated by a technique known as *dispersion management*. An optical line system can be designed to consist of two different types of fibers, one having normal dispersion and the other having anomalous dispersion (the transmission fiber itself can be a concatenation of the two types of fiber, or in the more popular design there is one type of transmission fiber and the other type of fiber, called *dispersion compensating fiber*, is located within the optical amplifiers). The fibers are chosen so that the overall accumulated chromatic dispersion for the entire system is nearly zero. In such situations there is no net temporal broadening of the self-phase-modulated pulses, albeit during propagation the pulses "breathe" — broaden as a result of the dispersion of one fiber and then narrow to approximately the original widths due to the opposite-sign dispersion in the second type of fiber.

SPM, like SRS, is a nonlinearity that can be exploited to advantage. Even in the absence of nonlinearity (e.g., at very low powers), pulses propagating in fibers broaden as a result of chromatic dispersion. Each pulse intrinsically contains a spread of wavelengths determined by the pulsewidth and other factors. These wavelength components travel at different speeds, and this leads to pulse broadening. In anomalous dispersion fibers we have seen that the consequence of SPM is pulse narrowing. This tendency to narrow can exactly balance out the broadening due to linear chromatic dispersion and can produce pulses that do not change shape as they propagate. Such pulses are called *solitons* [4]. Soliton technology is now finding its way into commercial transmission systems.

1.2.2. Cross-Phase Modulation. In WDM systems the intensity variations in any signal channel will affect the phases of all the other signals [9]. The origin of this cross-phase modulation (CPM) is the same nonlinear refractive index that gives rise to SPM. If the fiber chromatic dispersion were zero for all channels (all pulses propagate in lock step), the effects of CPM due to each interfering channel would be exactly twice as strong as the SPM effect. However, there are no practical "dispersion-flattened" zero-dispersion fibers. Consequently, the group velocities of various channels in a WDM system are different and pulses in different channels will pass through each other while propagating in the fiber. Under some conditions these pulse collisions virtually eliminate spectral broadening due to CPM. Figure 4 schematically depicts pulses from two different channels passing through each other (the figure is shown in the reference frame of

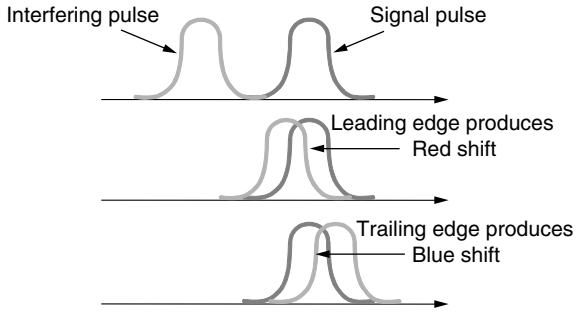

Figure 4. Effects of CPM on colliding pulses.

the signal pulse). Note that during the first half of the collision the interfering pulse produces a red shift in the signal pulse. In the second half of the collision the trailing edge of the interfering pulse produces a blue shift in the signal pulse. The blue shift exactly reverses the effects of the red shift if the intensities and shapes of the pulses have not significantly changed during the collision. Designing transmission systems around this cancellation effect is impractical for two main reasons:

1. A minimum wavelength spacing between neighboring channels is required for the pulse collisions to occur rapidly enough that their intensities do not appreciably change during the collision. This sacrifices precious spectral efficiency (channel bit rate divided by channel spacing) in many cases.
2. There is no way to avoid "partial" collisions. For example, two pulses in neighboring channels exit an optical amplifier partially overlapped. The leading-edge/trailing-edge symmetry is destroyed.

Partial collisions will frequency shift one part of a pulse relative to the remainder. This leads to different group velocities for different parts of a pulse. The occurrence of partial collisions is a random process depending on the presence or absence of marks in various channels. Consequently the arrival time of various marks in a particular signal channel will be random, leading to timing jitter at the receiver, another type of degradation in digital systems.

As with SPM, dispersion management can reduce the effects of CPM. Spectral broadening or frequency shifts do not give rise to dispersion penalties or timing jitter if the overall system dispersion is nearly zero.

1.2.3. Four-Photon Mixing. A third manifestation of the nonlinear refractive index in WDM systems is *four-photon mixing* (FPM). In the case of two signals (Fig. 5a) there exists an intensity modulation at the beat frequency that modulates the refractive index, producing a phase modulation at the difference frequency. This phase modulation creates two sidebands. These sidebands are called *two-tone products* because they were produced by the mixing of two signal waves. For three channels (Fig. 5b), in addition to the two-tone products created by each pair of signals, there are 3 three-tone products generated by all

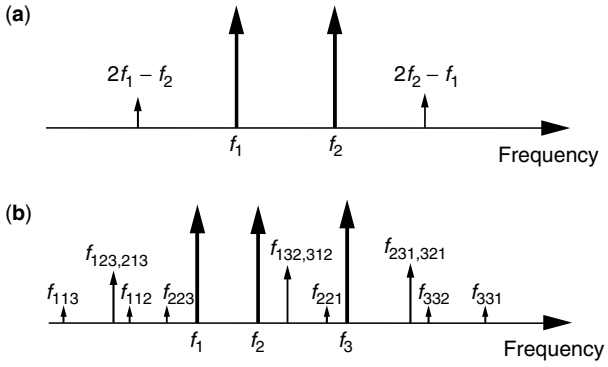

Figure 5. Phase modulation sidebands produced by FPM for (**a**) two signals and (**b**) three signals.

three signals (i.e., the beat frequency of one pair of signals produces sidebands on the third signal). Since there are two different ways of generating each three-tone electric field, the three-tone products are generated with four times the optical power of the two-tone products. For N channels there will be $N^2(N-1)/2$ mixing products generated. For example, in an 8-channel WDM system, 224 mixing products are generated.

Two different impairments are caused by FPM. The obvious and more benign degradation is depletion of signal power in creating the mixing products, especially in WDM systems with many channels. An even more serious degradation occurs if the signal channels are equally spaced. In this case many of the mixing products are produced with optical frequencies the same as the signal frequencies. These mixing products interfere coherently with the signals, either constructively or destructively depending on the (time-dependent) relative phases of the signals. Because it is the electric fields that interfere, small mixing products can produce severe degradations. For example, a mixing product with 1% of the power of one of the signals has an electric field magnitude 10% of the signal electric field and will produce 20% depletion in the signal channel if it destructively interferes with the signal.

To eliminate coherent mixing, a frequency allocation scheme for signals has been devised to ensure that no mixing product will have the same frequency as any signal [4]. This is accomplished by ensuring that the frequency spacing between any two signals is unique. This eliminates interference impairments and leaves only the less severe depletion effects with which to contend. The frequency allocation scheme requires control of signal frequencies to within several gigahertz, easily achievable with present transmitter lasers.

Since FPM is a phase-matched process, it depends strongly on chromatic dispersion [4]. In general, the intensity modulation generated by the beating between two or three signals propagates at a different speed than the signals themselves. If the difference in propagation velocities is large (large chromatic dispersion), the FPM generation efficiency becomes small (poor phase matching) and system degradations are inconsequential. In fibers with zero chromatic dispersion near the signal wavelengths, FPM is a very efficient nonlinear process and dramatic system degradations can occur in relatively short (≅20-km)

lengths of fiber. Dispersion management was initially invented in 1993 to combat the effects of FPM in high-speed systems that were sensitive to chromatic dispersion. The high local dispersion in any of the fiber segments suppresses FPM, but the overall dispersion is nearly zero, to avoid dispersion penalties for high-bit-rate signals. Subsequently dispersion management proved to be a useful technique in counteracting SPM and CPM effects.

FPM can also be exploited for useful purposes, namely, for parametric optical amplification [10]. Signals can be injected into a low-dispersion optical fiber along with a strong pump at a wavelength near the zero-dispersion wavelength of the fiber. FPM between the pump and the signals will produce strong FPM products located in frequency-reversed order (phase conjugation) at wavelengths on the opposite side relative to the pump. The noise figure (NF) of parametric amplifiers can be significantly smaller than the NF of conventional erbium-doped fiber amplifiers, and phase conjugation of amplified signals also reverses the effects of chromatic dispersion. In principle, a system based on parametric amplification would not need dispersion management.

2. CONCLUSION

In conclusion, silica optical fibers exhibit a rich collection of optical nonlinearities that have become important with the advent of practical optical amplifiers and the ultra-long-haul lightwave systems they enabled. Since the early 1990s an arsenal of techniques have been developed to mitigate the effects of nonlinearities. These techniques include dispersion management, frequency or phase modulation of sources, and optical filtering. However, the most tangible impact of optical nonlinearities is to provide gainful employment for systems engineers trying to maximize the ultimate information-carrying capacity of optical fibers by either counteracting or exploiting nonlinear effects in fibers. More advanced treatment of optical nonlinearities in fibers can be found in Chapter 8 of the article by Stolen and Lin [4] and references cited therein.

BIOGRAPHY

Andrew R. Chraplyvy received the B.S. degree in physics in 1972 from Washington University, St. Louis, Missouri, and the M.S. and Ph.D. degrees in physics from Cornell University in 1975 and 1977, respectively. He joined the Physics Department at General Motors Research Labs in 1977 as a Research Scientist. At GM he worked on ultra-high-resolution spectroscopy of gases and impurity modes in solids. Since 1980, he has been with Bell Laboratories, where he currently is Director of Lightwave Systems Research. Dr. Chraplyvy holds over 25 patents in the areas of lightwave systems and fiberoptics. He is the recipient of the 1999 Thomas Alva Edison Patent Award and the 1999 New Jersey Inventor of the Year Award. He is a Bell Labs Fellow, a member of the National Academy of Engineering and a Fellow of the Optical Society of America. His areas of interest are fiberoptics, lightwave communications systems, nonlinear optical interactions in fibers, fiber networks, and high-resolution spectroscopy of gases and solids.

NONUNIFORMLY SPACED TAPPED-DELAY-LINE EQUALIZERS FOR SPARSE MULTIPATH CHANNELS

FREDERICK K. H. LEE
PETER J. MCLANE
Queen's University
Kingston, Ontario, Canada

1. INTRODUCTION

The high data rate requirement in current and future broadband wireless communication systems has created a new regime of interesting and challenging problems for communication engineers of the new century. Of major concern in the physical layer is the growth of the lengths of the sampled channel impulse responses as a function of the transmission rate when measured in units of symbol intervals. Most commonly used equalization techniques for suppressing intersymbol interference (ISI) distortion caused by the multipath propagation phenomenon, such as the tapped-delay-line (TDL) equalizers, including the linear equalizers (LEs) and the decision feedback equalizers

(DFEs), and the maximum-likelihood sequence estimators (MLSEs), all exhibit structural and computational complexities that depend on the sampled channel lengths. An increase in transmission rate thus inevitably leads to an increase in complexity of these equalization techniques, which is particularly problematic for mobile receivers where resources are scarce because of constraints in cost, size, and battery power. While an impulse response can certainly be truncated to reduce its length, this would be undesirable if its tail portion contains a significant amount of energy. This is precisely the dilemma facing the family of wireless channels called *sparse multipath channels*.

2. SPARSE MULTIPATH CHANNELS

A sparse multipath channel is characterized by an impulse response consisting of only a few dominant multipath terms, but with any two terms separated by a large time delay, resulting in a long delay spread. Examples of sparse multipath channels include terrestrial broadcasting channels, such as those found in high-definition television (HDTV) systems; horizontal or vertical underwater acoustic channels, where reflections off the sea surface and the sea floor constitute the two main causes for the long reverberation of the multipath terms [1, Chap. 8]; as well as cellular land mobile radio channels encountered in hilly terrain environments. Combined with a high data rate, the lengths of the sampled channel impulse responses can range from several tens to hundreds of symbol intervals, depending on the specific application. For instance, in the proposed North American HDTV terrestrial broadcasting mode, 64-QAM (quadrature amplitude modulation) is used and the transmission rate is 5.38 Msps (megasymbols per second). With a typical delay spread of 20 μs, the sampled channel length spans 107.6 symbol intervals, but only a small number of the channel taps exhibit large magnitude due to the sparse nature of the channel [2]. An additional feature of these HDTV channels is the existence of strong precursor taps known as "ghost" signals, which adds to the difficulty of equalization. As another example, Fig. 1 shows the impulse response of a sparse underwater acoustic channel with delay spread that exceeds 80 ms. Hence, even with a modest transmission rate of 1.25 ksps, the sampled channel length is at least a hundred symbol intervals long.

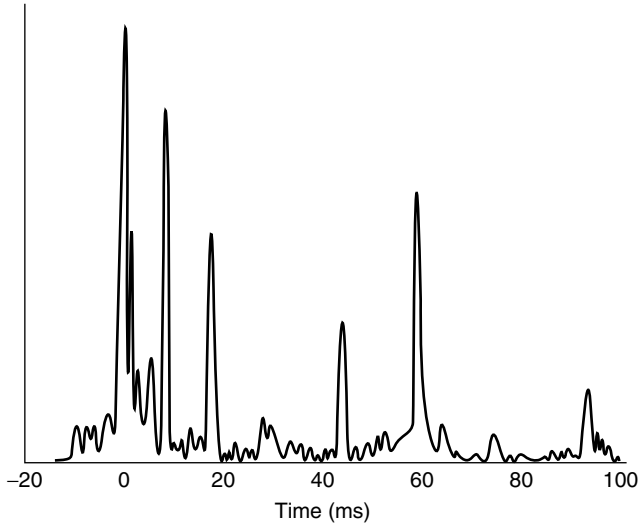

Figure 1. Impulse response of a sparse underwater acoustic channel. (*Source*: Ref. 7, Fig. 1(b).)

The description above clearly explains why existing equalization techniques cannot efficiently mitigate the ISI distortion intrinsic to a sparse multipath channel. Fortunately, as the majority of taps in a sampled sparse multipath channel contain zero or near-zero values, it is possible to develop new equalization methods with complexity associated with the number of large-magnitude taps instead of the entire channel length. One such feasibility is by using nonuniformly spaced TDL equalizers (NU-Es), which is the focus of this article. Interested readers can refer to the Further Reading list for references to other solutions that exploit the structure of sparse multipath channels.

3. NONUNIFORMLY SPACED TDL EQUALIZERS (NU-Es)

The distinguishing element of a NU-E is its variable spacings between taps, as opposed to fixed spacings in a uniformly-spaced TDL equalizer (U-E). For all practical purposes, however, a NU-E can be viewed as a U-E with a large number of zero-valued taps, as depicted in Fig. 2, since the spacings of the TDL in a NU-E are usually predetermined by a fixed-rate sampler. In other words, designing a NU-E is equivalent to choosing the best set of tap positions on a fixed-spaced TDL. There are a number

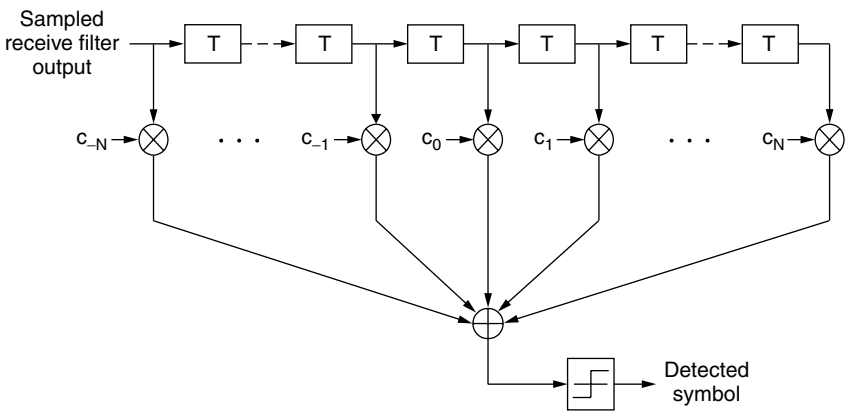

Figure 2. A T-spaced U-LE with $(2N + 1)$ taps. A T-spaced NU-LE can be viewed as a T-spaced U-LE with a large number of zero-valued taps.

of advantages to using a NU-E. First, an appropriately designed NU-E can achieve practically the same performance as a U-E but with fewer taps, hence reducing the computational load of the receiver. This is especially true for equalizing sparse multipath channels, where the number of taps required in a NU-E is proportional to the number of channel taps with large magnitude. In an adaptive NU-E, fewer taps implies faster convergence of the initial learning curve to the optimum tap values, which allows a shorter training sequence to be transmitted. The influence of noisy estimates at the output also tends to lessen without the need to train or track the near-zero-valued taps. For one case with a fractionally spaced TDL in a fixed-point implementation, tracking only a small set of taps decreases the degrees of freedom and thus minimizes the occurrence of the tap wandering phenomenon, an event that arises when tap values deviate from their exact optimum values due to noisy estimates and eventually accumulate to values that are too large and cause overflow.

Despite the many benefits of a NU-E, optimizing its tap positions is not an easy task. Closed-form solution to the optimum tap positions of a finite-length NU-E does not exist in general. Currently, two different approaches are available in the literature for finding these optimum tap positions. The first one, suggested by Raghavan et al. [3], uses a branch-and-bound algorithm to exhaustively search for the best combination of tap positions within a given span of the TDL. The second one, developed by Lee [4], involves numerically solving a set of nonlinear equations to obtain a NU-DFE with tap spacings and tap values that are locally optimum. Note that the normal convention of a fixed-space TDL is removed in the derivation of the nonlinear equations, which means that the resultant tap spacings in the feedforward filter (FFF) can be any real number. Unfortunately, due to the heavy computational burden and the long processing time, both methods are deemed unsuitable for real-time applications, and their usage is mainly restricted to off-line analysis for benchmarking purposes.

To circumvent the difficulty of finding the optimum tap positions, a number of suboptimum tap allocation schemes have also been proposed in the literature. A simple one is the strategy of thresholding, where taps of a U-E are first determined and only those with magnitude above a threshold are retained. Despite its simplicity, this method requires initial training of a large number of taps, which is inefficient. Moreover, the tap values are suboptimum with respect to the retained tap positions, though this problem can easily be corrected by re-optimizing the tap values after thresholding is completed, albeit at a further sacrifice of efficiency. Another easy method is to choose the positions of the channel taps with large magnitude as the positions of a NU-E, as has been adopted by Kocic et al. [5] to obtain a NU-DFE. Other more elaborate solutions include the one by Ariyavisitakul et al. [6], where the FFF of a NU-DFE is designed by selecting the set of taps that maximizes a simplified expression of the output signal-to-noise ratio (SNR), as well as an automated exchange-type algorithm by Lopez et al. [7] that allocates taps to the FFF and the feedback filter (FBF) of a NU-DFE alternatively in an iterative fashion until a desired level of performance is reached.

Similar to the optimum algorithms, the abovementioned suboptimum tap allocation schemes all share the common trait of attempting to find the tap positions of a finite-length NU-E directly. However, this is not the only way to tackle the problem. Given a sparse multipath channel, it turns out that certain infinite-length equalizers are inherently nonuniformly spaced, with the sparseness of those equalizers intimately related to the sparseness of the channel. Consequently, a logical alternative to designing finite-length NU-Es is to first identify the tap positions of an infinite-length NU-E, and then assign a subset of those positions to a finite-length NU-E. This design methodology is originally recognized by Geller et al. [8] and again by Berberidis and Rontogiannis [9], both using the infinite-length zero-forcing (ZF) LEs, and is later extended for designing infinite-length minimum mean-square error (MMSE) LEs and ZF/MMSE-DFEs by Lee and McLane [10]. The beauty of this approach lies in the application of the classical equalization theory to derive the infinite-length NU-Es, thus formally unifying the NU-Es with the well-known U-Es. In addition, provided that an infinite-length equalizer is nonuniformly spaced, the corresponding finite-length NU-E using its tap positions will be asymptotically optimum. Because of these advantages, this methodology is chosen over other existing techniques for designing finite-length NU-Es in this article. Details of the design process are described in the next two sections.

4. INFINITE-LENGTH SYMBOL-SPACED EQUALIZERS FOR SPARSE MULTIPATH CHANNELS

To begin, the infinite-length, symbol-spaced (T-spaced) LE and DFE under the ZF and the MMSE criteria are derived for any given sparse multipath channel. The goal is to determine which of these equalizers are nonuniformly spaced and, if so, their tap positions. Consider the baseband communication system shown in Fig. 3. The data source is an independent and identically distributed (iid) sequence where symbols can be taken from any QAM signaling scheme, and the impulse response of the transmit filter is a square-root raised-cosine (SRRC) pulse. The impulse response of a causal, M-ary sparse multipath channel is given by $h_c(t) = \sum_{i=0}^{M-1} a_i \delta(t - \tau_i T)$, where $\{\tau_i\}$ are restricted to be nonnegative integers

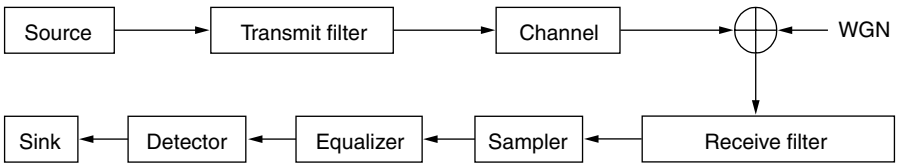

Figure 3. Block diagram of a baseband communication system model. (*Source*: Ref. 10.)

with $\tau_0 = 0$. For brevity, the channel is also denoted as $h_c = [a_0, \ldots, a_{\tau_i}, \ldots, a_{\tau_{M-1}}]$. Complex, zero-mean, white Gaussian noise $n(t)$ with two-sided power spectral density N_0 W/Hz is introduced at the output of the channel, and the noise process is assumed to be independent of the data sequence. At the receiving end, a matched filter (MF) and a SRRC receive filter are used alternatively. With T-spaced sampling at time instants $\{kT\}$, $k = 0, \pm 1, \ldots$, the sampled MF output is $f_s(t) = \sum_{i=-N}^{N} f_i \delta(t - \mu_i T)$, where $N \geq M - 1$ and $\{\mu_i\}$ are integers with $\mu_0 = 0$ and $\mu_i = \mu_{-i}$, and $f_s(t)$ remains a sparse impulse response. If the SRRC receive filter is used, the sampled output is simply $h_c(t)$.

4.1. Linear Equalizers (LEs)

According to classical equalization theory [11,12], the frequency response of the infinite-length, T-spaced ZF-LE under the MF system is

$$C_{\text{ZF-LE,MF}}(w) = \frac{1}{F_s(w)} \tag{1}$$

where $F_s(w) = \sum_{i=-N}^{N} f_i e^{-jw\mu_i T}$ is the (periodic) frequency response of $f_s(t)$. After some simple manipulations, Eq. (1) becomes

$$C_{\text{ZF-LE,MF}}(w) = \frac{k}{1 + \sum_{i=-N(i\neq 0)}^{N} g_i e^{-jw\mu_i T}} \tag{2}$$

where $k = 1/f_0$ and $g_i = k f_i (i \neq 0)$. Let $S(w) = \sum_{i=-N(i\neq 0)}^{N} g_i e^{-jw\mu_i T}$. If $|S(w)| < 1$, Eq. (2) can be expressed as

$$C_{\text{ZF-LE,MF}}(w) = k\left[1 + \sum_{n=1}^{\infty} (-1)^n S^n(w)\right] \tag{3}$$

by making use of the infinite series $1/1 + x = 1 - x + x^2 - x^3 + \cdots$ for $|x| < 1$. Expanding $S^n(w)$ term by term for each n and taking the inverse Fourier transform gives

$$c_{\text{ZF-LE,MF}}(t) = k\left[\delta(t) - \sum_{\substack{i=-N \\ i\neq 0}}^{N} g_i \delta(t - \mu_i T) + \sum_{\substack{i=-N \\ i\neq 0}}^{N} \sum_{\substack{j=-N \\ j\neq 0}}^{N} \times g_i g_j \delta\left(t - (\mu_i + \mu_j)T\right) - \cdots\right] \tag{4}$$

which shows that the tap positions of the ZF-LE are given by the nonnegative-integer-based linear combinations of the multipath delays of $f_s(t)$. Hence, the infinite-length, T-spaced ZF-LE under the MF system is nonuniformly spaced. In the sequel, this derivation method will be called the *infinite-series approach*.

The infinite-length, T-spaced MMSE-LE under the MF system can be determined similarly by using the frequency response

$$C_{\text{MMSE-LE,MF}}(w) = \frac{\sigma_I^2}{\sigma_I^2 F_s(w) + N_0} \tag{5}$$

where σ_I^2 denotes the variance of the data symbols. It is easy to verify that $c_{\text{MMSE-LE,MF}}(t)$ is exactly the same as $c_{\text{ZF-LE,MF}}(t)$ in Eq. (4) except $k = \sigma_I^2/(\sigma_I^2 f_0 + N_0)$, which implies that the ZF-LE and the MMSE-LE share the same tap positions. Hence, the infinite-length, T-spaced MMSE-LE under the MF system is also nonuniformly spaced, and it differs from the ZF-LE only in terms of their tap values. As $N_0 \to 0$, the values of k become the same for both equalizers, and the MMSE-LE converges to the ZF-LE, a well-known result. It is also interesting to note that N_0 actually helps satisfy the condition $|S(w)| < 1$ for the frequency response of the MMSE-LE to be written as an infinite series.

When the SRRC receive filter is used, the frequency response of the infinite-length, T-spaced ZF-LE is

$$C_{\text{ZF-LE,SRRC}}(w) = \frac{1}{H_c(w)} \tag{6}$$

where $H_c(w) = \sum_{i=0}^{M-1} a_i e^{-jw\tau_i T}$ is the frequency response of $h_c(t)$. Let τ_d denote the delay that corresponds to the multipath term with the largest magnitude. Equation (6) can then be expressed as

$$C_{\text{ZF-LE,SRRC}}(w) = \frac{1}{e^{-jw\tau_d T}[a_d + \sum_{i=0(i\neq d)}^{M-1} a_i e^{-jw(\tau_i - \tau_d)T}]} = \frac{k' e^{jw\tau_d T}}{1 + \sum_{i=0(i\neq d)}^{M-1} b_i e^{-jw\nu_i T}} \tag{7}$$

where $k' = 1/a_d$, $b_i = k' a_i$, and $\nu_i = \tau_i - \tau_d$ $(i \neq d)$. Using the infinite-series approach gives

$$c_{\text{ZF-LE,SRRC}}(t) = k'\left[\delta(t + \tau_d T) - \sum_{\substack{i=0 \\ i\neq d}}^{M-1} b_i \delta(t - (\nu_i - \tau_d)T) + \sum_{\substack{i=0 \\ i\neq d}}^{M-1} \sum_{\substack{j=0 \\ j\neq d}}^{M-1} b_i b_j \delta\left(t - (\nu_i + \nu_j - \tau_d)T\right) - \cdots\right] \tag{8}$$

which shows that the infinite-length, T-spaced ZF-LE under the SRRC receive filter system is nonuniformly spaced as well. In essence, its tap positions are obtained by time-shifting the nonnegative-integer-based linear combinations of the time-shifted multipath delays of $h_c(t)$, where the amount of time shift in both instances is τ_d. Note that for the MF system, the multipath term in $f_s(t)$ with

the largest magnitude is always found at $t = 0$. Hence, the time-shifting operations are not required.

For the infinite-length, T-spaced MMSE-LE, its impulse response under the SRRC receive filter system is given by

$$c_{\text{MMSE-LE,SRRC}}(t) = c_{\text{MMSE-LE,MF}}(t) \otimes h_c^*(-t)$$
$$= k \sum_{l=0}^{M-1} a_l^* \left[\delta(t + \tau_l T) - \sum_{\substack{i=-N \\ i\neq 0}}^{N} g_i \delta(t - (\mu_i - \tau_l)T) \right.$$
$$\left. + \sum_{\substack{i=-N \\ i\neq 0}}^{N} \sum_{\substack{j=-N \\ j\neq 0}}^{N} g_i g_j \delta(t - (\mu_i + \mu_j - \tau_l)T) - \cdots \right] \quad (9)$$

where $\otimes$ denotes convolution. This shows that the impulse response of the infinite-length, T-spaced MMSE-LE under the SRRC receive filter system is the sum of M scaled and time-shifted replicas of $c_{\text{MMSE-LE,MF}}(t)$, where the scale factors and delays are determined by $h_c^*(-t)$. In fact, $c_{\text{ZF-LE,SRRC}}(t)$ can also be expressed in the form of (9) with k, $\{g_i\}$ and $\{\mu_i\}$ being the variables of $c_{\text{ZF-LE,MF}}(t)$. Therefore, analogous to the MF system, the tap positions of the ZF-LE and the MMSE-LE under the SRRC receive filter system are identical, and they can be determined from either (8) or (9), even though the two equations appear to be different.

4.2. Decision Feedback Equalizers (DFEs)

To determine the infinite-length, T-spaced ZF-DFE under the MF system, the minimum-phase spectral factorization of $F_s(w)$, namely, $F_s(w) = A_P|P(w)|^2$, where A_P is a constant and $P(w)$ is the monic, causal, and minimum-phase (canonical) factor, is utilized. It is well known that [11] the FFF of the infinite-length, T-spaced ZF-DFE is a whitening filter with frequency response

$$C_{\text{ZF-FFF,MF}}(w) = \frac{1}{A_P P^*(w)} \quad (10)$$

which implies that the tap positions of $c_{\text{ZF-FFF,MF}}(t)$ can be obtained by invoking the infinite-series approach and are the nonnegative-integer-based linear combinations of the multipath delays of $p^*(-t)$. For the FBF, its impulse response is $c_{\text{ZF-FBF,MF}}(t) = p(t) - \delta(t)$, which means that its tap positions are merely the multipath delays of $p(t)$. It is obvious from these two relationships that the sparseness of the infinite-length, T-spaced ZF-DFE is directly dependent on the sparseness of $p(t)$. In fact, $p(t)$ is a sparse impulse response if and only if $h_c(t)$ is sparse and minimum-phase or maximum-phase. If $h_c(t)$ is a mixed-phase channel, $p(t)$ is nonsparse even if $h_c(t)$ is sparse [10]. Therefore, the infinite-length, T-spaced ZF-DFE under the MF system is nonuniformly spaced if and only if $h_c(t)$ is a sparse minimum-phase or maximum-phase channel.

By exploiting the minimum-phase spectral factorization of the received signal-plus-noise spectrum, i.e., $\sigma_I^2 F_s(w) + N_0 = A_Q|Q(w)|^2$, where A_Q is a constant and $Q(w)$ is the canonical factor, the infinite-length, T-spaced MMSE-DFE under the MF system can be derived in the same fashion as for the ZF-DFE. However, because of the noise term N_0, $q(t)$, the inverse Fourier transform of $Q(w)$, is nonsparse for any type of channel in general. As a result, the infinite-length, T-spaced MMSE-DFE under the MF system is uniformly spaced.

When the SRRC receive filter is used, the impulse response of the FFF of the infinite-length, T-spaced ZF-DFE is given by $c_{\text{ZF-FFF,SRRC}}(t) = c_{\text{ZF-FFF,MF}}(t) \otimes h_c^*(-t)$. Hence, similar to the ZF-LE under the SRRC receive filter system, $c_{\text{ZF-FFF,SRRC}}(t)$ is the sum of M scaled and time-shifted replicas of $c_{\text{ZF-FFF,MF}}(t)$ with the scale factors and delays determined by $h_c^*(-t)$. Note that if $h_c(t)$ is a minimum-phase channel, $c_{\text{ZF-FFF,SRRC}}(t)$ should reduce to a scalar. On the other hand, the FBF of the infinite-length, T-spaced ZF-DFE is identical to its counterpart under the MF system: $c_{\text{ZF-FBF,SRRC}}(t) = c_{\text{ZF-FBF,MF}}(t)$. Once again, both relationships hold true for the infinite-length, T-spaced MMSE-DFE. Therefore, conclusions regarding the sparseness of the both DFEs are the same as those under the MF system.

5. FINITE-LENGTH NU-Es FOR SPARSE MULTIPATH CHANNELS

Having derived the various infinite-length, T-spaced equalizers for sparse multipath channels, the next step is to exploit these results for designing finite-length NU-Es. Only the MMSE criterion is considered here, as MMSE equalizers are known to have better performance than ZF equalizers. The system model, notations, and assumptions of Section 4 remain unchanged throughout this section, except that the restriction on the channel will be relaxed later to allow its multipath delays to take on any real number.

For a finite-length, T-spaced NU-LE (i.e., a NU-LE implemented on a T-spaced TDL), its tap positions are obtained directly from its infinite-length counterpart as indicated in Eq. (4) or (8) for the MF system or the SRRC receive filter system, respectively. As a result, as long as the condition for expressing the frequency response of the channel as an infinite-series is valid (i.e., $|S(w)| < 1$), the finite-length, T-spaced NU-LE is asymptotically optimum. Priority is given to the low-order positions, as they correspond to taps with large magnitude. (In the tap allocation algorithms outlined below, this is achieved by choosing small positive values for the coefficients $\{r_i\}$ in determining the nonnegative-integer-based linear combinations.) However, the design procedure for a finite-length, T-spaced NU-DFE is not as straightforward, since its infinite-length counterpart is uniformly spaced and thus provides no useful information on how to select its tap positions. Fortunately, a simple suboptimum strategy can be employed for the MF system, which uses the tap positions on the anticausal side of a NU-LE as the tap positions for the NU-FFF. The NU-FFF under the SRRC receive filter system can then be designed by invoking the time-shifting property on the NU-FFF under the MF system. Once the NU-FFF is fixed, the tap positions of the NU-FBF can be obtained easily by taking the strictly causal portion of the convolution result between the impulse response at the receive filter

output and the impulse response of the NU-FFF. The tap allocation algorithms based on these principles are given below, one for each receive filter system. As an illustration on how to use the algorithms, the tap positions of the NU-LEs for a simple, artificial sparse multipath channel are listed in Table 1.

Algorithm 1 (MF System)

1. To design a finite-length NU-LE:
   a. Identify the positive multipath delays of the impulse response $h(t) = h_c(t) \otimes h_c^*(-t)$ and denote them by the set $\mathcal{S}_{\text{LE}}^1$.
   b. Assign taps at the positions that are the nonnegative-integer-based linear combinations of the elements in $\mathcal{S}_{\text{LE}}^1$ and denote them by $\mathcal{S}_{\text{LE}}^2$. Mathematically, $\mathcal{S}_{\text{LE}}^2 = \{\sum_{i=1}^{s_{\text{num}}} r_i s_i \mid r_i \in \mathcal{Z}^+, s_i \in \mathcal{S}_{\text{LE}}^1, s_{\text{num}} = |S_{\text{LE}}^1|\}$.
   c. Assign taps at the set of positions denoted by $\mathcal{S}_{\text{LE}}^3$, where $\mathcal{S}_{\text{LE}}^3 = \{-s \mid s \in \mathcal{S}_{\text{LE}}^2\}$.
2. To design the FFF of a finite-length NU-DFE:
   a. Assign taps at the set of positions denoted by $\mathcal{S}_{\text{FFF}}$, where $\mathcal{S}_{\text{FFF}} = \mathcal{S}_{\text{LE}}^3$.
3. To design the FBF of a finite-length NU-DFE:
   a. Assign taps at the set of positions denoted by $\mathcal{S}_{\text{FBF}}$, where $\mathcal{S}_{\text{FBF}} = \{s_1 - |s_2| \mid s_1 \in \mathcal{S}_{\text{LE}}^1, s_2 \in \mathcal{S}_{\text{FFF}}, s_1 - |s_2| > 0\}$.

Algorithm 2 (SRRC receive filter system)

1. To design a finite-length NU-LE:
   a. Identify the multipath delays of $h_c(t)$ and denote them by $\mathcal{T}_{\text{LE}}^1$.
   b. Denote as x the delay of $h_c(t)$ that corresponds to the multipath term with the largest magnitude.
   c. Define a new set of positions $\mathcal{T}_{\text{LE}}^2$ by renaming the positions in $\mathcal{T}_{\text{LE}}^1$ relative to x as follows: $\mathcal{T}_{\text{LE}}^2 = \{t - x \mid t \in \mathcal{T}_{\text{LE}}^1\}$.
   d. Define the set $\mathcal{T}_{\text{LE}}^3$ as the nonnegative-integer-based linear combinations of the elements in $\mathcal{T}_{\text{LE}}^2$. Mathematically, $\mathcal{T}_{\text{LE}}^3 = \{\sum_{i=1}^{t_{\text{num}}} r_i t_i \mid r_i \in \mathcal{Z}^+, t_i \in \mathcal{T}_{\text{LE}}^2, t_{\text{num}} = |\mathcal{T}_{\text{LE}}^2|\}$.
   e. Assign taps at the set of positions denoted by $\mathcal{T}_{\text{LE}}^4$, where $\mathcal{T}_{\text{LE}}^4 = \{t - x \mid t \in \mathcal{T}_{\text{LE}}^3\}$.
2. To design the FFF of a finite-length NU-DFE:
   a. Define x as in 1(b). However, if there exists one or more multipath terms with magnitude comparable to that of the largest magnitude term, denote x as the one closest to position 0.
   b. Assign taps at the set of positions denoted by $\mathcal{T}_{\text{FFF}}^1$, where $\mathcal{T}_{\text{FFF}}^1 = \{s - x \mid s \in \mathcal{S}_{\text{FFF}}\}$.
   c. Assign taps at the set of positions denoted by $\mathcal{T}_{\text{FFF}}^2$, where $\mathcal{T}_{\text{FFF}}^2 = \{-t \mid t \in \mathcal{T}_{\text{LE}}^1, t < x\}$.
3. To design the FBF of a finite-length NU-DFE:
   a. Assign taps at the set of positions denoted by $\mathcal{T}_{\text{FBF}}$, where $\mathcal{T}_{\text{FBF}} = \{t_1 - |t_2| \mid t_1 \in \mathcal{T}_{\text{LE}}^1, t_2 \in \mathcal{T}_{\text{FFF}}^1 \cup \mathcal{T}_{\text{FFF}}^2, t_1 - |t_2| > 0\}$.

Table 1. Tap Positions of NU-LEs for Equalizing $\boldsymbol{h_{c_1} = [a_0, a_3, a_5]}$, Where $\boldsymbol{a_0 = 1}$, $\boldsymbol{a_3 = 0.2828 + j0.2828}$, and $\boldsymbol{a_5 = 0.1299 + j0.075}$[a]

13-tap NU-LE (MF)	$\mathcal{S}_{\text{LE}}^2 = \{0, \mathbf{2}, \mathbf{3}, \mathbf{5}, 6, 8, 9\}$; $\mathcal{S}_{\text{LE}}^3 = -\mathcal{S}_{\text{LE}}^2$
6-tap NU-LE (SRRC)	$\mathcal{T}_{\text{LE}}^4 = \{0, \mathbf{3}, \mathbf{5}, 6, 8, 9\}$

[a]The positions in bold are elements of $\mathcal{S}_{\text{LE}}^1$ or $\mathcal{T}_{\text{LE}}^1$, which are used to form the nonnegative-integer-based linear combinations to obtain the other positions.
Source: Ref. 10.

As stated in Section 3, closed-form solution to the optimum tap positions of a finite-length NU-E generally does not exist. However, for a special type of sparse multipath channels whose multipath components are evenly delayed by mT, where m is a positive integer, it can be proved that the only nonzero-valued taps of a finite-length, T-spaced U-LE or U-DFE are located at positions that are multiples of m. In other words, the finite-length, T-spaced U-Es are inherently nonuniformly spaced for such channels and the optimum tap positions are $\{c_0, c_{\pm m}, c_{\pm 2m}, \ldots\}$, which are also the positions assigned by the algorithms. Another feature of the algorithms is their applicability to channels with multipath delays that are nonnegative real numbers. To design a T-spaced NU-E for such channels, an additional step is needed to quantize the assigned tap positions, which are now real numbers, to their nearest integral positions. If a T/2-spaced NU-E is desired, which is usually actually more suitable than a T-spaced NU-E for such channels, the assigned tap positions can be quantized to the nearest positions that are multiples of $\frac{1}{2}$. Similarly, the idea can be extended to design any fractionally spaced equalizers, although fractional spacings smaller than T/2 are seldom used in practice. As an example, Table 2 lists the tap positions of the T- and T/2-spaced NU-DFEs for a sparse multipath channel with delays that are multiples of $\frac{1}{2}$.

While the emphasis has been on the traditional types of NU-Es so far, there exists a different form of NU-DFE, called the *decision-directed feedback equalizer* (NU-DDFE), which has become increasingly popular for equalizing sparse multipath channels [e.g., 13–15] and thus deserves some attention as well. As shown in Fig. 4, the DDFE cancels the postcursor ISI before feedforward filtering via a FBF with impulse response identical to the strictly causal portion of the impulse response of the sampled receive filter output. This feature enables the FBF to fully exploit the sparseness inherent to the output and enjoy a substantial tap reduction, in contrast to the conventional DFE, in which the amount of sparseness in the output is usually diminished after feedforward filtering and thus makes a sizable FBF tap reduction without incurring a significant performance loss difficult. To determine the tap positions of the FFF of a NU-DDFE, Algorithms 1 and 2 can be applied directly, since it has been proved that the FFFs of a DFE and a DDFE are equivalent provided that all postcursor ISI is eliminated [13]. For the FBF of a NU-DDFE, the large magnitude taps in the strictly causal portion of the sampled receive filter output that satisfy a constraint [16] are selected. Note that if a T/2-spaced FFF is employed

Table 2. Tap Positions of NU-DFEs for Equalizing $h_{c_2} = [a_0, a_{1.5}, a_9]$, Where $a_0 = 0.2598 + j0.15$, $a_{1.5} = 1$, and $a_9 = 0.7071 + j0.7071$[a]

(8, 6)-tap NU-DFE (MF)	$\mathcal{S}_{\text{FFF}} = \{0, \mathbf{-1.5}, \mathbf{-7.5}, \mathbf{-9}, -10.5, -15, -16.5, -22.5\}$	T-spaced	$\{0, -1, -2, -7, -8, -9, -15, -16\}$
		T/2-spaced	$\mathcal{S}_{\text{FFF}}$
	$\mathcal{S}_{\text{FBF}} = \{1.5, 6, 7.5, 9\}$	T-spaced T/2-spaced	$\{1, 2, 6, 7, 8, 9\}$
(8, 6)-tap NU-DFE (SRRC)	$\mathcal{T}^1_{\text{FFF}} = \mathcal{S}_{\text{FFF}} - 1.5$	T-spaced	$\{0, -1, -2, -3, -9, -10, -11, -16\}$
	$\mathcal{T}^2_{\text{FFF}} = \{0\}$	T/2-spaced	$\{0, -1.5, -3, -9, -10.5, -16.5, -18, -24\}$
	$\mathcal{T}_{\text{FBF}} = \{1.5, 6, 7.5, 9\}$	T-spaced T/2-spaced	$\{1, 2, 6, 7, 8, 9\}$

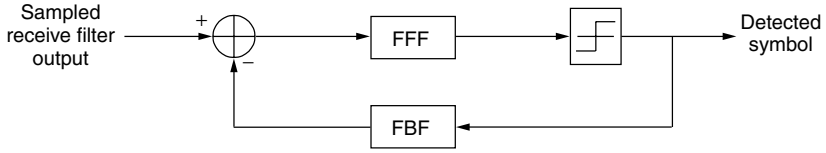

Figure 4. Structure of a DDFE.

in the NU-DDFE, the FBF of the NU-DDFE will be T/2-spaced as well.

Finally, it should be evident that some prior knowledge of the channel, from merely the positions of the taps with large magnitude to a complete estimate of the tap values, is required for most of the existing suboptimum tap allocation schemes discussed in Section 3. For Algorithms 1 and 2, knowing the positions of the taps with large magnitude and which one is the position of the largest magnitude tap are sufficient. Generally speaking, a key property of an appropriate channel estimation algorithm or detection method for the positions of the large magnitude taps is low complexity, so that the overall complexity when added together with a tap allocation scheme and an adaptive NU-E is still lower than the conventional approach of an adaptive U-E without the need of explicit channel estimation. Various channel estimation/detection methods tailored for sparse multipath channels are available in the literature; the more recent ones are specifically customized for use with subsequent equalization. While a discussion of these techniques is outside the scope of this article, a selected few are given in the Further Reading list for the interested reader. It should also be mentioned that, besides implementing an equalizer as an adaptive filter, the equalizer tap values can be computed directly from the channel estimates via fast algorithms with complexity of the order $O(n^2)$, where n is the number of equalizer taps. Unfortunately, such an approach may not be suitable for NU-Es, as these fast algorithms all utilize the Toeplitz nature of the input correlation matrices of U-Es and do not apply to those of NU-Es without the Toeplitz characteristic, which means that only standard algorithms with $O(n^3)$ complexity can be exploited to directly compute the tap values of a NU-E. Therefore, unless the reduction of taps is large, using a NU-E instead of a U-E in this manner may actually increase the computational load.

6. PERFORMANCE EXAMPLE

In this section, a representative example is selected to illustrate some fundamental properties of finite-length NU-Es. The system setup is the same as that shown in Fig. 3. The 4-QAM signaling scheme with constellations $\{\pm 1 \pm j\}$ is chosen and the excess bandwidth of the SRRC transmit and receive filters is set to 35%. Perfect channel knowledge is presumed at the receiver, and optimum tap values of the NU-Es are computed ideally using the matrix inversion approach once their tap positions are determined from the algorithms of Section 5. The bit error rate (BER) after equalization is evaluated analytically through the Beaulieu series as in Ref. 17, and perfect decision feedback is assumed in the DFEs.

Figure 5 shows the performance of the T- and T/2-spaced NU-DFEs for equalizing h_{TV}, one of seven test channels for HDTV systems [2] but with its precursor tap modified from −20 dB to −6 dB relative to the main response to increase the difficulty of equalization, as has been done in Ref. 13. An important result revealed in this plot is that the T-spaced NU-DFE under the MF system only performs better than the one under the SRRC receive filter system at low SNRs, with the crossover point of their BER curves around the SNR of 17.5 dB. This counterintuitive phenomenon is due to the incapability of an equalizer with a limited number of taps, such as a NU-E, to mitigate the extra ISI terms introduced by matched filtering. Although the MF maximizes the SNR before equalization, this gain is only minimal when the influence of noise is insignificant. As a result, if a NU-E is employed at a high SNR region, the benefit of using the MF to maximize the SNR will be insufficient for compensating the detrimental effect of the extra ISI terms introduced, and so the BER suffers. In fact, this phenomenon is even more apparent when the T/2-spaced NU-DFEs of the two systems are compared, with the one under the SRRC receive filter system having a lower BER curve than its counterpart under the MF system for the entire range of SNR shown. This is because a T/2-spaced equalizer can function as a MF, thus allowing the one under the SRRC receive filter system to enjoy the same benefit as the one under the MF system, but without the need to suppress the extra ISI terms that a preceding MF introduces. Therefore, the SRRC receive

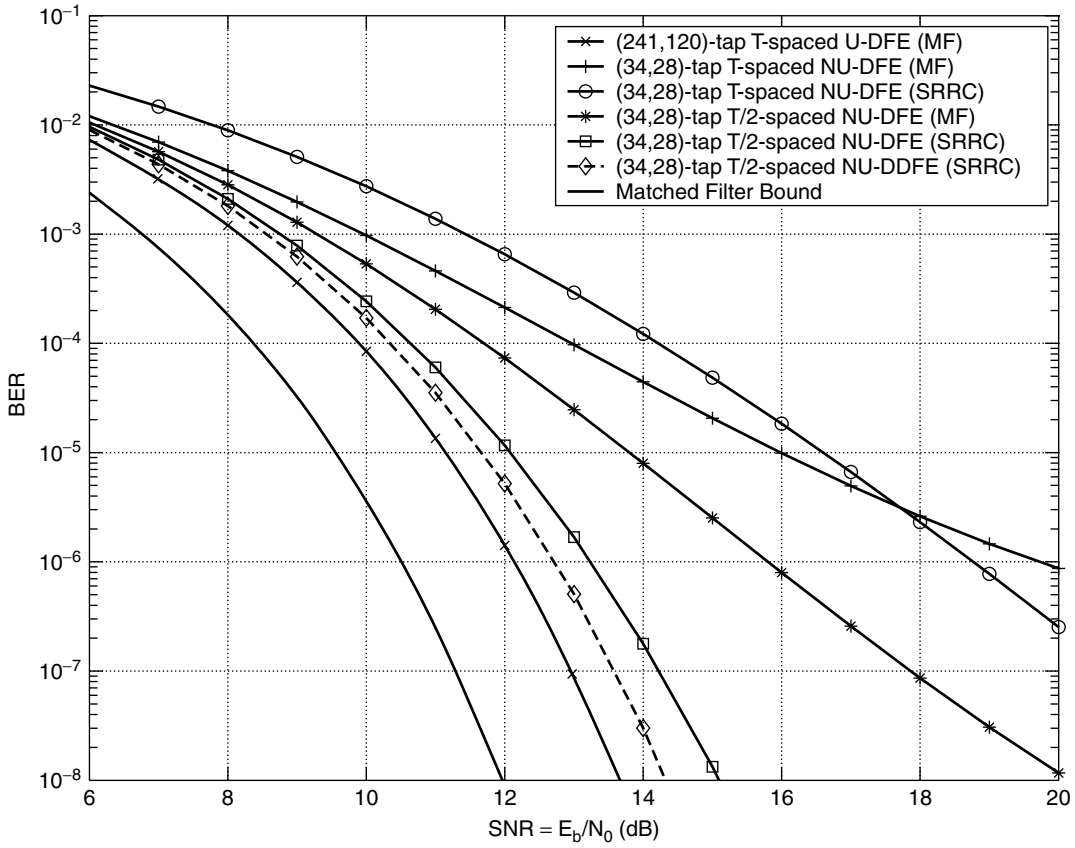

Figure 5. Performance of NU-DFEs for equalizing $h_{\mathrm{TV}} = [a_0, a_{9.68}, a_{10.49}, a_{19.37}, a_{40.35}, a_{106.52}]$, where $a_0 = 0.1549 - j0.4767$, $a_{9.68} = -1$, $a_{10.49} = 0.1$, $a_{19.37} = 0.0389 + j0.1197$, $a_{40.35} = -0.1614 + j0.1173$, and $a_{106.52} = -0.2558 - j0.1859$. (*Source*: Ref. 10.)

filter is a better front-end receive filter than the MF when followed by a NU-E. Note that the performance of the T/2-spaced NU-DDFE under the SRRC receive filter system is also included in Fig. 5. In accordance with the discussion of Section 5, it attains a lower BER curve than its traditional counterpart with only a SNR loss of about 0.7 dB relative to the reference U-DFE, which is used to approximate the performance of the infinite-length equalizer. However, for certain sparse multipath channels, the gain in using a NU-DDFE may not be as significant. More information regarding the strengths and weaknesses of the NU-DDFEs can be found in the paper by Lee and McLane [16].

7. CONCLUSIONS

The ever-increasing data rate in modern communication systems has prompted the quest for new equalization techniques to handle channels with long impulse responses efficiently. NU-Es are suggested in this article as a reduced-complexity solution for equalizing a special family of wireless channels called *sparse multipath channels* that exhibits this undesirable characteristic. Tap positions for the infinite-length, T-spaced ZF/MMSE-LEs/DFEs for such channels can be derived by expressing each frequency response as an infinite series, which in turn lead to simple tap allocation algorithms for designing finite-length NU-Es, including a modified form of the NU-DFE. A fundamental property associated with NU-Es is the nonoptimality of the MF as the front-end receive filter; a better substitute is the SRRC receive filter. Overall, good performance is attained by the NU-Es despite their large reduction in complexity. Together with an appropriate low-complexity channel estimation algorithm, it is conceivable that NU-Es can become a crucial component in future-generation mobile receivers that are expected to operate in a wide variety of channel conditions with ease.

BIOGRAPHIES

Frederick K. H. Lee received the B.Sc. degree in electrical and computer engineering in 1998 from Queen's University, Kingston, Ontario, Canada, where he is currently a Ph.D. candidate. During his postgraduate studies, he has been supported by two postgraduate Scholarships from the Natural Sciences and Engineering Research Council (NSERC) of Canada, a Fessenden Postgraduate Scholarship from the Communications Research Centre (CRC), Canada, and an Ontario Graduate Scholarship. His research interests are communications theory and signal processing algorithms for communications.

Peter McLane has been a Professor at Queen's University since 1969. He is a Fellow of the IEEE and served as the Chairman of the IEEE Communications Society Communication Theory Committee for 3 years. He has served as a Major Project Leader for both Communications and Information Technology Ontario (CITO) and for the Canadian Institute of Telecommunications Research (CITR). He has been a member of both Research and Scholarship Committees with NSERC. He jointly received two research awards: the 1994 Stentor Telecommunications Research Award and the TRIO Feedback Award in 1992. He is one of four authors of the books *Introduction to trellis Coded Modulation with Applications*, originally published by Macmillian in 1991. He has spent academic leaves at UBC, AT&T Bell Labs, Motorola, and Harris Canada.

OPTICAL COUPLERS

GERD KEISER
PhotonicsComm Solutions, Inc.
Newton Center, Massachusetts

1. INTRODUCTION

Optical couplers play a key role in wavelength-division multiplexing (WDM) applications for combining and separating wavelength channels, tapping off power for monitoring purposes, or adding and dropping specific wavelengths at a particular point in an optical fiber communication link [1–3]. Most optical couplers are passive devices in the sense that they do not need to be powered externally to perform their function on optical signals. Fundamentally, optical couplers connect three or more fibers to combine, split, or redirect light signals.

Since optical couplers perform many different functions, they can be made in several configurations, as shown in Fig. 1. The T coupler, Y coupler, or 1×2 coupler is a three-port device that is mainly used to tap off a portion of the light from a throughput fiber into a second fiber. The relative optical power level in each output branch is usually given in percentages. The design can be tailored to achieve any coupling ratio between the two outputs. This coupler nominally is used for signal-monitoring applications. In this case, a tradeoff between coupling loss in the primary fiber and an adequate level of power required for the measurement threshold in the secondary branch shows that a 10% tap is the optimal configuration [4]. This means that 90% of the input optical power continues through the device and 10% is tapped off for signal monitoring purposes.

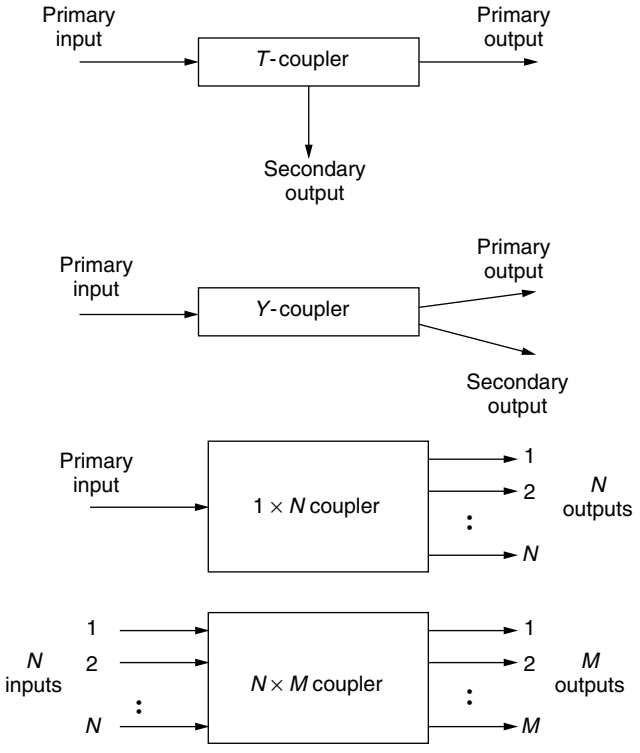

Figure 1. Example configurations for optical couplers.

The $1 \times N$ or tree coupler has one input fiber and N output fibers. In the most general case, this device is not wavelength dependent and it divides all the input optical power equally among the N output ports. Many of these devices are directional, which means that their function depends on the direction in which the light passes through it.

A more general configuration is the $N \times M$ or star coupler, which has N input ports and M output ports. In the broadest application, star couplers combine the light streams from two or more input fibers and divide them among several output fibers. In the general case, the splitting is done uniformly for all wavelengths, so that each of the M outputs receives $1/M$ of the power entering the device. A common fabrication method for an $N \times N$ coupler is to fuse together the cores of N single-mode fibers over a length of a few millimeters. The optical power inserted through one of the N fiber entrance ports gets divided uniformly into the cores of the N output fibers through evanescent power coupling in the fused region.

Wavelength-selective couplers form a more versatile category of devices for WDM applications. Among the technologies used for making these devices are 2×2 fused-fiber couplers, coupled planar waveguides, Mach–Zehnder interferometers, fiber Bragg gratings, and phased-array waveguide gratings.

2. COUPLER CONSTRUCTIONS

The 2×2 coupler is a simple fundamental device that we will use here to demonstrate the operational principles. These devices can be fabricated by microoptic, optical fiber, or integrated optic methods. A common construction is the fused-fiber coupler [3,5–7]. This is fabricated by twisting together, melting, and pulling two single-mode fibers so they get fused together over a uniform section of length W, as shown in Fig. 2. Each input and output fiber has a long tapered section of length L, since the transverse dimensions are gradually reduced down to that of the coupling region when the fibers are pulled during the fusion process. The total draw length is $2L + W$. This device is known as a fused biconical tapered coupler. Here P_0 is the input power, P_1 is the throughput power, and P_2 is the power coupled into the second fiber. The parameters P_3 and P_4 are extremely low signal levels (-50 to -70 dB below the input level) resulting from backward reflections and scattering due to bending in and packaging of the device.

As the input light P_0 propagates along the taper in fiber 1 and into the coupling region, an increasingly larger portion of the input field now propagates outside the core

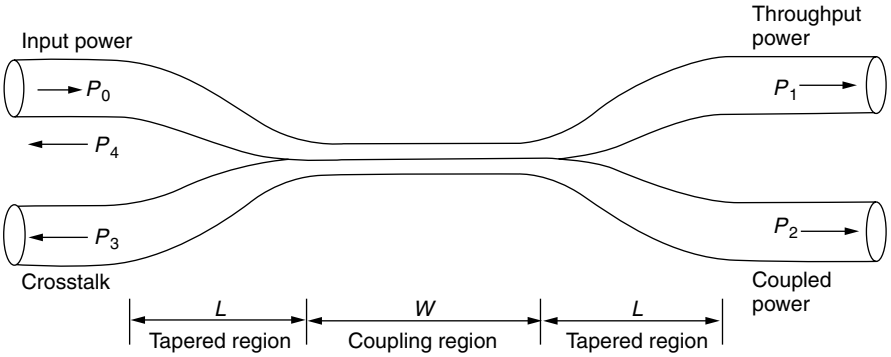

Figure 2. Cross-sectional view of a fused-fiber coupler having a coupling region W and two tapered regions of length L. The total span $2L + W$ is the coupler draw length.

of the input fiber and is coupled into the adjacent fiber. Depending on the dimensioning of the coupling region, any desired fraction of this decoupled field can be coupled into fiber 2. By making the tapers very gradual, only a negligible fraction of the incoming optical power is reflected back into either of the input ports. Thus these devices are also known as directional couplers.

Fused-fiber couplers have an intrinsic wavelength dependence in the coupling region. The optical power coupled from one fiber to another at a specific wavelength can be varied through three parameters: the axial length of the coupling region over which the fields from the two fibers interact; the size of the reduced radius r in the coupling region; and Δr, the difference in radii of the two fibers in the coupling region. In making a fused-fiber coupler, the coupling length W is normally fixed by the width of the heating flame that is used in the melting process, so that only L and r change as the coupler is elongated. Typical values for W and L are a few millimeters, the exact values depending on the coupling ratios desired for a specific wavelength, and $\Delta r/r$ is around 0.015. Assuming that the coupler is lossless, the expression for the power P_2 coupled from one fiber to another over an axial distance z is

$$P_2 = P_0 \sin^2(\kappa z) \tag{1}$$

where κ is the *coupling coefficient* describing the interaction between the fields in the two fibers. By conservation of power, for identical-core fibers we have

$$P_1 = P_0 - P_2 = P_0[1 - \sin^2(\kappa z)] = P_0 \cos^2(\kappa z) \tag{2}$$

Wavelength-dependent multiplexers can also be made using Mach–Zehnder interferometry techniques [8]. Figure 3 illustrates the constituents of an individual

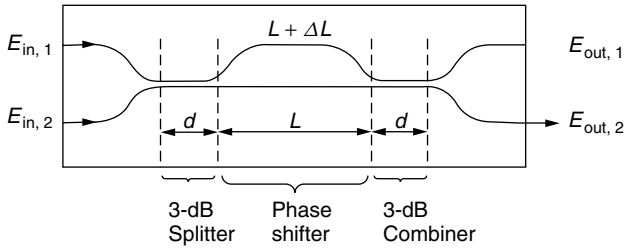

Figure 3. Constituents of an individual Mach–Zehnder interferometer (MZI). E_{in} and E_{out} are electric field intensities.

Mach–Zehnder interferometer (MZI). This 2×2 MZI consists of three stages: an initial 3-dB directional coupler which splits the input signals, a central section where one of the waveguides is longer by ΔL to give a wavelength-dependent phase shift between the two arms, and another 3-dB coupler which recombines the signals at the output. The function of this arrangement is that, by splitting the input beam and introducing a phase shift in one of the paths, the recombined signals will interfere constructively at one output and destructively at the other. The signals then finally emerge from only one output port.

A grating is an important element in WDM systems for combining and separating individual wavelengths. Basically a grating is a periodic structure or perturbation in a material. This variation in the material has the property of reflecting or transmitting light in a certain direction depending on the wavelength. Thus gratings can be categorized as either transmitting or reflecting gratings.

Figure 4 shows a simple concept of a demultiplexing function using a fiber Bragg grating [9,10]. To extract the desired wavelength, a circulator is used in conjunction with the grating. In a three-port circulator, an input signal on one port exits at the next port. For example,

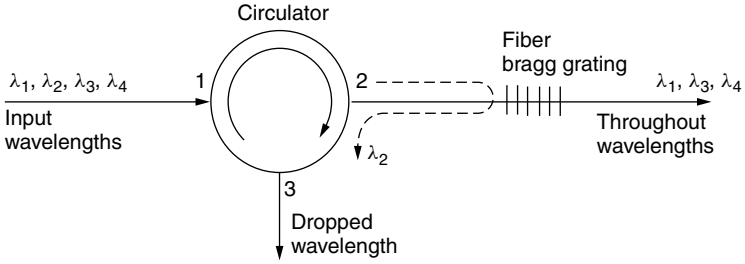

Figure 4. A simple wavelength demultiplexing function using a fiber Bragg grating.

an input signal at port 1 is sent out at port 2. Here the circulator takes the four wavelengths entering port 1 and sends them out port 2. All wavelengths except λ_2 pass through the grating. Since λ_2 satisfies the Bragg condition of the grating, it is reflected, enters port 2 of the circulator, and exits at port 3. More complex multiplexing and demultiplexing structures with several gratings and several circulators can be realized with this scheme.

A highly versatile WDM device is based on using an arrayed waveguide grating. This device can function as a multiplexer, a demultiplexer, a drop-and-insert element, or a wavelength router. A variety of design concepts have been examined [11,12]. The arrayed waveguide grating is a generalization of the 2×2 Mach–Zehnder interferometer multiplexer. One popular design consists of M_{in} input and M_{out} output slab waveguides and two identical focusing planar star couplers connected by N uncoupled waveguides with a propagation constant β. The lengths of adjacent waveguides in the central region differ by a constant value ΔL, so that they form a Mach–Zehnder-type grating, as Fig. 5 shows. For a pure multiplexer, we can take $M_{\text{in}} = N$ and $M_{\text{out}} = 1$. The reverse holds for a demultiplexer, that is $M_{\text{in}} = 1$ and $M_{\text{out}} = N$. In the case of a network routing application, we can have $M_{\text{in}} = M_{\text{out}} = N$.

3. PERFORMANCE CHARACTERISTICS

In specifying the performance of an optical coupler, one usually indicates the percentage division of optical power between the output ports by means of the splitting ratio or coupling ratio. Referring to Fig. 2, where P_0 is the input power and P_1 and P_2 the output powers, then

$$\text{Splitting ratio} = \left(\frac{P_2}{P_1 + P_2}\right) \times 100\% \tag{3}$$

By adjusting the parameters so that power is divided evenly, with half of the input power going to each output, one creates a 3-dB coupler. A coupler could also be made in which, for example, almost all the optical power at 1500 nm goes to one port and almost all the energy around 1300 nm goes to the other port.

In the analysis above, we have assumed for simplicity that the device is lossless. However, in any practical coupler there is always some light that is lost when a signal goes through it. The two basic losses are excess loss and insertion loss. The excess loss is defined as the ratio

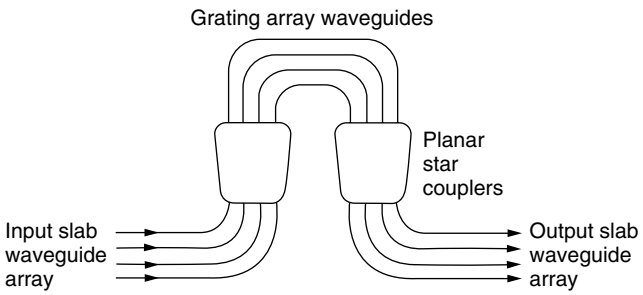

Figure 5. Adjacent waveguides in the central region differ in length to form a Mach–Zehnder-type grating.

of the input power to the total output power. Thus, in decibels, the excess loss for a 2×2 coupler is

$$\text{Excess loss} = 10 \log \left(\frac{P_0}{P_1 + P_2}\right) \tag{4}$$

The insertion loss refers to the loss for a particular port-to-port path. For example, for the path from input port i to output port j, we have, in decibels:

$$\text{Insertion loss} = 10 \log \left(\frac{P_i}{P_j}\right) \tag{5}$$

Another performance parameter is crosstalk, which measures the degree of isolation between the input at one port and the optical power scattered or reflected back into the other input port. That is, it is a measure of the optical power level P_3 shown in Fig. 2:

$$\text{Crosstalk} = 10 \log \left(\frac{P_3}{P_0}\right) \tag{6}$$

The principal role of any star coupler is to combine the powers from N inputs and divide them equally among M output ports. Techniques for creating star couplers include fused fibers, gratings, microoptic technologies, and integrated optics schemes. The fused-fiber technique has been a popular construction method for $N \times N$ star couplers. For example, 7×7 devices and 1×19 splitters or combiners with excess losses at 1300 nm of 0.4 and 0.85 dB, respectively, have been demonstrated. However, large-scale fabrication of these devices for $N > 2$ is limited because of the difficulty in controlling the coupling response between the numerous fibers during the heating–pulling process.

In an ideal star coupler the optical power from any input is evenly divided among the output ports. The total loss of the device consists of its splitting loss plus the excess loss in each path through the star. The splitting loss is given in decibels by

$$\text{Splitting loss} = -10 \log \left(\frac{1}{N}\right) = 10 \log N \tag{7}$$

For a single input power P_{in} and N output powers, the excess loss in decibels is given by

$$\text{Fiber star excess loss} = 10 \log \left(\frac{P_{\text{in}}}{\sum_{i=1}^{N} P_{\text{out},i}}\right) \tag{8}$$

The insertion loss and crosstalk can be found from Eqs. (5) and (6), respectively.

An alternative is to construct star couplers by cascading 3-dB couplers. Figure 6 shows an example for an 8×8 device formed by using twelve 2×2 couplers. This device could be made from either fused-fiber or integrated-optic components. As can be seen from this figure, a fraction $1/N$ of the launched power from each input port appears at all output ports. A limitation to the flexibility or modularity

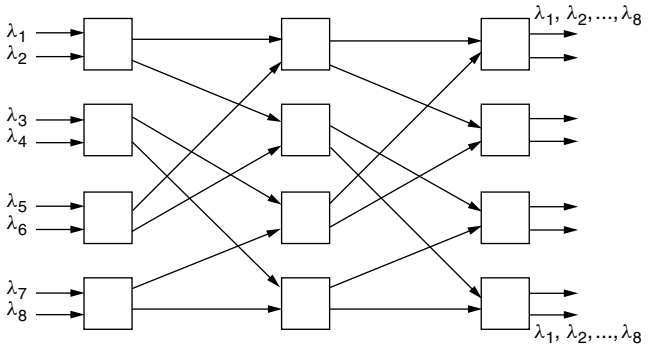

Figure 6. Example for an 8×8 device formed by using twelve 2×2 couplers.

of this technique is that N is a multiple of 2, that is, $N = 2^n$ with the integer $n \geq 1$. The consequence is that if an extra node needs to be added to a fully connected $N \times N$ network, the $N \times N$ star needs to be replaced by a $2N \times 2N$ star, thereby leaving $2(N-1)$ new ports being unused. Alternatively, one extra 2×2 coupler can be used at a port with the result that the outputs of the two new ports have an additional 3-dB loss.

As can be deduced from Fig. 6, the number of 3-dB couplers needed to construct an $N \times N$ star is

$$N_c = \frac{N}{2}\log_2 N = \frac{N}{2}\frac{\log N}{\log 2} \tag{9}$$

since there are $N/2$ elements in the vertical direction and $\log_2 N = \log N / \log 2$ elements horizontally.

If the fraction of power traversing each 3-dB coupler element is F_T, with $0 \leq F_T \leq 1$ (i.e., a fraction $1 - F_T$ of power is lost in each 2×2 element), then the excess loss in decibels is

$$\text{Excess loss} = -10\log(F_T^{\log_2 N}) \tag{10}$$

The splitting loss for this star is again given by Eq. (7). Thus, the total loss experienced by a signal as it passes through the $\log_2 N$ stages of the $N \times N$ star and gets divided into N outputs is, in decibels,

$$\begin{aligned}\text{Total loss} &= \text{splitting loss} + \text{excess loss} \\ &= -10\log\left(\frac{F_T^{\log_2 N}}{N}\right) = -10\left(\frac{\log N \log F_T}{\log 2} - \log N\right) \\ &= 10(1 - 3.322\log F_T)\log N \end{aligned} \tag{11}$$

This shows that the loss increases logarithmically with N.

BIOGRAPHY

Gerd Keiser is the founder and president of Photonics-Comm Solutions, Inc., Newton Center, Massachusetts, a firm specializing in consulting and education for the optical communications industry. He has 25 years experience at Honeywell, GTE, and General Dynamics in designing and analyzing telecommunication components, links, and networks. He is the author of the books *Optical Fiber Communications* (3rd ed. 2000) and *Local Area Networks* (2nd ed. 2002) published by McGraw-Hill. Dr. Keiser is an IEEE fellow and received GTE's prestigious Leslie Warner Award for work in ATM switch development. He earned his B.A. and M.S. degrees in mathematics and physics from the University of Wisconsin and a Ph.D. in solid state physics from Northeastern University, Boston, Massachusetts.

OPTICAL CROSSCONNECTS

Li Fan
OMM, Inc.
San Diego, California

1. INTRODUCTION

Massive information demand in the Internet is creating enormous needs for the capacity and communication bandwidth expansion in the service providers and the carriers. With the expectation that the new data traffic will have

exponential growth, the service providers are under pressure to find a new technology, which can dramatically reduce the cost of hardware and network management as well as solving the bandwidth bottleneck. Instead of chasing the growing bandwidth, service providers are desperate to keep ahead of the competition. In particular, they want to boost capacity by orders of magnitude. Optical networks are digital communications systems that use light waves in the fiber as a medium for the transmission or switching of data. This new optical layer is the future to providing cost-effective capacity. Dense wavelength division multiplexing (DWDM) is the ideal solution to dramatically increase bandwidth. With the enormous channels and traffic, optical crossconnects (OXC) is the emerging technology and component that will deliver and manage this new optical layer and the services running on it. Optical crossconnects can be used for protection and restoration in optical networks, bandwidth provisioning, wavelength routing, and network performance monitoring. It is one of the key elements for routing optical signals in an optical network or system for long-haul communication, metro area, and local access add-drop as shown in Fig. 1.

2. OPTICAL CROSSCONNECTS FABRIC

Currently, carrier backbones already carry information traffic with light over fiber. For long-distance fiber, the light has to be converted back into electrical and periodically regenerated depending on the fiber type. Most current OXC in fact use an electronic core for switching such as the synchronous optical network (SONET) system, fiber distributed data interface (FDDI) switches, asynchronous transfer mode (ATM) switches, and ethernet switches with fiber optic interfaces to convert the photons into electrical signals in order to switch them from one fiber to another at junction points. Sometimes the electronic switch is referred to as optical-electrical-optical (OEO) switch as shown in Fig. 2. In this OEO crossconnects, the input/output signals are optical, but receivers convert the input signals to electrical signals, then use electronic components to route the channels through the core. At the transceiver module, the electrical signals are converted back into photons. This solution is not future proof since when the data rate increases, the expensive transceivers and the electrical switch core have to be replaced.

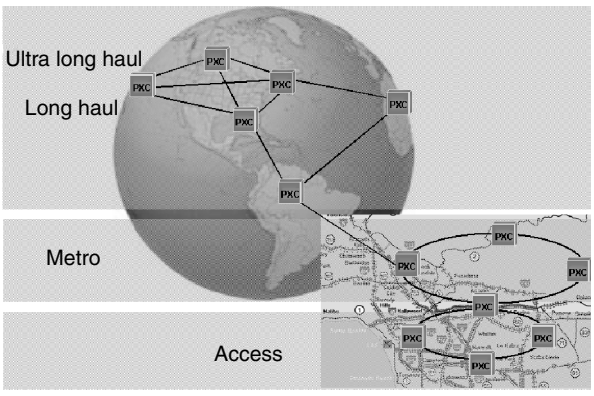

Figure 1. Use optical crossconnects to manage the optical network for wavelength routing, network performance monitoring, bandwidth provisioning, protection, and restoration in optical networks.

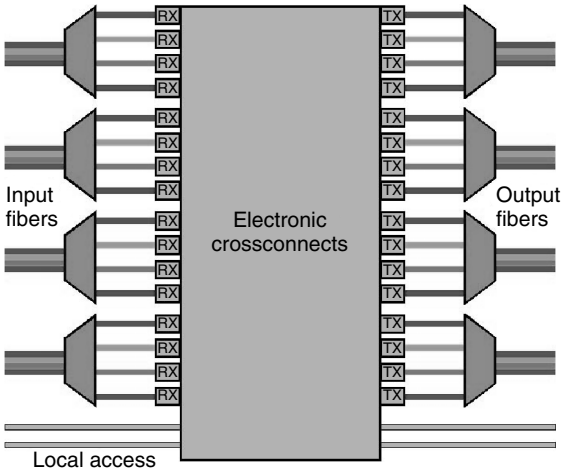

Figure 2. OEO electronic crossconnects. The wavelengths from DWDM fibers are converted into electrical signals by receivers. The switching and routing are done by the electronic core. The output signals are converted back into optical by transmitters.

All-optical crossconnects use light waves exclusively from end to end. The data is maintained in original optical format from the input fiber to the switch element. The data format is unchanged from switching elements to the output fiber. Sometimes the all-optical crossconnects is referred to as OOO crossconnects as shown in Fig. 3, which stands for optical-optical-optical. It is preferred to use the terminology "photonic crossconnects" for all-optical crossconnects rather than "optical crossconnects." This is to designate the fact that the data path of the switch is purely photonic, with no electrical conversions. The all-optical crossconnects are much more attractive because of the avoidance of the conversion stages and because the core switch is independent of data rate and data protocol, making the

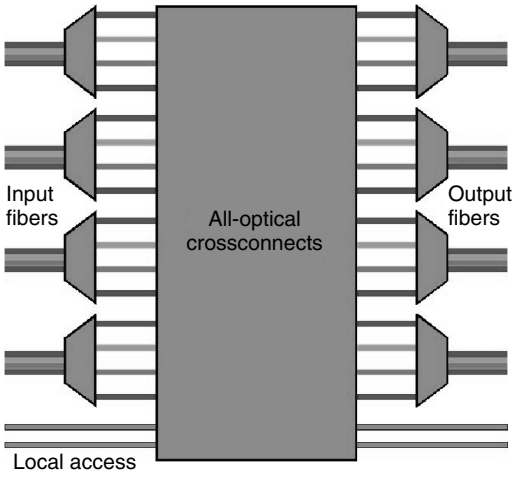

Figure 3. All-optical crossconnects. The data is maintained in original optical format from input fiber through the core switch to the output fiber. There is no need for expensive and high-power consumption high-speed electronics and transmitters and receivers.

cross-connect ready for future data rate upgrades. It provides a valuable capability for handling high bandwidth traffic, as there is no need for expensive and high-power consumption high-speed electronics, transmitters, and receivers. The system becomes less expensive in addition to the reduction of complexity. The all-optical crossconnects improve reliability and reduce the footprint when compared with OEO solutions. Another major benefit of all-optical devices is their greater scalability over OEOs.

Some advantages of the all-optical crossconnects are also disadvantages when we try to coexist this technology with current network. All-optical crossconnects maintain the original signal from input to output fibers without signal regeneration for cost saving. They use erbium doped fiber amplifiers (EDFA) to boost the signal, not regeneration. However, this approach also loses the advantages of signal regeneration. The network design would be challenging to route the same wavelength from the source to the destination and through the entire multirings or meshes network, eliminating the transponders and removing the capability of wavelength conversion. There is no visibility of bit error rate (BER) or monitoring. An all-optical network only has lambda (wavelength) level granularity and cannot perform sub-lambda mixing and grooming.

To combine the scalability of all-optical crossconnects and the wavelength regeneration and grooming, a compromise design is to integrate the all-optical crossconnects ports with an OEO switch as shown in Fig. 4. The majority of the fabric is a fully connected all-optical crossconnects. A small percent of the output ports and input ports are integrated with local add/drop switching through and OEO router. Since any input port can be connected to any output port and go through the OEO router, the data stream of the selected channel can be detected and processed by software at the individual packet level; the wavelength is capable of 3R (reshape/retime/regenerate) and wavelength translation if the network design is sufficiently advanced.

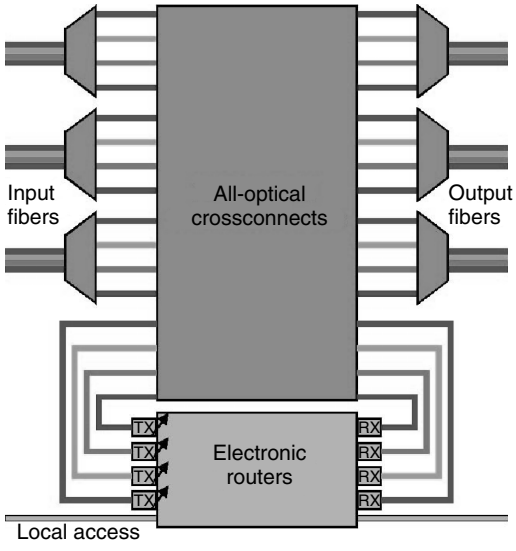

Figure 4. Compromised network design integrated all-optical crossconnects with electronic routers for 3R regeneration and wavelength conversion.

The more complex system may also use additional optical repeaters at each I/O module for 3R regeneration. The repeater is a receiver that can receive any wavelength, directly connected to a transmitter whose output wavelength matches the channel of the wavelength multiplexer.

3. OPTICAL CROSSCONNECTS ARCHITECTURE: 2D AND 3D

The architectures of OXC can be categorized into two approaches. The first configuration is the 2D approach. The devices are arranged in a crossbar configuration. Figure 5 shows the schematic diagram of an 8×8 crossconnects with switches arranged in a 2D array. Each mirror has a digital movement. The switch has only either on or off status, which makes the driving scheme very straightforward. The device can be controlled with a simple TTL signal and does not require feedback control. When a switch is set at the off position, the optical signal will pass through the switch with minimum insertion loss. When the switch is activated, it will bounce the optical signal by 90° and direct the light to the output fiber. The reflection can be achieved by total internal reflection from different refractive index or it can be reflected by a free-space micromirror. Additional functionality can be achieved for adding or dropping optical signals if plane 3 and plane 4 are utilized. Because of the crossbar arrangement, the required mirror number is not linear to port count. The mirror number is equal to N^2. This approach is ideal for small port count crossconnects. However, a large port count crossconnects such as 64×64 will require 4096 switching elements, which is still challenging for current technology.

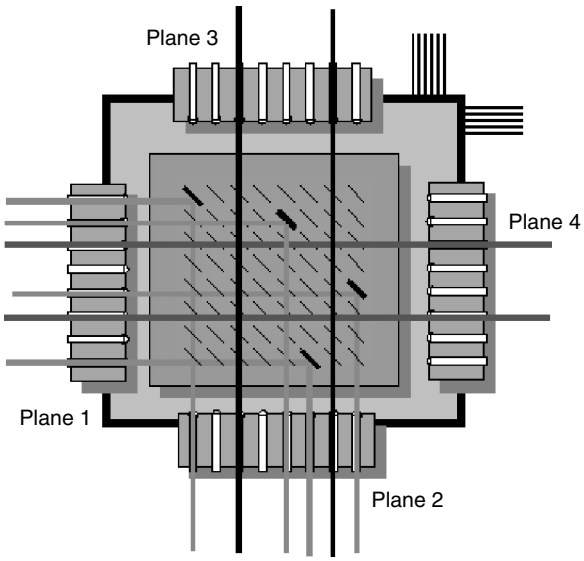

Figure 5. Schematic diagram of 2D digital crossconnects. It needs N^2 switches to configure an $N \times N$ crossconnects. Each switch has only two states: on and off. Optical signal will pass through the switch with minimum lose when the switch is at off position. The light will be reflected at 90° when the switch is activated.

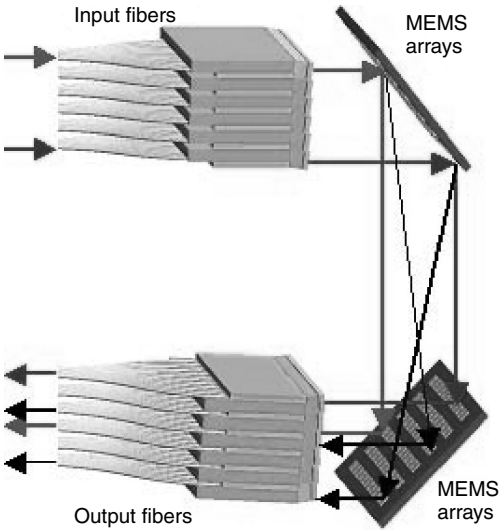

Figure 6. Schematic diagram of 3D crossconnects. The switch number is linearly proportional to channel number. It needs 2N switches to construct $N \times N$ crossconnects. Each mirror has N different states, which are able to point at all the output mirrors with high precision.

The second architecture for the crossconnects is the 3D approach as shown in Fig. 6. This approach has the advantage for switch number (2N), which is linearly proportional to channel number. The connection path is established by tilting two analog mirrors and directing the light from the input fiber to the output fiber. Each mirror has N different states, which need to be well controlled. The 3D approach is the most promising architecture for very large port counts, more than hundred or thousand. The analog fine-tuning of the mirror angle is another unique functionality from 3D that can be used to minimize the insertion loss and equalize uniformity. The drawback of this approach is the control loop and monitoring which can be very complex. The mirror stability, shock/vibration, and long-term drift need to be carefully controlled. The overall total states number for 2D and 3D are the same (Fig. 7). They both need $2N^2$ different states to complete the switching functionality. However, 2D puts more pressure on the switch number; 3D has a smaller switch number but puts more burden on mirror angle control.

Usually OXC are desired to be nonblocking; any input fiber can be switched to any output fiber. With 16 input fibers and 40 wavelengths, the crossconnects size can easily grow to several hundred or even thousand port count at the first installation. It is putting an incredible burden on current technology, especially a few years ago when there were only 2×2 switches commercially available. Even though the large port count crossconnects can be built from 2×2 switching elements, it is not practical or cost effective especially for the performance and scalability. Large nonblocking networks can be constructed with smaller switch fabric by using a multistage Clos network to reduce the number of crosspoints compared to simple matrices [1]. In blocking crossconnects, some connections cannot be established for certain choices or the switch paths are limited to certain zone area. However, the blocking switches can be used as an advantage to reduce the complexity of the crossconnects and enable a larger port count system from smaller modules. For example the wavelength-selective crossconnects (WSXC) is a stack of $N \times N$ switches, each dedicated to signals of the same wavelength as drawn in Fig. 8. For a network with sixteen input fibers, each carrying forty wavelengths, the crossconnects would need to be 640×640 if the system needs to be nonblocking. Because of the lack of wavelength conversion in the fabric, the wavelength is not interchangeable between different wavelengths. Therefore, crossconnects are needed only among the same wavelength. The same functionality network can be built with 40 packages of 16×16 switches, a pay-as-you-grow business model using smaller switches as building elements. New fabrics are added when new wavelengths are turned on. The total bandwidth capacity of a WSXC can be extremely large with low first-installed cost and scalability.

4. TECHNOLOGY

4.1. Planar Lightwave Circuit: Thermo-Optic and Electro-Optic

The planar lightwave circuits (PLC) are constructed with rectangular cross sections of different refraction index materials. The section that transmits the light has a slightly higher refractive index, so that total internal reflection acts to guide the light within the waveguides. The key elements of PLC switches are two directional couplers and the Mach-Zehnder interferometer (MZI). A directional coupler consists of two waveguides very close to each other, so that light waves can be coupled from one to the

	Array size	Switch number	States for each switch	Total states
2D	$N \times N$	N^2	2	$N^2 \times 2 = 2N^2$
3D	$N \times N$	2N	N	$2N \times N = 2N^2$

Figure 7. Two different approaches for OXC show different trade-off. However, the total states for each configuration are identical. Both 2D and 3D require total number of $2N^2$ different states in order to complete $N \times N$ crossconnects functionality. 2D approach has more weight on switch number, which will show bottleneck with larger port count. 3D approach only requires switch number linear proportional to channel number. However, the burden is shifted to the complexity of the switch design.

Figure 8. Wavelength-Selective Crossconnects uses small $N \times N$ switches as building block. The small switch port count (N) is equal to the input fiber number. The total package number (M) is increased when new wavelengths are turned on. The total bandwidth capacity of a WSXC is N times M, which can be extremely large with scalability and low first-install cost.

other. The MZI is a pair of waveguides with identical path lengths. They are separated far enough and will not couple energy between these two waveguides. The incoming light from the input waveguide is spit 50/50 in the first directional coupler. The upper branch goes through a controlled path while the lower branch goes through a reference pathway as illustrated in Fig. 9. The refractive index can be thermally controlled by locally heating the thin film heater above the waveguide [2], or it can be controlled by electro-optic lithium niobate technology [3]. Since the controlled branch and the reference branch of the MZI have identical path length, the light energy will be recombined in the second directional coupler and switch to the upper branch when the controller is off. The controller will change the refractive index and effectively change the path length and phase of the upper branch. The interference will switch the light wave to the lower branch when the controller is on.

Waveguide technology was among the first all-optical switches to be developed, typically in the 1×1, 1×2, and 2×2 range. Because of the planar technology, larger crossconnects can be formed by integrating basic 2×2 components on the same wafer. The optical performance parameters such as crosstalk and insertion loss could be unacceptable for optical network application. However, this technology is capable of integrating variable optical attenuators (VOA) optical switch and wavelength selective elements on the same substrate. It does not require free-space collimator alignment.

4.2. Microfluid

The microfluid and microbubble utilize the interfaces of different refractive index and cause total internal reflection to redirect the light beam. Bubble switches demonstrated the switching mechanism from intersecting waveguides [4]. At each intersection, a trench is etched into the waveguide. The trenches are filled with an index-matching fluid to direct the light in the through states. To direct the light, the thermal inkjet-like matrix-controller silicon chip element heats up the fluid and creates a microbubble in the liquid. The location of the bubble is at the intersection between the input waveguide and output waveguide. The light is reflected by total internal reflection from the liquid/bubble interface as shown in Fig. 10.

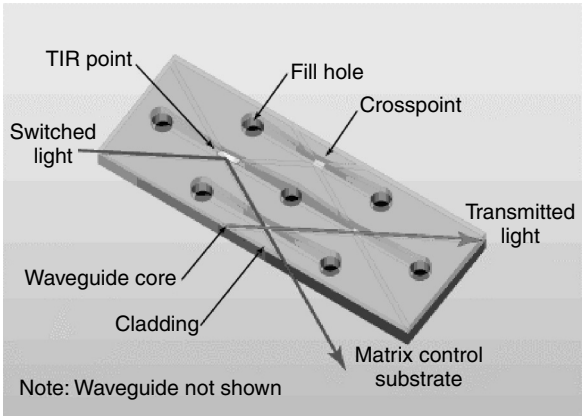

Figure 10. Bubble switch directs light from an input to an output, by using a thermal inkjet element to create a bubble in an index-matching fluid at the intersection between the input waveguide and the desired output waveguide. The light is redirected by means of total internal reflection. Courtesy of Agilent Technologies Inc.

A thermal-capillarity optical switch utilizes a similar total internal reflection concept [5]. The switch element consists of an upper substrate and an intersecting waveguide substrate that has a slit at each crossing point with refractive index matching oil in it and a pair of micro-heaters that produce a thermal gradient along the slit as shown in Fig. 11. The matching oil within the slit is driven by a decrease in interfacial tension of the air-oil interface caused by thermo-capillarity. This switch element also has bi-stable self-latching achieved by capillary pressure that depends on the slit width.

4.3. Liquid Crystal

Liquid crystal crossconnects uses liquid crystal to rotate the optical beam polarization by applying electric voltage to adjust the molecules orientation. Based on this rotation, a beam steering router displaces the signal to one of

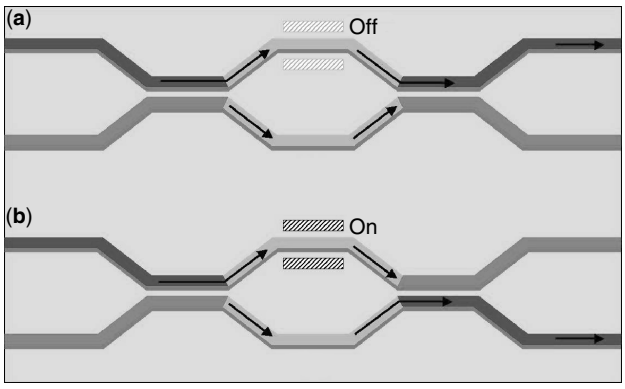

Figure 9. Light from input fiber enters a waveguide at the edge of the optical wafer and goes through a 50/50 split in a directional coupler. One branch goes through a refractive index controlled path (by thermal-optic or electro-optic) while the other goes through a reference pathway.

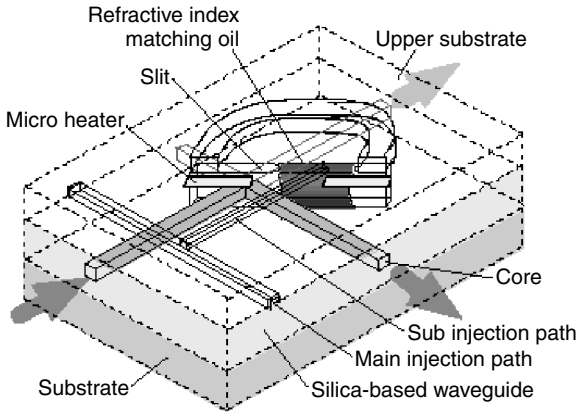

Figure 11. The basic structure of the thermo-capillarity optical switch element. The matching oil within the slit is driven by a decrease in interfacial tension of the air-oil interface caused by thermo-capillarity. Courtesy of NTT Electronics Corp.

two possible paths. Most vendors use this technology for variable optical attenuators rather than switches. This is because liquid crystals can be used to adjust the amount of light that passes through them, rather than simply deflect it. In the switch market, the technology is probably best suited to mid-size wavelength-selective devices. The absence of moving parts and low-power consumption make them a good candidate for test and measurement applications.

4.4. MEMS Micro Mirror

Micro-Electro-Mechanical Systems (MEMS) have been deployed for over a decade in a number of applications such as airbag sensors, projection systems, scanners, and microfluidics. Continued technical developments in the last five years has extended MEMS applications to include optical networking with devices such as all-optical switching fabrics and variable optical attenuators. The MEMS technology has opened up many new possibilities for free-space optical systems. The first commercial MEMS photonic crossconnects were made available in 1999. MEMS technology is using a batch-fabrication process, which is a similar process for making large scale integrated (VLSI) circuits. Wafer scale and chip scale batch process produced MEMS components with high-precision controlled movements. The micro-mechanical structures are smaller, lighter, faster, and more cost effective compared to traditional macro-scale components. The MEMS has become a very good candidate for optical applications, which require stringent reliability, precision, performance, and scalability. The dimension of the micromirror ranges from 0.1 mm to 1 mm for the "sweet spot" of OXC design space. The performance will be strongly limited by Gaussian beam diffraction if the dimension is too small. The large port count crossconnects will not be compatible or scalable with IC processes if the unit switch dimension is too large. The shock/vibration stability and the speed will also miss the SONET specs and Telcordia requirements. Figure 12 shows the OMM 2D digital mirror design and the 16×16 array by surface micromachining technology. The mirror is actuated by a simple TTL signal. The device is not sensitive to driving voltage fluctuations. Since a large force can be generated from this type of gap-closing actuator, the mechanical structure can be built more robust compared to a 3D scanning device. The MEMS array and collimators are hermetically sealed in the package. Maximum insertion loss as low as 1.7 db and 3.1 dB have been obtained for 8×8 and 16×16 2D crossconnects [6].

In the trend of building larger port-count systems and larger mirrors, the optics designs prefer to have a flat mirror surface. Bulk micromachining constructs MEMS devices from single crystal silicon. This technology also enables the possibility of using vertical comb drive to actuate the mirror with large force and more linear response. Figure 13 shows the Lucent LambdaRouter all-optical switch based on Bell Labs's innovative MicroStar 3D MEMS technology [7]. Each mirror angle can be continuously adjusted by voltage.

5. SUMMARY

Despite the overall slowdown in telecommunications since the year 2000, MEMS based crossconnects have proven to be a reliable and promising technology that can fulfill the stringent requirements of telecommunication industries. Optical crossconnects allow the carriers to add new flexibility and scalability to their optical network. 2D crossconnects are ideal for small port count, less than 64 channels. 3D crossconnects will be the candidate for large-scale networks such as a hundred or thousand channels. It is still not clear what is the optimized module size or approach for the future optical network. It is also not clear how the all-optical network is going to merge with existing opaque systems. The 2D array size has grown from 4×4, 8×8 to 16×16 and 32×32. There is high possibility that the 2D array could achieve larger size with new technology and design improvements. There is also potential that 3D crossconnects will lower the cost, which is competitive with 2D technology. The optical MEMS has gone through an explosive development period. It evolved from the first concept of a fixed stand-up mirror five years ago. Right now it has become a well-accepted technology for fiber communication. There is certainly development space for crossconnects once the demand is generated from the industry.

BIOGRAPHY

Li Fan is cofounder and chief technologist at OMM and is responsible for MEMS design and technology development. He has also successfully commercialized photonic crossconnect ranges from 4×4 to 32×32 based on his MEMS design. He received the Ph.D. in electrical engineering from UCLA in 1998. His research included Optical-Micro-Electro-Mechanical Systems (OMEMS), self-assembly micro-XYZ stage, fiber optical cross-connect, and beam-steering vertical cavity surface-emitting lasers (VCSEL).

1. INTRODUCTION

1.1. Overview

A major need in human society is the desire to send messages from one distant place to another. Some of the earliest communication systems were based on optical signaling. For example, in the eighth century B.C. the Greeks used a fire signal to send alarms, call for help, or announce certain events. Since then, many forms of communication methodologies have appeared. The basic motivation behind each new form was either to improve the transmission fidelity, to increase the data rate so that more information can be sent, to increase the transmission distance between relay stations, or a combination of these factors. The basic trend in these improvements was to move to higher and higher frequencies of the electromagnetic spectrum. The reason for this is that, in electrical systems, information is usually transferred over the communication channel by superimposing the data onto a sinusoidally varying electromagnetic wave, which is known as the *carrier*. Since the amount of information that can be transmitted is directly related to the frequency range over which the carrier operates, increasing the carrier frequency in turn increases the available transmission bandwidth, and, consequently, provides a larger information capacity.

Although these transmission links generally made use of radio, microwave, and copper-wire technologies, there has always been an interest in using light to communicate [1–4]. The reason for this is that, in addition to the optical fiber's inherently wide bandwidth capability, its dielectric nature renders it immune to electromagnetic interference and offers excellent electrical isolation, particularly in electrically hazardous environments. In addition, its low weight and hair-sized dimensions offer a distinct advantage over large, heavy copper cables, which is important not only for saving space in underground and indoor ducts but also for reducing the size and weight of cables on aircraft and in ships. Kao and Hockman first proposed the use of low-loss glass fiber in 1966, when they suggested that the intrinsic loss of silica-based glass could be made low enough to enable its use as a guiding channel for light [5]. The fabrication of a low-loss optical fiber by researchers at Corning in 1970 provided the key technology for finally realizing this in a practical way [6].

The optical spectrum ranges from about 50 nm (ultraviolet) to about 100 μm (far infrared), the visible region being the 400–700-nm band. Optical fiber communication systems operate in the 800–1600-nm wavelength

band. In optical systems it is customary to specify the band of interest in terms of wavelength, instead of frequency as in the radio region. However, with the advent of high-speed multiple-wavelength systems in the mid-1990s, researchers began specifying the output of optical sources in terms of optical frequency. The reason for this is that in optical sources such as mode-locked semiconductor lasers, it is easier to control the frequency of the output light, rather than the wavelength, in order to tune the device to different emission regions. Of course, the different optical frequencies ν are related to the wavelengths λ through the fundamental equation $c = \nu\lambda$. Thus, for example, a 1552.5-nm wavelength light signal has a frequency of 193.1 THz (193.1×10^{12} Hz).

1.2. Optical Fiber Link Applications

Communication networks composed of optical fiber links are sometimes referred to as *lightwave* or *photonic* systems. Network architectures using multiple wavelength channels per optical fiber can be utilized in local-area, metropolitan-area, or wide-area applications to connect hundreds or thousands of users having a wide range of transmission capacities and speeds. The use of multiple wavelengths greatly increases the capacity, configuration flexibility, and growth potential of this backbone. Moderate-speed regional networks attached to this backbone provide applications such as interconnection of telephone switching centers, access to satellite transmission facilities, and access to mobile-phone base stations. More localized, lower-speed networks offer a wide variety of applications such as telephony services to homes and businesses, distance learning, Internet access, CATV (cable television), security surveillance, and electronic mail (email). A major motivation for developing these sophisticated networks has been the rapid proliferation of information exchange desired by institutions such as commerce, finance, education, health, government, security, and entertainment. The potential for this information exchange arose from the ever-increasing power of computers and data-storage devices.

Once researchers showed in 1970 that it was possible to make low-loss fibers, the optical fiber communication field expanded rapidly to provide a broadband medium for transporting voice, video, and data traffic. In fact, optical fiber technology has been a key factor contributing to the extraordinary growth of global telecommunications. Optical fiber was being installed worldwide at the rate of 4800 km per hour by the year 2000, which is equivalent to a cable-laying rate of three time around the world every day [7,8]. Along with this high installation rate come numerous technological advances in photonic components. These advances permit more and more wavelengths to be transmitted at ever-increasing speeds on an individual optical fiber, which is resulting in an annual two-fold increase in the data-carrying capacity of an individual fiber strand. Table 1 illustrates this with a few of the many installations that have taken place since 1980. As shown in that table, in the year 2000, commercial systems were capable of transmitting 400 Gbps (gigabits per second) over distances of 640 km without regenerating the signal. To put this in perspective, this is equivalent to sending 12,000 encyclopedic volumes every second.

1.3. Basic Link Elements

Figure 1 shows typical components that are found within an optical fiber link. The key sections are a transmitter consisting of a light source and its associated drive circuitry, a cable offering mechanical and environmental protection to the optical fibers contained inside, and a receiver consisting of a photodetector plus amplification and signal-restoring circuitry. Additional components include optical amplifiers, connectors, splices, couplers, and regenerators (for restoring the signal shape characteristics). The cabled fiber is one of the most important elements in an optical fiber link. In addition to protecting the glass fibers during installation and service, it may contain copper wires for powering optical amplifiers or signal regenerators, which are needed periodically in long-distance links for amplifying and reshaping the signal.

Analogous to copper cables, the installation of optical fiber cables can be either aerial, in underground or indoor ducts, undersea, or buried directly in the ground. As a result of installation and/or manufacturing limitations, individual cable lengths will range from several hundred meters to several kilometers for terrestrial links. Cable lengths for oceanic links can be several tens of kilometers. Practical considerations such as reel size and cable weight determine the actual length of a single cable section. The shorter segments tend to be used when the cables are pulled through ducts. Longer lengths are used in aerial,

Table 1. Examples of Types of Multimode (MM) and Single-Mode (SM) Optical Fiber Systems Installed Since 1980

Year	Fiber Type	Wavelength (nm)	WDM Channels	Bit Rate per Channel	Bit Rate per Fiber	Regenerator Spans (km)
1980	MM	820	1	45 Mbps	45 Mbps	7
1985	SM	1300	1	417 Mbps	417 Mbps	50
1987	SM	1300	1	1.7 Gbps	1.7 Gbps	50
1992	SM	1300	1	2.5 Gbps	2.5 Gbps	50
1995	SM	1550	8	2.5 Gbps	20 Gbps	360
1997	SM	1550	16	2.5 Gbps	40 Gbps	360
1999	SM	1550	80	2.5 Gbps	200 Gbps	640
1999	SM	1550	40	10 Gbps	400 Gbps	640
2000	SM	1550	80	10 Gbps	800 Gbps	500

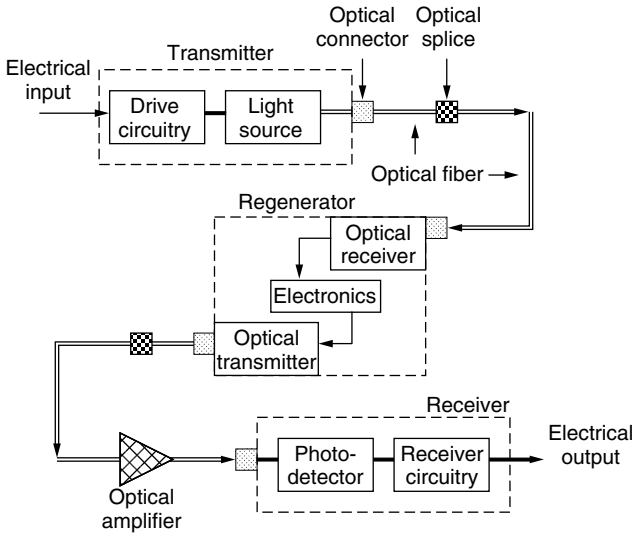

Figure 1. Typical components found within an optical fiber link.

directly buried, or undersea applications. Splicing together individual cable sections forms continuous transmission lines for these long-distance links. For undersea installations, the splicing and repeater-installation functions are carried out on board a specially designed cable-laying ship [9].

An optical fiber nominally is a thin cylindrical strand of two layers of glass surrounded by an elastic buffer coating, as shown in Fig. 2. The central cylinder has a radius a and an index of refraction n_1. This cylinder is known as the *core* of the fiber. The core is surrounded by a solid glass *cladding*, which has a refractive index n_2 that is slightly less than n_1. Since the core refractive index is larger than the cladding index, electromagnetic energy at optical frequencies can propagate along the fiber core through internal reflection at the core–cladding interface. Single-mode fibers, which sustain a single propagating mode along the core, have nominal core diameters of 8–12 μm.

One of the principal characteristics of an optical fiber is its attenuation as a function of wavelength, as shown in Fig. 3. Early technology made exclusive use of the 800–900-nm wavelength band, since in this region the fibers made at that time exhibited a local minimum in the attenuation curve, and optical sources and photodetectors operating at these wavelengths were available. This region is referred to as the *first window*. The large attenuation spikes in early fibers were due to absorption by water molecules (hydroxyl ions) in the glass. By reducing the concentration of hydroxyl ions and metallic impurities in the fiber material, in the 1980s manufacturers were able to fabricate optical fibers with very low loss in the 1100–1600-nm region. This spectral band is referred to

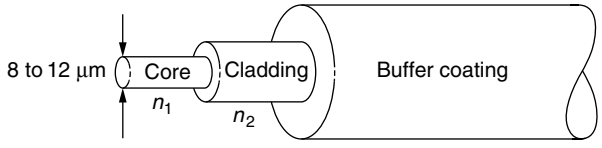

Figure 2. Physical configuration of an optical fiber.

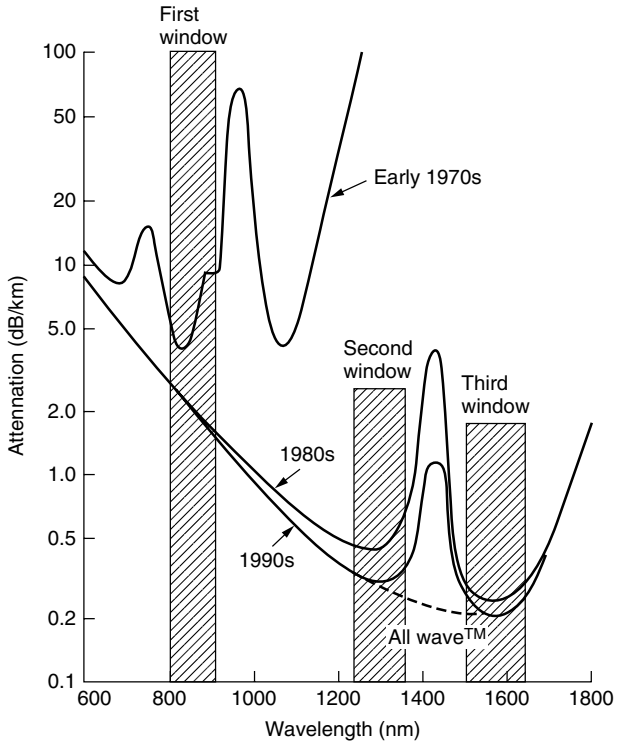

Figure 3. Attenuation as a function of wavelength.

as the *long-wavelength region*. As Fig. 3 shows, the two windows defined here are called the *second window* centered around 1310 nm and the *third window*, centered around 1550 nm.

In 1998 a new ultra-high-purification process patented by Lucent Technologies eliminated virtually all water molecules from the glass fiber material. By dramatically reducing the water attenuation peak around 1400 nm, this process opened the transmission region between the second and third windows to provide around 100 nm more bandwidth than in conventional single-mode fibers, as shown by the dashed line in Fig. 3. This particular AllWave fiber, which was specifically designed for metropolitan networks, gave local service providers the ability to cost-effectively deliver up to hundreds of optical wavelengths simultaneously.

Once the cable is installed, a light source that is dimensionally compatible with the fiber core is used to launch optical power into the fiber. Semiconductor light-emitting diodes (LEDs) and laser diodes are suitable for this purpose, since their light output can be modulated rapidly by simply varying the bias current at the desired transmission rate, thereby producing an optical signal. The electric input signals to the transmitter circuitry for the optical source can be either of an analog or digital form. For high-rate systems (usually greater than 1 Gbps), direct modulation of the source can lead to unacceptable signal distortion. In this case, an external modulator is used to vary the amplitude of a continuous light output from a laser diode source. In the 800–900-nm region the light sources are generally alloys of GaAlAs. At longer wavelengths (1100–1600 nm) an InGaAsP alloy is the principal optical source material.

After an optical signal is launched into a fiber, it will become progressively attenuated and distorted with increasing distance because of scattering, absorption, and dispersion mechanisms in the glass material. At the receiver a photodiode will detect the weakened optical signal emerging from the fiber end and convert it to an electric current (referred to as a *photocurrent*). Silicon photodiodes are used in the 800–900-nm region. The primary photodiode material in the 1100–1600-nm region is an InGaAs alloy.

The design of an optical receiver is inherently more complex than that of the transmitter, since it has to interpret the content of the weakened and degraded signal received by the photodetector. The principal figure of merit for a receiver is the maximum optical power necessary at the desired data rate to attain either a given error probability for digital systems or a specified signal-to-noise ratio for an analog system. The ability of a receiver to achieve a certain performance level depends on the photodetector type, the effects of noise in the system, and the characteristics of the successive amplification stages in the receiver.

1.4. Wavelength-Division Multiplexing

An interesting and powerful aspect of an optical communication link is that many different wavelengths can be sent along a fiber simultaneously in the 1300–1600-nm spectrum. The technology of combining a number of wavelengths onto the same fiber is known as *wavelength-division multiplexing* (WDM). Figure 4 shows the basic WDM concept [10,11]. Here N independent optically formatted information streams, each transmitted at a different wavelength, are combined with an optical multiplexer and sent over the same fiber. Note that each of these streams could be at a different data rate. Each information stream maintains its individual data rate after being multiplexed with the other streams, and still operates at its unique wavelength. Conceptually, the WDM scheme is the same as frequency-division multiplexing (FDM) used in microwave radio and satellite systems. WDM systems in which the channels are closely spaced are referred to as *dense WDM* (DWDM) systems.

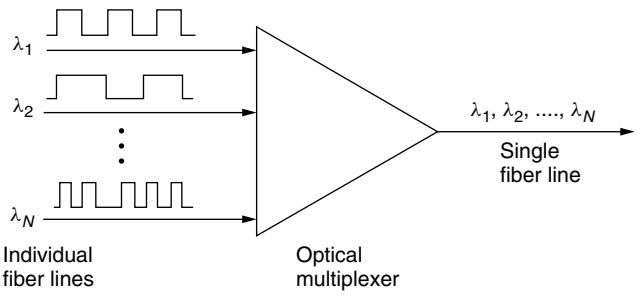

Figure 4. The basic WDM concept.

To realize this WDM scheme, one needs specialized components to efficiently multiplex an aggregate of wavelength channels into an optical fiber at one point and to divide them into their original individual channels at another location. Other WDM components are used to selectively add or drop one or more channels at specific points along a fiber link. These components include fiber Bragg gratings, arrayed waveguide gratings, dielectric thin-film interference filters, acoustooptic tunable filters, and Mach–Zehnder filters.

Figure 5 shows a simple concept of a demultiplexing function using a fiber Bragg grating. To extract the desired wavelength, a *circulator* is used in conjunction with the grating. In a three-port circulator, an input signal on one port exits at the next port. For example, an input signal at port 1 is sent out at port 2. Here, the circulator takes the four wavelengths entering port 1 and sends them out at port 2. All wavelengths except λ_2 pass through the grating. Since λ_2 satisfies the Bragg condition of the grating, it is reflected, enters port 2 of the circulator, and exits at port 3. More complex multiplexing and demultiplexing structures with several gratings and several circulators can be realized with this scheme.

1.5. Optical Amplifiers

Traditionally, when setting up an optical link, one formulates a power budget and adds repeaters when the path loss exceeds the available power margin. To amplify an optical signal with a conventional repeater, one performs photon-to-electron conversion, electrical amplification, retiming, pulseshaping, and then electron-to-photon conversion. Although this process works well for moderate-speed single-wavelength operation, it can be fairly complex and expensive for high-speed multiwavelength systems. Thus, a great deal of effort has been expended to develop all-optical amplifiers for the 1300-nm and the 1550-nm long-wavelength transmission windows of optical fibers. The main ones in use are *erbium-doped fiber amplifiers* (EDFAs) and *Raman fiber amplifiers* [12,13]. An EDFA can amplify optical signals in the 1530–1610-nm range, whereas Raman fiber amplifiers can amplify signals from 1270 to 1670 nm.

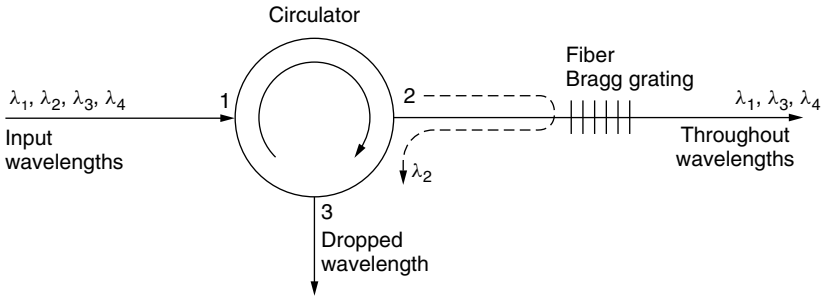

Figure 5. A simple wavelength demultiplexing function using a fiber Bragg grating.

Optical amplifiers have found widespread use in not only long-distance point-to-point optical fiber links but also in multiple-access networks to compensate for signal-splitting losses. The features of optical amplifiers has led to many diverse applications, each having different design challenges. Figure 6 shows general applications of optical amplifiers where the parameter G denotes gain.

In a single-mode link the effects of fiber dispersion may be small so that the main limitation to repeater spacing is fiber attenuation. Since such a link does not necessarily require a complete regeneration of the signal, simple amplification of the optical signal is sufficient. Thus an *inline optical amplifier* can be used to compensate for transmission loss and increase the distance between regenerative repeaters, as illustrated in Fig. 6a.

Figure 6b shows an optical amplifier being used as a front-end *preamplifier* for an optical receiver. In this way, a weak optical signal is amplified before photodetection so that the signal-to-noise ratio degradation caused by thermal noise in the receiver electronics can be suppressed. Compared with other front-end devices such as avalanche photodiodes or optical heterodyne detectors, an optical preamplifier provides a larger gain factor and a broader bandwidth.

Power or *booster amplifier* applications include placing the device immediately after an optical transmitter to boost the transmitted power, as Fig. 6c shows. This serves to increase the transmission distance by 10–100 km depending on the amplifier gain and fiber loss. As an example, using this boosting technique together with an optical preamplifier at the receiving end can enable repeaterless undersea transmission distances of 200–250 km. One can also employ an optical amplifier in a local-area network as a booster amplifier to compensate for coupler insertion loss and power-splitting loss. Figure 6d shows an example for boosting the optical signal in front of a star coupler.

2. LINK PERFORMANCE CHARACTERISTICS

The transmission characteristics are a major factor in determining what a signal looks like after it has propagated a certain distance. The three fundamental signal-distorting factors are attenuation, dispersion, and nonlinear effects in an optical fiber.

2.1. Attenuation

Attenuation of a light signal as it propagates along a fiber is an important consideration in the design of an optical communication system, since it plays a major role in determining the maximum transmission distance between a transmitter and a receiver. The basic attenuation mechanisms in a fiber are absorption, scattering, and radiative losses of the optical energy. Absorption is related to the fiber material, whereas scattering is associated both with the fiber material and with structural imperfections in the optical waveguide. Attenuation owing to radiative effects originates from perturbations (both microscopic and macroscopic) of the fiber geometry. As light travels along a fiber, its power decreases exponentially with distance. If $P(0)$ is the optical power in a fiber at the origin (at $z = 0$), then the power $P(z)$ at a distance z further down the fiber is

$$P(z) = P(0)e^{-\alpha_p z} \tag{1}$$

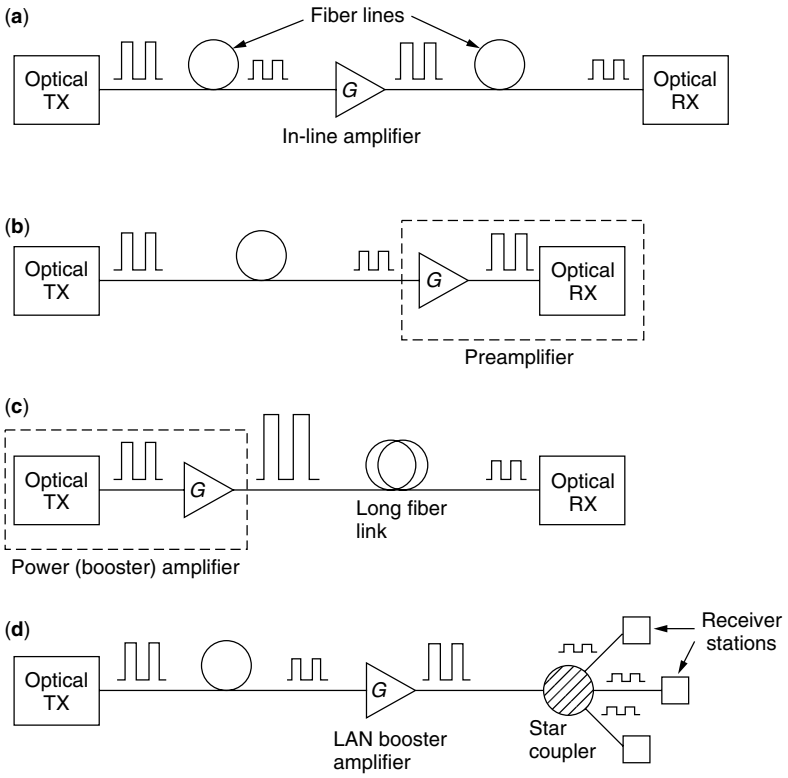

Figure 6. General applications of optical amplifiers.

where

$$\alpha_p = \frac{1}{z} \ln \left[\frac{P(0)}{P(z)} \right] \tag{2}$$

is the fiber *attenuation coefficient* given in units of, for example, reciprocal kilometers (km^{-1}). For simplicity in calculating optical signal attenuation in a fiber, the common procedure is to express the attenuation coefficient in units of *decibels per kilometer*, (dB/km). Designating this parameter by α, we have

$$\alpha(\text{dB/km}) = \frac{10}{z} \log \left[\frac{P(0)}{P(z)} \right] = 4.343\, \alpha_p(\text{km}^{-1}) \tag{3}$$

This parameter is generally referred to as the *fiber loss* or the *fiber attenuation*. Figure 3 illustrates the attenuation of optical power in a fiber as a function of wavelength.

2.2. Dispersion

Several different dispersion mechanisms in an optical fiber cause a light signal to become increasingly distorted as it travels along a fiber. These include material, waveguide, and polarization-mode dispersions [4,14]. *Material dispersion* arises because each optical pulse in a digital signal contains a small range of wavelengths. Since the refractive index n of silica glass varies slightly as a function of wavelength, the fundamental relationship for the velocity v in a material $v = c/n$, where c is the speed of light, shows that different parts of the pulse will travel at different speeds. Consequently, as a result of this material dispersion effect, a pulse will broaden as it travels along a fiber.

Waveguide dispersion occurs because a single-mode fiber confines only about 80% of the optical power to the core. The other 20% propagates in the cladding that surrounds the core. Dispersion arises since the light in the cladding sees a lower refractive index than in the core and thus travels faster than the light confined in the core. The amount of waveguide dispersion depends on the fiber design. Thus, through ingenious fiber construction, waveguide dispersion can be tailored to counteract the effects of material dispersion. In standard fiber designs, material and waveguide dispersions cancel at 1310 nm. To achieve zero total dispersion at 1550 nm, where the attenuation of a silica fiber is at its lowest point, the *dispersion-shifted fiber* was developed in the mid-1980s. This works well for single-wavelength operation, but is not desirable in WDM systems. Here nonlinear effects require different approaches, one of which is the dispersion management scheme described below.

Polarization-mode dispersion arises from the effects of fiber birefringence on the polarization states of an optical pulse [15]. *Birefringence* refers to slight variations in the indices of refraction along different axes of the fiber. This is particularly critical for high-rate, long-haul transmission links (e.g., 10 Gbps over tens of kilometers) that are designed to operate near the zero-dispersion wavelength of the fiber. Birefringence can result from intrinsic factors such as geometric irregularities of the fiber core or internal stresses on it. Deviations of less than 1% in the circularity of the core can already have a noticeable effect in a high-speed lightwave system. In addition, external factors such as bending, twisting, or pinching of the fiber can also lead to birefringence. Since all these mechanisms exist to some extent in any field-installed fiber, there will be a varying birefringence along its length.

A fundamental property of an optical signal is its polarization state. *Polarization* refers to the electric field orientation of a light signal, which can vary significantly along the length of a fiber. As shown in Fig. 7, signal energy at a given wavelength occupies two orthogonal polarization modes. A varying birefringence along the length of the fibre will cause all the polarization modes to travel at slightly different velocities and the polarization orientation will rotate with distance. The resulting difference $\Delta\tau$ in propagation times between the two orthogonal polarization modes will result in pulse spreading. This is known as *polarization-mode dispersion* (PMD).

2.3. Nonlinear Effects

Two different categories of optical nonlinear effects also have an adverse effect on signal quality [16–18]. The first category encompasses nonlinear inelastic scattering processes, which are interactions between optical signals and molecular or acoustic vibrations in a fiber. These

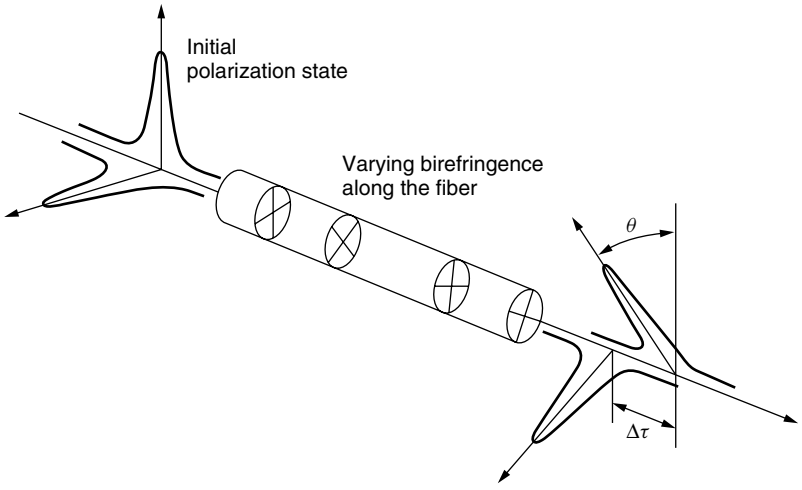

Figure 7. Signal energy at a given wavelength occupies two orthogonal polarization modes.

are stimulated Raman scattering (SRS) and stimulated Brillouin scattering (SBS). The second category involves nonlinear variations of the refractive index in a silica fiber that occur because the refractive index is dependent on intensity changes in the signal. This produces effects such as self-phase modulation (SPM), cross-phase modulation (XPM), and four-wave mixing (FWM). In the literature, FWM is also referred to as *four-photon mixing* (FPM), and XPM is sometimes designated by CPM.

SRS, SBS, and FWM result in gains or losses in a wavelength channel that are dependent on the optical signal intensity. These nonlinear processes provide gains to some channels while depleting power from others, thereby producing crosstalk between the channels. SPM and XPM affect only the phase of signals, which causes chirping in digital pulses. This can worsen pulse broadening due to dispersion, particularly in very high-rate systems (>10 Gbps). When any of these nonlinear effects contribute to signal impairment, an additional amount of power will be needed at the receiver to maintain the same BER (bit error rate) as in their absence. This additional power (in decibels) is known as the *power penalty* for that effect.

Stimulated Raman scattering is an interaction between lightwaves and the vibrational modes of silica molecules. If a photon with energy $h\nu_1$ is incident on a molecule having a vibrational frequency ν_m, the molecule can absorb some energy from the photon. In this interaction the photon is scattered, thereby attaining a lower frequency ν_2 and a corresponding lower energy $h\nu_2$. The modified photon is called a *Stokes photon*. Because the optical signal wave that is injected into a fiber is the source of the interacting photons, it is called the *pump wave*, since it supplies power for the generated wave. This process generates scattered light at a wavelength longer than that of the incident light. If another signal is present at this longer wavelength, the SRS light will amplify it and the pump wavelength signal will decrease in power. Consequently, SRS can severely limit the performance of a multichannel optical communication system by transferring energy from short-wavelength channels to neighboring higher-wavelength channels. This is a broadband effect that can occur in both directions. Powers in channels separated by up to 16 THz (125 nm) can be coupled through the SRS effect, thereby producing cross talk between wavelength channels. SRS may be controlled using fiber dispersion management techniques, as described below.

Stimulated Brillouin scattering arises when lightwaves scatter from acoustic waves. The resultant scattered wave propagates principally in the backward direction in single-mode fibers. This backscattered light experiences gain from the forward-propagating signals, which leads to depletion of the signal power. In silica this interaction occurs over a very narrow *Brillouin linewidth* of 20 MHz at 1550 nm. This means that the SBS effect is confined within a single wavelength channel in a WDM system, and thus accumulates individually for each channel. System impairment starts when the amplitude of the scattered wave is comparable to the signal power. For typical fibers the threshold power for this process is around 10 mW for single-fiber spans. In a long fiber chain containing optical amplifiers, there are normally optical isolators to prevent backscattered signals from entering the amplifier. Consequently, the impairment due to SBS is limited to the degradation occurring in a single amplifier-to-amplifier span. Several schemes are available for suppressing the effects of SBS [4].

The refractive index n of the glass material in an optical fiber has a weak dependence on optical intensity (equal to the optical power per effective area in the fiber). Since the intensity varies at the leading and trailing edges of each optical pulse in a digital datastream, the nonlinearity in the refractive index produces a carrier-induced phase modulation of the propagating signal. Consequently, parts of the pulse undergo a frequency shift in a process called *self-phase modulation* (SPM). As a result of dispersion in the fiber, this shift is transformed into pulse distortion. The effects of SPM can be reduced by maintaining a low overall dispersion in a fiber link.

In WDM systems, the refractive index nonlinearity gives rise to *cross-phase modulation* (XPM), which converts power fluctuations in a particular wavelength channel to phase fluctuations in other copropagating channels. This can be greatly mitigated in WDM systems operating over standard nondispersion-shifted single-mode fiber, but can be a significant problem in WDM links operating at 10 Gbps and higher over dispersion-shifted fiber. To mitigate XPM effects, the dispersion should be high, since pulses in different channels travel at different speeds, so that they walk through each other quickly, thereby minimizing their interactions.

Four-wave mixing (FWM) is a third-order nonlinearity in silica fibers, which is analogous to intermodulation distortion in electrical systems. The FWM effect arises from the beating between two or more channels, which creates new tones at other frequencies. When these new frequencies fall in the transmission window of the original frequencies, it can cause severe crosstalk. For DWDM systems, FWM can cause the highest power penalty of all the nonlinear effects. The efficiency of four-wave mixing depends on fiber dispersion and the channel spacings. Since the dispersion varies with wavelength, the signal waves and the generated waves have different group velocities. This destroys the phase matching of the interacting waves and lowers the efficiency at which power is transferred to newly generated frequencies. The higher the group velocity mismatches and the wider the channel spacing, the lower the effects of four-wave mixing.

2.4. Dispersion Management

Using current fiber designs, high-speed WDM systems are limited by nonlinear effects and dispersion. To mitigate these effects, dispersion management techniques are being used to maintain moderate dispersion locally and near-zero dispersion globally across the entire link [19–21]. This needs to be implemented across the wide spectrum of wavelengths used in WDM systems. To achieve this, one may use passive *dispersion compensation*. This consists of inserting into the link a loop of fiber having a dispersion characteristic that negates the accumulated dispersion of the transmission fiber. The fiber loop is referred to as a *dispersion-compensating fiber* (DCF). If the transmission

fiber has a low positive dispersion [say, 2.3 ps/(nm · km)], then the DCF will have a large negative dispersion [say, −16 ps/(nm · km)].

With this technique, the total accumulated dispersion is zero after some distance, but the absolute dispersion per length is nonzero at all points along the fiber. The nonzero absolute value causes a phase mismatch between wavelength channels, thereby destroying the possibility of effective FWM production.

3. MEASUREMENT METHODOLOGIES

The design and installation of an optical fiber communication system require measurement techniques for verifying the operational characteristics of the constituent components [4,22]. In addition to optical fiber parameters, system engineers are interested in knowing the characteristics of passive splitters, connectors, and couplers, and electrooptic components, such as sources, photodetectors, and optical amplifiers. Furthermore, when a link is being installed and tested, the operational parameters of interest include bit error rate, timing jitter, and signal-to-noise ratio as indicated by the eye pattern. During actual operation, measurements are needed for maintenance and monitoring functions to determine factors such as fault locations in fibers and the status of remotely located optical amplifiers.

4. FURTHER INFORMATION

Many of the concepts covered in this article are described in more detail elsewhere in this encyclopedia. For example, see: articles on nonlinear effects in fibers, optical amplifiers, optical couplers, optical fiber dispersion, optical filters, optical networks, optical receivers, optical transmitters, standards, and wavelength-division multiplexing.

BIOGRAPHY

Gerd Keiser is the founder and president of PhotonicsComm Solutions, Inc., Newton Center, Massachusetts, a firm specializing in consulting and education for the optical communications industry. He has 25 years experience at Honeywell, GTE, and General Dynamics in designing and analyzing telecommunication components, links, and networks. He is the author of the books *Optical Fiber Communications* (3rd ed. 2000) and *Local Area Networks* (2nd ed. 2002) published by McGraw-Hill. Dr. Keiser is an IEEE fellow and received GTE's prestigious Leslie Warner Award for work in ATM switch development. He earned his B.A. and M.S. degrees in mathematics and physics from the University of Wisconsin and a Ph.D. in solid state physics from Northeastern University, Boston, Massachusetts.

OPTICAL FIBER LOCAL AREA NETWORKS

MEHDI SHADARAM

1. INTRODUCTION

Technological advances in the analog, digital, and photonic systems have transformed communications into a highly dynamic field. Nowadays, communication between computers is an essential part of modern living, and telecommunications is one of world's fastest-growing industries. Most advances in this field are driven by social, economical, political, and technological reasons. It is a well-known fact that without a reliable communication infrastructure, nations cannot retain a prosperous economy. The need for computer and communication engineers to implement new ideas and to satisfy the growing demand for higher bandwidth is apparent more than ever. The data rate of computer networks used in university campuses, hospitals, banks, and elsewhere is doubling almost every year. The data rate has reached a point where a single transmission medium such as twisted-pair or coaxial cable is not capable of transmitting the load. In order to avoid multiple-cables laying beneath the ground and overloading buildings with wires, the need for one single transmission medium that can convey up to several gigabits of information per second is necessary. Since the early 1970s optical fibers have been utilized as transmission media in long- and short-distance communication links. Typical optical fiber attenuation has decreased from several dB/km at 0.8 μm wavelength in the early seventies to about 0.1 dB/km at 1.55 μm wavelength as we enter the new millennium. During the same period, the capacity of optical fibers has increased from several Mbps/km (megabits per second per kilometer) to $\sim$300 Gbps/km. Because of gradual maturing of multiwavelength optical fiber systems, wavelength-division multiplexing (WDM), and development of zero-dispersion optical fibers (solitons), the capacity of a single optical fiber could reach thousands of Gbps in the near future. Small size, light weight, and immunity to electromagnetic interference noise also provide a crucial advantage for optical fibers over other media. Although cost of implementing fiber-based systems still exceeds the cost to deploy other systems such as coaxial or twisted pair, prices for optical fiber systems are dropping as rapidly as 30% per year.

2. WHAT IS AN OPTICAL FIBER LOCAL AREA NETWORK?

Organizations such as universities, hospitals, banks, or even small offices use computers for a variety of applications. Very often different users within these establishments need to share data. Thus, for a reliable and high-speed data transfer, computers are connected through a network of point-to-point communication links. These types of networks are usually referred to as *local-area networks* (LANs). The size of a LAN can vary anywhere from two computers connected to one another in a room to several thousand computers connected together in a large campus. The distance between nodes within a LAN can vary from a few meters to as much as 2 km. If computers are connected via optical fiber links, the LAN is referred to as *optical fiber LAN*. Optical fiber cables conduct light along a thin solid cylinder-shaped glass or plastic fiber, known as a *core*. The core is surrounded by *cladding*, which in turn is surrounded by a plastic sheath as shown in Fig. 1a. Depending on the fiber type, the core diameter can be in the range of 8–62 μm. The typical diameter of cladding for optical fibers used in telecommunication is about 125 μm. In order to confine the light within the core, as shown in Fig. 1b, the refractive index of the core is slightly higher than the refractive index of the cladding, as can be seen in Fig. 1c. The block diagram shown in Fig. 2 exhibits a typical optical fiber link used between two nodes within the network. The link typically consists of a laser diode (LD) or light-emitting diode (LED) in the transmitter unit, which launches an optically modulated signal into an optical fiber cable. At the receiver site, the cable is terminated by a photodiode, which converts the optical signal into an electric current.

In the early days of optical fiber technology, because of major developments in gallium arsenide devices, most fiber links were operating at short wavelengths ($\sim$0.8 μm). These links could carry bit rates of $\leq$100 Mbps with an attenuation of $\sim$10 dB/km. Nowadays, most optical fiber links operate at around 1.3 μm, minimum dispersion wavelength; or 1.55 μm, minimum attenuation wavelength. Development of dispersion-shifted fibers has made it possible for fibers to exhibit minimum dispersion and minimum attenuation at 1.55 μm. Links employing dispersion-shifted fibers are commonly used for long-distance communication purposes.

The main purpose of a LAN is to share resources such as files, printers, programs, and databases among the nodes in the network. The initial LAN designs were intended for communication between computers at short distances. However, the length of the links has grown from a few meters to a few kilometers.

To reach longer distances there are wide-area networks (WANs), which typically employ the infrastructure of a telecom service provider or carrier. A single network manager usually controls the LAN operation, but the WAN requires the coordination between the service provider and the LAN administrator. Very often, carrier networks require an initial setup of a connection between the end nodes, while LANs do not require that setup.

Through the years the capacity and the transmission distance of the networks have increased. The process has created a hybrid type of network between a LAN and a WAN. This type of network is called a *metropolitan-area network* (MAN). The MAN is capable of covering an entire city using the simplicity of the LAN protocols at 100 Mbps and above. On the other hand, there is a new specialized small network called *storage-area network* (SAN). The purpose of a SAN is to allow very-high-speed communication between computer processors and dedicated peripherals such as large disk arrays.

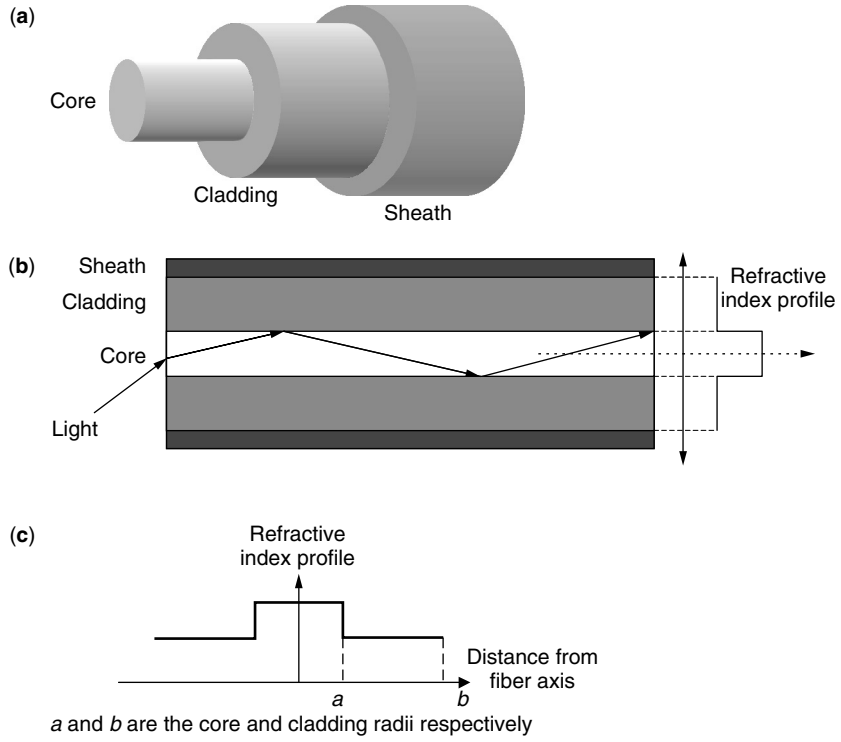

Figure 1. Optical fiber.

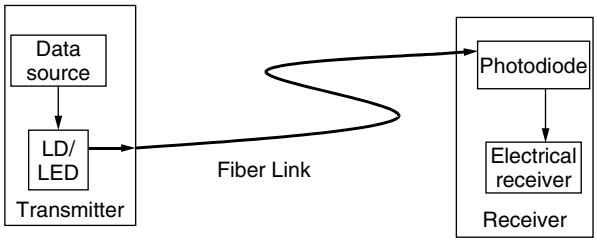

Figure 2. Typical optical fiber link.

3. NETWORK TOPOLOGIES

As pointed out previously, a network allows users to share information in an efficient, fast, and reliable manner. As images, audio, and video files become a regular part of the datastream, the need for networks with higher bandwidth becomes more apparent. Increasing the number of point-to-point links within a network or increasing the bandwidth of point-to-point links can increase the network bandwidth. Optical fiber is usually favored over other cables, since it is capable of very high data transfer rates. An optical link can replace an electric link as long as all electrical interface requirements such as voltage or current signal levels, timing, and control signals are met.

Implementation of an optical fiber LAN may follow one of two approaches. The first method involves the creation of a completely new network with optical fiber links. The second approach requires the replacement, within a conventional LAN, of electric links with optical links while meeting all original interface requirements. As a result, many LANs expand their reach by adding special repeaters with fiber segments.

There are two types of signal couplings to the fiber, known as active and passive. Figure 3a shows that, for active coupling, the network behaves like a series of point-to-point links and each node must be operational to maintain the network working. For passive coupling, stations broadcast the signals into a common fiber and each node captures only a small amount of their power. As seen in Fig. 3b, an inactive station does not affect the operation of the network. An alternative for inactive nodes is to include an optical bypass at each station, as shown in Fig. 4.

The network topology establishes a path for the flow of information between the transmitter and the rest of the network. The ring, star, and bus network topologies have become popular for most optical fiber LANs. For example, rings are used in the Fiber Distributed Data Interface (FDDI), the IEEE 802.6 Dual Queue Dual Bus (DQDB) standard uses a dual bus, and star configurations are encountered in switched systems. The LAN logical topology may differ from the physical cable layout. The

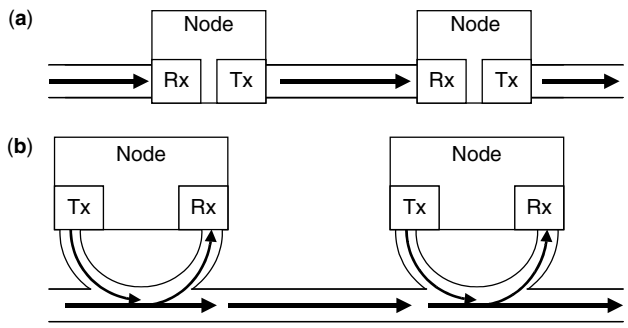

Figure 3. Types of coupling for optical links: (**a**) active and (**b**) passive coupling.

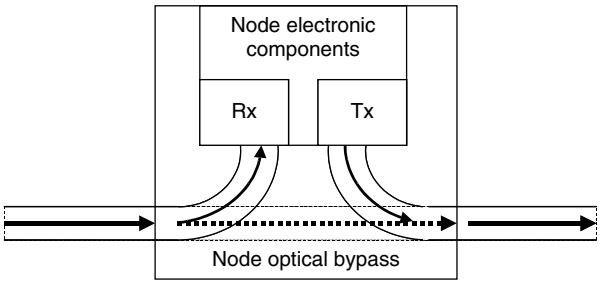

Figure 4. Optical bypass of a node.

budget, time, and resources usually dictate how the cable should be laid. For example, a ring topology can be folded to resemble two buses going in opposite directions using different fiber strands.

The technique to control the fair share of the transmission medium is defined by the medium access control (MAC) protocol and is dependant on the topology. The most common types of MAC protocols use token-passing, reservation, or collision avoidance techniques. The token-passing technique allows only the station holding the token to transmit at a time. The token is circulated through all the stations with a predefined mechanism that prevents unfair behavior and restores lost tokens. The reservation mechanism requires an arbiter that collects reservation requests from the stations and then allocates turns to transmit; this is commonly used in networks with asymmetric traffic needs. The collision mechanism allows stations to talk at any time, but two nodes trying to transmit simultaneously produce a collision. In that case, they cease transmission and wait a random time before retransmission. This method causes one of them to start before the other, reducing the probability of a new collision.

3.1. Ring Topology

Logic ring architecture, as can be seen in Fig. 5, establishes the circulation of information in a specific direction around the ring. The ring passes through all the stations in the LAN, enabling all of them to receive the same message until it completes the loop. The vulnerability of this network is that a single interruption in the ring disrupts the whole LAN. To maintain the reliability, the most common approaches are to create a second counterrotating ring for restoration, as shown in Fig. 6, or to add a bypass device for the damaged segment.

The most common mechanism to control access to the medium is the use of token-passing techniques. The ring nature simplifies the process to circulate the token among the stations. Only the station that possesses the token may transmit, and the rest remain silent. When the turn finishes, the station passes the token to the next on the ring, giving an opportunity to all nodes to transmit.

3.2. Bus Topologies

The bus topology establishes a sequence of nodes in line as exhibited in Fig. 7. The more commonly used access control mechanisms are collision detection and reservation of resources. Stations in a bus could use either active or passive coupling. The transmission into the bus

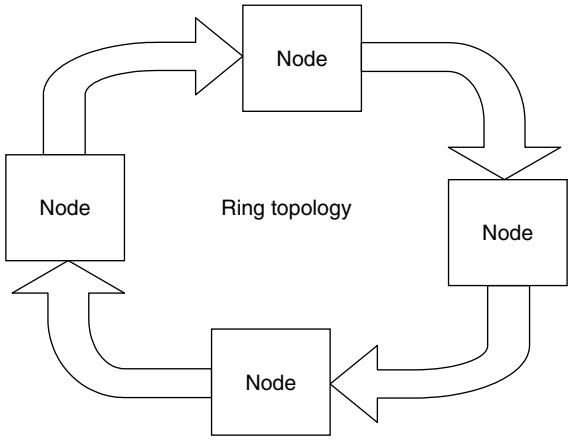

Figure 5. Ring topology.

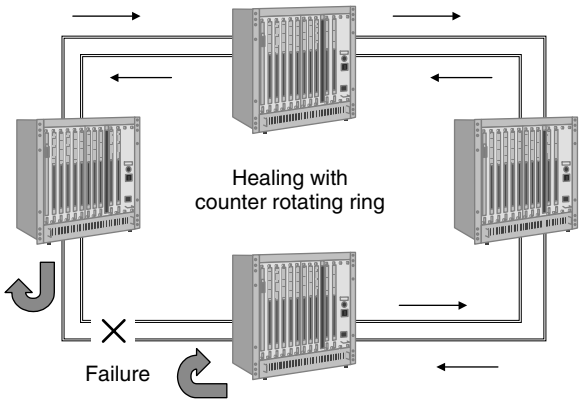

Figure 6. Self-healing ring.

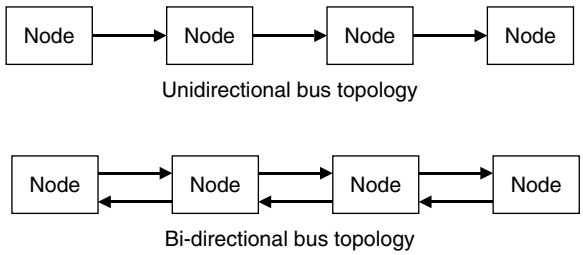

Figure 7. Bus topologies.

can be made in both directions; however, it is usually unidirectional for fiberoptic networks. For unidirectional fiber segments we need a return path, so typically there are two buses going in opposite directions. A station in a logic bus transmits information into the cable, and the remaining stations receive the transmission downward. The network will be divided into two independent segments if there is a break in the bus, unless there is an alternate path to rejoin the segments together.

3.3. Star Topologies

The star topology links several stations to a single central point. The connectivity in the network could be active

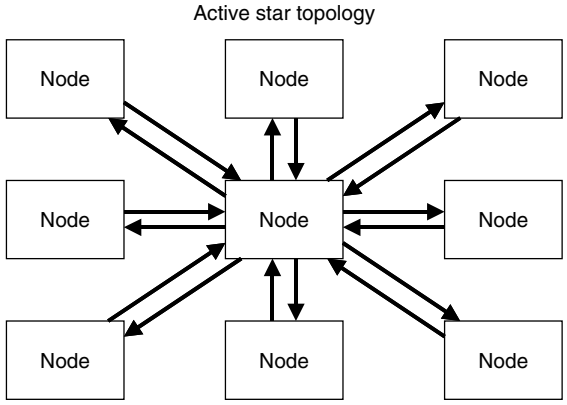

Figure 8. Active star topology.

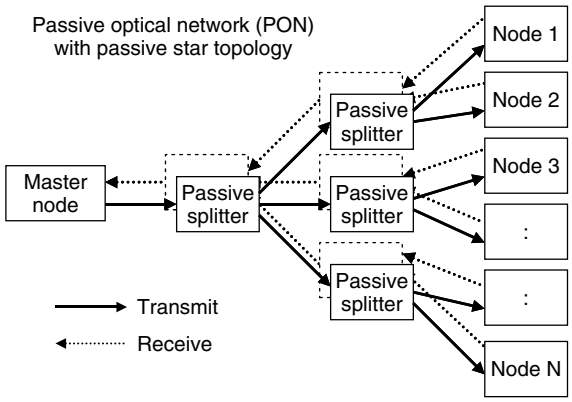

Figure 9. Passive star topology.

or passive, as illustrated in Figs. 8 and 9, respectively. Most configurations require the central station to be the controller for the rest of the network. It acts as a switch for messages between stations or performs as an arbiter for the allocation of resources. Fewer star networks distribute the MAC functionality to the nodes using token-passing or collision detection techniques. The more vulnerable point of the network is the central station because a break affects all the stations below the point of rupture.

The use of passive optical components, splitting the light among different fibers, allows several stations to receive the same broadcast from a single transmitter as shown in Fig. 10. These types of networks are commonly known as *passive optical networks* (PONS). The PON architecture normally requires a central station that controls the rest of the network. The access control is made by reservation of a resource, either a time slot or a whole optical channel.

Ethernet-type networks have collapsed the bus to a single-hub device, similar to the twisted-pair cabling option of Ethernet (known as *10BASE-T*). In addition, they have extended the individual links for each station using optical fiber. Therefore, the physical layout is a star and the links are point-to-point.

4. NETWORK DESIGN CONSIDERATIONS

Two important parameters need to be evaluated before designing a network: power loss and dynamic range. The assessment of these constraints depends on the network topology. In the bus topology, the optical signal is typically tapped by using an optical coupler at each node. In the ring topology, the coupling between the ring and the node can be either passive or active as illustrated in Fig. 3. In the star topology with N nodes, an $N \times N$ optical fiber star coupler is usually used to distribute the signal from one input to N outputs equally.

If we assume that couplers used in a bus topology couple C percent of the power from the bus to a node with a typical coupling loss of α dB, the total power coupling from the bus to a node will be $C \times 10^{-\alpha/10}$. In this case, the maximum power loss from one node to another node will be

$$L_{\text{bus}} = \frac{10^{\alpha N/10}}{(1-C)^{N-2}C^2}$$

$$L_{\text{bus,dB}} = 10(2-N)\log_{10}(1-C) - 20\log_{10} C + \alpha N \text{ dB} \quad (1)$$

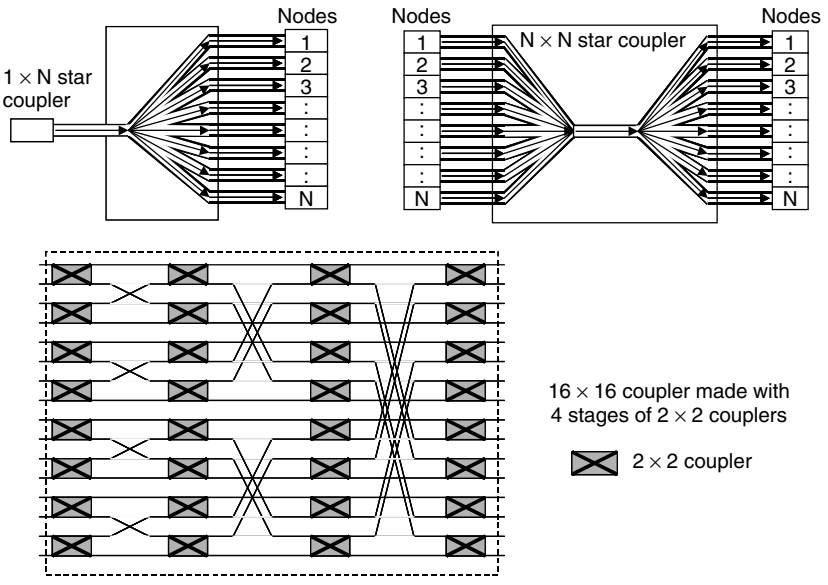

Figure 10. Optical star couplers.

where N is the total number of nodes. The maximum power loss occurs when the transmitting and the receiving nodes are at two opposite ends of the bus. As can be seen, the maximum power loss is a function of coupling ratio C and N. The optimum value of C, which minimizes the maximum power loss, is given by

$$C_{\text{opt}} = \frac{2}{N} \tag{2}$$

Substituting C_{opt} from Eq. (2) into Eq. (1) results in

$$L_{\text{bus,dB,min}} = 20\log_{10}(N-2) - 10N\log_{10}\left(\frac{N-2}{N}\right) + \alpha N - 6 \text{ dB} \tag{3}$$

The dynamic range (DR) is defined as the ratio of the maximum received power to the minimum received power by a node. In the single-bus topology, the maximum received power occurs when the signal comes from the adjacent node, and the minimum received power occurs when the receiving and transmitting nodes are farthest apart from each other. The DR for bus topology can be evaluated using the following procedure:

$$P_{\max} = P_0 C^2 10^{-2\alpha/10}$$
$$P_{\min} = P_0 C^2 (1-C)^{N-2} 10^{-N\alpha/10}$$
$$DR_{\text{bus}} = \frac{P_{\max}}{P_{\min}} = (1-C)^{2-N} 10^{(\alpha/10)(N-2)}$$
$$DR_{\text{bus,dB}} = \alpha(N-2) - 10N\log(1-C) + 20 \text{ dB}$$

where P_0 is the transmitted power.

An $N \times N$ star coupler typically consists of $\log_2 N$ stages of 2×2 couplers as shown in Fig. 10. In the star topology, the transmitted signal is equally distributed to N nodes. Thus, the power loss from a transmitter at one input to a receiver at one of the outputs can be evaluated using the following equation:

$$L_{\text{star}} = N10^{[(\alpha \log_2 N)/10]}$$
$$L_{\text{star,dB}} = (3+\alpha)\log_2 N \text{ dB} \tag{4}$$

where α is the coupling loss at each 2×2 stage. Since the transmitted power is equally divided among the receiving nodes, the DR in star topology is unity.

5. NETWORK PROTOCOLS

Most of the current LAN protocols are derived from the standards defined in the IEEE 802 series [1]. They specify the packet formats and medium access techniques for various types of transmission media. However, there are other types of networks defined by Industry associations and standards bodies. Table 1 shows the main characteristics of popular optical fiber LANs and we will describe the more relevant types below.

5.1. FDDI

In the late 1980s, The American National Standard Institute (ANSI) defined the protocol denominated Fiber Distributed Data Interface (FDDI) [2]. The accredited standards committee (ASC X3T9.5) had the objective to develop an inexpensive high-speed optical network functioning as the backbone of other slower LANs. Later,

Table 1. Characteristics of Common Optical LANs

Network Type	Fiber Type	Speed (Mbps)	Coding	Maximum Segment Distance	Topology	Access Method
FDDI	Multimode, 1300 nm	100	4B/5B NRZI	2 km (maximum 100 nodes)	Ring	Token passing
Ethernet 10BASE-T (fiber)	Multimode	10	Manchester	500 m	Active star	CSMA/CD
Ethernet 10BASE-FP	Multimode	10	Manchester	1 km (maximum 33 nodes)	Passive star	CSMA/CD
Ethernet 10BASE-FL/FB	Multimode or single-mode	10	Manchester	2 km	Active star	CSMA/CD
100BASE-FX/SX	Multimode	100	4B/5B NRZI	2 km	Active star	CSMA/CD
1000BASE-SX	Multimode	1000	8B/10B	275–550 m	Active star	CSMA/CD
1000BASE-LX	Multimode or single-mode	1000	8B/10B	550 m–5 km depending on fiber type	Active star	CSMA/CD
ATM LAN emulation	Single-mode	43, 155, 622	Any valid SONET, SDH, or DS3 line	Any valid SONET, SDH, or DS3 line	Active star	Switched central control
Fiber channel	Multimode or single-mode	100, 200, 400 & 800	8B/10B	175 m–10 km depending on fiber type	Active star	Switched central control

the International Standards Organization (ISO) published the same specifications under the ISO 9314 series.

FDDI specifies a 100-Mbps LAN using ring topology and token-passing access control. It employs multimode optical fiber and LEDs because they are more economical than laser diodes and single-mode fibers. The maximum distance between nodes is 2 km, and there is a maximum of 100 nodes per ring. The maximum frame size is 4500 bytes. The network is composed of two rings; the primary is for normal operation, and the secondary is reserved for restoration. Faults in the ring are resolved by sending the traffic through the secondary ring in the opposite direction, as shown in Fig. 6. Inactive nodes are optically bypassed, either internally or using a central hub with connection only to the primary ring.

5.2. IEEE 802.3 (Ethernet)-Type Protocols over Fiber

The Ethernet, developed by Xerox, is the basis for the IEEE 802.3 [1] standard using the CSMA/CD technique. It is the most popular protocol for LANs and has been improved to work at various speeds over many types of media. Since the first Ethernet implementations, there have been optical transceivers extending point-to-point connections [3]. However, there are newer standards to support higher speeds over several types of fiber. Most implementations use point-to-point fiber links in an active star configuration. The hubs convert the optical signals to electronic format and process them similar to other Ethernet LANs. The exception is a passive star defined in 10BASE-FP protocol. Lasers and single-mode fibers allow longer links for optical LANs; however, they are limited because they need to detect collisions. To overcome the problem, many networks employ bridges or switches in point-to-point links. Some equipment manufacturers have created proprietary solutions to reach distances of several hundreds of kilometers.

All the specifications employ the same frame format as 802.3. Only one station may transmit at a time, and if two nodes generate a collision, the hub sends a "collision presence" signal to the remaining stations. The standards 10BASE-FL and 10BASE-FB define 10-Mbps networks that may use multimode or single-mode fiber links. The difference between the standards is the retiming provided by the repeaters in 10BASE-FB. The 100-Mbps standards tried to reuse existing elements from other networks. For example, 100BASE-FX uses the same optical components similar to FDDI, and 100BASE-SX employs fiber compatible with the 10BASE-FL standard. The Gigabit Ethernet standard (1000BASE-SX/LX) specifies 1 Gbps transmission over multimode and single-mode fibers. There is an effort, by telecommunications service providers, to deploy 10-Gbps Ethernets. The standards are based on optical components similar to SONET OC-192 systems.

5.3. ATM Lan Emulation and Fiber Channel

5.3.1. ATM. The asynchronous transfer mode (ATM) protocol was designed by the telecom industry to handle all types of communication. It fragments the information into fixed-size packets, called cells, to work with real-time applications and bursty traffic. The definitions were made to support the backbone for carriers and the LANs in the corporations. ATM was designed to work principally on top of synchronous optical network (SONET) [4] links; the advantage is that the links can span very large distances using standard carrier equipment. ATM was expected to gradually replace LAN [5] protocols; however, the combination of Ethernet with TCP/IP dominated the LAN market.

ATM is a switching protocol that requires the establishment of virtual circuits between stations before a communication can be effected. The network administrators manually configure typical ATM implementations; however, LANs operate under a connectionless approach. The nodes in a LAN just send packets with enough information to reach the destination without the need to negotiate circuit establishment. ATM emulates a LAN relying in a signaling protocol that manages the connections.

The LAN emulation (LANE) standards define a mechanism in which the ATM stations behave like a LAN. The nodes employ a server that controls the establishment of the circuits and keeps track of the stations registered as members of the LAN. The individual nodes need to register their address with this server before requesting a connection to send packets. There is a second server used for broadcasting; it replicates a broadcast packet and sends it to all stations. This solution offers high-performance links between stations because there is no contention for resources in the switch. However, companies have limited its use because LAN switches are simpler and inexpensive compared to ATM switches.

5.3.2. Fiber Channel. The Fiber Channel standard was created to support communication between computers and intelligent distributed peripherals at short distances. When peripherals required higher transfer speeds, the interfaces using copper cable were more difficult to implement and the distances were reduced. The proposed solution for the problem defined a switched network with a star configuration. Each optical link is a point-to-point connection between switches and nodes. The standard was designed to encapsulate other types of protocols in point-to-point connections (ATM, SCSI, HPPI, IP, IEEE 802, etc). Fiber Channel supports multiple speeds, multimode or single mode fiber, and distances ranging from few meters up to 10 km. This protocol is normally used to communicate storage-area networks.

6. MULTIWAVELENGTH NETWORKS

WDM is a technique used to multiplex several optical channels through the same optical fiber. The operation is equivalent to combining and splitting light rays with different colors using a prism. A dense WDM system can be viewed as a parallel set of optical channels, each operating at a different wavelength, as illustrated in Fig. 11. This technology can increase the capacity of existing networks without the need for expensive additional cabling, reducing the cost of upgrades.

The bandwidth required for a channel transmission is in the order of gigahertz; however, the optical fiber

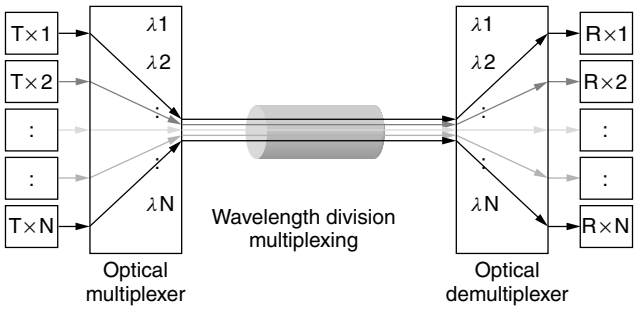

Figure 11. Wavelength-division multiplexing.

supports many terahertz in the available optical windows. WDM generally exploits the capacity of the optical fiber at 1300- and 1550-nm optical windows. The earlier WDM systems used only two channels, one at each window. The number of channels was increased later with the aid of optical filters, reaching separation between wavelengths in the range of tens of nanometers. More recently, the use of coherent techniques allowed separations of less than 1 nm. With this technology, the capacity of a single optical window expands to several dozens of channels known as *dense WDM* (DWDM).

There are several methods to allocate channels in WDM networks, where each wavelength corresponds to a channel. The major problem for these networks is to tune transmitters and receivers to different wavelengths.

Some methods propose fixed wavelengths assigned to each transmitter or each receiver. In order to establish communication, the other device will change its operating wavelength to match the desired station. This tuning process, in only one type of device, simplifies the network construction. However, it restricts the number of nodes to be the same as wavelengths available, and is subject to conflicts when two stations try to access the same destination.

In multihop [9] configurations the wavelength assignment is fixed for all the devices, and each station has several transmitters and receivers. A node can use other machines as repeaters, when it needs to talk to a station with an incompatible wavelength. This limits the number of nodes that can be reached from a particular source. However, the assignment of wavelengths is designed to create a sequence between stations forming a logical ring. This method simplifies the construction of the devices and reduces the conflict probability. On the other hand, it increases the traffic and the delay because it may require several retransmissions of the information.

Another technique enables all stations to tune the transmitters and receivers to any available wavelength. The method allows direct communication between all the stations and reduces the probability of blocking. Some disadvantages are complexity of the protocols required and more expensive devices. The nodes normally use a central control station to assign the wavelengths; however, they can employ techniques such as predefined sampling of channels, ALOHA protocol variants [6], and token passing. Those methods are not commonly used because they increase the delay and complexity of nodes.

In some networks, the signaling for call control is associated with the channel to use. This method blocks a resource just for the transmission of control information. A more efficient method for signaling employs a dedicated control channel that is independent of the information channels.

6.1. Phases for the Application of WDM Technology

The introduction of the WDM technology into optical fiber LANs, will follow an assimilation process similar to long-distance networks. At the beginning, it will serve the demand for increased bandwidth on some point-to-point links. Later, it will permeate to the backbone facilities, and finally will reach user interfaces. The evolution of DWDM technology seems likely to follow the stages shown below:

1. Increase the transmission capacity for congested point-to-point links.
2. Creation of an optical backbone that should add restoration capabilities.
3. Introduction of optical cross-connects allowing entire optical paths between end devices; however, the circuits are manually configured.
4. Usage of optical circuit switches. The stations will establish the optical circuits automatically, but will require sophisticated signaling protocols.
5. Introduction of optical packet routing. In the later stages the optical networks will be able to route individual packets without converting them to an electric form.

There is a trend, in the communications industry to create an all-optical network. The process will take several years to widely deploy commercial products. Meanwhile several experimental networks have been created to study their behavior. Some examples are Bellcore's Lambdanet [7], Lightning [8], Columbia's Telecomm Center TeraNet [9], IBM's RAINBOW [10,11]; All Optical Networking Consortium (AON) [12,13], Stanford's STARNET [14], and the European Advanced Communications Technologies and Services KEOPS [15] project.

6.2. DWDM System Components

Optical transmission systems may be divided into transmitters, receivers, amplifiers, and passive components. Each has to meet particular requirements to work in a WDM environment. The transmitters used for conventional optical fiber systems are light-emitting diodes or lasers. The link distance limits the available bandwidth, mainly due to a phenomenon called *dispersion*. It is a function of the type of fiber and transmitters used. Short-distance systems, in the order of few hundred meters, may use LEDs. For longer-distance transmission, the links require low dispersion; hence the use of lasers. All DWDM systems require a light source with a very narrow linewidth. This is accomplished with special types of lasers or with external filters.

The receiver must have good sensitivity and fast response for high-speed systems. The selection of a particular wavelength is obtained using optical filters.

There are several types of fixed filters manufactured for a specific optical channel; however, there are experiments to obtain a tunable receiver that is suitable for mass production.

For DWDM the most common optical amplifier is the erbium-doped fiber amplifier (EDFA) [16]. It amplifies the optical power of all the channels simultaneously, eliminating the need for several electronic devices. Mixing different wavelengths requires the use of optical couplers [16]. These devices combine different optical wavelengths at the inputs and distribute the mixed signal to all the outputs.

The International Telecommunications Union (ITU) proposed, through the Study Group 15 Work Project 4, a standard for wavelength assignment. It is based on a frequency reference of 193.1 THz, and a range of frequencies from 191.1 to 196.5 THz spaced 100 or 200 GHz each as shown in Table 2 (~0.8- or 1.6-nm spacing from 1568.77 to 1525.66 nm). It is ITU-T recommendation G.692 [17], "Optical interfaces for multichannel systems with optical amplifiers." This standard allows the creation of compatible devices from different vendors that operate on the same wavelengths.

7. CONCLUSION

Homes and corporations use LANs more and more each day, and the Ethernet family of protocols is the fastest-growing segment in LANs. Because of the high-bandwidth demand and wide range of applications, Ethernet is evolving into a hybrid network. The applications with lower requirements normally use conventional copper wiring; however, some of them have started to transform into wireless LANs. Users that need the higher data rates employ Gigabit Ethernet and 10-Gigabit Ethernet. This is the segment that needs more benefits from optical LANs. One lesson learned during this evolution is to reuse the existing technology, as much as possible, to make the products commercially viable. Fast Ethernet employs several elements from FDDI, and there is a trend for 10-Gigabit Ethernet to use the same optical technology as SONET OC-192 transport. Several optical LAN protocols are technically superior compared to Ethernet; however, the market has put them in disuse.

More recently the WDM technology has been utilized for the MANs. More likely in few years this technology will enter the LAN environment as the need for bandwidth increases. The major drivers for optical fiber networks are the multimedia applications and the communication between computers and peripherals in distributed computing environments.

The service providers have recognized that corporations need to link their LANs without the hassle of converting protocols. Therefore, they are currently offering LAN access ports to the customers. All the users share a high-capacity backbone segmented with virtual LANs (VLANs). This allows the corporations to reduce the costs to interconnect sites at high speeds; however, they are

BIOGRAPHIES

Mehdi Shadaram received his B.S.E.E. degree from the University of Science and Technology in Tehran in 1976, his M.S. and Ph.D. degrees from the University of Oklahoma, both in electrical engineering, in 1980 and 1984, respectively. Currently, he is the Schellenger endowed professor and the chairman of the Department of Electrical and Computer Engineering at the University of Texas at El Paso. His research activities are focused in the field of optical fiber communications and photonic devices. During the last few years, he has investigated the performance of analog optical fiber links, WDM networks, and application of tapered single-mode optical fibers. NASA, Jet Propulsion Laboratory, National Science Foundation, Office of Naval Research, Department of Defense, Texas Instruments, Nortel Networks, and Lucent Technologies have funded his research projects. He has published more than 60 articles all in his area of research, most of them in refereed journals and conference proceedings. Dr. Shadaram is a registered professional engineer in the state of Texas. He is a senior member of IEEE, member of the International Society for Optical Engineering, Optical Society of America, and Eta Kappa Nu. He has received numerous awards for teaching and research excellence. He is cited in Marquis *Who's Who in America*.

Virgilio Gonzalez received his B.S. degree in Electrical Engineering in 1988 and M.S. degree in Industrial Engineering in 1991 from the Instituto Tecnologico y de Estudios Superiores de Monterrey (ITESM-CEM), Mexico. Later he obtained his Ph.D. degree in electrical engineering from the University of Texas at El Paso, in 1999, with the dissertation "Performance Analysis of a Fiber Optic Local Area Network Based in DWDM and ATM." From 1989 to 1993 he worked at the ITESM-CEM as telecommunications director developing the communications infrastructure for the different campus of ITESM University system. He worked from 1996 to 2001 in Alestra, the AT&T subsidiary Carrier in Mexico, as technology planning manager. His main responsibilities were the architecture design, technology development, and testing for all network functions in the carrier national network. In Mexico, he established the first Internet connection to Mexico City in 1989, set up the largest computer network in the country in 1991, and deployed the first DWDM network in 1998. Since 2001, he has been a professor at the University of Texas at El Paso. His areas of interest are high-speed optical communications, multiservice networks, and data communications protocols.

Eveleigh, Australia

1. INTRODUCTION

An optical filter introduces a wavelength- or frequency-dependent change in the amplitude or phase of an optical signal passing through it. They are important components in modern optical communications networks that exploit the ability to simultaneously transmit information on more than one wavelength along a single optical fiber or

link [wavelength-division multiplexed (WDM) networks]. These WDM networks require components that can manipulate, combine, change, and reroute information based on the wavelength of light; optical filters perform many of these functions [1–4].

Filters can operate as either selective or corrective devices, or often combining both attributes. *Selective* devices extract or separate an optical signal into separate components based on wavelength or frequency and are used in optical demultiplexing, add/drop filters, optical switching, and also to create narrow wavelength selective mirrors in various lasers or other optical cavity–based devices. *Corrective* devices are used to adjust the amplitude or phase of the optical signal to remove a distortion introduced by another component or part of the network. A common example of an amplitude-corrective filter is a gain-flattening filter designed to compensate for the strong wavelength dependence of optical amplifiers. An example of a phase-corrective filter is a dispersion compensator that is used to undo the undesirable effects of dispersion in long-distance communication links, or to remove the chirp from laser pulses.

Almost all optical filters rely on optical interference between two light waves for their filtering behavior. Optical information is carried on waves that oscillate with specific frequencies. Two different waves in the same location can combine to produce a locally higher intensity if their oscillations are in phase (constructive interference), or they can combine to produce a very low or zero intensity if their oscillations are out of phase (destructive interference). The mechanisms used to split the light into parts that can be interfered, and how the interference patterns or outputs are manipulated determine the type of filter. There are a few fundamental configurations or building blocks for optical filters. Each of these is described briefly here and in more detail later.

The Fabry–Perot interferometer (Fig. 1a) utilizes multiple traversals of the same path to produce interference. The signal is split into parts by partially reflecting mirrors at either end of a cavity and reflected back and forth: some parts of the signal traverse the path multiple times before interfering with the other parts of the signal. The fraction of the signal that emerges is determined by interference conditions that depend on the optical path length of the cavity formed by the mirrors, the angle of propagation and also on the reflectivity of the mirrors.

Bulk diffraction gratings act as filters by either reflecting or transmitting (refracting) light in a wavelength-dependent manner. The most common configuration in optical communications is reflection. A reflective diffraction grating consists of closely spaced parallel grooves on a reflective surface (Fig. 1b). The periodic structure of the surface produces an interference between the small fields reflected at each groove that enhances reflections in certain directions, and suppresses them in others. An incident wave is broken up into several orders on reflection from the grating. The directions of the diffracted waves depend on the wavelength of light. Such a device can be used to spatially separate and filter out various wavelengths.

A thin-film stack or dielectric interference filter (Fig. 1c) is a sequence of alternating layers with different refractive

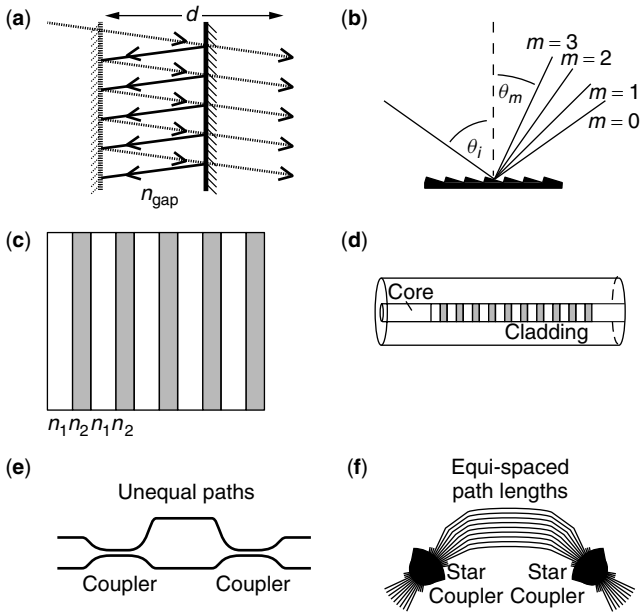

Figure 1. (**a**) A Fabry–Perot interferometer; (**b**) a planar diffraction grating; (**c**) a thin-film interference filter; (**d**) fiber Bragg grating; (**e**) a Mach–Zehnder interferometer; (**f**) an arrayed waveguide grating router.

indices (and sometimes different widths). Small amounts of energy are reflected at each interface between different refractive indices. In a similar way to the Fabry–Perot interferometer, interference between the various reflected waves results in a wavelength-dependent transmission through the stack. The major difference is that the thin-film stack utilizes multiple layers where each interface provides moderate reflectivity; the Fabry–Perot interferometer usually uses a single cavity bounded by a pair of reflecting elements with extremely high reflectivity. (Note that in a Fabry–Perot interferometer the reflecting elements either can be simple metallic mirrors or can themselves be a thin-film stack.)

Waveguide grating filters (Fig. 1d) are essentially dielectric interference filters that exist within the guiding region of an optical waveguide or fiber. Light traveling along the waveguide or fiber interacts with the layered structure and the light is reflected, coupled into different traveling modes of the guide or ejected in a wavelength-dependent manner. If the periodicity of the layers is on the order of the wavelength, the light is usually reflected at the resonant wavelength; these structures are called *Bragg gratings* or *counterpropagating gratings*. Long period gratings, however, usually couple the light to a different mode of the structure traveling in the same direction and are also called *mode-converting gratings*. If the planes of the layers are tilted with respect to the axis of the waveguide or fiber, then light will be coupled out of the guide; these gratings are called side-tap gratings.

The Mach–Zehnder interferometer (Fig. 1e) differs from the Fabry–Perot interferometer and the grating filters in that it acts as a filter by interfering two parts of the signal that have traveled along different paths. The incoming signal is equally split between the two alternate

paths by the input coupler, and on exit the signals in the two paths are recombined by a second coupler. The optical path difference between the two paths determines what fraction of each wavelength appears at each output port. When used as a demultiplexing device, it can be designed to send a particular wavelength completely to one output and another wavelength to the other output.

The arrayed waveguide grating router (Fig. 1f) is a generalization of the Mach–Zehnder interferometer to multiple arms or pathways. Incoming signals can arrive along several input ports. All of these are connected to an input star coupler. The input star coupler splits the signal equally between several pathways that are reconnected at their distant ends to another star coupler. Each pathway differs from its adjacent pathways by a fixed optical path delay. The output star coupler recombines the signals. Interference between the signals determines which output waveguide each wavelength emerges from. The structure is designed so that each wavelength from each input port is shuffled onto a different output port.

1.1. Tunable Filters and Switches

The wavelength(s) of operation of a filter depends (depend) on the optical and geometric properties of the structure. Changing any of these properties will affect the spectral properties of the filter, such as the peak value of transmission, the location of the wavelength at which maximum or minimum transmission occurs, or the extent of the band over which transmission is suppressed. This results in both undesirable effects such as the filter characteristics being temperature- or pressure-sensitive, and desirable effects in that the mechanism can be used to tune the filter.

Various controlling mechanisms (thermal, acoustic, electro-optic, nonlinear) can be used to alter one or more optical characteristics of the filter. If the filter characteristics can be changed sufficiently such that signals are completely diverted from their existing pathways to alternate pathways, the filter can be made to behave as a wavelength-dependent switch. Combining the ability to select wavelengths and to select pathways produces very powerful and useful optical components.

Reconfigurable and adaptive optical components are a current and highly active area of research, as communication networks continually move toward incorporating more flexibility, responsiveness, and intelligence into the optical layer [1,4]. It is far from clear which technologies will emerge as the leaders in this area, though it is likely to involve a hybrid of electronic, optical, micromechanical, and possibly chemical or biological technologies.

2. FILTER EXAMPLES AND APPLICATIONS

2.1. Fabry–Perot Filter

A basic Fabry–Perot filter or interferometer [5,6] consists of an optical cavity between two reflective mirrors. The incident light undergoes multiple reflections from the mirrors at either end of the cavity. The transmitted waves will constructively interfere to produce a maximum when the round-trip optical path length is an integral number of wavelengths:

$$2n_{\text{gap}}\, d \cos\theta = m\lambda \tag{1}$$

This resonance condition depends on the size of the cavity d, the refractive index in the cavity n_{gap}, and the angle of incidence θ.

The transmitted intensity for a cavity with equally reflective mirrors at both ends is given by

$$I_{\text{out}} = I_{\text{in}} \frac{1}{1 + \dfrac{4R}{(1-R)^2} \sin^2\left(2\pi n_{\text{gap}} \dfrac{d}{\lambda} \cos\theta\right)} \tag{2}$$

where R is the reflectivity of each mirror.

The transmission spectrum (Fig. 2) is periodic function of frequency. Each peak is associated with a different order m and the separation of successive peaks or orders is called the *free spectral range* (FSR) and is given by

$$\text{FSR} = \frac{c}{2n_{\text{gap}} d \cos\theta} \tag{3}$$

in frequency units. The sharpness of the transmission peaks is related to the reflectivity of the mirrors. The FWHM Δf (in frequency units) or $\Delta\lambda$ (in wavelength units) is given by the relationship

$$\frac{\Delta f}{f} = \frac{\Delta\lambda}{\lambda} = \frac{1-R}{m\pi\sqrt{R}} \tag{4}$$

The ability of a Fabry–Perot filter to resolve different signals is determined by the ratio of the FSR to the FWHM. This ratio is called the "finesse" $\mathcal{F}$ of a Fabry–Perot filter:

$$\mathcal{F} = \frac{\pi\sqrt{R}}{1-R} \tag{5}$$

Note that the expression for finesse is independent of order m. High finesse or high resolution is achieved for highly reflective mirrors. This expression is for the ideal or maximum value. In any real device the finesse will be smaller because it is limited by imperfections, such as a lossy medium and tilted or nonflat mirrors.

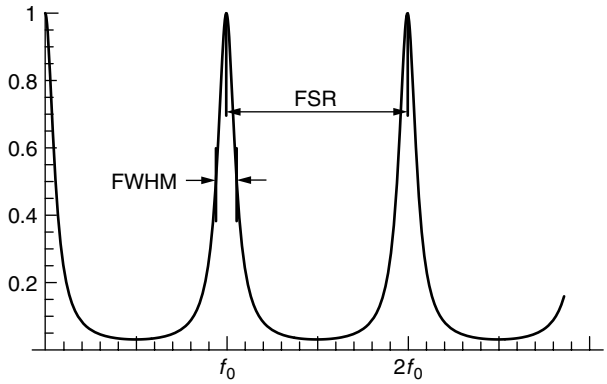

Figure 2. Transmission spectrum for a Fabry–Perot interference filter, depicting the free spectral range (FSR) and the full-width half-maximum (FWHM).

The contrast of the filter is a function of the reflectivity R:

$$\frac{T_{\max}}{T_{\min}} = \frac{(1+R)^2}{(1-R)^2} \tag{6}$$

In all the expressions above, the mirror reflectivity R has been taken to be a constant. In a real device, R is also potentially a function of wavelength and a function of angle, which complicates the analysis of the filtering characteristics. Nevertheless, the operation of the filter remains conceptually the same.

Ideally, one would like very high reflectivities suggesting the use of metallic mirrors. However, this is difficult to achieve in practice without simultaneously introducing excessive loss. Alternatively, these metallic mirrors can be replaced with dielectric stacks that have a broad reflectance peak around the spectral range of interest. The wavelength-dependent R introduced by using dielectric stacks depends on the index difference Δn of the stack. The analysis is not trivial, but as a general rule of thumb it will reduce the FWHM of the filter from the ideal value given above by a factor $\Delta n/\overline{n}$, where $\overline{n}$ is the average index in the stack.

2.1.1. Multipass and Multicavity Cascaded Fabry–Perot Filters. The finesse of a simple Fabry–Perot filter is limited by the reflectivity of the mirrors. Various improvements to the basic filter can be made by modifying the cavity structure [5,6].

A high finesse structure can be made by cascading multiple low finesse structures. There are two approaches. In the *multipass* method, the light passes twice (or multiple) times through the *same* cavity yielding a filter function which is the square (or higher power) of the original filter function. In the *multicavity* method several independent cavities are concatenated and the resulting filter function is the product of the filter functions of the individual cavities. In these configurations it is vital to keep the cavities isolated so that there is no resonating backreflection between the cavities. This can usually be done by slightly misaligning the orientations of each cavity so that spurious reflections will gradually deviate or walk away from the axis of the system.

If the cavities have identical free spectral ranges (FSRs) the cascaded system will have a transmission function with the same FSR but a much narrower FWHM, thus improving the finesse. The free spectral range of the cascaded system can be vastly increased by choosing the cavities to have different FSR (usually in the ratios of different integers). The Vernier principle can be exploited so that the FSR of the cascaded system will be determined by the coincidence of two different orders of the individual cavities (Fig. 3).

2.2. Bulk Diffraction Gratings

Bulk diffraction gratings are surfaces or plates with periodic grooves that can act as either reflective or transmissive structures [1,3]. Light incident on the grooves is split into components that are reflected in various directions depending on the angle of incidence, the wavelength, and the period of the grating. The zero-th order reflected ray is in the direction of specular reflection (equal angles of incidence and reflection); the higher order rays are referred to as diffracted rays and their direction is given below.

The basic diffraction grating equation in reflection is

$$\sin\theta_i + \sin\theta_m = m\frac{\lambda}{\Lambda} \tag{7}$$

where θ_i is the angle of incidence, θ_m is the angle of reflection of the mth-order diffracted ray, Λ is the period of the grating, and λ is the wavelength of the incident light. The fraction of light that ends up in each diffracted order is determined by the detailed shape of the diffraction grooves.

Diffraction gratings can be used in various configurations as wavelength selective elements; the most common is to combine a focusing element (either a lens or a concave mirror) with the grating. One configuration is shown in Fig. 4.

The light emerging from each waveguide hits the focusing mirror, which not only redirects the light onto the grating but also counteracts the diffractive spreading of the light as it exits the waveguide. Each wavelength

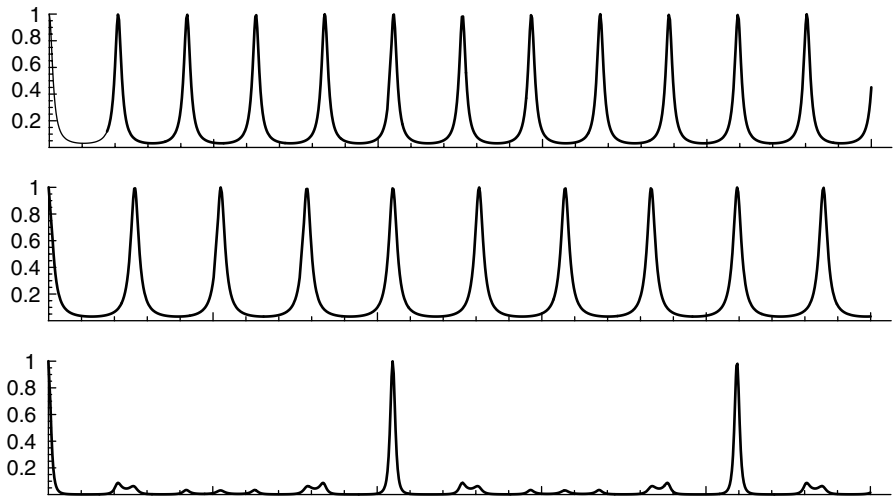

Figure 3. Transmission spectrum for a multicavity cascaded Fabry–Perot interference filter, exploiting the Vernier principle to improve the finesse.

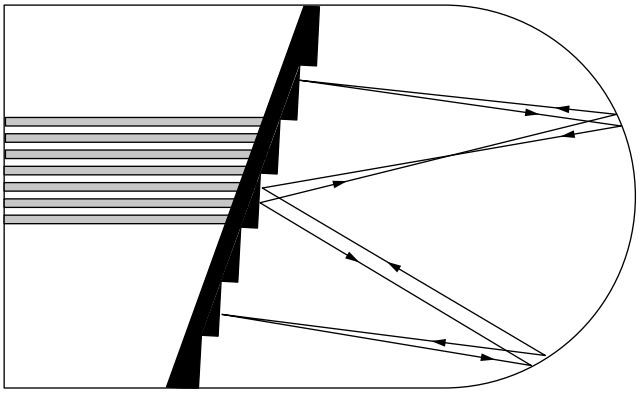

Figure 4. An example of a diffraction grating mounted onto a focusing lens or mirror.

is diffracted by a slightly different angle and therefore is reflected by the mirror to a different position, the subsequent reflections then refocus it onto a different exit waveguide.

2.3. Dielectric Thin-Film Stacks

The first historical observation of thin film interference was in 1817 by Fraunhofer, when he observed that glass with a thin layer of tarnish was less reflective than fresh glass. The simplest antireflection coatings consist of a thin layer of thickness d with an index n_1, which is intermediate between the indices n_0 and n_2 of the materials on either side. In the absence of the antireflective layer, the reflection for normal incidence is $R = r_{2,0}^2$, where

$$r_{i,j} = \frac{n_i - n_j}{n_i + n_j} \tag{8}$$

For an air–glass interface this reflectance is about 4%. In the presence of the thin layer, the reflectance becomes

$$R(\lambda) = \frac{r_{2,1}^2 + r_{1,0}^2 + 2r_{2,1}r_{1,0}\cos\left(\dfrac{4\pi n_1 d}{\lambda}\right)}{1 + r_{2,1}^2 r_{1,0}^2 + 2r_{2,1}r_{1,0}\cos\left(\dfrac{4\pi n_1 d}{\lambda}\right)} \tag{9}$$

When the individual interface reflections are low, this expression can be approximated by its numerator (which is equivalent to ignoring multiple or higher-order reflections). In either case, the minimum reflection occurs when the argument of the cosine function is an odd multiple of π. Thus, the minimum reflection occurs for wavelengths that satisfy $2n_1 d = (m + \frac{1}{2})\lambda$, where m is an integer. When $m = 0$, the thinnest possible antireflective coating is obtained with an optical thickness of $n_1 d = \lambda/4$. This is why these layers are also referred to as *quarter-waveplates*.

The value of the minimum reflection is

$$R_{\min} = \left(\frac{r_{2,1} - r_{1,0}}{1 + r_{2,1}r_{1,0}}\right)^2 \tag{10}$$

This minimum drops to zero if $n_1 = \sqrt{n_0 n_2}$ the geometric mean of the indices on either side.

A stack of thin-film layers of alternating refractive index each one quarter-wavelength thick will produce a very-high-contrast filter, with additional layers producing even greater contrast. A general thin-film filter or stack will consist of many layers of alternating refractive indices. A vast variety of filter characteristics can be designed by varying the layer thicknesses and refractive indices and incorporating more complicated patterns of alternating layers. The filters can be designed to be lowpass filters, highpass filters, and bandpass filters [7]. One general observation is that to obtain sharp cutoff filtering characteristics, the refractive index between the layers needs to be as high as possible. Some of the common materials used for visible light filters and their typical refractive indices are magnesium fluoride (1.39), zinc sulfide (2.35), cryolite (1.35), titanium dioxide (2.3), silicon dioxide (1.46), and various rare-earth oxides. In the infrared, silicon (3.5), germanium (4.0), and tellurium (5.1) can also be used in combinations with low index materials. Countless other oxides and fluorides are also used.

The wide variety of materials and deposition processes available for thin-film filters and the accuracy with which the layer thicknesses can be manufactured make thin-film filters among the most versatile and accurate of filtering devices. Thin-film filters can also be extremely narrow band and accurately manufactured to a precise wavelength; they are the ideal device to use in monitoring the wavelength drift of other devices. For example, a wavelength locker is used to monitor and control the wavelength of a laser source. The locker consists of two cascaded filters with equal bandwidths accurately located on either side of the desired operating wavelength. The optical signals transmitted through this pair of filters are compared and used to provide an electrical feedback signal to compensate for wavelength drift.

A set of thin-film filters can be cascaded to form a WDM demultiplexer (Fig. 5), with each filter either reflecting or transmitting a different specific wavelength channel. The simplest configuration utilizes each filter as a bandpass filter: transmitting a specific wavelength and rejecting all others. The filters can be conveniently deposited on both sides of a transparent dielectric slab, which also provides for accurate parallel alignment of the filters. The output wavelengths can be collimated and launched into fibers with a set of graded-index (GRIN) lenses. Note that since

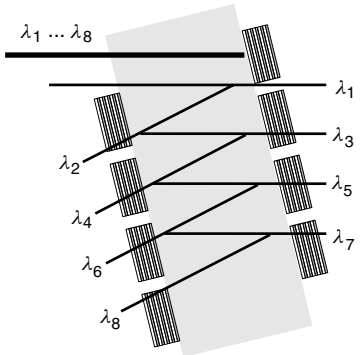

Figure 5. A cascaded set of thin-film filters used to demultiplex eight wavelengths.

all the filters are tilted with respect to the direction of the incident light, the filter layer thicknesses must be designed according to this angle. This type of cascaded filter is suitable for up to about 32 WDM channels.

2.4. Waveguide and Fiber Gratings

Gratings in waveguides and fibers are fundamentally similar to thin-film stacks. Both are structures with periodically varying optical properties [8,9]. The differences arise mainly because thin-film stacks are bulk-optic structures, whereas waveguide gratings are embedded in an existing guiding structure. The embedded gratings thus are restricted to a much smaller range of index differences since they are created by modifying the properties of a single material rather than interleaving different materials. Thus rather than use a moderate number of high contrast layers, embedded gratings use an extremely large number of low contrast layers.

The current importance of Bragg gratings is directly attributable to the photosensitive process whereby permanent index changes can be induced in glass materials using various specific wavelengths of light (mostly in the ultraviolet but also using two photon processes in the visible). An interference pattern is produced by combining two beams of light obtained from a diffraction phase mask or other source (Fig. 6). The periodic pattern of light in turn produces a periodic variation in the induced refractive index change. This is the preferred approach for writing gratings with micron and submicrometer periods. If the period of the grating is longer, then each layer of the grating can in principle be written individually. Those grating structures that can be produced by a holographic process may consist of many (thousands of) periods as opposed to manufactured thin-film stacks that have a much smaller number of layers.

Gratings can be used to selectively reflect light by coupling light from a forward traveling mode of the waveguide or fiber, to a backward-traveling mode. Such gratings are called *Bragg gratings* and have periods comparable to the wavelength of light. Gratings can also be used to selectively couple light between *different* modes traveling in the same direction. Such gratings are called *mode-converting* or *long-period gratings* and can have periods from several micrometers to centimeters.

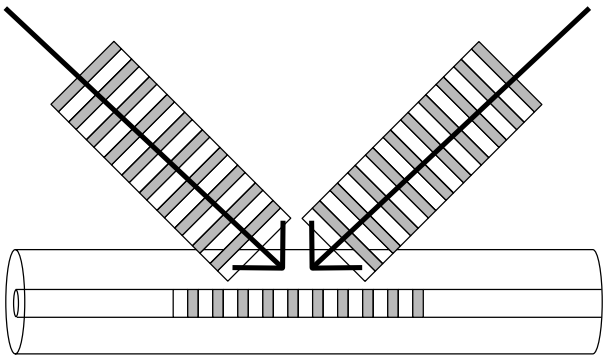

Figure 6. Two interfering beams of light used to produce a grating.

The relationship between the resonant wavelength (or Bragg wavelength) and the period of the gratings involves the effective refractive indices of the modes of the underlying waveguide. In any waveguide, each mode has its own characteristic phase velocity, which determines an effective refractive index (intermediate between the smallest and largest refractive indices occurring inside the waveguide structure). For a grating that couples between modes A and B the resonance condition is

$$\lambda_0 = (n_A \pm n_B)\Lambda \tag{11}$$

where Λ is the period of the grating, n_A and n_B are the effective indices of the modes and λ_0 is the free-space wavelength at which the coupling is most efficient. The positive sign is used for Bragg gratings (where the modes are traveling in opposite directions), and the negative sign is used for gratings that couple modes traveling in the same direction.

The actual efficiency of the grating and how it varies as the wavelength departs from the resonant value depend on other properties of the grating such as its length and the depth of modulation of the refractive index. This is explored briefly later in the section on coupled mode theory. In general, for simple gratings, Bragg gratings operate over a narrow range of wavelengths (a few nanometers) and long-period gratings operate over many tens of nanometers.

A wide variety of spectral characteristics can be obtained from gratings for a diverse range of applications [8,9]. Common applications of Bragg gratings are in optical add drop multiplexers (OADMs). Gratings can be easily designed to strongly reflect over a narrow range of wavelengths, referred to as the bandgap or reflection band of the grating. Unfortunately, most WDM applications of filters require a bandpass rather than a bandreject functionality and so various configurations have been developed to exploit reflective gratings.

Two different configurations are shown in Fig. 7. In the first configuration, the grating is located between two 3-port circulators. All incoming wavelength channels are sent by the first circulator toward the grating. All wavelength channels except one are passed by the grating and then sent by the second circulator back out to the network.

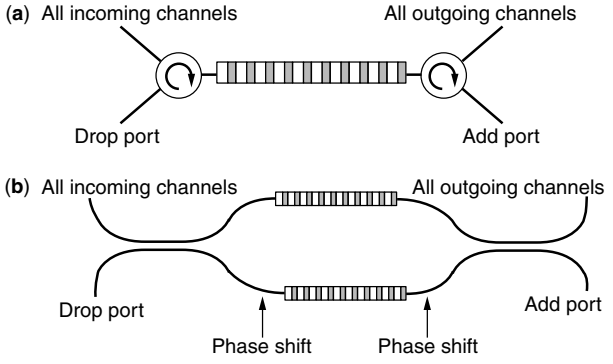

Figure 7. (**a**) Optical add-drop multiplexer formed by a grating and two circulators; (**b**) alternative configuration with two couplers.

The grating is designed to reflect the wavelengths corresponding to one of the channels: the drop channel. These wavelengths are reflected by the grating and after passing back through the first circulator are delivered to the drop port. Likewise, signals arriving at the add port are passed by the second circulator toward the grating. The add channel is reflected by the grating, and then, after passing back through the second circulator, these wavelengths join the other channels passing out to the network.

The high cost of circulators has stimulated alternative designs. The second configuration requires a pair of *identical* gratings located between two couplers. The drop channel wavelength is reflected by both gratings simultaneously, but picks up an extra π phase shift in one arm. As it passes back through the coupler, it is recombined onto the other port of the coupler, because of the phase shift. The analogous thing happens on the other side with the drop channel.

Another important application of gratings is in gain flattening. The output of an erbium-doped fiber amplifier (EDFA) varies strongly as a function of wavelength over its band of operation (Fig. 8). When a signal passes through many such amplifiers, the nonuniformity is accentuated, and this severely limits the usable bandwidth of the system. Gratings having a filter profile that is the opposite of the gain spectrum of the EDFA can be used to flatten the profile and thus extend the usable bandwidth. Various types of long-period gratings have been successfully used to modify the profile over a range of tens of nanometers.

The final important application of gratings considered here is the dispersion compensator. Signals traveling over long distances in standard telecommunications fiber near 1.55 μm experience dispersion-induced broadening since the longer wavelengths travel slightly more slowly than shorter wavelengths. This group velocity dispersion will lead to signal degradation. A chirped Bragg grating is one where the period of the grating varies along its length. If the grating period is longer at the front than at the back, the shorter wavelengths will travel further into the grating before being reflected. This introduces a wavelength-dependent delay on reflection that can be used to compensate for the delay induced by dispersion (see Fig. 9). The dispersive properties of gratings are a very important area of investigation [10].

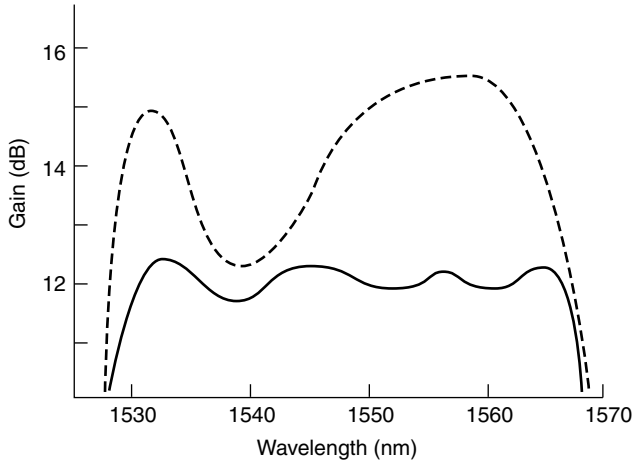

Figure 8. Output spectrum of a typical EDFA before (dashed) and after (solid) passing through a gain-flattening filter.

Figure 9. Dispersion-compensating Bragg grating.

A major problem associated with gratings is temperature dependence. Not only does the grating physically expand with temperature causing the period to shift, but a more important effect is the temperature-dependent refractive index of most glasses, which also results in a shift in the resonant or Bragg wavelength. Temperature compensation in grating packaging is a critical component of grating technology.

2.4.1. Coupled-Mode Theory. Coupled-mode theory is used extensively for the modeling and analysis of gratings. The coupling strength of the grating is encapsulated in a parameter κ, which is proportional to the index modulation. The frequency of the incoming signal is described by a detuning that is proportional to the frequency difference between the signal and the resonant or Bragg frequency.

More precisely, the coupling strength is defined by

$$\kappa = \eta \frac{\pi}{\lambda} \Delta n \tag{12}$$

where Δn is the index modulation and η is an efficiency factor describing how well the grating overlaps with the transverse intensity profile (or modal profile) of the light traveling along the waveguide; the detuning is defined by

$$\delta = (n_A \pm n_B)\frac{\pi}{\lambda} - \frac{\pi}{\Lambda} \tag{13}$$

where, as before, the positive sign is used when the modes are counterpropagating and the negative sign when they are copropagating.

A general rule of thumb for all gratings is that coupling is very efficient if the detuning δ is smaller than the grating strength κ and is very inefficient when the detuning is larger than κ. For Bragg gratings the detuning range between $\pm\kappa$ is also referred to as a *bandgap*.

The coupled-mode equations are the fundamental system of equations used to describe both Bragg (copropagating) gratings and long-period (counterpropagating) gratings [8,9]. The first mode (usually forward-traveling) has an amplitude that varies as $u(z)$; the second mode (either forward- or backward-traveling) has an amplitude varying as $v(z)$. The coupling of energy by the grating is represented by a pair of simple differential equations connecting these two amplitudes. For uniform gratings the equations are

$$iu'(z) + \delta u(z) + \kappa v(z) = 0 \tag{14}$$

$$-iv'(z) + \delta v(z) \pm \kappa u(z) = 0 \tag{15}$$

where the positive sign is used with counterpropagating modes and the negative sign is used with copropagating modes.

A typical spectrum for a uniform Bragg grating is shown in Fig. 10. The peak reflectivity is given by

$$R = \tan h^2(\kappa L) \tag{16}$$

where L is the length of the grating. The longer the grating, the stronger the reflection. The bandwidth of the spectrum is directly proportional to κ and can be represented in

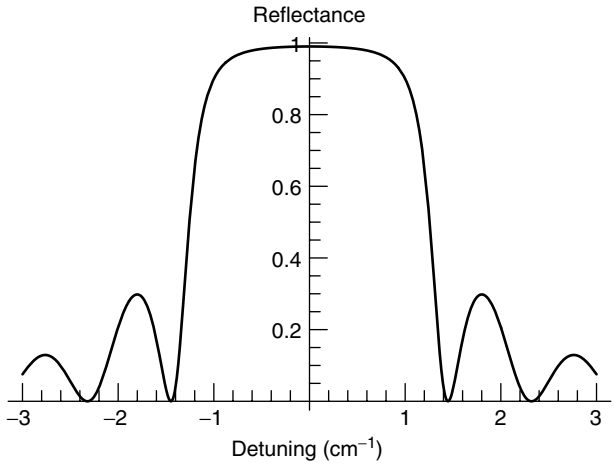

Figure 10. Reflection spectrum for a Bragg (counterpropagating) grating with a total grating strength $\kappa L = 3$.

various ways. As a rough rule

$$\frac{\Delta\lambda}{\lambda} \sim \frac{\Delta n}{n} \tag{17}$$

Very short gratings will have an apparent bandwidth wider than this, but as the grating becomes longer, the spectrum will stabilize to this fixed bandwidth. Making the grating extremely long will *not* narrow the reflection band any further.

For copropagating (or long period) gratings, it is still true that the most efficient energy coupling occurs at zero detuning. However, since both modes continue to travel in the same direction, if the grating is long enough, the coupling process will start to couple energy back into the original mode again. This phenomenon is called *overcoupling*. Figure 11 shows three typical spectra for a copropagating grating demonstrating ideally coupled and overcoupled gratings. The ideal condition for 100% coupling is first achieved for $\kappa L = \pi/2$.

2.5. Acoustooptic Filters

Acoustooptic filters exploit the interaction of light and sound in materials that are photoelastic [1,4]. The periodic compressions and expansions in the material produced by the presence of the sound wave result in corresponding variations in the refractive index via the photoelastic coefficient. A commonly used material with a high photoelastic coefficient is lead molybdate, $PbMoO_4$.

The period Λ of the index modulation produced by the photoelastic effect is equal to the wavelength of the

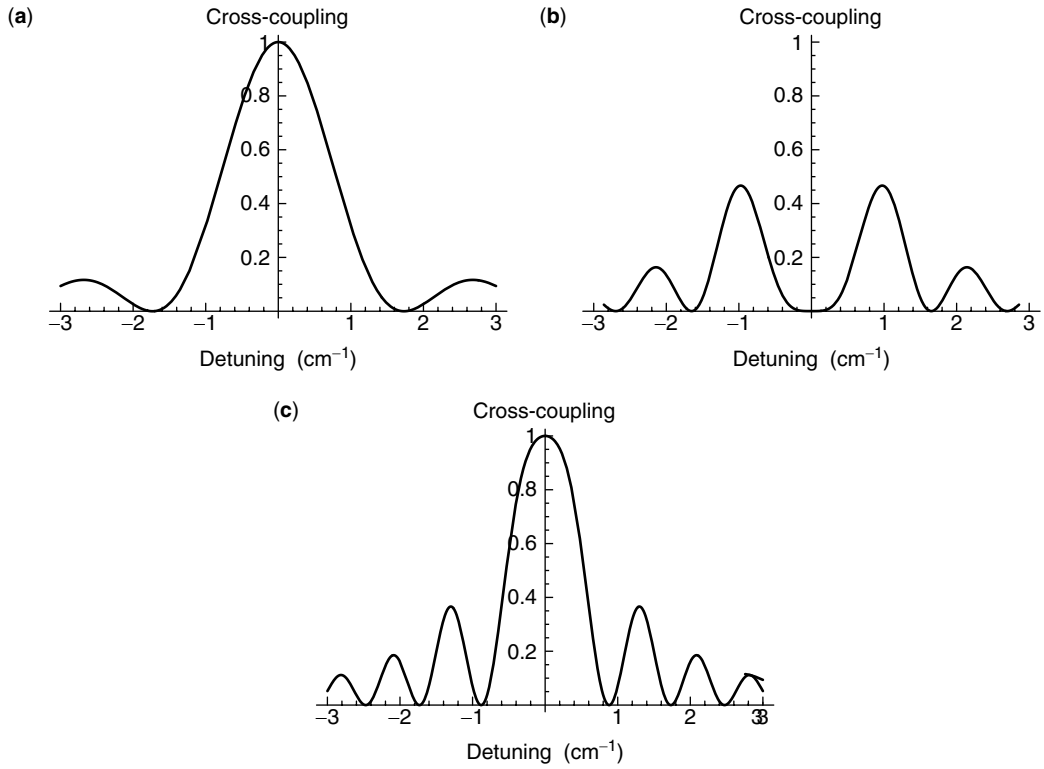

Figure 11. Cross-coupling spectra for copropagating gratings with three different values of total grating strength: (**a**) $\kappa L = \pi/2$; (**b**) $\kappa L = \pi$; (**c**) $\kappa L = 3\pi/2$.

sound wave in the material. Sound velocities in typical materials are on the order of several thousand meters per second. Thus acoustic frequencies of around 100 MHz will produce gratings with periods of several tens of micrometers. A common configuration is to use such gratings to couple energy between lightwaves traveling in the same direction but experiencing different refractive indices. The different refractive indices are obtained by using a birefringent material and exploiting the different refractive indices (ordinary n_o and extraordinary n_e) for the two polarizations. The wavelength at which maximum coupling of energy from one polarization to the other occurs is given by the condition

$$\lambda = (n_o - n_e)\Lambda \tag{18}$$

The bandwidth over which effective coupling occurs is roughly given by the relationship

$$\frac{\Delta\lambda}{\lambda} \sim \frac{\Lambda}{L_{\text{int}}} \tag{19}$$

where the interaction length L_{int} is the distance over which the acoustic and optical waves overlap and interact.

Acoustic gratings share many properties with waveguide gratings and thin-film stacks and can be analyzed by the same techniques. However, the most important difference is that the acoustic grating is a transient phenomenon, and can be easily controlled or modified by changing the properties of the acoustic wave, thus leading to various tunable filter configurations.

2.6. Mach–Zehnder Interferometer

The basic principle behind the Mach–Zehnder (MZ) interferometer is the interference of two parts of a signal that have traversed different optical paths [11]. In one of the simplest configurations (Fig. 1e) two waveguide arms of different optical lengths are connected by two 3-dB couplers. For simplicity, any wavelength-dependent properties of the couplers themselves are ignored (at least over the wavelength interval of interest). The light is split equally at the first coupler and recombined at the second coupler. The interference is produced by the phase difference between the waves traversing the two arms of the interferometer. The phase difference is given by

$$\Delta\phi = \frac{2\pi}{c} f n_{\text{eff}} \Delta L = \frac{2\pi n_{\text{eff}}}{\lambda} \Delta L \tag{20}$$

The intensities obtained from the two ports, respectively, are given by

$$I_1 = I_{\text{in}} \cos^2 \frac{\Delta\phi}{2} \tag{21a}$$

$$I_2 = I_{\text{in}} \sin^2 \frac{\Delta\phi}{2} \tag{21b}$$

Thus, interference between the two arms leads to a difference in power between the outputs of the second coupler.

The filtering characteristics are periodic in frequency and the channel spacing (also called *free-spectral range*) of this device is

$$\Delta f = \frac{c}{2n_{\text{eff}} \Delta L} \tag{22}$$

In more realistic devices, the perfect periodicity of the transmission spectrum will be modulated by the wavelength-dependent properties of the 3-dB couplers (which in turn depend on how the couplers are made).

If we contrive to have constructive interference for a specified frequency while having destructive interference for a second specified frequency, this will determine the length. For a 1.3/1.55-μm channel splitter, the length required is $L = 2.78$ μm (assuming a silica waveguide with $n_{\text{eff}} = 1.45$). The filtering characteristics are shown in Fig. 12. On the other hand, to create a device that separates 100-GHz channels (interleaving them) would require a length of $L = 1$ mm.

The filter can also be used in reverse as a multiplexer for combining wavelengths. For example, to combine a 980-nm-pump wavelength with a 1550-nm signal, the appropriate length would be $L = 0.92$ μm (for a pump at 1.48 μm the length becomes $L = 11.3$ μm). However, it is more common for this operation to be done by exploiting the wavelength-dependent coupling of a single simple directional coupler. Such a wavelength-dependent coupler can also be used to separate two wavelengths.

A cascaded series of MZ filters (sometimes called an MZ "chain") can be used to systematically separate or demultiplex a full-WDM channel set. Consider a set of equally spaced frequencies. The first MZ filter is designed to separate all the even channels from all the odd channels. Thus each output arm of the first device now carries a set of equally spaced frequencies with a spacing twice that of the original signal set. A second MZ filter that has a pathlength difference ΔL half that of the original will subsequently filter out every other channel in this reduced set and so on. Thus, for example, a cascaded chain of MZ filters 7 deep could demultiplex a 128-channel system.

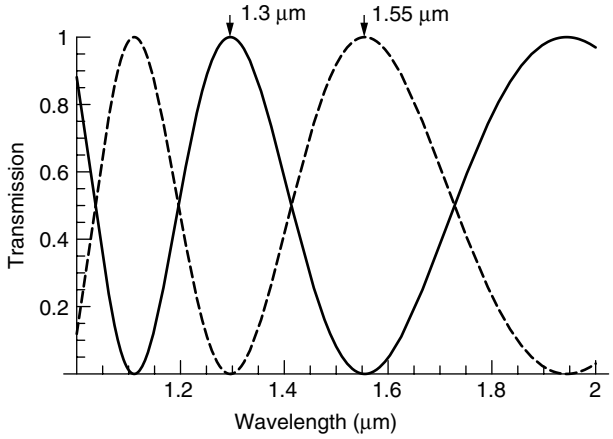

Figure 12. Filtering characteristics of the two output ports as functions of wavelength. If shown versus frequency, the characteristics would appear periodic.

2.7. Arrayed Waveguide Grating Router

The arrayed waveguide grating router (AWGR) can be regarded as a generalization of the Mach–Zehnder filter to multiple ports [3,4]. The input and output couplers are replaced by star couplers that have the property that the light entering at any port is split equally between all output ports. (Information about which specific input port the light came from is retained or encoded into the relative phases of the split signals.) If the multiple paths connecting the two star couplers were all of identical optical lengths (the relative phases would be preserved), then the second star coupler would just undo or reverse the action of the first star coupler; light entering a specific port on the left emerges from the corresponding port on the right (for all wavelengths). When the optical pathlengths of the arms are different, the signals arriving at the second star coupler will have different phases and interference will direct the output to a different port (which port will also depend on wavelength).

A useful analogy to understand the AWGR is to replace the star couplers with lenses and the array of arms with a triangular dispersive prism as in Fig. 13. The different input ports correspond to different point sources A, B, and so on. in the focal plane of the input lens. Light from each of these point sources after passing through the lens is transformed into *plane waves* traveling at different angles, each angle corresponding to a different input source. In the absence of any intervening structures, plane waves hitting the output lens are focused onto its focal plane, with the position of the image determined by the incident angle. Thus the arrangement of the output images corresponds precisely to the input sources (apart from a simple overall inversion).

The triangular prism refracts each incoming wave changing its direction, thus altering the location at which the output image is formed. Furthermore, because the amount of refraction will vary for different wavelengths, each wavelength will form an output image in a different location.

Using the notation $\lambda_i^{(j)}$ to indicate a channel with wavelength λ_i entering through port j, where $i = 0, 1, \ldots, N-1$ and $j = 0, 1, \ldots, N-1$, then such a signal emerges from port $j + i$(moduloN), (i.e., if $i + j$ is larger than $N - 1$, the port numbers wrap around.) The 4×4 example is shown explicitly in Fig. 14. The wraparound effect is obtained by ensuring that the frequency spacing between adjacent channels Δf and the optical pathlength difference $n\Delta L$ between adjacent arms satisfy $N \times \Delta f \times n\Delta L = 2\pi c$.

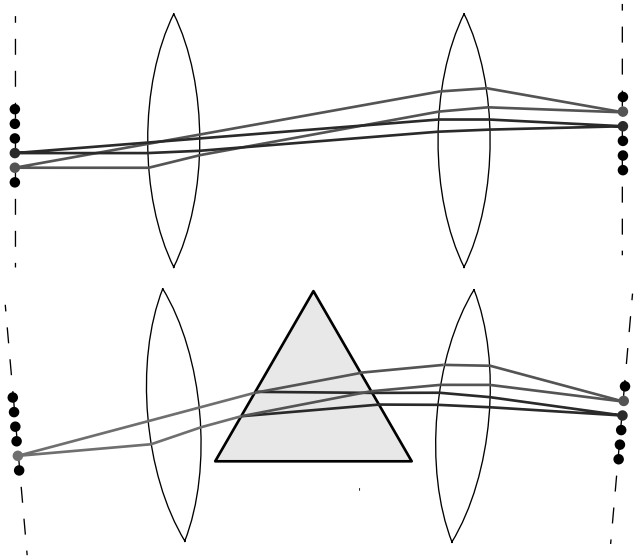

Figure 13. Analogy of an AWGR using two lenses and a triangular prism.

3. FILTER CHARACTERISTICS

Several important parameters characterize the spectrum of a filter, especially WDM filters designed for channel selection. The parameters are shown for a typical spectral profile in Fig. 15.

The peak wavelength is as the name suggests: the wavelength with the least loss. For an asymmetric spectrum, this will be different from the *center wavelength*, which is defined as the average of the upper and lower cut wavelengths or limits of the passband. Flexibility exists in the definition of these limiting wavelengths, as they are the wavelengths on either side of the peak for which the spectrum first falls to some predetermined level in decibels. For example, the 0.5- and 3-dB bandwidths are shown in Fig. 15. If the spectrum is significantly asymmetric, the bandwidth and centre wavelength will depend on the choice of level.

The isolation is given by the largest transmission levels (lowest loss) in the adjacent WDM channels. It is not necessary that this extreme value occur at the edge of the adjacent channels, nor that it even occur for the immediately adjacent channel. The figure of merit for

Figure 14. Input port and wavelength redistribution for a 4×4 AWGR.

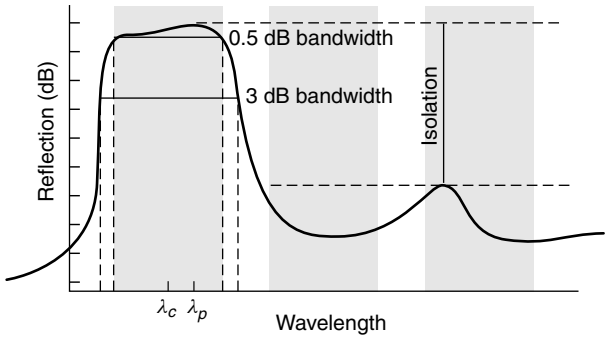

Figure 15. Typical WDM filter profile showing both the peak and central wavelengths, the bandwidth at various decibel levels, and the channel isolation or crosstalk.

a WDM filter can be defined by the ratio of utilizable bandwidth to the channel separation.

4. EVALUATION

Each filter technology or configuration has its own specific merits and disadvantages; the various designs are all competing for use in commercial optical network systems. Some of the important criteria are precision, temperature stability, low loss, low polarization dependence, manufacturing cost, packaging and pigtailing (i.e., connecting fibers to chip-based devices), scalability to large numbers of wavelength channels, isolation and crosstalk between channels, and design flexibility.

In terms of wavelength precision and stability, the thin-film filters are extremely attractive components for optical networks. The deposition process yields very accurate layers, and the variety of materials available make it easy to design for low loss and minimal temperature dependence [4] (as low as 5×10^{-1} nm/°C). The polarization dependence for these devices can also be kept low. However, scaling to larger numbers of channels usually requires the cascading of devices, which could impact both cost and overall loss.

An advantage of diffraction gratings is that the insertion loss is independent of the number of channels, making these devices more attractive for high-channel-count systems. Unfortunately, one problem with diffraction gratings is their polarization-dependence. These devices also do not fare too well on the cost criterion; the diffraction grating/concave reflector configuration is a bulk device that is not easy to fabricate.

Devices that have the best polarization-independent performance are the fiber Bragg grating filters. Passive temperature stabilization is possible for fiber gratings, giving stability similar to that of thin-film filters [4]. The holographic fabrication technique also provides this class of devices with an unrivaled ability to make unusual and customized filter responses by simply varying the chirp and apodization profiles of the grating. This technology does not excel in scaling with the number of wavelengths. It is possible to overlay a limited number of gratings with different center wavelengths, or to concatenate several gratings within the same length of fiber; however, most multiplexing schemes still require some form of cascading, which introduces the additional overheads of couplers, isolators, and circulators.

Certainly, arrayed waveguide grating routers appear to have the advantage of scalability, at least to moderate numbers of channels (from 16 to 64). However, because this is a planar or chip-based technology, polarization dependent loss may be a problem. A number of strategies for reducing the polarization dependence are available [3]; the simplest is to introduce a polarization-retarding plate half-way across the array waveguide region. The biggest disadvantage of the AWGR is the packaging and pigtailing cost of connecting fibers to the device.

The demand for greater bandwidth will continue to drive the development of components for WDM networks. There is a growing shift toward more intelligence within the optical layer of such networks, suggesting a trend toward devices with multiple functions. For example, early WDM filters concentrated mostly on filter shape, whereas later designs will also look closely at the implications of dispersive effects. Filters will be both selective and corrective at the same time, as well as combining other attributes such as switching and tunability.

The need to reduce packaging costs will also favor devices that can easily be integrated, and the incorporation of light sources, modulators, filters, and detectors onto the same substrate may be one possibility to achieve a scaling in production.

Although it has been possible to identify which attributes will become more important in future optical filter designs, it is still not possible to tell which of the existing technologies will best evolve to fit the needs of the next generation of optical networks. Almost certainly a diversity of designs and technologies will continue to exist, as no single solution will be able to meet all the needs of optical networking.

BIOGRAPHY

Leon Poladian received his B.Sc. degree in 1986 and a Ph.D. degree in theoretical physics in 1990 from the University of Sydney, Australia. His thesis was on the optical properties of periodic structures. He joined the Optical Sciences Centre at the Australian National University in 1990 as a postdoctoral fellow working on nonlinear fibre couplers and spatial solitons. Since 1992, he has been at the Optical Fibre Technology Centre at the University of Sydney, first as a Queen Elizabeth II fellow, then an Australian Research Council senior research fellow and currently as an Australian professorial fellow. Dr. Poladian has published over 80 journal and conference papers and holds five patents in the areas of fiber design and grating fabrication. His areas of interest are computational algorithms for novel fiber design; grating design, fabrication and characterization, and the optical properties of periodic and almost-periodic photonic structures in one, two, and three dimensions. Dr. Poladian also holds a graduate diploma in education from the University of New England, Armidale, Australia.

OPTICAL MEMORIES

MICHAEL RUANE
Boston University
Boston, Massachusetts

1. INTRODUCTION

An optical memory is any system that stores and retrieves digital information using optical methods. Optical memories are mass storage devices, competing directly with magnetic hard drives and magnetic tape. Their high capacity, low cost per megabyte, reliability, and removability have made optical memories the preferred mass storage solution for many applications. They are standard components in personal computers and workstations, and support important consumer electronics. Digital versatile disc (DVD) players are now making significant inroads into the VHS tape market, and rewritable DVD (DVD-RW) is a candidate for the local storage of movies and multimedia distributed over the Internet. Optical memory is a natural component of an all-optical system for data retrieval, transmission, and storage, and will play an important role in advanced communications systems.

As of 2001, global production of content is expected to require 1–2 exabytes or roughly 1.5 billion gigabytes of storage. This is approximately 250 MB (megabytes) per person for every person on earth. This content in print, film, magnetic, and optical forms exceeds the production of content for all history before this year [1]! Consumer high bandwidth applications drive the need for inexpensive, removable memory, while high-performance military, industrial, and enterprise processing systems are investigating advanced optoelectronic devices and optical interconnections that will naturally interface with optical memories. Optical jukeboxes, for example, support enterprise-level storage-area networks (SAN), storing multiple terabytes in one system.

Sony and Phillips first developed optical media and players for the distribution of digital audio in the 1970s, building on laserdisc technology. The compact disc–digital audio (CD-DA or simply CD) was standardized in 1980 to provide a high-fidelity alternative to the conventional LP (long-playing) vinyl record. The computer industry quickly recognized that the CD, configured with stronger error correction as a data read-only memory (CD-ROM), allowed inexpensive distribution of large volumes of data [one CD-ROM holds about 450 HD (high-density) floppy disks]. In 1988 write-once optical memories CD-recordable (CD-R) allowed users to create small numbers of their own discs for storage, testing, or distribution. Fully rewritable systems [CD-rewritable (CD-RW)] followed in 1996, enabling removable optical RAM. Early CD-RW systems were much slower than comparable magnetic devices, but these problems have been largely overcome through higher rotation speeds and the availability of data compression.

DVD technology arrived in the late 1990s. DVD increased optical memory capacity and data transfer speed, making read-only optical memories suitable for full motion video and large data sets, such as high-resolution images. The 10-millionth DVD videoplayer was sold $3\frac{1}{2}$ years after introduction; it took 7 years to ship the 10-millionth CD audio player. Newer PCs increasingly have DVD drives, and DVD-R and DVD-RW units now entering the marketplace are providing high-capacity write-once and rewritable optical memories. Still in the laboratory are optical systems that further extend serial, disc-based optical memories, and new page-oriented optical systems based on holography. Such advanced systems seek capacities above 125 GB/disc and data transfer rates of 25 MBps (megabytes per second), about 25 times that of DVD. Figure 1 summarizes the growth of optical memory capacity.

Despite this success, optical memories face vigorous, application-dependent competition. Storage-area networks both compete with local removable optical memories and create demand for increased server memory. Magnetic tape and hard-disc systems promise significant improvements in capacity, data transfer rate, and access times [2]. Innovative data compression will also change the competitive memory scene, allowing tradeoffs among processor speeds, data transfer rate, and memory.

Optical memories are a specialized communications link (Fig. 2). The "transmitter" of an optical memory encodes, modulates, and writes digital data to the media "channel." Every media channel will introduce characteristic distortion, errors, and noise whose characteristics are determined by the interaction of the optical writing and reading systems with the storage medium. The "receiver" actively probes the channel to create a read data signal, which is detected and decoded to recreate the user's stored data. An important distinction is that stored data can remain "in the channel" indefinitely through the physical modification of the media during writing. The read system recovers stored data when a read beam interacts with the modified media, and experiences modulation of phase, amplitude, polarization, or frequency. The channel media can age, suffer abuse, or simply deteriorate from many cycles of the storage process. Channel characteristics also depend on the performance of control systems for maintaining rotation speed, tracking and focusing.

2. DISC-BASED SERIAL MEMORIES

This section discusses the general characteristics of available optical memories [3]. Commercial optical memories store data as an encoded serial binary bitstream on a

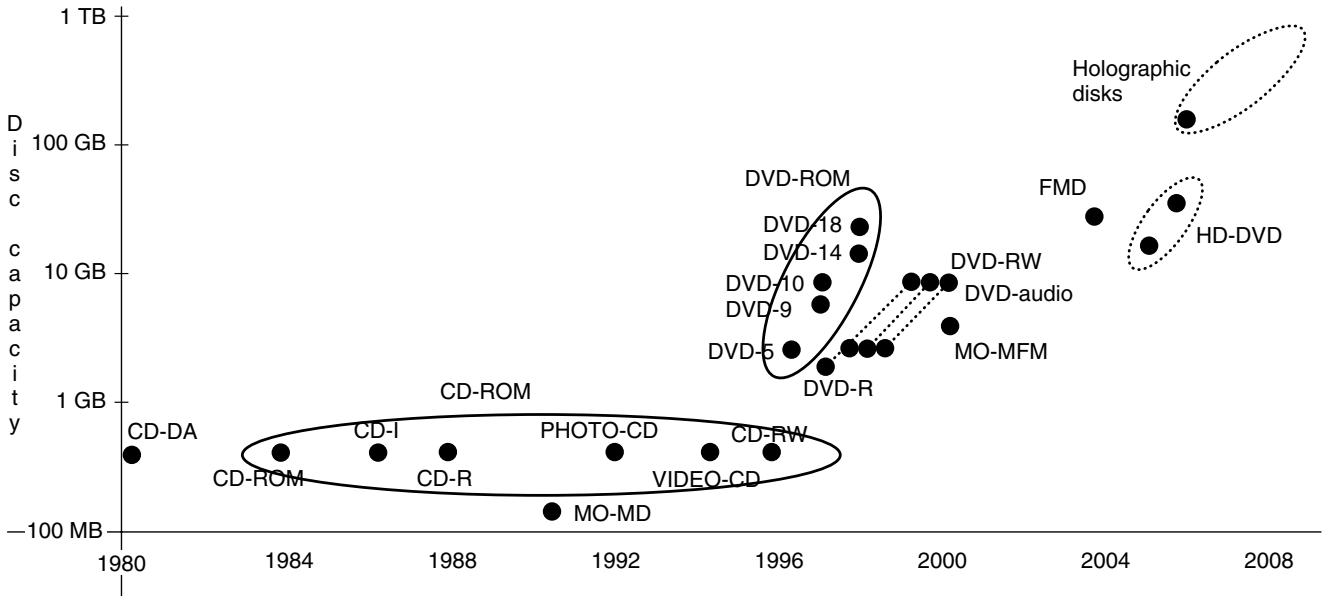

Figure 1. Evolution of optical memory capacity. Media and head constraints dictated initial CD-ROM capacity while different application formats evolved. DVD laser improvements enabled most of the 1990s increase in single layer systems, while disc capacities grew with multilayers. Continued growth will come from blue lasers in high-density DVD, fluorescent multilayers (FMD), and holographic discs. Other approaches are less established.

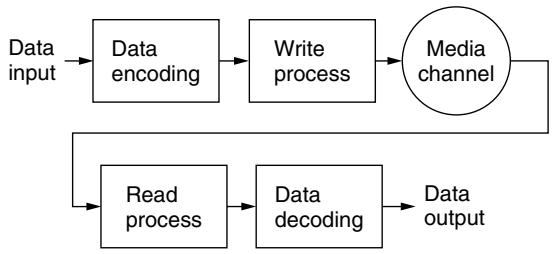

Figure 2. Block diagram of an optical memory. Optical memories are a form of communications link where the data reside in the media channel. User data undergo error coding and is organized into blocks and directories to produce a datastream that drives the write process. The "media channel" stores the data as an imperfect modulation of some property of the media. Readout recovers the media data, but with noise, bursty data loss, crosstalk, and other problems. Data decoding removes overhead, performs error checking, and regenerates the original data.

disc with one or more storage layers, accessible from one or both sides. Disc-based memories are standardized to a 120-mm-diameter disc, although minidiscs (80 mm), card discs, and other formats are specified under published standards.

CD-ROM and DVD-ROM media are mastered and injection molded. First a laser records data as exposed marks in photoresist spun on a polished glass substrate. When developed, the photoresist has holes where the data were written. Next, a conductive conformal nickel layer is deposited and thickened by electroforming to become the "father" stamper, from which "mother" and "daughter" stampers are produced. A daughter stamper is mounted in an injection molding system which is filled with molten polycarbonate under high pressure to form the final CD or DVD substrate. Injection molding takes about 10 s per disc; about 3000 CDs can be produced from one stamper. A reflective metallization layer, usually aluminum, is sputtered onto the molded substrate. Finally, a protective lacquer coating and screen printing or labels are applied.

Recordable and rewritable discs are more complex, with a mastered spiral tracking groove that usually has header marks, focusing marks, and even laser power calibration areas. Grooves sometimes have a deliberate mechanical timing wobble in their walls. An active layer stores the data by absorbing energy from the write beam and changing in some manner [4]. A reflective layer and possibly a complex optical stack enhance the active layer.

CD-ROM standards proliferated as optical memories attracted new applications that required better error control, storage of mixed media, management of multiple sessions, and extended capacities. All CD-ROMs have physical leadin and leadout areas to identify the start and end of data, and use physical data sectors of 2352 bytes, read at 75 sectors per second in a single-speed ($1\times$) drive. Different CD-ROM standards distinguish how the 2352 bytes are allocated to data, synchronization, headers, error detection, and error correction. Some standards require that entire discs must be written at one time, while others allow multiple sessions. Generally, data must be organized to meet all disc and data sector formatting requirements, and recorded without gaps (buffer underflow).

Data must be error encoded and framed to be reliable. Disc mastering has unavoidable defect rates of 10^{-4} or 10^{-5} while surface contamination often destroys or

obscures many adjacent marks. To combat these burst errors, interleaving and Reed–Solomon encoding are used. In CD audio, for example, stereo 16-bit samples are taken at 44.1 kHz, making four 8-bit symbols. A shortened Reed–Solomon (28,24) code operates on a frame of six stereo samples, or 24 8-bit symbols. The 28 output symbols are interleaved and encoded by a (32,28) Reed–Solomon code. Those 32 symbols are regrouped in even–odd groupings, extended by 8 bits for control and display, and then modulation encoded as "eight-to-fourteen modulation" (EFM), with 3 merge bits. This run-length encoding makes optical pickup and timing more reliable. An additional 27 synchronization and merging bits are then added, such that the initial frame of 192 user bits is expanded to 588 encoded bits; 32 such frames form one physical sector.

Encoded and run-length modulated data drive the laser that exposes the photoresist or modifies the active layer in a recordable medium. When read, the medium modulates the amplitude, polarization, or phase of the read beam. Frequency modulation, while possible, is not yet competitive. CD-ROM and CD-R modulate net reflectivity at the disc surface, changing read beam intensity by controlling diffraction from the physical relief of the mastered data pits or controlling the reflectivity of recordable dye materials. CD-RW switches a phase change material between crystalline and amorphous states, depending on its temperature rise under laser heating and subsequent cooling. Having different reflectivities, these amorphous and crystalline states are read as amplitude modulated data. In magnetooptical discs, thermomagnetic laser writing modifies the magnetic state of certain amorphous thin films. Read beam polarization is rotated by the magnetic state, recreating the stored data modulation.

Optical memory access time, the sum of track seek time, drive settling time, and track latency, is relatively slow. An optical head is complex (Fig. 3) and slow to accelerate. Constant-linear-velocity (CLV) drives must adjust rotation speed for each seek. For a 1× DVD, with constant linear velocity of 3.8 m/s, rpm (revolutions per minute) changes from 574 rpm at the outermost track to 1528 rpm at the innermost track. Access times are not greatly improved by higher disc speeds, but greater linear velocity improves data transfer rate. CD-ROMs are read at about 1.41 Mbps (megabits per second) (1×) while 1× DVDs have a user rate of 11.08 Mbps. Optical memories using zoned linear velocity (ZLV) eliminate settling time during localized head movements. Some advanced DVD drives, mimicking magnetic drives, use constant angular velocity (CAV).

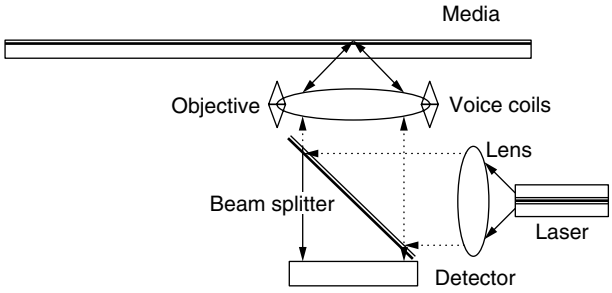

Figure 3. Schematic of a CD head. The laser diode emits elliptical light that is circularized and collimated by a lens. A thin plate directs the beam to the objective lens for focusing through the substrate and onto the pits, just below the lacquer layer. Reflected light, modulated by the effective surface reflectivity, is directed to a detector which reads the data and also senses tracking and focusing servo signals. Voice coils on the objective allow fine pitch tracking and focusing while the entire head moves for coarse tracking.

Optical memories have good lifetime and reliability. Heads fly millimeters above the media, avoiding catastrophic head crashes, while accelerated life testing predicts a shelf life of decades for aluminum-sputtered (silver) ROM media, and longer for gold media. Recordable and rewritable media have projected shelf lives of about 100 years. Mechanical handling damage is a concern, but most contamination is a minor problem because surface contaminants are out of focus. CDs can correct up to about 500 bytes (a 2.4-mm scratch); DVDs can correct about 2800 bytes (a 6-mm scratch).

The compact-laser diode "optical stylus" enables the high capacity of optical memories. A laser beam of wavelength λ in optics with numeric aperture NA can be focused to a diffraction-limited spot diameter [5] of $0.6\,\lambda/\mathrm{NA}$ and depth of focus $0.8\,\lambda/\mathrm{NA}^2$. Typical CD semiconductor infrared diodes have $\lambda = 780$ nm, and head $\mathrm{NA} = 0.5$, giving a full-width, half-maximum (FWHM) spot diameter of about 0.9 μm, and a depth of focus of 2.5 μm. Focus, track wobble, and disc runout pose demanding requirements for disc control servos at these dimensions. Table 1 compares existing disc memories.

3. COMPACT DISCS

3.1. Plain CDs

Compact discs remain the most common optical memories. CDs have mastered marks that are about 0.6 μm wide and from 0.83 to 1.7 μm long. Data are encoded in a non-return-to-zero-inverted (NRZI) format, so 1s (ones) occur at both

Table 1. Comparison of Commercial Optical Memories[a]

Type	CD-ROM	DVD-ROM	DVD-RAM	DVD-R	DVD-RW	MO
Capacity (GB)	0.68	4.7–17.1	4.7 or 9.4	4.7 or 9.4	4.7 or 9.4	2.6
Transfer rate (Mbps)	1.23	11.08	22.16	11.08	11.08	31.2
Rewrite Cycles	NA	NA	>100,000	NA	>1000	>1,000,000

[a]Transfer rates are for single speed drives. CD-ROM 40× drives can deliver up to Mbps transfer rate under constant angular velocity readout. DVD capacity ranges depend on layers in the media. Rewrite cycles are ultimately limited by thermally induced degradation of the active media layer. GB = 10^9 bytes.

edges of marks and 0s are clocked within marks and on the intervening lands. Marks, called "pits" because they are about 130 nm below the surface of the surrounding land, are approximately $\lambda/4$ deep for a 780-nm read laser in polycarbonate ($n = 1.58$). A diffraction pattern arises when the read beam overlaps a pit and its adjacent land regions (Fig. 4). Some diffracted modes do not reenter the read lens, so reading over a pit returns less light than a flat land area.

CD digital audio established the basis for the CD product family. CD-DA can hold up to 74 min of audio, played at 150 kbps, and organized in up to 99 "tracks" per disc. One continuous spiral of data is written. A single directory area after leadin locates tracks on the spiral. Multiple recording sessions or incremental writes are not possible.

The *Red Book* standard (ISO 10149) specifies CD formats [6,7]. Both level 0 (physical layer) and level 1 (sector and track formatting) specifications are given. Level 0 requires cross-interleaved Reed–Solomon code (CIRC) for error correction and EFM for establishing a (2,10) run-length-limited (RLL) disc format. RLL encoding improves mark edge detection, synchronization, and frequency management in playback.

3.2. CD-ROMs

The *Yellow Book* standard established CD-ROM. The CD-ROM sector provides 2048 data bytes (compatible with computer data structures), and uses the rest of the standard sector for additional error correction (mode 1 CD-ROM). The Yellow Book standard also specifies logical sector and logical file organization, and allows retention of a Red Book audio region with CIRC error correction on the disc (mode 2 CD-ROM). Mode 2 access times were slow, as players moved between computer applications (video clips) and the accompanying audio, in later sectors, making multimedia applications unsatisfactory. Mode 1 Yellow Book CD-ROMs can store computer data, compressed audio, and compressed video, and have stronger error correction than mode 2. A Yellow Book extension for multimedia, CD-ROM XA (extended architecture), stores compressed audio (adaptive differential PCM, ADPCM) close to the multimedia sectors to allow smooth access to images and sound. This also allows efficient compressed audio storage. Up to 18 h of monaural sound can be stored on one CD-ROM XA.

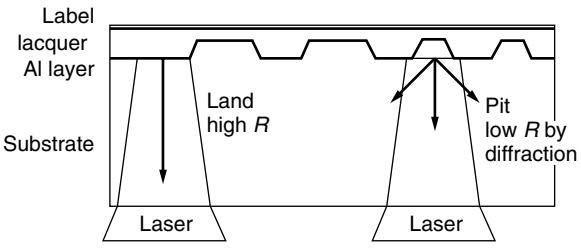

Figure 4. CD disc diffraction structure. As the laser read beam focuses on the flat land, most light is reflected back to the detector by the aluminum layer. Pits and their adjacent off-track land diffract the laser beam away from the objective, yielding a lower effective reflectivity. Polycarbonate substrates are 1.2 mm thick, while pits are only 130 nm deep, and lie just below the top surface.

Specialized standards evolved as CD-ROM was expanded into more demanding applications. The *Green Book* standard addressed efficient storage and access of a mix of data types, primarily for set-top interactive devices, such as Phillips Compact Disc Interactive (CD-I). The same track holds different data types, with each sector having a field that identifies its data type. For example, four levels of sound, from Red Book "CD quality" to various ADPCM levels of quality can be mixed with video, MPEG 1 and 2, and still pictures. CD-I has not made much market impact, and DVD is making the Green Book standard obsolete. The *White Book* standard addresses video CD (CD-V), CD-I, and PhotoCD exchange. While CD-V has been successful in China, Japan, and parts of Europe, it has had little impact in North America and is being replaced by DVD. PhotoCD is evolving its own hybrid standard from the Green Book and Orange Book standards.

The ISO 9660 standard, which evolved from the High Sierra File (HSF) format, addresses file structure and naming problems arising in cross-platform CD-ROM compatibility. ISO 9660 provides a common file structure to CD-ROM developers and is now used by most CD-ROM, CD-R, and CD-RW systems to convert the raw sector data to files, directories, and volumes. There continue to be modifications to the ISO 9660 standard, including Universal Disc Format (UDF) [8] for DVDs and UDF Bridge, which gives backward compatibility to ISO 9660 for readers that accept CD-ROM and DVD.

3.3. CD-R Media

CD-R media, initially called *CD write-once* (CD-WO) or *write-once read-many* (WORM) media, support permanent recording of a single CD. CD-R allows inexpensive, removable, archival optical memory, suitable for limited distribution of applications, images, video, audio, or data, testing of CDs before mass replication and mastering of data images for sending to a disc replicator. CD-R media store up to 650 MB of data and are compatible with all more recent drives under ISO 9660. Data must be streamed continuously throughout each session recording, or the directory information will be incorrect or missing. CD-R is not erasable, so errors in recording cannot be corrected. Typically an image of a complete session is created in a hard-drive partition or on another CD-R. Data buffering gives some security against short interruptions during writing.

On the physical layer, CD-R discs have an active dye layer of cyanine (greenish), phthalocyanine (gold-green), or metal azo (blue) between the polycarbonate substrate and the reflective metallic layer. During writing the dyes absorb heat under the laser spot and permanently change their local reflectivity. Dyes are designed to give high reflectivity change, high speed of response, good consistency, and long shelf life. Early ablative WORM recording thermally vaporized pits in a thin surface metallic film, giving us the term "burning" a CD. Some drive manufacturers wobble the mastered tracking groove to produce extended capacity CD-R discs storing about 700 MB, but these may not be compatible on playback

with all drives. Poor quality dyes on low-cost media may also prevent drives from reading CD-R discs.

The *Orange Book* standard specifies how the various CD application standards should be written onto recordable media, including not only CD-R but also CD-RW and magnetooptic (CD-MO and MO). Orange Book Part I discusses MO systems; Part II describes recording on CD-R, CD-WO and WORM devices; Part III discusses CD-RW. The Orange Book standard defines multisession recording, specifically how data should be stored in the data sectors, where track, session, and directory data are located, how disc and session lead-in and leadout are handled, and where write laser calibration regions occur. Each session of recording requires about 13 MB of overhead for its leadin/leadout and directory areas.

3.4. CD-RW

Rewritable CD-ROM, CD-RW, is the most versatile form of CD optical memory, allowing archiving, testing, distribution, and mastering for replication like the CD-R, with the addition of erasability. The physical data recording process, and the organization of the disc differ from CD-R, and drive requirements are more stringent.

CD-RW media have a polycarbonate substrate, with a mastered pregrooved spiral track. An optical stack manages heat absorption and diffusion during writing and facilitates reflectivity-based readout. The active layer is a metallic semiconductor, usually GST ($Ge_2Sb_{2.3}Te_5$), or AIST (AgInSbTe). These switch from a crystalline state to an amorphous state when the film is heated above its melt temperature. A weaker laser pulse, reaching only the glass transition temperature, returns an amorphous region to crystalline. Since these states have different reflectivity, marks can be written. CD-RW can perform direct overwrite (DOW), allowing faster data transfers. Phase change reflectivity signals are weaker than CD-ROM or CD-R signals, so older drives cannot read CD-RW media. Newer multiread drives have automatic gain control to adjust laser power to CD-RW signals.

In addition to Orange Book requirements, the Universal Disc Format packet writing scheme can be used to give CD-RW compatibility with DVD players. Under UDF, CD-RW discs must be formatted with logical sectors, a process that takes up to 30 min. Preformatted CD-RW media are entering the market. Depending on formatting, a CD-RW contains from 650 MB to 535 MB of user data. CD-RW phase change materials suffer from limited cycle lifetimes. CD-RW media must support at least 1000 write–read cycles; some media manufacturers claim 10,000 cycles.

4. DVD

DVD-ROM is the baseline digital data storage standard for all DVD applications, including DVD video and DVD audio [9]. Unlike CDs, where computer data standards evolved from the audio Red Book, DVDs were designed from the beginning for data memory use. DVD-ROM media store their data as pits that modulate readout intensity, similar to CDs.

Several engineering improvements increase bit density from about 480 Mb/in.^{2} (megabits per square inch) on CDs to over 2.2 Gb/in.^{2} on single-layer DVDs. Marks can be made smaller and closer because a higher NA (0.6), and a red (635-nm) laser yield a smaller diffraction-limited spot ($\approx$0.6 μm). The DVD spiraling data pattern is also more compact, with track pitch 0.74 μm and minimum mark spacing 0.4 μm. A DVD-5, which is a one-sided, one-layer DVD, holds approximately 7 times the capacity of a CD-ROM.

The second innovation of the DVD family is multilayered memory. DVD-ROMs are made from two 0.6-mm injection-molded polycarbonate discs, which are bonded together. Individual single-layer discs are mastered much like CDs. A single-sided disc has a data-bearing disc bonded with a spacer disc. For two-layer storage, two one-sided discs can be bonded, or two layers can be fabricated on one disc, which is then bonded with a spacer disc. In a single-sided two-layer disc, the first layer is injection-molded and covered with a semitransparent reflective layer. A second layer is bonded above the reflective layer, stamped with its own data, and coated with a full reflection layer. Two such 0.6-mm discs can be bonded to make a four-layer DVD (Fig. 5). During reading and writing the laser must focus on the appropriate layer. On a two-layer structure, the laser must read through the top layer of data to the deeper second layer, an additional distance of 55 μm. Two-sided discs must be flipped over or have two heads.

DVDs are defined by a set of application standards, also called "books," maintained by an industry consortium. The standards have not had the wide formal review of a standards organization like ISO/IEC, but nonetheless facilitate the spread of compatible media and players. The entire DVD family is based on the DVD-ROM (Book A), which supports computer applications. DVD-Video (Book B), DVD-Audio (Book C), DVD recordable (DVD-R, Book D), and DVD-rewritable (DVD-RAM, Book E) build on the Book A standard. The consortium (Hitachi, Ltd., Matsushita Electric Industrial Co., Ltd., Mitsubishi Electric Corporation, Phillips Electronics N.V., Pioneer Electronics Corporation, Sony Corporation, Thomson Multimedia, Time-Warner Inc., Toshiba Corporation, Victor Company of Japan, Ltd.) has established a

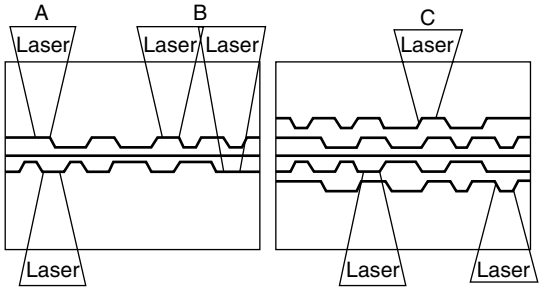

Figure 5. DVD disc structures. Two 0.6 mm CD-like discs are bonded together. A one-sided DVD (not shown) bonds a data disc to a blank substrate. Two-layered DVDs usually bond two data discs, and must be read from two sides (A). Careful reflectivity control allows two-layered DVDs that are read from one side only (B). If two, two-layered discs are bonded together, a four-layered DVD results. These require precise reflectivity control and two-sided reading (C).

jointly owned company (DVD Format/Logo Licensing Corporation) to license DVD formats and logos to third parties and to distribute the DVD Format Books [10].

DVD data are always organized in sectors of 2064 bytes, of which 2048 are data and the rest overhead for addressing, error correction, and copy protection. A combination of 16 byte Reed–Solomon code for the data columns and a 10 byte inner Reed–Solomon code for the rows are used. An $\frac{8}{16}$ run-length modulation is used to generate an acceptable physical sector (4836 bytes), and NRZI transitions produce the actual pit pattern on the disc.

4.1. DVD ROM

The simplest DVD-ROM is the DVD-5, which has a single-layer mastered disc and a blank spacer disc. It is read from one side, at one depth, and has the usual lacquer covering and printed label. Capacity is 4.7 GB per disc. A DVD-9 has two single-layer discs, but is read from one side only. DVD-9 capacity is 8.5 GB. DVD-10 has two single-side discs, each with fully reflective coatings. DVD-10 is read from both sides, and holds 9.4 GB. DVD-18 has two double-layer 0.6-mm discs, each with both partial and full reflection coating, and is read from both sides. Capacity is 17.1 GB. Raw bit densities for all DVD formats remain at about 2.2 Gb/in.^{2}.

A proliferation of DVD applications has created problems with compatibility among DVD memories. DVDs most often use the UDF file system and ISO 9660 file system. As data storage media, they could use other file systems, but this would increase the possibility of drive–media incompatibilities. The DVD Forum has created many application formats, and not all players support all formats. The MultiRead and MultiRead 2 specifications of the Optical Storage Technology Association, and the Multi logo of the DVD Format/Logo Licensing Corporation guarantee that drives will read certain classes of DVDs (and CDs).

4.2. DVD Application Standards

Application standards build on the physical layer specifications of DVD-ROM, file structures such as UDF and ISO 9660, and their extensions. DVD video is an application standard that delivers video, high-performance audio, presentation control information (PCI), and data search information (DSI). DVD video is supported worldwide by computer makers, movie studios, and content publishers. Typical data rates are about 4.7 Mbps, while peak application data rates are over 10 Mbps.

The basic DVD-ROM can accept a variety of video and audio streams, including MPEG-1 and MPEG-2 video, and MPEG-1, MPEG-2, PCM, and Dolby Digital audio, with playing times from one to 13 hours for DVD-5. DVD video media and players should conform to the UDF standard or to the MicroUDF format, which places additional constraints on file structures to simplify consumer electronics.

DVD video supports MPEG-2 video, a choice of multichannel audio formats, and extensive supplemental materials. Players output analog NTSC and PAL, digital interfaces for S-video and HDTV, and different video aspect ratios and display formats.

DVD audio shares many features with DVD video, including storing video and still pictures to accompany audio tracks. This has spawned multiple players, including DVD audio/video, video-capable audio players, and audio-only players. Audio is stored with linear PCM at 16, 20, or 24 bits/sample, with sampling frequency ranging from 44.1 to 192 kHz. Lossy and lossless compression are allowed in the specifications.

The market for DVD-ROM is led by DVD-5, with about 78% of disc releases. DVD-9 and DVD-10 each have about 10% of the total, while DVD-18 has been well under 1%. Almost all these releases have been video titles or games. Player sales rapidly in 2001, and may soon surpass VCR sales.

4.3. Recordable DVD Media

Recordable DVD-R media and players with 4.37-GB capacity began appearing widely in late 2000. The Book E standard is split into DVD-R(A) for authoring and DVD-R(G) for general or home use. These differ in laser wavelengths and land prepit addressing schemes. DVD-R(A) is single-sided, while DVD-R(G) is two-sided and must be flipped over to access both sides. Like CD-R, both DVD-R discs record data permanently by modifying a dye layer, and can support both disc-at-once and session recording. Multilayer DVD-R is not available. DVD-R cannot be erased.

Three rewritable versions of DVD are competing: DVD–RW, DVD–RAM, and DVD+RW. All use phase change materials and support 4.37-GB capacity. +RW and –RW can be rewritten about 1000 times before the phase change materials become unreliable, while RAM, which uses random shifts of the starting write position to reduce media stress, are supposed to withstand up to 100,000 rewrites. RAM and +RW use cartridges, while –RW is usually a bare disc.

DVD-RAM (random-access memory) is the closest product to a fully rerecordable optical memory, and has several technical innovations compared to other DVD rewritable systems. Its data transfer rate is 22.16 Mbps, equivalent to an 18× CD, and marks are recorded both in the land and in the premastered grooves. Zoned linear velocity is used to give good access times. A defect management scheme allows control of manufacturing and formatting defects for more reliable recording.

Rewritable media use *content protection for recordable media* (CPRM) to prevent content theft through unauthorized duplication of DVDs, a major concern of video content suppliers. CPRM places a unique 64-bit media ID in the substrate within the burst cutting area, a band just outside the clamping diameter. The media ID is used to encrypt and decrypt the disc data, such that a rerecorded disc, lacking the media ID, will be unplayable. Other security schemes are being pursued.

5. MAGNETOOPTIC DISCS

Magnetooptic discs offer rewritable, removable, high-capacity optical memory [11,12]. MO media have a shelf life projected to be over 100 years, do not require a

cartridge, and have been rewritten over a million times without losing reliability. One product, the Sony MiniDisc, has been moderately successful, but overall MO discs have not had a widespread market impact on optical memories. MO media and players have been significant in niche markets where high capacity, removability, and long archival lifetimes are important. For most applications MO memories face strong competition from improving magnetic drives and now DVD recordable media.

MO media record in an active layer containing a rare-earth transition metal amorphous alloy, such as TbFeCo, whose magnetic spins prefer to align perpendicularly to the film surface. During thermomagnetic writing, a high-power laser spot heats the active layer to about 250 °C. This elevated temperature reduces the film's magnetic coercivity, allowing a bias field of a few hundred oersted to flip the magnetization. On cooling, the reversed domain persists, creating a mark. Track pitch is typically 1.6 μm, and error-correction coding is similar to CD systems. Run-length encoding of data is used to enhance the readability of the magnetic marks. The MO layer is usually in an optical stack to enhance laser coupling to the metal. A reflective and heat-absorbing layer lies under the stack.

An alternate writing scheme uses magnetooptic magnetic field modulation (MO-MFM) to create domains in a continuously heated stripe under the moving laser beam. This can give higher along-track densities than laser power modulation, but is limited by the dynamics of the biasing magnet.

Readout uses the Kerr effect, in which the polarization of a laser read beam is rotated by the magnetic state of the film. Kerr effect rotation is less than one degree between mark and land, so a differential detection system is needed, with two detectors and polarizing elements in the head. This more complex head, and the bias magnet, require careful design if access speeds are to be maintained. Direct overwrite has also been difficult to achieve, although ingenious use of magnetic multilayers and careful control of pulse power and duration have demonstrated direct overwrite.

Preformatted grooves, including synchronization and header marks, are used to guide the writing and reading processes. The grooves are similar to CD and DVD pregrooves, and create a push–pull tracking and focusing signal. MO capacities are similar to DVD-5, but discs are typically 133 mm. The Orange Book standard applies to commercial MO media.

6. ADVANCED DISC MEMORIES

Near-term improvements in disc-based optical memories will require writing smaller marks to increase areal density, and better focusing and tracking to allow more layers. Several technologies are under development and show strong promise of continuing improvement in capacity and data transfer rate.

6.1. Blue-Violet Lasers

Blue laser diodes, at about $\lambda = 400$ nm, allow increased areal densities in phase change and MO media to over 6 Gb/in.^{2} or 15 GB per disc. Systems for mastering blue laser DVDs are available, but reasonably priced and reliable players must wait for improved blue semiconductor laser diodes. Research in this area is represented by Kondo et al. [13], who report a test on a 19.8-GB single-layer disc, mastered with a 351-nm krypton ion laser, and read with a blue-violet 405-nm laser diode (NA 0.70). Partial-response maximum-likelihood encoding and Viterbi decoding were used.

6.2. Solid Immersion Lens Technologies

Near-field optics [14] optically reduce the size of the coupled spot on the media. Solid immersion lens (SIL) heads incorporate a hemispherical lens that is cut or polished to give an effective NA well above 1.0. A conventional objective lens focuses onto the SIL, which couples a subwavelength spot to the surface. The major drawback is that the SIL must fly above the disc at a height less than 40–80 nm, similar to the flying height of a magnetic head. This compromises removability and robustness of the media head system. Areal density of 50 GB per disc and data transfer of 20 Mbps have been claimed; tracking control remains a problem.

6.3. Novel Laser Configurations

New structures for lasers and new laser-media configurations offer the possibility of higher capacities and data transfer rates. Vertical cavity surface-emitting lasers (VCSELs) are inexpensively manufactured in arrays. Present power levels and wavelengths are not impressive for optical memories, but their array structures suggest the possibility of highly parallel reading and writing. Novel apertured lasers are coated at their front facet, and small apertures are then ion-milled to release a near-field beam smaller than the wavelength. Flying close to the disc, these lasers write and read with a subdiffraction limit spot. A laser-media scheme by Aikio and Howe [15] uses the media itself as part of an external cavity to the read laser. As surface reflectivity is modulated by the data, the reflected light returning to the laser cavity varies and modifies the laser output power. Power can be monitored from the rear facet photodetector common on laser diodes.

6.4. Fluorescent Discs

Frequency multiplexing in the same media volume is possible if the read beam stimulates emission at different wavelengths. This concept underlies the fluorescent multilayered disc (FMD). Many thin active layers would be deposited on a single disc (structures with up to 500 layers have been proposed). With adequate focusing control a small band of layers could be excited by the read beam. If these layers fluoresced at different wavelengths, then one single layer could be filtered and read. A continuing AFOSR project has reported successful design of the head and detectors for this system [16,17].

6.5. Advanced Magnetooptic Systems

SIL near-field optics apply to MO systems, and can be combined with magnetic field modulation and superresolution

multilayered magnetic media to attain extremely high densities. The possibility of MO writing up to 100 Gb/in.^{2} has been claimed with these combined methods [18]. Using just magnetic superresolution with blue lasers has yielded 11 Gb/in.^{2} or 15 GB per disc.

7. HOLOGRAPHIC OPTICAL MEMORIES

After over four decades of effort, holographic memories have shown significant progress recently with impressive laboratory capacities and data rates [19,20]. These demonstrations, while not yet yielding commercial products, have benefited from improved enabling technologies [lasers, spatial light modulators, and CCD (charge-coupled device) cameras] and novel storage media. Holographic memories promise capacities of 125 GB per disc, data rates of 1–10 Gbps, and rapid access times. As a volumetric storage method, their capacities will grow as $1/\lambda^3$ when laser wavelengths get shorter, rather than as $1/\lambda^2$ for surface methods. Both stationary solid media and disc-based media are under study.

Holographic memories store information in a thick photosensitive medium as a phase modulation pattern (hologram) created by the interference of two coherent laser beams: a reference beam and the object or data beam (Fig. 6). The interference pattern of the two beams, captured by changes in the absorption, index of refraction or thickness of the photosensitive medium, can later be probed with a replica of the reference beam. An incident reference beam will be diffracted by the phase pattern to recreate the original data beam, traveling forward as that beam had originally done. It also creates a phase-conjugate beam that travels back toward the original data beam source. This allows reuse of the high-quality writing optics during readout.

Writing is not done bit-by-bit, but rather with a 2-D pattern of data, a page image, typically created by a spatial light modulator (SLM) similar to a LCD display.

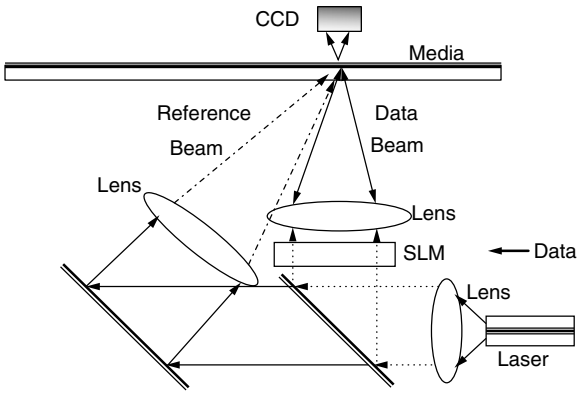

Figure 6. Schematic of a holographic disc system. The laser emits a beam that is collimated and split. One path goes through a spatial light modulator (SLM) that carries a data page, spatially modulating the beam. The second beam is directed as a reference beam. The beams interfere in the disc media creating a hologram indexed by the reference beam angle. On readout the reference beam creates a transmitted beam that is read as a page on the CCD device.

The recreated page image beam can be read by any 2-D array of detectors, e.g., a CCD camera. Multiple pages can be written in the same medium, since individual gratings can be distinguished by multiplexing the incident angle or tuning the laser to another wavelength. Focusing of the beams localizes the holographic patterns in the media. Theoretical capacities depend on the storage media, but exceed 100 Tb/in^3. Considerable technical problems must be overcome to make robust commercial systems based on holography. DARPA has supported the Photo Refractive Information Storage Materials (PRISM) consortium and the Holographic Data Storage System (HDSS) consortium to explore these problems and some progress was demonstrated, including 10 Gb/s data transfer rate [21]. An important tradeoff exists between data transfer rate and media storage density in holographic materials with fixed dynamic range.

Moving a laser probe beam is relatively simple compared to moving a massive read head. Access speeds could therefore be better in holographic memories. Since data is read a page at a time, and since multiple independent probe beams can be read at the same time, aggregate data rates also could be high. Finally, holographic memories offer an associative memory capability that is not possible with any other storage method. When the medium is probed with a search pattern (a *partial* replica of a desired data beam), reconstructed source beams will be created. Each will have intensity proportional to the overlap of their image with the search image. By reading the most intense beam's location with a reference beam, the original data page can be reconstructed.

BIOGRAPHY

Michael F. Ruane received his B.E.E. in 1969 from Villanova University, Villanova, Pennsylvania, and the S.M.E.E. and Ph.D. (Systems) from Massachusetts Institute of Technology, Cambridge, Massachusetts, in 1971 and 1980, respectively. He was a staff member at the MIT Energy Laboratory from 1971 until 1976, and joined Boston University, Boston, Massachusetts in the Electrical and Computer Engineering Department in 1980. At BU he was one of the developers of the Photonics Center, where he maintains the Magnetic and Optical Devices Laboratory, and is also the BU education coordinator for the Center for Subsurface Sensing and Imaging System (CenSSIS). His laboratory studies data storage media and systems, and has contributed to magneto-optical devices, phase change media, disc mastering, and conventional magnetic media. Dr. Ruane has two patents in ellipsometry for optically active media. His areas of interest are in optical systems, the optical storage channel, micromagnetic modeling, and image processing.

OPTICAL MODULATORS — LITHIUM NIOBATE

RANGARAJ MADABHUSHI
Agere Systems, Optical Core Networks Division
Breinigsville, Pennsylvania

1. INTRODUCTION

With the advent of the laser, a great interest in communication, at the optical frequencies, was created. A new era of optical communication was launched in 1970, when an optical fiber, having 20 dB/km attenuation, was fabricated at the Corning Glass Works. Dr. Kaminow and a team from Bell labs reported the concept of electrooptic light modulators [1]. At the same time, Miller [2] coined the term "integrated optics" and heralded the beginning of various efforts in a number of optical components including light sources, waveguide devices, and detectors. The demand for fiberoptic telecommunication systems and larger bandwidth requirements, has increased tremendously since the early 1990s, with the advent of time-division multiplexing (TDM) and wavelength-division multiplexing (WDM) systems. In these systems, the transmitter part basically consists of a laser, which provides the coherent optical (light)wave and the modulator (either external or the direct modulation of lasers), where the desired signal is modulated and is placed on the coherent lightwave.

The direct modulation of lasers is limited by the achievable bandwidth, chirp, or dispersion and the ability to be transmitted to longer distances. The advantages, for short-distance transmission applications include small device size and cost-effectiveness. On the other hand, external modulators are bulky and costly and increase the system requirements. But the advantages, such as large bandwidths and capability to propagate long distances, make these external modulators the winners in optical communication systems. The external modulators include

devices made of dielectric crystals, such as lithium niobate and lithium tantalite; semiconductors such as GaAs, InP, and InGaAs; and polymers such as PMMA. The lithium niobate–based modulators have the advantages of large bandwidth capabilities, low chirp characteristics, low insertion loss, better reliability, and improved manufacturing capabilities. The disadvantages include higher driving voltages, large size of the device, and high cost. The semiconductor modulators have the advantages of smaller size, low driving voltages, relatively low cost (for large volumes), and compatibility of future integration with other semiconductor devices. The disadvantages include large insertion loss, smaller transmission distances, chirp, and manufacturing yields. The polymers are just emerging, and although they can achieve large bandwidths and low driving voltages, the long-term reliability is still being investigated. The $LiNbO_3$ modulator technology, which started in late 1960s, advanced in terms of the material properties, fabrication process, and various modulation schemes in all these years [3–9]. Here, the lithium niobate external modulators are discussed.

1.1. Optical Modulation

It is possible to realize various optical devices, by controlling externally, the lightwave propagating in the optical waveguide. Optical modulators are the devices made of optical waveguides on some material with special properties, where the information is placed on the lightwave externally by imposing time-varying change on the lightwave. The information content is then related to the bandwidth of the imposed variation. Similarly, switches are devices that change the spatial location of the lightwave with respect to the switching signal. These modulators and switches are important components in most of the optical communication systems. The materials may have physical properties, such as electrooptic effect, acoustooptic effect, magnetooptic effect, and thermooptic effect [4].

The modulation types include intensity or amplitude modulation, phase modulation, frequency modulation, and polarization modulation. The intensity modulators are those in which the intensity or amplitude of the coherent lightwave varies according to a time-varying signal. In phase modulation, the phase of the lightwave responds to the applied signal. If the signal is time-varying, the phase change also varies with time. The amplitude of the first sideband and the carrier amplitude are related to the Bessel functions. In polarization modulation, using the electrooptic effect, the polarization states of the lightwave respond to the signal applied. In general, when there is no signal applied, the lightwave emerges as a linearly polarized light. The changes from linear to elliptical polarization, through the applied signal, are characteristics of polarization modulators that use the electrooptic effect. In case of magnetooptic polarization modulators, the light remains linearly polarized but rotated in directions as a function of the applied signal. These polarization modulators are usually used as switches. The last one is frequency modulation, in which the frequency or the wavelength is changed with the applied signal. The detection of such frequency shifts gives rise to more complicated heterodyne system applications.

1.2. Electrooptic Effect

The *electrooptic effect* is, in general, defined as the change of refractive index inside an optical waveguide in optical anisotropic crystals, when an external electric field is applied. If the refractive index changes linearly with the amplitude of the applied field, it is known as the *linear electrooptic effect* or the *Pockels effect*. This effect is the most widely used physical effect for the waveguide modulators. The details can be found in the existing literature [e.g., 4]. Some of the basic fundamentals are given here.

The linear change in the refractive index coefficients due to the applied electric field E_z is given by

$$\Delta n_o = 0.5 r_{13} n_o^3 E_z, \qquad \Delta n_e = 0.5 r_{33} n_e^3 E_z \tag{1}$$

where n_o is the ordinary refractive index, n_e is the extraordinary refractive index, and r_{ij} is the electrooptic constant. For $LiNbO_3$, $r_{33} = 30.8 \times 10^{-12}$ m/V, $r_{13} = 8.6 \times 10^{-12}$ m/V, $r_{22} = 3.4 \times 10^{-12}$ m/V, $r_{33} = 28.0 \times 10^{-12}$ m/V, $n_o = 2.2$, and $n_e = 2.15$ at $\lambda = 1.5$ μm.

2. BASIC STRUCTURE AND CHARACTERISTICS OF THE MODULATORS

In general, the Mach–Zehnder interferometer-type structure is used in the lithium niobate–based intensity modulators. The modulator basically consists of an input divider, an interferometer, and an output combiner. The input divider consists of a straight waveguide and an input Y-branch waveguide, which divides the incoming light into two parts. The interferometer consists of two arms, to which the signal can be applied in the form of voltage. The output combiner consists of an output Y-branch waveguide that combines the two waves from the interferometer arms and finally an output straight waveguide. When there is no signal/voltage applied ($V = 0$), the input wave (field) will be divided into two equal parts, E_A and E_B. At the interference arms they propagate with the same amplitude and phase and recombine at the output Y branch and propagate in the output waveguide without change in intensity (Fig. 1a).

When a voltage is applied, the two waves at the interferometer arms change the phase of the two waves and when the applied voltage, V, is equal to the voltage required, to achieve a π-phase shift, V_π, the output waves from the interferometer have the same amplitude, but a phase difference of π. The output light will become zero by destructive interference (Fig. 1b). For the values of the voltage between V and the V_π the output power varies as

$$P_{\text{out}} = 0.5\{(|E_A| - |E_B|)^2 + 2|E_A| \cdot |E_B| \cos^2 \Delta\varphi\} \tag{2}$$

$$= 0.5 P_{\text{in}} \cdot K_1 + K_2 \cos^2 \frac{\pi V}{2V_\pi} \tag{3}$$

where the phase shift is

$$2\Delta\varphi = \frac{\pi V}{V_\pi} \tag{4}$$

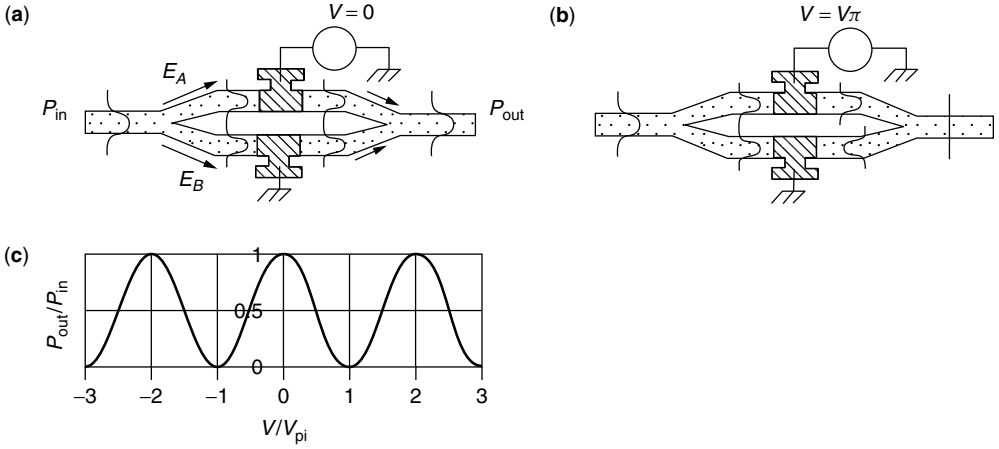

Figure 1. Basic principle of operation of a Mach–Zehnder-type optical modulator, (**a**) without, (**b**) with applied voltage; (**c**) the output intensity as a function of applied voltage.

Figure 1c shows the output intensity as the function of switching/driving voltage, which is represented by Eq. (3).

2.1. Driving Voltage

The change in the index as a function of voltage is

$$\Delta n(V) = \frac{n_e^3 r_{33} V \Gamma}{2G} \tag{5}$$

The phase difference in each arm of the interferometer will be φ, and as the voltage is applied on both arms, the push/pull effect can be used and the total phase difference will be 2φ, where

$$2\varphi = \frac{\pi V}{V_\pi}$$

The voltage length product is

$$V_\pi L = \frac{\lambda G}{2 n_e^3 r_{33} \Gamma} \tag{6}$$

where λ is the wavelength of operation (say, 1.5), n_e is the extraordinary refractive index of the $LiNbO_3$ waveguide (say, 2.15 at λ 1.5 μm), r_{33} is the electrooptic coefficient, 30.8×10^{-12} m/V, V is the voltage applied, Γ is the overlap integral between optical and electric (RF) fields (usually a value of 0.3–0.5), G is the gap between the electrodes, and L is the electrode length.

Depending on the crystal orientation (z-cut, x-cut, or y-cut), the electrodes configuration, whether the electrodes are placed on the waveguides or on the sides of the waveguide, will result in the use of vertical or horizontal fields (Fig. 2).

The overlap integral Γ is better for the z-cut modulator compared to that in the x-cutone. The driving voltage will be less in the case of the z-cut crystal orientation/vertical field, due to the large overlap factor. But there is a need to place a dielectric layer in between the electrode and the waveguides, to minimize the waveguide insertion loss for a TM mode propagation. This will increase the driving voltage. The parameters of the dielectric layer, usually the SiO_2 layer, can be used as a design parameter to achieve larger bandwidths.

2.2. Extinction Ratio and Insertion Loss

If I_o is the intensity at the output of the modulator, when no voltage is applied, $I_{\max}$ is the maximum intensity, and $I_{\min}$ is the minimum intensity when the voltage is applied, then the insertion loss is defined as

$$10 \log \frac{I_{\max}}{I_o} \tag{7}$$

and the extinction ratio (ER) is

$$10 \log \frac{I_{\min}}{I_{\max}}. \tag{8}$$

2.3. Chirp

In case of small-signal applications, the dynamic chirp $\alpha'(t)$ is the instantaneous ratio of the phase modulation to amplitude modulation of the transmitted signal and is expressed as

$$\alpha'(t) = \frac{\dfrac{d\Psi}{dt}}{\left[\left(\dfrac{1}{2I}\right)\left(\dfrac{dI}{dt}\right)\right]} \tag{9}$$

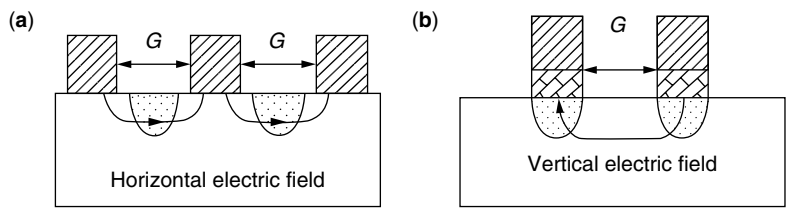

Figure 2. The normally used electrode configurations and the respective field conditions: (**a**) horizontal field used for the x- or y-cut crystal orientations; (**b**) vertical field used for the z-cut crystal orientation.

where Ψ and I are respectively the phase and intensity of the optical field and t denotes the time. In the case of the intensity modulator using the Mach–Zehnder type, the α' can be represented in a simplified form as

$$\alpha' \sim \frac{\Delta\beta_2 + \Delta\beta_1}{\Delta\beta_2 - \Delta\beta_1} = \frac{\Delta V_2 + \Delta V_1}{\Delta V_2 - \Delta V_1} \tag{10}$$

where $\Delta\beta_1$, $\Delta\beta_2$ are the electrooptically induced phase shifts and ΔV_1, ΔV_2 are the peak-to-peak applied voltages of the two arms of the interferometer. Although this expression can be applied in general to the small-signal region, it can also be applicable, to a large extent, for the large-signal region, due to the shape of the switching curve. Also, the value of α' can take minus $(-)$ or plus $(+)$ values, and the chirp can be used to the advantage, depending on the optical transmission system. For systems that operate away from the zero-dispersion wavelength region, and depending on the fiber used for transmission, a negative chirp can be advantageous to achieve low dispersion penalties [10]. In general, for a lithium niobate intensity modulator with a traveling-wave-type electrode, the value can be -0.7. Depending on the crystal orientation and the type of the electrode structure, the value can be zero or can be variable.

3. COMMON ELECTRODE STRUCTURES

A simple electrode structure, consisting of two symmetric electrodes on both interferometer waveguides, otherwise known as "lumped" electrode structure, is shown in Fig. 3a. As the bandwidth, in this case, is limited by the RC (load resistance and modulator capacitance), it is difficult to achieve large bandwidths.

The widely used electrode structure, for large bandwidths, is the traveling-wave electrode structure, where the modulator electrode structure is designed as an extension of the load resistance. Figure 3b shows the structure of a CPW, (coplanar electrode structure), which consists of a central signal electrode and two ground electrodes on both sides of the signal electrode. The two ground electrodes, have widths that are assumed to be sufficiently larger than the signal (or central) electrode structure. Figure 3c shows the asymmetric coplanar stripline (ACPS), or asymmetric stripline (ASL) electrode structure, which consists of a central signal and one ground electrode, where the ground electrode width is assumed to be sufficiently larger than that of the signal electrode. In both of these cases the bandwidth is not limited by the capacitance of the modulator but is dependent on the velocity matching and microwave attenuation of the electrode structures.

The other important characteristics include the following optical characteristics — wavelength of operation, optical return loss, maximum power, and polarization dependency, the following electrooptic and microwave characteristics — bandwidth (frequency response), microwave attenuation, characteristic impedance; and the following mechanical and long term stability — size, temperature, and DC drift stability, humidity, shock, and vibration stability, and fiber pull strength.

These characteristics need to be addressed by the modulator designer, from the initial stage. The waveguide technology is mature enough to satisfy most of the characteristics. The main characteristics that need special attention are the bandwidth and the driving voltage. The usual system requirements are larger bandwidths with lower driving voltages, due to the limitations of available low-driving-voltage drivers. Both bandwidth and driving voltage of lithium niobate modulators are in a tradeoff relationship; one has to be sacrificed for the other. For many years, modulator design has concentrated on optimizing various parameters and finding ways to achieve both larger bandwidths and lower driving voltages [11–19].

The bandwidth of a modulator is dependent on the velocity mismatch between the optical and microwave (RF) and the microwave attenuation of the electrode structure. The velocity mismatch can be controlled by the electrode/buffer-layer parameters. But once the electrode/buffer-layer parameters are fixed, the microwave attenuation (α) is also fixed. In other words, the microwave attenuation, which gets fixed by the electrode/buffer-layer parameters, limits the achievable bandwidth, even though perfect velocity matching is achieved. The driving voltage or V_π is also dependent on the electrode/buffer-layer parameters.

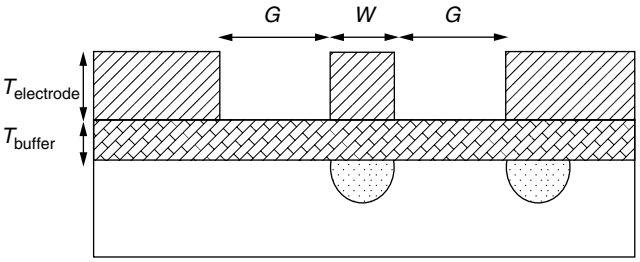

Figure 4. Cross section of a typical Mach–Zehnder optical modulator, with a CPW electrode structure.

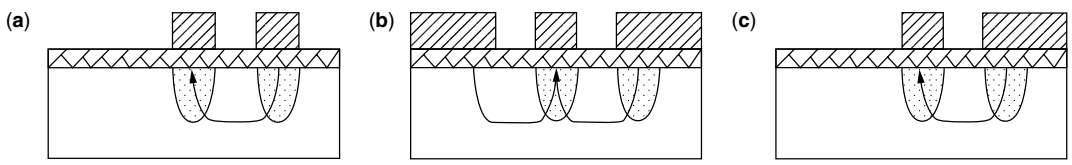

Figure 3. The most commonly used electrode structures: (**a**) lumped; (**b**) coplanar waveguide (CPW) (coplanar electrode structure); (**c**) asymmetric coplanar stripline (ACPS) electrode structure.

As the effective refractive indices of the optical wave (2.15, for TM mode, at 1.55 μm) and that of the microwave (4.2) are different, there exists the velocity mismatch between the two fields, which are propagating simultaneously. This mismatch limits the achievable optical bandwidth value. It is possible to reduce the microwave refractive index to that of the optical refractive index by optimizing the electrode/buffer-layer parameters. Figure 4 shows a cross-sectional view of the Ti-diffused $LiNbO_3$ Mach–Zehnder modulator with a CPW electrode structure. The parameters that are controlled and optimized are W, the width of the signal electrode; G, the gap between the signal and ground electrodes; $T_{\text{electrode}}$, the thickness of the electrode; T_{buffer}, the thickness of the buffer layer; and ε, the dielectric constant of the lithium niobate crystal.

Two-dimensional finite-element analysis can be used for microwave analysis to calculate the capacitance, effective microwave index, and characteristic impedance. The beam propagation method (BPM) or the propagation beam method (PBM) is used for optical field analysis.

The parameters used include the refractive index (TM modes) at 1.55 μm of wavelength, with $n_e = 2.15$, and the dielectric constants of the z-cut $LiNbO_3$ 28 for the z direction and 43 in other directions. The buffer layer is assumed to be SiO_2 with a dielectric constant of 3.9. Figure 5a,b shows the microwave refractive index n_m, and the characteristic impedance, Z, as functions of the electrode width : gap ratio, W/G, buffer-layer thickness, and electrode thickness. It can be observed that n_m decreases with increase in the buffer layer and electrode thickness. These design values depend on various experimental factors and fabrication conditions. Hence, care should be taken in incorporating the experimental values with the modulator design parameters and to ensure that the necessary optimization is performed.

The bandwidth of a modulator can be obtained from the optical response function, which can be defined as

$$H(f) = \frac{[1 - 2e^{-\alpha L}\cos 2u + e^{-2\alpha L}]^{1/2}}{[(\alpha L)^2 + (2u)^2]^{1/2}} \tag{11}$$

where

$$u = \frac{\pi f L(n_m - n_o)}{C} \tag{12}$$

$$\alpha = \frac{\alpha_0 f^{1/2}}{(20\log e)} \tag{13}$$

where α_0 = microwave attenuation constant
f = frequency
n_m = effective microwave index
n_o = effective optical index
$(n_m - n_o)$ = velocity mismatch
L = length of electrode
C = velocity of light

It is evident that even when a perfect velocity matching is achieved, the bandwidth is limited by the microwave attenuation. Thus, reduction of microwave attenuation is the key in achieving very large bandwidths.

The velocity matching using the thick electrodes and thick buffer layer is in the ACPS electrode structure reported by Seino et al. [12]. For an electrode length of 2 cm, a driving voltage of 5.4 V, a bandwidth of 20 GHz, and a microwave attenuation of 0.67 dB/[cm $(\text{GHz})^{1/2}$] were achieved. One problem of the ACPS structure is the resonance problem at higher frequencies, so there is a need to reduce the chip thickness and width. For CPW electrode structure, thick electrodes and buffer layer are utilized [13,14]. For an electrode length of 2.5 cm, a driving voltage of 5 V, and a bandwidth of 20 GHz with a microwave attenuation 0.54 dB/[cm $(\text{GHz})^{1/2}$] was achieved. The issue with a CPW electrode was higher microwave loss due to the higher-order mode propagation. Reduction of chip thickness is needed.

Reduction of microwave attenuation is the main factor in achieving very large bandwidths. The total microwave attenuation of the electrode structure can be reduced by reducing the stripline loss, higher-order mode propagation loss, losses due to bends/tapers, connector, connector-to-pad contact loss, and other package-related loss [20]. A potential reduction of the stripline electrode structure is the use of a two-stage electrode structure. For an electrode length of 4 cm, the driving voltage is 3.3 V, and the bandwidth is 26 GHz with a microwave attenuation of 0.3 dB/[cm $(\text{GHz})^{1/2}$] [21].

3.1. Driving Voltage Reduction

The driving voltage is given by Eq. (6). The driving voltage reduction can be realized mainly by increasing the electrode length or increasing Γ, the overlap integral, between the optical and RF waves, or decreasing G, the gap between the two arms of the interferometer. There is a limit to decrease of G. If the arms are too close, there is a problem of mode coupling between these two arms. This will cause a degradation of the extinction ratio. Also, G is

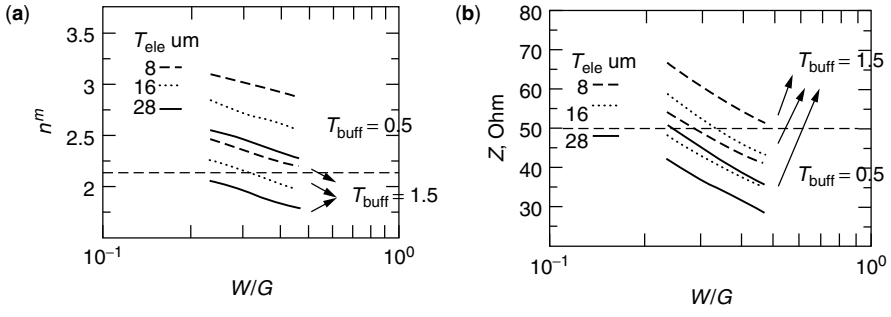

Figure 5. The calculated values of (**a**) microwave refractive index n_m, and (**b**) characteristic impedance, Z, as functions of the electrode width : gap ratio, W/G, buffer layer thickness, and electrode thickness.

the parameter that was fixed in earlier velocity matching design. Increasing the electrode length poses problems on the achievable bandwidth due to microwave attenuation problems. The driving voltage is dependent on the overlap integral between the optical and the microwave fields. The overlap integral needs to be as large as possible, and it depends on the waveguide fabrication parameters and diffusion parameters. The waveguide parameters include the titanium thickness, the titanium concentration, and the gap between the electrodes; the diffusion parameters include the diffusion time and temperature. All these parameters are to be optimized, in order to achieve strong mode confinement. Also, the position of electrodes vis-à-vis the waveguide position dictates the overlap integral value. The other important parameter is buffer-layer thickness, which increases with increase in driving voltage but decrease in overlap integral. Thicker buffer layers are needed to achieve the velocity matching, as explained above. Once the velocity matching condition is obtained, the buffer-layer thickness and the achievable driving voltage are fixed. Optimization of the waveguide/electrode parameters to achieve a strong confinement is usually the remaining issue to achieve the lower driving voltages.

Other methods to reduce the driving voltage include a dual-electrode structure, a ridge waveguide structure, and a controlled buffer-layer structure. In a dual-electrode structure [22], where the two arms of the interferometer are driven by two independent signal electrode structures, the driving voltage can be reduced by approximately half. This structure has the advantage of controlling the chirp value. By individually controlling the voltages applied to the two arms, it is possible to obtain a zero chirp or a negative/positive chirp. In the ridge waveguide structure, by etching ridges in the region, the overlap integral can be increased. At the same time, it is possible to design a modulator to achieve both the velocity matching and the required characteristic impedance. In the controlled buffer-layer structure, the thickness of the buffer layer across the waveguides to achieve both large bandwidth and low driving voltage has been reported [21,23]. The thickness is varied so that both the velocity matching condition and the low driving voltage are achieved at the same time. For the electrode lengths of 4 and 3 cm, driving voltages of 2.5 and 3.3 V, and bandwidths of 25 and 32 GHz were achieved, respectively.

3.2. Reliability

The long-term reliability was the main performance parameter that is vital for using these devices for commercial and practical systems. The DC drift and the temperature stability (and humidity drift) are the main long-term reliability issues [24,25].

3.3. DC Drift

DC drift is the optical output power variation under the constant DC bias voltage application.

Figure 6a shows the output power of the modulator as a function of the applied voltage. The dashed lines show the output power as a function of applied voltage when only AC voltage is applied (and no DC is applied, at $t = 0$), and the solid line shows the same, after $t = t_1$, when DC voltage is also applied in addition to the previous AC signal voltage. The shift between these two curves, ΔV, is the measure of the DC drift. When these types of modulator are used in practical systems, the signal is usually applied at the center of the switching curve (i.e., intermediate between maximum and minimum), which is known as the *driving point*. Once the shift due to DC drift occurs, driving point voltage must be brought back to the previous operating point, using an automatic bias control (ABC) circuit or feedback control (FBC) circuit. It is desirable to minimize this shift, and in most of the cases, a negative shift is more desirable as it facilitates a smaller voltages application through the ABC circuit. The cause of the DC drift can be attributed to the movement of ions, including OH ions, inside the lithium niobate substrate and that inside the buffer layer. It is influenced by the balance of the RC time constants, in both horizontal and vertical directions in the equivalent-circuit model as shown in Fig. 6b. It was also found that the DC drift is affected to a greater extent by the buffer layer. In the circuit model of Fig. 6b, all layers, the $LiNbO_3$ substrate, the Ti : $LiNbO_3$ optical waveguide, and the buffer layer are represented in resistances R, and capacitances C, in both vertical and horizontal directions.

It has been experimentally proved that DC drift can be reduced by decreasing the vertical resistivity of the buffer layer or by increasing the horizontal resistivity of the buffer layer (or that of the surface layer). The surface layer is the boundary layer between the buffer layer and the substrate. The reduction of the vertical resistivity is obtained by doping the SiO_2 buffer layer using TiO_2 and In_2O_3. The increase of the horizontal surface resistivity can be obtained by making a slit in the Si/SiO_2. In both

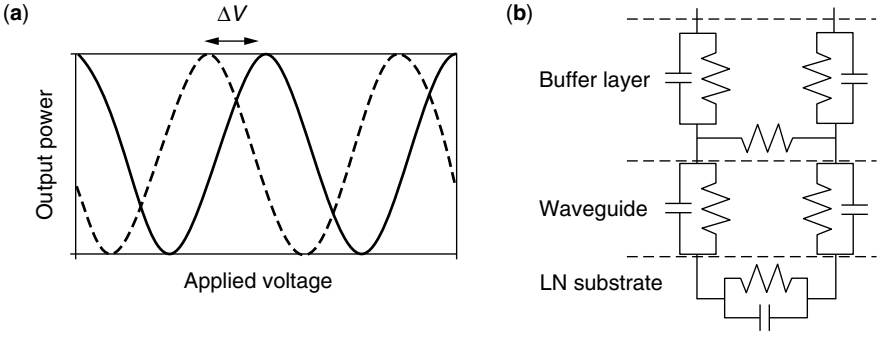

Figure 6. DC drift: (**a**) output power of the modulator as the function of the driving voltage, with and without the DC applied voltage; (**b**) equivalent RC circuit model of the structure, with vertical and horizontal components.

cases, the movement of ions, especially between the two interferometer arms (waveguides), is arrested.

3.4. Thermal Drift

Thermal drift is the optical output power variations as a function of changes in temperature. Once the temperature changes, the piezoelectric charges are induced on the surface of the LN substrate. This causes a surface charge distribution across the two arms of the interferometer, affecting the electric field. This results as a shift in the switching curve and the driving point/operation point shifts, similar to those in DC drift. Hence, in order to reduce this thermal drift, there is a need to distribute or dissipate the charges that are accumulated on the LN surface and between the electrodes. A method in which the charges are dissipated using the semiconductor layers such as Si [26] and other materials was proved to reduce the thermal drift. Another method, in which a Si double slit and a reduction of the resistivity by one order of magnitude, was reported [27].

BIOGRAPHY

Rangaraj Madabhushi received his B.S. and M.S. degrees in physics/mathematics and applied physics in 1974 and 1977, respectively, from Andhra University, Visakhapatnam, India, and a Doctor of Engineering in electronics in 1989 from Tohoku University, Sendai, Japan (optical waveguide devices based on $LiNbO_3$). After working in India, during 1977–1980 (project associate, Indian Institute of Technology, Madras, India) and 1980–1984 (senior scientific officer, Instruments Research and Development Establishment, Dehradun, India), he came to Japan in 1984 on a Japanese government scholarship. After completing a Japanese language course and a doctorate, he joined the NEC corporation, Kawasaki, Japan, in 1989. He worked at the NEC (Central research labs), in various capacities; researcher, assistant manager, manager, on the research, development, and management of $LiNbO_3$ devices, including switches, filters and high-speed modulators for optical communication. In 1999, he came to the United States and joined Lucent Technologies (now Agere Systems) as the technical manager and subsequently promoted as a director in 2000. Since then, he is managing the $LiNbO_3$ and SiWG product development at Breinigsville, Pennsylvania. Dr. Madabhushi holds over 15 Japanese and 10 U.S. patents in the area of $LiNbO_3$ devices and is the author of more than 40 papers in international conferences and journals. He is the senior member of IEEE/LEOS USA, OSA USA, and IEICE, Japan.

OPTICAL MULTIPLEXING AND DEMULTIPLEXING

ALEXANDROS STAVDAS
National Technical University of Athens
Athens, Greece

1. INTRODUCTION

Optical multiplexing is a technique used in optical fiber networks for enhancing the capacity of point-to-point links as well as for simplifying the routing process within the optical layer. It is found in two forms. Borrowing the concept from its historic predecessor FDM, the optical domain equivalent [which is termed wavelength-division multiplexing (WDM)] is the predominant type of optical multiplexing for reasons to be explained in the following paragraphs. In WDM several information bearers, that is, optical carrier wavelengths, each modulated by a separate data pattern, are launched into (multiplexed) or decoupled from (demultiplexed) an optical fiber (Fig. 1a). The other technique first used in the PCM systems, namely, TDM, also has its optical equivalent, *optical time-division multiplexing* (OTDM). In OTDM, two (or more) pulses of equal energy from the same carrier wavelength are interleaved in time (Fig. 1b). To upgrade a system with bit rate B (pulse duration T) to a system with bit rate $2B$ (pulse duration $T/2$) using OTDM, the following steps are required: (1) generation of pulses with duration $T/2$ in time (at twice the initial power) and (2) delay, probably passive of one stream for $T/2$ with respect to the other before interleaving.

Wavelength multiplexing as a concept exists since the early days of the optical fiber revolution [1]. However, it emerged as a realistic solution only at the end of the 1980s, thanks to optical amplifiers. The advent of the erbium-doped fiber amplifier (EDFA) not only allowed viewing the optical fiber as a "lossless pipe" but also paved the way for collective power restoration of many

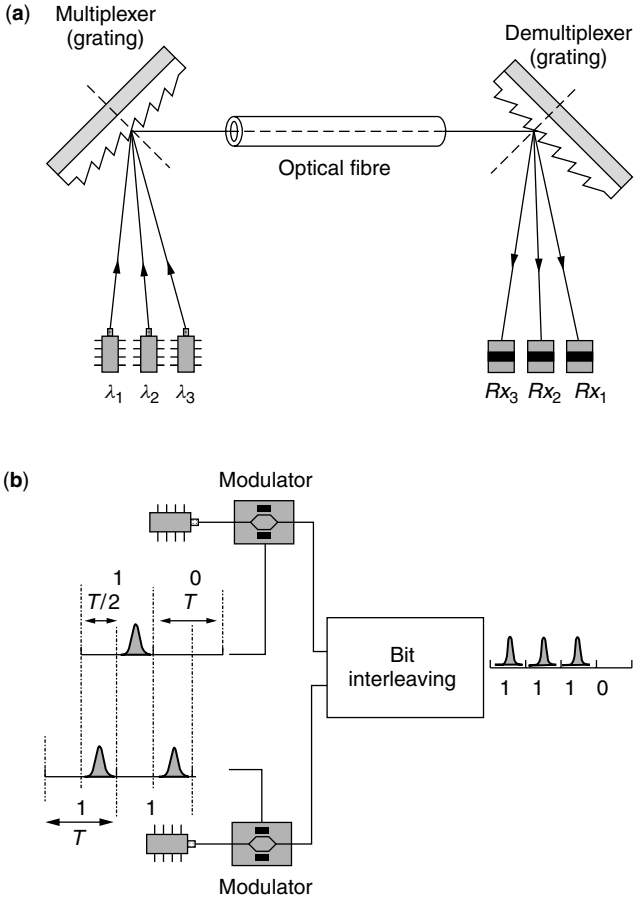

Figure 1. (**a**) Three wavelength channels are multiplexed, transmitted through an optical fiber, demultiplexed at the end and detected from the corresponding receivers (WDM); (**b**) to OTDM two bit streams, two pulses of half duration the initial time are derived (using active components) and a mutual time delay by a half time slot is introduced before interleaving (using passive components).

optical signals simultaneously. For comparison purposes it is mentioned that the first fiberoptic systems employed a single wavelength per fiber were expensive optoelectronic repeaters were used to compensate for the distortions (primarily power attenuation) due to transmission through the optical fiber. Capacity upgrade was achieved by deploying many single-wavelength fibers, something that increased the number of regenerators linearly. In contrast, the EDFA with the ability to restore the power of multiple wavelength channels when they are transmitted over the same single fiber made possible the replacement of these regenerators, leading to enormous cost savings. Wavelength multiplexing was first introduced in the field when it was realized that there is an economic incentive to upgrade from 2.5 to 10 Gbps (gigabits per second) using four wavelengths at 2.5 Gbps instead of one wavelength at 10 Gbps.

In addition, this form of optical multiplexing offers significant routing simplifications within the optical transport layer. Until the 1990s in all commercial telecommunications systems there were only electronic

switching fabrics, rendering electronic switching (and data processing) at the line rate mandatory. Given that the largest fraction of traffic at any node, like in a SDH ring, is transit traffic, processing of the entire traffic volume was becoming progressively more difficult, especially at increasingly higher bit rates. Adopting the principle of wavelength routing, where the final destination is uniquely identified by the wavelength (frequency) of the carrier, it is possible to isolate and process the information content of just the local traffic while the transit traffic, at a different carrier wavelength, could get through the node intact. In current commercial systems with capacity that is scaling up to Tbps (and even tens of Tbps in future systems), wavelength multiplexing is the indispensable technique for capacity upgrade.

On the component level there is a fundamental difference in the nature of the devices used for WDM and for OTDM. In OTDM, the pulses of two or more lower-speed sources are interleaved, generating a datastream with a speed equal to that of the aggregate rate. Thus, very fast "active" (i.e., electrically controlled) devices are needed. For optical processing of this stream in contrast, wavelength multiplexing makes use of "passive" devices. It is the passive nature of these devices that gives WDM all these desirable characteristics generally identified as "transparency": bit-rate independence as well as modulation format and protocol insensitivity. Because of its dominant role in real telecommunication systems, we will consider only wavelength multiplexing for the remaining part of this article.

2. OPTICAL (DE)MULTIPLEXING DEVICES

2.1. Physics of the Devices

When seen from the point of view of technical applications, the most important phenomena of light are *interference* and *diffraction*. Hence, the techniques used for optical (de)multiplexing (regardless of the form in which they appear) are primarily based on one of them. There is no satisfactory explanation of the difference between these two terms [2], but for any practical reason when two optical sources interfere, the result is called *interference*, while when there are a large number of them, the term *diffraction* is more appropriate. For optical (de)multiplexing purposes, the exploitation of two-beam interference is made through devices based on division of the amplitude of the incident beam before they are superposed again. Under this category are devices such as the Mach–Zehnder (MZI), Michelson (MMI), and Sagnac (SI) interferometers. An important family of (de)multiplexing devices are based on arrangements involving multiple divisions of the amplitude or multiple divisions of the wavefront of the incoming wave and they are classified as either (1) interference filters (Fabry–Perot interferometers, multilayer thin-film filters and fiber Bragg gratings) or (2) diffraction gratings (integrated optic, free-space or acoustooptic devices), respectively.

2.2. Functionality

The choice of the technology to be used strongly depends on the type of application under consideration. Hence, for low- to medium-capacity networks, that is, for up to 8-wavelength-channel WDM systems (with bit rates ranging from 644 Mbps to 10 Gbps per wavelength), all the aforementioned devices could be used indistinguishably (Fig. 2). When the total number of wavelength channels N is the predominant consideration for the choice of technology (in particular, when $N \geq 32$), the diffraction gratings are the primary candidates. Nevertheless, regardless of the technological platform, a higher wavelength channel count can be obtained by adding up groups of band-optimized devices. For example, (de)multiplexing devices with up to 60 channels are commercially available using interleaving of band-optimized interference filters in a parallel or cascadable configuration (Fig. 2c,d), while with band-optimized diffraction gratings, several hundred to thousands of channels could be produced.

In Fig. 2, the four different arrangements produce the same final result from a systems point of view. In Fig. 2b, the star coupler facilitates in distributing the same multiwavelength signal to all its N ports (each one will collect $1/N$ of the original optical power). Then a *thin-film* (or a *fiber-grating*) filter will select the requested wavelength. From a functionality point of view, the final outcome is the same as if a diffraction grating is used.* In any case, the diffraction grating-based devices are expected to dominate in the high-capacity systems and, therefore, will be dealt in more detail here. In Section 3 a more detailed comparison between the technological platforms will be provided.

2.3. Diffraction Gratings

2.3.1. Principle of Operation. A diffraction grating is any physical arrangement that is able to alter the phase (optical length) between two of its successive elements by a fixed amount. The impact of this progressive phase alteration becomes evident at the far-field intensity distribution. Consider the case of a plane reflection grating (Fig. 3). The incident plane wavefront PQ first reaches point A, which then becomes a source of secondary wavelets, and hence it advances point B. Finally the incident wavefront reaches B, which then becomes a source of secondary wavelets. These wavelets are exceeding those originating from A at the same time. Hence, the path difference from the corresponding points of the two neighboring grooves (spaced by d), as measured at a distant point of observation, is

$$AD - BC = d(\sin\alpha - \sin\beta) \tag{1}$$

If the incident beam is on the same side of the normal as the diffraction beam, then the sign in Eq. (1) should be replaced with a *plus*. For a more detailed presentation, the reader is referred to classic textbooks such as those by Born and Wolf [3] and Longhurst [4]. In any case it can be shown that the far-field intensity distribution of a planar diffraction grating is the same as that of N rectangular

* Nevertheless the performance in terms of crosstalk, losses [see below] might be different.

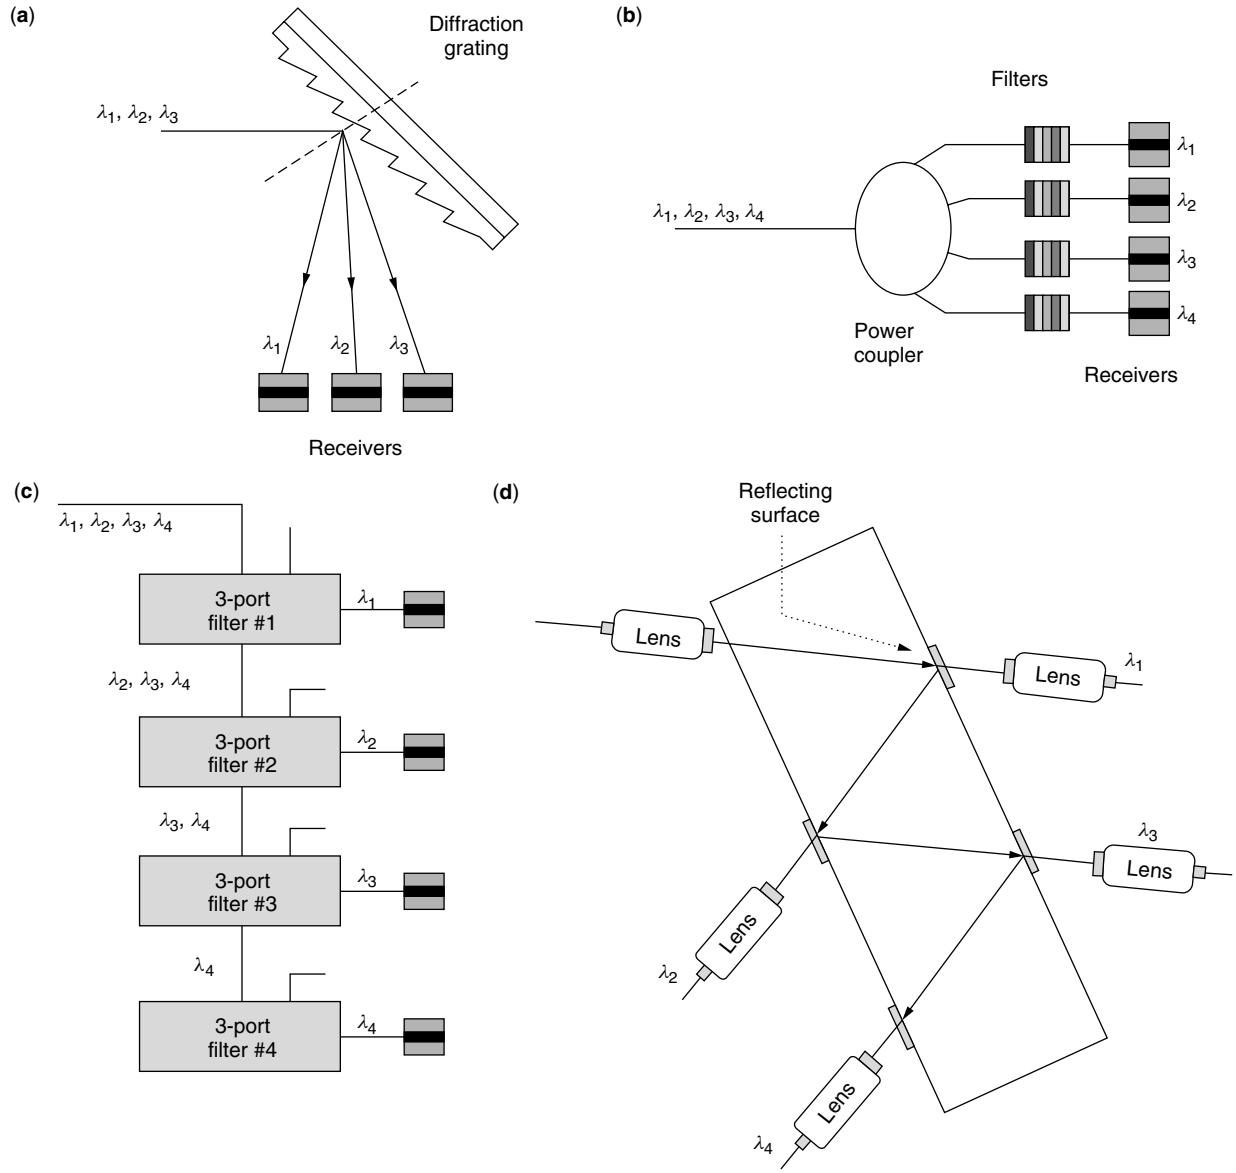

Figure 2. Four equivalent demultiplexing arrangements: (**a**) diffraction grating; (**b**) star coupler (for broadcasting) and fixed-wavelength filters; (**c**) a cascade (bus) of 3-port devices; (**d**) modified "cascade" configuration for two-port devices based on interference (thin-film) filters.

slits modulated by the diffraction envelope of a large slit. Constructive interference occurs when

$$d(\sin\alpha - \sin\beta) = m\lambda \tag{2}$$

where m is a constant called the *diffraction order* and λ is the wavelength (at free space) of the channel. The number N of the grooves/slits determines the sharpness of the principal maximum of the intensity distribution. For example, according to the Rayleigh criterion for the resolution limit, two equal-intensity wavelengths spaced by $\Delta\lambda$ are just resolved if the spatial distance between them is such that the two intensity distributions are crossing each other at 0.8 of their maximum value. The theoretical resolution limit for any diffraction grating is defined as

$$R = \frac{\lambda}{\Delta\lambda} = mN \tag{3}$$

2.3.2. Diffraction Grating Classification. The diffraction gratings could be either concave or planar, and they can operate either at a reflection or transmission mode. A planar diffraction grating — regardless the technological platform and the mode of operation — cannot be used as a standalone component when it is employed as a (de)multiplexer in optical communications. A practical (de)multiplexer based on a planar grating is always implemented in a spectrographic configuration employing two auxiliary optical components: one for collimating the incoming beam (i.e., for transforming the spherical wave to a plane wave) and a telescopic system for focusing the outgoing beam. The wavelength channels are diffracted at different angles determined by Eq. (2), and the telescopic system transforms this angle separation into a spatial separation at the image plane. This spatial

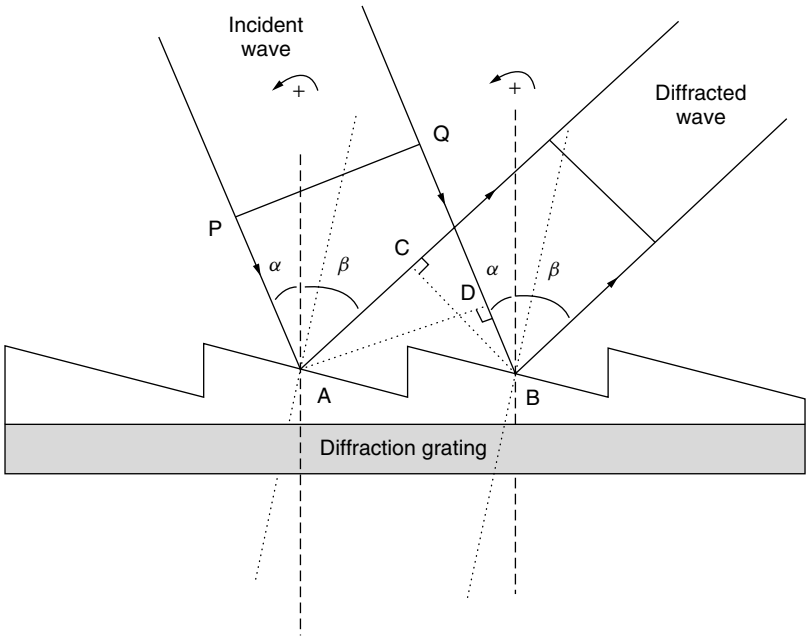

Figure 3. The principle of operation of a planar diffraction grating.

separation (Δx) between wavelength channels ($\Delta\lambda$) in the image plane is given by the reciprocal linear dispersion ($d\lambda/dx$ in nm/mm). Differentiation of Eq. (1) gives

$$\frac{d\lambda}{dx} = \frac{d\lambda}{fd\beta} = \frac{d\cos\beta}{mf} \tag{4}$$

where f is the focal length of the focusing part of the spectroscopic system. In practice, when the spectrograph is used as a (de)multiplexer, Δx is dictated by the minimum distance between the output waveguide/fiber cores.

2.3.3. Spectrograph Overview. The most important configurations for planar grating spectrographs are the *Ebert–Fastie* and the *Czerny–Turner* (Fig. 4a,b). In the former case, the spectrograph is constructed from a planar grating and a large concave mirror (or lens). The *Czerny–Turner* configuration offers the alternative of using two smaller concave mirrors instead of a single large one. The main drawback of these configurations is the use of the auxiliary optics off-axis, something that generates large aberrations. As a result, a point source is imaged as a geometric extended entity that degrades the performance of the optical system (Section 2.4).

A concave grating does not need auxiliary optics since it is a complete spectrograph. The corrugated surface provides the necessary diffraction for wavelength separation or recombination while the geometric properties of the concave surface allow focusing of the diffracted wavelengths. Since concave gratings operate off-axis, they also suffer from large geometric aberrations. However, there are specific geometric arrangements, called *focal curves*, which minimize the adverse effect of these aberrations. The best-known focal curve of concave gratings is the *Rowland circle* (Fig. 4c). For a concave substrate with radius of curvature R, the Rowland circle has a diameter R and is tangent to the apex of the substrate. The important characteristic of this geometric locus is that when a point source A is placed on it ($r_A = OA = R\cos\alpha$), an image free from second- and third- as well as reduced fourth-order Seidel meridional aberrations is produced at a location B on the Rowland circle ($r_B = OB = R\cos\beta$).

2.3.4. (De)multiplexer Performance Considerations. For assessing the quality of any (de)multiplexing device, a number of interrelated issues have to be considered. These include the spectral spacing between adjacent channels, the total number of wavelength channels, the passband flatness, the coupling losses, and the level of outband crosstalk. The best device is the one that allows the largest number of channels with the flattest bandpass, the smallest coupling losses per channel, and the largest optical isolation between adjacent channels with the minimum spectral separation between them.

From Eq. (3) it is concluded that the larger the size of the grating W (i.e., $W = Nd$), the sharper the intensity distribution is and the wider the spatial separation between two wavelength channels can be. Given that sufficiently large optical isolation is available between two adjacent channels, the number of grooves/slits should be considerably greater than that required for satisfying the Rayleigh criterion.

The *coupling loss* of any (de)multiplexer for a given wavelength channel is defined as the ratio of the incoming power to the outgoing power. This could vary with wavelength and depends on many parameters. For diffraction grating devices, these are the propagation material (free-space, Si, III–V semiconductor), the optical aberrations (that depend on the size of auxiliary optics for a planar grating and the clear aperture size for a concave grating), the mode mismatch between the device and the fiber (for integrated optic devices), and the type of the final receptor (e.g., detector, single-mode fiber, or multimode fiber with a clear aperture of 20, 10, and 50 μm, respectively).

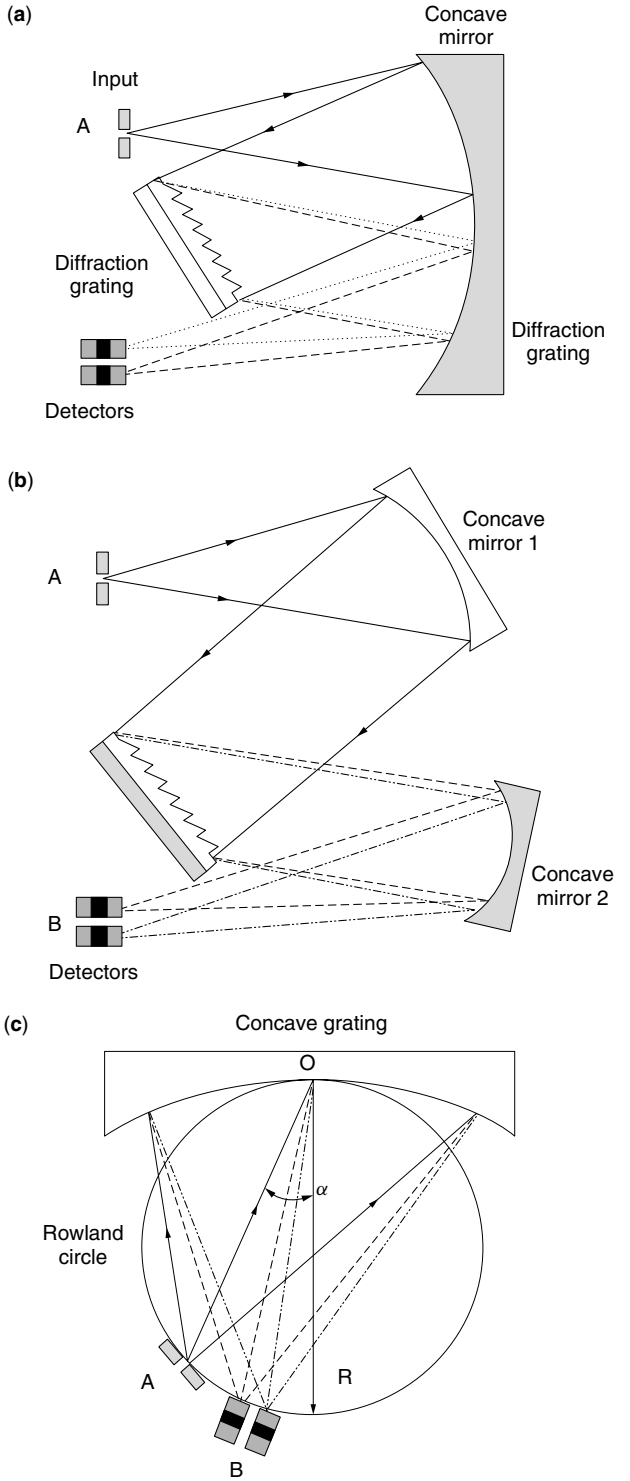

Figure 4. Spectrographs: (**a**) Ebert–Fastie; (**b**) Czerny–Turner; (**c**) Rowland circle.

A fraction of the optical power of a given wavelength that is not coupled to the corresponding outgoing receptor (detector, fiber) could be coupled to the adjacent-channel receptors generating *crosstalk*. In this way, crosstalk is the unintended coupling of signals from adjacent channels due to device imperfections. These phenomena can be better understood by considering the impulse response of any (diffraction grating) demultiplexer (Fig. 5). The impulse response has an intensity distribution with a Gaussian-like central part (due to the Gaussian intensity distribution emitted from a single-mode fiber) and a sinc-square function ($\sin^2 x/x^2$) distribution at the outer parts. As a practical rule of thumb, good optical isolation (low crosstalk) is achieved when the ratio of the optical signal bandwidth (measured at the $1/e^2$ point from its peak value) over the channel spacing is less than 0.25. The fact that the main part of the impulse response has a Gaussian intensity distribution profile leads to passband narrowing when many of these devices are cascaded. For this reason optical techniques are necessary in order to flatten the passband.

2.3.5. Practical Diffraction Grating Devices

2.3.5.1. Arrayed-Waveguide Grating (AWG). The most widely deployed (and studied) type of a grating-based (de)multiplexer is the arrayed-waveguide grating. This is a two-dimensional integrated-optic device (see Refs. 5,6, and references cited within). A special geometric arrangement of two slab waveguides and an array of single-mode waveguides forms a spectrographic setup based on a transmission grating.

The principle of operation, when the device is used as a demultiplexer, is as follows. The multiwavelength channel signal enters the device from the input slab waveguide (Fig. 6a), where it freely propagates. The input and output slab waveguides in most cases are constructed using the Rowland circle (Figs. 3c,6b). In principle, other geometric arrangements (generalized focal curves) are also possible. In any case, aberration-free focal curves are mandatory since the array of the single-mode waveguides is placed at the circumference of a spherical arc. The signal is coupled to the array of the waveguides probably via tapering for best coupling conditions. The array of waveguides plays the role of the grooves/slits in classic gratings [consider Eq. (3)]. Despite the use of the slabs on a Rowland circle, the entire setup has a planar grating configuration (a diffraction grating and two auxiliary optical systems). The length of the array waveguides is chosen such that the optical path length difference ΔL between adjacent waveguides is equal to an integer multiple of the central wavelength of the (de)multiplexer.

Because of the additional phase change introduced by the arrayed-waveguide length difference (that results in "hardwiring" all phases), the corresponding grating [Eq. (2)] is modified to

$$n_s d_0(\sin\alpha + \sin\beta) + n_c \Delta L = m\lambda \tag{5}$$

where n_s is the refractive index of the waveguide slab, n_c is the refractive index of the waveguides in the array (in the most general case, they are not the same), and d_0 is the distance between two successive waveguides in the array. To understand the reasons behind implementation of the AWG using this additional path length difference ΔL, one should consider the following.

Advances in integrated-optic fabrication techniques based on lithographic etching made possible the demonstration of AWGs on InP, Si/SiO_2, or $LiNbO_3$. Despite these

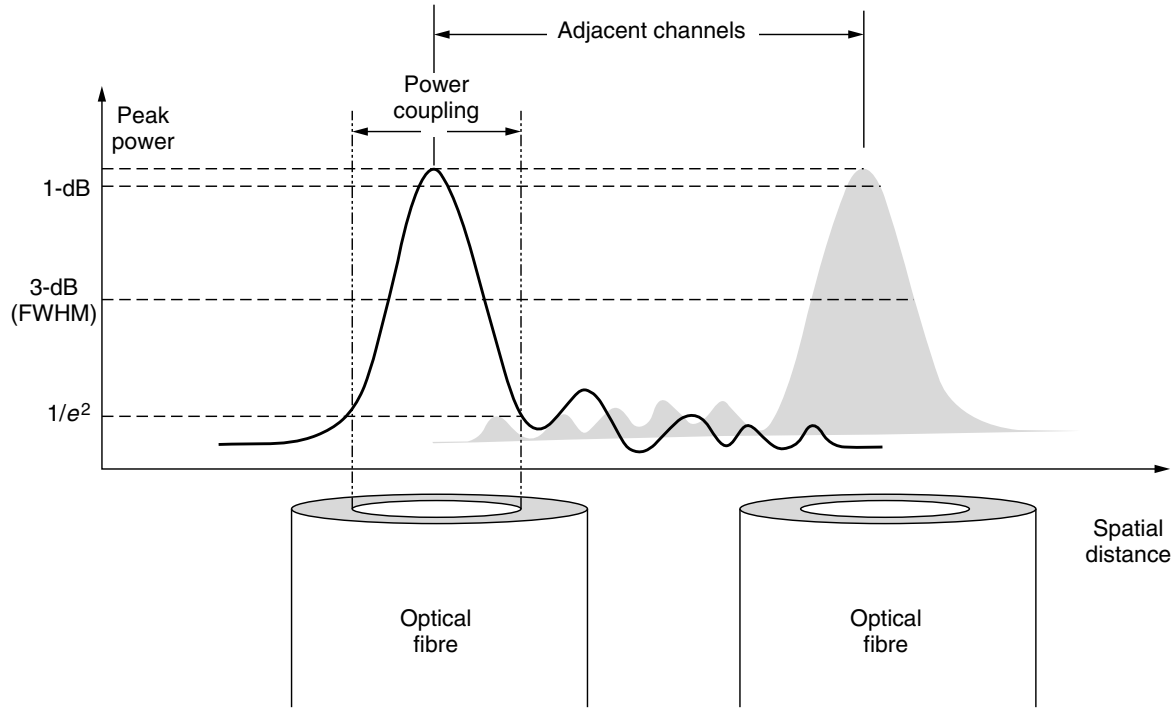

Figure 5. Coupling efficiency and crosstalk between adjacent channels. The part of the intensity not coupled to the destined output fiber smears with the wavelength signal destined to the adjacent fibers.

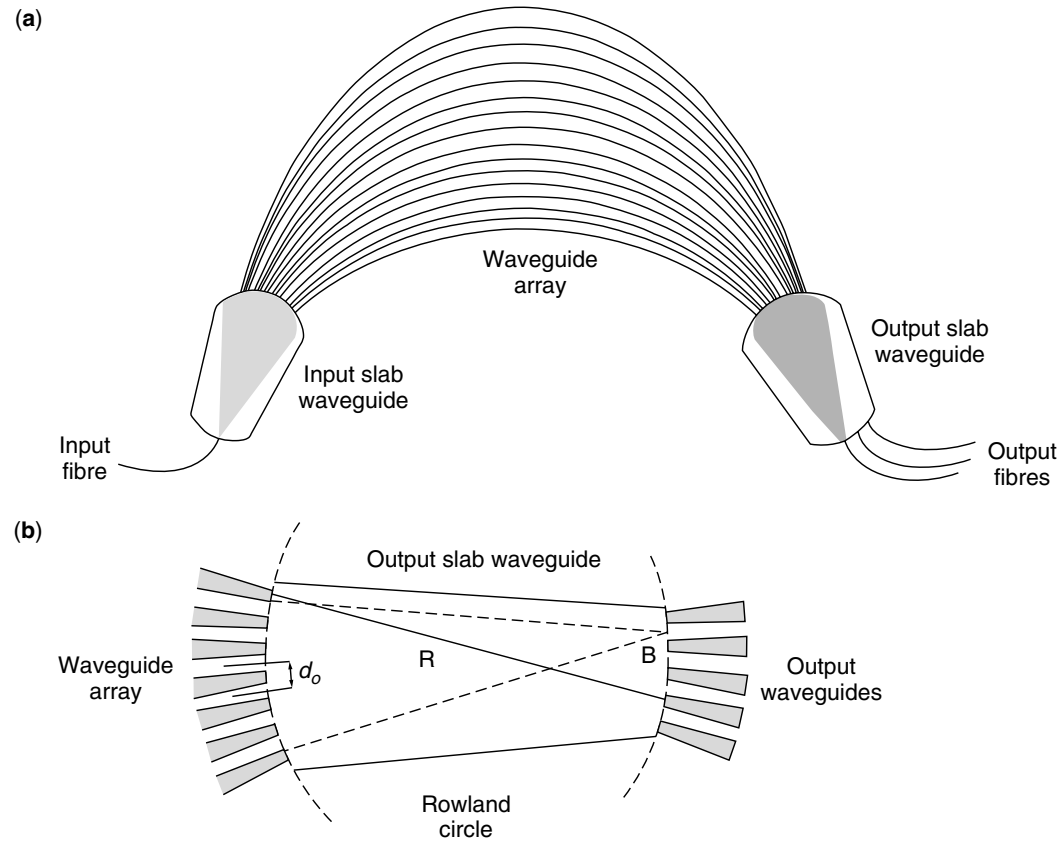

Figure 6. Schematic illustration of the arrayed-waveguide grating (AWG).

advances, there are limitations on the size of the wafers that could be practically used. Because of these size restrictions (resulting in small focal lengths), the required linear dispersion, Eq. (4), is obtained operating the AWG in high diffraction orders. From Eq. (5) the diffraction order equals to $\Delta L = m^{\mathrm{AWG}}\lambda/n_c$ and $m^{\mathrm{AWG}} + 1 = m$. However, the free spectral range (FSR) of the AWG is $\mathrm{FSR} = \Delta\lambda = \lambda/m$, and given that $50 < m < 100$, the FSR < 30 nm. This is one of the main limitations of this approach; specifically, the AWG can be used only in the context of limited spectral range. From an engineering point of view this problem can be solved, as mentioned earlier, by cascading coarse AWG demultiplexers followed by band-optimized fine-granularity AWGs. In this way, a 480-WDM-channel 10-GHz spaced (de)multiplexer has been reported, consisting of a WDM coupler and two 100-GHz-spaced AWGs, followed by 64 10-GHz-spaced AWGs [7]. The largest reported number of channels with a single AWG is 64 channels spaced by 50 GHz (0.4 nm) [8] or 128 channels spaced by 25 GHz [9], both developed on silica.

To improve the performance of the AWGs in terms of diffraction efficiency, modifications of known spectroscopic techniques have been applied [10,11]. The technique requires varying the optical path length (and hence the "hardwired" phase difference) between the waveguides in a nonuniform way, resulting in redistribution of the energy at the image plane. The effect is further improved after a suitable defocusing of the input/output waveguides. The former method is the integrated-optic equivalent of techniques used in aberration-corrected holographic concave gratings where the intensity distribution in the image plane is altered when the corresponding grooves are not equidistant parabolas.

Practical constraints in the fabrication of the AWGs are also attributed to the difficulty of the lithographic system to truly simulate a focal curve such as the Rowland circle. In addition, this mount requires the axis of the input/output waveguides to point toward the pole of the slab, implying that the waveguides have to be tilted with respect to each other. When this condition is not met, the consequent *vignetting* degrades the performance of the outer wavelength channels in the spectrum. Overall, the AWG is a very good candidate device for a demultiplexer operating within a single transmission band (like the *C* band of the EDFA), but it is problematic or impractical for wider optical bandwidth applications. Another issue, common to all integrated-optic devices, is the inherent birefringence of the materials used that leads to TE/TM polarization mode dispersion (PMD)-like problems. Also, temperature controllers are needed to thermally stabilize the operational conditions of the devices.

2.3.5.2. Other Integrated-Optic Spectrographs. Other practical integrated-optic spectrographs used as (de)multiplexers include a *two-dimensional concave grating* [12–15] and a modified *Czerny–Turner* configuration [16]. The former type has been implemented on both silica and III–V semiconductor compounds. Rowland circle or generalized focal curves have been used for producing aberration-free images [13]. The fabrication of this device, in contrast to the AWG, requires deeply etched grating facets, and this is achieved using ion-beam etching. A subsequent problem is the attainable degree of verticality of the grating wall. Another important consideration is associated with the rounding errors of the diffraction grating facets due to lithographic inaccuracies [14]. Again, because of the limited size of the wafers used, the requested linear dispersion [which in the current case is expressed as $d\lambda/dx = n_s d\cos\beta/(mf)$, where n_s is the refractive index of the slab] is achieved by operating the grating at high orders.

The difference between the 2D concave gratings and the AWGs is that in the arrayed-waveguide case the grating constant (pitch) equals to the distance between two successive waveguides. Given that the waveguide length is of the order of a millimeter, the waveguides need to be sufficiently apart to avoid exchange of energy between them (in Si-based devices the distance is at the order of 20 μm). This restriction does not apply to two-dimensional concave gratings. As a result, a grating pitch of few micrometers is feasible and the requested linear dispersion is attained operating the device at a lower order than the AWG (typically at 10th–30th order). Thus, these devices may operate in a wider spectral range compared to their AWG counterparts. With this technology, a device with 120 channels and 0.29-nm channel spacing has been reported [15]. A simple rule for identifying the tradeoff between grating pitch and diffraction order for the integrated optic concave gratings can be obtained by solving the equation for the linear dispersion and the grating equation that leads to

$$\frac{m}{d} = \frac{2\lambda n_s \sin\alpha + 2n_s\sqrt{(d\lambda/dx)^2 f^2 + \lambda^2 - (d\lambda/dx)^2 f^2 \sin^2\alpha}}{2((d\lambda/dx)^2 f^2 + \lambda^2)} \tag{6}$$

On the other hand, the *Czerny–Turner* mount consisting of a transmission grating and two parabolic mirrors used off-axis has been reported [16]. A paraboloid, although the spherical aberration, when it is operated off-axis. Introduces a significant amount of meridional coma. A *Czerny–Turner* spectrograph should be deployed using two spherical mirrors with different radii of curvature in order to compensate for meridional coma that degrade crosstalk.

In any case, both (de)multiplexer types manifest the same dependence for temperature control and compensation for the PMD-like dispersion due to material birefringence as the AWGs.

2.3.5.3. Free-Space Gratings. Practical free-space optical (de)multiplexers can be found in the form of either planar grating mounts or a holographic concave grating. Free-space grating multiplexers were the first to be tested in conjunction with WDM system experiments. The most established planar grating (de)multiplexer is implemented on the basis of a modification of the *Ebert–Fastie* configuration where the source and the image are almost collocated at the optical axis of a parabolic mirror. This is now a commercial product called STIMAX [17]. Operating an optical system on-axis results in an aberration-free image from second- and third-order Seidel aberrations. Fourth-order

Table 1. Performance of Diffraction Grating Devices

	Channel Spacing (nm)	Number of Channels	Losses (dB)	Crosstalk (dB)	Comments
AWG[a]	0.8	40	<6	< −20	Si/SiO_2
AWG[a]	0.8	≤40	<8	<−25 dB	1-dB band, ∼0.16 nm
AWG[a] flat passband	0.8	≤40	<9	<−24 dB	1-dB band, ∼0.32 nm
AWG [9][b]	0.2	128	3.5–5.9	<−16 dB	Si/SiO_2
Free-space planar[a]	0.8	≤40	<5.5	<−30 dB	1-dB band, >28 GHz
STIMAX[a]	0.8	≤64	<5.5	<−30 dB	—
Minilat[a]	0.8	≤92	<8	<−33 dB	1-dB band, ∼0.2 nm
Holographic concave[b] [24]	0.4	64	<8	<−30 dB	—
2D concave[b] [12]	1	50	16	<−19 dB	InP
2D concave[b] [15]	0.29	120	20–40	<−44 dB	Si-based

[b] Laboratory results.

aberrations (spherical aberrations) do exist, and they are compensated by means of the parabolic mirror.

The STIMAX (de)multiplexer has a very high wavelength channel count (Table 1). The main limitation of this configuration is the rapid increase of third-order Seidel aberrations (coma) for the outer wavelength channels of the spectrum due to the use of the parabolic mirror off-axis. Mechanical and thermal stability issues have been successfully addressed. As a result of the free-space operation, PMD-like problems are inherently absent while the polarization dependence of the diffraction efficiency is an issue especially for wider bandwidth applications.

Another configuration uses a planar grating together with retroreflectors at the image plane that facilitate in producing a zero-dispersion focused light, reducing bandwidth narrowing due to cascaded (de)multiplexers [18]. In principle, this approach provides a bandwidth flattening technique that is still applicable even when the device is operated as a demultiplexer, something that is not the case with other solutions used in AWGs [19]. A variant of this technique is used to eliminate the polarization dependence of the diffraction efficiency [20].

Concave diffraction gratings are single-element optical systems that simultaneously provide dispersive and focusing properties. A single optical element is very attractive because of easier optical alignment and reduced packaging problems. For this reason concave gratings were used as (de)multiplexers even at the very early stages of WDM transmission [21]. However, it has been recognized that the main disadvantage of this optical system is the large inherent aberrations associated with the spherical concave substrate and, thus, aberration-corrected gratings need to be deployed [22].

The holographic concave gratings are the primary candidates for providing aberration corrected (de)multiplexers [23]. The principle of operation of the holographic concave grating is as follows (Fig. 7). The concave substrate is covered with a suitable photoresist material sensitive to a specific wavelength (e.g., Ar^+ laser). A laser beam is split and focused in two pinholes such that two coherent point sources (C and D) are created. In general, the resulting spherical waves interfere on the substrate, generating fringes that are neither equidistant nor straight. This is the recording phase. When the device is used as a demultiplexer, the single-mode fiber carrying a multiwavelength signal is placed at point A. Then a particular wavelength is imaged at point B, which, however, is not a point source, due to large optical aberrations. The aberrations can be eliminated by placing the two point sources C and D such as the generated fringes introduce a phase shift that cancel out the aberrations introduced by the spherical substrate. It has been demonstrated that up to 1000 wavelength channels can be (de)multiplexed using these devices, covering a spectral range of 200 nm [24]. Nevertheless, these devices are still available only in laboratories. As with all free-space devices, mechanical stability and polarization-dependent diffraction efficiency is an issue, and in particular when the number of wavelength channels are more than a hundred, the problem of an efficient fiber mount has to be tackled. The performance of all diffraction grating devices is summarized in Table 1.

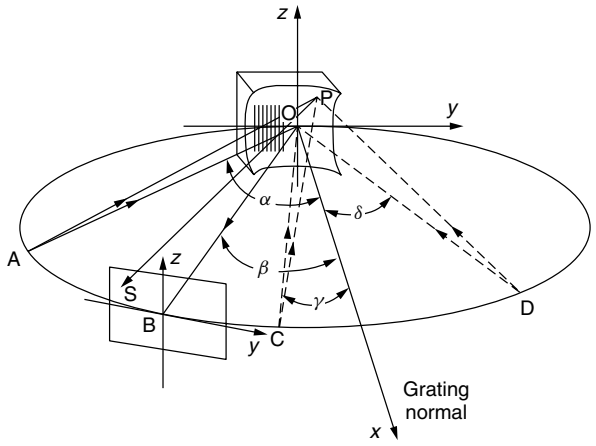

Figure 7. Schematic illustration of a holographic concave grating.

2.3.5.4. Acoustooptic Grating. This is an *active* device. The principle of operation of this device is based on the interaction of light with sound resulting in a transmission

grating. A sinusoidal sound wave travelling at the surface of an appropriate material generates periodic variations of the density (or strain) of the material according to the frequency of the wave. As a result, the macroscopic effect is a periodic change of the refractive index, and these periodic changes act as partially reflecting mirrors. Hence an incident plane wave, when specific conditions are met, will be diffracted at an angle according to its wavelength. The grating formed by the sound wave is a dynamic (time-varying) one.

The effect of the sound wave on the impinging plane wave can be understood in two ways. The distance between two "partially reflecting mirrors" depends on the frequency Ω of the sound wave. Conservation of energy and momentum require that $\omega_i = \omega_d + \Omega$, and $\mathbf{K}_\mathrm{i} = \mathbf{K}_d + \mathbf{K}$, respectively, where the index i indicates the incident wave while the index d the diffracted. $\mathbf{K}$ is the wavevector of the sound wave, and since $\Omega \ll \omega_i$ it is $\omega_i \cong \omega_d$. Thus, apart from a negligible frequency shift, the effect of the sound wave on a multiwavelength signal is to change the direction of propagation according to wavelength (demultiplexing) (Fig. 8a). Alternatively, it could be argued that an optical path length (phase) delay occurs between the two "partially reflecting mirrors" similar to what is produced by the grooves of a diffraction grating. When the distance between them satisfies the grating equation (which now is termed the *Bragg condition*), the elementary planes add constructively. The intensity distribution of the impulse response has the known sinc-square form and its sharpness will depend on the number of reflecting mirrors, namely, the total interaction length L (the sharpness will depend on the ratio L over the wave number determined by Ω).

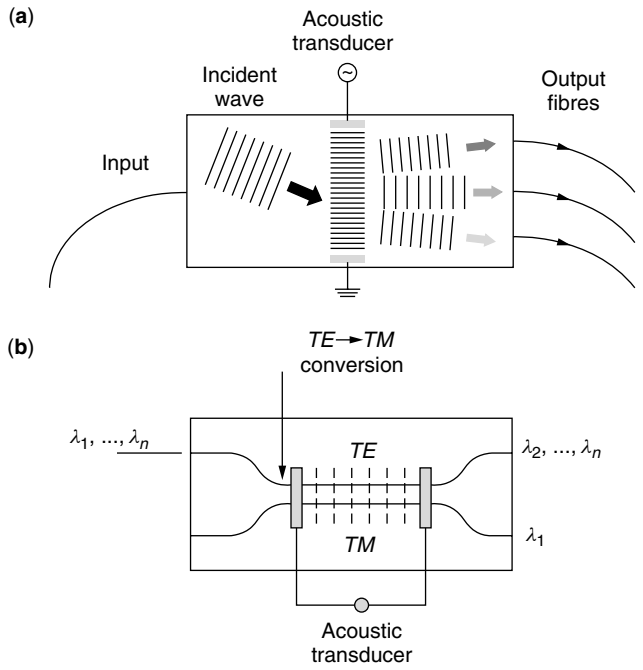

Figure 8. (**a**) The principle of operation of an acoustooptic grating; (**b**) a four-port acoustooptic filter.

2.4. Optical Filters

2.4.1. Acoustooptic Filters (AOFs). When an acoustic wave is applied on an acoustically active material, the induced birefringence (i.e., a dissimilar change of the refractive index for the ordinary and the extraordinary rays) of the medium alters the state of polarization of the incident wave. This principle is used for constructing acoustooptic filters (Fig. 8b). A multiwavelength signal enters a four-port device like a single coupler design. At the input stage, the incoming signal is 3-dB split by the directional coupler and the light at the lower branch also undergoes a phase delay of $\pi/2$. In other words, at the lower branch a polarization rotation is observed from the TE to the TM mode. When no acoustic wave is applied, another $\pi/2$ phase delay occurs at the output part and all channels exiting from the symmetric to the input port (e.g., upper-in, upper-out). When an acoustic wave is applied, the exact matching conditions are altered via the acoustooptic effect and the requested channel is selected from the lower output port. An interesting feature of the acoustooptic filter is that many acoustic frequencies could copropagate, allowing a simultaneous selection of more than one channel. Hence, the AOF can be used as a band-selecting filter in hierarchical (coarse/fine) WDM (de)multiplexing since it has a tunability of hundreds of nanometers. The crosstalk figure of the AOF is not as good as that of the other commercial diffraction gratings.

2.4.2. Interference Filters. These filters appear in the literature under many different names such as dielectric thin films, multilayer interferometric filters, and multistack thin-layer filters. Further, they are constructed from many different compounds ranging from liquid crystals to various oxides (SiO_2 or TiO_2) to multi-quantum-well (MQW) III–V semiconductors. Nevertheless, the principle of operation for all these structures is easily understood considering a Fabry–Perot etalon [25] that is an interferometer based on multiple divisions of the amplitude. Note that collimating optical devices [like bulk or GRID rod lenses] are mandatory at the input/output.

Let us assume that a material A with higher refractive index (n_H) compared to a material B (n_L) forms a cavity as shown in Fig. 9a. The reflected and transmitted intensities I_R and I_T of the Fabry–Perot etalon, respectively, normalized to the incident intensity, are given by

$$\frac{I_R}{I_i} = \frac{4R\sin^2(\delta/2)}{(1-R)^2 + 4R\sin^2(\delta/2)},$$
$$\frac{I_T}{I_i} = \frac{(1-R)^2}{(1-R)^2 + 4R\sin^2(\delta/2)} \tag{7}$$

where $\delta = (4\pi n_H \cos\theta_d L)/\lambda$ and R is the fraction of the intensity reflected at each interface like n_H/n_L and n_L/n_H .

Maximum power transfer to the reflected beam occurs when the thickness of the high-refractivity region is equal to a quarter-wavelength ($\delta/2 = m\pi/2$) while maximum transmission occurs when the thickness is one half-wavelength thick ($\delta/2 = m\pi$), assuming that $R \cong 1$. The former case is depicted in Fig. 9b. Many

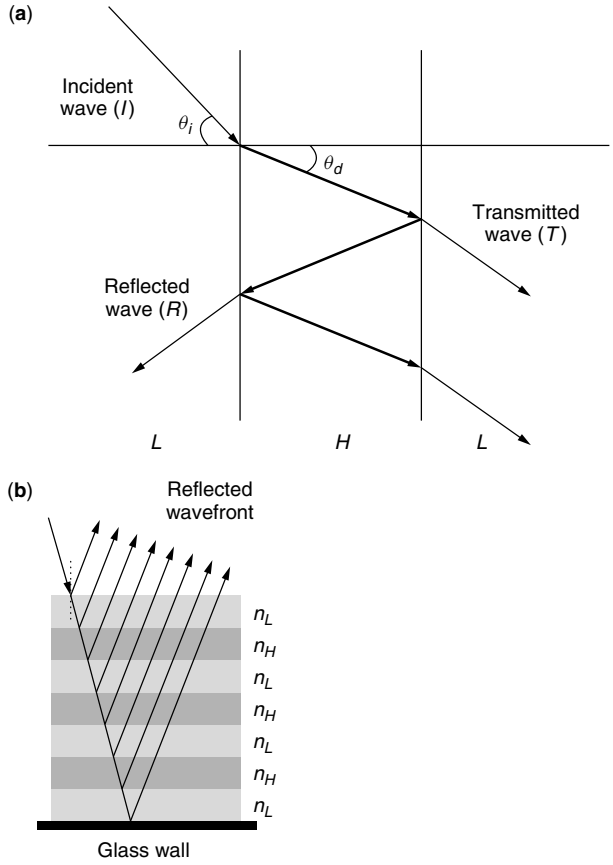

Figure 9. (**a**) A Fabry–Perot etalon; (**b**) a multilayer stack operated on a reflection mode.

different configurations could emerge by adding up such multistacks; for example, two structures as shown in Fig. 9b with a space layer between them form an additional Fabry–Perot cavity of the type HLH(2L)HLH, assuming that each layer has a quarter-wavelength thickness. It can be shown that sharper cutoff characteristics are obtained by increasing the number of layers or cavities. However, when all cavity lengths are the same, the overall structure produces a narrower passband. Hence, layers of unequal thickness are used, something that requires the addition of further layers for phase matching, leading to a complex optimization problem. Also, the passband increases with increasing values of n_H/n_L [26]. Overall, practical constructions lead to filters offering optical isolation up to -30 dB. The losses are range between 1 and 5 dB depending on the material, the number of channels, and other factors.

It is pointed out that these are the only filter devices that could be implemented using all the three configurations of Fig. 3b–d. Nevertheless, the reader should be aware that should the configurations of Fig. 3c,d be used in a practical system, power equalization techniques should be employed for compensating the loss variation (which could be a problem when these devices are cascaded if the number of channels is high).

2.4.3. Mach–Zehnder Filters. These filters are four-port devices that can be either *passive* or *active*. The

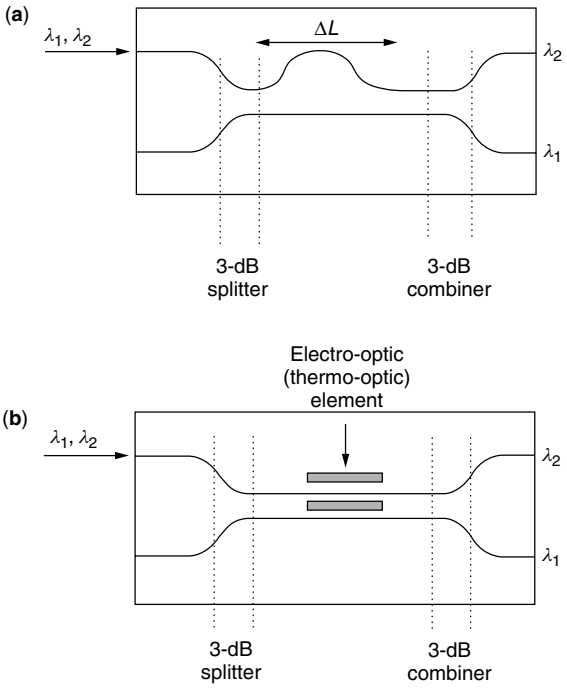

Figure 10. (**a**) The asymmetric Mach–Zehnder and (**b**) the symmetric configurations.

integrated-optic version of the Mach–Zehnder interferometer, illustrated in Fig. 10, consists of three parts. The input and the output parts are 3-dB couplers, while the central section has two waveguide arms (upper and lower) with different path lengths. The configuration is called *asymmetric*. For a signal entering the upper port, the overall phase difference due to the asymmetric length is

$$\Delta\phi = \frac{2\pi n_u}{\lambda}(L + \Delta L) - \frac{2\pi n_l}{\lambda}L = \frac{2\pi n}{\lambda}\Delta L \qquad (8)$$

where n_u and n_l are the refractive indices of the upper and lower waveguides, respectively. In this case they are assumed to be equal to n. The upper ports are labeled as 1 and $1'$ at the input/output, respectively, and likewise the lower ports as 2 and $2'$. The transmittance from port 1 to $1'$ is given by T_u and from 1 to $2'$, by T_l.

$$T_u = \sin^2(\Delta\phi), \quad T_l = \cos^2(\Delta\phi) \qquad (9)$$

when $(2\pi n/\lambda_1)\Delta L = (m + 1)\pi/2$ and $(2\pi n/\lambda_2)\Delta L = m\pi$, with m an integer, then T_u is unity for λ_1 and zero for λ_2 and vice versa (T_l is unity for λ_2 and zero for λ_1). In this way, the wavelengths λ_1 an λ_2 are collected from different ports. When the device is carefully designed, it can operate as a wavelength channel (de)interleaver. The *symmetric* configuration (Fig. 10b) has waveguide arms of equal length, so the phase difference occurs as a result of electrooptically or thermooptically [27] induced change of the refractive index, resulting in different n_u and n_l when the control signal is on.

The loss figure depends on the number of wavelengths that can be demultiplexed from a single module, as well as the host material (Si or III–IV semiconductor). In general,

the optical isolation between adjacent channels is not better than −30 dB.

3. OVERALL ASSESSMENT OF (DE)MULTIPLEXING TECHNIQUES

Having presented the main technological platforms currently used for optical (de)multiplexing, it would be interesting to highlight their pros and cons. As pointed out earlier, the main question when a technology is assessed is the type of application in mind. In general, the configurations illustrated in Fig. 2b,c have different drawbacks.

A layout like the one in Fig. 2b, based on a power coupler and optical filters, is a flexible solution up to approximately 8 wavelength channels. Beyond this point, splitting losses tend to be high that the grating solution is advised. Optical filters with tailormade spectral characteristics (e.g., through wavelength) can be used in this configuration leading to a (de)multiplexer construction, offering a wavelength comb with unequal channel spacing allocation (to combat, e.g., fiber nonlinearities such as four-wave mixing). Nevertheless, when systems with a large number of wavelength channels are desired, the cost of the system scales proportionally to channel count.

The "bus" architecture of Fig. 2c is implemented only via three-port or four-port devices. Thus, the loss performance is not uniform across the spectrum of interest; the first channel has the lowest losses while the final channel suffers from the worst losses. It is this loss figure that determines the maximum number of channels to be used per band. In general, the performance of the optical filters is good in terms of optical isolation. The loss performance of the device itself is good, but for practical applications a cascade of other optical components, such as band (de)multiplexers, is required.

With diffraction gratings the cost is not proportional to channel count and, indeed, devices with a very large number of channels have been demonstrated. AWG suffers from polarization-induced phenomena, while free-space gratings do not. Free-space gratings offer perhaps the best optical isolation from all (de)multiplexing devices and have no restrictions with respect to the total optical bandwidth they can handle. In principle, the free-space devices can explore the parallelism of optics to generate many (de)multiplexers in parallel or to be used in conjunction with other free-space devices such as microelectromechanical switches (MEMSs) in optical cross-connects.

BIOGRAPHY

Alexandros Stavdas received his B.Sc. in physics from the University of Athens, Greece, in 1988, his M.Sc. in optoelectronics and laser devices from Heriot-Watt University/St-Andrews University in 1990, and his Ph.D. from the University College of London, United Kingdom, in 1995 (supervisor, Professor J.E. Midwinter) in the field of wavelength routed WDM networks. He worked in the design of free-space and integrated optics demultiplexers, wavelength cross-connects and on issues related to optical switching and wavelength routing systems. In the past he worked on the ACTS COBNET Project on alternative ring architectures and in design considerations and scalability of WDM rings, and on ACTS PLANET in the area of generic architectures for the WDM upgrade of SuperPONs. Currently, he is leading the project ULTRA funded by Nortel Networks on ultra-wideband DWDM systems and he is the technical leader for NTUA on the IST-DAVID project dealing with packet-over-WDM in Metropolitan Networks. He served as chairman of the Optical Network Design and Modelling Conference (ONDM 2000). Current interests include physical layer modeling of optical networks, ultra-high capacity end-to-end optical networks, OXC architectures, WDM access networks, and optical packet switching.

OPTICAL SIGNAL REGENERATION

GEERT MORTHIER
JAN DE MERLIER
Ghent University — IMEC
Ghent, Belgium

1. INTRODUCTION

It is well known that signals are significantly distorted when they propagate through optical fiber networks (see OPTICAL FIBER COMMUNICATIONS). In modern WDM communications, many channels at different wavelengths and each carrying signals of 10 or even 40 Gbps (gigabits per second) are sent through long stretches of fiber and are traversing several optical amplifiers and optical switches. The propagation of large-bandwidth signals through dispersive optical fiber gives rise to pulse broadening and distortion. The optical amplifiers add noise to the signals and the optical switches can give rise to crosstalk. In large optical networks, the resulting *deterioration* of the signals due to dispersion, noise, and crosstalk may be so large that errorless transmission is no longer possible unless the signals are regenerated at intermediate nodes. This is illustrated in Fig. 1, which schematically shows the increase in bit error rate (BER) as a function of the distance in an optical transmission link with and without *regeneration*.

Regeneration can be achieved by converting the optical signals into electronic signals (using optical receivers), regenerating the electronic signals, and by retransmitting the signals optically (i.e., using a laser). However, because of the involvement of power electronics, this *optoelectronic regeneration* becomes more and more costly as the bit rate increases. All-optical regeneration becomes a very interesting alternative to optoelectronic regeneration in this case. The fact that *all-optical regeneration* can in principle be extended to multichannel regeneration is, for WDM systems, especially attractive.

Different types of optical regenerators, based on fiber loops or on *photonic integrated circuits* (PICs), have been proposed so far in the literature. The regenerators based on PICs are in general much more stable than the ones based on fiber loops (which require, e.g., *polarization control*). The latter can be operated at higher speeds though. Fiber loop regenerators and high-speed regenerators in general are usually aiming at *return-to-zero* (*RZ*) *signals*. Regeneration of *non-return-to-zero* (*NRZ*) *signals* is often limited to lower bit rates.

2. FIGURES OF MERIT

One typically classifies regeneration into 1R, 2R, and 3R regeneration; 1R consists of simple reamplification, 2R includes *reamplification* and *reshaping*, and 3R includes reamplification, reshaping, and *retiming*. Figure 2 illustrates 3R regeneration. It is generally believed that 2R regeneration may suffice at bit rates below 10 Gbps. From 10 Gbps on, optical regeneration could consist of 3R regeneration at selected nodes and 2R regeneration at other nodes. At these very high bit rates, *timing jitter* or, in other words, fluctuations in the duration of the individual bits (see OPTICAL NOISE) can be a serious cause of degradation and must be alleviated by retiming techniques.

A number of properties determine the performance of regenerators. The quality of the *regeneration* itself is characterized by the extinction ratio improvement

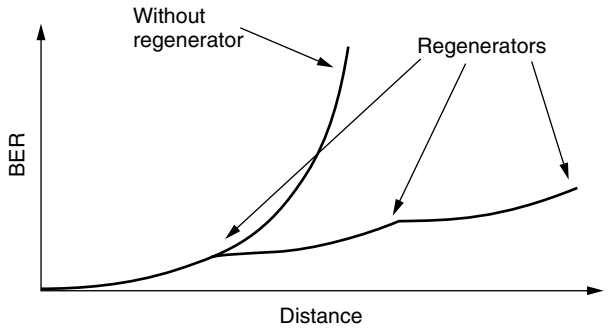

Figure 1. Increase of BER versus link distance with and without regeneration.

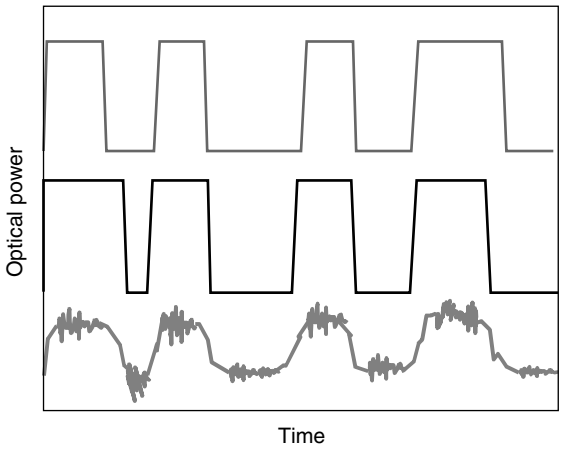

Figure 2. Schematic illustration of 3R optical regeneration; lower trace — signal before regeneration; middle trace — signal after 2R regeneration; upper trace — signal after 3R regeneration.

(see OPTICAL MODULATION) and by the *noise reduction* (determined by the flatness of the output vs. input power characteristic for both spaces and marks). An ideal 2R regeneration or *decision characteristic* as well as a more realistic characteristic are shown in Fig. 3. The *extinction ratio improvement* can be defined as $(P_{2,\text{out}}/P_{1,\text{out}})/(P_{2,\text{in}}/P_{1,\text{in}})$. In addition, the maximum bit rate should be as high as possible, while the required input power levels to the regenerator should be low or modest. The minimum required input power (for a digital one) is related to the decision threshold.

Finally, the ability to use the same device for regeneration over a broad wavelength range, even if one or more current settings have to be changed, is considered as a major advantage for WDM applications.

3. 2R REGENERATION

In order to obtain optical 2R regeneration, the nonlinear effects in optical waveguides (see OPTICAL WAVEGUIDES) are exploited. The incident light is used to influence the refractive index of the material through which it propagates. This happens via the interaction with the charge carriers in semiconductor waveguides. The refractive index variation in turn affects the propagation delay in the waveguides or, in other words, the phase of

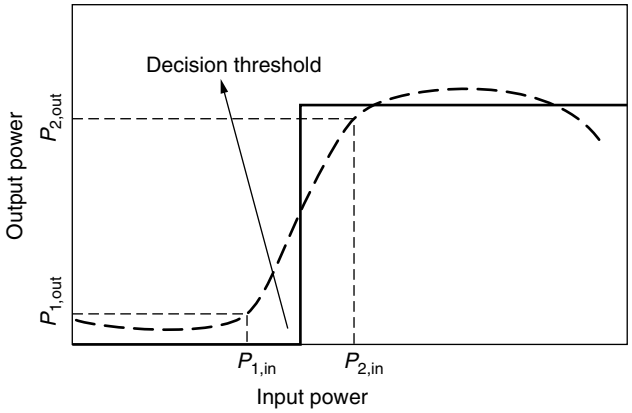

Figure 3. Ideal (full line) and realistic (dashed line) decision characteristic.

the optical field at the other end of the waveguide. The resulting phase changes can cause drastic changes in the output of a component when the waveguides are used in an *interferometric layout*.

3.1. SOA-Based Regenerators

The most promising results, in terms of regeneration, have been achieved with interferometric structures, such as the *Mach–Zehnder interferometer* (MZI) or Michelson interferometer (MI), containing a *semiconductor optical amplifier* (SOA) (see OPTICAL AMPLIFIERS) in each arm. With these interferometric structures, shown in Fig. 4, regeneration can be obtained through simultaneous *wavelength conversion* (see OPTICAL FREQUENCY CONVERSION) or without wavelength conversion, using a passthrough scheme.

When regeneration is performed using a passthrough scheme, the currents in both SOAs are chosen such that destructive interference is obtained at low input powers. Because of the difference in current, the saturation behavior of both SOAs will also differ. As a result, the phase difference between both arms will be modulated by the power variation in the data signal. This phase modulation is converted to an amplitude modulation at the output of the interferometer. Regeneration (although mainly for logical '1s') without wavelength conversion has been demonstrated at 40 Gbps using the Mach–Zehnder interferometer. When using a *Michelson interferometer*, input and regenerated signal have to be separated using a circulator.

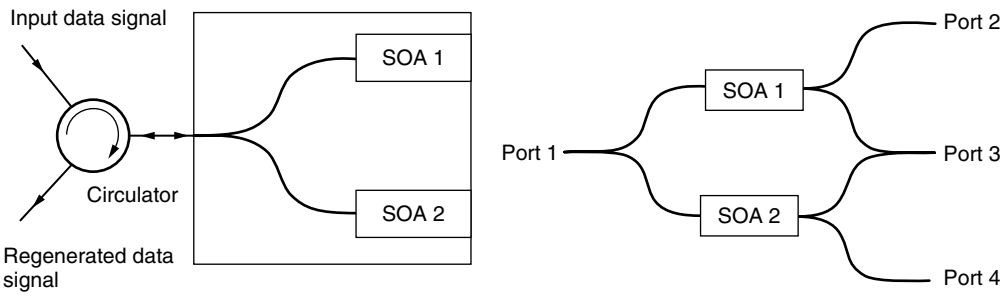

Figure 4. Michelson interferometer–based regenerator (left) and Mach–Zehnder interferometer–based regenerator (right).

The highest speed can theoretically be achieved with Mach–Zehnder interferometers and with simultaneous wavelength conversion. Wavelength conversion in the codirectional scheme (Fig. 4) is obtained by injecting a CW signal in port 3 and injecting the data signal in port 2. The electron density in SOA 1 is then modulated by the data signal. This causes a change in the phase difference between the arms, which causes modulation of the power in the CW signal at the output of the MZI. The CW signal can also be coupled into port 1, in a *counterdirectional scheme*. This allows the in- and output wavelengths to be the same and avoids the need for a filter at the output. Because of the sinusoidal dependence of the output on the phase difference between the arms, the polarity of the converted signal can be maintained or converted as compared to the incident data signal.

This scheme can be used at bit rates up to 40 Gbps for RZ signals. For the very high bit rates, however, a RZ input signal is converted to a NRZ signal [1], due to the finite lifetime of the electron density. Therefore other schemes are used at these very high bit rates.

Differential delay techniques make specific use of the fact that the interferometer output depends on the phase difference. In this scheme (Fig. 5), the data signals are injected in the SOAs in both arms of the MZI with a small delay between both pulses. The induced phase change in the arm where the data signal is injected first (e.g., ϕ_1), can be canceled out once the other pulse is injected into the other arm (giving a phase change ϕ_2). This differential control scheme has been shown feasible at bit rates of 40 Gbps. A filter is obviously required at the output to suppress the signal at λ_1.

Other SOA-based regenerators have been proposed on the basis of the nonlinear properties of, e.g., an active *multimode interference* (MMI) *coupler* and an active directional coupler. Both devices have been verified only by static measurements of the transfer characteristic, but for this static regime (and hence also for the low-bit-rate regime) they exhibited improved regeneration characteristics as compared to the MZI- and MI- based regenerators [e.g., 2].

3.2. Nonlinear Optical Loop Mirrors

Optical regenerators based on the *nonlinear optical loop mirror* (NOLM) make use of the ultrafast but weak Kerr nonlinearity (Fig. 6; see NONLINEAR EFFECTS IN FIBERS). This layout has the disadvantage that very high powers and several hundreds of meters of dispersion-shifted fiber (DSF) are required. The data signal is coupled in and out of the NOLM using a wavelength-dependent coupler (WDC). A CW-signal enters the NOLM through port 1 of a 50–50 coupler. Therefore, 50% of the CW signal propagates clockwise and 50% of it propagates counterclockwise in the ring. If a data pulse is present, the CW signal copropagating with the pulse experiences a nonlinear phase shift that is proportional to the data pulse intensity. At the output of port 2, one obtains interference between the phase-modulated clockwise and the counterclockwise propagating CW light. The light at the CW wavelength that is coupled out of the ring at port 2 is therefore a regenerated version of the data signal. The regenerative capabilities of the NOLM have been demonstrated at 80 Gbps, but this NOLM-based regenerator should be capable of regeneration at bit rates well over 100 Gbps [3].

3.3. Electroabsorption Modulators

Nonlinear behavior in a reverse-biased *electroabsorption modulator* (EAM) is achieved by using an intense input optical pulse to produce a large number of photogenerated charged carriers in the highly absorptive waveguide. Drift and diffusion of these carriers distort the electric field and cause a reduction of the field. As a result of the reduced electric field, the absorption decreases and a

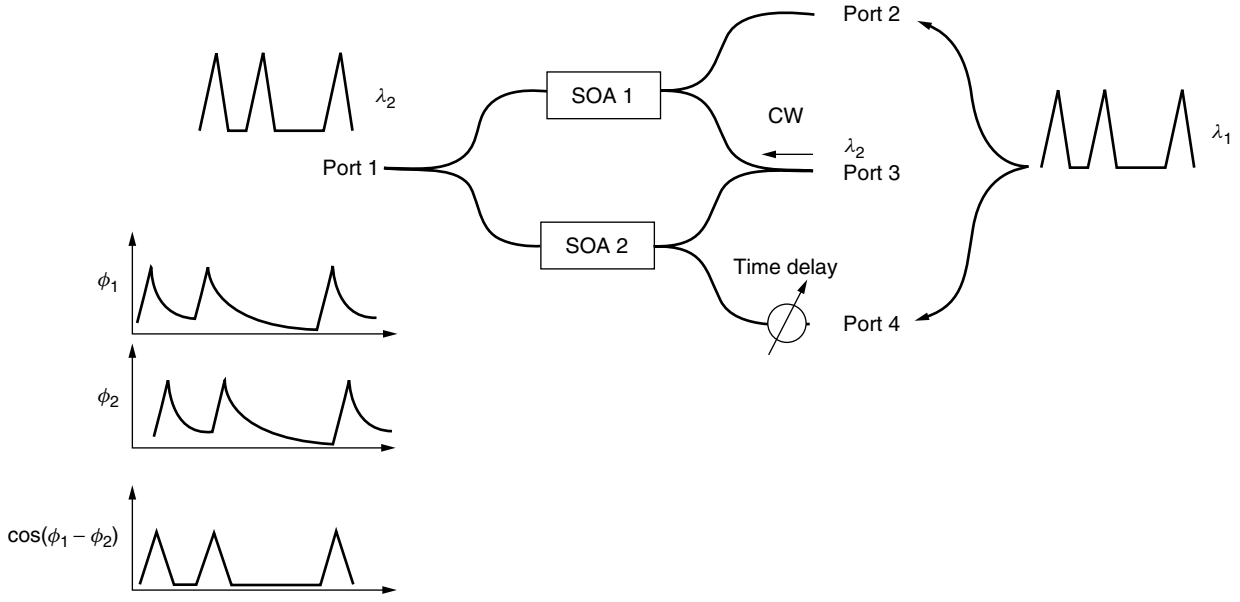

Figure 5. Differential delay scheme for a MZI-based regenerator.

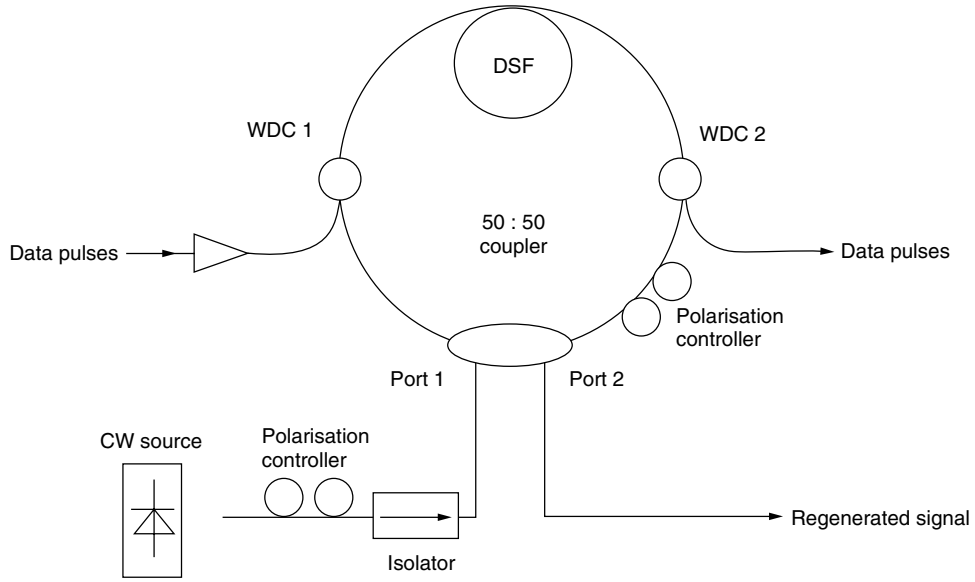

Figure 6. Scheme of nonlinear optical loop mirror (NOLM)-based regenerator.

transmission window is created for the pulse. When an intense optical pulse propagates through the EAM, a CW probe signal traversing the waveguide experiences the transient increase in transmission followed by a fast resumption of the absorption. As a result, a short pulse is generated at the wavelength of the probe signal. Weak input signals are absorbed without changing the transmission state of the EAM. This type has been demonstrated at bit rates of 40 Gbps.

3.4. Q-Switched Lasers

The *Q-switched laser* consists of three sections: two Bragg sections and one integrated phase tuning section Fig. 7. The second Bragg section is biased near transparency and is used as a dispersive reflector. The different sections are designed and biased such that lasing is achieved in the laser section only when a matched feedback is obtained from the reflector section.

Injection of a high-power data pulse changes the refractive index in the reflector section, which, in turn, causes a shift in the reflection band away from the lasing wavelength (change of Q factor), stops the required feedback and eventually ends the lasing in the laser section. Lasing starts again when the power in the signal falls again. Optimization of this scheme has led to successful tests up to 10 Gbps.

4. OPTICAL CLOCK EXTRACTION AND 3R REGENERATION

3R regenerators consist of 2R regenerators in combination with *optical clock extraction*. The periodic optical clock is then typically modulated in a more or less digital manner by the 2R-regenerated signal. Optical clock extraction itself is generally based on the use of self-pulsating laser diodes of which the self-pulsation frequency locks to the bitrate of the incoming signal. The self-pulsating laser diode can be either a *mode-locked laser* [4] or a multisection DFB laser [5]. Clock recovery up to 40 Gbps has been demonstrated with both types of devices.

The scheme for clock extraction based on a multisection DFB laser is the same as the scheme of Fig. 7, except that the regenerated signal is replaced by a clock signal. The DFB laser (see OPTICAL TRANSMITTERS AND RECEIVERS) now has to be designed such that lasing occurs in a self-pulsating regime and at a wavelength far away from the wavelength of the injected signal. The self-pulsation frequency of the free-running laser is determined by the injected currents

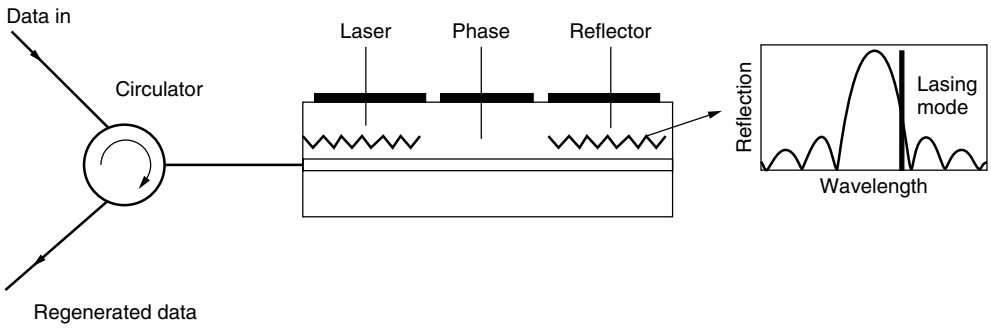

Figure 7. 2R regenerator based on a Q-switched laser.

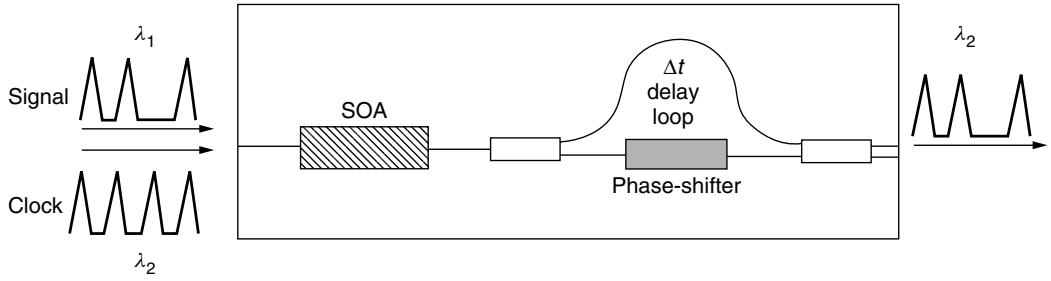

Figure 8. Scheme of semiconductor optical amplifier delayed interference device.

and can typically vary from 5 to over 40 GHz. When a data signal with a bit rate close to the repetition rate of the self-pulsation is injected, the self-pulsation synchronizes to the data signal and assumes a frequency (in GHz) that is exactly the bit rate (in Gbps).

All-optical 3R regeneration has been proposed by various groups [4–6]. In all cases, only a RZ signal format is considered. A recent idea is the use of a SOA *delayed interference device*, shown in Fig. 8. The delay Δt matches the period of the clock. The delayed interference coupler therefore produces at its output the interference of each clock pulse with the previous clock pulse. Pulses are produced in the lower arm of the coupler in the case of constructive interference and in the upper arm in the case of destructive interference. However, the phase and amplitude of the clock pulses are modulated in the SOA by the power of the data signal pulses. If the power of the data pulses is chosen carefully, a phase shift of π in the clock pulses can be obtained after each data pulse. Hence, each data pulse results in a constructive interference at the coupler and thus a clock pulse in the lower output of the coupler.

Optical 3R regeneration for NRZ signals has not been reported so far.

5. MULTICHANNEL REGENERATION

Multichannel optical regeneration is generally devised as a combination of phased-array multiplexers and demultiplexers and an array of single-channel regenerators. A possible concept for multichannel 2R regeneration, for instance, is depicted schematically in Fig. 9. The channels are demultiplexed by the *phased array* (see Optoelectronic Devices), and individual channels are fed to active Michelson interferometers [3]. After regeneration (and reflection), the channels are multiplexed again in the phased array. At the output waveguide of the phased array a circulator guarantees that the regenerated WDM signal is routed in another direction than that of the incoming signal.

Multichannel 3R regeneration requires simultaneous all-optical clock recovery of all WDM channels. This has been demonstrated recently using a module consisting of a demultiplexer, an array of SOAs (see Optical Amplifiers) and a multiplexer, all placed in an actively mode-locked fiber ring laser configuration [7]. The clock recovery module is shown in Fig. 10. The circuit of Fig. 10 forms an actively mode locked laser for each incoming channel. The mode locking results from the injection of a datastream into each SOA, which causes amplitude and

phase modulation of the light. The presence of the *tunable band-pass filter* allows the use of different phased array orders for the data and the extracted clock.

BIOGRAPHIES

Geert Morthier received the M.S. and Ph.D. degrees in electrical engineering from the University of Ghent, Belgium, in 1987 and 1991, respectively. He joined IMEC in 1991 and has been a group leader since 1992. Since 2001, he is also parttime professor at the University of Ghent. He has been author or co-author of approximately 100 publications and holds 5 patents. His areas of interest are DFB and tunable laser diodes and optical signal processing.

Jan De Merlier received the degree in physical engineering in 1998 at Ghent University, Belgium, and is currently working toward a Ph.D degree in electrical engineering at the Department of Information Technology, Ghent University. His main research interests are the dynamic properties of semiconductor optical amplifiers for use in all-optical regenerators.

OPTICAL SOLITONS

Magnus Karlsson
Peter Andrekson
Chalmers University of Technology
Göthenburg, Sweden

1. INTRODUCTION

A traveling wave that is localized in the sense that it does not spread its energy while propagating, is defined as a *solitary wave*. A *soliton* is a solitary wave with the additional property that it can collide with other solitons and emerge unaffected with respect to energy, shape and momentum after the collision. Over the years, however, it has become common practice, especially in optics, to use "soliton" also in the less strict definition, although the mathematical differences between solitons and solitary waves are profound.

In 1834, the Scottish engineer John Scott Russel made the first scientific observation of a soliton, in the form of a single water wave that rolled forward in a canal with unchanged velocity and shape. The phenomenon was mathematically explained sixty years later in terms of a solution to a nonlinear partial differential equation that governs the motion of shallow water waves. Further progress on soliton physics came in the 1960s, when novel analytic methods were developed to exactly solve equations governing solitons.

It was realized in 1973, by Hasegawa and Tappert [1] that the weak Kerr nonlinearity present in optical fibers (which makes the refractive index increase in proportion to the optical intensity) might counteract the pulse broadening induced by group velocity dispersion (GVD). In fact, the two effects can form a stable balance in the form of a soliton pulse, which then propagates without changing shape.

Because of the lack of short-pulse laser sources at wavelengths above 1.3 μm, and low-loss silica fibers, it took another seven years for optical soliton pulses to be experimentally verified. In an experiment by Mollenauer et al. [2] in 1980, soliton pulse transmission over 700-m fiber was demonstrated. During the 1980s the soliton research aimed toward the use of solitons as information carriers in optical communications, and in 1990 the first data transmission experiment using solitons [2.8 Gbps (gigabits per second) over 23 km of fiber] were reported by Iwatsuki et al. [3].

During the 1990s, soliton-based communication systems have matured, an important reason being the development of the erbium-doped fiber amplifier (EDFA), which made high power levels commercially available. The most recent development has been toward the use of solitons in alternating dispersion maps (so called *dispersion management*), and such systems have reached performance levels near commercialization.

In the present review, we discuss both theoretical and experimental aspects of soliton transmission. We will distinguish between *conventional solitons*, which have constant dispersion during the transmission, and *dispersion managed solitons* (although solitary waves would be the proper mathematical name) for which the dispersion varies periodically during transmission.

2. WAVE PROPAGATION IN OPTICAL FIBERS

We restrict the treatment here to forward-going (in the z direction) waves along single-mode fibers. This means that the lightwave propagates according to $\exp(-i\beta z)$, where the wavenumber $\beta = n\omega/c$ is a function of the angular frequency ω, the refractive index n, and the vacuum speed of light c. In fused silica fibers the refractive index depends on the frequency and intensity of the light, and it is usually modeled as

$$n = n_0(\omega) + n_2|E|^2 \tag{1}$$

where $n(\omega)$ is the frequency-dependent part, n_2 is the nonlinear part, and E is the electric field of the wave. This nonlinear dependence on the wave intensity is known as the *optical Kerr effect*. In fused silica, the Kerr coefficient n_2 is very small; on the order of 10^{-20} m^2/V^2. The nonlinear part of the refractive index will enter as a nonlinear part in the dispersion relation, which can be written as $\beta = \beta_{\text{lin}}(\omega) + \beta_{\text{nonlin}}$. After averaging the nonlinear index over the mode profile, the nonlinear part becomes

$$\beta_{\text{nonlin}} = \frac{2\omega Z_0 n_2}{c n_0 A_{\text{eff}}}|u|^2 = \gamma|u|^2 \tag{2}$$

where $Z_0 \approx 120\pi\,\Omega$ is the wave impedance of vacuum, n_0 is the average refractive index, and A_{eff} is the effective mode area of the fiber. All these constants are contained in the nonlinear fiber coefficient γ, which has units of m^{-1} W^{-1}. We also use the wave amplitude u of the light, normalized so that the transmitted power is given by $|u|^2$. The value for γ varies from different fiber types, due to the dependence on the core area A_{eff}, but for standard single-mode fibers at $\lambda = 15.50$ nm it is approximately 2.2 m^{-1} W^{-1}.

2.1. Linear Dispersive Fiber Transmission

Linear transmission is straightforward to carry out in the frequency domain, where the wave amplitude spectrum $\tilde{u}(z,\omega)$ propagates according to $\tilde{u}(z,\omega) = \exp(-iz\beta_{\text{lin}}(\omega))\tilde{u}(0,\omega)$. This can also be expressed in the time domain, but then the function $\beta_{\text{lin}}(\omega)$ should be interpreted as the operator $\beta_{\text{lin}}(-i\partial/\partial t)$. In general we can Taylor expand the dispersion relation $\beta_{\text{lin}}(\omega)$ around the carrier frequency ω_0 to arbitrary orders. The first two terms of this expansion will correspond to the phase and group velocities of the wave, and can be removed with a suitable choice of coordinate system. Thus we can write

$$\beta_{\text{lin}}(\omega) = \frac{\beta_0''}{2}\omega^2 + \frac{\beta_0'''}{6}\omega^3 + \cdots \tag{3}$$

where now ω is measured from the carrier wavelength ω_0. The coefficient β_0'' is known as the *group velocity dispersion* (GVD) *coefficient*. The GVD is said to be *normal* if v_g decreases with frequency (i.e., $\beta_0'' > 0$), and *anomalous* if v_g increases with frequency (i.e., $\beta_0'' < 0$). Another common measure of the fiber dispersion is the *dispersion parameter*, D. The dispersion parameter D [ps/(km · nm)] is related to the GVD coefficient β_2 [ps^2/km] as $D = -\beta_2 2\pi c/\lambda^2$. In standard single-mode fibers (SMFs) the GVD is to a good approximation a linear function of the frequency, with slope $\beta_0''' \approx 0.1$ ps^3/km and zero at the *zero-dispersion wavelength* λ_0, at which $\beta_0'' = 0$. Above (below) this wavelength we have anomalous (normal) GVD. In standard single-mode fibers $\lambda_0 \approx 1.33\,\mu m$, whereas in dispersion-shifted fibers (DSFs) $\lambda_0 \approx 1.55\,\mu m$. The fiber manufacturing of today has reached a very mature level, and it is possible to tailor fibers to have a wide range of dispersion zeros and dispersion slopes.

It is instructive to consider the linear evolution of the Gaussian pulse $u(0,t) = u_0\exp(-t^2/2T_0^2)$, which is

$$u(z,t) = u_0\frac{T_0}{\sqrt{T_0^2 + i\beta_0'' z}}\exp\left(-\frac{t^2}{2(T_0^2 + i\beta_0'' z)}\right) \tag{4}$$

and where β_0''' has been neglected. The pulsewidth is determined by the real part of the exponent, which means that the width will broaden according to $T(z) = \sqrt{T_0^2 + (\beta_0'' z/T_0)^2}$. The imaginary part of the exponent corresponds to a phase modulation over the pulse, of the form $\exp(-iC(z)t^2)$, which does not affect the pulse width. Instead, this phase modulation (known as the *linear chirp* of the pulse) shows that the frequency components are redistributed within the pulse so that the slow and fast frequency components are put in the respective trailing or leading edges of the pulse. This is evident by considering the instantaneous frequency $\omega_i(t)$ of the pulse which is defined as $\omega_i(t) = d(\arg(u))/dt$, and for the Gaussian pulse it will be $\omega_i(t) = -2tC$, which reveals that the trailing (leading) part of the pulse is red (blue)-shifted for positive C (i.e., anomalous dispersion). For normal dispersion it is the other way around.

2.2. Nonlinear Fiber Transmission: Self-Phase Modulation

If we neglect the linear parts in the dispersion relation for the moment and concentrate on the nonlinear part, we see that an initial pulse $u(0,t)$ will propagate according to $u(z,t) = u(0,t)\exp(-i\gamma z|u(0,t)|^2)$. This is called *self-phase modulation* (SPM) as the pulse modulates its own phase. The corresponding instantaneous frequency will be $\omega_i(t) = -\gamma z d(|u|^2))/dt$, which is negative in the leading edge and positive in the trailing edge of the pulse, which is the same as for normal dispersion. As a result the nonlinearity will increase the dispersive spreading for normal dispersion, and decrease it for anomalous dispersion. In the case when the nonlinearity and the dispersion exactly cancel out, an optical soliton that propagates without dispersive spreading is formed.

3. CONVENTIONAL FIBER SOLITONS

3.1. The Nonlinear Schrödinger Equation

Taking both self-phase modulation and dispersion into account, we get the following propagation equation valid

for light in an optical fiber:

$$i\frac{\partial u}{\partial z} + \frac{\beta_0''}{2}\frac{\partial^2 u}{\partial t^2} - \gamma|u|^2 u = i\frac{\alpha}{2}u + i\frac{\beta_0'''}{6}\frac{\partial^3 u}{\partial t^3} \tag{5}$$

where $1/\alpha$ is the fiber loss length, which is of the order of 25 km at $\lambda = 15.50$ nm. For fiber lengths less than 1 km this can be ignored. Retaining only the terms on the left-hand side, gives the *nonlinear Schrödinger* (NLS) *equation*, which was derived for fibers originally by Hasegawa and Tappert in 1973 [1]. The NLS equation is a universal nonlinear propagation equation in the sense that it arises in many different fields of physics, and it has, for nonlinear partial differential equations the unusual and nice feature that it is *integrable*, which means that its initial-value problem can be solved exactly.

It is the anomalous dispersion case that is of most interest to us, and we will summarize the properties of the NLS equation in this case. For this it is convenient to work with the NLS equation in normalized form, and we introduce the "soliton normalizations"

$$q = u\sqrt{\frac{\gamma}{L_d}} \quad \tau = \frac{t}{t_0} \quad \xi = \frac{z}{L_d} \equiv \frac{z|\beta_0''|}{t_0^2} \tag{6}$$

where t_0 is the pulse width and L_d the dispersive length. In the case of anomalous dispersion, the NLS equation in these normalized units becomes

$$i\frac{\partial q}{\partial \xi} = \frac{1}{2}\frac{\partial^2 q}{\partial \tau^2} + |q|^2 q \tag{7}$$

The mathematical theory for the solution of this equation, which demonstrates the *inverse scattering transform* (IST) for the NLS, was given 1972 in an important paper by Zakharov and Shabat [4]. They found that a crucial role is played by the *soliton* solution to Eq. (7)):

$$q_{\mathrm{sol}}(\xi,\tau) = A\,\mathrm{sech}(A(\tau - V\xi)) \times \exp\left[-iV\tau + i\frac{(V^2 - A^2)\xi}{2}\right] \tag{8}$$

where A is an arbitrary soliton amplitude and V is an arbitrary frequency shift. Note that the soliton moves with the "velocity" V in the retarded reference frame due to this shift, which means that the soliton moves with the group velocity of the carrier wavelength. Because the soliton does not broaden dispersively, it seems very attractive for information transfer.

The IST reveals that all solutions to the NLS equation consist of solitons and dispersive radiation [i.e., dispersively broadening pulses like in Eq. (4)]. Early numerical simulations [1] also demonstrated the stable-attractor properties of the soliton. The theory also shows that any number (say, N) solitons can be present simultaneously, forming an "N soliton" solution. This can be either N well-separated soliton pulses, or if the pulses are clumped together, an oscillating N-soliton structure, called a *breather*.

One important implication of the IST is that we can already from the initial condition $q(0,\tau)$ conclude what kind of soliton will emerge for large values of ξ. For the initial condition $q(0,\tau) = A\mathrm{sech}(\tau)$, the emerging soliton is an N : th order soliton, where $A = N + \eta$, N is an integer and $|\eta| < \frac{1}{2}$. In the case where the initial pulse is given by $(1+\eta)\mathrm{sech}(\tau)$, an emerging soliton with $A = 1 + 2\eta$ is formed [5]. For an arbitrarily shaped real initial pulse, the condition for soliton creation is that the pulse area exceeds $\pi/2$ in normalized units. Note that the soliton area, $\int_{-\infty}^{+\infty} q_{\mathrm{sol}} d\tau = \pi/2$ is independent of the free parameters A and V, so that there is a critical *area* for soliton creation, rather than a critical power level. Therefore, solitons having all power levels $|q(0,0)|^2 = A^2$, and energies $\int |q_{\mathrm{sol}}|^2 d\tau = 2A$ exist. For a given pulse duration and shape, however, the condition for creation gives the necessary power to obtain a soliton, and this can be viewed as a critical power level.

Finally it is instructive to transform back to physical parameters and write the fundamental soliton of duration t_0 as

$$u_{\mathrm{sol}}(z,t) = \sqrt{\frac{|\beta_0''|}{\gamma t_0^2}}\mathrm{sech}\left(\frac{t}{t_0}\right)\exp[-iz\beta_{\mathrm{sol}}] \tag{9}$$

where the soliton wavenumber $\beta_{\mathrm{sol}} = |\beta_0''|/2t_0^2 = (2L_d)^{-1}$. It should be emphasized that the soliton wavenumber β_{sol} must lie in a regime where it cannot equal linear wavenumbers. For the NLS equation we have $\beta_{\mathrm{lin}} = -|\beta_0''|\omega^2/2 < 0$ and $\beta_{\mathrm{sol}} > 0$. Examples of cases when this condition is not fulfilled are when higher-order dispersion or periodic amplification is present. The soliton peak power P_s [W] and energy E_s [J] can be expressed as $P_s = |u_{\mathrm{sol}}(z,0)|^2 = |\beta_0''|/\gamma t_0^2$ and $E_s = 2P_s t_0 = 2|\beta_0''|/\gamma t_0$.

Next, we will review the effects of a few of the most important perturbations of solitons in fibers, and see how the right-hand side terms of Eq. (5) affect soliton propagation.

3.2. Solitons in Presence of Third-Order Dispersion

The significance of third-order dispersion (3OD) depends on the amount of soliton energy that lies in the normal-dispersion regime, which in practice depends on the pulsewidth and the carrier wavelength. The effects from 3OD are particularly important near the zero-dispersion wavelength, and the governing equation is then

$$i\frac{\partial q(\xi,\tau)}{\partial \xi} = \frac{1}{2}\frac{\partial^2 q}{\partial \tau^2} + |q|^2 q + i\varepsilon\frac{\partial^3 q}{\partial \tau^3} \tag{10}$$

where $\varepsilon = \beta_0'''/6|\beta_0''|t_0$. Using perturbation theory, it is possible to find the lowest-order (in ε) corrections to the soliton $q = A\mathrm{sech}(A\tau)\exp[-i\xi A^2/2]$, which reveals that the soliton will be spectrally shifted into the anomalous dispersion regime an amount εA^2, and as a result acquire a new group velocity. However this is not the whole story.

We note that the linear dispersion relation when third-order dispersion is present is $\beta_{\mathrm{lin}} = -|\beta_0''|\omega^2/2 + \beta_0'''\omega^3/6$, and the soliton wavenumber is $\beta_{\mathrm{sol}} = |\beta_0''|/2t_0^2$. Evidently, at a certain frequency β_{sol} equals β_{lin}, and for that frequency the soliton will act as a source for linear waves, which will then radiate and leave the soliton. The radiating frequency ω_r is approximately equal to $(2t_0\varepsilon)^{-1}$ when ε is small. This frequency lies in the normal dispersion regime. Since it is the soliton that acts as a

source for the radiation, the amplitude of the radiation will be proportional to the soliton spectral amplitude at ω_r, which is $u_{\rm sol}(t_0\omega_r) \sim \mathrm{sech}(\pi t_0\omega_r/2) \sim \exp(-\pi t_0\omega_u/2) = \exp(-\pi/(4\varepsilon))$ [e.g., 6]. Thus the radiation is exponentially small for small ε, but the fact that it cannot be expressed as a Taylor series in ε makes conventional perturbation analysis very difficult [7]. In communications, this kind of radiation must be avoided, and the solution is to make sure the soliton is sufficiently located to the anomalous dispersion regime, specifically, that ε is small enough. As a design criterion $\varepsilon < 0.04$ has been suggested [7].

3.3. Solitons in Presence of Amplification and Loss

The most important property that has been neglected in the derivation of the NLS equation for optical pulses is the effect of loss. We base the discussion on Eq. (5), retaining only the loss term $\alpha/2u$ on the right-hand side. For a soliton solution $q_{\rm sol} = A\mathrm{sech}(A\tau)\exp[-i\xi A^2/2]$, one can show that the amplitude and width are adiabatically modified according to $A(\xi) = A_0\exp[-\alpha L_d\xi]$. However, after an initial phase this rate of pulse broadening and amplitude decay will be replaced by conventional linear dispersive broadening and amplitude decay [8].

In soliton communication systems the effect of fiber loss must be compensated for by periodically spaced amplifiers. This will introduce a periodic perturbation on the soliton, with period equal to the amplifier distance L_a, and with a corresponding perturbation wavenumber $\beta_{\rm per} = 2\pi/L_a$. This wavenumber can make up for the wavenumber difference between the linear waves and solitons, and if the equation $\beta_{\rm sol} = \beta_{\rm per} + \beta_{\rm lin}(\omega)$ has any solutions, the corresponding frequencies will be unstable and radiate. From the condition above we find the radiating frequencies ω_r as $1 + (t_0\omega_r)^2 = 4\pi L_D/L_a$, and since the soliton spectral width is of the order t_0^{-1}, it suffices that $t_0\omega_r \gg 1$, and usually $L_D > L_a$ is adopted as a design criterion. This fact, that the dispersive length must be larger than the amplifier spacing is a serious obstacle for conventional soliton systems at high bit rates, and as a result solitons in the early 1990s showed most success in transoceanic systems, where the total system length is very long, but where the data rate is relatively moderate.

Finally it should be emphasized that the launched peak power of the soliton at each amplifier should be such that the path-average power between the amplifiers equals the soliton power, P_s. Since the peak power $P_{\rm peak}$ falls off as $\exp(-\alpha z)$, the average peak power over one amplifier span is $P_{\rm peak}(1-\exp(-\alpha L_a))/\alpha L_a = P_{\rm peak}(G-1)/G\ln(G)$, where $G = \exp(\alpha L_a)$ is the amplifier gain.

3.4. Sources of Timing Jitter

Another transmission obstacle is the various sources of random movement in the bit slot, namely, timing jitter of the pulses in the data transmission link. There are various sources of timing jitter, such as soliton interaction, Gordon–Haus, acoustic, and WDM–collision-induced types of jitter.

3.4.1. Soliton Interactions. Because solitons are nonlinear pulses, they will *interact* with adjacent pulses in the pulsetrain, as pointed out quite early [9]. Interaction between solitons of the same polarization and wavelength is *phase-sensitive*, so in-phase solitons will attract each other whereas out-of-phase solitons will repel each other. The interaction can be quantified via the collapse distance z_c at which in-phase solitons merge, and one can show that $z_c \approx \exp(T/2t_0)L_D\pi/4$, where T is the bit separation. The relative pulse separation is usually defined as T/T_{FWHM}, where $T_{FWHM} = 1.76t_0$ is the soliton width [in the full-width half-maximum (FWHM), sense]. A typical separation used in experiments is $T/T_{FWHM} \approx 5$.

Orthogonally polarized solitons interact substantially less, since it is then the intensity overlap that causes the interaction, rather than the amplitude overlap as for copolarized solitons. Polarization-multiplexed solitons, where adjacent pulses have orthogonal polarization can therefore be packed almost twice as dense, and $T/T_{FWHM} \approx 2.5$ is a commonly used separation.

3.4.2. Gordon–Haus Jitter. The noise from the inline amplifiers will give rise to a small jitter in the carrier frequency of each soliton, thereby changing the group velocity and hence affect the arrival time of each pulse. This is known as the *Gordon–Haus effect* after the authors of Ref. [10], and it has to be accounted for in long-distance systems. The variance of the timing jitter can be expressed as

$$\langle \delta t^2 \rangle = t_0^2 \frac{2n_{sp}(G-1)^2}{9N_s G\ln(G)} \frac{L^3}{L_d^2 L_a} \tag{11}$$

where $N_s = 2P_s t_0/h\nu$ is the number of photons in the soliton. The fact that Gordon–Haus jitter grows cubically with distance makes it particularly important at transoceanic lengths, typically exceeding 1000 Km.

3.4.3. Acoustic Jitter. The electrostriction nonlinearity in the fiber gives rise to a mechanical pressure proportional to the optical intensity, which in turn modifies the refractive index of the fiber. In particular, an intense optical pulse like a soliton will give rise to a pressure (acoustic) wave moving radially outwards from the fiber center. The pulses in the wake of this wave will experience a randomly changing local refractive index, and hence (just as for Gordon–Haus jitter) a randomly changing carrier frequency that transforms into a timing jitter. An approximate expression for the standard deviation of this jitter has been found as [11]

$$\langle \delta t^2 \rangle^{1/2} = 0.0138 D^2 B L^2 (B - 1.18)^{1/2} \tag{12}$$

where D is the dispersion in ps/(nm·km), L is the system length in million meters [Mm], and B is the bit rate in gigabits per second (Gbps). Here a soliton separation $T/T_{FWHM} = 5$ has been assumed. We see that the variance of the jitter scales with distance to the fourth power: more rapid than Gordon–Haus jitter at large distances. This is because the acoustic perturbation is constant along the fiber, whereas the amplifier noise (which is the source for Gordon–Haus jitter) increases linearly with the system length.

3.5. WDM Considerations

Wavelength-division multiplexing (WDM) is another way of increasing the bit rate of soliton systems, where several frequency bands are used for solitons transmission. This technique was pioneered by Olsson et al. [12] 1991. The problem with WDM transmission using solitons stems mainly from collisions between solitons from different wavelength channels. In a perfectly ideal NLS equation solitons would collide elastically without changing carrier wavelength. However, the presence of losses and amplification may cause the collisions to be asymmetric if they occur around an amplifier, and a result will be a frequency displacement and a concomitant timing jitter. One solution to this problem is to force the collisions to be sufficiently long, forcing the collision distance to be larger than several amplifier spans. Widely separated WDM channels, however, collide over a short distance of fiber (simply because of dispersion) so this condition will restrict the accessible optical bandwidth to WDM solitons.

3.6. Soliton Control

Soliton control is the common name for methods to control the soliton parameters such as wavelength and position. There are two different approaches: passive and active control.

Passive soliton control has been suggested in the form of filters that are inserted along the transmission path. This helps to keep the soliton wavelength fixed. In this way not only Gordon–Haus and acoustic jitter can be remedied, but also interaction jitter and WDM-collision-induced jitter. A problem with this kind of filtering is that it defines a spectral region with excess gain, in which amplifier noise will grow excessively. A way around that problem is to slightly shift the center wavelength of the filters along the transmission path. In that way the solitons will follow the frequency shift, but the linear noise will not. Such sliding filter experiments have demonstrated 8×10 Gbps WDM soliton transmission over 10000 Km [13].

Active control usually acts in the time domain by using phase or amplitude modulators to retime and reshape the solitons. Using this technique, 10 Gbps over unlimited distances [14] has been demonstrated. However, this kind of active reshaping of the pulses suffers from the same drawbacks as the conventional electronic regeneration, specifically, incompatibility with WDM, complexity, and high cost.

3.7. Polarization Effects

A single-mode fiber is not strictly single-mode, since it always allows for two polarization modes. Imperfections along the fiber cause birefringence that will accumulate randomly during propagation, and eventually cause a net birefringence that is nonnegligible. This effect, known as *polarization-mode dispersion* (PMD), is considered by several researchers as a fundamental limit for linear pulse propagation since it drifts randomly as the fiber cable is exposed to temperature and/or pressure changes. Soliton pulses, however, are found to be more robust to PMD [15] than linear pulses. The reason for this is that an attractive interaction force between the polarization states works to keep the pulses together. However, some amount of radiation is shed by the solitons as a result of the random birefringence of the fiber, and that gives rise to pulse broadening, although not as significant as that for linear pulses. The soliton robustness to PMD was recently verified by transmission on installed fibers [16].

PMD will also limit the benefit of using polarization multiplexing to suppress pulse interactions. It has been shown [17] that for high PMD, a copolarized pulsetrain will perform better than a polarization multiplexed one.

There is another timing jitter effect stemming from the birefringence of the fiber, the so-called birefringence-mediated timing jitter [18]. This effect arises from the fact that amplifier noise will give rise to a small uncertainty in the soliton polarization state, which via the birefringence is transformed to a timing jitter. Also WDM collisions of soliton trains will give rise to polarization changes, which will add to this timing jitter. This source of jitter can be reduced with inline synchronous modulation. Passive filters, however, will not work in this case, as no frequency jitter is associated with the timing displacement.

4. DISPERSION-MANAGED SOLITONS

4.1. Introduction

Since the very late 1990s, solitons have become substantially more attractive through the rapidly emerging strategy of improving the performance of soliton transmission with dispersion management (DM). While the DM strategy, which involves altering the local dispersion between a large positive and a large negative GVD (group velocity dispersion) such that the average GVD is small, has long been used in linear systems it was only relatively recently appreciated that the same technique, if properly implemented, gives rise to several very striking improvements over conventional soliton transmission systems. While DM solitons are clearly nonlinear pulses, they are by no means classical solitons.

From a commercial viewpoint, however, the most important benefit with using DM solitons is that they, in principle, can use the already installed conventional fibers (with zero dispersion at 1300 nm) allowing a much more cost-effective upgrade together with dispersion-compensating fibers (DCFs) or chirped fiber gratings (then likely collocated with inline EDFAs), at certain intervals in the link.

4.2. Properties

DM solitons are not real solitons (they are rather solitary waves) in the sense that they have an inverse scattering transform that can be used to find the most relevant properties. Instead they emerged from extensive simulation work, and it was quite surprising to many researchers that the simulations revealed such stable and strictly periodic pulses.

In Fig. 1 the evolution of the temporal and spectral widths for a DM soliton is shown. Also shown is the dispersion map, which is a plot of how the dispersion changes with propagation distance. A lossless model is assumed, which is applicable to dense amplifier

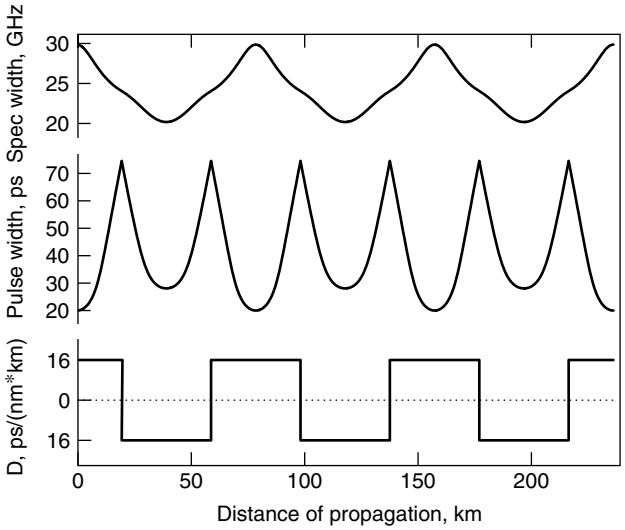

Figure 1. The evolution of the spectral width (top) temporal width (middle) of a DM soliton with zero average dispersion and map strength $S \approx 4$. The bottom plot shows the dispersion map. The symmetry of the evolution within the map period is due to the lossless model employed. (Figure contributed by A. Berntsson.)

spacing, but even when losses are included the qualitative conclusions and general properties will still hold. One difference in the lossy case is, however, that the symmetry of the propagation dynamics is removed, and the spectral dynamics will be concentrated to the positions in the dispersion map where the power is largest.

As a result of massive simulation work done by many groups the following properties of DM solitons have been found.

- The pulsewidth, chirp, and spectral width oscillates periodically in the dispersion map. There are two points within the period at which the pulse is chirp-free, and those correspond to local minima of the pulsewidth. One of those points is the global minimum width, referred to as the "shortest pulse" below.
- A central parameter that is useful for the characterization of DM solitons is the *map strength*, $S = (L_1|\beta_1''| + L_2|\beta_2''|)/T_{\mathrm{FWHM}}^2$, where L is length, β'' is dispersion, T_{FWHM} is the minimum pulsewidth in the full-width half-maximum sense, and subscripts 1,2 refer to the two fibers in the dispersion map. Physically the map strength is the number of dispersive lengths the pulse propagates in one period. DM solitons have been found for map strengths ranging from $S = 0$ (which is the same as conventional solitons) to $S \approx 12$, although this upper limit is a transition regime in which the pulses radiate and a perfect periodic evolution never arises.
- DM solitons have been found for anomalous, normal, and zero average dispersion $\overline{\beta}''$, defined as $\overline{\beta}'' = (L_1\beta_1'' + L_2\beta_2'')/(L_1 + L_2)$. Normal average dispersion is only possible for map strengths above 3.9.
- The shape of the shortest pulse ranges from hyperbolic secant at $S = 0$ to Gaussian for higher map strengths, and this is also evident from the time–bandwidth product, which increases with S from 0.32 (Sech) at $S = 0$ to 0.44 (Gaussian) and even higher for large values of S. In addition, the shortest pulse has oscillating tails in the pulse wings.
- The energy of a DM soliton pulse is enhanced relative to a soliton with the same average dispersion and pulsewidth.
- The interaction between DM solitons is less than that of conventional solitons, and an optimum map strength exists that minimizes the interaction.

The fact that DM solitons can work for an average net zero GVD and even for normal dispersion, was a striking and unexpected feature that would not work with conventional solitons. This can be understood by the fact that the spectral width of the pulses are larger when they propagate in the local anomalous dispersion regime than when they propagate in the normal dispersion regime (see Fig. 1). The pulses then effectively sense a net anomalous dispersion that is balanced by the nonlinearity as for conventional solitons.

The technical improvements with DM solitons over conventional ones are numerous. The signal-to-noise ratio is improved since the DM solitons have a larger peak power than do the corresponding conventional solitons. DM solitons have less Gordon–Haus and acoustic timing jitter, since the system average GVD is much smaller in these systems. A very important added benefit appears in wavelength-division-multiplexed (WDM) systems. Because of the alteration between large positive and negative GVD along the path, the jitter induced from WDM, soliton collisions is greatly reduced. This, in turn, allows for very dense WDM, which will improve the spectral efficiency substantially. The soliton PMD robustness is maintained or improved for DM solitons.

An important practical consequence of using DM solitons is that they reduce (or eliminate) the need for inline soliton control such as synchronous modulation or sliding filters. Yet soliton control methods are still applicable and will give improvement in terms of signal-to-noise ratio for DM solitons as well.

Quite impressive circulating loop experiments including WDM have been reported. In the study by Le Guen et al. [19] 51 very densely packed WDM channels each operating at 20 Gbps were transmitted over 1000 km with 100-km sections of standard fiber, clearly demonstrating the strength of the DM soliton technique.

4.3. Intrachannel Impairments

DM solitons have so many attractive features that they are likely to be implemented commercially in the near future. However, there are some novel transmission impairments, unique to DM solitons that need to be accounted for and analyzed in more detail. They are the so-called intrachannel effects; intrachannel four-wave mixing (ICFWM), and intrachannel cross-phase modulation (ICXPM) [20], and arise due to the nonlinear interaction between two neighboring pulses. Four-wave mixing (FWM) and cross-phase modulation (XPM) are

usually effects associated with WDM transmission. However, the fact that DM solitons are chirped and broadened, will cause different frequency components from neighboring pulses within the same wavelength channel to overlap in time, thereby causing FWM and/or XPM.

ICFWM arises for two neighboring pulses, that via four-wave mixing (FWM), creates new frequency components that in the time domain will give rise to a new pulse (commonly referred to as a "ghost pulse"), next to the two. The ghost pulse will then give rise to intersymbol interference and reduction of the eye opening. ICFWM is most prominent for large map strengths and high power.

ICXPM can be viewed as DM soliton interaction, and physically, it manifests as the frequency shift of one pulse induced by the presence of a neighboring pulse, which, by the dispersion transforms into a timing jitter. The effect can be minimized by selecting proper map strength and prechirp of the DM soliton.

As a rule, however, it seems that map strengths in the range 1–8 make best use of the unique features of DM solitons. This means that the use of installed standard fiber becomes difficult at very high bit rates (say, beyond 30–40 Gbps) as shorter pulses require a more rapidly varying dispersion map to maintain a proper S value. This is a limitation similar to the amplifier spacing limitation in conventional soliton systems, but it is much less severe. If an option is to install new dispersion-shifted fiber, on the other hand, this limitation becomes essentially unimportant.

5. EXPERIMENTS AND FIELD TRIALS

5.1. Soliton Pulse Sources

When doing soliton experiments, be it conventional or DM solitons, particular importance is placed on the properties of the pulse source, as it sets the lower limit of the system performance. A high-bit-rate soliton pulse source needs to produce low-chirp, low-timing-jitter pulses with proper duration (in the picosecond regime), repetition rate (10–40 GHz) and shape.

One possible choice is gain-switched (GS) laser diodes, possibly with an external cavity for tunability. However, they suffer the drawback of producing pulses that are strongly chirped, asymmetric and often too wide.

For laboratory experiments fiber ring lasers (FRLs) are very attractive, as they provide wavelength and pulse width tunability, besides meeting the above mentioned demands. Their drawback is that they are bulky, need active stabilization and sometimes also temperature control to achieve long-term stability.

Finally, it appears quite clear that electroabsorption modulators (EAMs) [whether integrated or not with a distributed feedback (DFB) laser] are very useful and simple sources for soliton transmission. While such sources were developed for linear NRZ (non-return-to-zero) systems, they have now proven to be near ideal in soliton systems as well. Although EAMs are not commercially available at 40 GHz yet, they are likely to be so within the near future.

Special considerations need to be taken in DM soliton systems, however, as the launch condition is different than for conventional solitons. The pulses should have a linear chirp such that it fits seamlessly in the periodically induced chirp variation along the link. This can be achieved by incorporating a proper length of fiber (or chirped fiber grating) in the transmitter once the overall dispersion map is known.

5.2. Loop Experiments

In order to investigate really long distances (megameters) of transmission, the loop experiments were developed in the early 1990s. This means that the data pulses are injected in a loop consisting of transmission fiber and amplifier, and then left to propagate a number of laps corresponding to a certain transmission distance. Acoustooptic switches are used to switch the pulse train in and out from the loop at proper time intervals. The drawback of loop experiments is that they may be poor models of reality when it comes to things like dispersion variation along the fiber, PMD or various kinds of drifts that may arise. In addition, a real system has more options to fine-tune, for example, amplifiers along the transmission line. However, as long as these drawbacks are recognized, loop experiments are very powerful indeed, and invaluable in lab evaluations of long-distance transmission.

5.3. Field Trials

In the field, many transmission link design restrictions and fiber properties make the systems far from optimal. The actual fiber parameters are nonperiodic with propagation distance as the systems are straight lines rather than relatively short loops. Both loss (in particular when including many contacts and splices along the link) and the PMD are typically much higher than in the laboratory. In particular, the PMD is higher since the fiber is no longer wound on a small drum making the mode coupling length longer, but also often simply because the installed fiber is old, being made before PMD was considered a real obstacle. The dispersion (or more specifically the zero-dispersion wavelength) might vary significantly along a fiber span. In addition, it may not be possible to tailor the dispersion map and amplifier locations to reach an optimal state. All these examples of nonidealities justify the need for field experiments.

Several soliton field experiments have been conducted in Japan by NTT [21–25], in the United States by MCI/Pirelli [26], and in Europe by the Advanced Communication Technologies & Services (ACTS) projects [27–30]. This is a good indication that solitons are indeed foreseen as very interesting candidates in commercial systems. Table 1 summarizes some data for the 10 soliton field experiments conducted from 1995 through 1999s. Much of the work has been at a bit rate of 40 Gbps, which is natural as this is expected to be the next standard trunk TDM rate. Again, it is not very easy to compare the results as the situation in each case differs. All the systems operated in the 1550 nm range, used optical time-division demultiplexing to the 10 Gbps electronic base rate, and the average loss/km ranged from 0.24 to 0.33 dB/km. Dispersion-shifted fiber was always used, apart from in

Table 1. Overview of the Soliton Field Experiments Conducted to Date[a]

Capacity (Gbps × 10^6 m)	Soliton Source	L_a (km)/ G (dB)	PMD (ps/km$^{1/2}$)/ DGD · T^{-1}	T/T_{FWHM}	Fiber	Ref./Year
10 × 2.7	EAM/GS	90/—	—	5	DSF	[25]/1995
10 × 2	FRL/GS	55/16	—	5	DSF	[21]/1995
10 × 0.3	—	50/12	0.04 / 0.7 %	2	SMF	[27]/1998
10 × 0.9	—	75/20	0.9 / 27 %	3.3	SMF+DCF	[26]/1998
4 × 10 × 0.45	—	75/20	0.9 / 27 %	3.3	SMF+DCF	[26]/1998
20 × 2	FRL	55/16	—	5	DSF	[22]/1995
40 × 1	FRL	55/16	selected	5	DSF/DCF	[24]/1998
40 × 1.4	FRL	55/16	selected	5	DSF/DCF	[25]/1998
40 × 0.4	FRL	57/19	0.3 / 24 %	2.5	DSF	[28]/1999
40 × 0.5	EAM	100/24	0.25 / 22 %	2.5	DSF	[29]/1999
80 × 0.2	FRL	57/19	0.11 / 12 %	2.8	DSF	[30]/1999

[a] Here, G and L_a denote the amplifier gain and separation; T, the bit separation; DGD, the differential group delay; and T/T_{FWHM}, the relative soliton separation.

two cases [26,27], where standard fiber was used. The study by Robinson et al. [26] deserves particular attention because DCF was used for dispersion compensation, which makes this the only DM soliton field experiment to date. In addition, that study [26] describes the transmission of four WDM channels (4 × 10 Gbps) but then over half the distance (450 km).

Polarization multiplexing was used in four experiments [27–30] and this serves mainly to allow the use of relatively wide pulses, which in turn allows for larger amplifier spans. Polarization multiplexing, however, is not as useful if the PMD of the system is high, as then the orthogonally polarized pulses would start to drift statistically in time relative to each other thereby creating intersymbol interference and increasing the soliton interaction. In the 40-Gbps cases and above, PMD was found to be the main capacity limiting factor. In two cases a special selection of low-PMD fiber was made [24,25].

Most of the more recent experiments used a mode-locked fiber ring laser (FRL) as a source, probably because these provide excellent pulse quality as well as tunability in terms of wavelength and pulse width. Other experiments used either gain-switched (GS) lasers or electroabsorbtion modulators (EAMs).

In only one case [25] was inline soliton control used (in the form of intensity modulation), and this experiment also achieved the highest capacity (54 Tbps · km).

Future soliton field trials are expected to (1) take advantage of the now well-known strategy of improving soliton transmission performance with dispersion management, as this method is very attractive for upgrading existing fiber plants; (2) implement dense WDM (in non-DS fiber lines) to boost aggregate capacity; (3) utilize different forms of inline control, particularly at high bit rates; and (4) further address the implications of PMD and techniques to combat it. The interesting WDM-TDM tradeoff for optimization of overall aggregate capacity will depend on the details of the fiber line parameters.

6. EVALUATION AND FUTURE OUTLOOK

To conclude, we note that the motivation for using solitons as information carriers have changed over the years. The property of being resistant to dispersive broadening was originally the main feature, but this was considered less important when the dispersion-compensating fibers became commercially available. Instead, this led to the development of the dispersion-managed soliton. The advantage of the DM soliton over linear transmission are features like the large power (which enables high signal-to-noise ratio) and PMD robustness. On the other hand, the difference between linear and nonlinear pulses are becoming increasingly fuzzy, and perhaps the distinction should be made between RZ (return-to-zero) and NRZ modulation rather than between linear and nonlinear transmission.

It is nevertheless interesting to note that solitons are now not only considered for oceanic systems but also for shorter terrestrial systems. There are still several challenges and opportunities remaining in order to take full advantage of solitons and to reach a better understanding. PMD remains an important topic that is not entirely understood when using solitons. Further work is also needed on WDM soliton and very-high-speed TDM soliton-systems. The use of DM solitons is a very recently established technique and there are thus many issues to consider. These include studies of robustness to deviations of optimum conditions, such as improper pulse launch condition, impact of nonperiodic dispersion maps and of PMD (both of which are difficult to study in loop experiments), and intrachannel effects. Nevertheless, solitons have now reached a level of maturity such that commercialization seems very near.

BIOGRAPHIES

Magnus Karlsson was born in Gislaved, Sweden, 1967. He received his M. Sc in engineering physics in 1991 and his Ph.D in electromagnetic field theory in 1994 from Chalmers University of Technology, Gothenburg, Sweden. The title of his Ph.D thesis is "Nonlinear propagation of optical pulses and beams." Since 1995, he has been with the Photonics Laboratory at Chalmers, first as assistant professor, and since 2001 as associate profesor in photonics. At the Photonics Lab his research has been devoted to fiber optic communication

systems, in particular transmission aspects such as fiber nonlinearities, solitons, four-wave mixing and polarization effects. He has authored or coauthored around 50 journal articles, 30 conference contributions, and two patents.

Peter A. Andrekson received his M.S. degree in electical engineering in 1984, and his Ph.D. degree in optoelectronics in 1988 from Chalmers University of Technology, Gothenburg, Sweden. During 1989–1992 he was with AT&T Bell Laboratories, Murray Hill, New Jerse, working on high speed fiber-optic transmission systems. He returned to Chalmers University in 1992 where he currently holds a professorship in photonics. Dr. Andrekson is the author and coauthor of over 200 technical publications and conference papers, and holds three patents. He also serves on several technical conference program committees. In 2000 he was awarded the Telenor Nordic Research Award for his contribution to optical technologies. Since 2000 he is on leave from Chalmers University, working as director of research at CENiX Inc. His interests cover essentially all aspects of high-capacity optical fiber communications.

1. INTRODUCTION

Since the early 1980s an increasing fraction of the worlds telecommunication traffic has been carried on optical fiber, and since the late 1980s virtually all new trunk lines have been based on fiberoptics. Optical fibers are now the dominating medium for a variety of communication systems, ranging from short-distance data links to transoceanic telecommunication systems.

The dramatic increase in traffic brought about by the Internet has made optical fibers even more attractive because of the several terahertz of transmission bandwidth they offer. The wide bandwidth can be exploited by multiplexing a number of optical sources operating on different optical frequencies. This technology is known as *wavelength-division multiplexing* (WDM).

Different fiberoptic communication systems place different requirements on the optical sources used in the systems. The basic properties and characteristics of these sources are reviewed in this article.

2. HISTORICAL DEVELOPMENT

Since the late 1960s there has been an interesting interaction between the development of optical fibers and optical sources. Semiconductor lasers were first demonstrated in 1962, but it was only after the demonstration of room-temperature continuous-wave (CW) operation in 1970 that the practical use of these lasers became a reality. We note in passing that this improved laser performance was due to the introduction of the *heterostructure*, Alferov and Kroemer shared half the 2000 Nobel Prize in Physics for their work on this topic.

The use of optical fibers for long-distance communication was proposed in 1966, and the fiber loss was reduced to 20 dB/km in 1970. In the early fibers the minimum loss occurred at relatively short wavelengths, well suited to the emission wavelength of GaAs based lasers, which is in the 800–900-nm range. The fibers at that time were multimoded, and reduced fiber losses meant that transmission distances were limited mainly by modal dispersion (i.e., different fiber modes having different group velocity, thus leading to pulse distortion).

Further improvements resulted in fiber losses below 0.2 dB/km by 1980. As the fiber losses were reduced, the spectral range where the losses were lowest moved toward longer wavelengths. A wavelength region of particular interest was around 1300 nm, where the fiber dispersion was minimized. This new wavelength range was exploited by introducing lasers and LEDs based on InGaAsP compounds using InP substrates, this development started around 1980. These devices can cover the wavelength range from about 1100 nm to about 1700 nm. One of the first examples of a commercial long-distance transmission system at these "long wavelengths" was the London–Birmingham link in the early 1980s, based on LEDs operating around 1300 nm.

From the early 1980s single-mode fibers were being introduced, thus eliminating modal dispersion. The lowest loss for these fibers occurs at wavelengths around 1550 nm, which is within the range accessible by InGaAsP/InP lasers. However, the InP-based lasers have a tendency to operate simultaneously in several longitudinal modes. From the laser cavity length (typically about 300 μm), it follows that the longitudinal mode spacing (in frequency) is about 120 GHz, corresponding to a spectral spacing of about 1 nm (in wavelength). At a wavelength of 1550 nm a standard single-mode fiber has a chromatic dispersion of about 17 ps/(km $\cdot$ nm). Consequently, multimode laser operation will give rise to dispersion problems for high-speed systems operated over a long fiber length, and the development of single-frequency lasers (i.e., lasers operating in a single longitudinal mode) then became a priority. Single-frequency operation can be achieved by incorporating a wavelength selective element in the laser, typically a grating as in the DFB (distributed feedback) laser.

The development of the fixed wavelength DFB laser in turn made the efficient use of wavelength-division multiplexing (WDM) possible. In these systems the signals from a number of lasers, operating at different optical frequencies, are multiplexed together and transmitted over a single fiber, thus increasing the transmission capacity of the fiber significantly. As an example, a spectral range of 30 nm (around a wavelength of 1550 nm) corresponds to a frequency range of about 3800 GHz; using lasers spaced in frequency by 50 GHz will allow 76 separate channels, each of which can carry data at a rate of, for example, 10 Gbps (gigabits per second), thus giving an aggregate capacity of 760 Gbps. This capacity can be increased even more by the use of a wider spectral range, and/or a higher spectral efficiency (ratio of data rate to channel spacing).

The development of wavelength selective lasers and tunable lasers also opens new possibilities. Not only can these lasers be used as flexible spares or as "uncommitted" wavelength sources; they also allow the use of wavelength routing, where the path of a signal through a network is entirely determined by the wavelength of the signal. Ultimately the use of lasers that can switch fast between wavelengths opens the possibility for packet switching on the optical level.

Other interesting developments include lasers and LEDs specifically designed for (short-distance) data links, and pump lasers for optical amplifiers.

The reader is referred to Refs. 1 and 2 for more details on the history of the development of semiconductor lasers.

3. LIGHT-EMITTING DIODES

Red *light-emitting diodes* (LEDs) are well known from their use in displays and as indicator lights. LEDs based on GaAs or InP emit in the near infrared and are used for communication purposes. The basis for the operation

of an LED is that carriers (electrons and holes) are injected into a forward-biased *p-n* junction and recombine spontaneously, thereby generating photons. The photon energy (and hence the wavelength of the generated light) is determined mainly by the bandgap of the region where the recombination takes place. However, the carriers have a spread in energy, leading to a spectral width of the emitted light of a few times kT, where k is Bolzmann's constant and T is the operating temperature. Consequently the spectral width for an LED operating in the 1300-nm spectral region will be of the order 100 nm.

Not all the electrical power supplied to the LED is converted to light: (1) some power is lost because of electrical losses, (2) the radiative (spontaneous) recombination competes with various nonradiative recombination processes, and (3) only a finite fraction of the generated light is able to escape from the structure. This last effect is due to the process of total internal reflection; since the refractive index of the (semiconductor) LED structure is high compared to that of the surrounding medium (air), only light propagating at an angle nearly perpendicular to the surface will be able to escape from the structure. Additional optical losses occur when the light is coupled into a fiber. For coupling into a standard multimode fiber with a core diameter of 50 μm the overall efficiency (optical power in the fiber compared to electrical power supplied to the LED) is typically of the order of 1%, corresponding to coupled power levels of the order of 100 μW.

The light output from an LED can be modulated directly by varying the current passed through the device. In the absence of parasitics, the maximum possible modulation speed is approximately given by the inverse of the recombination time. With recombination times in the nanosecond range, it follows that LEDs can typically be used at data rates of up to a few hundred megabits per second (Mbps).

It should be noted that LEDs can be optimized for power levels of up to several milliwatts, and higher coupled power levels can be achieved by using large core fibers. Obviously, the wide spectral width of LEDs leads to chromatic dispersion, and the use of multimode (in particular large-core) fibers leads to modal dispersion. However, since LEDs are used at moderate data rates, they are an attractive simple and low-cost solution for links of a modest length (i.e., up to a few kilometers).

Finally, it should be mentioned that near infrared LEDs are also widely used for very short range free space communication between computers and peripheral equipment.

4. LASERS

4.1. Laser Basics

In order to understand the workings of a laser, we consider a system where the constituents (electrons, atoms, ions, or molecules) have two possible energy states. Transitions between these two states are accompanied by the absorption or the emission of photons, where the photon energy is equal to the difference in energy between the two states. In 1917 Einstein explained the relation between the energy distribution of a gas of molecules and that of the radiation field (Planck's law) by assuming that the following three processes occur:

1. *Spontaneous Emission*. Transition from the higher to the lower state accompanied by the emission of a photon.
2. *Absorption*. Transition from the lower to the higher state brought about by the absorption of a photon.
3. *Stimulated Emission*. In this process the transition from the higher to the lower state is triggered by incoming photons with energy equal to the transition energy; the additional photon emitted in the transition is in phase with the incoming photons. The transition probability is proportional to the number of incoming photons.

In thermal equilibrium the higher-energy state is less densely populated than the lower one, and it follows that an incoming stream of photons will be attenuated. However, if a situation is created where the higher-energy state is more densely populated than would be possible at the lower amplification level, this would be known as *population inversion*. Such a system is shown schematically in Fig. 1.

The basis for the acronym *LASER* (light amplification by stimulated emission of radiation) becomes clear from this description. The normal use of the word *laser*, however, refers to light generation (rather than amplification), and in order to construct an oscillator working at the lasing frequency, it is also necessary to provide feedback. A laser is usually constructed by placing material with an inverted population between a pair of partly reflecting mirrors. Light moving back and forth between the mirrors is amplified as a result of the stimulated emission process.

The combination of amplification and feedback from the mirrors forms an oscillator, and oscillation takes place if the amplification balances the loss caused by light escaping through the mirrors. With a gain factor g, a cavity length

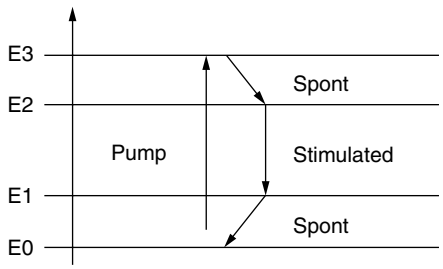

Figure 1. Schematic diagram of a four-level laser system. The upper energy level 3 is short-lived, giving a fast decay to the upper level 2 involved in the lasing transition, this level is long-lived. From the lower laser level 1 there is a fast decay to the ground level 0. "Pumping" from the ground level to the highest level is done by flashlamp, electric discharge, or the use of another laser, and population inversion can be achieved between levels 2 and 1.

L, and two mirrors both with a power reflectivity of R, this condition can be written as

$$\exp(gL)R\exp(gL)R = 1 \tag{1}$$

Since photons created by the stimulated emission process are emitted in phase with the incoming photons, the light emitted from the laser cavity is coherent.

A large number of laser types exist (gas lasers such as HeNe and CO_2, solid-state lasers such as Nd:YAG, etc.), and are being used in numerous fields (material processing, medical applications, etc.). The laser type of interest for optical fiber communication is the semiconductor laser. This laser type is also used in CD and DVD players, as well as in scanners and pointers.

4.2. Semiconductor Lasers

Nearly all semiconductor lasers are based on the double *heterostructure*. In this structure, a material with a relatively narrow bandgap — the *active layer* — (normally undoped) is sandwiched between a pair of n-type and p-type materials with wider bandgaps — the *confinement layers*. When this structure is under forward-biased *quasi-Fermi levels* are formed, and electrons and holes are injected into the active layer from the n-type and p-type materials, respectively. The Fermi level(s) determine the energy distribution of electrons in the conduction band and holes in the valence band. Population inversion, and thereby gain, is achieved when the quasi-Fermi level separation exceeds the bandgap of the active layer (see Fig. 2).

If the bandgap difference is sufficiently large, carriers injected into the active layer cannot escape over the heterobarrier, and carrier recombination can take place only in the active layer. Light generated in the active layer is not absorbed in the confinement layers since semiconductors are transparent to light with a photon energy lower than the bandgap. The photon energy is given by the product of Planck's constant h and the optical

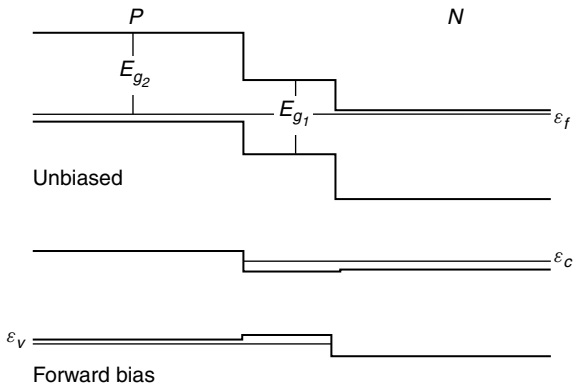

Figure 2. Double heterostructure formed with a material with a narrow bandgap E_{g1} placed between n-type and p-type materials with a wider bandgap E_{g2}. Carriers cannot have energies corresponding to states within the bandgap. Without bias the Fermi level ε_f is continuous. Under forward bias quasi-Fermi levels ε_c and ε_v are formed in the conduction and valence bands, respectively.

frequency ν, which is in turn equal to the speed of light in vacuum, c, divided by the wavelength λ, hence

$$h\nu = \frac{hc}{\lambda} \tag{2}$$

At a given optical frequency, a narrow bandgap semiconductor generally has a higher refractive index than a semiconductor with a wider bandgap. Consequently the structure shown in Fig. 2 also forms a planar dielectric waveguide with a high-index core between a pair of low-index cladding layers, analogous to an optical fiber. It is characteristic for a dielectric waveguide that only a part of the optical power is present in the core since the power distribution extends well into the cladding layers. The power fraction in the core is known as the *confinement factor*, and denoted by the symbol Γ.

The optical field distribution supported by the waveguide is known as a *mode*, and the structure is usually designed in such a way that only a single mode exists. The optical field propagates at a speed given by c/n_{eff}, where the *effective index* n_{eff} is higher than that of the cladding layers, but lower than that of the core.

The width of the optical power distribution is characterized by the *spotsize*, which is on the order of, or even less than, 1 μm. Since this is small compared to the wavelength, the output beam from a semiconductor laser is usually quite divergent. The optical mode in a fiber, on the other hand, has a spotsize in the 5–10 μm range. As the laser and fiber spotsizes are not compatible, lenses are required in order to ensure a reasonably efficient coupling of light from a semiconductor laser into a fiber.

The laser cavity forms a resonator, and the cavity length L and the effective index n_{eff} are related to the lasing wavelength λ by

$$n_{\text{eff}}L = \frac{M\lambda}{2} \tag{3}$$

which states that the optical length of the cavity is an integer number of half-wavelengths, where $M \gg 1$ is known as the (longitudinal) *modenumber*. The separation, *modespacing*, between two wavelengths (*longitudinal modes*) satisfying this condition (corresponding to modenumbers M and $M+1$) is

$$\Delta\lambda = \frac{\lambda^2}{2n_{\text{eff}}L} \tag{4}$$

A typical value for the modespacing (for a cavity length of about 300 μm) is about 1 nm. For a laser operating at a wavelength of about 1550 nm, this corresponds to a spacing between the optical frequencies of about 120 GHz.

As is indicated in Fig. 2, the lasing transition in a semiconductor laser is between *energy bands*, rather than between discrete energy levels. An important consequence of this is that the gain curve is quite wide, much wider than the modespacing given by Eq. (4). This wide gain can lead to simultaneous lasing in several longitudinal modes, thereby giving an effective spectral width of several nanometers. Such a wide spectral width will lead to

dispersion problems for systems operating at high data rates over a long length of dispersive fiber.

Another characteristic feature is that the gain levels can be very high. This means that the lasing condition, as expressed in Eq. (1), can be satisfied even for low values of the reflectivity R. Since semiconductors typically have refractive index values around 3.5, sufficient reflectivity (about 30%) can be obtained from a cleaved facet, and there is no need for special high reflectivity external mirrors as is the case for other laser types.

Two material systems are of particular importance for semiconductor lasers. The first is $Ga_{1-x}Al_xAs/GaAs$. Substituting a part of the group III element Ga by Al gives a material with a wider bandgap, but with nearly the same lattice constant. This means that structures containing varying amounts of Al can be grown on GaAs substrates without lattice mismatching. A band structure as shown in Fig. 2 is obtained by having a lower Al fraction in the active layer than in the confinement layers. Lasers based on this system usually operate in the 800–900-nm spectral region (the exact wavelength depends on the Al content in the active layer), and are widely used in CD players.

The material system of particular importance for fiberoptics is $In_{1-x}Ga_xAs_{1-y}P_y/InP$. By using two group III elements and two group V elements, there are 2 degrees of freedom in the composition. The first can be used to ensure lattice matching to an InP substrate, and the second can be used to adjust the bandgap. These materials are used in lasers for the important 1300-nm (minimum dispersion) and 1550-nm (minimum loss) fiber communication wavelength regions. Figure 3 shows a schematic of an InP-based communication laser.

The layers in a laser structure are normally grown by the *MOVPE* (metal-organic vapor-phase epitaxy) process, which allows the deposition of thin layers that are uniform in both thickness and material deposition. The active stripe is formed by a combination of photolithographic and etching processes followed by an overgrowth, and metallic contacts are formed to the n-type and p-type sides of the laser. Pumping of the upper laser level is performed simply by passing a current through the structure.

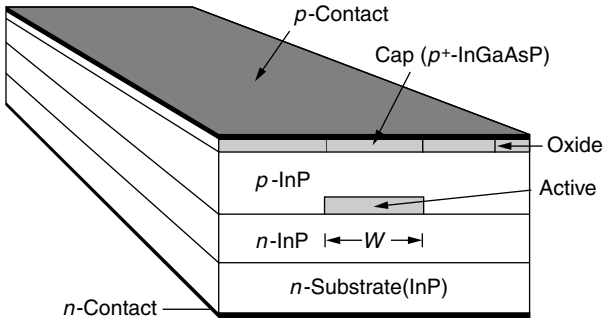

Figure 3. Diagram of communication laser. Typical dimensions are as follows: cavity length 300 μm, total width 100 μm, active region width (W) a few micrometers, substrate thickness 100 μm, active layer thickness a few tenths of a micrometer.

A semiconductor laser acts as a threshold device. For low values of the current, there is insufficient gain to satisfy the lasing condition, Eq. (1), and no laser light is emitted. Lasing starts as soon as the current is sufficient to give enough gain (this is known as the *threshold current,* I_{th}), and above this current level the output laser power increases in proportion with $(I - I_{\text{th}})$. Typically several milliwatts of optical power is emitted for a current in the range 10–100 mA. See Refs. 3–5 for more details on laser structures, and Ref. 6 for more advanced devices.

4.3. Laser Dynamics

As carriers (electrons and holes) are injected into the active region, they can recombine either spontaneously or by stimulated recombination brought about by the photon density in the active region. The photon density, on the other hand, is subject to both gain, due to the stimulated recombination of the carriers, and to losses, either internal losses or losses due to photons being emitted from the end facets of the laser. The interactions between the carrier density, N, and the photon density, S, is described by the so-called *rate equations* for the laser. In their simplest form these equations can be written as

$$\frac{dN}{dt} = \frac{I}{eV} - \frac{N}{\tau_s} - GS \tag{5}$$

$$\frac{dS}{dt} = GS - v_g\,(\alpha_{\text{int}} + \alpha_{\text{end}})\,S + \beta\frac{N}{\tau_s} \tag{6}$$

Equation (5) gives the time dependence of the carrier density. The first term on the right-hand side (RHS) is the pump term, where I is the current supplied to the laser, e is the unit charge, and V is the active volume of the laser. The second term accounts for spontaneous recombination, where τ_s is the spontaneous lifetime. Finally, the last term accounts for stimulated recombination, where G is the gain (per unit time). The second rate equation, Eq. (6), describes the time dependence of the photon density. The first term on the RHS is recognized as the stimulated recombination term. The second term accounts for losses, where α_{int} is the internal loss coefficient and α_{end} describes facet losses, both loss coefficients are losses per unit length, and v_g is the group velocity of the light in the laser. The final term occurs because a fraction β of the spontaneous emission events add a photon to the lasing mode.

The gain factor G is related to the gain per unit length in the active region, g_{act}, by

$$G = v_g \Gamma g_{act} \tag{7}$$

where the confinement factor Γ accounts for the fact that the laser active layer forms an optical waveguide with some of the power propagating outside the active region. The gain in the active region in turn is an increasing function of the carrier density N.

The facet loss α_{end} is caused by light being emitted from the ends of the laser. From Eq. (1) α_{end} can be found from

the gain required to balance the loss of photons through the facets

$$\alpha_{\text{end}} = \frac{1}{L} \ln\left(\frac{1}{R}\right) \tag{8}$$

It is a unique feature of a semiconductor laser that it can be modulated directly by varying the current [first term on the RHS of Eq. (5)], and the response of the laser can be found from the rate equations. Since these equations are nonlinear, due to the dependence of the gain on the carrier density, the rate equations cannot in general be solved analytically; however, a number of important results can still be derived from them. In the case of weak modulation, where the current I consists of a bias current plus a superimposed small-signal modulation current, the rate equations can be linearized. The result of this analysis shows that for low frequencies the optical output power will be modulated in proportion to the modulation current. For higher modulation frequencies the laser response has a resonance, with the resonance frequency increasing roughly in proportion to the square root of $(I - I_{\text{th}})$. The resonance frequency is typically in the gigahertz range. For modulation frequencies above the resonance frequency the laser response drops off rapidly. The resonance frequency provides a reasonable estimate on how fast the laser can be modulated directly, assuming that the laser response is not deteriorated by parasitic elements (such as the laser series resistance and parallel capacitance).

Other results that can be derived from the rate equations include harmonic distortion [7], and approximate expressions for the (large signal) turnon and turnoff times [8]. As spontaneous emission does not occur at a constant rate, but is a statistical process, it is possible to derive results on the laser intensity noise and its spectral distribution. Readers should consult Ref. 9 for more details on modulation and noise properties of semiconductor lasers.

4.4. Single-Frequency Lasers

In order to reduce the dispersion in optical fibers, it is necessary to restrict lasing to a single longitudinal mode. The conventional way to achieve this is by incorporating a periodic structure (*grating*) in the laser, as shown schematically in Fig. 4. In this structure the grating provides internal reflections at a wavelength determined by the grating period. This type of laser is known as a *distributed-feedback laser* (DFB).

The wavelength selected by the grating is given by

$$\lambda_{\text{DFB}} = 2n_{\text{eff}}\Lambda \tag{9}$$

where n_{eff} is the effective index and Λ is the grating period. Since the grating only provides efficient internal feedback for wavelengths very close to λ_{DFB}, any wavelength different from λ_{DFB} will have a higher rate of loss through the end facets, and as a result lasing will occur at λ_{DFB}. The discrete (and nonselective) reflections from the end facets will interfere with the distributed reflection from the grating, and usually the reflection from the front facet is suppressed by applying an *antireflection* (AR) coating.

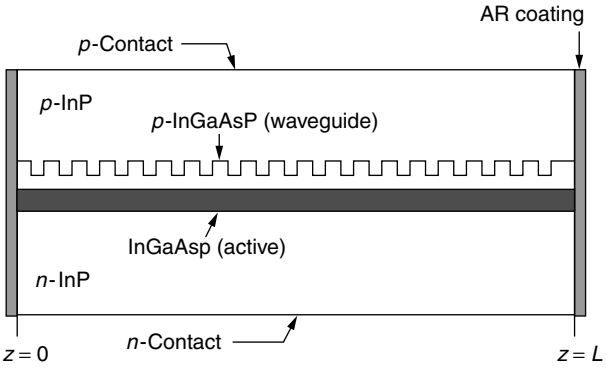

Figure 4. Outline of a DFB laser. The waveguide layer has a bandgap (and consequently a refractive index) between that of the active layer and InP.

The detailed theory for DFB lasers is rather involved, and readers are referred to Refs. 10 and 11 for more information on this topic.

Gratings can be fabricated by covering the waveguide layer with a photoresist, which is then exposed to an optical interference pattern, and the developed resist is used as an etch mask. After grating etching the remaining layers in the laser structure are grown.

The refractive index of a laser structure is quite sensitive to temperature; according to Eq. (9), this will lead to a temperature dependence of the lasing wavelength. A typical value is about 0.1 nm per degree (corresponding to a change in the optical frequency of about 10 GHz per degree). Whereas temperature tuning can be used to trim the wavelength to a given value, the temperature dependence also means that in order to ensure that the lasing frequency is within 10 GHz of a given value, the laser temperature has to be stabilized to within 1 degree.

In WDM systems signals from several lasers are multiplexed before transmission, and in order to ensure interoperability of equipment from different manufacturers, ITU has set a standard for optical transmission frequencies. This standard is based on a frequency grid with a 100-GHz spacing. Consequently the range from 192.1 THz (=1560.61 nm) to 195.9 THz (=1530.33 nm) consists of 39 channels.

4.5. Wavelength-Selectable Lasers

In order to achieve single-frequency lasing at a number of different wavelengths, arrays of DFB lasers can be formed. If these lasers are integrated with a combiner, several optical signals can be coupled into the same fiber. However, simultaneous operation of several closely spaced lasers will lead to crosstalk problems, and it may be more advantageous to consider *selectable* structures, where only one laser is operated at any time. An example of such a structure is shown in Fig. 5. This approach allows redundancy by having more than one laser per wavelength. The exact optical frequency is achieved by temperature tuning.

A different type of array is constructed by *cascading* of DFB lasers (several DFB lasers on a common optical

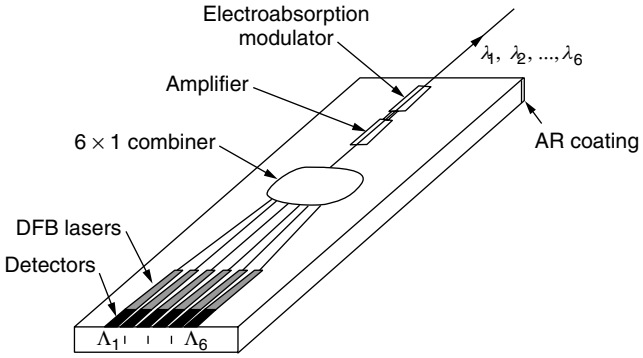

Figure 5. Selectable array with six DFB lasers and a combiner [5]. This *optoelectronic integrated circuit* also contains an amplifier to compensate for the combiner loss, a modulator for data encoding and monitor detectors for the lasers [12].

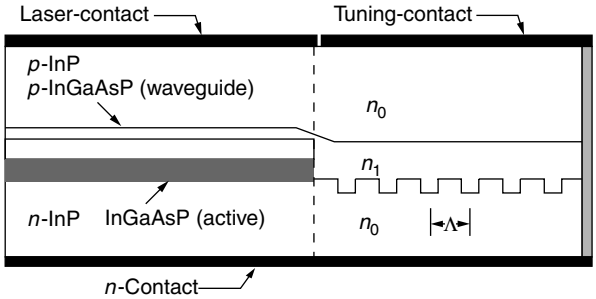

Figure 6. Two-section DBR laser. The output power is controlled by the laser current supplied to the active region. The tuning current supplied to the Bragg reflector region controls the carrier density in that region, and hence its refractive index. According to Eq. (9), this in turn tunes the wavelength at which the grating gives efficient reflection. Tuning ranges can be up to 10–15 nm [e.g., 14].

waveguide). By operating a single laser element above threshold and the other lasers close to threshold, the lasing wavelength is determined by the grating in the element operated above threshold. Several branches, each with several lasers, can be combined, and by using a high degree of temperature tuning, a wavelength range of 30 nm has been covered [13].

The wavelength range that can be covered by an array is limited by the number of array elements and by the degree of temperature tuning. For applications where many optical frequencies are required, or where a high degree of temperature tuning is undesirable, arrays may not be the best solution.

4.6. Tunable Lasers

The wide optical gain curve in a semiconductor laser makes it possible to achieve tuning of the lasing wavelength. As already mentioned, tuning is possible by changing the operating temperature. However, unless a large temperature variation is allowed, the tuning range will be limited to a few nanometers in wavelength (a few hundred gigahertz in frequency), and thermal tuning is comparatively slow (microsecond–millisecond range).

The fact that the refractive index depends on the carrier density can be applied for tuning. However, in a simple structure (such as Fig. 3 or 4), the carrier density is clamped to the value which is required to give sufficient gain to satisfy the lasing condition, and tuning by carrier density changes is not possible. This limitation can be overcome by using structures with two (or more) separate regions. One example is the *distributed Bragg reflector* (DBR) laser shown in Fig. 6. The tuning speed will be limited by the carrier lifetime in the tuning region (nanosecond range).

It should be noted that the tuning of a DBR laser is not continuous, but shows jumps between the wavelengths that satisfy the resonance condition given by Eq. (3).

Whereas the tuning range of a two-section DBR laser is limited by the extent to which the refractive index of the tuning section can be changed, wider tuning ranges can be achieved using somewhat more complicated structures.

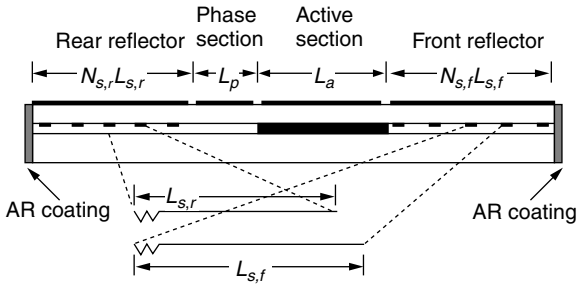

Figure 7. Sampled-grating DBR. Instead of a continuous grating the two reflectors have sampled gratings. These gratings give reflection spectra that have a comb of reflection peaks with a spacing determined by the sampling period. By using two different sampling periods, two reflection combs with different periodicities are obtained.

An example of such a structure is the *sampled-grating DBR* (SGDBR), which is shown in Fig. 7.

A small change of the refractive index of one of the tuning sections gives a large change in wavelength since a new pair of reflection peaks will coincide. This behavior is recognized as the *Vernier effect*; see Ref. 15 for more details. This principle leads to greatly enhanced tuning ranges; up to about 100 nm has been reported. Similar tuning ranges have also been achieved by combining a tunable codirectional coupler with a sampled grating [16].

A particular problem with the tunable laser structures described above is that several control currents are required for a specific combination of power and wavelength. Tunable lasers must therefore be characterized in sufficient detail to identify the current combinations required for various wavelengths, and the laser driver electronics must contain this information in such a form that tuning can be achieved in response to simple external instructions.

Other semiconductor laser structures capable of very wide tuning include external cavity lasers and vertical cavity lasers (see Section 4.7). Ultimately, the tuning range is of course limited by the width of the gain curve.

More details on various tunable laser types can be found in Ref. 17.

4.7. Vertical Cavity Surface-Emitting Lasers

In a *vertical cavity surface-emitting laser* (VCSEL), the direction of lasing is perpendicular to the active layer. Since this means that the active cavity is very short, it follows from Eq. (8) that very high end-reflectivities are required. Such high reflectivities can be achieved by having a stack consisting of a large number of layers with alternating high and low refractive index.

It is a considerable advantage of the short cavity that only one longitudinal mode exists because of the resulting wide modespacing [cf. Eqs. (3) and (4)]. This means that a VCSEL by its nature is a single frequency laser. Other major advantages include: the possibility of matching the laser spot size to that of a fiber, making coupling simpler and more efficient, and the use of on-wafer testing in the fabrication process. See Ref. 18 for more details and a review.

The various advantages of GaAs VCSELs make them highly suitable as relatively low-cost transmitters in short-distance systems operating at relatively short wavelengths, such as data links. The technology for VCSELs operating at the "telecoms" wavelength of 1300 and 1550 nm has proved to be considerably more difficult. One possible way of overcoming some of the problems is the use of 980-nm lasers for optical pumping as an alternative to electrical pumping.

Tunable VCSELs have been fabricated by incorporating an electrostatically deformable reflecting membrane at one end of the laser. A tuning range of up to 50 nm is then achieved by a simple voltage control of the cavity length [19].

4.8. Related Optical Components

A number of optical components are related to semiconductor lasers, because they are either of a similar structure or used together with semiconductor lasers:

Pump Lasers. Fiber amplifiers, used in long-haul linkage, require high-power optical pumping at specific wavelengths, usually 980 or 1480 nm. The pump power is supplied by specially designed high-power semiconductor lasers.

Semiconductor Optical Amplifiers (*SOAs*). These amplifiers are an alternative to fiber amplifiers and are very similar to lasers in structures. However, lasing is suppressed because SOA facet reflectivity is very low. Whereas SOAs can be integrated with other semiconductor components (see Fig. 5), the low coupling efficiency to fibers makes them less attractive for use as inline amplifiers in transmission systems.

Modulators. At data rates of 2.5 Gbps, directly modulated semiconductor lasers can be used, but direct modulation becomes increasingly problematic as the data rate increases, thus making dedicated modulators attractive in high data rate systems. Modulators are made from $LiNbO_3$ or semiconductors. Semiconductor-based electroabsorption modulators may be integrated with other elements, including lasers (see Fig. 5).

4.9. Packaging and Modules

In order to provide a fixed and robust coupling from a semiconductor laser to an optical fiber, the laser must be supplied in a suitably designed package. In addition to the *coupling optics*, a laser package may contain several of the following additional elements:

An *optical isolator* to prevent instabilities in the laser operation due to external reflection

A *thermoelectric element* to keep the laser temperature constant and prevent wavelength drift caused by variations in the ambient temperature

Drive electronics to provide bias current and modulation, in the case of external modulation a separate modulator may also be included

A *monitor detector* for control of the optical power from the laser

An example of a laser module is shown in Fig. 8.

BIOGRAPHY

Jens Buus was born in 1952 in Copenhagen, Denmark. He is an electrical engineer (MSc in electrophysics), graduated from the Technical University of Denmark (DTU) in August 1976. He also holds Lic. techn. (Ph.D.) and Dr. techn. (DSc) degrees from DTU. From 1979 to 1983 he was a postdoctoral fellow at DTU; from 1983 to 1992 he was with Marconi Caswell (formerly Plessey Research Caswell). Since January 1993 he has been a consultant at Gayton Photonics Ltd., United Kingdom. He

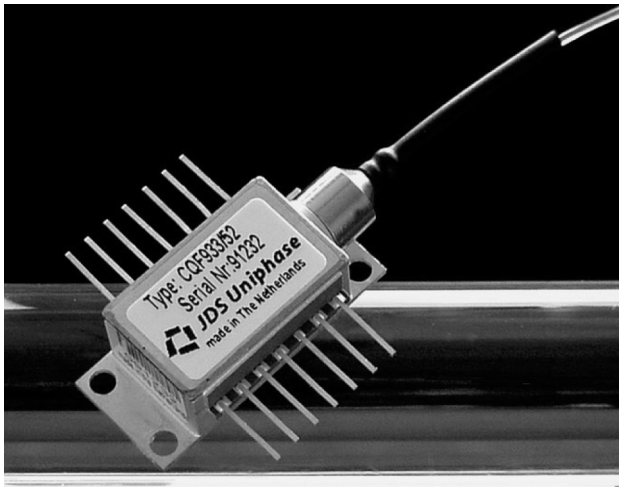

Figure 8. Packaged laser. This unit contains a fixed-frequency DFB laser (one of the standard ITU frequencies) and is designed for operation at a data rate of 2.5 Gbps. The package length is 30 mm, and the pins provide access to temperature control, monitor diode, as well as DC and AC input to the laser. (Courtesy of JDS Uniphase.)

has been project manager in the European RACE and ACTS programs and is currently project manager for a project under the IST program. Dr. Buus has served on several conference committees and given invited talks, tutorials, and short courses at several conferences; he has authored or coauthored about 60 papers, over 60 conference papers, and 2 books. During the academic years 1998–2000 he was a LEOS Distinguished Lecturer. He is a fellow of the IEEE, and a member of the Optical Society of America, the Institute of Electrical Engineers, and of the Danish Physical Society. His research has included contributions to the understanding of the properties of semiconductor lasers and optical waveguides, as well as contributions to work on gratings, integrated optics, and coherent optical communication.

1. INTRODUCTION

Optical transport networks have been deployed around the world for many years. As an article [1] in *Nature* indicated, the theoretical maximum bandwidth of a typical optical fiber in access networks is estimated to be about 150 Tbps (terabits per second). Even though it may be hard to estimate if this "glass ceiling" of 150 Tbps will actually hold, the speed of commercial transport systems has already been reaching 40 Gbps (i.e., OC[1]-768) in synchronous optical networks (SONETs). On the other hand, dense wavelength-division multiplexing (DWDM) systems can deliver information in a number of wavelengths in one optical fiber. NEC[2] was successful in transmitting 10.92 Tbps in a 117-km-long fiber with 273 wavelength channels at 40 Gbps per channel data rate. With 40 Gbps channels, we need 3750 channels to reach this fiber bandwidth limit. In the case that if we will be able to build a futuristic 160-Gbps channel, 900 channels will suffice to reach this limit. The technology of the optical transport system has been evolving rapidly. Obviously, the switching nodes are the bottlenecks in today's optical networks. Without optical logic technology, the switching nodes need to undergo signal conversions from photons to electrons in order to switch packets to their respective outgoing ports. Thereafter, the packets will be converted and delivered in the form of photons. As of today, all SONET optical switching systems carry out optical–electrical–optical (OEO) conversions.

[1] OC-N stands for optical carrier digital signal rate of $N \times$ 53 Mbps in SONET.

[2] NEC announced the DWDM transmission capacity world record on March 22, 2001. Exactly one year later, Lucent announced the transmission distance world record of 4000 km with 64 channels running 40 Gbps on March 22, 2002.

Active research on optical switches has been carried out with the goal of constructing all-optical networks that do not require any OEO conversions. A switching core may need to switch information from L incoming fibers to L outgoing fibers. Each fiber carries multiple, W, wavelength channels of information with the DWDM technology. Therefore, the designs of the optical cross-connects (OXCs) are getting complicated with the rapidly increasing number of wavelength channels per fiber. The architectural designs of OXCs are in two dimensions that involve the space and wavelength-switching domains [2,4–6]. That is, an ultimate OXC design should switch information from one particular wavelength channel at an input port to a specific output port with a selected outgoing wavelength channel. Therefore, given an $N \times N$ optical cross connect design, then $N \geq L \cdot W$ is required to provide an internally nonblocking switching matrix for any wavelength channel to any fiber. Figure 1a shows a system design of an OXC

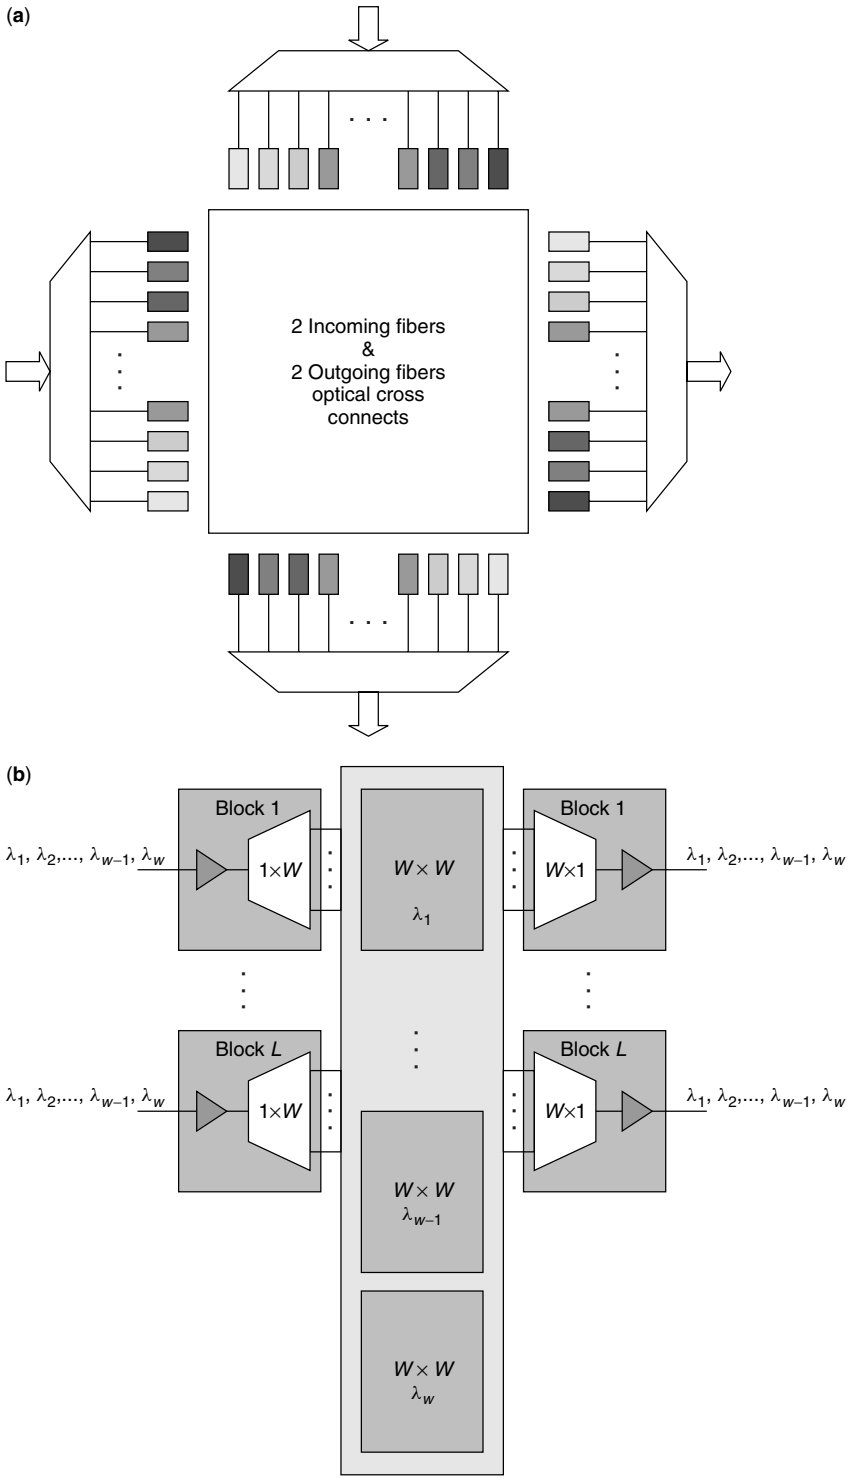

Figure 1. (**a**) Nonblocking OXC; (**b**) blocking 3-stage OXC.

with two incoming fibers and two outgoing fibers. We need to install wavelength filters and converters to produce a flexible design. Unfortunately, the cost of those converters is expensive. Traditionally, the Clos networks [3] are nonblocking multistage circuit-switched networks in the electronic domain. The alternative multistage design, as shown in Fig. 1b, has lower cost without any wavelength converters; however, it is not a nonblocking architecture. In this article, we discuss different architectural designs of the OXCs from a system perspective with consideration for device constraints.

2. DESIGN CONSTRAINTS

The performance of the next-generation all-optical networks relates to the optical properties and the functionalities of optical devices, and hence the throughput performance of the resulting OXC architectures. With different characteristics of optical devices, the selection criteria of the device components will definitely affect both the design architecture and the performance of the resulting optical cross-connects. Currently, the research on OXCs is still at an early phase. There are several technologies that are generally recognized to have the potential to construct the next-generation optical switches. They include the electrooptic, thermooptic, acoustooptic, thermobubble, liquid crystals, optomechanical, and beam-steering technologies. Among the initial investigations, some device level designs have already demonstrated that they are excellent candidates to be the basic building blocks for constructing the next-generation OXCs.

Before we describe the designs of optical switches, we consider several limiting factors of optical devices that may affect the architectural designs. With the wide bandwidth for transporting optical signals in fibers, the switching rate in OXC will be a limiting factor on the signal transfer rate. The switching time is determined through the rate of changing states on forwarding or detouring optical signals in devices. It may fall in the range from nanoseconds to milliseconds. The smaller the switching time, the better it is. It determines the information transfer rate in terms of bits, packets, and bursts. Moreover, it also indicates if the resulting optical networks can operate with circuit-switching, packet-switching, or burst-switching technology. Apart from switching time, port count, reliability, size, and cost are important design criteria with the space and wavelength switching in optical networks.

The overall loss budget is an important criterion that determines the power consumption and the placements of the optical amplifiers. There are different loss factors that include insertion loss, crosstalk, chromatic dispersion, polarization-dependent loss (PDL), and polarization-mode dispersion (PMD). Moreover, some architectures may be wavelength-dependent, and some may have a wide variation of losses between ports. In general, the maximum loss budget for an OXC should be around 25–30 dB. Therefore, it is seldom justifiable to create multistage networks if the per stage module has a high loss factor; otherwise, we need to provide signal amplification between stages. In the following, we focus on reviewing some important parameters: the insertion loss, crosstalk and switching time.

2.1. Insertion Loss

Whenever a photonic device is introduced in a lightpath, it introduces an insertion loss due to the mismatch at the interface. Ideally, it should be as small as possible in order to minimize the total loss budget, especially if the optical signal needs to travel through multiple OXCs. It is also important to determine a switching module that has uniform loss distribution with different interconnection patterns. If the insertion loss changes with different interconnection patterns, then a variable equalizer is required between switching stages. The resulting design is undesirable for it complicates the system control and increases the cost of the switch.

Free-space optical systems have the lowest insertion loss. For example, the microelectromechanical systems (MEMSs) belong to the optomechanical design class. The insertion loss of a MEMS OXC can reach as low as 1 dB. It is usually in the range from 1 to 6 dB depending on the size of the MEMS switch. Liquid crystal electrooptic is another switching technology for constructing OXCs. Its insertion loss is comparable to the MEMS switch as it can also reach 1 dB loss [23]. However, polarization loss may occur in the liquid crystal module. It relates to the Fresnel reflection on the glass–air interface and it can be as high as 3 dB. The Fresnel reflection occurs at a planar junction of two materials that have different refractive indices and is not a function of the angle of incidence. There are currently no reports on building large-scale liquid crystal switches.

For the other device technologies, for example, the insertion loss of thermooptic switches is usually in the range of 6.6–9 dB;[3] the lithium niobate ($LiNbO_3$) electrooptic switch[4] has an insertion loss of <9 dB. There has been some steady progress on improving both of these technologies. We can find moderately sized OXCs with these technologies in the market. However, the insertion loss is still considered to be comparatively high for next-generation large-scale OXCs. As a result, the $LiNbO_3$ switch is usually used in the external modulation rather than in the lightpath routing. This is because the external modulated information is usually amplified before it is transmitted.

2.2. Crosstalk

Crosstalk may be caused by either interference from signals on different wavelengths, the interband crosstalk, or interference from signals on the same wavelength on another source, the intraband crosstalk. Interband usually determines the channel spacing. Intraband crosstalk usually occurs in switching nodes where multiple signals

[3] The insertion loss of the 8×8 switch using a thermooptic Mach–Zehnder interferometer is <8 dB from NTT Electronics at *http://www.nel-dwdm.com/profile/profile.html*. Its switching speed is < 3 ms.

[4] The insertion loss of the 8×8 crossbar switch using $LiNbO_3$ planar lightwave circuit is <9 dB from Lynx Photonic Networks at *http://www.lynxpn.com/*. Its switching speed is <5 ns.

on the same wavelength are being switched from different inputs to different outputs. The degree of intraband crosstalk depends on the switch architectures.

In an optical device, crosstalk happens when a portion of the input signal "leaks" into another signal as they copropagate through the switch fabric. The ratio of the power at the unselected output port over the total input power in a switch element is referred to as the *crosstalk ratio* of the switch, since crosstalk is the noise usually introduced from the nearby connections. Therefore, crosstalk is usually more serious if the switch architecture design is complicated, especially if it has a large number of ports and connections. Since crosstalk measures the power of the loss signal to the input signal power [4–6], it is desirable if the value of crosstalk is as negative as possible in decibels.

With free-space optomechanical designs, MEMS optical switches provide the best crosstalk performance among all switching fabric technologies. Its crosstalk is in the range of −55 to −60 dB [29–33]. Besides, liquid crystal provides excellent insertion loss performance, and the crosstalk can reach −48 dB in general. There was a report on constructing an 8×8 crossbar liquid crystal switch with 1×8 switch arrays and the crosstalk could reach −59.5 dB [18,22,23]. This result is comparable to the MEMS switches. Unfortunately, there are still difficulties in building large-scale liquid crystal crossbar switches with the tradeoff between loss uniformity and the crosstalk level. Nevertheless, the liquid crystal switching technique is expected to improve with time, and is considered as a good candidate for building optical switching modules.

For the silica-based thermooptic switch using double-Mach–Zehnder interferometer (MZI) waveguide units, the crosstalk can reach −43 dB through a sophisticated hardware architecture design. There is a tradeoff between hardware complexity and the crosstalk level. To achieve this excellent crosstalk performance, we need to increase the hardware complexity by interconnecting 256 double-MZI units for a 16×16 silica thermooptic switch [12]. The resulting switch had an insertion loss and extinction ratio[5] of 17.5 and 32.9 dB, respectively. It will not be a cost-effective approach to construct an OXC with a large port count with thermooptic waveguide designs.

Some $LiNbO_3$ electrooptic switches are used to construct directional couplers by altering the refractive index of the waveguide with electric energy. These directional couplers were initially considered to have the potential to construct multi-stage switching networks. However, they cannot be used for OXCs because they have poor crosstalk isolation and a large insertion loss. On the other hand, there are $LiNbO_3$ acoustooptic tunable switches (AOTS). Acoustooptic switching technology uses surface acoustic waves to generate birefringence grating and alter the polarization of a lightbeam. Switching occurs at high speed, and it can reach as low as 3 μs.[6] An AOTS introduces about 5–6 dB insertion loss; however, its crosstalk ratio is about −20 dB [11–13]. The crosstalk of a single-channel acoustooptic 1×300 demultiplexer can reach about −35 dB. AOTS suffers both interband and intraband crosstalk. A double-stage devices or weighted coupling schemes may be required to reduce intraband crosstalk. Since interchannel interference may create intrinsic modulation of the transmitted signal, it affects the bit error rate (BIT) performance, and hence the device may not be working for long-haul optical systems. Both of these electrooptic and acoustooptic $LiNbO_3$ devices have yet to demonstrate that they can be used to build large-scale OXCs. Therefore, only small-scale OXCs [13] can be found in the market with these technologies. All in all, the optomechanical switch provides the best performance in crosstalk level compared to the other technologies.

2.3. Switching Time

The switching time describes the time it takes for a switch to establish an interconnection pattern. The desirable value must be as small as possible. As the data rate exceeds 10 Gbps per wavelength, a submicrosecond switching time is necessary to provide dynamic path provisioning, grooming, and path restoration on failure. This is an important parameter that determines the performance of future optical networks. Today's optical core networks are configured statically. When the optical device is able to switch states actively, future optical core networks are expected to provide dynamic path routing capability.

Among all the switch fabric technologies, the electrooptic switches have the fastest switching time compared to the other two technologies. The $LiNbO_3$ and semiconductor optical amplifier (SOA) switches are able to switch in the range of nanosecond response time. As discussed before, the $LiNbO_3$ device is suitable only for providing external modulations.

On the other hand, the thermooptic switch offers a switch time within the range of 1 ms. This response time is acceptable in optical path-switching applications. Unfortunately, the thermooptic switch's insertion loss is also considered to be too high when designing a large-scale switch. On the other hand, the mechanical switches, for example, fiber bundle switches [7], can achieve a good crosstalk level as well as low insertion loss. However, these fiber bundle mechanical switches usually have slow switching times. Fortunately, with the introduction of MEMS optical switching systems, apart from having excellent crosstalk ratio and low insertion loss, good mechanical design can also lead to good switching time, such as 700 μs [36]. At the moment, MEMS becomes the most appealing switch fabric technology for designing large-scale OXCs for future optical networks. In Table 1, we outline the characteristics of different available optical device technologies for building OXCs.

On concluding this part, we would like to outline the basic requirements for designing the OXCs as follows. The design should have (1) low insertion loss (typically <1 dB), (2) low crosstalk (typically <-50 dB), (3) low polarization-dependent loss (PDL), (4) switching time faster than or, at least, equal to millisecond range, (5) low power consumption, (6) long-term reliability, (7) small size, (8) low cost, (9) scalability to large port count, and

[5] The extinction ratio is defined as the ratio of the optical power transmitted for a bit "0" to the power transmitted for a bit "1."

[6] This is the 1×300 demultiplexer reported by the Light Management Group at *http://www.lmgr.net/*.

Table 1. Comparisons Between Different Optical Device Technologies

	Free-Space		Guided-Wave Integrated Optics		Guided-Wave Active Component
	MEMS	Liquid Crystal	Thermooptic, Bubble	Electrooptic	Semiconductor Optical Amplifier
Switching time	1–10 ms	2–5 ms[a]	1–10 ms	nsec	nsec
Insertion loss	Very good	Moderate	Moderate	Moderate	Acceptable
Crosstalk	Very good	Average	Average	Acceptable	Acceptable
Polarization-dependent loss	Good	Good	Good	Acceptable	Acceptable
Wavelength dependence	Good	Good	Average	Average	Acceptable
Bit rate transparency	Good	Good	Good	Good	Good
Power consumption	Good	Good	Bad	Good	Bad
Expandability/size	Large	Moderate	Small	Small	Small

[a]There was a report that could have a switching time of ~35 μs. However, the commercial products are usually in microseconds.

(10) self-holding or latching mechanism design. Since the total loss should be less than 30 dB, it then also limits the number of cascaded modules in the architectural design.

3. PROMISING SWITCHING FABRIC TECHNOLOGIES

Optical cross-connects can be classified into two broad classes: active and passive. Without optical logic devices, today's optical network can only offer a high-speed and large capacity transport system. Hence the optical routing paths are comparatively static and mostly preconfigured through the optical add/drop multiplexers (OADMs). In the near future, we expect higher deployments of the passive OXCs. These passive OXCs are usually designed with traditional doped waveguide technology. The switching characteristics are predefined and fixed; that is, an output signal pattern depends on the architectural design of a passive OXC and a specific arriving input signal pattern. In contrast, the switching points in active OXCs should be set according to the destination ports of the incoming signals. Most of the available technologies for constructing active OXCs are listed in Table 1. In Section 3.1, we will discuss the design of passive OXCs using arrayed waveguide gratings (AWGs). The technologies for constructing active OXCs is different from those for passive OXCs, and the designs can be found in Section 3.2.

3.1. Passive Optical Cross-Connects

Bulk optic or all-fiber filters and devices are used in a number of WDM applications. With the improvement of technology, the trend is to move toward monolithic integration of devices and components. One of those generic devices is the *arrayed waveguide grating* (AWG) multiplexer, also known as *waveguide grating router* (WGR). DWDM networks permit large capacity optical signal transfer. AWG can be used to split and combine optical signals of different wavelengths in the systems. The silica AWG allows the fusion splice of fiber to chip; however, it has low-contrast waveguide structure and its size is relatively large [8]. The AWG device can also be fabricated on indium phosphide (InP) [8] that provides high-index contrast and it is suitable for large-scale system integration. As shown in Fig. 2, an AWG [4–6,9] consists of two free-space couplers connected by a grating array. The first coupler has N inputs and N' outputs (where $N \ll N'$), while the second one has N' inputs and N outputs. For the first coupler, there is a regular angular distance between any adjacent input ports. Similarly, there is also another regular angular separation between any adjacent output arrayed waveguides. The setup of the second coupler is simply a mirror image of the first one. The grating array between couplers consists of N' waveguides, with lengths $l_0, l_1, \ldots, l_{N'-1}$, where $l_0 < l_1 < \cdots < l_{N'-1}$. The length difference between any two adjacent waveguides is constant. The constant difference in the lengths of the waveguides creates a phase difference in adjacent waveguides. This phase shift depends on the propagation constant in the waveguide, the effective refractive index of the waveguide, and the wavelength of the light. At the input of the second star coupler, the phase difference in the signal will be such that the signal will constructively recombine only at a single output port.

With this design, two signals of the same wavelength coming from two different input ports will not interfere with each other in the grating because of an additional phase difference created by the distance between any two input ports. The two signals will be combined in the grating but will be separated again in the second coupler and directed to different outputs. AWGs have been successfully demonstrated for a number of WDM enabling devices that include multiplexers, demultiplexers, channel dropping filters/equalizers, and tunable lasers.

Several important fundamental properties of AWGs enable the construction of passive OXCs [10]:

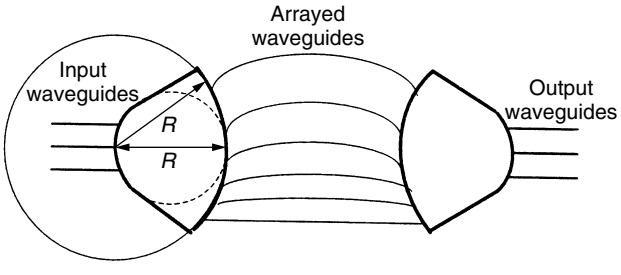

Figure 2. Arrayed waveguide grating (AWG).

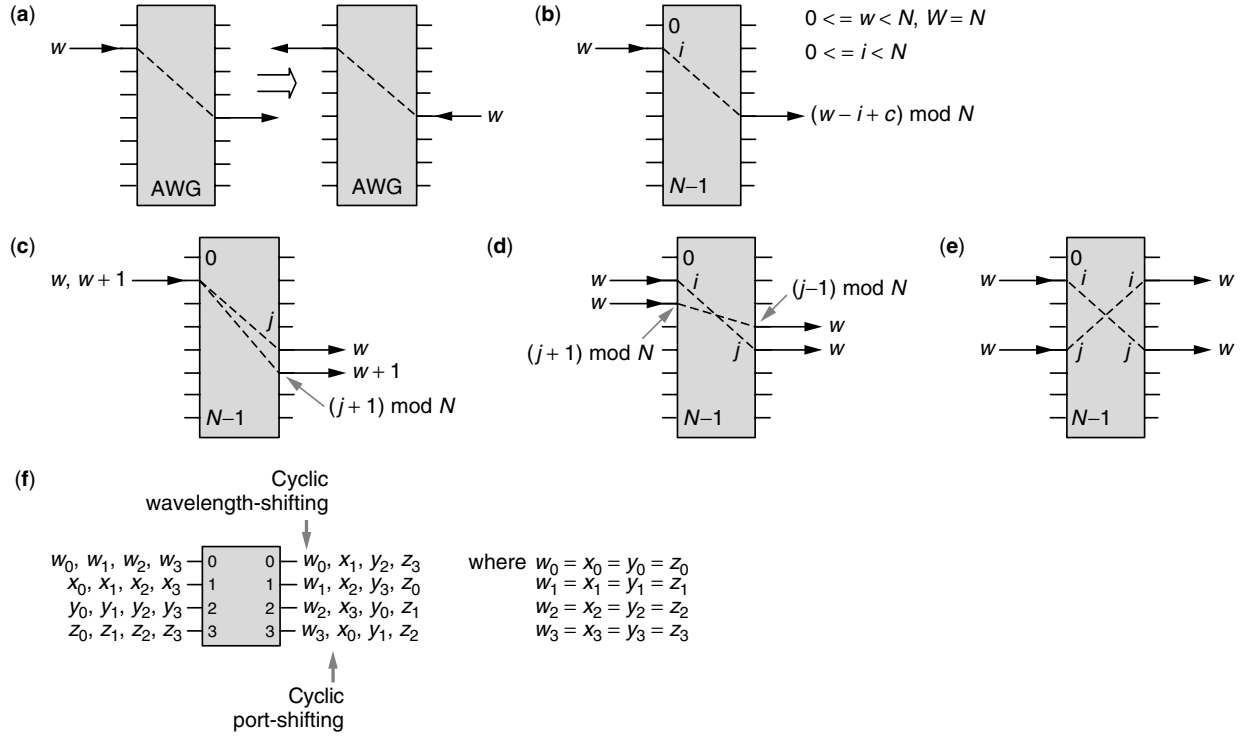

Figure 3. Routing properties of AWG.

1. *Reciprocity* (Fig. 3a). If a signal of a wavelength propagates from one input port to an output port, then any signal of the same wavelength injected at that output port will propagate backward to the input port in exactly the same way.
2. *Periodicity in Frequency* (Fig. 3b). A given frequency bandwidth may contain a number of wavelength channels. If all these wavelength channels in that frequency range follow the same transfer function in a device, then this frequency period is known as *free spectral range* (FSR). An $N \times N$ AWG has N input and output ports, and supports W wavelength channels, denoted by the sets $\mathcal{N} = \{0, 1, \ldots, N-1\}$, and $\mathcal{W} = \{0, 1, \ldots, W-1\}$ in an FSR, respectively. In general, $\mathcal{W} = \mathcal{N}$. Within an FSR, the wavelength channels have constant-frequency spacing instead of constant-wavelength spacing. For the periodicity property, a wavelength signal $w \in \mathcal{W}$ enters an input port $i \in \mathcal{N}$ is delivered to an output port $[(w - i + c) \bmod N]$. This c is an integer known as the FSR constant that depends on the selection of the FSR.
3. *Cyclic Wavelength Shifting* (Fig. 3c). If an input signal of wavelength w leaves AWG from port j, then any input signal of wavelength $w + 1$ entering the same port leaves the AWG from port $[(j + 1) \bmod N]$.
4. *Cyclic Port Shifting* (Fig. 3d). If an input signal enters port i and leaves AWG from port j, then any input signal of the same wavelength entering port $[(i + 1) \bmod N]$ leaves the AWG from port $[(j - 1) \bmod N]$.
5. *Symmetry* (Fig. 3e). If an input signal enters port i and leaves port j, then any input signal of the same wavelength entering from port j will leave the AWG from the port i.

As an example, the wavelength routing assignments of an AWG are shown in Fig. 3f. It is a 4×4 AWG with four wavelength channels in an FSR, specifically, $N = W = 4$. The four incoming ports are identified with w, x, y, and z from top to bottom. Assuming that c is zero and observing the top input port, then for an incoming wavelength numbered zero, w_0, the outgoing port is $[(w - i + c) \bmod N] = 0$, the top output port, with the periodicity property. With the cyclic wavelength-shifting property, we can arrange all four w wavelength channels sequentially at the outgoing ports as shown. Then observing the second top input port, the incoming wavelength numbered zero, x_0, goes to the outgoing port $[(-1) \bmod 4] = 3$ from the cyclic port-shifting property. The other wavelength channels can then be arranged with both the cyclic wavelength-shifting and cyclic port-shifting properties. The resulting wavelength assignment is shown in Fig. 3f. Moreover, it also satisfies the symmetry property.

There is a channel spacing concept in AWGs that allows more flexible wavelength assignments with the AWGs. In the following, a system with channel spacing of k is considered. From architectural point of view, two successive wavelengths that enter the same input port will be routed to two output ports x and $x + k$ with the wavelength-shifting property. From the setup of wavelength channels in an FSR, the two output ports are $[x = (w - i + c) \bmod N]$ and $[x + k = (w + k - i +$

c) mod N] with the periodicity property. This implies a spacing k between two successive wavelength channels at the input. Therefore, a wavelength set $\mathcal{S}$ is said to have a channel spacing of k if $\mathcal{S} = \{(s + ik) \bmod N : 0 \le i < |S|\} \subseteq \mathcal{W}$, for an $s \in \mathcal{S}$.

3.1.1. Compatible Ports. In order to have an AWG to perform as an OXC, we need to explore different routing properties that enable an AWG to do switching. Since one fiber can carry multiple wavelength channels, only some subsets of the N ports should be used for inputs and outputs. Given an $N \times N$ AWG with L incoming fibers, and if each fiber carries a set of wavelength channels $\mathcal{W}$, where $|\mathcal{W}| = W$, then we have $N \ge L \cdot W$ for the AWG to do proper switching.

A set of compatible ports $\mathcal{P}$ is defined with respect to $\mathcal{W}$ if for any pair of wavelengths in $\mathcal{W}$ that enter any two ports in $\mathcal{P}$ will be routed to two different output ports. With this compatible port concept, all incoming signals can be routed to some predetermined outgoing ports, and that will be useful for designing a passive OXC. In the following, two different cases for compatible ports will be examined. Given $\mathcal{N} = \{0, \ldots, N-1\}$, $|\mathcal{W}| = \mathcal{W}$ and $N \ge L \cdot W$ for both of them, $\mathcal{P} = \{p_i \in \mathcal{N} : 0 \le i \le L-1\}$ is defined as a set of L ports for L incoming fibers.

First, considering a channel spacing of 1, if $N = 8$, $W = 4$, and $L = 2$, then we have $\mathcal{P} = \{p_0, p_1 \in \mathcal{N}\}$. One possible arrangement of both the $\{p_0, p_1\}$, where $0 \le p_0 < p_1 < N$, can be found in Fig. 4a if $c = 0$. Mathematically, $\mathcal{P}$ is compatible with respect to $\mathcal{W}$ if and only if $p_i - p_{i-1} \ge W$, for all $1 \le i \le L-1$, and $p_{L-1} - p_0 \le N - W$. In particular, if $N = LW$, then $\mathcal{P}$ is compatible with respect to $\mathcal{W}$ if and only if $\mathcal{P}$ has an equal spacing of W. Second, if the channel spacing is L and N is a multiple of L, then the set of compatible port is $\mathcal{P} = \{p_i, p_j \in \mathcal{N} : p_i \bmod L \ne p_j \bmod L, \forall\, 0 \le i < j \le L-1\}$. The corresponding example can be found in Fig. 4b.

3.1.2. Self-Blocking Ports. With a selected set of compatible ports, only certain numbers of input and output ports are used. If some idle ports can be used for intermediate processing, then the number of AWGs may be possibly reduced to construct an OXC. For this purpose, a set of input ports $\mathcal{P}$ is defined as self-blocking with respect to $\mathcal{W}$ if they are mutually exclusive with their outgoing ports: $\mathcal{P} \cap \{(w - i + c) \bmod N : i \in \mathcal{P}, w \in \mathcal{W}\} = \emptyset$. This implies that the same set of self-blocking input ports of an AWG switch can be used as the output set and should not be used for any intermediate processing. An example shown in Fig. 4c has parameters $c = 1$, $W = 4$, and $N = 5$, and the top link is the self-blocking port.

It is desirable to construct a passive OXC with one AWG having such a set of input ports that is both compatible and self-blocking. For L incoming fibers, a necessary condition for the existence of L self-blocking and compatible ports with respect to $\mathcal{W}$ is $N \ge L \cdot (W + 1)$.

3.1.3. Compatible and Self-Blocking Ports. In order to design a preconfigured architecture with one AWG, it will be desirable to find a set of ports $\mathcal{P}$ that is both compatible and self-blocking with respect to $\mathcal{W}$:

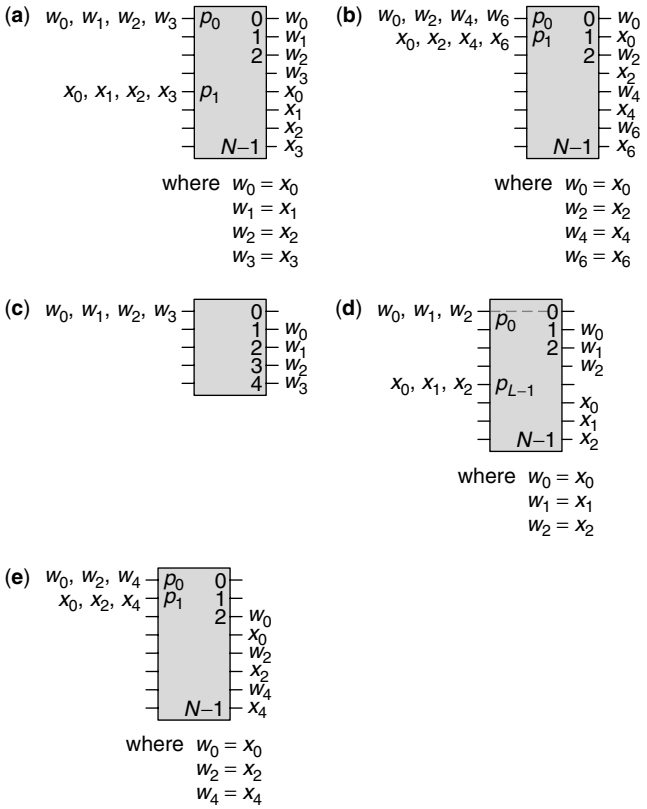

Figure 4. (**a**) Compatible ports with $k = 1$; (**b**) compatible ports with $k = 2$; (**c**) self-blocking port; (**d**) compatible and self-blocking ports with $k = 1$; (**e**) compatible and self-blocking ports with $k = 2$.

1. $\mathcal{P}$ is invariable with respect to some wavelength $w \notin \mathcal{W}$
2. $\mathcal{P}$ is compatible with respect to $\mathcal{W} \cup \{w\}$.

The invariable principle states that both the input and output ports are identical with respect to a specific wavelength w that is not in $\mathcal{W}$. The final design of the OXC includes the wavelength channels that are delivered to the set of compatible ports excluding the invariable ports with respect to w. These invariable ports are then the self-blocking ports with respect to $\mathcal{W}$.

As shown in Fig. 4d, a derived set of compatible and self-blocking ports is shown if the channel spacing is 1. This can be easily modified from the set of compatible ports shown in Fig. 4a. Mathematically, if N is a multiple of $(W+1)$, then the set of input ports can be described as $\mathcal{P} = \{i : 0 \le i < N, i \bmod (W+1) = q\}$ for some $0 \le q \le W$. If

$$[w - (2q+1) + c] \bmod (W+1) = 0$$

then $\mathcal{P}$ is compatible and self-blocking with respect to $\mathcal{W}$. On the other hand, when the channel spacing is L, then $\mathcal{W} = \{(w + Lx) \bmod N : 0 \le x < W\}$ for some integer w and $0 \le w \le N-1$. A possible configuration can be found in Fig. 4e, which can be easily obtained from Fig. 4d. Mathematically, if N is a multiple of L, then $\mathcal{P} = \{(q+i) \bmod N : 0 \le i \le L-1\}$, for some $0 \le q \le N$, is

compatible and self-blocking with respect to $\mathcal{W}$ if

$$[w - (2q + 2L - 1) + c] \bmod N = 0$$

or

$$[w + L(W - 1) - (2q - 1) + c] \bmod N = 0.$$

Detailed proofs can be found in Wan's treatise [10].

3.1.4. Implementations of Passive OXCs with AWGs. In this subsection, designs of different OXCs with AWGs will be discussed. It is assumed that there are L input fibers and each of them carries W wavelength channels. A design shown in Fig. 5a is equivalent to the one in Fig. 1b with $L = W$, a number of multiplexers, demultiplexers, and space switches. From Fig. 5b, only two AWGs are required to build a 2-line 4-wavelength OXC if the channel spacing is 1. The drawbacks are that some complicated crossover links must be set up between AWGs and the 2×2 space-switching modules. The designs of these 2×2 space-switching modules can be found in Section 3.2.

On careful investigation, there is a simple way to improve that design by selecting a wavelength set $\mathcal{W}$ with channel spacing L, where N is a multiple of L and L is even. As shown in Fig. 4b, a set of compatible ports, $\mathcal{P} = \{(q + i) \bmod N : 0 \le i < L\}$ for some $0 \le q < N$, is selected. Another desired requirement is to make sure that no waveguides are required to connect the top and bottom portions of an AWG to a space switch. This is achievable if any wavelength w from port $[(q + L - 1) \bmod N]$ is routed to a port that is a multiple of L, specifically, $\{[w - (q + L - 1) \bmod N + c] \bmod N\} \bmod L = 0$. An OXC can be built as long as q is selected such that $(w + c + 1 - q) \bmod L = 0$ is satisfied. If $w = c = 0$ and $q = 3$, then a cascaded configuration of a 2-line 4-wavelength OXC with a channel spacing of 2 is as shown in Fig. 5c.

So far, two AWGs are needed to build the designs shown in Fig. 5b,c. There are unused ports on the input sides in these designs. If a set of compatible and self-blocking ports with respect to $\mathcal{W}$ can be formulated as shown in Fig. 4d, then only one AWG with loopback links can be constructed as an OXC. Given $N \ge L\ (W + 1)$, the AWG operates as a multiplexer and demultiplexer in an OXC with the symmetric property. Furthermore, it may even reduce the insertion loss[7] in a single-AWG design. The AWG initially demultiplexes the L input fibers into $L \cdot W$ wavelength components. For those L identical wavelength channels, there is an $L \times L$ space switch. By taking advantage of the symmetric property, the signals can be rerouted to the input channels of the AWG. These

[7] The insertion loss of a 1-fiber 40-channel AWG from NTT Electronics is at worst 6 dB.

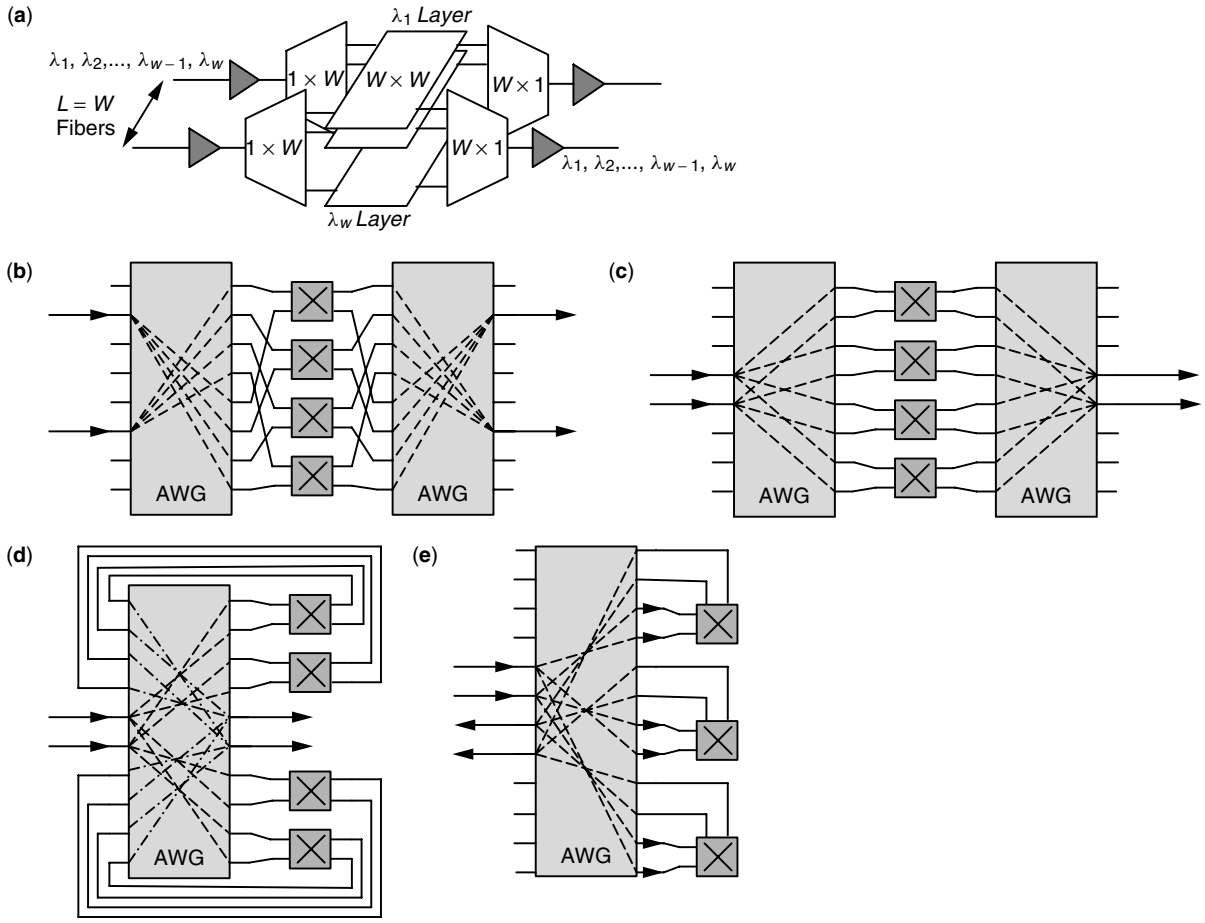

Figure 5. Optical cross-connects with AWGs.

multiple wavelength channels can then be remultiplexed at the L output ports. An example can be found in Fig. 5d with only one AWG. In this design, N is equal to $L \cdot (W+1)$ to minimize the cost, and the channel spacing is 1. To characterize the architecture mathematically, there is a set of compatible and self-blocking ports, $\mathcal{P} = \{0 \le i < N : i \bmod (W+1) = q\}$ with respect to the wavelength channels, $\mathcal{W} = \{(w+x) \bmod N : 0 \le x < W\}$. Provided $[w - (2q+1) + c] \bmod (W+1) = 0$ for some $0 \le w < N$ and $0 \le q \le W$, we obtain a passive loopback 2-line 4-wavelength OXC as shown in Fig. 5d with $w = 0, c = 1, q = 4$.

The design of a loopback architecture is effective on port utilization of an AWG. However, it may not be desirable to construct those recirculating fibers from switches to the input side of the AWG. Therefore, there is a foldback design as shown in Fig. 5e. In this design with $N \ge 2LW$, a set of double-sized compatible ports with respect to $\mathcal{W}$ is required. Suppose that $\mathcal{P}_1$ and $\mathcal{P}_2$ are the sets of L input and L output ports, respectively. It is desirable for $\mathcal{P}$ to be the set of compatible ports if $\mathcal{P} = \mathcal{P}_1 \cup \mathcal{P}_2$. Similar to the last design of OXC, the AWG initially demultiplexes incoming signals into $L \cdot W$ wavelength components. Subsequently, an $L \times L$ space switch does the proper signal switching for each wavelength channel. In this design, a switch accepts the wavelength signals from a set of L input ports, $\{(w - i + c) \bmod N : i \in \mathcal{P}_1\}$, and delivers the signals to another set of L output ports, $\{(w - i + c) \bmod N : i \in \mathcal{P}_2\}$. The design makes use of both the reciprocal and symmetry properties by folding back wavelength signals onto the L output lines. The final foldback design without any crossovers is found in Fig. 5e with $w = 0$, $c = 1$, and $q = 4$ for a 2-line 3-wavelength OXC. However, there are certain input ports that are not used to construct an OXC. This is the only drawback in this design.

3.2. Active Optical Cross-Connects

Space-switching architectural designs have been created since the invention of the telephone. Currently, space-switching architectures are quite mature. Unfortunately, these space-switching designs cannot be applicable to the optical domain because of unavailable optical logic and storage devices. These architectures are still useful mostly in constructing large-scale electronic switches. They probably can provide only a limited number of stages on switch expansions because of the loss issues in the optical domain. In the following, we outline the designs of several optical cross-connects that are based on three of the latest popular optical device technologies. The designs of these OXCs are still closely related to the device technology. They are built with the liquid crystal, thermobubble/thermocapillary and MEMS technologies.

3.2.1. Liquid Crystal Switches. Despite the name given, liquid crystals [18–23] are not truly liquid. They exist in a state between liquid and solid called *mesophasic*. A liquid crystal molecule has an elongated shape, and is often represented as a rod. Under the proper conditions, the orientation of these molecules can be changed so that they face in a certain direction. The orientation can affect the optical properties of the liquid crystal, which in turn affects the polarization of the light passing through it.

There are several types of liquid crystals, including nematic, discotic, cholesteric, and various kinds of smectic phases, which can be characterized by different arrangements of the molecules. Utilizing a magnetic or electric field can often change the optical properties of a liquid crystal. Liquid crystal switches have low insertion loss and excellent performance at the same time. A major advantage with the liquid crystal is its ability to add and drop different colors of light without having to demultiplex all wavelengths of the incoming signal.

In constructing basic liquid crystal switching modules, an early result was reported [20]. The 1×2 splitter is shown in Fig. 6a. The polarization beamsplitter (PBS) is used for lowering crosstalk. It divides the input light into two linearly polarized lightbeams. The twisted nematic liquid crystal (TN-LC) provides polarization switching. It provides 90° polarization rotation without an applied voltage, but it keeps the original polarization with an applied voltage. The function of the birefringent crystal block (BRB) is for extraordinary wave walkoff. The switching operations from one input to one of the two output ports are shown in Fig. 6b,c.

In the following, an architectural design of multichannel liquid crystal switches is described. There are three different basic liquid crystal components that can be used to construct a multistage interconnection of optical switches. These components are a 2×2 polarization switch, an optical beam router, and a beam shifter.

The 2×2 polarization switch is shown in Fig. 7a,b. It is constructed with the transmission-type twisted nematic liquid crystal spatial light modulator (LC-SLM) arrays. A thin nematic liquid crystal layer at the center is surrounded by two glass plates that are bonded to transparent electrodes, such as indium tin oxide. When it is in OFF state, it rotates the light with a 90° polarization angle. When it is ON, then no polarization state will be changed. Therefore, the 2×2 polarization switch operates like a switch between two orthogonal polarizations. For the second component, the optical beam router, its operation model is shown is Fig. 7c. Its goal is to exchange one of the polarization components with a lightbeam that propagates along an adjacent path. The PBS operates differently on the two polarization orientations, the polarizations that are parallel and perpendicular to the surface, the P component and the S component. As shown in Fig. 7d, a basic beam router is composed of five PBSs. Each of these PBSs reflects only the S component of a projecting lightbeam. With the arrangement of these PBSs, the two adjacent S components will be exchanged on leaving the beam router. However, this architecture requires high accuracy in assembly in order to stabilize the coupling loss. The third component is a beamshifter. Its functional model and hardware construction are shown in Fig. 7e,f, respectively. A basic beamshifter consists of three PBSs. Similar to the optical beam router, each PBS reflects only the S component of the lightbeam. It uniformly displaces one of the polarization components, and takes in another S component from its adjacent beam path. After designing all these basic components, we can move forward to construct

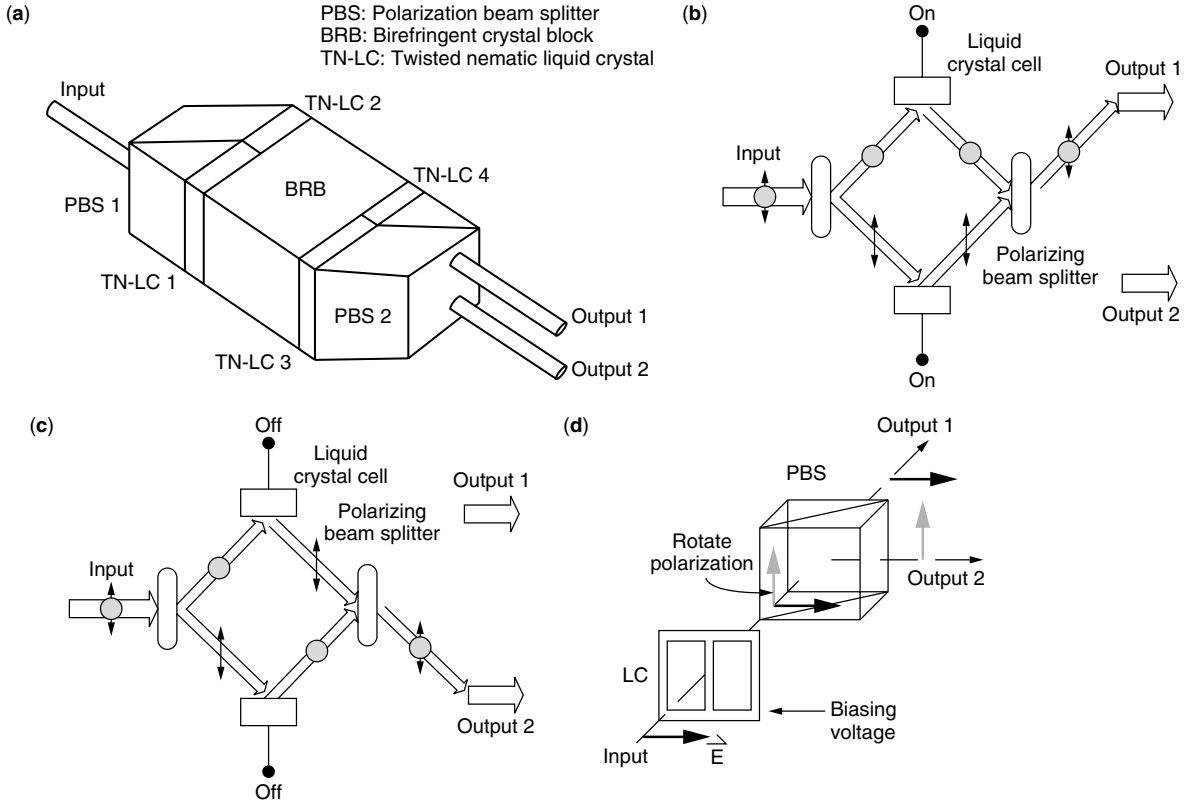

Figure 6. Liquid crystal switch and its operations.

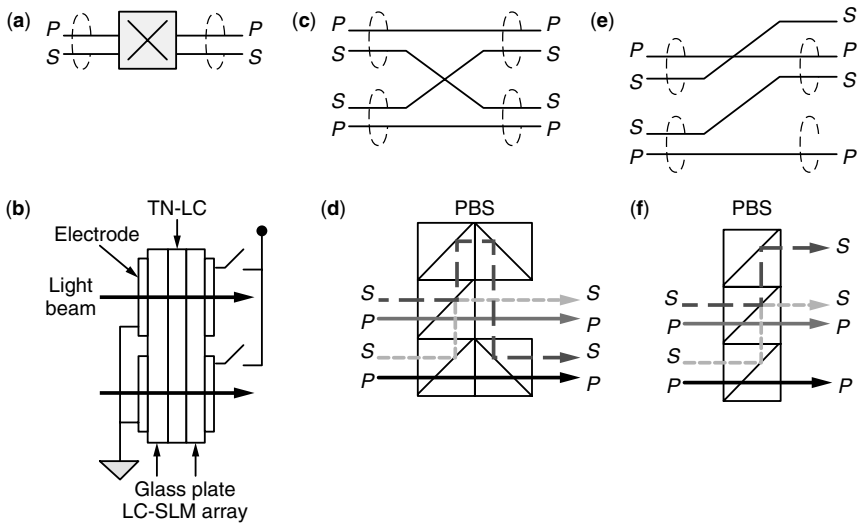

Figure 7. (**a**,**b**) 2×2 Polarization switch; (**c**,**d**) optical beam router; (**e**,**f**) beamshifter.

optical switch systems. Two optical switch architectures are as shown in Fig. 8. They demonstrate the feasibility of constructing multistage optical interconnection networks with the liquid crystal technology. Currently, the size of an optical liquid crystal switch will be limited because of the physical construction, alignment, and the signal loss issues.

In a relatively earlier design, the switching mechanism with the liquid crystal switch was based on the total internal reflection of the liquid crystal. A 2×2 switch consists of two glass prisms of equal refractive index and base angle [18]. The inside face of both prisms have been coated with a transparent electrode and thin polyamide layer. The prisms are bonded together using an epoxy edge seal loaded with spacers of the desired diameter in the range of few micrometers. Liquid crystal with OFF-state alignment is introduced between the prisms by vacuum filling, and the cell is sealed. The OFF-state alignment of the liquid crystal reflects light from the input port 1 back to the output port 1. The ON state is switched by applying a voltage to the electrode. It changes the alignment of the liquid crystal normal to the face of the prisms so that

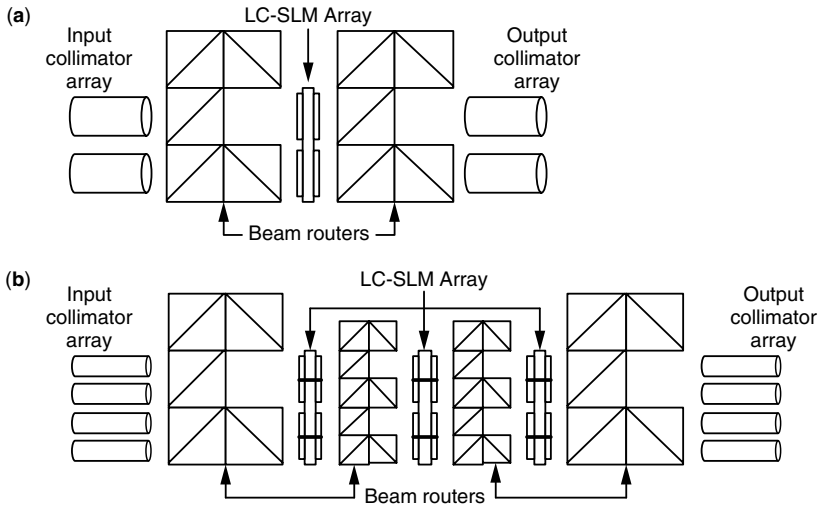

Figure 8. (**a**) 4×4 and (**b**) 8×8 optical switches.

light will be able to pass from input port 1 to output port 2 through the liquid crystal. However, this architecture is not easily extensible to construct large-sized optical switches. A design of 8×8 channels crossbar switch has been proposed [19]. The switch uses an array of eight 1×8 liquid crystal switches for signal divergence and eight 8×1 liquid crystal switches for signal convergence.

The switch performance of the 2×2 liquid crystal switch [18] has an average transmit state crosstalk of 33 dB, and the switching speed is <5 ms. The insertion loss obtained for the liquid crystal itself is 0.5 dB, excluding the Fresnel reflection at the glass–air interface and the 3 dB polarization loss [18]. For the 4×4 switch, it experiences an average crosstalk level of -22 dB and the insertion loss is 0.8 dB. The switching time should be longer because it is required to set up more electrodes along the switching path. The 8×8 liquid crystal crossbar switch described by Noguchi [19] has an average crosstalk level of -59.5 dB and an insertion loss of 3.44 dB. The improvement of the crosstalk level is due to the isolation of all the optical signal paths within the switch by a set of 1×8 and 8×1 liquid crystal array. The increase in insertion loss is due to the additional stage required within the switch body.

3.2.2. Bubble and Thermocapillary Switches. A bubble switch developed by Agilent is based on low-cost thermal inkjet bubble technology. The earliest report on bubble switching was provided by Jackel et al. [24]. The design concept of the basic bubble-switching component is simple. There are two core paths for light transmission. These two paths are crossing each other, and at the crosspoint, there is a trench holding refractive index-matching fluid. There is also a heater that makes the liquid boil, and forms a bubble. In the switch, this bubble is critical to reflecting the light onto a new path. When it forms, the bubble displaces the fluid from the trench, which makes the space more like air. It creates an interface between the glass and the bubble that shifts the light with the total internal reflection principle [25]. Even though there are no moving parts in the systems, the switching time for the device with the software control is around 10 ms as reported by Fouquet. The commercialized 32×32 two-dimensional crossbar switch from Agilent has a specification of -50 dB crosstalk.

Bubble switches are usually made on glass waveguides. The glass is etched to produce capillary channels that contain index-matching fluid and air bubbles. Usually, rough capillary walls are formed by reactive-ion etching or acid etching of glass, and they produce high scattering loss when the air bubble is located at the waveguide intersection. Typical losses of 2.2 dB have been reported [25] for glass waveguide devices. Switching in a bubble switch is shown in Fig. 9.

Bubble switch operations rely on the heating processes that create air bubbles in the index fluid. In order to keep the bubbles at their positions, continuous power has to be applied. On the other hand, there is a thermocapillary process being developed [26–28]. As reported by Sato et al., the structure of the thermocapillary switch is as shown in Fig. 10. A deep trench is formed at each cross

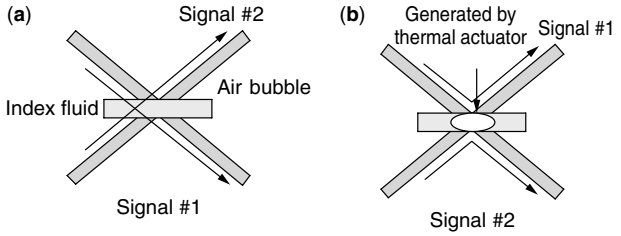

Figure 9. Optical bubble switch operations: (**a**) bar state; (**b**) cross state.

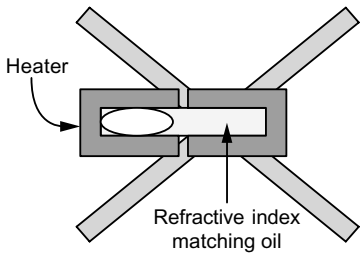

Figure 10. Thermocapillary switching module.

point of the waveguide cores. Refractive-index-matching oil is injected into the trench, which is sealed by a glass lid. The trench is half-filled with the oil; the other half, with a bubble. On top of the trench, there is a pair of microheaters to produce a thermal gradient along the trench. When the oil is heated, the surface tension of the bubble on the heater side is decreased, and then the bubble moves to the side of the actuating heater with a capillary force. This actuation mechanism with the thermal gradient is called thermocapillary. When the bubble is located at the cross point of the waveguides, the light is switched into the crossing waveguide because of the total internal reflection on the glass–air interface. This operation is identical to the operating principle in the bubble switch. However, the mechanism of the bubble action is completely different. For example, the bubbles in Agilent's switch are created through heating, while in the thermocapillary switch, the bubbles always exist and their motions are activated through the capillary force. On the performance side, this thermocapillary switch was reported to have an insertion loss of ~4 dB [27]. However, the switching time takes 50 ms to move the bubble for this specific design. The advantage of this design is that the bubble will latch on the wall and no extra power is required to keep it stationary at that position.

Further improvement can be made on both thermobubble and thermocapillary switches. In order to improve the performance, there are polymer-based thermocapillary switches. In this design, the fluid and air capillary is formed by precision laser ablation yielding a much smoother capillary wall. Optical surfaces achieved via laser ablation result in a polymer waveguide. This design has excellent insertion loss. The loss in the air bubble is less than 0.2 dB. When index fluid fills the capillary at the waveguide intersection, a loss of 0.1 dB is typical for polymer waveguides and glass waveguides.

As of today, there are several firms working on producing optical switches based on bubble technology. To date, only two-dimensional crossbar switches have been constructed with bubble technology.

3.2.3. Microelectromechanical Systems. We have already discussed the constructions of optical switches using the liquid crystal and bubble-switching technologies. Both of them show promising research results and they have the potential to be deployed for commercial use in the near future. However, as of today, the only OXC designs available on the market are made with the microelectromechanical systems (MEMS) technology [29–32], such as Lucent's LambdaRouter [33]. MEMS optical switches are different from the conventional mechanical switches, which are based on macroscopic bulk optics and utilize the advantages of free-space optics. These conventional mechanical switches suffer from large size and mass with slow switching time.

With the introduction of MEMS technology, MEMS optical switches not only retain their conventional advantages of free-space optics such as low losses and low crosstalk but also include additional advantages such as small size, small mass, and submillisecond switching times. Furthermore, MEMS fabrication techniques allow integration of microoptics, microactuators, complex micromechanical structures, and possibly microelectronics on the same substrate to realize integrated microsystems.

For the MEMS devices, their operating units are the micromirrors. The size of these mirrors may be as small as several hundreds of micrometers, and they are made with standard IC fabrication technology [32–38]. Since existing fabrication technology is quite mature, the cost is low for constructing MEMS devices. At the moment, there is a common fabrication process that is well accepted and is known as MUMPs (multiuser MEMS processes) from Cronos[8] for MEMS. The process is composed of both bulk and surface micromachining. Bulk micromachining, such as deep-silicon reactive-ion etching (DRIE), helps set up the overall outlook of a silicon system structure. The surface micromachining and LIGA[9] processes create the details of the final operating structure of a device. These MEMS optical switches consist of many moving mirrors. Therefore, there should be microactuators to drive or oscillate these moving parts in the MEMS device. For example, there may be moving micromirrors to switch laser beams from one fiber to another. There are currently a variety of methods to achieve these microactuation functions, for example, electrostatic, electromagnetic, piezoelectric, magnetostrictive, and thermal expansion. Currently, the electrostatic mechanism is the most common and best-developed method.

For the electrostatic actuators, several types of designs are suitable for constructing OXCs: parallel-plate capacitors, comb drives, and torsional bars. We roughly review the designs of the parallel-plate and comb drive mechanisms. The structure of a parallel-plate MEMS device is shown in Fig. 11a. In general, for all parallel-plate structures, the device stores some capacitance energy, that is, $W = CV^2/2$. When the plates move toward each other, the work done by the attractive force between them can be computed as a change in W with a displacement, x. Therefore, the force can be computed as $F = V^2(\partial C/\partial x)/2$. In the parallel-plate capacitor architecture, only attractive forces can be generated. The design will be more attractive if a larger force can be produced to carry out the heavier workload. It is desirable to offer a larger change in capacitance with respect to distance. This leads to the development of the electrostatic comb drives as shown in Fig. 11b. The comb drives consist of many interleaving fingers. When a voltage is applied, an attractive force is developed between fingers and they move toward each other. With this structural design, there is an increase in capacitance that is proportional to the number of fingers. Therefore, the larger number of fingers can generate larger forces. A potential problem is to carefully control the lateral gaps between fingers. A finger may swing and stick if the gaps are not identical on both sides.

As many reports [29–36] indicate, MEMS optical switches are able to demonstrate their superiority in

[8] Cronos is a division in JDS Uniphase.

[9] LIGA is a German acronym for lithography, electroplating, and molding.

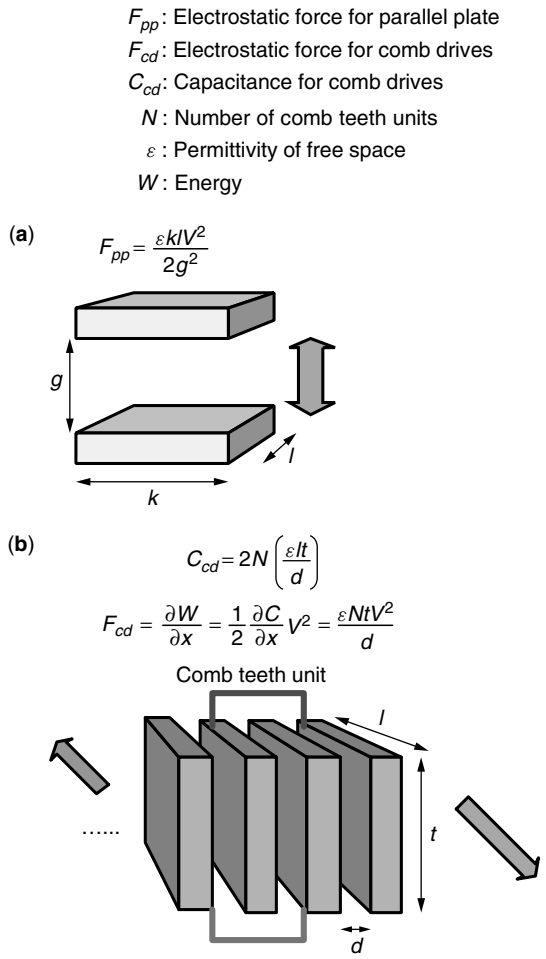

Figure 11. Electrostatic designs: (**a**) parallel-plate capacitor, (**b**) comb drives.

the areas of scalability, insertion loss, polarization-dependent loss (PDL), wavelength dependency, small size, low cost, crosstalk, switching speed, manufacturability, serviceability, and long-term reliability. Among these reports on system performance, the switching time is ~4 ms [33] with ~3 dB insertion loss. In general, we expect that the switching time may fall within the range 1–10 ms, and the insertion loss is between 1 and 6 dB. With steady advancement of the latest fabrication technology, the switching time will be performing even better in the future. For example, the switching time is less than 1 ms when scratch drive actuators are used [35].

In the following, we describe how MEMS technology helps us to construct optical switches. There are currently two broad approaches to implement MEMS optical switches: 2D and 3D MEMS optical switches. Even though both 2D and 3D MEMS optical switches operate on micromirrors in crossbarlike architectures, there are striking differences in terms of how the mirrors are controlled and their ability to redirect lightbeams. However, both of them have shown promise in finding their niche in telecommunication networks. There are already several large 2D MEMS optical switches in the market. Lucent/Agere's WaveStar LambdaRouter is the most sophisticated and the largest 3D MEMS optical switch available in the marketplace today. The delivery of the 1024 × 1024 WaveStar LambdaRouter is expected by the year 2002.

3.2.3.1. 2D MEMS Optical Switches. With the given MEMS technology, many two-dimensional crossbar optical switches were made. In this planar architecture, mirrors are always arranged in a crossbar configuration as shown in Fig. 12a. Each mirror has only two positions and is placed at the intersections of lightpaths between the input and output ports. They can be in either in the ON position to reflect light or in the OFF position to let light pass uninterrupted. The binary nature of the mirror positions greatly simplifies the control scheme. Typically, the control circuitry consists of simple transistor–transistor logic (TTL) gates and appropriate amplifiers to provide adequate voltage levels to actuate the mirrors. For an $N \times N$ switch, a total of N^2 mirrors are required to implement a strictly nonblocking optical crossbar switch fabric. For example, a 16×16-port switch will require 256 mirrors. Moreover, the capability of signal resynchronization within an optical switch is not possible,

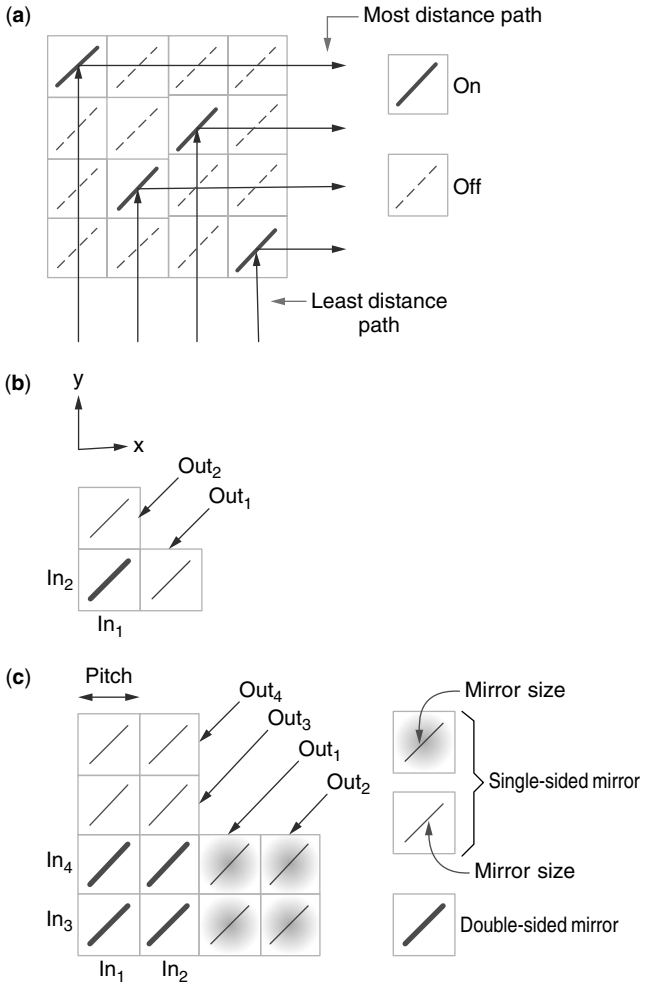

Figure 12. (**a**) Crossbar switch; (**b**) 2×2 and (**c**) 4×4 L-switching matrices.

and the free-space beam propagation distances among port-to-port switching are not constant. As a result, the insertion loss due to Guassian beam propagation is not uniform for all ports. Consequently, there are variations in losses among ports. The minimum and maximum insertion losses of AT&T's 8×8 switch with scratch drive actuators [36] are 3.1 and 3.5 dB, respectively. A simple way to improve the system performance of a 2D crossbar MEMS switch is to decrease the pitch size per mirror unit. It can then reduce the pathlength differences and signal loss as well as increase the port count in the 2D MEMS switch. Certainly, this also leads to smaller mirror size, which can cause signal loss due to the spreading of the Guassian beam. Therefore, more sophisticated and accurate fabrication may be needed to fabricate these systems.

An alternative approach to increasing port count is to interconnect smaller 2D MEMS switching modules to form multistage networks, for example, the three-stage Clos networks. However, this cascaded architecture typically requires up to thousands of complex interconnects between stages, thus decreasing serviceability of the overall switching system. Up to the current stage, extensive research is being performed on the device level. Yeow et al. [39] investigated double-sided mirror design to see if it can provide benefits in existing designs. A planar L-switching matrix design [39] was proposed. Figure 12b,c shows 2×2 and 4×4 L-switching matrices, respectively. The longest-distance path, l_{ldp}, in L-switching matrix is always 25% shorter than that of the regular two-dimensional crossbar switch; whereas the shortest-distance path in the L-switching matrix, l_{sdp}, is always about one-third of the l_{ldp}. As a result, when it is compared to the regular crossbar switch, the maximum path difference in the L-switching matrix grows slowly with the number of input or output ports. It helps slow down the impact of the loss nonuniformity issue [37,38] in 2D MEMS switches due to the pathlength difference problem. The current achievable port count of a 2D MEMS crossbar switch is 32×32, whereas we expect that the L-switching matrix should be able to scale to 64×64 without installing collimators with varying focal lengths for the system. Moreover, these L-switching modules can be used to construct larger-sized Clos networks. Comparison of the construction of three-stage Clos networks with that of the regular 2D crossbar MEMS switches reveals that the one with the L-switching matrix modules has substantially reduced accumulated insertion loss by almost 57% with the pathlength difference issue when only the pathlengths within the switches are counted [39]. However, there are shortcomings in the L-switching matrix; for instance, it may not be possible to establish a new connection without modifying existing connection configurations. Fortunately, the number of paths between an input and an output may have multiple possible paths. If the number of ports is N, the number of possible paths can be $N/2$ for some cases. As an example, you can find two setups for one set of connection requests in Fig. 13.

3.2.3.2. 3D MEMS Optical Switches. All lightbeams in a 2D MEMS switch reside on the same plane.

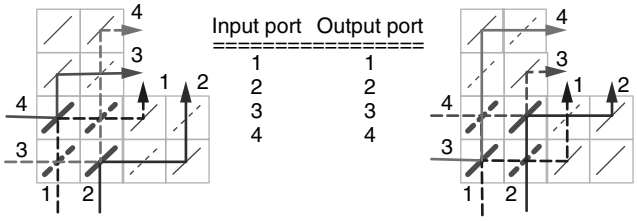

Figure 13. Two path configurations for one set of connection requests in a 4×4 L-switching module.

This arrangement usually results in unacceptable high and uneven loss for large port counts. The 3D MEMS switch [29,33] makes use of the three-dimensional space as an interconnection region that allows scaling far beyond 32 ports with acceptable optical losses. These analog or 3D MEMS switches have mirrors that can rotate freely on two axes as shown in Fig. 14, and light can be redirected precisely in space to multiple angles. The port count would be limited only by insertion loss that results from finite acceptance angle of fibers or lens. Another advantage is that the differences in free-space propagation distances among port-to-port switching are much less dependent on the scaling of the port count. Typically, the optical pathlength scales only as $\sqrt{N}$ instead of N, so port counts of several thousands are achievable with high uniformity in losses ($<$10 dB). Inevitably, much more complex switch design and continuous analog control are needed to improve stability and repeatability of the mirror angles.

To design 3D MEMS optical switches, N or $2N$ mirrors may be required. For example, Nortel Networks' 3D switching architecture [32,40] utilizes two sets of N mirrors. The first plane of N mirrors redirect light from N input fibers to the second plane of N mirrors. All mirrors on the second plane are addressable by each mirror on the first plane making nonblocking connections. In turn, mirrors on the second plane can each be actively and precisely controlled to redirect light into desired output fibers with minimum insertion loss. On the other hand, Lucent's WaveStar MEMS switches, shown in Fig. 14,

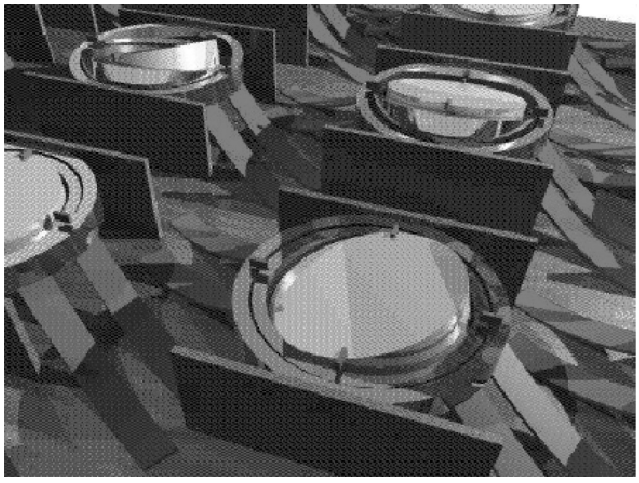

Figure 14. 3D MEMS mirrors.

use only N mirrors and a comparatively large and fixed reflective mirror tilted toward the mirrors. Light from an incoming fiber arrives at one 3D MEMS mirror and is reflected to the large reflective mirror. Then the light will return to another MEMS mirror on the same MEMS plane and be sent to an outgoing fiber. Typically, the mirror can rotate on two axes and is continuously controllable to tilt by at most $\pm 10^{\circ}$ [30]. Moreover, the reported switching module has a maximum insertion loss of 6 dB and a switching time of <10 ms. This 3D optical architecture clearly presents real hope for developing a scalable large-port-count OXC. A WaveStar LambdaRouter with more than one thousand ports is expected to be available in 2002.

4. CONCLUDING REMARKS

Optical switches are the most important components in the future all-optical networks. Numerous companies are producing the next-generation optical switches. Since the late 1990s, the properties of AWGs that allow predefined path setup in the optical domain have been more clearly understood. However, AWGs can provide a platform only for constructing passive OXCs. Therefore, the latest exciting research is on designing active OXCs. At the moment, multiple technologies have been showing promising results. Among them, 3D MEMS is the first one to show exciting and promising results for designing large-scale OXCs. Numerous issues still need to be investigated to further improve the performance of 3D MEMS switches, including the fabrication process, packaging, deposition uniformity on small mirror surfaces, and analog tilting open-loop and closed-loop control [30]. Until now, the research has focused on device-level technology. Novel architecture design on optical switches can also be investigated from the system level with the learnt hardware properties, for example, the L-switching matrix design [39] by integrating different component structures in one system design.

BIOGRAPHY

K. L. Eddie Law received the B.Sc.(Eng.) degree in electrical and electronic engineering from the University of Hong Kong, the M.S. degree in electrical engineering from Polytechnic University, Brooklyn, New York (USA), and the Ph.D. degree in electrical and computer engineering from the University of Toronto in Canada in 1995. From 1995 to 1999, he joined Nortel Networks in Ottawa, Canada, and worked in three different groups: Passport Research, Next Generation ATM Systems, and Computing Technology Lab. Since September 1999, he has been an Assistant Professor in the Communications Group in the Edward S. Rogers Sr. Department of Electrical and Computer Engineering at the University of Toronto. His current research interests are on the active networks, policy-based management on the Internet, TCP/IP protocol design and development, reconfigurable network design, and photonic switch design.

1. INTRODUCTION

The major advances in optical technology have led to the development of optical communication systems and networks, beginning with long-haul communication systems to metropolitan-area networks, even to access networks, which are the final leg in communication systems, in the form of fiber to the curb (FTTC), fiber to the building (FTTB), and fiber to the home (FTTH).

There are a few reasons why *optical networks* are considered as a solution for transmission infrastructure:

1. Optical networks can provide vast bandwidth with low attenuation. Typically, optical systems use wavelengths in three ranges: previously 800–900 nm and 1280–1350 nm, and currently 1510–1600 nm. As a result of low attenuation, optical systems require fewer repeaters or amplifiers. The potential bandwidth of optical signals (wavelengths) is huge since the typical frequency is in the few hundred terahertz (10^{12}). This means that the data rate of optical systems can be much higher than that of communication systems using frequencies in the megahertz (10^6) or gigahertz (10^9) range. Currently, a single wavelength can operate at 10 Gbps (gigabits per second), and even at 40 Gbps. Furthermore, using dense wavelength division-multiplexing (DWDM) technology, it is possible to put many wavelengths into a single fiber. It is now possible to multiplex 80–100 wavelengths, creating Tbps capacity per fiber.
2. Optical networks provide a *transparency* to protocol, data format, and data rate. Thus, once a communication pipe is established between two client points, optical networks are easily able to accommodate any existing network protocols such as IP, ATM, and SONET/SDH. In addition, an optical network can carry data regardless of its format (e.g., analog or digital) and its data rate.
3. Because of WDM technology and transparency, optical networks can provide a cost-effective and futureproof way to building the transport network. As traffic demand grows, it is easy to upgrade

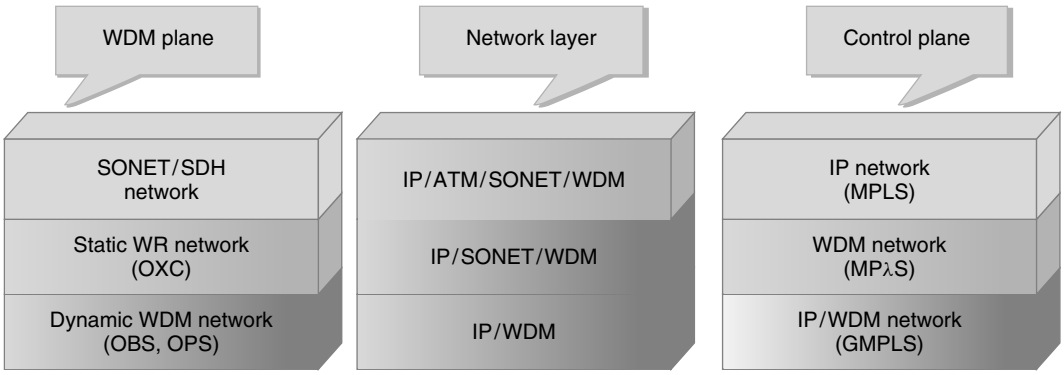

Figure 1. Evolution of optical networks.

network capacity using WDM technology. It is also easy to interface any existing or newly emerging network technology with optical networks due to service transparency.

4. Finally, optical networks become a more feasible solution as the internetworking technologies such as generalized multiprotocol label switching (GMPLS) [1] are actively developed and standardized.

Since it has been deployed in real systems (e.g., carrier systems), optical networking technology keeps evolving to seek better networking solutions in both cost and performance. Figure 1 shows the direction that optical networks have been evolving. We categorize the optical networking technology into three areas: WDM plane, network layer and control plane.

In the *WDM plane*, synchronous optical network (SONET)/synchronous digital hierarchy (SDH) systems were introduced as a first-generation (1G) optical network [2,3]. *SONET/SDH* are designed for carrying voice traffic over the optical fibers with very high transmission capacity. Currently, many carriers have buried many fibers and built SONET/SDH networks for transporting their voice traffic. Although SONET/SDH can be categorized as an optical network, it lacks the optical networking technology such as routing and switching. Thus, it can be said that SONET/SDH only takes advantage of the huge bandwidth of an optical transmission system. In order to enhance the networking capability in the optical network (or layer), *wavelength routing* (*WR*) *networks* [2,3] has been introduced. WR networks placed *optical cross-connect (OXC)* at the switching node, which switches individual wavelengths. In addition, WR networks perform a routing function in the optical domain, owing to the *control plane* such as MPλS (optical-domain MPLS) or GMPLS. On receiving a request from the clients (IP, ATM, SONET/SDH), WR networks set up an end-to-end *lightpath*, which is the process of assigning a wavelength to a particular path by routing and wavelength switching. Simply, WR networks provide a lightpath service to its client layers.

Depending on how frequently a network changes its virtual topology (or *lightpath topology*), an optical network can be classified either a static or dynamic. In a *static WDM optical network*, once established, a lightpath exists for a long period of time (e.g., years or months). This is the type of most optical networks deployed today. The drawback of a static network is that it results in inefficiency when traffic demand changes frequently. A *dynamic WDM optical network* can efficiently support bursty traffic by changing its virtual topology according to traffic demand. Thus, the lightpath in a dynamic WDM network reconfigures itself in much faster time scale. There are two optical switching technologies for dynamic WDM networks under active research and development (R&D), specifically, optical burst switching (OBS) [4–7] and optical packet switching (OPS) [8–10]. Both aim to switch optical packets (or optical bursts) in the optical domain as a conventional packet switching network does in the electronic domain.

In the network layer (layer in the OSI Reference Model), the evolution of optical networks is closely related to how to efficiently support IP traffic. Considering the unprecedented increase in Internet traffic since the mid-1990s, the network architecture should be optimized for the data traffic. Initially, the architecture includes ATM (asynchronous transfer mode) to carry IP packets due to its high-speed switching capability and QoS (quality-of-service) support. However, IP routers are improving their performance in capacity and forwarding speed, exceeding ATM's capability with the help of MPLS (multiprotocol label switching) technology. Thus, the architecture is simplified to IP over SONET over WDM, eliminating the ATM layer. In the next step, the IP layer is directly supported by the WDM layer without the SONET layer. Although the SONET layer provides fast restoration in the event of failure, the *IP over WDM architecture* without the SONET layer has few advantages: (1) SONET is designed for voice traffic, not for data traffic; (2) network control and management can be much simpler; and (3) it is more cost-effective, since SONET equipment increases in cost linearly with bit rate and the number of ports.

At the *control plane*, MPLS [11] was developed for IP networks. By introducing the concept of *label switching*, IP networks can forward packets much faster and overcome the shortcoming of connectionless service with a label-switched path (LSP). In addition, it is much easier to employ traffic engineering. While optical networks become a more attractive solution for transmission networks, MPλS was introduced, which is the application of MPLS

to the optical domain. The wavelengths and lightpaths in MPλS correspond to the labels and LSPs in MPLS, respectively. *GMPLS* [1] was developed for IP over WDM networks with a unified control plane. It is a generalized control plane in a sense that it encompasses packet-switch-capable (PSC), time-division-multiplex-capable (TDM), lambda-switch-capable (LSC), and fiber-switch-capable (FSC) interfaces. With GMPLS, it is possible to control different networks with a single unified control plane.

In the following discussion, we focus on optical switching techniques: wavelength routing, optical packet switching (OPS), and optical burst switching (OBS).

2. OPTICAL SWITCHING TECHNIQUES

Now, we look into the characteristics and issues in optical switching techniques. The general architecture of IP over WDM optical networks (optical Internet) is shown in Fig. 2 [12]. Multiple optical networks exist in the optical domain, where an ENNI (external network-to-network interface) is used for signaling between optical networks. A single optical network consists of multiple suboptical networks, where the INNI (internal network-to-network interface) is used for signaling between them. Again, a suboptical network has multiple optical nodes (e.g., OXCs or optical routers) interconnected with optical fibers. As clients, IP, ATM, and SONET networks are interfaced with optical networks via a UNI (user-to-network interface).

The optical switching techniques that we are interested in determine the service provided by optical networks to client networks. *Wavelength routing*, *optical burst switching*, and *optical packet switching* networks provide lightpath-level, burst-level, and packet-level services, respectively, to client networks.

2.1. Wavelength Routing Network

A *lightpath* is the service unit that the wavelength routing network provides. A *wavelength routing network* consists of multiple OXCs, which are interconnected with optical fiber links. At the network planning stage, for the estimated input traffic, network resources (e.g., number of wavelengths) are dimensioned so that the performance (e.g., blocking probability) can be satisfied.

When setting up a lightpath for a request from a client network, the edge node in the wavelength routing network sends out a lightpath request. In this process, the ingress edge node performs routing to find an optimal route to the egress edge node. The signaling mechanisms in GMPLS may be used in this routing process. Thus, the lightpath setup is done by the control plane. There are two ways of implementing the control plane: by centralized control or by distributed control. Both approaches have advantages and disadvantage. The interested reader may refer to two papers published in 1996 and 1997 [13,14].

When setting up a lightpath, OXCs in the wavelength routing network perform the key function: switching the wavelength to its destined port. The general *architecture of OXC* is shown in Fig. 3. There are M input fibers and M output fibers, each of which carries W wavelengths. The W wavelengths are demultiplexed and put into the optical switch, which has the dimension of $MW \times MW$. The OXC control is in charge of generating control signals to optical components such as optical switch and wavelength converters. The control signal is based on the decision made in the control plane where the lightpath setup requests are processed.

The OXC may have *wavelength converters* for the purpose of increasing performance. It is obvious that having wavelength converters decreases the blocking probability since without wavelength converters, the same wavelength should be used in every link (wavelength continuity), while with wavelength converters, any wavelength can be used. The wavelength conversion can be done either electrically or optically. If the conversion is performed electrically, the optical signal is terminated with O/E (optical to electrical) conversion, then transmitted over the different wavelength after E/O (electrical to optical) conversion. However, its cost linearly increases with the number of transponders per wavelength.

On the other hand, if the conversion is performed optically, the optical signal can be transparently transmitted without O/E/O conversion. However, the cost of optical wavelength converters is still high. Thus, it is desirable

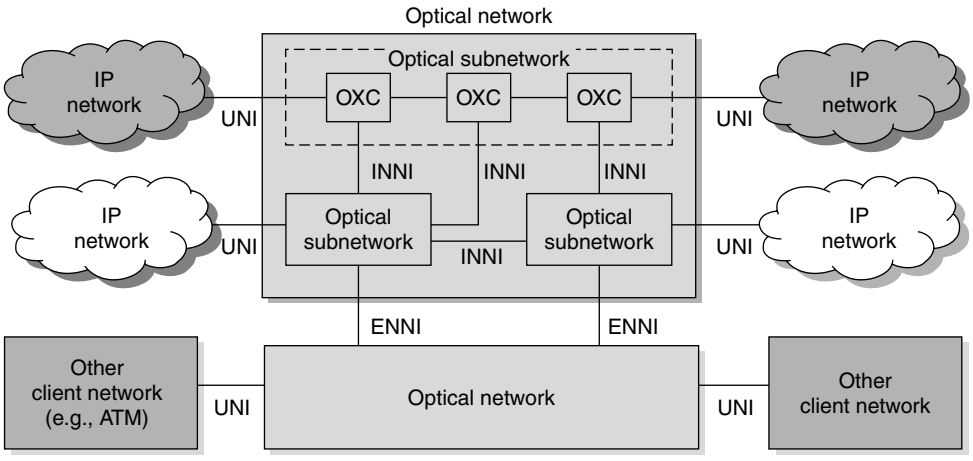

Figure 2. IP over WDM optical networks.

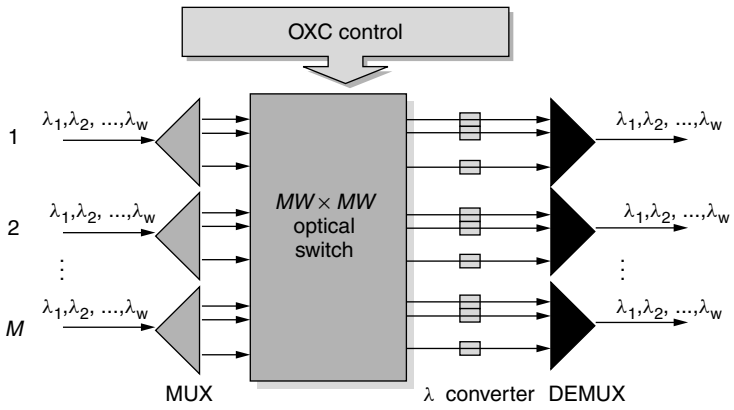

Figure 3. OXC architecture.

to keep the wavelength conversion capability minimum (no conversion or limited conversion). There are studies showing that the gain of full wavelength conversion over no wavelength conversion is a function of the number of wavelengths and the number of hops to traverse [15]. Thus, with proper network planning (e.g., short network diameter and enough wavelengths), it is possible to keep the conversion capability low.

Now, let us look at the characteristics of a wavelength routing network. A wavelength routing network is in the form of circuit switching, and thus we also call it an *optical circuit switching* (OCS) network. It requires *two-way reservation* for lightpath establishment. In other words, a lightpath is established when the acknowledgment comes back as a response to the setup request. This process introduces a setup delay, which is proportional to the round-trip propagation delay over the distance between the two points. Although the setup delay is ignored in a static OCS network with relatively long session time (e.g., years or months), the setup delay may affect the performance of a dynamic OCS network when the session time is of the same order of magnitude as the setup delay. It is another shortcoming of a wavelength routing network that the bursty traffic may result in poor performance due to the static nature of a wavelength routing network. Another important issue in a wavelength routing network is the routing and wavelength assignment (RWA). With an efficient RWA algorithm, it is possible to reduce the network resources for the given input traffic. However, in spite of intensive research on RWA [16], it is still a hard problem to solve, especially when RWA is performed online.

Although there are some disadvantages, a wavelength routing network is the feasible solution in the near term, due to immaturity of optical technology.

2.2. Optical Packet-Switching Network

In a *packet-switching network*, user data are segmented into packets. Each packet consists of two parts: a *header* containing the control information (e.g, routing information) and *data*. As an example, IP datagrams and ATM cells are the packets in IP and ATM networks, respectively. In a packet-switching network, there are two types of service: datagram service (or connectionless service) as in an IP network and virtual circuit service (or connection oriented service) as in an ATM network. While each packet takes the same path in the *virtual circuit service*, each packet may take a different path in a *datagram service*. In either case, each packet goes through intermediate packet switching nodes until it reaches its destination. The key functions performed by intermediate nodes is routing and forwarding, namely, deciding the next hop node and forwarding the packet. These are the characteristics of a packet switching network in the electrical domain.

The *optical packet switching* (*OPS*) *network* is to perform the same packet switching functions in the optical domain. Thus, an optical packet is transmitted and processed by the optical packet-switching nodes. The general architecture of an optical packet switching node is shown in Fig. 4.

An *OPS node* consists of the input and output processing units, a switching unit, a buffering unit, and control unit. The optical packets arrive at input processing unit, where synchronization and header extraction take place. If the system operates in time slots with a fixed size of packets, then synchronization is required for the alignment of multiple incoming packets, which may arrive at different times. The tunable delay, which can be implemented with fiber delay lines (FDLs) and 2×2 optical switches, may be used for synchronization.

When an optical packet arrives, its header is detached and sent to the control unit for processing. Currently, the implementation of the control unit using optical logic is very difficult. Thus, after being extracted, the header part goes through O/E conversion, while the data remain in optical form. To facilitate tapping the optical signal, optical packets are encoded using a technique such as subcarrier multiplexing (SCM). Once the header is decoded in the control unit, the routing process is performed to determine the output port. This process may be layer 3 IP routing or layer 2 label switching. In this process, the control unit generates the control signals to the switching unit (small and fast optical switch) and the buffering unit. The buffering unit resolves the contention problem when multiple packets are destined to the same output port. Since optical memory is not commercially available today, the buffering unit is usually implemented using FDLs, which provide only limited time of buffering.

Finally, the header part and data part are rejoined at the output processing unit before sending it out to the next switching node. If the information in the header needs to

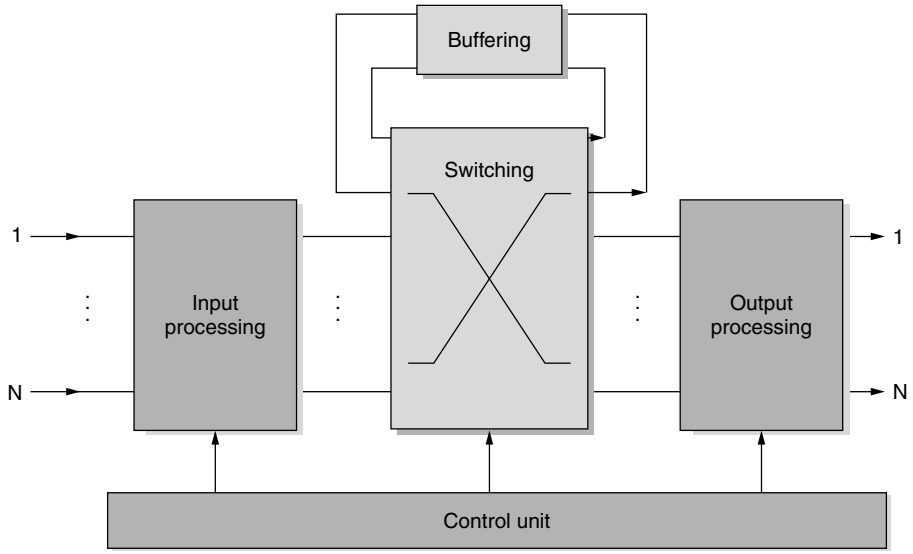

Figure 4. OPS node architecture.

be updated (e.g., by label update after label swapping), the rewriting process takes place.

Although an optical switching network overcomes some of the shortcomings of a wavelength routing network (e.g., inefficiency due to static nature), it is technically hard to implement packet-switching functions with current optical technology. The optical burst switching (OBS) technique attempts to effect balance between wavelength routing and optical packet switching by overcoming the disadvantages of both techniques, while preserving their merits.

3. OPTICAL BURST SWITCHING NETWORK

So far, we have described the characteristics of a wavelength routing network and an optical packet-switching network. Now, we focus on another alternative, *optical burst switching* (OBS), and look at its characteristics in some detail.

3.1. OBS Protocol

The distinction between OBS and OCS is that the former uses a one-way reservation while the latter uses a two-way reservation. It is called the two-way reservation when there must be a connection setup procedure before the data transmission takes place. It is called the *one-way reservation* when the data (which is called the data burst) follow the connection setup request immediately after waiting for some delay. This delay will be called an *offset time*, which will be explained later. Note that the connection setup request in the OBS will be called a *control packet* or a *burst control packet* (BCP).

Although OBS and OPS have similar characteristics (e.g., statistical multiplexing on the links), the distinction between the two is that the former has some unique features such as the offset time and the delayed reservation [4,5]. In addition, the payload in the OBS is much larger than that in the OPS. The payload unit in OBS networks will be referred as the data burst hereafter.

The operations of the *OBS protocol* are illustrated in Fig. 5a. When the source node S has a data burst to send, the burst control packet (BCP) is generated and transmitted first. At each node, the BCP takes δ time unit to be processed and makes the reservation for the following data burst. Meanwhile, the data burst, after waiting

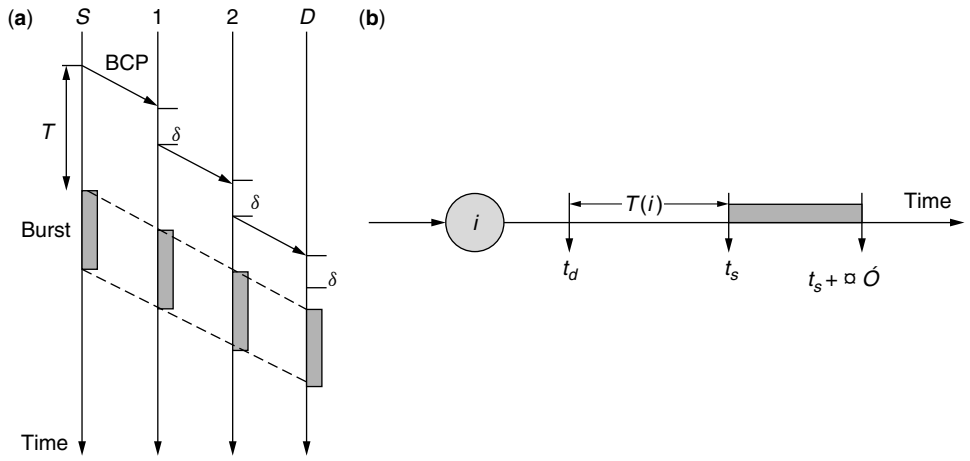

Figure 5. Offset time (**a**) and delayed reservation (**b**) in OBS.

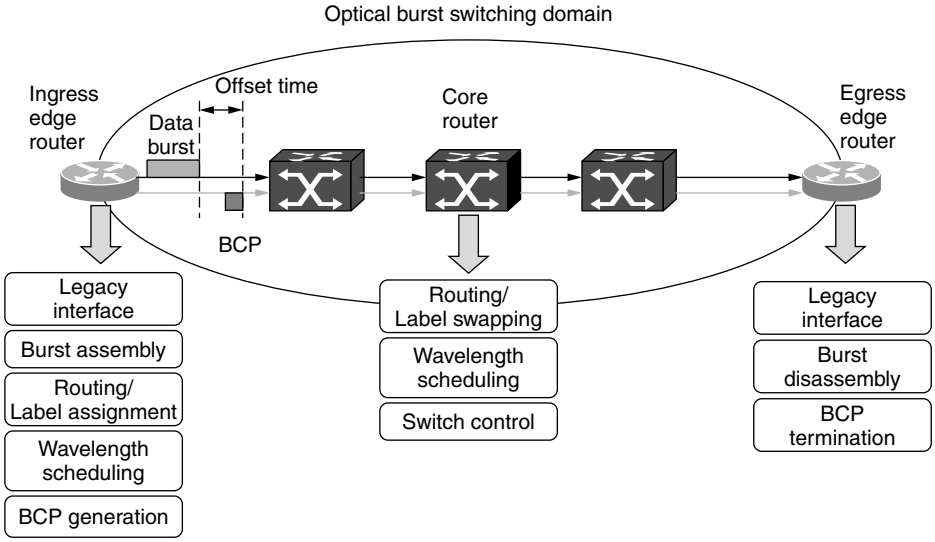

Figure 6. OBS network.

for an offset time, which is denoted as T, at the edge router, immediately follows the BCP. Since the BCP has already set up the necessary configurations, including the resource reservation, the data burst does not need to be delayed (buffered) for processing at the intermediate nodes (nodes 1 and 2), and just cuts-through to the destination node D. Thus, OBS networks can provide the data plane with the end-to-end transparency without going through any optical–electrical–optical (O/E/O) conversions.

The advantage of the offset time is to decouple the BCP from the data burst in time, which makes it possible to eliminate the buffering requirement at the intermediate nodes. In order to ensure that the data burst does not overtake the BCP, the offset time should be made long enough by considering the expected processing time at each intermediate node and the number of hops to be traversed by the BCP [4,5].

Another feature of OBS is the *delayed reservation* (DR), which makes it possible to statistically multiplex data bursts on the links. The DR is illustrated in Fig. 5b, where $T(i)$ is the offset time at node i, 1 is the transmission time of the data burst at node i, and t_a and t_s indicate the arriving time of the BCP and its corresponding data burst, respectively. According to DR, after being processed, the BCP reserves the resources at a future time (at the arrival time of the data burst), which can be obtained from the offset time $T(i)$. Also, the reservation is made for just enough time to finish the transmission (data burst duration 1). In OBS, two parameters — the offset time and the mean data burst size — need to be selected carefully in the design step since they have a great impact on performance.

3.2. OBS Network and OBS Routers

Now, we discuss architectural aspects of OBS [6]. For simplicity, we focus on a single OBS domain, where all nodes (or *OBS routers*) are well aware of the OBS protocols. Note that the terms *OBS domain* and the *OBS network* will be used interchangeably. Depending on the location in the OBS domain, the OBS routers are classified as *edge routers* and *core routers* as shown in Fig. 6. Note that the edge routers should be equipped with both capabilities as an *ingress edge router* (*IER*) and as an *egress edge router* (*EER*). Thus, the edge router functions as an ingress router when there are inbound data to the OBS domain, whereas the edge router functions as an egress router when there are outbound data from the OBS domain. In the following discussion, we describe the functions and general architectures for each type of OBS router.

The general *architecture of the IER* is shown in Fig. 7. The IER should provide the interface between the OBS network and other legacy networks. It also needs to provide the signaling interface between two different networks. When the IER receives incoming data (e.g., IP packets, ATM cells, or voicestreams) from the line interface cards, the burst assembly process takes place in which multiple packets are packed into a data burst. We will discuss the burst assembly process later. The arriving packets are switched to the appropriate assembly queues according to their destination and QoS. The first packet arrival in an assembly queue initiates the BCP generation where some BCP fields such as burst size, offset time, and label are to be determined and filled later when the *burst assembly* is completed.

When the burst is assembled long enough to meet the requirements, the BCP obtains the field information of burst size and offset time. On the basis of the routing decision, a label is assigned to establish the label-switched path (LSP). If the LSP already exists (has been set up by the previous BCP), the previously used label is assigned. Otherwise (i.e., if a new LSP needs to be set up or the existing LSP needs to be changed), a new label is assigned. The downstream nodes perform the label swapping, where the inbound label is mapped into the outbound label at the local node. The label information in the BCP should be updated accordingly. How the labels are distributed and assigned depends on the label distribution protocols such as RSVP-TE and CR-LDP [17,18].

According to OBS protocols, the BCP is transmitted to the core OBS router an offset time earlier than its corresponding data burst. The wavelength assignment

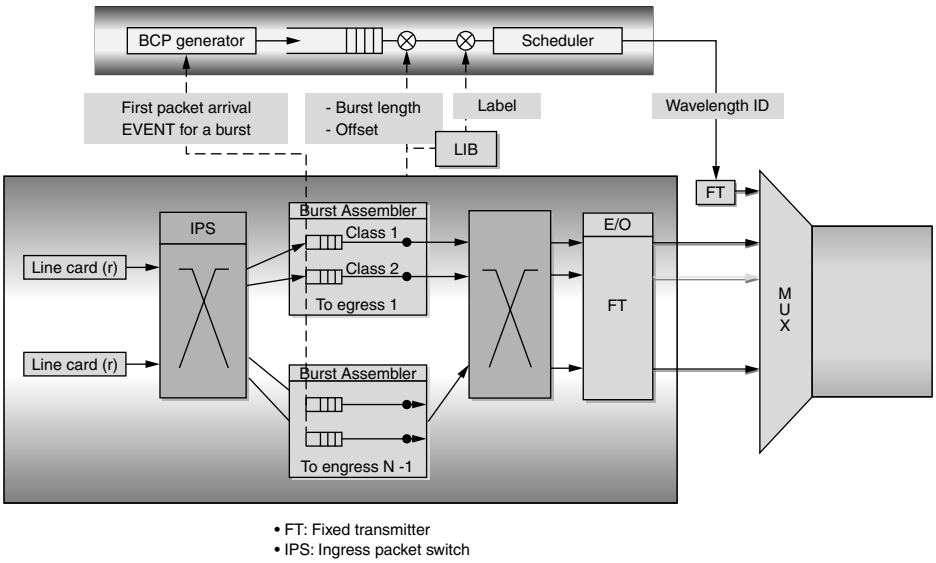

Figure 7. Architecture of ingress-edge router (IER).

and scheduling is required in this step. There are two kinds of wavelengths (or channels) in the OBS domain: the *control channels*, which carry the BCPs, called the *control channel group* (CCG); and the data burst channels, which carry the data bursts, called the *data burst channel group* (DCG). Thus, two wavelengths are assigned and scheduled for transmission of the BCP and its data burst. The wavelength scheduling on the DCG (for data bursts), which can enhance the utilization, is an interesting research area. There are a few scheduling algorithms proposed to date, such as first fit, horizon scheduling, and void-filling scheduling [6,19]. It is noted that while the labels carry the path (LSP) information, the wavelengths are meaningful only at the local node. In this way, the downstream nodes can assign the wavelengths dynamically, which combines with the label only for the duration of the data burst.

The *architecture for the EER* is shown in Fig. 8. The main functions of the EER are the BCP termination and the data burst disassembly. When a BCP arrives, the EER processes it and reserves the buffer space as required by the burst length field for the burst disassembly process. On arrival, the data burst, after being converted to an electrical signal, goes through the burst disassembly process. Then the disassembled packets are distributed to their destination ports.

The core router has the general architecture shown in Fig. 9. It consists of two parts: a switch control unit and a data burst unit. While the switch control unit is responsible for processing the BCPs on the CCG, the data burst unit is responsible for switching the data burst to the destined output port, which is controlled by the switch control unit. Most of the functions in the core router take place in the switch control unit, which includes the label swapping for establishing the LSP, local wavelength scheduling, burst contention resolution, and generation of the control signal to the data burst unit. The data burst unit consists roughly of demultiplexers, inlet fiber delay lines (FDLs) (for adjusting the timing jitter of offset time between the BCP and the data burst), optical switches, wavelength converters, FDL buffers (for

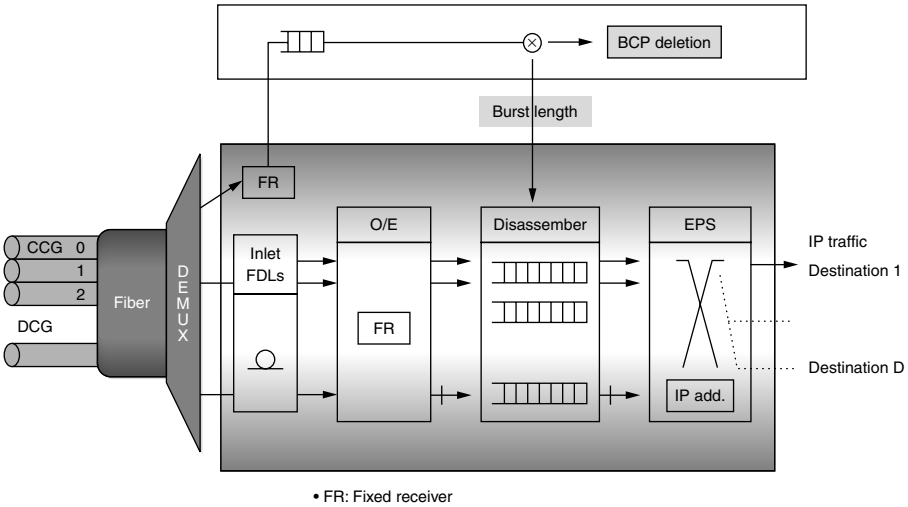

Figure 8. Architecture of egress edge router (EER).

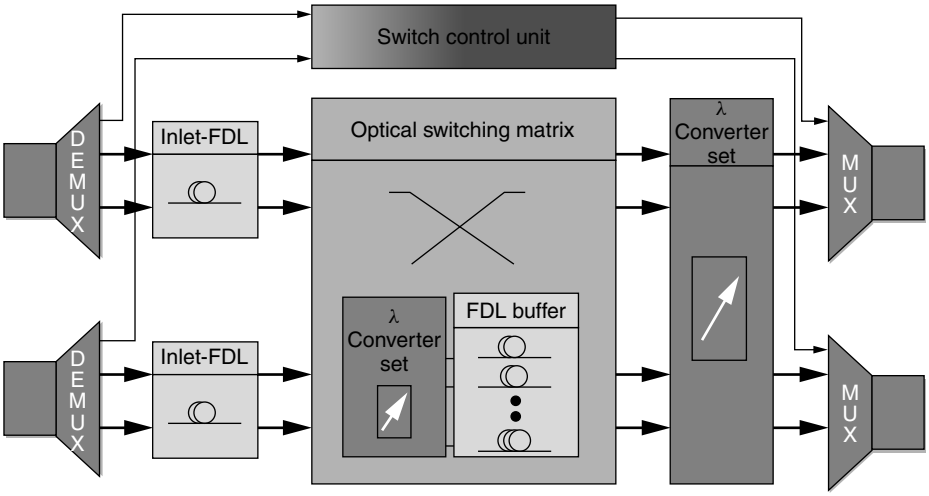

Figure 9. Architecture of core router.

contention resolution), and multiplexers. The components of the data burst unit are passively configured by the control signals from the switch control unit.

Before we conclude this description, of the architecture, it is worth mentioning some important design parameters such as the capacity of the core router, the switching speed of the optical switch, and the average burst size. The capacity of the router is determined by the number of incoming fibers and the number of wavelengths available in each fiber. For example, a core router of 10 Tbps capacity needs 32 incoming fibers, each of which has 32 wavelengths operating at 10 Gbps per wavelength. Of course, since some wavelengths are dedicated to the CCG, the router capacity is determined only by the number of wavelengths in the DCG.

The core router requires two switches; one is in the switch control unit, and the other is in the data burst unit. While the former switches the BCPs on the CCG, which can be implemented with a small electronic switch (depending on the number of wavelengths in the CCG), the latter switches the data bursts on the DCG, which can be implemented with an optical switch. The dimension of the optical switch depends on the number of wavelengths in the DCG. The architecture of the optical switch may be either a simple single stage if a large optical switch is available [e.g., MEMS (microelectromechanical systems) crossbar switch [20]] or multistage interconnection network (MIN) as in an ATM switch [21] if multiple small optical switches are used.

Next, consider the switching speed of an optical switch and the average burst size. The *switching time* of an optical switch is the delay that it takes to change from one state to another state. The switching speed imposes an overhead on the switch throughput. In other words, the slower the switching speed, the worse the throughput. However, the overhead caused by the switching speed can be reduced if the data burst is long compared to the switching time. Thus, for optimum switch throughput, the average burst size should be selected according to the switching speed of the optical switch in use. This average burst size is the requirement that the burst assembler should meet.

3.3. QoS in OBS Network

Given that some real-time applications (such as Internet telephony and videoconferencing) require a higher *QoS* than do non-real-time applications [such as electronic mail (email) and general Web browsing], the QoS issue should be addressed. Although QoS concerns related to optical (or analog) transmission (e.g., dispersion, power and signal-to-noise ratio) also need to be addressed, here, we focus on how to ensure that critical data can be transported in the OBS domain more reliably than noncritical data. Unlike the existing QoS schemes that differentiate the services using the buffer, the QoS scheme to be introduced in the following discussion takes advantage of the offset time, which was explained earlier. We call this an *offset-time-based QoS scheme*. For this purpose, we introduce a new offset time, which is called the *extra offset time*. Note that the offset time introduced previously, which is called the *base offset time* is different from the extra offset time.

We now explain how the offset-time-based QoS scheme works [22,23]. In particular, we explain how *class isolation* (or service differentiation) can be achieved by using an extra offset time in both cases with and without using fiber delay lines (FDLs) at an OBS node. Note that one may distinguish the following two different contentions in reserving resources (wavelengths and FDLs): the *intraclass contentions*, caused by requests belonging to the same class; and the *interclass contentions*, caused by requests belonging to different classes. In what follows, we focus on how to resolve interclass contentions using the offset-time-based QoS scheme.

For simplicity, we assume that there are only two classes of (OBS) services: classes 0 and 1, where class 1 has priority over class 0. In the offset-time-based QoS scheme, to give class 1 a higher priority for resource reservation, an extra offset time, denoted by t_o^1, is given to class 1 traffic (but not to class 0, i.e., $t_o^0 = 0$). In addition, we also assume that the base offset time is negligible as compared to the extra offset time, and will refer to the latter as simply the *offset time* hereafter. Finally, without loss of generality, we also assume that a link has only one wavelength for data (and an additional wavelength for control).

3.3.1. The Case Without FDLs. In the following discussion, let t_a^i and t_s^i be the arriving time and the service-start time for a class i request denoted by req(i), respectively, and let l_i be the burst length requested by req(i), where $i = 0, 1$. Figure 10 illustrates why a class 1 request that is assigned an (extra) offset time obtains a higher priority for wavelength reservation than does a class 0 request in the case of no FDLs. We assume that there is no burst (that arrived earlier) in service when the first request arrives. Consider the following two situations where contentions among two classes of traffic are possible.

In the first case as illustrated in Fig. 10a, req(1) comes first and reserves a wavelength using DR, and req(0) comes afterward. Clearly, req(1) will succeed, but req(0) will be blocked if $t_a^0 < t_s^1$ but $t_a^0 + l_0 > t_s^1$, or if $t_s^1 < t_a^0 < t_s^1 + l_1$. In the second case, as in Fig. 10b, req(0) arrives first, followed by req(1). When $t_a^1 < t_a^0 + l_0$, req(1) would be blocked had no offset time been assigned to req(1) (i.e., $t_o^1 = 0$). However, such a blocking can be avoided by using a sufficient offset time so that $t_s^1 = t_a^1 + t_o^1 > t_a^0 + l_0$. Given that t_a^1 may only be slightly behind t_a^0, t_o^1 needs to be larger than the maximum burst length over all bursts in class 0 in order for req(1) to completely avoid being blocked by req(0). With that much of offset time, the *blocking probability* of (the bursts in) class 1 becomes only a function of the offered load belonging to class 1, that is, independent of the offered load belonging to class 0. However, the blocking probability of class 0 is determined by the offered load belonging to both classes.

3.3.2. The Case with FDLs. Although the offset-time-based QoS scheme does not mandate the use of FDLs, its QoS performance can be significantly improved even with limited FDLs so as to resolve contentions for bandwidth among multiple bursts. For the case with FDLs, the variable B will be used to denote the maximum delay that a FDL (or the longest FDL) can provide. Thus, in the case of blocking, a burst can be delayed up to the maximum delay B.

Figure 11a,b illustrates class isolation at an OBS node equipped with FDLs where contention for both wavelength and FDL reservation may occur. In Fig. 11a, let us assume that when req(0) arrives at $t_a^0(t_s^0)$, the wavelength is in use by a burst that arrived earlier. Thus, the burst corresponding to req(0) has to be delayed (blocked) for t_b^0 units. Note that the value of t_b^0 ranges from 0 to B, and a FDL with an appropriate length that can provide a delay of t_b^0 will be chosen. Accordingly, if $t_b^0 < B$, the FDL is reserved for a class 0 burst as shown in Fig. 11b (the burst will be dropped if t_b^0 exceeds B), and the wavelength will

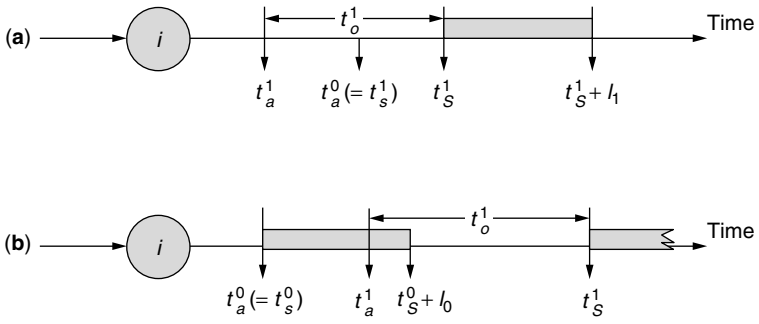

Figure 10. Class isolation in the case without FDLs.

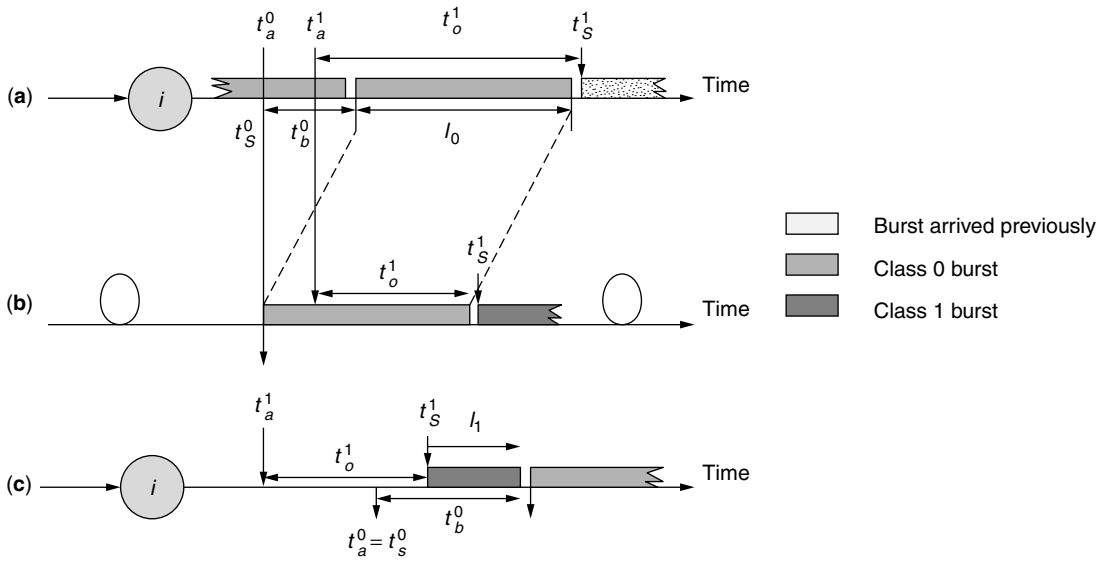

Figure 11. Class isolation in the case with FDLs.

be reserved from $t_s^0 + t_b^0$ to $t_s^0 + t_b^0 + l_0$ as shown in Fig. 11a. Now assume that req(1) arrives later at t_a^1 (where $t_a^1 > t_a^0$) and tries to reserve the wavelength. req(1) will succeed in reserving the wavelength as long as the offset time is so long that $t_s^1 = t_a^1 + t_o^1 > t_a^0 + t_b^0 + l_0$. Note that had req(1) arrived earlier than req(0) in Fig. 11a it is obvious that req(1) would not have interclass contention caused by req(0). This illustrates that class 1 can be isolated from class 0 when reserving a wavelength because of the offset time. Of course, without the offset time, req(1) would be blocked for $t_a^0 + t_b^0 + l_0 - t_a^1$, and it would be entirely up to the use of FDLs to resolve this interclass contention.

Similarly, Fig. 11b illustrates class isolation in FDL reservation. More specifically, let us assume that req(0) has reserved the FDLs as described earlier, and because t_o^1 is not long enough, req(1) would be blocked in wavelength reservation and thus needs to reserve the FDLs. In such a case, req(1) will successfully reserve the FDLs if the offset time is still long enough to have $t_s^1 = t_a^1 + t_o^1 > t_a^0 + l_0$. Otherwise (i.e., if $t_s^1 < t_a^0 + l_0$), req(1) would contend with req(0) in reserving the FDL and would be dropped.

As shown in Fig. 11c, if req(1) comes first and reserves the wavelength based on t_o^1 and delayed reservation (DR), and req(0) comes afterward, req(1) is not affected by req(0). However, req(0) will be blocked either when $t_a^1 < t_a^0 < t_s^1$ but $t_a^0 + l_0 > t_s^1$, or when $t_s^1 < t_a^0 < t_s^1 + l_1$. Similarly, if req(1) arrives first, it can reserve the FDL first regardless of whether req(0) succeeds in reserving the FDL. As mentioned earlier, this implies that class 1 can be isolated from class 0 in reserving both the wavelength and the FDL by using an appropriate offset time, which explicitly gives class 1 a higher priority over class 0. As a result of having a low priority on resource reservations, class 0 bursts will have a relatively high blocking and loss probability.

Although the offset-time-based QoS scheme does provide good service differentiation even when buffering is not possible, it has some disadvantages that need to be enhanced. For example, the offset-time-based QoS scheme introduces delay overhead caused by the extra offset time. Since the highest class suffers from the longest delay [22,23], the QoS provisioning will be strictly restricted in a given delay budget. It also lacks the controllability on the QoS, which can be enhanced by introducing the measurement based QoS provisioning and assigning the appropriate weight to each QoS class. In addition, it is worth considering how the offset-time-based QoS scheme can be integrated with the existing QoS domain such as DiffServ.

3.4. Burst Assembly

As we mentioned earlier, the *burst assembly* process takes place at the ingress edge router. The incoming data (e.g., IP packets) are assembled into a super packet, which is called the *data burst*. In the following discussion, we look into the issues of burst assembly.

It is obvious that IP packets would be the dominant traffic in future networks. Unlike the traffic from traditional telephone networks, Internet traffic is quite difficult to predict. This is because Internet traffic shows self-similarity [24,25]. *Self-similarity* means that even with a high degree of multiplexing, the burstiness of traffic still exists at all timescales, which makes the network resource dimensioning and traffic engineering harder.

One advantage of the burst assembly is that it may reduce the self-similarity of Internet traffic [26]. Figure 12 shows an example configuration of an OBS network for burst assembly [27]. IP routers in the IP domain inject IP packets into the OBS network. The OBS edge routers located at the boundary of the OBS network take IP packets and perform the burst assembly process.

The incoming IP packets are classified and queued into an assembly buffer according to their destination and QoS requirements. A simple burst assembly process is illustrated in Fig. 13. The burst assembler at the end of the assembly buffer runs a timer, which expires at a given time (i.e., the assemble time). Whenever the timer expires, the burst assembler takes the burst (multiple IP packets queued during a given period of time) out of the assemble buffer for transmission. The key parameter of the burst assembler is the *assemble time*, which controls the size of the data burst. The distribution of assemble time could be deterministic or random, in which case it is called either a constant assemble time (CAT) or a variable assemble time (VAT), respectively. The burst assembler waits for a constant time when using the CAT, whereas it waits for a random amount of time when using the VAT. Alternatively, the burst assembler adaptively controls the assemble time by monitoring both assemble time and the

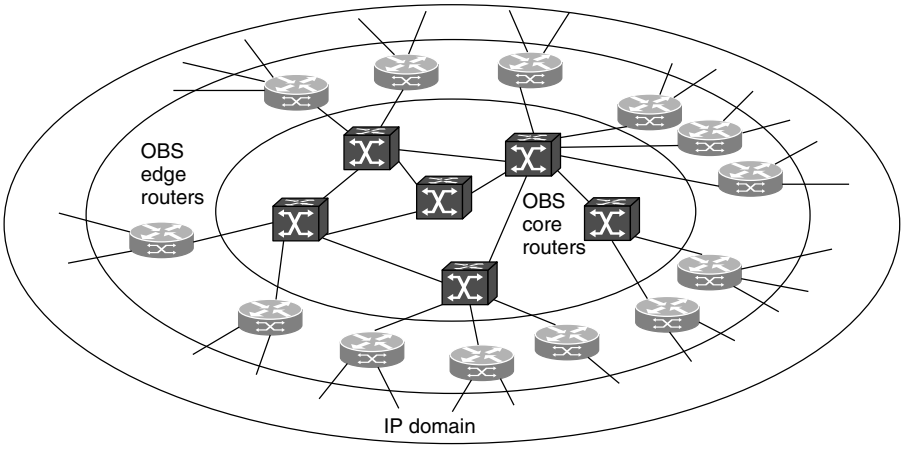

Figure 12. OBS edge routers for burst assembly.

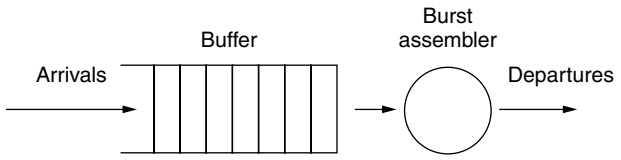

Figure 13. Burst assembly process.

size of the assembled IP packets. The optimization of the burst assembly process is a topic that requires further investigation.

4. SUMMARY

Because of its advantages over conventional communication networks, optical networks have been firmly positioned as a feasible solution for the next-generation networks. The optical networking technology keeps improving starting, from SONET to static wavelength routing network, and eventually, to dynamic optical networks. We have discussed optical switching techniques available today for optical networks: wavelength routing, optical burst switching, and optical packet switching.

Table 1 summarizes the qualitative comparison among these techniques. Wavelength routing is a simple and technically matured technology, but it may result in poor performance. On the other hand, optical packet switching may show its dynamicity in networking as in an electrical packet-switching network, but is technically immature for the implementation. Optical burst switching achieves balance between wavelength routing and optical packet switching by improving the inefficiency of wavelength routing and at the same time, by lessening the technical difficulty of optical packet switching. Thus, while the optical technology is mature enough to implement optical packet switching, optical burst switching appears to be a practical interim solution for optical networks.

BIOGRAPHIES

Myungsik Yoo received the B.S. and M.S. degrees in electrical engineering from Korea University, Seoul, Korea, in 1989 and 1991, respectively, and the Ph.D. degree in electrical engineering from State University of New York at Buffalo (SUNY at Buffalo), Buffalo, New York (USA) in 2000. He was a Senior Research Engineer in Nokia Research Center, Burlington, Massachusetts. Since 2000, he has been an Assistant Professor in the School of Electronic Engineering, Soongsil University, Seoul, Korea. His current research interests are optical networks and optical Internet, including optical burst switching, protection/restoration, QoS support, and GMPLS.

Chunming Qiao is an Associate Professor at the University at Buffalo (SUNY). He has over 10 years of academic and industrial experience in optical networks. Dr. Qiao has published more than 100 papers in leading technical journals and conference proceedings, and several book chapters. He has given several keynote speeches, tutorials, and invited talks and is recognized for his pioneering research on optical Internet and in particular, the optical burst switching (OBS) paradigm. Dr. Qiao is the IEEE Communication Society's Editor-at-Large for optical networking and computing; an editor of several other journals and magazines, including *IEEE/ACM Transactions on Networking* (ToN), as well as a guest editor for *IEEE JSAC* and other publications. He has chaired and co-chaired many conferences and workshops on optical communications and networking, including the Optical Networks Symposium (ICC'03), and Opticomm 2002. Dr. Qiao is also the founder and Chair of the Technical Group on Optical Networks (TGON) sponsored by SPIE, and a Vice Chair of the IEEE Technical Committee on Gigabit Networking (TCGN).

Table 1. Comparison Between Optical Switching Paradigms

Switching Paradigm	Bandwidth Utilization	Implementation Difficulty	Switching Granularity
Wavelength routing	Poor	Low	Coarse
Optical packet switching	High	High (not mature)	Fine
Optical burst switching	Moderate	Moderate	Moderate

1. INTRODUCTION

Optical communication systems in the optical fiber play a main part of the digital communications in backbone networks, high speed local-area networks (LANs) using a fiber distributed data interface (FDDI), metropolitan-area network (MAN), and a next-generation subscriber system such as a fiber to the home (FTTH). The main advantages of the optical fiber communications are the high speed, large capacity and high reliability by the use of the broadband of the optical fiber. A desirable feature for future optical networks would be the ability to process information directly in the optical domain for purposes of multiplexing, demultiplexing, filtering, amplification, and correlation. Optical signal processing would be advantageous since it can potentially be much faster than electrical signal processing and the need for photon–electron–photon conversion would be obviated.

Asynchronous multiple-access methods where network access is random and collisions occur, such as token passing and carrier-sense multiple-access, are well suited to LANs with low traffic demand. However, these asynchronous access methods suffer from cumulative delay as the traffic intensity increases. Also, contention protocols generally proposed for low traffic demands are not suitable if traffic delay is a major issue, as, in networks where information must be transmitted simultaneously. On the other hand, synchronous accessing methods where transmissions are perfectly scheduled provide more successful transmissions than asynchronous methods. As a typical synchronous protocol, time-division multiple access (TDMA) is an efficient multiple-access protocol in networks with heavy traffic demands, since it can accommodate higher traffic demands and do not suffer from cumulative delay. However, in situations where the channel is sparsely used, TDMA is inefficient.

As an alternate optical multiplexing technique, there is wavelength-division multiple access (WDMA). The term WDMA rather than the popular wavelength-division multiplexing (WDM) is used to indicate the access, routing and switching functionality in addition to the transmission multiplex. Tuned lasers are used as the optical source for each transmitter, and the modulated data are transmitted within its assigned band. At the receiver, an optical filter is tuned to the desired band, while all others are filtered out. A photodetector and a decoder are followed to obtain the data. WDMA technique partitions the available spectrum to different users, and offers a means of increasing capacity at minimal cost within the existing optical fiber infrastructure. The fundamental disadvantage in WDMA is that sophisticated hardware such as wavelength-controlled tunable lasers and high-quality narrowband tunable filters for each channel is required. Although WDMA can be used as a degree of design freedom with respect to routing and wavelength selection, the usable wavelength might be limited because of the crosstalk caused by the nonlinearity within the optical fiber. Wavelength routing can offer the switching function for dense WDMA networks; however, it may cause the crosstalk problem in the cross-connects based on space and wavelength, and thus, network reliability and flexibility are restricted.

Code-division multiple-access (CDMA) is a multiple access protocol that is efficient with low traffic and has zero access delay. Especially, direct detection optical CDMA

systems have been investigated widely to apply for high-speed LAN, because they allow multiple users to access the network simultaneously. In the case of data transfer where traffic tends to be bursty rather than continuous, CDMA can be used for contention-free, zero delay access. Compared with TDMA, CDMA is attractive in other points. Channel assignment is much easier with CDMA. CDMA isolates irregular channels so that they do not influence other channels, while with TDMA, even one irregular channel, such as continuous emission from a transmitter, causes the failure of all other channels.

In optical CDMA, incoherent systems using narrow pulse laser sources are mainly implemented, since optical links have vast bandwidth and the optical components can produce very narrow pulse precisely in time and offer extrahigh optical signal processing. In the transmitter and receiver, low-cost devices with high cost performance and high reliability, such as Fabry–Perot laser diode and avalanche and pin photodiodes, are available. Thus, in optical CDMA, intensity modulation/direct detection (IM/DD) is mainly used. In IM/DD systems, other arriving pulse sequences having positive pulses happen to overlap a pulse of the desired sequence, and produce correlation crosstalk. In optical CDMA, multiple user interference called multiple-access interference (MAI) is dominant compared to photodetector shot noise, dark current and thermal noise. Thus, the elimination or suppression of MAI is the key issue in optical CDMA. Most published optical CDMA systems are based on discrimination in the time domain to reduce the effects of pulse overlaps. This time-encoding process is most commonly implemented by encoding each data bit with a high-rate sequence; that is, a pulse laser source is intensity-modulated by electrical (0,1) data bit and the narrow pulse is emitted in the first chip in a slot. Here, data are usually modulated in on/off keying (OOK) or pulse position modulation (PPM) formats, and a slot is divided into chips where the number of chips in a slot equals to the length of the spreading code consisting of 1 and 0 allocated for users. Then, in the time encoder, a narrow pulse is time-spread into several chips within the slot according to each user's unipolar signature code. Thus, the time-encoding process relies on a simple, intensity-based, pulse time addressing process, and the sequence encoder and decoder in the time domain can be easily and cost-effectively implemented by using tapped optical delay lines. At the receiver, optical incoherent direct detection is done by an optical delay-line decoder matched to the encoder at the transmitter. After decoding, unwanted signals are time-spread over much larger time intervals than is the desired user's signal, and the crosstalk from adjacent chips are rejected to some extent by this time-despreading process.

For optical CDMA systems, both asynchronous and synchronous systems have been studied. In an asynchronous optical CDMA system, the synchronization among users is not required, and optical orthogonal codes (OOC) with good correlation properties [1] are widely used. However, in asynchronous CDMA systems, the available number of signature sequence codes is very small; hence the number of users is very limited. To solve this problem, synchronous CDMA systems, in which all users are synchronized in frame, is considered. With synchronous CDMA, the available number of signature codes is larger than that of asynchronous CDMA systems, because the same code can be reused with different phases. The modified prime sequence codes are known as typical "signature codes for optical synchronous CDMA," in which time-shifted versions of the prime sequence code can be used [2]. The cross-correlation peak between two time-shifted versions of the sequence code is as high as the autocorrelation peak; however, it always occurs either delayed or ahead of the autocorrelation peak. Since in the synchronized CDMA the receiver can be synchronized to the expected position of the autocorrelation peak, the autocorrelation peak can be distinguished from adjacent cross-correlation peaks. For a given value of bit error rate, synchronous CDMA systems can accommodate more simultaneous users than asynchronous CDMA systems. Furthermore, synchronous CDMA can be efficiently used in conjunction with TDMA and WDMA on multimedia communication networks where multiple services with different traffic requirements are to be integrated.

In Section 2, a family of good optical unipolar pseudoorthogonal (non-zero-cross-correlation) codes suitable for optimal CDMA IM/DD system with OOK and PPM signaling is described. In Section 3, the IM/DD systems with OOK and PPM signaling are described as typical optical synchronous CDMA systems. Also, as an alternative optical CDMA system, a frequency-encoded spread-time optical CDMA system utilizing bipolar codes is briefly introduced. Since the performance of the optical CDMA is degraded by the multiple-user interference, the interference cancellation is the key to realize the practical optical CDMA system. In Section 4, we describe two typical interference cancellation techniques for optical synchronous CDMA, based on the use of properties of modified prime sequence codes and optical hard-limiter.

2. SEQUENCES FOR OPTICAL SYNCHRONOUS CDMA

Many classes of binary signature sequences that are suitable for radio CDMA have been studied. In most of these codes, a strong autocorrelation peak and zero-cross-correlation function can be obtained through bipolar $(-1,+1)$ sequences. However, optical IM/DD systems can only accommodate unipolar $(0,+1)$ sequences, since incoherent systems use only positive narrow pulses emitted from laser sources. Therefore, codes intended for communication systems in which both positive and negative levels are available, are not necessarily optimal in a fiberoptic environment using optical signal processing. Compared to conventional electronic bipolar $(-1,+1)$ codes such as maximum-length sequence codes and Gold codes, the cross-correlation function of unipolar codes is high and the number of codes in the family is very low. The minimum value of the cross-correlation that unipolar codes can achieve is limited to be one, since at least one pulse is overlapped for asynchronous unipolar sequences. Thus, sets of sequences having no more than one pulse overlap in the pairwise cross-correlation are often called as *pseudoorthogonal codes* in optical CDMA.

The characteristics needed for the unipolar codes suitable for optical CDMA are good autocorrelation and cross-correlation properties. Sharp autocorrelation property is needed to achieve the synchronization as well as the discrimination between the time-shifted sequence codes in optical synchronous CDMA where the time-shifted codes are assigned to other users. The minimum value of the cross-correlation function should be as small as possible to discriminate between the desired user and others as well as to mitigate multiple user interference. In optical CDMA IM/DD systems, other arriving pulse sequences having positive pulses that happen to overlap a pulse of the desired sequence produce correlation crosstalk called *multiple access interference* (MAI), which might degrade the decoding performance. The code length and weight (the number of "1"s) also affect the system performance. Long codes and sparse codes comprising very few ones and narrow pulses are preferred to support a large number of users and higher transmission capabilities, respectively. On the other hand, short codes and a large weight are preferred to increase data rate and improve signal-to-interference ratio, respectively.

In this section, as good optical unipolar codes suitable for optical CDMA IM/DD system with OOK and PPM signaling, the prime code family is described. Especially for optical synchronous CDMA systems, the family of modified prime sequences is known to have good correlation properties.

2.1. Prime Code

Prime codes are defined as follows [3]: from the Galois field $\mathrm{GF}(P) = \{0, 1, 2, \ldots, P-1\}$, where P is a prime number, a set of P prime sequences $\{S_i^P : i = 0 \text{ to } P-1, \text{ and } j = 0 \text{ to } P-1\}$ is first generated, each with P elements given by

$$S_i^P(j) = [i,j]_P \quad \text{for } i = 0 \text{ to } P-1, \text{ and } j = 0 \text{ to } P-1 \tag{1}$$

where $[\ ]_P$ denotes reduction modulo P. For example, the family of prime sequences for $P = 7$ is shown in Table 1. For each sequence S_i^P, a binary code C_i^P of length P^2 chips is then constructed using the following rules:

$$C_i^P(n) = \begin{cases} 1, & \text{for } n = jP + S_i^P(j) \quad \text{for } j = 0 \text{ to } P-1 \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

This requires that the code C_i^P be divided into P frames, each consisting of P chips. Within the jth frame, the chip shifted relative to the start of the frame by $S_i^P(j)$ is a "1"; all other chips are zero. The code C_i^P is therefore a time-mapped, binary version of the sequence S_i^P. The set of prime codes for $P = 7$ is shown in Table 2, where the frames have been slightly separated for clarity.

Table 1. Prime Sequences for $P = 7$

	$j=0$	$j=1$	$j=2$	$j=3$	$j=4$	$j=5$	$j=6$
Sequence S_0^7	0	0	0	0	0	0	0
Sequence S_1^7	0	1	2	3	4	5	6
Sequence S_2^7	0	2	4	6	1	3	5
Sequence S_3^7	0	3	6	2	5	1	4
Sequence S_4^7	0	4	1	5	2	6	3
Sequence S_5^7	0	5	3	1	6	4	2
Sequence S_6^7	0	6	5	4	3	2	1

The correlation functions arising in an IM/DD system, assuming on/off keyed data, are the aperiodic and periodic correlation functions, $C_{i,j}(l)$ and $\Theta_{i,j}(l)$, which are defined respectively as follows:

$$C_{i,j}(l) = \sum_{n=0}^{L-1} C_i^P(n) \cdot C_j^P(n+l) \tag{3}$$

$$\Theta_{i,j}(l) = \sum_{n=0}^{L-1} C_i^P(n) \cdot C_j^P([n+l]_L) = C_{i,j}([l]_L) + C_{i,j}([l]_L - L) \tag{4}$$

where $L = P^2$, $[\ ]_L$ denotes reduction modulo L, and $C_i^P(n) = 0$ for $n < 0$ and $n \geq L$, for all i. These are autocorrelation functions when $i = j$, and cross-correlation functions when $i \neq j$. The aperiodic form is generated at the matched filter output by an isolated "1" in the incoming datastream, while the periodic form is generated by adjacent "1"s; incoming "0"s produce no response. This periodic correlation is simply the number of positions where C_i^P and a cyclically shifted version of C_j^P both have "1"s. This means that the autocorrelation peak for any code (which occurs for $l = 0$, $i = j$) is equal to the number of "1"s it contains, or P in the case of a prime code:

$$\Theta_{i,j}(0) = C_{i,j}(0) = P \quad \text{for all } i \tag{5}$$

Note that the maximum number of coincidences of "1"s between two distinct prime codes C_i^P and C_j^P, having any

Table 2. Prime Codes for $P = 7$

	Frame 0	Frame 1	Frame 2	Frame 3	Frame 4	Frame 5	Frame 6
Code C_0^7	1000000	1000000	1000000	1000000	1000000	1000000	1000000
Code C_1^7	1000000	0100000	0010000	0001000	0000100	0000010	0000001
Code C_2^7	1000000	0010000	0000100	0000001	0100000	0001000	0000010
Code C_3^7	1000000	0001000	0000001	0010000	0000010	0100000	0000100
Code C_4^7	1000000	0000100	0100000	0000010	0010000	0000001	0001000
Code C_5^7	1000000	0000010	0001000	0100000	0000001	0000100	0010000
Code C_6^7	1000000	0000001	0000010	0000100	0001000	0010000	0100000

relative shift, is 2, so that all periodic cross-correlation functions are bounded by

$$\Theta_{i,j}(0) \le 2 \quad \text{for all } l, \text{ and all } i, j \text{ such that } i \ne j \tag{6}$$

From Eq. (4), it is clear that $\Theta_{i,j}(l) \ge C_{i,j}(l)$ for all l (note that Θ and C are both positive functions); thus the above bound also applies to any interference contribution, regardless of the data it carries.

2.2. Quasiprime Code

Quasiprime codes are derived from prime codes as follows [4]: with the prime code C_i^P, a set of cyclically shifted versions of the code $\{C_{ik}^{SP} : k = 0 \text{ to } P-1\}$ is defined where C_{ik}^{SP} is obtained by cyclically shifting C_i^P left by k complete frames. The elements of C_{ik}^{SP} are thus given by

$$C_{ik}^{SP}(n) = C_i^P([n + kP]_L) \qquad \text{for } n = 0 \text{ to } P^2 - 1. \tag{7}$$

For each shifted code C_{ik}^{SP}, a quasiprime code C_{ik}^{SP} may then be defined for any positive integer Q, where

$$\begin{aligned} C_{ik}^{QP}(n) &= C_{ik}^{SP}([n]_L) \quad \text{for } n = 0 \text{ to } QP - 1 \\ &= C_i^P([n + kP]_L) \end{aligned} \tag{8}$$

Each quasi-prime code then comprises QP chips taken cyclically from a shifted prime code, and contains Q "1"s. For example, Table 3 shows two of the seven quasiprime codes in the set $\{C_{2k}^{87} : k = 0 \text{ to } 6\}$ together with prime code C_2^7. Both are derived from the same prime code C_2^7.

We have to take care to define correlation functions for quasiprime codes, because truncating or extending the shifted prime codes destroys the periodicity of the basic prime code, and this must be restored if the quasiprime codes are to show good periodic cross-correlation properties. Accordingly, when the length QP of the quasiprime codes lies between $\Lambda - 1$ and Λ lengths of the original prime codes, it is made up to Λ lengths by packing each code with "0"s. The aperiodic and periodic correlation functions are then defined as

$$C_{i,j}(l) = \sum_{n=0}^{\Lambda L - 1} C_{ik}^{QP}(n) \cdot C_{jl}^{QP}(n + l) \tag{9}$$

$$\Theta_{i,j}(l) = \sum_{n=0}^{\Lambda L - 1} C_{ik}^{QP}(n) \cdot C_{jl}^{QP}([n + l]_{\Lambda L}) \tag{10}$$

where $(\Lambda - 1)L < QP \le \Lambda L$, $[\ ]_{\Lambda L}$ denotes reduction modulo ΛL, and $C_{ik}^{QP}(n) = 0$ for $n < 0$ and $n \ge QP$, for all i, k.

Different quasiprime codes derived from the same prime code cannot act as distinct, orthogonal members of an asynchronous CDMA code set. This means that a quasiprime code set can contain a maximum of P codes (one for each code in the original prime code set). The correlation properties of such a set are as follows: first, each code contains Q "1"s, so that the autocorrelation peak is given by

$$\Theta_{i,j}(0) = C_{i,j}(0) = Q \quad \text{for all } i \tag{11}$$

In addition the periodic cross-correlation $\Theta_{i,j}$ between two distinct quasiprime codes C_{ik}^{QP} and C_{jl}^{QP} is bounded by

$$\Theta_{i,j}(l) \le 2\Lambda \quad \text{for all } l, \text{ and all } i, j, k, l \text{ such that } i \ne j \tag{12}$$

Considering (11) and (12), the interference probability obtained with quasiprime codes might be expected to be worse than that obtained with prime codes in general. For example, the number of interfering signals that can be accommodated without error is expected to be $\lfloor Q/2\Lambda \rfloor$, where $\lfloor x \rfloor$ is the integer part of x, and this is less than or equal to the prime code result $\lfloor P/2 \rfloor$. In fact, this is pessimistic, because when QP is only slightly greater than $(\Lambda - 1)L$, the bound $\Theta_{i,j}(l) \le 2(\Lambda - 1)$ can still apply, and in such cases the quasiprime codes would be able to achieve better interference probability.

2.3. 2^n Prime Code

Usually, the 2^n codes are defined as collections of binary N-tuples with weight 2^n [5]. Using the serial optical encoders, the distribution of the pulses in each generated codeword must be symmetric (i.e., the distribution of the current 2^m pulses highly depends on that of the previous 2^{m-1} pulses, where $1 < m \le n$) and results in a very restrictive pulse distribution constraint. Alternatively, it is sometimes more convenient to represent the pulse distribution in terms of delay distribution. Therefore, the constraint can be equivalently presented as a delay distribution constraint.

The delay distribution constraint functions as follows. For a given integer n, integers x, y, and z are assumed such that $x \ne y$, $0 \le x \le 2^n - 2$, $0 \le y \le 2^n - 2$, and $1 \le z \le n - 1$. If both x and y are divisible by 2^z, then adjacent relative cyclic delays $[t_0, t_1, \ldots, t_q, \ldots, t_{2^n-1}]$ of each codeword of the 2^n codes are related such that

$$t_{x \uplus (2^{z-1}-1) \uplus m} = t_{y \uplus (2^{z-1}-1) \uplus m} \tag{13}$$

for a given integer $m \in [0, 2^n - 1]$, where "$\uplus$" represents modulo-2^n addition. t_q denotes the adjacent relative cyclic delay (or simply the separation in chips) between the qth

Table 3. Quasiprime Codes for $Q = 8$, $P = 7$ Based on C_2^7

Code	Frame 0	Frame 1	Frame 2	Frame 3	Frame 4	Frame 5	Frame 6	Frame 7
C_2^7	1000000	0010000	0000100	0000001	0100000	0001000	0000010	
C_{20}^{87}	1000000	0010000	0000100	0000001	0100000	0001000	0000010	1000000
C_{25}^{87}	0001000	0000010	1000000	0010000	0000100	0000001	0100000	0001000

and $(q+1)$th pulses. For the last delay t_{2^n-1}, the codeword is wrapped around to obtain the separation between the last and first pulses.

Example 1. Assuming that $n = 2$ (i.e., code weight of 4), we get $0 \le x \le 2$, $0 \le y \le 2$, $z = 1$, and $m \in [0, 3]$ from the above mentioned delay distribution constraint. The adjacent relative cyclic delays $[t_0, t_1, t_2, t_3]$ are related such that $t_0 = t_2$ for $m = \{0, 2\}$, or $t_1 = t_3$ for $m = \{1, 3\}$. Using sequence codes 100001010000100, 110000100010000, and 100010000100100 as examples, their corresponding adjacent relative cyclic delays are [5,2,5,3], [1,5,4,5], and [4,5,3,3], respectively. On the basis of the constraint, the first two are valid sequence codes, while the last one is not.

According to the symmetric property described above, the algebraic construction on the 2^n prime-sequence codes begins with Galois field $\mathrm{GF}(P) = \{0, 1, \ldots, P-1\}$ of a prime number P. As an example, the prime sequences in GF(13) are shown in Table 4 in a form different from that in Table 1. By inspection, the adjacent relative cyclic delays of the codeword generated by S_i^P can be found according to

$$t_j = \begin{cases} S_i^P(j+1) - S_i^P(j) + P, & \text{for } j = \{0, 1, \ldots, P-2\} \\ S_i^P(0) - S_i^P(j) + P, & \text{for } j = P-1 \end{cases} \tag{14}$$

for $i \in GF(P)$. Table 5 shows the adjacent relative cyclic delays for the prime sequences in GF(13).

The adjacent relative cyclic delays for each prime sequence S_i^P are then determined depending on whether the delay-distribution constraint is satisfied. If the constraint is satisfied, the prime sequence S_i^P will be modified: the elements $S_i^P(j)$ and $S_i^P(j+1)$ whose relative cyclic delay t_j satisfies the constraint are kept unchanged, while the remaining elements are replaced by Xs. Note that every X in the replaced prime sequences is simply mapped to P zeros. However, this S_i^P will be discarded if none of the delays satisfies the constraint.

Example 2. Using $2^n = 8$ and $i = 3$ as an example, the adjacent relative cyclic delays for S_3^{13} are [16, 16, 16, **16**, **3**, **16**, **16**, **16**, **3**, **16**, 16, 16, 3] as shown in Table 5. Those delays that satisfy the delay distribution constraint are boldfaced. From (13), S_3^{13} satisfies the two conditions $t_m = t_{m+2} = t_{m+4} = t_{m+6}$ and $t_{m+1} = t_{m+5}$ with $m = 3$. The remaining elements $S_3^{13}(0)$, $S_3^{13}(1)$, $S_3^{13}(2)$, $S_3^{13}(11)$, and $S_3^{13}(12)$ are then replaced by Xs as shown in Table 6, where the replaced prime sequences for $P = 13$ and $2^n = 8$ are tabulated. Note that the prime sequences S_5^{13} and S_8^{13} are discarded since the delay distribution constraint cannot be satisfied.

Finally, the codewords of the 2^n prime sequence codes are generated by mapping each replaced prime sequence S_i^P into a binary code sequence $C_i^P = (C_i^P(0), C_i^P(1), \ldots, C_i^P(k), \ldots, C_i^P(N-1))$ of length $N = P^2$ according to

$$C_i^P(k) = \begin{cases} 0, & \text{for } k = S_i^P(j) + jP \text{ and } S_i^P(j) \ne \mathrm{X} \\ 1, & \text{otherwise} \end{cases} \tag{15}$$

for $i, j \in \mathrm{GF}(P)$ and $k = \{0, 1, \ldots, N-1\}$.

2.4. Modified Prime Code

For prime sequence codes of length P^2, the number of sequence codes is limited to P; therefore, so is the number of total subscribers. In order to generate more sequence

codes for the same length, that is, the same bandwidth expansion, at the expense of requiring synchronization among users, modified prime sequence codes have been proposed [2]. Modified prime sequence codes are time-shifted versions of prime sequence codes. Each original P prime sequence S_x^P is taken as a seed from which a group of new sequence codes can be generated. The sequence codes of the first group (i.e., $x = \{0\}$) are obtained by left-rotating the prime sequence code C_0^P. C_0^P can be left-rotated $P-1$ times before being recovered, so that $P-1$ new sequence codes can be generated from C_0^P. For the other $P-1$ groups (i.e., $x = \{1, \ldots, P-1\}$), the elements of the corresponding prime sequence S_x^P can be left-rotated $P-1$ times to create new prime sequences $S_{x,r}^P = (S_{x,r}^P(0), S_{x,r}^P(1), \ldots, S_{x,r}^P(P-1))$, where r represents the number of times S_x^P has been left-rotated. Therefore, P prime sequences per group are obtained. Each prime sequence $S_{x,r}^P$ is then mapped into a binary sequence code $C_{x,r}^P = (C_{x,r}^P(0), C_{x,r}^P(1), \ldots, C_{x,r}^P(i), \ldots, C_{x,r}^P(P^2-1))$ according to

$$\theta_{x,r}^P(i) = \begin{cases} 1, & \text{for } i = S_{x,r}^P(j) + jP, j = 0, 1, \ldots, P-1 \\ 0, & \text{otherwise} \end{cases} \tag{16}$$

The set of prime sequence S_x^P and their associated sequence codes C_x^P for GP(5) are tabulated in Table 7. The set of new prime sequences $S_{x,r}^P$ and their associated sequence codes $C_{x,r}^P$ for $GF(5)$ are tabulated in Table 8. Note that each new sequence code has P binary "1"s. Considering all groups, the total number of modified prime sequence codes is P^2. For a synchronous system, the cross-correlation between the modified prime sequence codes of the xth and the yth users can be written as [2]

$$\theta_{x,y} = \begin{cases} P, & x = y, \\ 0, & x \text{ and } y \text{ are in the same group} \\ 1, & x \text{ and } y \text{ are in the different groups} \end{cases} \tag{17}$$

The modified prime code has unique characteristics in that there is no correlation between any two users among the same group and the interference from other groups has the equal effect on the user in the same group. On the other hand, the optical orthogonal code (OOC) has the problem that it has to set the weights and sequence code independently and keep the number of spreading codes small to attain good correlation properties. Table 9 shows the OOCs with the code length $F = 32$ and weight $K = 4$. The total number of OOCs is given by the integer part of $(F-1)/(K^2-K)$, and there are only two codes when $K = 4$ and $F = 32$, because the maximum value of the cross-correlation should be 1. To satisfy this condition, the distance of any two "1"s should be different in all codes as shown in Table 9. Therefore, to increase the number of spreading codes in OOC, the frame length has to be increased or weights have to be smaller. In practice, in order to make 25 spreading codes with weight 5, the sequence code length needs to be 501. Therefore, OOC needs 20 times larger frame length compared to the modified prime sequence code, and the bit rate decreases when OOC is used. When the weights are decreased in OOC, the correlation property is degraded. Therefore, the modified prime sequence code whose weights are the same as those of OOC is more effective in a synchronous optical CDMA, because the modified prime sequence code can make more spreading codes with a shorter frame length.

3. SYSTEM MODEL OF OPTICAL SYNCHRONOUS CDMA

3.1. Optical Time-Encoded CDMA Systems

In optical CDMA, intensity modulation/direct detection is used mainly in conjunction with on/off keying (OOK) and pulse position modulation (PPM) signaling formats. A pulse laser source is intensity-modulated by electrical (0,1) data bits. Data are modulated by emitting optical positive pulses at the first chips of the slots in OOK or PPM signaling. In optical time-encoded CDMA, a slot is divided into chips and the number of chips in a slot equals the spreading code length. In optical synchronous CDMA systems, synchronization between transmitter and receiver is required, and the synchronization is achieved by adding to the correlated signal the receiver clock signal delayed by a proper amount. The delay must be such that the peak of the autocorrelation function coincides with the optical clock pulse. Code synchronization can be realized through a two-stage process: a coarse alignment referred to as *code acquisition* and a subsequent fine alignment referred to as *code tracking*.

In OOK, a "1" information bit is transmitted by emitting a optical pulse at the first chip of the slot. When no pulse is emitted in chips within a slot, this means that "0" information bit is transmitted. Thus, one bit binary information is conveyed in a slot. At the decoder, threshold detection is used in OOK. Since the threshold value depends on the intensity level of received signal pulse, multiple-user interference, and noise, proper adjustment of the threshold level is required. In an M-ary PPM, a narrow pulse is emitted at the first chip of one of M slots in a PPM frame to represent data. Since the combination of selecting one slot among M slots in a frame is $\log_2 M$, $\log_2 M$ bits can be conveyed in a frame. This results in a low channel traffic in PPM compared to OOK in terms of the number of transmitted pulses, due to the pulse position multiplicity of PPM signaling. PPM can utilize maximum-likelihood detection in which the slot with largest intensity level in a frame is selected in maximum likelihood manner, and thus, no precise threshold adjustment is required.

Each user is assigned a signature sequence with length F, which serves as its address. In time encoding, the encoder consists of the tapped optical delay lines, and the

laser pulse emitted in the first chip in a slot is time-spread in F chips within a slot corresponding to "1"s of the spreading codes. That is, ON information is transmitted as a sequence of F chipped pulses and OFF information is sent as an all-zero sequence. Note that the repetition rate of the light source limits the transmission rate, because the light source has difficulty to generate long successive optical pulse transmissions in time. Thus, time encoding is useful because there is no successive optical pulse transmission in adjacent chips. Optical pulse sequences transmitted from users are combined in the star coupler and then transmitted over the fiber to the desired destination. At the receiver, an optical incoherent passive filter-matched detection is done by an optical delay-line decoder matched to the encoder at the transmitter. It produces a peak in the correlation output for the intended bits. Data bits are discriminated in the chip duration using a photodiode followed by a threshold process.

The "near/far" problem is an essential issue in most CDMA systems, especially in wireless applications. Fortunately, the transceivers in an optical fiber networks are fixed, and to a certain extent, the optical path loss between the transmitter and the receiver can be predicted. Hence, a gain-clamped preamplifier can be used to compensate for optical power loss, so that all the transmitted optical signals originating from different locations can be received at similar optical power levels.

In the following subsection, the IM/DD systems with OOK and PPM signaling are described as typical optical synchronous CDMA systems. Also, as an alternative optical CDMA system, an optical frequency-encoded CDMA system utilizing bipolar codes is briefly introduced.

3.1.1. Optical Synchronous OOK CDMA. Figure 1, shows the transmitter block diagram of a direct-detection

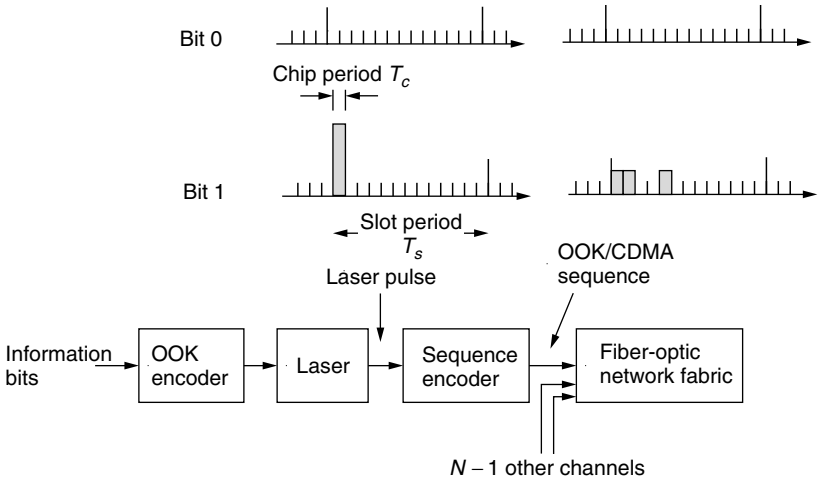

Figure 1. The transmitter block diagram of a direct-detection optical OOK CDMA system.

optical CDMA system. The output of the information source is fed into the OOK encoder where the information bitstream is directly converted into the OOK pulse sequences. When a logical "1" is to be conveyed, the laser is pulsed on at the first chip of the slot; when a logical "0" is to be conveyed, the laser is not pulsed on. Then the output laser pulse is converted into the assigned optical code sequence, that is, the signature sequence by a tapped optical delay line [6] shown in Fig. 2 that converts the initial laser pulse into a specific train of output pulses. When a logical "0" is to be conveyed, an all-zero sequence is transmitted. Light pulse sequences from all sources are combined in the fiber-optic network fabric and then transmitted over the fiber to the desired destination.

Figure 3 shows the receiver block diagram of the direct-detection optical OOK CDMA system. At the receiver, the matched optical correlator is used to recognize the arrival of the desired sequence. Figure 4 shows the optical correlator comprising a set of optical delay lines inversely matched to the pulse spacings. When the desired optical sequence passes through the correlator, the output light intensity traces out the correlation function of the sequence. At the last chip position, the sum of received optical intensity located in the same positions as the positions of "1" of the signature codes used for the desired channel is obtained. The correlator output is converted into an electrical signal by the photodetector and is then passed to the OOK decoder. The OOK decoder compares the correlator output voltage over the last chip position with the threshold level, then decides that "1" is sent if the output voltage is larger than the threshold level, and

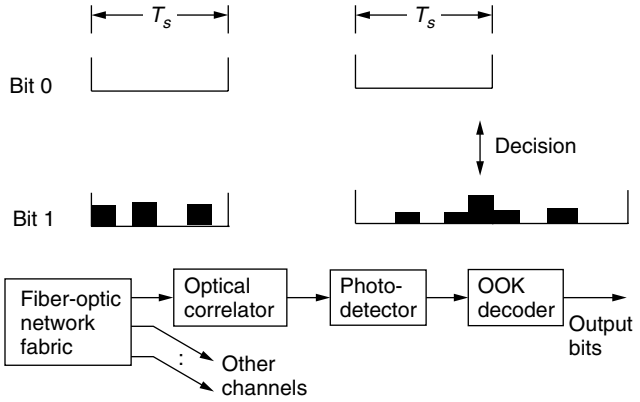

Figure 3. The receiver block diagram of a direct-detection optical OOK CDMA system.

"0" is sent otherwise. In this way each user can recover his own logical sequence.

3.1.2. Optical Synchronous PPM CDMA. Figure 5 shows the block diagram of an optical M-ary PPM CDMA transmitter and a signaling format. At the transmitter, a data bitstream is first blocked into words of length $\log_2 M$ bits in the PPM encoder and then each word is encoded into a M-ary PPM signaling format, that is, one of M slot positions. Every slot consists of F chips with the same chip period T_c, where F is the spreading factor of the CDMA signals. The laser is pulsed on at the first chip of the proper slot representing the word and the other slots

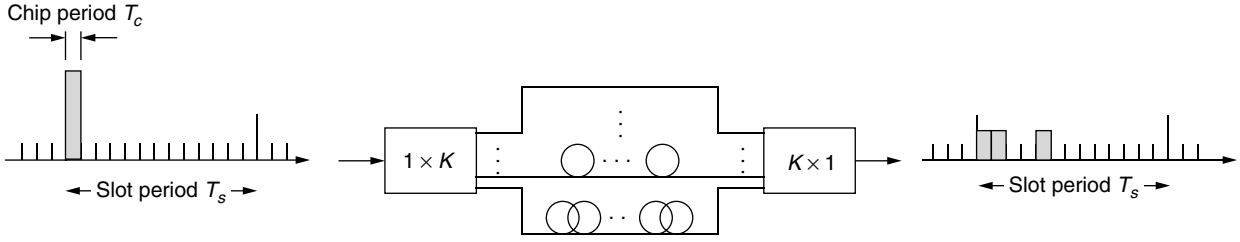

Figure 2. A sequence encoder consisting of tapped optical delay lines.

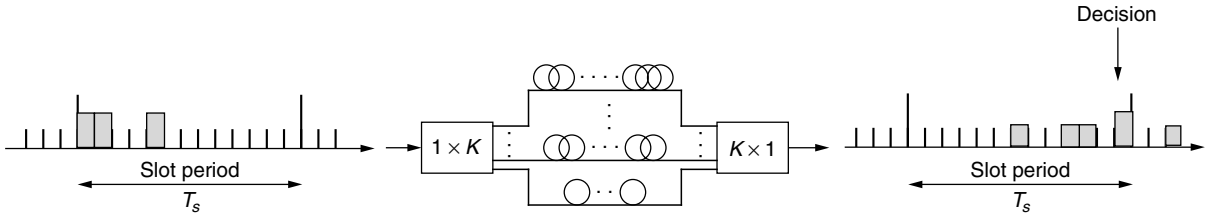

Figure 4. An optical correlator comprising tapped optical delay lines.

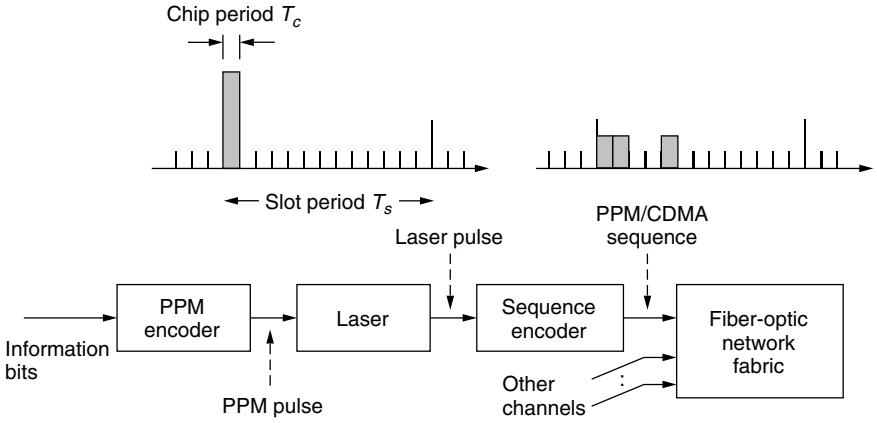

Figure 5. The transmitter block diagram of a direct-detection optical PPM CDMA system.

have no pulse. Then the output laser pulse is converted into the assigned optical code sequence, that is, the signature sequence by a set of tapped optical delay lines [6] that converts the initial laser pulse into a specific train of output pulses. The transmitted PPM CDMA signal in the pulsed slot have K pulses according to the assigned sequence code. Light pulse sequences from all the sources are combined in the fiberoptic network fabric and then transmitted over fiber to the desired destination.

The block diagram of an optical PPM CDMA receiver is shown in Fig. 6. At the receiver, a matched optical correlator is used to recognize the arrival of the desired sequence. The optical correlator is a set of optical delay lines inversely matched to the pulse spacings of the sequences. When the desired optical sequence passes through the correlator, the output light intensity traces out the correlation function of the sequence. In the photodetector the correlator output is converted into the electrical signal that is passed to the PPM decoder. The PPM decoder compares the output voltage over the last chips of all the slots and decides the slot having the highest voltage as the pulsed slot. Finally, the PPM decoder declares the corresponding word as the transmitted word.

There are two main advantages of synchronous M-ary PPM CDMA over OOK CDMA. The first advantage is that, under a bit error rate constraint, the maximum number

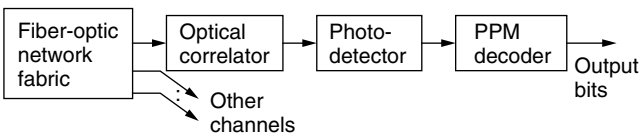

Figure 6. The receiver block diagram of a direct-detection optical PPM CDMA system.

of simultaneous users can be increased by increasing M and keeping the average power fixed. On the other hand, in the case of OOK CDMA, this number cannot be increased without increasing the average power. The second advantage is that any number of users can be accommodated by increasing M is the case of PPM CDMA. In the case of OOK CDMA, however, we may not be able to accommodate all the subscribers, even if the average power is increased. The reason is that, when the number of users is N, the average number of interfering optical pulses reduces to $(N-1)/M$ for PPM CDMA, whereas this number is equal to $(N-1)/2$ for OOK CDMA. Of course, these advantages of PPM CDMA over OOK CDMA are gained at the expense of increasing the system complexity [7].

3.2. Optical Frequency-Encoded CDMA System

In the previous two sections, we explained the time-encoded optical CDMA systems with OOK and PPM signaling and unipolar codes. Here, we introduce a frequency-encoded CDMA (FECDMA) system as an alternative optical CDMA using bipolar codes. Note that FE-CDMA can be used as both synchronous and asynchronous CDMA. The advantages of optical FECDMA are random-access, self-routing capability by the code itself, and the independence of the bit rate and processing gain, since coding and decoding are done by shifting phase without expanding the frequency band. In FECDMA, bipolar sequence codes such as pseudonoise (PN) sequences are assigned to each user, and the Fourier transform of the transmitted pulse for a given user is determined by encoding the phase of the desired transmitted spectrum by the user's PN sequence. The system model of the FE-CDMA is shown in Fig. 7. The FECDMA scheme is based on encoding and decoding of

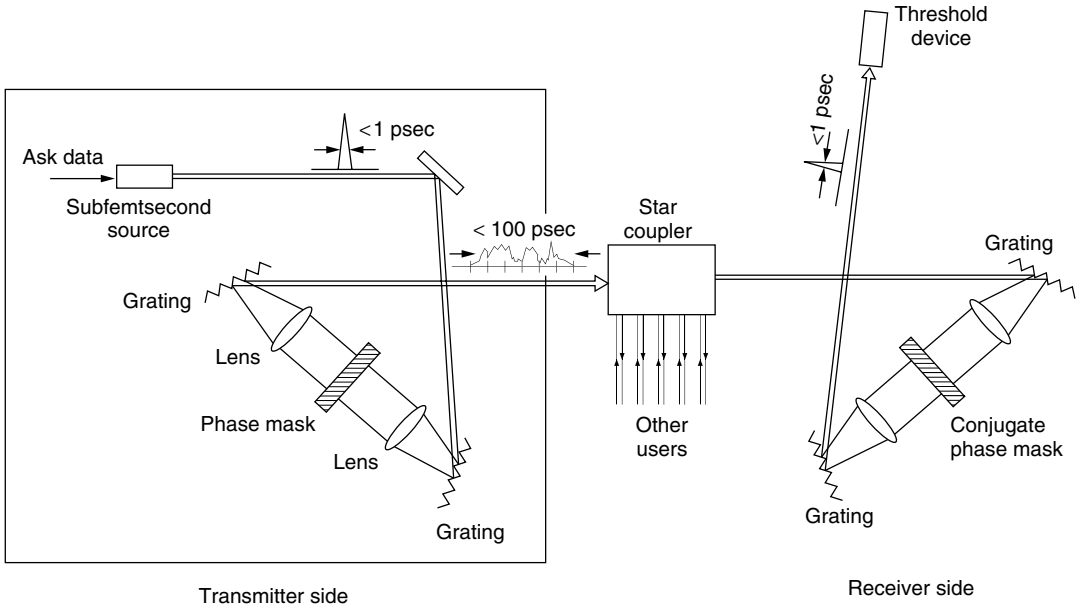

Figure 7. System model of FE-CDMA.

an ultrashort light pulse with duration τ_c and peak power P_0, and the operation is accomplished by using femtosecond pulseshapers. The pulseshapers offer high-resolution pulseshaping, programmability, and the flexibility to apply arbitrary phase codes of different code lengths. The operation of encoding and decoding is performed by using two fixed conjugate phase masks successively in the same pulse shaper. The liquid crystal modulator (LCM) is used to set the spectral phases to maximum-sequence phase. The LCM has a fully programmable linear array and individual pixels can be controlled by applying drive levels resulting in phase shifts (0 or π). By a phase mask, the dispersed bandwidth of a pulse is partitioned into N_c frequency chips, where each chip has the bandwidth W/N_c. Each chip is assigned a phase shift (i.e., 0 or π) depending on the user's PN sequence. The spectrum of the resulting pulse is reassembled by an inverse Fourier transform, and the encoded pulse is spread out within a time slot in synchronous CDMA as a low-intensity pseudonoise burst with average power P_0/N_c and duration T, as shown in Fig. 8. The transmitted data for a particular user can be recovered by sampling the output of a filter matched to the user's pulse. The phase mask and grating are implemented to perform the Fourier transform and matched filtering. At the receiver side, the spectral decoder consists of Fourier transformation of the time-windowed received signal followed by correlation with the PN sequence matched to the transmitter code. The spectral-phase code of the decoder is the complex conjugate of the encoder's spectral-phase code. The correctly decoded signal becomes a replica of the original short pulse with duration τ_c and peak power P_0, whereas the MAI signal remains a low intensity pseudonoise burst. The disadvantages of FECDMA are that the effects of MAI are large as the number of simultaneous user increases and a high-resolution phase mask as well as a narrow pulse are required to improve discrimination ability.

4. CHANNEL INTERFERENCE CANCELER FOR OPTICAL SYNCHRONOUS CDMA

Optical CDMA has several advantages over optical TDMA, including complete utilization of the entire time-frequency domain by each subscriber, flexibility in network design (because the quality depends on the number of active users), and security against interception. Synchronous CDMA has an additional advantage over asynchronous CDMA, where the number of available sequence codes (and in turn the number of subscribers) is much higher in the former under a given throughput constraint. The latter does not require, however, any time management as in the former. It follows that synchronous CDMA is suitable for very high speed networks with real time requirements (e.g., voice and digitized video). In contrast, asynchronous CDMA is suitable for bursty traffic with no stringent time requirements (e.g., data transmission). On the other hand, optical CDMA has a disadvantage over TDMA that is due to the multiple-user interference in the former. This leads in turn to a serious degradation in the bit error probability as the number of simultaneous users increases. This degradation cannot be overcome even for arbitrary high optical power. In fact, there will be an asymptotic error floor which limits the number of users that can communicate simultaneously and reliably. Several interference cancellation techniques have been proposed aiming at lowering these asymptotic error floors. These interference cancellation techniques are classified into two groups. One is based on the use of properties of modified prime sequence codes, and the other is based on the use of optical hard-limiters. The cancellation techniques using the properties of modified prime sequence codes have been proposed for both OOK CDMA and PPM CDMA systems [8–19]. These techniques estimate the amount of interference from a knowledge of some other users' sequence codes by using the correlation properties of modified prime sequence codes.

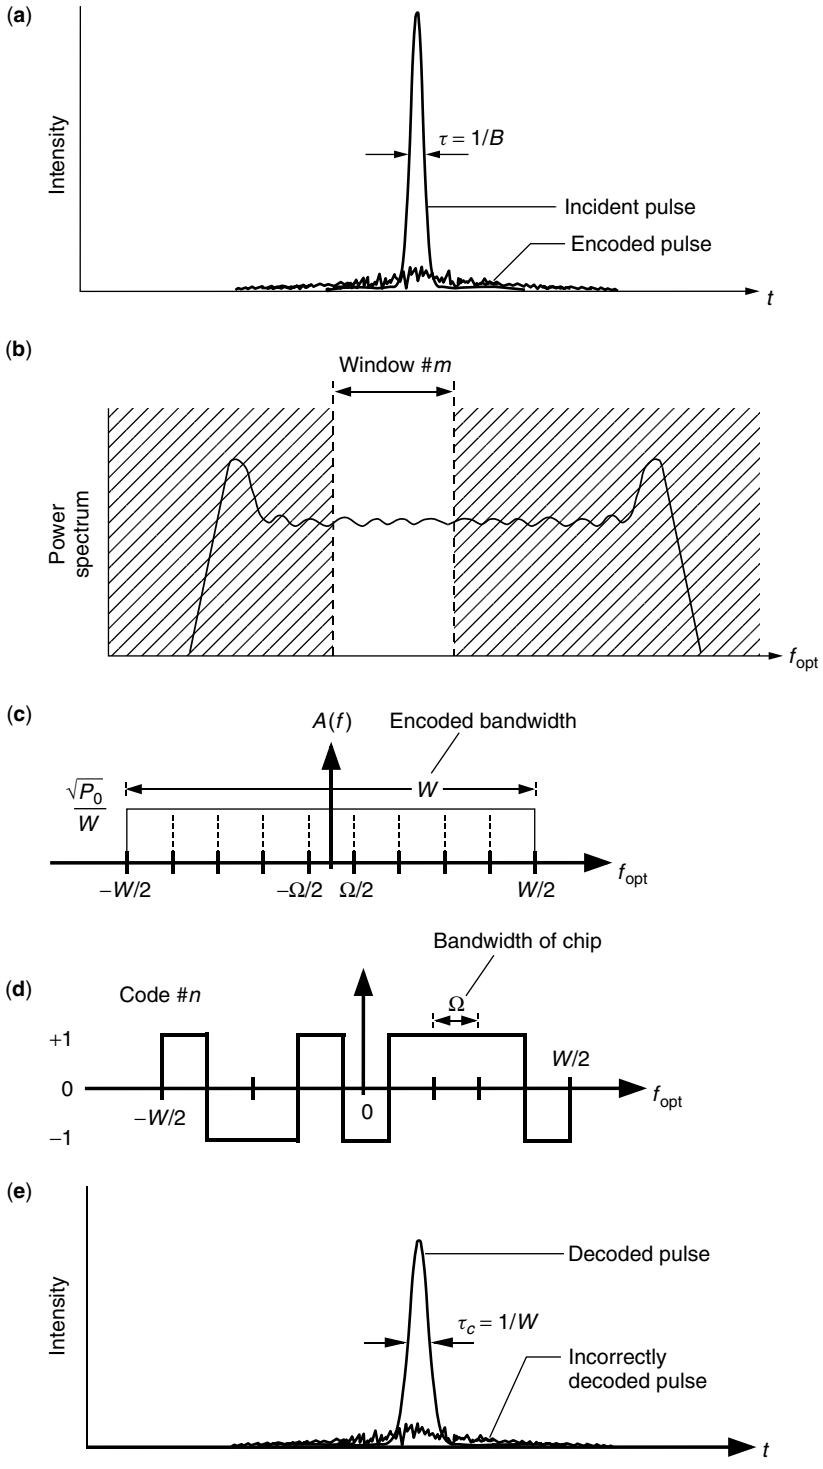

Figure 8. Frequency encoding.

As for the cancellation techniques based on the use of optical hard-limiters, Salehi and Brackett [20] used an optical hard-limiter that is placed before the optical correlator at the receiver side. This optical hard-limiter is shown to be able to remove some of the interference patterns. Ohtsuki et al. [21] proposed a synchronous optical CDMA system with double optical hard-limiters placed before and after the optical correlator. This system introduces an improvement in the performance over the system with a single optical hard-limiter as long as the number of users is not very large. In the case of asynchronous optical CDMA, Ohtsuki [22,23] showed that this improvement continues for all possible number of users. In Ohtsuki [24] was also able to reduce the error floor even lower than that of the system with double hard-limiters. Lin and Wu [25] suggested a synchronous optical CDMA system with an adaptive optical hard-limiter (or equivalently, a tunable optical attenuator) placed after

the correlator receiver. They were able to show that the performance can be improved as compared to the system with double hard-limiters.

We briefly review some cancellation techniques in the following sections.

4.1. Channel Interference Canceler Using Properties of Modified Prime Sequence Codes

We describe the channel interference canceller using a time-division reference signal [11,12] as an example of the channel interference cancellation technique using the properties of modified prime sequence codes.

Each user is assumed to be assigned a unique prime sequence code of length P^2 and weight P. In the system each user is allowed to access the network $P-1$ times out of P times, and $P-1$ users out of P users can access the network in each group simultaneously; that is, one user in each group is not allowed to access the network at each time; unallowable user's channel in each group at the time is used as a reference signal for other users in the same group at the time to cancel the effects of channel interference, because every code in the same group suffers the same amount of channel interference from other groups and every code in the same group does not interfere with each other.

Figure 9 shows an example of the access timing pattern for the first group in the system with the canceler where each user is not allowed to access the network at the marked time in the table. For instance, the first user is not allowed to access the network at time t_1, and the output of the first channel is used as a reference signal for other users in the same group at time t_1 to cancel the effects of channel interference. Notice that all the users in the same group suffer the same amount of channel interference from other groups. The bit rate of each user is thus

$$R_b = \frac{P-1}{PT} \tag{18}$$

At the same bit rate, the slot width of the proposed system is $(P-1)/P$ times as long as that of the system without canceler; thus the proposed system needs a slightly broader bandwidth.

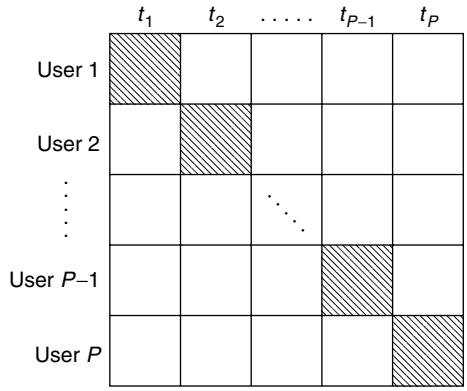

Figure 9. An example of the access timing pattern for the first group in the system with the canceler where each user is not allowed to access the network at the marked time in the table.

Figure 10 shows the receiver block diagram for the first user of the system. At the receiver, the matched optical correlators are used to recognize the arrival of the desired sequence. At the last chip position, the sum of the received optical intensity located in the same positions as the positions of "1" of the modified prime sequence code used for the desired channel is obtained. The correlator output is converted into an electrical signal by the photodetector. According to the table of the access timing pattern, the switch is connected to the reference channel that is not used at the time; the output of the reference signal is subtracted from the desired signal to cancel the effect of the channel interference. The signal after subtraction is passed to the OOK decoder. The OOK decoder compares the correlator output voltage over the last chip position with the threshold level and decides the data.

Figure 11 shows the bit error probability of OOK CDMA versus the received laser power P_W for some values of P where $N = P^2$, that is, the full-load case. As shown in Fig. 11, the received signal of each user is split into P

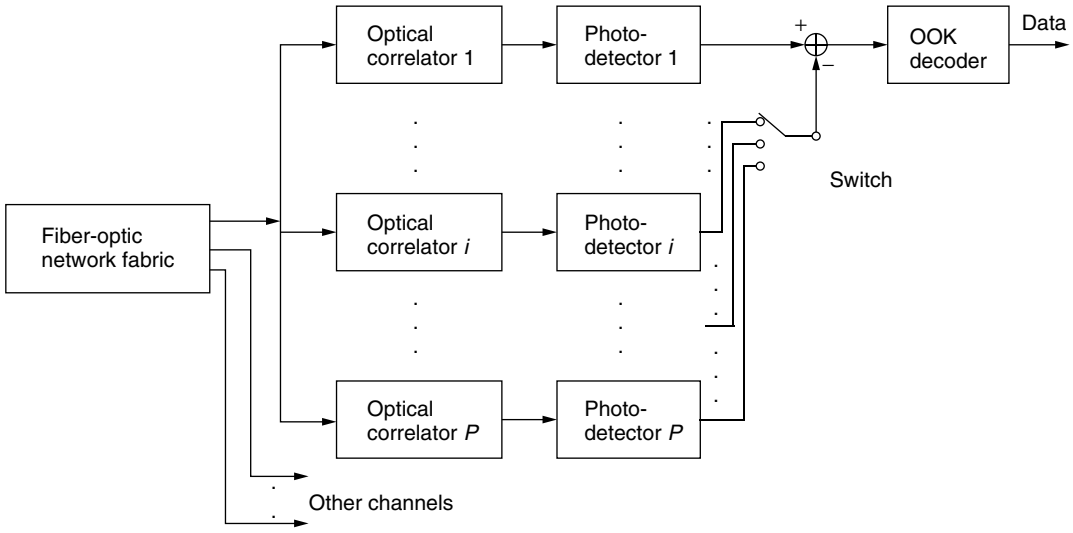

Figure 10. The receiver block diagram for the first user of the system with the canceler.

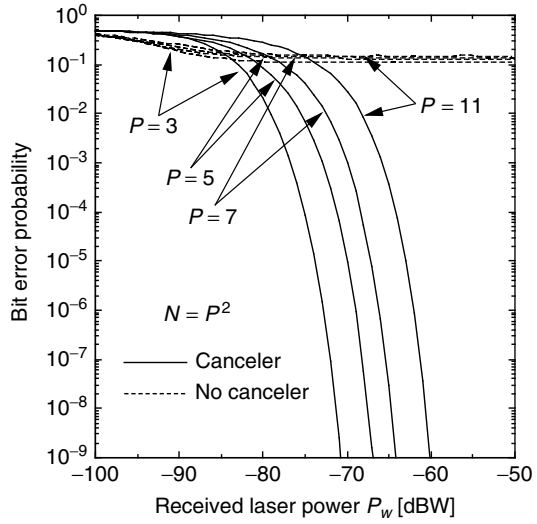

Figure 11. Bit error probability of OOK CDMA versus received laser power P_W for some values of P: $N = P^2$.

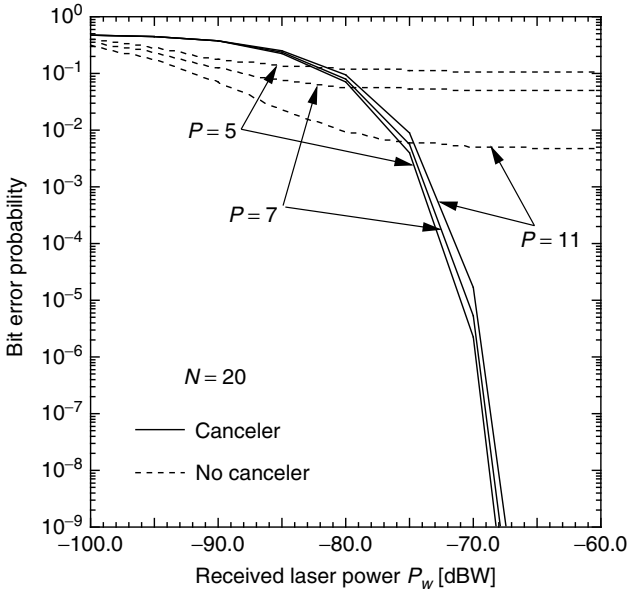

Figure 12. Bit error probability of OOK CDMA versus received laser power P_W for some values of P: $N = 20$.

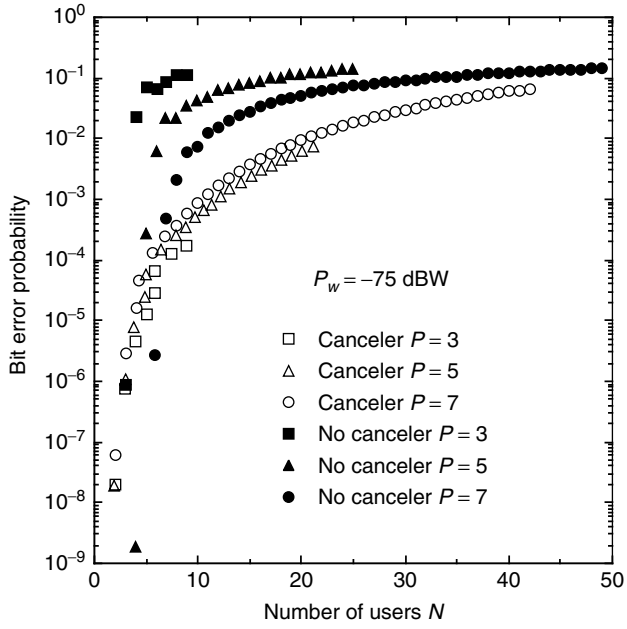

Figure 13. Bit error probability of OOK CDMA versus the number of users N for some values of P: $P_W = -75$ dBW.

branches at the receiver in the system with the canceler, and thus the unit received laser optical power in the delay-line of the optical correlator of the system with the canceler P_W is $1/P$ times as large as that of the system without the canceler. It can be seen that the system with the canceler has better performance than the conventional system without the canceler when P_W is not appreciably small; as P_W increases, the bit error probability of the system with the canceler is improved, while the error floor exists for the conventional systems without the canceler, because the effect of the channel interference is so large in the case of full load. Since the system with the canceler can reduce the effects of the channel interference, the error floor does not exist for the system with the canceler even in the case of full load. As P increases, the effect of the channel interference also increases in the case of full load, and thus the system with the canceler with larger P needs more power to have better performance.

Figure 12 shows the bit error probability of OOK CDMA versus the received laser power P_W for some values of P where $N = 20$. It can be seen that the system with the canceler has better performance than the conventional system without the canceller when P=5 and 7, and P_W is not appreciably small. Although the system with the canceler can reduce the effects of channel interference, it needs somewhat large power to have better performance than the system without the canceler, because the received signal of each user is split into P branches. It can be also seen that the system with the canceler has almost the same performance for any P, because when the number of simultaneous users is the same, the ratio of the signal power to the channel interference power is almost the same for any P. In addition, the system with the canceler can cancel the effects of the channel interference. Thus, the system with the canceler has almost the same performance for any P.

Figure 13 shows the bit error probability versus the number of users N for some values of P where $P_W = -75$ dBW. It can be seen that the system with the canceler has better performance when N is not appreciably small: when $N > 6$ for P=7, the system with the canceler has better performance. The effects of the channel interference are small when N is small. Thus the system with the canceler does not have better performance when N is small. It can be also seen that the system with the canceler has almost the same performance for any P, while the bit error probability of the conventional system is improved as P increases. In the conventional system without the canceler, the effect of channel interference is almost the same for any P at the same N, while the signal intensity becomes

larger as P increases even at the same N. In addition, the system with the canceler can reduce the effect of channel interference. Thus, the bit error probability of the conventional system is improved as P increases, while the system with the canceler has almost the same performance for any P.

4.2. Channel Interference Canceler Using Optical Hard-Limiters

Figure 14 shows the receiver block diagram of the direct-detection optical OOK CDMA system with a single optical hard-limiter [20]. In optical CDMA systems, the channel interference is the prime noise factor; it degrades the performance seriously and produces an asymptotic floor to the error probability. An optical hard-limiter is used to reduce the channel interference and to improve the system performance. An optical hard-limiter is defined as

$$g(x) = \begin{cases} v_f, & x \geq \text{Th} \\ 0, & 0 \leq x < \text{Th} \end{cases} \tag{19}$$

where v_f is the fixed value dependent on the signal intensity and Th is the threshold level. If an optical light intensity x is larger than or equal to the threshold level Th, the hard-limiter would clip the intensity back to v_f, and if the optical light intensity x is smaller than Th, the response of the optical hard-limiter would be zero. This optical hard-limiter would improve the system performance in the ideal link, because it would reduce the effect of the channel interference generated by some combinations of interference patterns. As shown in Fig. 14, the optical hard-limiter is placed before the optical correlator in the conventional optical CDMA systems. At the receiver, the matched optical correlator is used to recognize the arrival of the desired sequence. The optical correlator is a set of optical delay lines inversely matched to the pulse spacings. When the desired optical sequence passes through the correlator, the output light intensity traces out the correlation function of the sequence. At the last chip position, the sum of received optical intensity located in the same positions as the positions of "1" of the signature sequence code used for the desired channel is obtained.

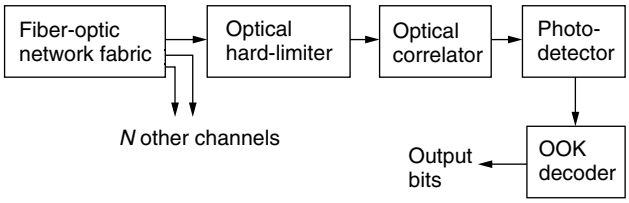

Figure 14. The receiver block diagram of a direct-detection optical OOK CDMA system with the single optical hard-limiter.

Figure 15 shows an example of an interference pattern on the desired signal over a sequence period $T = 9T_c$ when the desired signal sends "1" where T_c is the chip duration: the second and the third marks of the desired user are hit by one undesired interferer's mark, respectively. The interference is removed by the first optical hard-limiter. Note that, however, the interference would contribute to the optical light intensity of the desired user when the desired user sends "1" if the optical hard-limiter is not used.

Figure 16 shows an example of an interference pattern on the desired signal over a sequence period $T = 9T_c$ when the desired signal sends "0"; the first mark position of the desired user is hit by two undesired interferers' marks, and the second mark position of the desired user is hit by one undesired interferer's mark. As shown in this figure, there are some interference patterns that are not completely removed with the first optical hard-limiter when the desired user sends "0."

To improve the system performance by excluding some combinations of interference that cause incorrect bit decisions for "0" bit transmission, optical synchronous CDMA systems with double optical hard-limiters have been proposed. Figure 17 shows the receiver block diagram of the system with double optical hard-limiters. In the system, optical hard-limiters are placed before and after the optical correlator. The optical hard-limiters placed before and after the optical correlator are referred to as the *first* and the *second optical hard-limiters*, respectively.

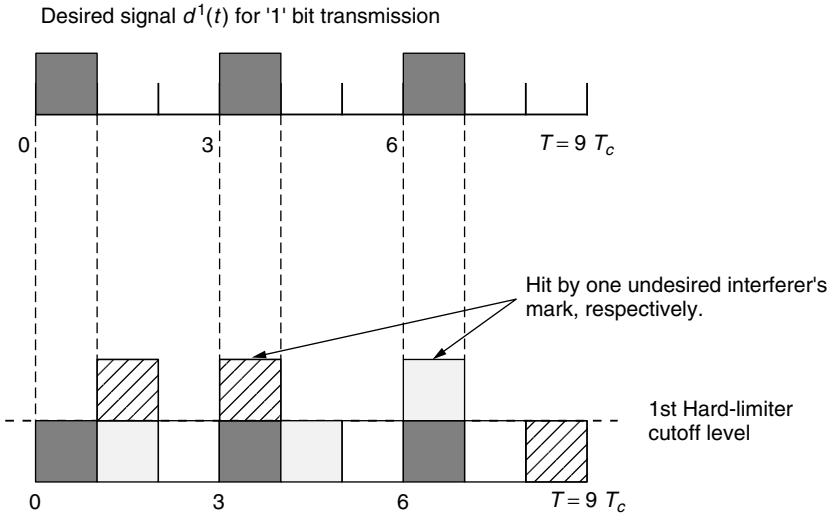

Figure 15. An example of an interference pattern on the desired signal over a sequence period $T = 9T_c$ when the desired signal sends a "1"; the second mark of the desired user is hit by one undesired interferer's mark, and the third mark of the desired user is hit by one undesired interferer's mark.

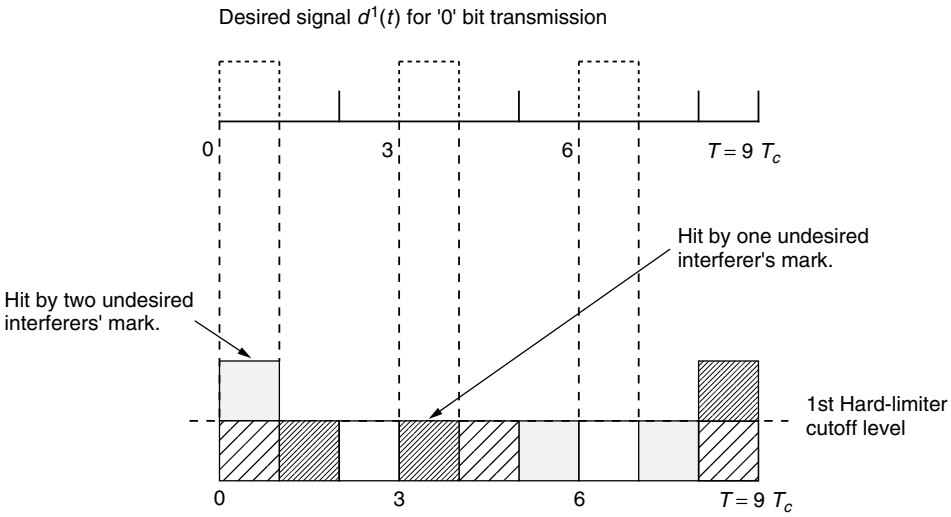

Figure 16. An example of an interference pattern on the desired signal over a sequence period $T = 9T_c$ when the desired signal sends "0"; the first mark position of the desired user is hit by two undesired interferes' mark, and the second mark position of the desired user is hit by one undesired interferer's mark.

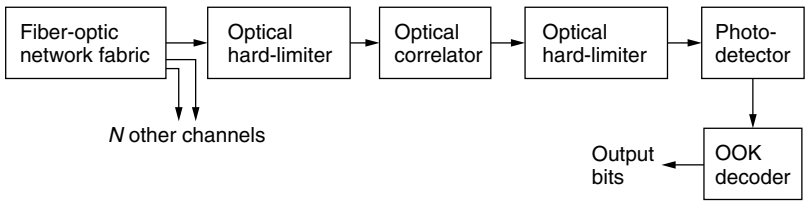

Figure 17. The receiver block diagram of a direct-detection optical CDMA system with double optical hard-limiters.

The first and the second optical hard-limiters are defined as the same as in the optical CDMA systems with the single optical hard-limiter given by Eq. (19). The first optical hard-limiter would clip the intensity back to v_f, and thus exclude or reduce the channel interference by other undesired interferers' marks. The second optical hard-limiter is used to exclude some interference patterns that are not completely removed with the first optical hard-limiter when the desired user sends "0" as shown in Fig. 16.

The second optical hard-limiter would clip the output intensity from the optical correlator back to zero if the optical light intensity x is smaller than Th. Therefore, the system using double optical hard-limiters would improve the system performance, because it would exclude the effect of the channel interference generated by some combinations of interference patterns as shown in Fig. 16.

Figure 18 shows the bit error probability versus the average received photocount in the last chip K_s for the optical OOK CDMA systems without the optical hard-limiter, with the single optical hard-limiter, and with the double optical hard-limiters for some values of P. It can be seen that using the single optical hard-limiter placed before the optical correlator slightly degrades the performance of an optical synchronous CDMA system using modified prime sequence codes. Using the single optical hard-limiter excludes some combinations of interference patterns; however, it also excludes some combinations of interference patterns contributing to the optical intensity of the desired user. Thus, using the single optical hard-limiter slightly degrades the performance under the Poisson shot noise model for the receiver photodetector. It can be also seen that the

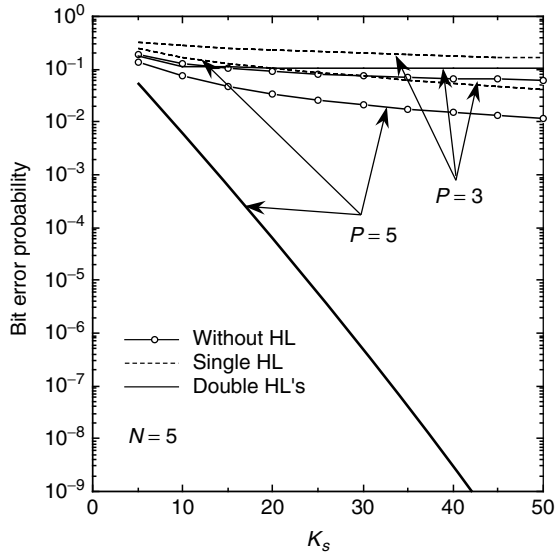

Figure 18. Bit error probability versus K_s for the optical OOK CDMA systems without the optical hard-limiter, with the single optical hard-limiter, and with double optical hard-limiters for some values of P where $N = 5$.

optical CDMA system with double optical hard-limiters has better performance than do the other two systems when $P = 5$; when $P = 3$ using the system with double optical hard-limiters has a performance slightly worse than that of the system without the optical hard-limiter and slightly better that of than, the system with the single optical hard-limiter. The double optical hard-limiters can exclude combinations of interference patterns that the

single optical hard-limiter cannot exclude; all the mark positions of the desired user are not hit by undesired interference marks when the desired user sends "0." When $P = 3$ and $N = 5$, there are still some combinations of interference patterns that the double optical hard-limiters cannot exclude, while there is no combination of interference patterns that the double optical hard-limiters cannot exclude when $P = 5$ and $N = 5$. Thus, the error floor exists for the optical CDMA systems with double optical hard-limiters when $P = 3$ and $N = 5$ and does not exist when $P = 5$ and $N = 5$. Moreover, it can be seen that all the systems with $P = 5$ have better performance than do those with $P = 3$, respectively. This is because the probability that the undesired users' marks hit the desired user's mark positions is small when $P = 5$. Thus all the systems with $P = 5$ have better performance.

Figure 19 shows the bit error probability versus the number of users N for the optical OOK CDMA systems without the optical hard-limiter, with the single optical hard-limiter, and with double optical hard-limiters with $P = 7$ and $K_s = 30$. It can be seen in the figures that the optical CDMA system with double optical hard-limiters has the constant low bit error probability when N is smaller than or equal to P: $N \leq 7$. This is because the optical hard-limiters can exclude all the combinations of interference patterns when $N \leq P$, that is, the number of interferers is smaller than P. It can be also seen that the performance of the optical CDMA system with double optical hard-limiters becomes worse than that of the optical CDMA systems without the optical hard-limiter when N is large. When N is large, the probability that all the mark positions of the desired user are hit by the undesired interference marks becomes high, and thus the number of combinations of interference patterns that the double optical hard-limiters cannot exclude becomes large and the performance is degraded. Therefore, using the double optical hard-limiters is effective in improving the performance of optical synchronous CDMA systems when the number of simultaneous users is not so large.

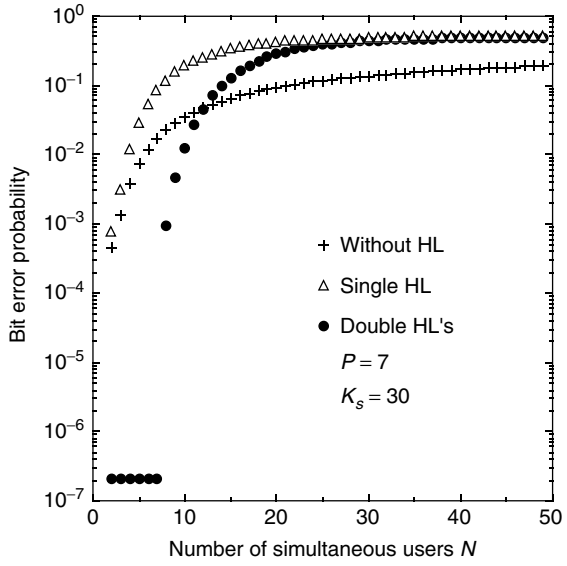

Figure 19. Bit error probability versus the number of simultaneous users N for the optical OOK CDMA systems without the optical hard-limiter, with the single optical hard-limiter, and with double optical hard-limiters: $P = 7$ and $K_s = 30$.

BIOGRAPHY

Tomoaki Ohtsuki received his B.S., M.S., and Ph.D. degrees in electrical engineering from the Keio University, Yokohama, Japan in 1990, 1992, and 1994, respectively. From 1994 to 1995 he was a postdoctoral Fellow and a visiting researcher of electrical engineering at the Keio University. From 1993 to 1995 he was a special researcher of fellowships of the Japan Society for the Promotion of Science for Japanese Junior Scientists. He joined the Tokyo University of Science in 1995 as an assistant professor. Since 2000 he has been a lecturer tenured of the Tokyo University of Science. He has been working on optical communication systems, wireless communication systems, and information theory. He was the recipient of the 1997 Inoue Research Award for Young Scientist, the 1997 Hiroshi Ando Memorial Young Engineering Award, the Erricson Young Scientist Award 2000, and the 2002 Funai Information and Science Young Scientist Award.

Iwao Sasase received his B.E., M.E., and Ph.D. degrees in electrical engineering from Keio University, Yokohama, Japan, in 1979, 1981, and 1984, respectively. He is currently a professor of information and computer science at Keio University. His research interests include mobile, satellite and optical communications, and information networks. He has authored more than 170 journal papers and 260 international conference papers. He was the recipient of the 1984 IEEE Communications Society Student Paper Award, 1986 Inoue Memorial Young Engineer Award, 1988 Hiroshi Ando Memorial Young Engineer Award and 1988 Shinohara Memorial Young Engineer Award, in 2002. He is the IEEE Communications Society Satellite and Space Communications Technical Committee Chair and Asia Pacific Region vice director.

OPTICAL TRANSMITTERS, RECEIVERS, AND NOISE

PETER J. WINZER
Bell Laboratories, Lucent Technologies
Holmdel, New Jersey

1. INTRODUCTION

Driven by the desire to meet the ever-growing bandwidth demand of our communication society while steadily reducing the cost per transmitted information bit, per-channel data rates in wavelength-division multiplexed (WDM) optical communication systems have continuously been increased, with 40-Gbit/s systems being commercially available today. Aggregate single-fiber transmission capacities on the order of 10 Tbit/s, as well as capacity-times-distance products exceeding several 10 Pbit/s km have been reported [1]. Conversely, tremendous advances in optical filter design and optical multiplexer technology have enabled channel spacings of some 10 GHz in dense WDM systems. Thus, 40 Gbit/s has become the data rate at which optics and electronics have met, and — for the first time in optical communications — has made *spectrally efficient modulation* a major issue.

As a consequence, the investigation of cost-effectively manufacturable transmitters for bandwidth-efficient optical modulation formats, as well as the optimization of high-speed optical receivers for dense WDM systems have become key topics of optical communications research and development. The quest is on for identifying combinations of modulation formats and receiver structures that can best cope with optical noise as well as with various linear and nonlinear signal-distortions accumulated along the fiber-optic transmission path [2], with the aim to trade high receiver sensitivities for longer transmission distances, relaxed component tolerances, or increased system margins.

Another field that asks for highly optimized optical transmitters and receivers is free-space optical communications. With applications both in terrestrial broadband access and in space-borne intersatellite links [3,5], free-space optical communications will enable future high-speed mobile data networking, bringing broadband data services to remote locations on the globe as well as to users on airplanes.

This section intends to open up the field of optical modulation and reception on an introductory level by discussing a selection of optical modulation techniques currently viewed as being most promising. Further, high-performance optical receiver structures and their noise properties are outlined, both for the fiber channel and for the free-space channel. Basic receiver design rules as well as important performance trade-offs are extracted. Frequently used concepts for quantifying receiver performance, such as *receiver sensitivity, quantum limit, Q-factor*, and *optical signal-to-noise ratio* (OSNR) are explained. To probe beyond the overview given in this chapter, and to acquire a more complete picture of the wide field of optical transmission, reception, and noise, the reader is kindly referred to the selection of excellent texts referenced at the end of the section.

2. OPTICAL MODULATION FORMATS AND THEIR IMPLEMENTATION

After giving a general classification of optical modulation formats, this section discusses the most important optical modulation techniques known today, with a particular view on their practical implementation by means of state-of-the-art high-speed opto-electronic components.

2.1. Classification

2.1.1. What to Modulate? The optical field[1] has three physical attributes that can be used to carry information: *Amplitude, phase* (including *frequency*), and *polarization*.

Depending on which of the three quantities is used to convey information, we distinguish between *amplitude-modulated, phase-modulated* (*frequency-modulated*), and *polarization-modulated* formats. Hybrid formats that simultaneously modulate two or more properties of the optical field (e.g., quadrature amplitude modulation (QAM)) have not yet made their way into high-speed optical communications. These formats are widely used in microwave communications, as well as in the related field of optical subcarrier-multiplexing, predominantly for cable-TV applications [6]. Here, several individually modulated signals on separate radio-frequency (RF) carriers are imprinted on an optical field by (linear) amplitude modulation.

[1] In optical communications, the term *optical field* is used to denote either one of the four electromagnetic field quantities observing the wave equation. It is usually expressed as a complex baseband quantity by eliminating the optical carrier frequency and is normalized such that its squared magnitude represents the optical power.

While amplitude and phase modulation have been widely used in high-speed optical communications, polarization modulation has received comparatively little attention so far [7]. This can primarily be attributed to the random polarization changes in optical fibers, necessitating active polarization control at the receiver. For amplitude- or phase-modulated formats and direct-detection receivers, however, polarization control is only required if polarization-mode dispersion (PMD) becomes an issue [8]. From a receiver point of view, this additional complexity would only be justifiable if polarization modulation offered significant baseline receiver sensitivity improvements over amplitude modulation, which it does not [9].

Note that our classification does not require a phase-modulated optical field to be constant-envelope, nor an amplitude-modulated field to have constant phase. It is the physical quantity from which information is extracted at the receiver that drives our classification. To give some examples: Differential phase shift keying (DPSK, cf. Section 2.3.1) is a phase-modulated format, regardless of whether it is transmitted constant-envelope or by means of phase-modulated optical pulses in the form of return-to-zero-DPSK (RZ-DPSK). Conversely, carrier-suppressed return-to-zero (CSRZ, cf. Section 2.2.3) is an amplitude-modulated format, regardless of the fact that the optical field's phase is additionally modulated in order to beneficially influence the spectrum.

2.1.2. How Many Symbols? The most widely used classes of optical receivers use *direct detection* (cf. Sections 3.2 and 3.6), that is they make use of the optical *power* $P = |E|^2$, the squared magnitude of the complex optical field amplitude E. If no optical phase-to-amplitude converting element is employed prior to detection, a direct-detection receiver is unable to distinguish between the two received symbols $E_{1,2} = \pm|E|$, since they both have the same optical power, $P_1 = P_2 = |\pm E|^2$. The additional degree of freedom gained by this ambiguity can be beneficially employed to shape the optical spectrum, or to make a format more resilient to distortions accumulated along the transmission line. Formats making use of this potential fall in the class of *pseudo-multilevel* or *polybinary* signals, depending on whether bit-correlations are introduced (as for duobinary formats, (M)DB, cf. Section 2.2.4) or not (as for carrier-suppressed return-to-zero, CSRZ, cf. Section 2.2.3). It is important to realize that these two classes of modulation formats use more than two symbols to encode a single bit of information, but transmit symbols at the bit rate R. For the formats of interest in optical communications today, the symbol alphabet $\{+|E|, -|E|, 0\}$ is used, which is mapped onto $\{0, |E|^2\}$ at the receiver. Pseudo-multilevel and polybinary signaling must not be confused with *multilevel* signaling, where $\log_2(M)$ bits are encoded on M symbols, and are then transmitted at a reduced symbol rate of $R/\log_2(M)$. Both multilevel amplitude shift keying [10] and (differential) quadrature phase shift keying (DQPSK, cf. Section 2.3.2) are multilevel optical modulation techniques. The difference between polybinary, pseudo-multilevel, and multilevel signaling is

Table 1. Symbol Encoding Examples for Multilevel, Pseudo-Multilevel, and Polybinary Signaling

Bit Sequence	0	0	1	0	1	1	1	0	0	1	0	1
pseudo-multilevel (CSRZ)	0	0	1	0	1	−1	1	0	0	−1	0	−1
polybinary (DB)	0	0	1	0	−1	−1	−1	0	0	−1	0	1
multilevel (DQPSK)	0		$+\pi/2$		π		$+\pi/2$		$-\pi/2$		$-\pi/2$	

visualized in Table 1, showing a data bit stream with three different symbol encodings.

2.1.3. Both Sidebands Needed? Apart from shaping (and compressing) the optical signal spectrum by means of (pseudo)-multilevel or polybinary signaling, it is possible for some modulation formats to additionally suppress half of their spectral content by appropriate optical filtering: Since the spectrum of real-valued baseband signals is symmetric around zero frequency, filtering out the redundant half of the spectrum (i.e., one of the two spectral '*sidebands*') preserves the full information content. This is exploited in *single-sideband* (SSB) signaling, where one sideband is completely suppressed, and in *vestigial-sideband* (VSB) signaling, where an optical filter with a gradual roll-off is offset from the optical carrier frequency to suppress major parts of one of the two sidebands, while at the same time performing some filter action on the other, desired sideband [11].

While broadband optical SSB is hard to generate in practice because of difficulties in implementing appropriate optical filter functions [10], optical VSB has been successfully demonstrated [12] on non-return-to-zero on/off keying (NRZ-OOK, cf. Section 2.2.1). Note that in fiber communications, VSB filtering is preferably done at the *receiver* instead of the transmitter, since if a sideband was suppressed at the transmitter, it would quickly reconstruct itself upon nonlinear fiber propagation. The advantage of using VSB comes from reduced WDM channel crosstalk for the desired sideband, if unequal channel spacings are employed. This situation is visualized in Fig. 1 [12], showing the composite spectrum of five wavelength-division multiplexed NRZ-OOK signals with alternating channel spacings of 1.2 and 1.7 times the data rate R. Severe WDM crosstalk is introduced for the sidebands on the closer-spaced sides (region A), making them useless for detection. Conversely, significantly less crosstalk is found for the sidebands on the larger-spaced sides (region B) than would be present if the channels were spaced on an equally-spaced frequency grid.

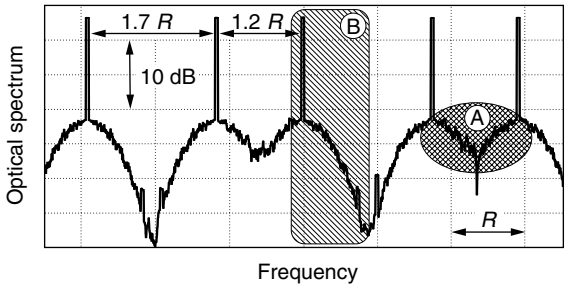

Figure 1. Vestigial sideband (VSB) transmission of optical signals on an unequally-spaced frequency grid to avoid WDM channel crosstalk [12].

2.2. Amplitude Modulation Formats

2.2.1. Non-Return-to-Zero On/Off Keying (NRZ-OOK). The simplest of all optical modulation formats is non-return-to-zero on/off keying (NRZ-OOK), often just called NRZ. This format imprints data on an optical carrier by switching light on and off. Historically, this was the first, and is still the most widely deployed optical modulation format. It has been used to *directly modulate*[2] both light-emitting diodes (LEDs) and lasers. Unfortunately, directly modulated laser light is highly chirped, that is, it exhibits strong residual phase modulation, which broadens the optical spectrum and degrades transmission performance through interaction with optical fiber dispersion in many important transmission scenarios. Thus, for modulation speeds above 2.5 Gbit/s and/or for long-haul fiber communication systems, *external modulation* has to be used. Here, the light of a continuously operating laser source is modulated by means of an external device, engineered for low chirp, or even designed for chirp-free operation. The two most important external modulators are semiconductor *electro-absorption modulators* (EAMs) and Lithium-Niobate ($LiNbO_3$) *Mach-Zehnder modulators* (MZMs). Both are commercially available for 40-Gbit/s modulation today.

EAMs [13] have the advantage of low-drive voltages (typ. 2 V), and are cheap in volume production. However, they still produce some residual chirp, have dynamic extinction ratios (maximum-to-minimum modulated light power) typically not exceeding 10 dB, and have limited optical power-handling capabilities (typ. 10 dBm). Their fiber-to-fiber insertion losses are about 10 dB, which has led to the integration with laser diodes, thus avoiding the input fiber-to-chip interface. *Electro-absorption modulated lasers* (EMLs) with output powers on the order of 0 dBm are widely available today. Another way of eliminating the high insertion losses of EAMs is the integration with semiconductor optical amplifiers (SOAs), which can even yield some net fiber-to-fiber amplification [14]. Figure 2a shows typical transmission characteristics of an EAM as a function of drive voltage. Note that the absorption of the EAM saturates at high drive voltages.

MZMs have excellent extinction performance (typ. 20 dB), can be made chirp free by balanced driving, and have lower insertion losses than EAMs (typ. 5 dB). The

[2] Using *direct modulation*, data are directly superimposed on a light-emitting device's drive current, which otherwise has biasing functionality only.

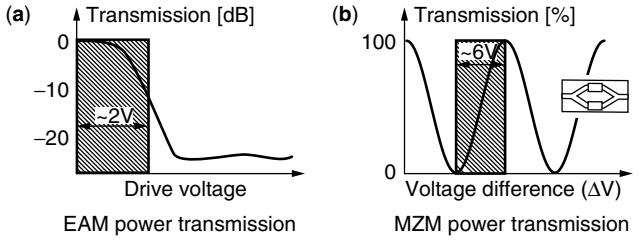

Figure 2. Typical optical power transmission characteristics of EAMs (**a**) and MZMs (**b**).

required (high-speed) peak-to-peak drive voltages of some 6 V, however, often represent serious practical problems. The MZM transfer characteristics is sinusoidal, owing to the Mach-Zehnder structure of the device (cf. inset to Fig. 2b): The incoming light is split into two paths at an input coupler. One (or both) paths are equipped with phase modulators that let the two fields acquire some phase difference relative to each other. Finally, the two fields interfere (destructively or constructively, depending on the modulated phases) at an output coupler. The optical field transfer function $T_E(V_1, V_2)$ thus reads

$$T_E(V_1, V_2) = \tfrac{1}{2}\{e^{j\phi(V_1)} + e^{j\phi(V_2)}\} = e^{j(\phi(V_1)+\phi(V_2))/2}\cos[(\phi(V_1) - \phi(V_2))/2] \quad (1)$$

where $\phi(V_{1,2})$ are the voltage-modulated optical phases of the two MZM arms. Since the phase modulation is a linear function of the drive voltage, the MZM *power* transfer function depends only on the drive voltage difference ΔV, $T_P(V_1, V_2) = |T_E(V_1, V_2)|^2 = T_P(\Delta V)$, which gives an additional degree of freedom in adjusting modulator chirp [15]. If the two modulator arms are driven by the same amount, but in opposite directions ($\phi(V_1) = -\phi(V_2)$), the phase term in Eq. (1) vanishes, resulting in purely real-valued transmission characteristics (i.e., in chirp-free operation). This driving condition is known as *balanced driving* or *push-pull operation*. Note that balanced driving cannot only be used to eliminate chirp, but also to reduce the output power requirements of the RF driver amplifiers by 6 dB (at the expense of having to use an additional amplifier, of course). Optical NRZ data signals are usually generated by driving the MZM from its minimum transmission to its maximum transmission, as visualized in Fig. 2b. Note that the non-linear parts of the MZM transfer function at high and low transmission can suppress overshoots and ripple on the electrical NRZ drive signal.

Figure 3 shows optical spectrum and optical eye diagram[3] of an idealized NRZ signal. The optical spectrum, defined as the bit-pattern-averaged squared magnitude of the optical field's Fourier transform, is composed of a continuous portion, which reflects the shape of the individual NRZ data pulses, and discrete tones at integer

[3] *Eye diagrams* are important means of visualizing the quality of digital signals. They are formed by plotting on top of each other copies of the same modulated bit pattern, shifted by integer multiples of the bit duration.

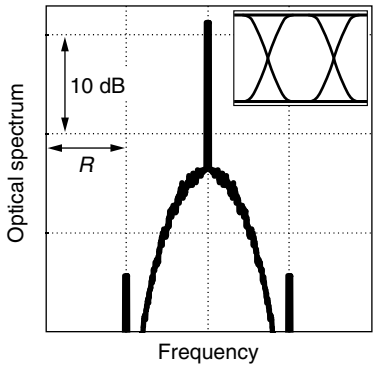

Figure 3. Optical spectrum and eye diagram of an NRZ signal.

multiples of the data rate. The weight of these tones is determined by the optical spectrum of the NRZ data pulses, and therefore depends on the NRZ rise/fall times. For ideal (rectangular) NRZ signals all tones vanish, apart from the one at zero frequency.

2.2.2. Return-to-Zero On/Off Keying (RZ-OOK). Regardless of the modulation format (phase or amplitude), NRZ often suffers from bandwidth-limitations, both at the transmitter and at the receiver, leading to the presence of intersymbol interference (ISI) in the bit sequence to be detected. ISI denotes the corruption of bits (most notably, of isolated '0'-bits) by their neighboring '1'-bits. In optical communications, ISI is particularly harmful, since detection noise often grows linearly with signal amplitude (cf. Sections 3.2, 3.4, and 3.6). Figure 4 shows typical NRZ and RZ electrical eye diagrams at the decision gate of a receiver for the same average optical input power and under the same filtering conditions, where the effect of ISI on NRZ becomes evident. In addition to ISI introduced by bandlimiting (optical or electrical) elements, NRZ formats degrade rapidly in many important fiber transmission scenarios. *Return-to-zero* (RZ, *impulsive coding*) coding mitigates these problems, and leads to enhanced system performance [16,17]. In the case of RZ-OOK, information is encoded on the presence or absence of optical pulses. By well centering the pulses in the bit slots, pattern effects coming from limited NRZ drive signal bandwidths are largely eliminated.

The advantages found for RZ coding come at the expense of higher optical transmission bandwidth requirements, as well as of more complicated transmitter structures, as shown in Fig. 5. Usually, RZ-OOK is generated from an optical NRZ signal by carving out pulses by

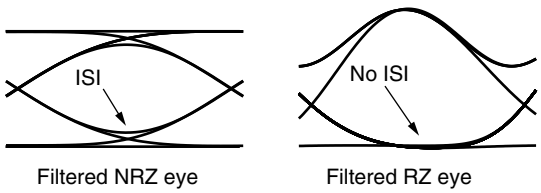

Figure 4. Eye diagrams for NRZ and RZ signals. Intersymbol interference (ISI) affects NRZ performance, while it is not seen for RZ.

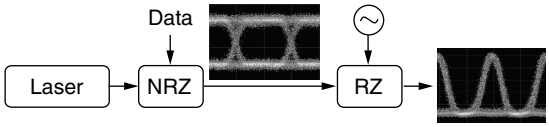

Figure 5. Structure of a typical RZ transmitter, consisting of a laser source, an external NRZ modulator, and a RZ pulse carver.

means of an additional modulator, termed *pulse carver*. Typically, pulse carvers are implemented as sinusoidally driven EAMs or MZMs.

Using an EAM, short (a few ps) optical pulses can be realized by biasing the modulator well in its absorption region, and letting only the peak portion of the sinusoidal drive signal reach appreciable transmission, as shown in Fig. 6. This technique is therefore widely used in optical time-division multiplexing (OTDM) transmitters [18,19].

If a MZM is used for pulse carving, three operating conditions have to be distinguished:

- Sinusoidally driving the MZM at the data rate between minimum and maximum transmission results in optical pulses with a full-width-half-maximum (FWHM) of 50% of the bit duration (a duty cycle of 50%), as shown in Fig. 7 (dashed). Decreasing the modulation swing while adjusting the modulator bias such as to still reach good extinction between pulses, the duty cycle can in principle be reduced to 36%, however, with significant excess insertion loss, since the modulator is then no longer driven to its transmission maximum. At a duty cycle of 40%, the excess insertion loss amounts to 2.2 dB. Increasing the drive voltage to reduce the pulse width (as can be done in the case of EAMs) is not possible with MZMs, owing to the periodic nature of the MZM transmission function.
- Sinusoidally driving the MZM at *half* the data rate between its transmission minima produces a pulse whenever the drive voltage passes a transmission maximum, as visualized in Fig. 7 (solid). This way, duty cycles of 33% can be realized, however, without the possibility for adjustments by varying the drive voltage. The doubled peak-to-peak drive voltage requirements usually pose little technical problems, since narrow-band RF amplifiers can be used.
- Sinusoidally driving the MZM at half the data rate between its transmission maxima results in pulses with 67% duty cycle and with alternating phase. The resulting format is called *carrier-suppressed RZ* (CSRZ), and will be discussed in Section 2.2.3.

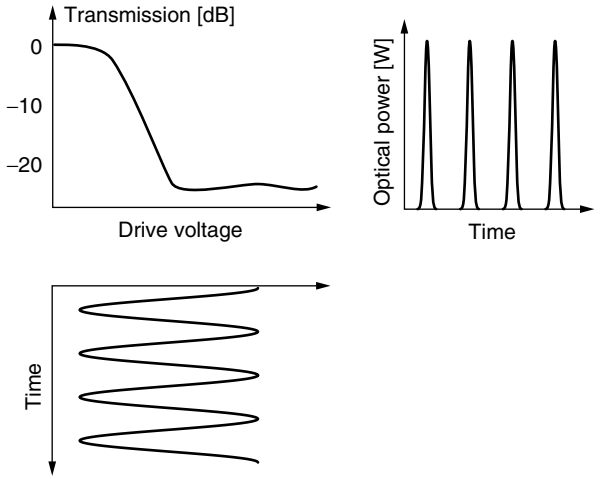

Figure 6. Sinusoidally driven EAM used as RZ pulse carver to attain short optical pulses, with duty cycles below 33%.

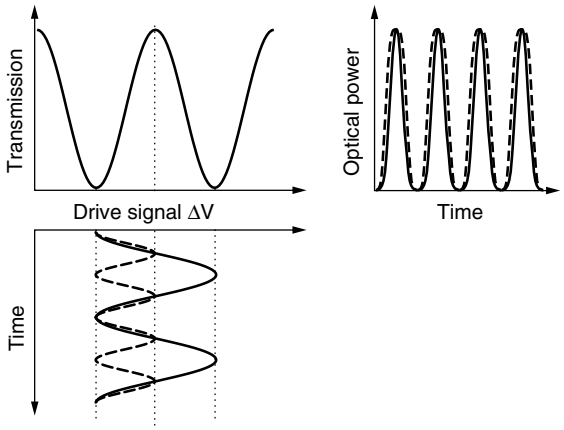

Figure 7. Sinusoidally driven MZM as pulse carver for 33%-duty-cycle RZ (solid) and 50%-duty-cycle RZ (dashed).

Other, less frequently used RZ-OOK modulation techniques include mode-locked lasers in combination with external NRZ-modulators to achieve very low duty cycle pulses for OTDM applications [20], single-step RZ-OOK modulation by means of an electrical RZ drive signal [21], and techniques employing the rising and falling edges of the electrical NRZ signal for RZ pulse generation [22,23]. Note that these methods make do with a single external optical modulator, without the need for a pulse carver.

Spectra and eye diagrams of 50% duty cycle RZ (gray) and 33% duty cycle RZ (black), as produced by a MZM in push-pull operation, are shown in Fig. 8.

2.2.3. Carrier-Suppressed Return-to-Zero (CSRZ). Carrier-suppressed return-to-zero (CSRZ) is a pseudo-multilevel modulation format, characterized by reversing

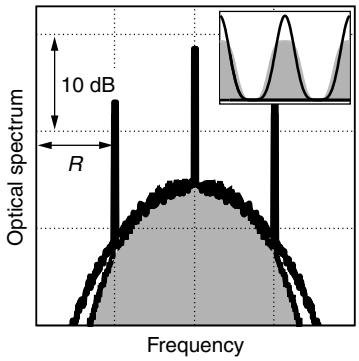

Figure 8. Optical spectra and eye diagrams for 50% duty cycle RZ (gray) and 33% duty cycle RZ (black), as produced by a MZM in push-pull operation.

the sign of the optical field at each bit transition. In contrast to the duobinary formats detailed in Section 2.2.4, the sign reversals occur at *every* bit transition, and are completely *independent* of the information-carrying part of the signal. CSRZ is most conveniently realized by sinusoidally driving a MZM pulse carver at half the data rate between its transmission maxima, as visualized in Fig. 9. Since the optical field transfer function $T_E(\Delta V)$ (dashed) of the MZM changes its sign at the transmission minimum (cf. Eq. (1) for push-pull operation), phase inversions between adjacent bits are produced. Thus, on average, the optical field of half the '1'-bits has positive sign, while the other half has negative sign, resulting in a zero-mean optical signal. As a consequence, the carrier at the optical center frequency vanishes, giving the format its name.

Using a MZM to generate CSRZ results in a duty cycle of 67%, which can be brought down to 50% at the expense of excess insertion loss by reducing the drive voltage swing. At a duty cycle of 55%, an excess insertion loss of 2 dB has to be accepted. It is important to note that, due to its most widely used practical implementation with MZMs, the duty cycle of CSRZ signals usually differs from the one of standard RZ. Thus, care has to be taken when comparing the two formats, since some performance differences result from the carrier-suppressed nature of CSRZ, while others simply arise from the different duty cycles.

Spectrum and eye diagram of 67%-duty cycle CSRZ, as generated by a MZM in push-pull configuration, are shown in Fig. 10. For comparison, the spectrum of a (hypothetical) 67%-duty cycle RZ signal is also given (gray). Note that the *only* difference between the two spectra is the location of the discrete tones.

2.2.4. Duobinary and Modified Duobinary (DB, MDB). Duobinary (DB) and modified duobinary (MDB) signals are polybinary signals, a subset of the partial response signaling format [11,24]. In optical communications they have also become known under the keywords *phase-shaped binary transmission* (PSBT) [25] and *phased amplitude-shift signaling* (PASS) [26]. Most conveniently, optical (M)DB signals, like CSRZ, employ

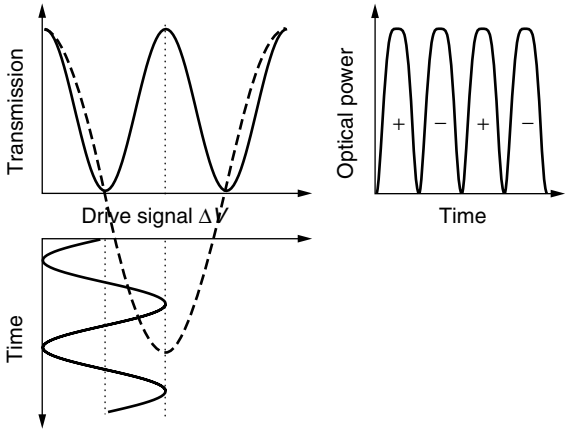

Figure 9. Sinusoidally driven MZM as pulse carver for 67%-duty-cycle CSRZ. The solid and dashed transmission curves apply for the optical power ($T_P(\Delta V)$) and field ($T_E(\Delta V)$), respectively.

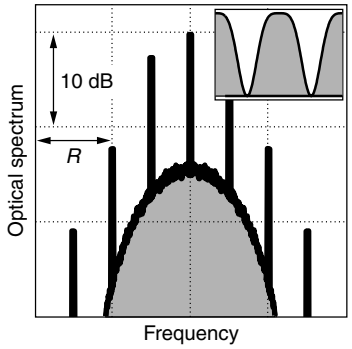

Figure 10. Optical spectrum and eye diagram of 67%-duty cycle CSRZ, as generated by a MZM in push-pull configuration (black). The spectrum of a 67%-duty cycle RZ signal without phase reversals is given for comparison (gray).

the signaling set $\{0, \pm|E|\}$, taking advantage of the power-detecting property of direct detection optical receivers that automatically converts the three optical symbols to the two electrical symbols $\{0, |E|^2\}$. However, unlike with CSRZ, the optical phases of the individual bits additionally depend on the bit pattern: For DB signaling, a phase change occurs whenever there is an odd number of '0's between two successive '1's, whereas for MDB the phase changes for each '1' (even for adjacent '1's), independent of the number of '0's inbetween (cf. also Table 1).

(M)DB signals are more tolerant than conventional binary signals with respect to chromatic dispersion, narrow-band optical filtering (thus allowing for closer WDM channel spacings), as well as to some non-linear transmission impairments. Explanations can be given both in the frequency domain [10,27] and in the time domain [25,26,28], the latter lending itself to a particularly intuitive interpretation: Consider the bit pattern ...0010100..., with the '1'-bits being represented by the tall, shaded pulses in Fig. 11. When transmitted through narrow-band optical filters or over dispersive optical fiber, the pulses broaden (hatched) to let some energy spill into the isolated '0'-bit. If the two pulses have the same optical phase, their optical fields add up constructively, leading to severe ISI (dashed). For (M)DB, however, two pulses separated by an isolated '0'-bit always have opposite phases, which lets them interfere destructively and thus reduces ISI (solid).

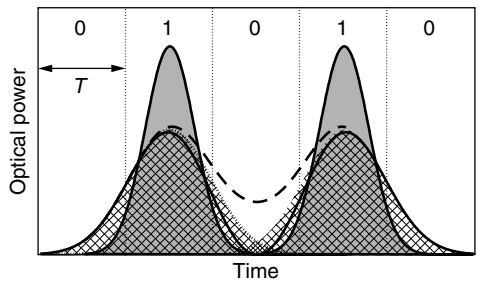

Figure 11. Initially narrow optical pulses (shaded) broaden through fiber dispersion or optical filtering (hatched). If the two pulses have the same optical phase, their optical fields add up constructively (dashed). For (M)DB, the two pulses have opposite phases, which lets them interfere destructively (solid) [25,26].

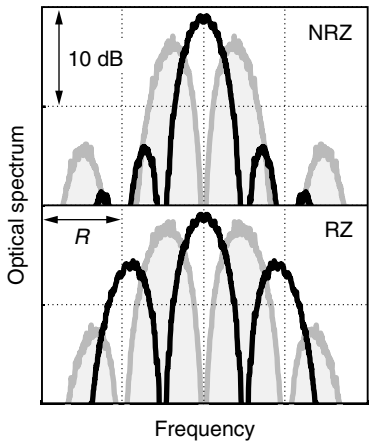

Figure 12. Optical spectra of duobinary (black) and modified duobinary (gray) signals in NRZ coding (upper) and RZ coding (lower).

Both DB and MDB can be implemented in RZ or NRZ format. Figure 12 shows the optical spectra of NRZ (upper) and RZ (lower) DB (black) and MDB (gray). A characteristic feature is the spectrally compressed main lobe as compared to NRZ-OOK (cf. Fig. 3). For NRZ-DB, the side lobes are filtered out for optimum performance [10]. Note that (M)DB spectra have no discrete spectral components, which helps to suppress stimulated Brillouin scattering (SBS) in optical fibers [29].

Duobinary transmitters are usually implemented using a three-level electrical drive signal $\{-1, 0, +1\}$ in combination with a MZM driven between its transmission maxima (like for CSRZ, Fig. 9, but using the data signal instead of a sinusoid). The methods resulting in chirp-free (M)DB signals operate the MZM in push-pull mode. As shown in Fig. 13a, the three-level electrical drive signal can be generated using analogue addition (DB) or subtraction (MDB) of the bit sequence with a 1-bit-delayed replica of itself, provided that appropriate precoding is performed on the data [11,27]. Since the required three-level (linear) RF driver electronics are hard to implement in practice, one usually resorts to method (b), taking a highly low-pass filtered version of the precoded data signal to drive the MZM. The filter bandwidth B has to be chosen on the order of one fourth the data rate R [27]. A third realization (c) uses a MZM as a phase modulator (cf. Section 2.3.1) to generate an intermediate DPSK signal, which is transformed to (M)DB using an optical delay interferometer [30]. By reducing the optical delay to values less than the bit duration T, variable duty cycle RZ-MDB can be generated without the need for a pulse carver [23,31].

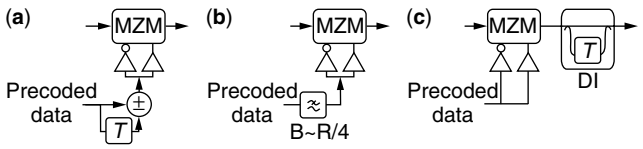

Figure 13. (Modified) duobinary signals are either generated by driving a MZM around its transmission minimum (cf. Fig. 9) using a 3-level electrical drive signal [(a) and (b)]. Alternatively, (M)DB can be generated using a MZM as phase modulator, and passing the resulting DPSK signal through a delay interferometer (DI) (c).

2.2.5. Chirped Return-to-Zero (CRZ). Chirped return-to-zero (CRZ) is predominantly used for ultra-long-haul fiber communication, as found in transoceanic (submarine) systems [32,33]. CRZ signals are generated by sinusoidally modulating the phase of a RZ signal at the data rate, using a separate phase modulator. The intentionally introduced chirp on the one hand beneficially influences nonlinear fiber transmission performance, but on the other hand broadens the signal spectrum. In WDM systems, the amplitude of the sinusoidal phase modulation has thus to be optimized by trading the gain due to enhanced nonlinear propagation performance against WDM channel crosstalk. Typically, the optimum phase modulation amplitude amounts to $\sim$1 rad [32].

The benefits of CRZ obviously come at the expense of more complex transmitter architectures, comprising a total of three external modulators whose drive signals have to be carefully synchronized. Integrated GaAs/AlGaAs modulators for CRZ, combining NRZ data modulator, RZ pulse carver, and CRZ phase modulator in one module, have been reported [34].

2.3. Phase Modulation Formats

The most widely used class of optical receivers employs direct detection, that is, the receiver is only sensitive to optical *power* variations (cf. Sections 3.2 and 3.6). To detect modulation of the optical field's *phase*, phase-to-amplitude converting elements therefore have to be inserted into the optical path prior to detection. Since these elements are unable to offer an absolute optical phase reference, the phase reference has to be provided by the signal itself: Each bit acts as a phase reference for another bit, which is at the heart of all *differential phase shift keying* formats.

2.3.1. Differential Phase Shift Keying (DPSK). Binary differential phase shift keying (BDPSK, or simply DPSK) encodes information on a binary phase change between adjacent bits. A logical '1' is encoded onto a π phase change, whereas a logical '0' is represented by the absence of a phase change. Thus, like for (M)DB, an appropriate precoding circuit has to be employed at the transmitter prior to modulation. Like OOK, DPSK can be implemented in RZ and NRZ format. The main advantage from using DPSK instead of OOK comes from a 3-dB sensitivity improvement at the receiver, provided that balanced detection is employed [9,35]. This enhanced sensitivity directly translates into increased transmission distance [36].

An optical (N)RZ-DPSK transmitter is shown in Fig. 14. The phase of the optical field of a narrow-linewidth laser source is flipped between 0 and π using the precoded (differentially encoded) version of the NRZ data signal, as visualized by the two bit patterns in the figure. If a straight-line phase modulator (PM) is used, the speed of the phase transitions is limited by the combined bandwidth of driver amplifier and phase modulator, while the

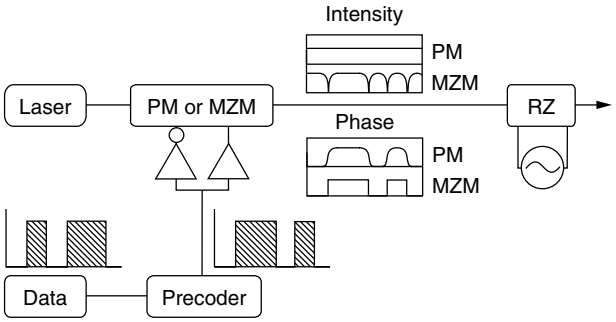

Figure 14. Setup of a RZ-DPSK transmitter. Phase modulation can either be achieved using a MZM, or by means of a straight-line phase modulator (PM), resulting in different amplitude and phase waveforms.

intensity of the phase-modulated light is constant. Instantaneous π phase jumps can be realized at the expense of some residual intensity modulation of the phase modulated light by using a dual-drive MZM, symmetrically driven around zero transmission [37], in analogy to the (M)DB transmitter of Fig. 13(a) and (b) and the CSRZ transmitter of Fig. 9. Typical intensity and phase waveforms of the two modulation techniques are shown at the output of the phase modulator in Fig. 14, where the upper traces apply to PM and the lower traces to MZM phase modulation. Like for OOK, a subsequent pulse carver converts the NRZ-DPSK signal to RZ-DPSK, if desired.

Figure 15 shows spectra and eye diagrams for RZ-DPSK (black) and NRZ-DPSK (gray), as generated by a MZM operated as a phase modulator. The carrier-free nature of the spectra, like for (M)DB, owes to the balance of $-|E|$ and $+|E|$ amplitude levels. Note the absence of a '0'-bit rail in the eye diagrams, which is characteristic for phase-coded formats. The deep amplitude dips between two bits

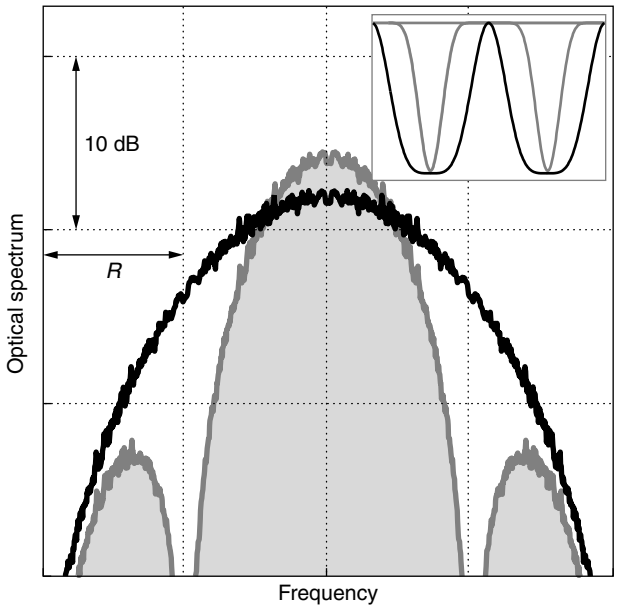

Figure 15. Optical spectra and eye diagrams of NRZ-DPSK (gray) and 33%-duty cycle RZ-DPSK (black), as produced by a MZM as phase modulator.

in the NRZ-DPSK eye represent the residual amplitude modulations of the MZM caused by the finite NRZ drive signal bandwidth.

Since DPSK cannot directly be received with direct-detection techniques, an optical delay interferometer (DI) is inserted in the optical path at the receiver to convert the differential phase modulation into amplitude modulation. As shown in Fig. 16, a DI splits the phase modulated signal into two paths, into one of which a delay equal to the bit duration T is introduced. At the DI's output coupler, the phase modulated optical field thus interferes with its one-bit-delayed replica to produce destructive interference at port $\mathcal{A}$ whenever there is *no* phase change, and constructive interference whenever there *is* a phase change, in agreement with the DPSK-coding rule described above. To exploit the 3-dB sensitivity advantage of DPSK over OOK, a *balanced receiver* has to be employed, where the second DI-output port $\mathcal{B}$, yielding the inverted data pattern, is also made use of, and the difference signal is detected [9,35].

2.3.2. Differential Quadrature Phase Shift Keying (DQPSK). Instead of using two phase levels (DPSK), one can use four phase levels $\{0, +\pi/2, -\pi/2, \pi\}$ to produce differential quadrature phase shift keying (DQPSK). DQPSK is a true four-level signaling format, transmitting symbols at *half* the aggregate bit rate (cf. Table 1). While the receiver sensitivity benefit over OOK that is gained for DPSK is largely lost for DQPSK, the transmission bandwidth is significantly reduced, potentially allowing for higher spectral efficiency in WDM systems, as well as for increased tolerance to chromatic dispersion and PMD [38].

A DQPSK transmitter is best implemented by taking advantage of the *exact* π-phase shifts produced by a MZM operated as a phase modulator (cf. Fig. 9). Figure 17 shows the corresponding transmitter setup [38], consisting of a continuously operating laser source, a splitter to divide the light into two paths of equal intensity, two MZMs operated as phase modulators, a $\pi/2$-phase shifter in one of the paths, and a combiner to produce a single output signal. While the modulated field E_1 of the upper path can take on the values $\pm E_0/\sqrt{2}$, the lower path produces $E_2 = \pm E_0 e^{j\pi/2}/\sqrt{2}$, leading to the four symbols $E_0/\sqrt{2} \cdot \{e^{j\pi/4}, e^{j3\pi/4}, e^{j5\pi/4}, e^{j7\pi/4}\}$ after the combiner. A pulse carver can optionally be added to yield RZ-DQPSK.

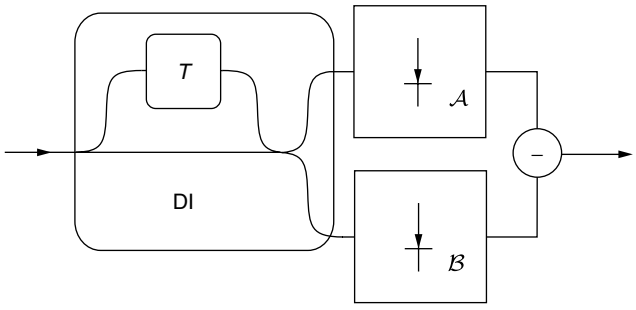

Figure 16. Balanced DPSK receiver using an optical delay interferometer (DI) to convert the phase modulation to amplitude modulation.

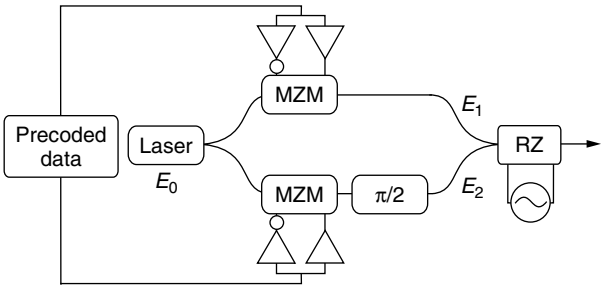

Figure 17. Structure of a DQPSK transmitter. Two MZMs are used as phase modulators, and the two separately modulated fields are combined with a $\pi/2$ phase shift [38].

The *shape* of the DQPSK optical spectra is identical to those of DPSK (Fig. 15). However, the DQPSK spectrum is compressed in frequency by a factor of two due to the halved symbol rate for transmission at the same bit rate.

At the receiver, the DQPSK signal is split, and *two* balanced receivers of the form depicted in Fig. 16 are used in parallel to simultaneously demodulate the two data streams contained within the DQPSK signal [38]. Note that the DI delay has to equal the *symbol* duration for DQPSK demodulation, which is *twice* the bit duration. Due to the DQPSK phase shifts of $\pi/2$ (instead of π for DPSK), the two DIs cannot simultaneously be operated to full destructive and to full constructive interference, which results in a reduced demodulated eye opening for DQPSK.

3. OPTICAL RECEIVER CONCEPTS AND NOISE

3.1. The *Q*-Factor

Before embarking on optical receiver concepts, we will briefly discuss the *Q-factor* as an important parameter that is widely used in optical communications to describe receiver performance. Although occasionally frowned upon by theoreticians, since its derivation relies on (sometimes hard to justify) approximations, the *Q*-factor allows for intuitive interpretations, reasonably accurate quantitative predictions, and has also become an indispensable tool for experimentalists [32].

The *Q*-factor was first introduced by Personick in 1973 [39] to relate mean and variance of the electrical signal at the receiver's decision gate to a bit-error ratio (BER), the quantity of ultimate interest when assessing the performance of digital communication systems. Leaving the derivation of the *Q*-factor to more comprehensive texts [35,40,41], we restrict ourselves to its definition,

$$Q = \frac{|s_1 - s_0|}{\sigma_1 + \sigma_0}, \tag{2}$$

where $s_{0,1}$ are the mean electrical signal amplitudes for a logical '0' and '1' at the decision gate, and $\sigma_{0,1}$ are the associated noise standard deviations. Under the assumption of Gaussian detection statistics, which is sufficiently accurate in most situations of practical interest [42], the BER is related to the *Q*-factor via

$$\mathrm{BER} = 0.5\ \mathrm{erfc}[\mathrm{Q}/\sqrt{2}], \tag{3}$$

where $\mathrm{erfc}[x] = (2/\sqrt{\pi}) \int_x^\infty \exp(-\xi^2)\, d\xi$ denotes the complementary error function. For $\mathrm{BER} = 10^{-9}$, which is often taken as a baseline for specifying receiver sensitivities, we have $Q \approx 6$.

Note that σ_0 and σ_1 may differ from each other, since many important noise terms encountered in optical communications are *signal-dependent*, that is, the noise variance is a function of the optical signal power. For purely *signal-independent* noise ($\sigma_1 = \sigma_0 = \sigma$), Eqs. (2) and (3) reduce to $\mathrm{BER} = 0.5\ \mathrm{erfc}[|s_1 - s_0|/(2\sqrt{2}\sigma)]$, a well-known expression in classical communication theory [11].

3.2. *Pin*-Receiver

The *pin*-receiver depicted in Fig. 18 is the simplest optical receiver structure. It consists of a *pin*-photodiode,[4] some postdetection electronic amplification and filtering with (single-sided) bandwidth B_e (electronics impulse response $h(t)$), and a sampling-and-decision device that restores the digital data. Detection of the filtered signal $s(t)$ is corrupted by two types of noise in a pin-receiver, *shot noise* and *electronics noise*.

Shot noise is a direct consequence of the quantum nature of light: Interactions of light and matter can only take place in discrete energy quanta (*photons*), governed by the rules of quantum statistics. Thus, a discrete, random number of electron-hole pairs is generated in a semiconductor diode when light impinges on it, causing the photocurrent to leave the diode in individual elementary impulses, each carrying the elementary charge $e \approx 1.602 \cdot 10^{-19}$. As, as visualized in Fig. 19. This fine structure of the electrical signal is perceived as shot noise [43,45]. On average, a fraction η of the incoming optical power $p(t)$ is converted to an electric current, leading to an average electrical signal amplitude of

$$\langle s(t) \rangle = (R_T) \cdot S(p * h)(t) \tag{4}$$

where $S = \eta e/(hf)$ [A/W] is the receiver's responsivity. The symbol * denotes a convolution, and $h(t)$ is normalized to let the low-frequency portion of its spectrum equal unity. Depending on whether the electrical signal $s(t)$ is specified in terms of current or of voltage, a resistance R_T has to be taken into account that converts the current-output of the *pin*-photodiode into a voltage. This resistance is

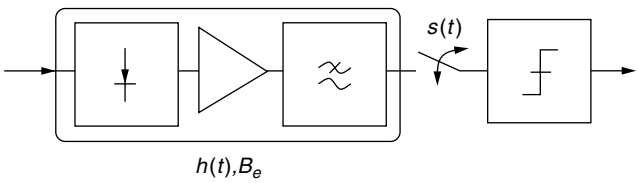

Figure 18. Setup of a *pin*-receiver, incorporating a *pin*-photodiode, an electrical preamplifier, electrical low-pass filtering, and a sampling-and-decision device.

[4] The abbreviation *pin* stands for *p-doped/intrinsic/n-doped*, and describes the basic layer structure of the associated semiconductor device.

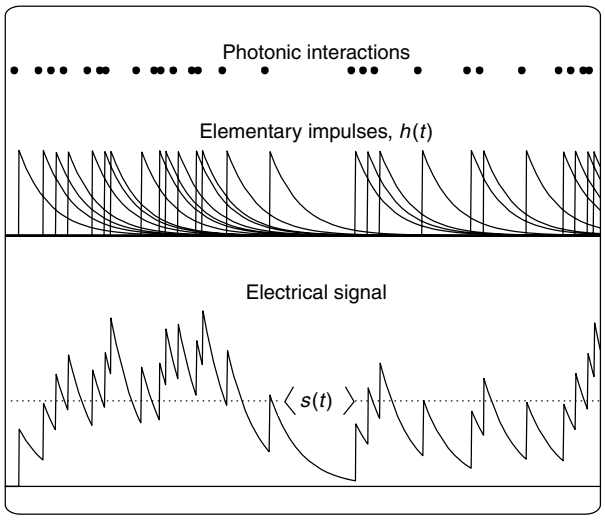

Figure 19. Photons arrive at random, dictated by quantum statistics. Each photonic interaction produces an elementary electronic impulse. The impulses add up to produce the overall electrical signal, whose fluctuations are known as shot noise [43].

frequently referred to as *transimpedance; hf* denotes the photon energy. ($h \approx 6.626 \cdot 10^{-34}$ Js is Planck's constant, and f stands for the optical carrier frequency of light.) The shot noise variance associated with photodetection is given by [43]

$$\sigma^2_{shot}(t) = (R_T^2) \cdot eS(p * h^2)(t) \approx (R_T^2) \cdot 2eSp(t)B_e \qquad (5)$$

The approximation in Eq. (5) applies for optical power variations that are slow compared to the speed of the electronics. Note that shot noise is a *nonstationary*, non-Gaussian noise process in general; its statistical parameters, most notably its variance, change with time.

Electronics noise is the sum of all stationary noise sources generated within the opto-electronic circuitry, *independent* of the optical signal, such as thermal noise, transistor shot noise, $1/f$-noise, or dark-current shot noise. The design of the receiver front-end electronics significantly impacts its noise performance, and is detailed in numerous excellent texts [39,46].

On a system level, electronics noise is often characterized by an *equivalent noise current density* $i_n[\mathrm{A}/\sqrt{\mathrm{Hz}}]$, which can be converted to an electronics noise variance σ^2_{elec} at the decision gate by

$$\sigma^2_{elec} = (R_T^2) \cdot i_n^2 B_e \qquad (6)$$

In the Gbit/s-regime, i_n is typically on the order of some 10 $\mathrm{pA}/\sqrt{\mathrm{Hz}}$. Alternatively, the noise performance of receivers can be specified using the *noise equivalent power* (NEP) $[\mathrm{W}/\sqrt{\mathrm{Hz}}]$, which is usually defined as the average optical power per square-root electrical receiver bandwidth that would be required to make the average electrical power equal to the electronics noise variance,

$$\sigma^2_{elec} = (R_T^2) \cdot S^2 \mathrm{NEP}^2 B_e \qquad (7)$$

3.3. Receiver Sensitivity and Quantum Limit

Instead of using equivalent noise current density or NEP, optical receiver front-ends are sometimes also characterized in terms of their *receiver sensitivity*, defined as the average optical power that is required at the receiver input to obtain a certain BER (typ.10^{-9}) at a certain data rate and for a certain modulation format (typ. NRZ-OOK). While the receiver sensitivity is undoubtedly of high interest in optical receiver design, it comprises not only the degrading effects of noise, but also encompasses essential properties of the received signal, such as extinction ratio, signal distortions and intersymbol interference (ISI), generated either within the transmitter or within the receiver itself. Thus, knowledge of the receiver sensitivity alone does not allow trustworthy predictions on how the receiver will perform for other formats (e.g., for RZ-OOK).

Although electronics noise usually dominates shot noise, it can in principle be engineered to zero. Shot noise, however, is fundamentally present. The limit, when *only* fundamental noise sources determine receiver sensitivity is called *quantum limit* in optical communications. The existence of quantum limits makes optical receiver design an exciting task, since there is always a fundamental measure against which practically implemented receivers can be compared, much like the Shannon-limit in information theory. Note, however, that each class of receivers in combination with each class of modulation formats has its own quantum limit.

The quantum limit for the *pin*-receiver using OOK is obtained by ignoring thermal noise, assuming a perfect ($\eta = 1$) receiver, and evaluating the BER for the Poissonian photon statistics of perfect laser light [43,44]. Leaving the derivation to more detailed texts [9,35,41], we merely cite the result,

$$\mathrm{BER} = 0.5 \exp[-2\overline{n}] \qquad (8)$$

where $\overline{n}$ is the average number of photons/bit at the receiver input. For $\mathrm{BER} = 10^{-9}$, the *quantum limited receiver sensitivity* of the *pin*-receiver is $\overline{n} = 10$ photons/bit (average power), or $n_1 = 20$ photons per '1'-bit. Note that specifying the receiver sensitivity in terms of *photons / bit* leads to more fundamental statements than specifying it in terms of an average optical power $\overline{P}$ ([W] or [dBm]), since both wavelength dependence and bit-rate dependence of receiver performance are eliminated. The two measures are related via

$$\overline{P} = \overline{n} hfR \qquad (9)$$

where R denotes the data rate. The intriguingly low-receiver sensitivity of *pin*-receivers, however, does not apply to practically implementable receivers, since in reality electronics noise by far dominates shot noise. As a consequence, receiver sensitivities achieved by *pin*-receivers are typically 20–30 dB off the quantum limit: Assuming an equivalent noise current density of 10 $\mathrm{pA}/\sqrt{\mathrm{Hz}}$ and a 10-Gbit/s receiver with some 7-GHz bandwidth operating at a wavelength of 1550 nm, the electronics noise variance amounts to $7 \cdot 10^{-13}\mathrm{A}^2$, while the '1'-bit shot noise variance going with the detection of 10 photons/bit comes to about $4 \cdot 10^{-17}\mathrm{A}^2$, four orders of magnitude below electronics noise. For realistic BER, the Q-factor is thus entirely determined by electronics noise, and for $Q = 6$ we arrive at a receiver sensitivity of some $\overline{n} \approx 5000$ photons/bit, 27 dB above the quantum limit.

To achieve higher receiver performance, more advanced receiver types must be employed. There are basically three ways to proceed: *Avalanche photodetection, coherent detection*, and *optically preamplified detection*. These rather diverse techniques, which will be discussed in the following sections, have still one common attribute: They all amplify the received signal before or at the stage of photodetection, while at the same time introducing additional noise. In the limit when the newly introduced noise terms dominate electronics noise, receiver performance becomes independent of electronics noise, leading to the respective quantum limits. In that limit, any further increase of the respective gain mechanism does *not* affect receiver performance any more. In contrast to *pin*-receivers, the quantum limits can be closely approached with these receiver types in experimental reality.

3.4. Avalanche Photodiode (APD) Receiver

An avalanche photodiode (APD) is the semiconductor equivalent to a photomultiplier tube. The incoming light generates primary electron-hole pairs (like in a *pin*-diode), which are then accelerated in a high-field region to launch an avalanche multiplication process through ionizing collisions [43]. The average number of the resulting secondary electron-hole pairs relative to the primary electron-hole pairs is called *avalanche gain* M_{APD}. The avalanche multiplication process is by itself a random process, since the exact number of secondary electron-hole pairs generated by a primary pair varies randomly. The unavoidable shot noise present for primary photodetection (cf. Fig. 19) is thus enhanced. This increase in detection noise is quantitatively captured in the APD's *noise enhancement factor* $F_{APD} > 1$ via the *multiplied shot noise* relationship [43]

$$\begin{aligned}\sigma^2_{shot,APD}(t) &= (R_T^2)\cdot eSM^2_{APD}F_{APD}(p * h^2)(t)\\ &\approx (R_T^2)\cdot 2eSM^2_{APD}p(t)F_{APD}B_e \end{aligned} \tag{10}$$

where the approximation, again, holds for optical power variations slow compared to the detection electronics' speed. In addition to multiplied shot noise, an APD also generates multiplied dark current shot noise through avalanche multiplication of dark current charge carriers, which is stationary and independent of the optical power, and can thus be added to the electronics noise variance.

In the desired limit when multiplied shot noise dominates electronics noise, the Q-factor for high-signal extinction ratios ($s_0 \ll s_1$) approaches[5]

$$\begin{aligned}Q &= \frac{(R_T)\cdot SM_{APD}P_1}{\sigma_{elec}+\sqrt{\sigma^2_{shot,APD}+\sigma^2_{elec}}}\\ &\xrightarrow{\sigma^2_{shot,APD}\gg\sigma^2_{elec}} \sqrt{\frac{\eta\overline{n}R}{F_{APD}B_e}} \sim \sqrt{2\overline{n}/F_{APD}}\end{aligned} \tag{11}$$

[5] Note that while Eq. (11) reveals general trends, care has to be taken with quantitative predictions, since the Gaussian assumption of detection statistics breaks down for shot-noise limited direct detection: Specializing equation (11) for *pin*-reception ($F_{APD} = 1$), we arrive at a quantum limit of $\overline{n} =$ 18 photons/bit, which is off its correct value by 2.6 dB.

with $P_1 = 2\overline{P}$ equal to the '1'-bit optical signal power for NRZ-OOK. Thus, the excess noise factor F_{APD} takes the role of a noise figure in degrading detection performance. Note that optimum performance of an APD receiver is in general *not* attained at the highest possible multiplication M_{APD}, since F_{APD} is a complicated and highly technology-dependent function of M_{APD}, necessitating joint optimization of M_{APD}, F_{APD}, and σ^2_{elec} [40,43,46].

Good APDs ($M_{APD} \sim 100, F_{APD} \sim 5$) for operation up to 1 Gbit/s are available in Silicon technology, which limits their operating range to wavelengths below $\sim$ 1100 nm. Receiver sensitivities of 200 photons/bit have been achieved at 50 Mbit/s [47]. InGaAs or InAlAs-based APDs for use in the 1550-nm wavelength region, however, exhibit fairly low multiplication ($M_{APD} \sim 10$) for 10 Gbit/s detection. Receiver sensitivities of 1000 photons/bit have been demonstrated at 10 Gbit/s [48].

3.5. Coherent Receiver

Another way of amplifying the signal and boosting the accompanying noise above the electronics noise floor is known as *coherent detection* [9,35,41,49]. A coherent receiver, as depicted in Fig. 20 a, combines the signal with a *local oscillator* (LO) laser by means of an optical coupler. Upon detection, the two fields beat against each other, and the average electrical signal reads

$$\begin{aligned}\langle s(t)\rangle = (R_T)\cdot S\{&\varepsilon P_s(t) + (1-\varepsilon)P_{LO}\\ &+ 2\mu\sqrt{\varepsilon(1-\varepsilon)}\sqrt{P_s(t)P_{LO}}\cos(2\pi f_{IF}t + \phi_s(t))\}\end{aligned} \tag{12}$$

where $P_s(t)$ and $\phi(t)$ denote the modulation-carrying received signal's power and phase, respectively, P_{LO} stands for the LO power, and f_{IF}, the beat frequency between signal and LO, is called intermediate frequency, since the IF signal is usually mixed down to baseband after photodetection, using standard microwave techniques. The parameter ε captures the splitting ratio of the optical coupler, which has to be chosen as high as possible such as not to waste too much signal power, and as low as acceptable to let sufficient LO power reach the detector to achieve shot-noise limited performance (see explanation below). The heterodyne efficiency μ accounts for the degree of spatial overlap as well as for the polarization match between LO field and signal field. If both LO and signal

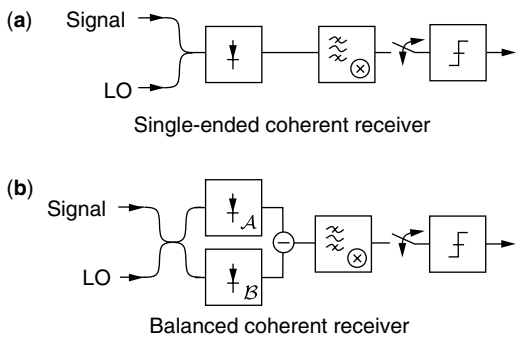

Figure 20. Single-ended (a) and balanced (b) coherent receiver. After photodetection, various kinds of electronic signal-processing can be performed.

are provided copolarized in single-mode optical fibers, μ equals unity.

If the frequency of the LO differs from the signal frequency, we speak of a *heterodyne* receiver. If LO and signal have the same frequency, such that $f_{IF} = 0$, we speak of a *homodyne* receiver. Homodyne detection strictly requires optical phase locking between the LO and signal optical fields, which implies significant technological effort.[6] In the desired range of operation, the LO power is chosen much stronger than the signal power $[(1-\varepsilon)P_{LO} \gg \varepsilon P_s(t)]$, and the first term in Eq. (12) can be neglected compared to the second and third. Filtering out the temporally constant second term in Eq. (12), we are then left with an exact replica of the received *optical field's amplitude* $\sqrt{P_s(t)}$ and *phase* $\phi_s(t)$ (as compared to the optical *power* accessible in direct-detection receivers). Thus, any amplitude or phase modulation scheme can directly be employed in combination with coherent receivers.

Due to the high LO power reaching the detector, the main noise contribution in a coherent receiver is the shot noise produced by the LO, $\sigma^2_{LO-shot} = 2eS(1-\varepsilon)P_{LO}B_e$. If this noise term dominates electronics noise ($\sigma^2_{LO-shot} \gg \sigma^2_{elec}$), optimum receiver performance is achieved. This limit is known as the *shot noise limit* in the context of coherent receivers. The highest receiver sensitivity with the potential of practical implementation that is known today can be achieved using homodyne detection of phase shift keying[7] (PSK), where the data bits are directly mapped onto the phase $\phi_s(t)$ of the optical signal, $\{0, 1\} \rightarrow \{0, \pi\}$. Without going into the derivations [9], the quantum limit for homodyne PSK can be shown to equal only 9 photons/bit, with a reported receiver sensitivity record of 20 photons/bit at 565 Mbit/s [51]. Using OOK instead of PSK, the sensitivity degrades by 3 dB. Going to heterodyne detection results in an additional loss of 3 dB in terms of receiver sensitivity. A detailed discussion of quantum limits for coherent receivers can be found in [9].

An alternative implementation of coherent receivers is shown in Fig. 20b. It makes use of *balanced detection* with $\varepsilon = 1/2$. While a balanced coherent receiver has *exactly* the same quantum-limited sensitivity as its single-ended equivalent, it offers the advantage of utilizing the full optical signal and LO power, and of being more robust to LO relative intensity noise (RIN).

Although still seriously considered for inter-satellite link applications due to the high achievable sensitivities, the interest in coherent receivers has vanished for fiber-optic systems with the availability of Erbium-doped fiber amplifiers (EDFA) in the early 1990s. To understand this evolution, let us look at the main advantages of coherent receivers, and how they have become outdated:

- Receiver sensitivities of coherent receivers by far outperform those achieved with pin-receivers and APDs, thus allowing for increased transmission distances in unamplified optical links. BUT: Optically preamplified receivers (cf. Section 3.6) exhibit similar receiver sensitivities to coherent receivers, are polarization-insensitive, and take less serious hits in performance if inline amplification is present.
- The possibility of correcting for chromatic dispersion in the microwave regime is offered in coherent detection, since both amplitude *and* phase of the optical field are converted to an electronic signal. BUT: Efficient and adaptive broadband phase corrections can only be performed on RF *bandpass* signals, asking for heterodyne detection. Since f_{IF} has to be chosen about 3 times the data rate [41], unrealistically high receiver front-end bandwidths would be needed for the high data rates used today. Conversely, all-optical dispersion compensators and adaptive optical filters are quickly advancing technologies [52], allowing for efficient phase corrections in the *optical* regime.
- Coherent receivers allow for the separation of closely spaced WDM channels by means of RF bandpass filters with sharp roll-offs. BUT: Optical filter technology has advanced dramatically, thus enabling channel spacings on the order of 10 GHz with sharp optical filter roll-offs, which opens up the possibility of *optical* channel filtering even for ultradense WDM applications.

But even if coherent reception is highly unlikely to reenter the high-speed fiber-optical communications market, the technique is far from being history: With coherent receiver terminals in their final product development phases [53], coherent receivers will soon find applications in nonfiber optical communications scenarios, most notably in free-space optical communications, where the enormous link distances of up to 80,000 km for geostationary intersatellite links ask for utmost receiver performance, and make homodyne PSK an attractive candidate.

3.6. Optically Preamplified Receiver

The historically youngest class of highly sensitive optical receivers uses *optical preamplification* to boost the weak received signal to appreciable optical power levels prior to detection, as shown in Fig. 21. At the same time, and fundamentally unavoidable, amplified spontaneous emission (ASE) with a power spectral density per (spatial and polarization) mode of

$$N_{ASE} = hfGF/2 \tag{13}$$

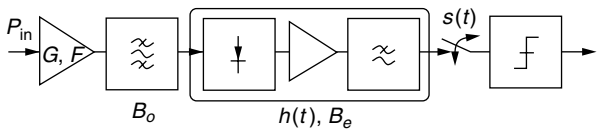

Figure 21. An optically preamplified receiver uses an optical amplifier in combination with an optical bandpass filter prior to detection with a *pin*-receiver.

[6] Using square-law detection of the electrical signal, one can also build a quasi-homodyne receiver without phase-locking and $f_{IF} \approx 0$ [50].

[7] Because the LO provides an optical phase reference, true PSK can be used instead of DPSK in direct detection receivers.

is introduced by the amplification process [43,54,55]; G and F denote the optical amplifier's gain and noise figure,[8] respectively. Today's high-performance Erbium-doped fiber amplifiers (EDFAs) exhibit gains between 15 dB and 30 dB, while having noise figures closely approaching their fundamental limit of 3 dB. These intriguing performance characteristics of EDFAs have made optically preamplified receivers the most important detection technique known today. Since the gain spectrum (and thus also the ASE spectrum) is much broader than the signal spectrum (typ. 30 nm in the 1550-nm wavelength band), an optical bandpass filter is employed to suppress out-of-band ASE. Upon detection, the random ASE field beats against the signal field (as well as against itself), leading to *signal-ASE beat noise* and *ASE-ASE beat* noise[9] after electrical filtering [42,16,17],

$$\sigma^2_{\mathrm{s-ASE}}(t) = (R_T^2)\cdot 2S^2 N_{ASE}\mathrm{Re}\left\{\iint_{-\infty}^{\infty} e(\tau)e^* \times(\tilde{\tau})r_n(\tau-\tilde{\tau})h(t-\tau)h(t-\tilde{\tau})\,d\tau d\tilde{\tau}\right\} \quad (14)$$

and

$$\sigma^2_{\mathrm{ASE-ASE}} = (R_T^2)\cdot M_{pol}S^2N_{ASE}^2\int_{-\infty}^{\infty}|r_n(\tau)|^2 r_h(\tau)\,d\tau \quad (15)$$

where $r_n(\tau)=\langle n^*(\tau)n(\tilde{\tau})\rangle$ is the autocorrelation of the optically filtered ASE field $n(t)$, and $r_h=\int h(\tau)h(\tau-t)\,d\tau$ is the autocorrelation of the detection electronics. The number of ASE modes reaching the detector is denoted M_{pol}. In a single-mode fiber system, M_{pol} usually equals 2, since polarization filtering typically is not done. The optically filtered signal field is denoted $e(t)$. In the limit of rectangular filters and constant input power P_{in} to the optical preamplifier, the above relations simplify to [56]

$$\sigma^2_{\mathrm{s-ASE}} \approx 4S^2GP_{in}N_{ASE}B_e \quad (16)$$

and

$$\sigma^2_{\mathrm{ASE-ASE}} \approx M_{pol}S^2N_{ASE}^2B_e(2B_o-B_e) \quad (17)$$

where B_o stands for the optical filter bandwidth. From Eqs. (14) through (17), we see that the signal-ASE beat noise variance is *nonstationary*, grows linearly with signal power, and is independent of B_o, as long as the optical filter does not significantly influence the signal spectrum. Also, we see that the ASE-ASE beat noise variance is *stationary*, grows linearly with B_o, and linearly depends on M_{pol}. Owing to the linear dependence of N_{ASE} on G (cf. Eq. (13)), both beat noise standard deviations as well as the detected electrical signal amplitude SGP_{in} grow linearly with G. Thus, the Q-factor becomes independent of G as soon as the beat noise terms starts to dominate electronics noise. This limit is called *optical noise limit* or *beat noise limit*, and forms the usual operating condition of optically preamplified receivers. Idealizing the beat noise limit ($F=3$ dB, $B_e=R/2$), we arrive at a quantum limit of 38 photons/bit for OOK, and of 20 photons/bit for DPSK [9]. Experimentally, sensitivities of 43 photons/bit at 5 Gbit/s [57] (52 photons/bit at 10 Gbit/s [58]) have been achieved for OOK, and 30 photons/bit at 10 Gbit/s [59] (45 photons/bit at 40 Gbit/s [36]) have been demonstrated for DPSK using balanced detection (cf. Fig. 16).

3.7. Bandwidth Optimization

Once the gain of the optical amplifier is chosen high enough to let optical beat noise dominate electronics noise, the main impact on receiver performance comes from optical and electrical filter characteristics. In the frame of a single-pulse theory (i.e., neglecting ISI), optimum receiver performance is achieved if the *optical* filter is matched to the data pulses,[10] and if the *electrical* filter is made sufficiently broadband to have no influence on the detected signal [41]. By constructing a receiver of this type, the same performance could in principle be achieved for NRZ and RZ signaling formats. However, the electrical bandwidth is usually upper-bounded by technological constraints and cost considerations, especially at data rates in the multi-Gbit/s regime, and ISI often *does* have a significant impact on detection. Thus, other than matched filter characteristics frequently turn out to be superior in practice, and the equality of NRZ and RZ formats is eliminated: NRZ formats usually take a noticeable hit in performance with respect to RZ '0'-bit ISI (cf. Figs. 4 and 23).

Figure 22 [60,61] shows a typical dependence of receiver performance on B_o and B_e for NRZ-OOK and 33%-duty cycle RZ-OOK. The contours give the dB-penalty relative to the quantum limit. RZ can be seen to have a better optimum sensitivity than NRZ, and, by the wider spacing of the contour lines, to be more tolerant to suboptimum choices of optical and electrical filters. For both formats, the performance decrease at larger-than-optimum filter bandwidths can be attributed to increased detection noise. At lower-than-optimum filter bandwidths, RZ is affected by pulse amplitude reductions due to filtering, while NRZ is predominantly affected by ISI. The different degrading effects for NRZ and RZ at low bandwidths become evident in Fig. 23, showing the dB-sensitivity penalty relative to the quantum limit for RZ and NRZ as a function of electrical filter bandwidth for fixed $B_o=2R$ (left) and as a function of optical filter bandwidth for fixed $B_e=0.8R$ (right). The solid curves apply for a pseudo-random bit sequence (PRBS) of length 2^7-1, and are section lines of Fig. 22. The dashed curves represent the results obtained for a single optical pulse, thus eliminating the effect of

[8] It has become common to call F a *noise figure*, although this terminology is somewhat sloppy, since it only considers the influence of signal-ASE beat noise [55].

[9] Note that the "beating"-picture is only correct in the frame of a classical consideration. Using quantum mechanical reasoning, the signal-ASE beat noise turns out to result from the fact that each photon is amplified by a random, integer number within the amplifier, similar to the random multiplication of electron-hole pairs in APDs [54].

[10] The impulse response of a *matched filter* is identical to the temporally reversed pulse to be detected [11].

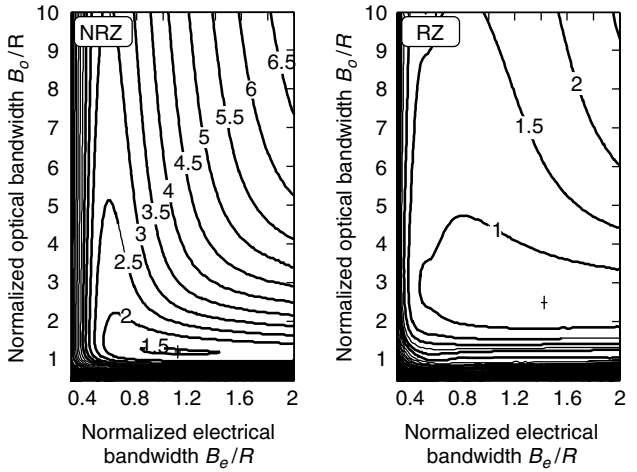

Figure 22. Dependence of receiver sensitivity on optical and electrical filter bandwidths for NRZ-OOK and 33%-duty cycle RZ-OOK. The contours are labelled in terms of dB-penalties relative to the quantum limit [60,61].

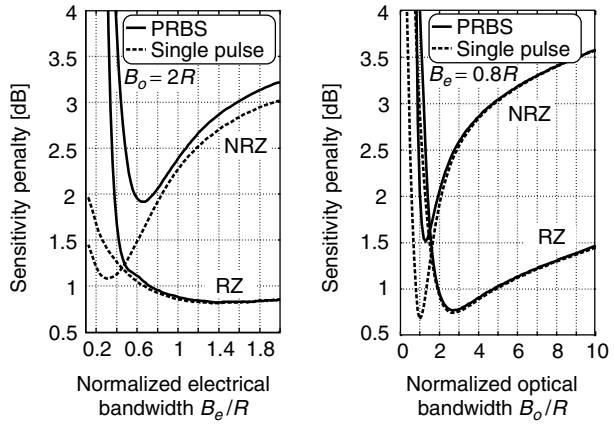

Figure 23. Sensitivity penalty to the quantum limit for NRZ and RZ as a function of electrical filter bandwidth (left) and optical filter bandwidth (right). Solid lines apply to ISI-corrupted detection, while dashed curves represent the ISI-free case [61].

ISI. For RZ, the ISI-free curves and the PRBS-curves run in parallel until well below the optimum bandwidth constellations, indicating that the RZ bandwidth optima are *not* influenced by ISI. For NRZ, however, the two curves depart for $B_e \lesssim 0.8R$ and $B_o \lesssim 1.5R$, which clearly shows that the optimum NRZ-receiver bandwidths are determined by trading ISI against detection noise.

In addition to the above bandwidth considerations, when optimizing operational, cost-effective receivers for WDM systems, one further has to take into account the effects of WDM channel crosstalk, optical source frequency offsets and drifts, filter concatenations effects due to a large number of optical add/drop multiplexers, as well as technological constraints on high-speed receiver bandwidths and receiver imperfections, such as jitter of the sampling phase.

3.8. Required Optical Signal-to-Noise Ratio (OSNR)

Specifying an optical receiver in terms of its *receiver sensitivity* dates back to pre-EDFA times, when the ultimate limit to fiber-optic link distances was given by the lowest possible receive power at which a specified receiver performance could still be guaranteed. With the deployment of in-line optical amplifiers this situation has changed, and optical signals can be transmitted over much longer distances through periodic optical reamplification. Since each amplifier fundamentally introduces ASE according to Eq. (13), it is now the *total* ASE N_{tot} accumulated along the transmission line per polarization mode rather than the received signal power level that sets limits on the maximum transmission distance, and the ability of a receiver to cope with ASE determines its performance in a system.

Figure 24 visualizes the situation of beat-noise limited detection in an in-line amplified transmission system. It shows the receiving end of a transmission line carrying a WDM signal with average per-channel power $\overline{P}_s^{\lambda_i}$, onto which the total ASE accumulated along the line is added. A WDM demultiplexer simultaneously acts to separate the WDM channels and to suppress out-of-band ASE. Comparing Fig. 24 to Fig. 21, we notice equivalence with

$$\overline{P}_s^{\lambda_i} \longleftrightarrow GP_{in} \quad \text{and} \quad N_{ASE} \longleftrightarrow N_{tot} \tag{18}$$

These substitutions are most conveniently captured in the definition of the *optical signal-to-noise ratio* (OSNR) as the ratio of the average optical signal power $\overline{P}_s^{\lambda_i}$ to the (unpolarized) ASE power within some reference bandwidth B_{ref},

$$\text{OSNR} = \frac{\overline{P}_s^{\lambda_i}}{2N_{tot}B_{ref}} \tag{19}$$

The bandwidth B_{ref} is typically (but not exclusively) chosen to be 0.1 nm at a wavelength of 1550 nm, that is, $B_{ref} \approx 12.5$ GHz. Using the relations (18), the OSNR required at a beat-noise limited receiver to attain a certain BER can be directly related to the input sensitivity of a preamplified receiver that is operated with a 'clean' input signal $\overline{P}_{in}$ (more precisely, with an input signal satisfying $GN_{in} \ll N_{ASE}$, where N_{in} denotes the ASE power spectral density at the optical amplifier input). It thus makes sense to also define the *quantum limited OSNR* as the minimum OSNR an ideal beat-noise limited direct detection receiver has to have at its input to produce a certain BER, for example, BER $= 10^{-9}$. The quantum-limited OSNR is then connected to the quantum limit of an optically preamplified receiver by

$$\text{OSNR} = \frac{\overline{n}R}{2B_{ref}}. \tag{20}$$

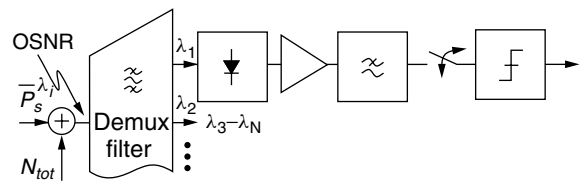

Figure 24. Beat-noise limited detection of optical WDM signals corrupted by noise accumulated along the transmission line through optical in-line amplification.

3.9. Photonic Integrated Receiver

A newly emerging class of optical receivers with a high potential for deployment is called *photonic integrated receiver* [62]. It is basically an optically preamplified receiver *without* optical bandpass filtering, and typically consists of a *pin*-photodiode following an on-chip integrated semiconductor optical amplifier (SOA). This receiver type is used to boost the optical signal power prior to detection to improve upon receiver performance, thus eliminating the need for an external optical preamplifier. Due to the absence of optical filtering, the bandwidth of the ASE generated by the SOA is solely determined by the amplifier's gain bandwidth, letting the ASE-ASE beat noise reach appreciable values. However, depending on the relationship of the ASE-ASE beat noise due to ASE from the SOA to the other receiver noise terms, significant improvements in receiver performance can be achieved. For example, if the signal-ASE beat noise originating from ASE produced along the transmission line is well above the ASE-ASE beat noise produced by the SOA, no receiver degradation will be noticed.

4. SUMMARY

In this article we discussed modulation formats with the potential of being used in high-speed fiber-optic communications. We distinguished between amplitude-modulated and phase-modulated formats, discussed the role of the number of signaling levels, and showed how the optical spectrum can be influenced to achieve high-spectral efficiency. We outlined optical receiver concepts, gave an introduction to their performance evaluation by means of frequently used performance measures, and discussed important receiver design trade-offs.

Acknowledgments
I would like to acknowledge many valuable discussions on modulation formats and receiver design with my present and former colleagues René-Jean Essiambre, Jake Bromage, Alan H. Gnauck, S. Chandrasekhar, Hoon Kim, Herwig Kogelnik, Martin Zirngibl, Klaus H. Kudielka, A. Kalmar, Martin M. Strasser, Martin Pfennigbauer, Martin Pauer, and Walter R. Leeb.

BIOGRAPHY

Peter J. Winzer was born in Vienna, Austria, in 1973. He studied electrical engineering/communications engineering at the Vienna University of Technology, and received his Dipl.-Ing. (M.S.) and Dr.techn. (Ph.D.) degrees in 1996 and 1998, respectively. His work, largely supported by the European Space Agency (ESA), was related to the analysis and modeling of noise in Doppler wind lidar and space-borne optical communication systems. Following his assistant professorship at the Vienna University of Technology, Dr. Winzer joined Bell Laboratories in Holmdel, New Jersey, in 2000, where he has since been working on fiber-optic communications, with an emphasis on Raman amplification, 40-Gbit/s optical transmitter and receiver optimization, and spectrally efficient optical modulation formats. Dr. Winzer has authored and co-authored some 60 papers and holds several patents. His present areas of interest include transmission and reception aspects in both fiber-optic and free-space optical communication systems.

OPTICAL TRANSPORT SYSTEM ENGINEERING

Herndon, Virginia

1. INTRODUCTION

In the time officially deemed as "the information era," we are witnessing the insatiable demand for high information capacity and distance-independent connectivity. Optical networking has been the most efficient solution in satisfying this ongoing demand for bandwidth and connectivity. Optical fiber has been laid down all the way to the curb, building, home, and desk. In general, all optical networks can be considered as part of a global optical network; they are all owned either by private enterprises or by telecommunication carriers.

Several logical parts in a global optical network can be identified, as illustrated in Fig. 1:

- *The core optical network*, which is a long-haul network interconnecting big cities or major communication hubs. Connections between big cities on different continents are made by submarine optical cables. The *core network* is a generic name, but very often we refer to the core network as a wide-area network (WAN) if it belongs to an enterprise, or as the interchange network if it is operated by a telecommunication carrier.
- *The edge optical network*, which covers a smaller geographical area, usually a metropolitan area. Again, we can refer to the edge network either as a metropolitan-area network (MAN) if it belongs to an enterprise, or as a local exchange network if it is operated by telecommunication carriers.
- *The access optical network*, which is the part of the network related to last-mile access and bandwidth distribution to individual end users (in corporate, government, medical, entertainment, scientific, and private sectors). Both the enterprise local-area networks (LANs) and the distribution part of the carrier network connecting the central office with individual users belong to the access network.

The physical network topology that best supports traffic demand is generally different for different parts of a global optical network, as presented in Fig. 1. It could vary between mesh, ring, or star topology. In spite of different network topologies, the main consideration of optical transport engineering is always an optical (lightwave) path, since an optical network is just the means of supporting an end-to-end connection via the lightwave path. Optical transport engineering is related to the physical layer of an optical network, and takes into account the optical signal propagation length, characteristics of optical elements used (fibers, lasers, amplifiers etc.), modulation bit rate, networking impact and transmission requirements.

In this article we will introduce fundamentals of optical transport system engineering. Although an optical signal can take on either a digital or an analog form, our focus will be on digital signals, since the majority of modern applications are related to digital signal transmission.

2. OPTICAL TRANSMISSION PARAMETERS

The simplest optical transmission system is a point-to-point connection on a single optical wavelength, which propagates through an optical fiber. An upgrade to this is the deployment of WDM (wavelength-division multiplex) technology, where multiple optical wavelengths are

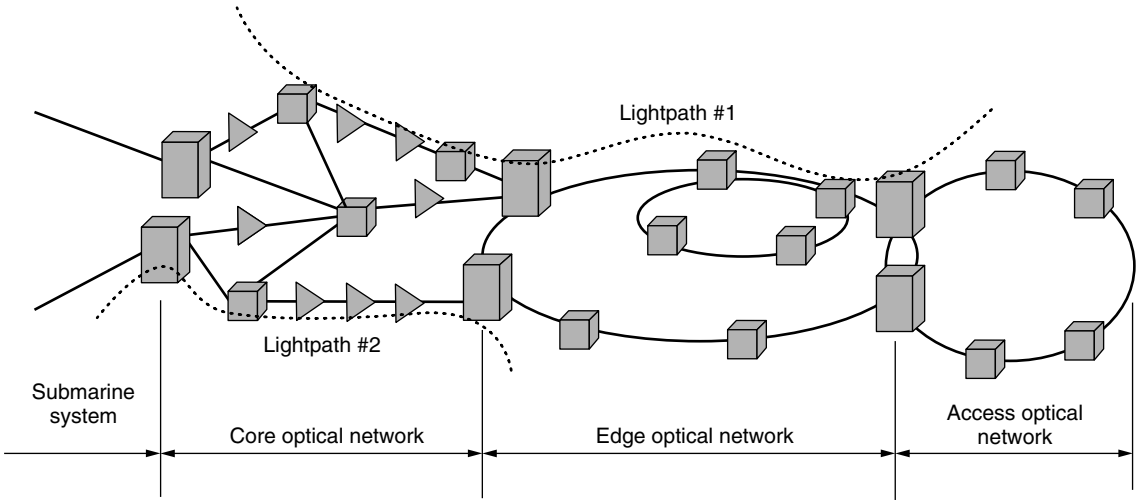

Figure 1. Optical networking structure.

combined to travel over the same physical path. WDM technology originally served to increase the bandwidth of already installed fiber, but it has quickly become the foundation of optical networking by combining optical signal transport over arbitrary distances with wavelength routing and optical protection.

The general scheme of an optical transport system is shown in Fig. 2. Several optical channels, carrying independent modulation signals, have been multiplexed by WDM technology, and sent to the optical fiber line. The aggregated signal is then transported over some distance before it is demultiplexed and detected (converted back to an electrical level). The optical signal transmission path can include a number of optical amplifiers, crossconnects, and optical add/drop multiplexers. The illustrated set of parameters, related either to enabling technologies or to transmission and networking issues, can be attached to Fig. 2.

Providing stable and reliable operation of an optical transport system over time requires proper design and engineering. Optical transport systems engineering involves accounting for all effects that can alter an optical signal on its way from the source (laser) on through photodetection by photodiode, and then to the threshold decision point. Different impairments will degrade and compromise the integrity of the signal before it arrives to the decision point to be recovered from corruptive additives (noise, crosstalk, and interference). The transmission quality is measured by the received signal-to-noise-ratio (SNR), which is defined as the ratio of the signal level to the noise level at the threshold point. The other parameter used to measure signal quality is the bit error rate (BER). BER is interrelated with SNR and defines the probability that a signal space (or a logic 0) will be mistaken for a signal mark (a logic 1), and vice versa. The main goal in optical signal transport is to achieve the required BER between end-to-end users, or between two specified points. Evaluating the BER requires determining the received signal level at the threshold point, calculating the noise power, and quantifying and including the influence of various relevant impairments.

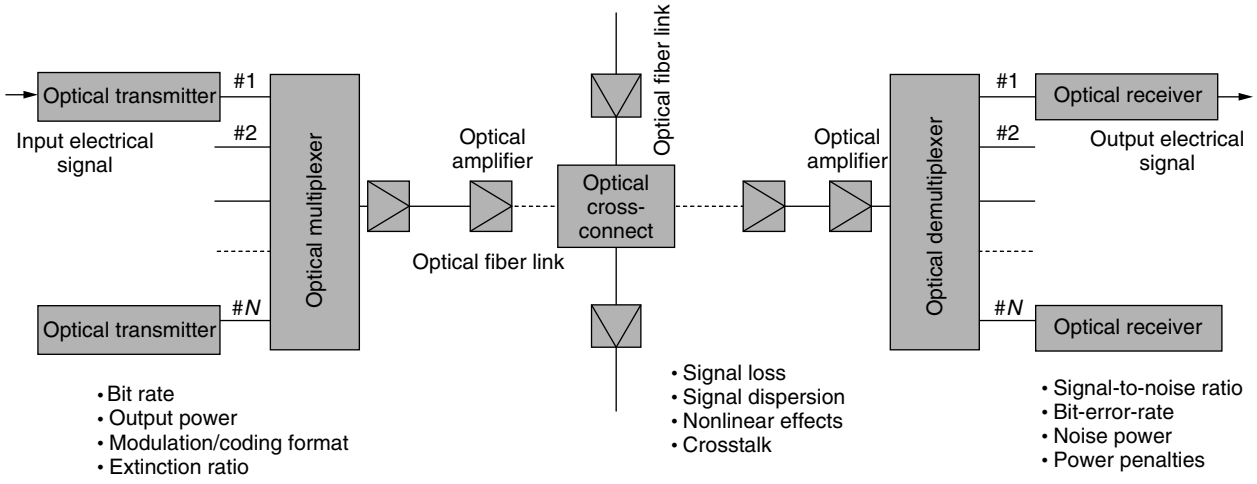

Figure 2. Optical DWDM system.

2.1. Optical Signal Path

The end-to-end signal path from Fig. 1 includes both the electrical and optical path portions. Conversion from the electrical to the optical level is done in the optical transmitter, while conversion from the optical level to an electrical signal takes place in the optical receiver. The key elements on an optical signal path are

1. *Semiconductor lasers* that convert an electrical signal to optical radiation. The bias current flows through the laser p-n junction and stimulates the recombination of electrons and holes, producing photons. If the current is higher than a certain threshold, recombination occurs in an organized way, with strong correlation in phase, frequency, and direction of radiated photons that form the output optical signal (called "stimulated emission of radiation.") Semiconductor lasers could either be directly modulated by an electrical signal or simply biased by a DC voltage and operate in combination with an external optical modulator. Each laser generates a specified optical wavelength, but some spectral linewidth is associated with the generated optical signal as well. These lasers are known as single-mode lasers (SMLs), characterized by a distinguished single longitudinal mode in the optical spectrum. If a set of separated longitudinal modes can be recognized under the optical spectrum envelope, the lasers are called *multimode lasers* (MMLs).
2. *Optical fibers* that transport an optical signal to its destination. The combination of low signal loss and extremely wide transmission bandwidth allows high-speed optical signals to be transmitted over long distances before regeneration becomes necessary. There are two groups of optical fibers. The first group, called *multimode optical fibers*, transfer light through multiple spatial or transversal modes. Each mode, defined through a specified combination of electric and magnetic field components, occupies a different cross-sectional area of the optical fiber core, and takes a slightly distinguished path along the optical fiber. The difference in mode pathlengths causes a difference in arrival times at the receiving point. This phenomenon is known as multimode dispersion and causes signal distortion and limitations in transmission bandwidth. The second group of optical fibers effectively eliminates multimode dispersion by limiting the number of modes to just one through a much smaller core diameter. These fibers, called *single-mode optical fibers*, do however introduce another signal impairment known as *chromatic dispersion*. Chromatic dispersion is caused by a difference in velocities among different wavelength components within the same pulse. There are several methods to minimize chromatic dispersion at a specified wavelength, involving either the introduction of new single-mode optical fibers, or the utilization of different dispersion compensation methods.
3. *Optical amplifiers* that amplify weak incoming optical signals through the process of stimulated emission, without conversion back to the electrical level. Optical amplifiers should provide enough gain to amplify a specified number of optical channels. There are different types of optical amplifiers currently in use, such as semiconductor optical amplifiers (SOAs), erbium-doped fiber amplifiers (EDFAs), or Raman amplifiers. Amplifier parameters are gain, gain flatness over amplification bandwidth, output power, bandwidth, and noise power. The noise generated in an optical amplifier occurs due to a spontaneous emission process that is not correlated with the signal. All amplifiers degrade the SNR of the output signal because of amplified spontaneous emission (ASE) that adds itself to the signal during its amplification. SNR degradation is measured by the noise figure. Optical amplifiers can take several positions along the optical path, as indicated in Fig. 2. The output power could be enhanced by a booster amplifier within a transmitter, on the transmission line (inline amplifier), or before the receiver (to act as a preamplifier to increase the receiver sensitivity).
4. *Photodiodes* that convert an incoming optical signal back to the electrical level through a process just opposite to the one that takes place in lasers. Photodiodes can be classified into PIN or avalanche photodiodes (APD). The process within the PIN photodiodes is characterized by *quantum efficiency*, which is the probability that each photon will generate an electron–hole pair. In the avalanche photodiode each primary electron–hole pair is accelerated in a strong electric field, which can cause the generation of several secondary electron-hole pairs through the effect of impact ionization. This process is random in nature and avalanchelike.

A more elaborate analysis of advanced optical transport systems can be found in the bibliography [1–4].

2.2. Optical Signal Parameters

There are a set of parameters along the lightwave path that determines the received signal power:

- *Output power* from the laser/modulator coupled to the fiber pigtail. Optical power is defined per individual wavelength and depends on the lasers/modulators used. The output optical power is usually expressed in decibels per milliwatt (dB_m), defined as $dB_m = 10\log(P)$, where the output power P is expressed in milliwatts.
- *The extinction ratio*, which is the ratio between the optical power related to a logic 1 (mark) to the power related to a logic 0 (space). By increasing the extinction ratio, the signal to noise ratio is increased as well, but at the cost of additional penalties in the modulation speed and laser chirp.
- *Optical amplifier gain*, which determines the level of an optical signal that is being amplified. Optical amplifier gain is correlated to noise parameters,

which means that higher gain will generate more noise and vice versa.

- *Photodiode responsivity*, which defines the ratio between the number of electrical carriers produced and the number of incoming photons.

2.3. Noise Parameters

The total noise under consideration in optical transport system engineering is generated along the lightwave path and during the photodetection process. There are some additive noise components (the noise components remaining even if the signal is not present), and some multiplicative noise components (which are produced only if the signal is present). The additive noise components are

- *Dark-current noise* generated in photodiodes due to the thermal process.
- *Amplified spontaneous emission* (ASE) noise generated by any optical amplifier along the lightwave path.
- *Crosstalk*, which occurs in multichannel systems. Components introducing crosstalk in WDM systems are optical filters, optical multiplexers and demultiplexers, optical switches, semiconductor optical amplifiers, and optical fibers through nonlinearities. Crosstalk can either be intrachannel (occurs when another signal of the same wavelength interferes with the signal in question), or interchannel (occurs when some portion of a neighboring channel has been spread out, and detected by the specified signal's receiver).
- *Thermal noise*, which is created in the resistive part of the input impedance of an electrical preamplifier that follows the photodiode. The noise created in the electronic amplification stages following the preamplification process is thermal noise in nature as well.

The multiplicative noise components are

- *Avalanche shot noise*, caused by the random nature of the amplification of primary electron–hole pairs through the effect of impact ionization in avalanche photodiodes.
- *Laser intensity noise*, which occurs as a result of microvariations in the laser output power intensity. This noise is characterized through the relative intensity noise (RIN) parameter, and is more relevant for analog transmission systems.
- *Laser phase noise*, which is related to microvariations in phase of generated photons. The output optical signal, as a collection of individual photons, exhibits finite nonzero spectral width.
- *Modal noise*, which arises in multimode fibers through the random process of excitation of transversal modes.

2.4. Impairment Parameters

Impairment parameters relevant to optical transport system engineering are either optical power related or optical wavelength related. They can also be constant or time-dependent. Each of them results in a *signal power penalty*, which means that a higher signal power is required at the receiver to keep the BER at a level that would exist if the impairment were negligible.

Optical power-related impairments are

- *Optical fiber attenuation*, or fiber loss, which is the ratio between the output and input optical power at the defined optical fiber section. Optical attenuation is characterized by an attenuation coefficient α, usually expressed in decibels per kilometer. The decibel is defined as $\mathrm{dB} = 10\log(P_2/P_1)$, where P_2 and P_1 are the output and input power respectively.
- *Insertion losses* in different optical components along the lightwave path, such as optical connectors, optical splices, optical couplers, optical multiplexers, and optical filters. These losses are sometimes added to the optical fiber loss and are considered together.

Impairments that are optical power related, but are also functions of time are

- *Polarization mode dispersion* (PMD), a stochastic process that appears in real fibers, caused by variations in the shape of their core along the fiber length. The light in an optical fiber can be considered as a superposition of two polarized components. If they travel at the same speed, no polarization dispersion occurs, but if they travel at different speeds, as in real fibers, the light will separate into its faster and slower components, leading to a difference in propagation of the two polarization states and to pulse spreading. Both mechanical stresses and temperature effects contribute to PMD.
- *Polarization-dependent loss* (PDL), which is similar in nature to PMD, but this time the difference between polarization states is in transmission losses, rather than in arrival times. These differential losses accumulate in the system, since there might be many components having polarization-dependent loss. Since polarization fluctuates with time, the SNR at the end of the lightwave path will fluctuate as well, causing a power penalty.

Impairments that are dependent on both the optical power and optical wavelengths are

- *Four-wave mixing* (FWM), a nonlinear effect where a new optical frequency is generated when three frequencies mutually interact. It causes crosstalk noise in channels, since the newly generated optical frequency might coincide with one of the original channels.
- *Stimulated Raman scattering* (SRS), a nonlinear effect that occurs when a propagating optical power interacts with glass molecules in the fiber undergoing a wavelength shift. The result is a power transfer from one wavelength to another, which causes crosstalk between channels.

Impairments that are dependent on optical wavelength, but are also functions of time are

- *Chromatic dispersion* caused by the dependence of the fiber refractive index on the wavelength. Since a laser is not an ideal monochromatic source, each pulse in its time domain contains different spectral components that travel at different velocities through an optical fiber. Chromatic dispersion induces pulse broadening when the neighboring pulses cross their allotted time slot borders, which can severely limit system transmission rates. Chromatic dispersion is also a cumulative effect that increases with optical fiber length.
- *Laser chirp*, which is the modulation of optical frequency (or wavelength) when the optical signal, is intensity-modulated by a specific electrical waveform. The change in the frequency causes laser spectral linewidth broadening and, in the interaction with chromatic dispersion, leads to optical pulse distortion and the intersymbol interference effect [see Eq. (4)]. Chirp can be reduced by decreasing the extinction ratio, but this decrease would introduce additional power penalties, requiring some compromise [5].

Finally, there are some impairments that are dependent on both the optical power and optical wavelength, and are also functions of time:

- *Stimulated Brillouin scattering* (SBS), a nonlinear effect that occurs when a high optical power reflects off the grating formed by acoustic vibrations, downshifts in optical frequency, and comes back. The SBS can cause signal attenuation if the launched power is higher than a certain threshold. Optical signal dithering with low frequencies helps to increase the SBS threshold and effectively suppress SBS effect.
- *The self-phase modulation* (SPM) *effect*, which results from the fact that a higher fiber refractive index causes wavelengths at the center of the pulse to accumulate phase more quickly than at the wings. This stretches the wavelengths at the leading edge (called "red shift") of the pulse and compresses wavelengths at the trailing edge ("blue shift"). This phase modulation effect broadens the spectrum, which causes pulse spreading. If combined with positive dispersion in the optical fiber under controlled conditions, it can lead to suppression of the chromatic dispersion effect. This is the basis for soliton transmission, where return-to-zero (RZ) soliton pulses propagate over very long distances without optoelectronic regeneration.
- *Cross-phase modulation* (XPM), which has the same nature as SPM, occurs following the interaction between multiple optical frequencies.

3. ASSESSMENT OF THE OPTICAL TRANSPORT LIMITATIONS AND PENALTIES

3.1. Attenuation

A silica-based optical fiber is the central point of an optical signal transmission, offering wider available bandwidth, lower signal attenuation, and smaller signal distortion than other wired physical media. The output power P_2 from an optical fiber can be calculated from the input power P_1 and the optical attenuation coefficient α. For the lightwave path with length L, $P_2 = P_1 \exp(-\alpha L)$. If parameters P_2, P_1, and α are expressed in decibels, then the relation becomes $P_2 = P_1 - \alpha L$.

Four low-attenuation bands can be recognized within the usable optical bandwidth of silica-based optical fibers. They are usually referred as U, S, C, and L bands, although this nomenclature is not standardized yet. The C band occupies wavelengths from 1530 to 1560 nm, while the L band includes wavelengths between 1580 and 1610 nm. Both these bands have been considered as the most suitable bands for high-channel-count WDM transmission. The S band (sometimes called the S+ band) and U band (sometimes referred to as the S− band) cover shorter wavelengths down to approximately 1230 nm, where optical fiber attenuation is slightly higher than in the wavelength region covered by the C and L bands.

3.2. Noise

Detected photocurrent is the sum of signal and noise contributions after the photodetection process has taken place. It can be expressed as $I_p = I + i_s + i_{\text{th}}$, where I is the signal current calculated as a product of incoming optical power P and photodiode responsivity R (R is expressed in amperes per watt). Noise components, expressed by currents $i_s + i_{\text{th}}$, correspond to the quantum (shot) and thermal noise, respectively. The power of the total noise that appears after photodetection is equal to the product of the sum of noise spectral density components and the noise electric bandwidth Δf. In the case where direct detection without optical preamplification takes place, the total noise power can be expressed as

$$\langle i^2 \rangle_{tot} = \left[2qM^2F(M)I + \frac{4kT}{R_L} \right] \Delta f \tag{1}$$

where the first term in brackets describes the quantum noise, while the second is related to the thermal noise generated at a load resistance R_L. In the previous equation q represents the electron charge ($q = 1.6 \times 10^{-19}$ C), M is the avalanche amplification factor, $F(M)$ is the avalanche excess noise factor, k is Boltzmann's constant ($k = 1.38 \times 10^{-23}$ J/K), and T is absolute temperature in kelvins. If the PIN photodiode is used, the factor $M^2F(M)$ becomes unity.

In case an optical amplifier precedes the photodiode the major noise contribution comes from ASE noise. The spectral density of ASE noise is

$$S_{\text{sp}} = \frac{(G-1)N_f h\nu}{2} \tag{2}$$

where G is amplifier gain, N_f is the amplifier noise figure, h is Planck's constant ($h = 6.63 \times 10^{-34}$ J/Hz), and ν is optical frequency in hertz. The total noise power in this case becomes

$$\langle i^2 \rangle_{\text{tot}} = 2qR[GP + S_{\text{sp}}B_{\text{op}}]\Delta f + 4R^2 \text{GPS}_{\text{sp}}\Delta f + 2R^2 S_{\text{sp}}^2 [2B_{\text{op}} - \Delta f]\Delta f + \frac{4kT}{R_L}\Delta f \tag{3}$$

Parameter B_{op} refers to the optical filter bandwidth. A standard deviation $\sigma = [\langle i^2 \rangle_{tot}]^{1/2}$ is usually used in signal-to-noise ratio and bit-error-rate calculations [see Eq. (12)].

3.3. Chromatic Dispersion

Recall that chromatic dispersion is the cause of pulse spreading and the occurrence of intersymbol interference. Pulse spreading is proportional to the fiber dispersion parameter D, expressed in picoseconds per nanometer and kilometer (ps/nm.km). The dispersion parameter is an ascending linearlike, wavelength-dependent function, characterized by its zero value cross-point and a dispersion slope. There are several fiber types that differ in their dispersion parameter profile [6]:

- *Standard single-mode fibers* (SMFs), where the parameter D has zero value at the 1310 nm wavelength and the dispersion slope of approximately 0.072 ps/km.nm^2. With this, the chromatic dispersion parameter reaches the value of 17–20 ps/nm.km in the wavelength region belonging to C and L bands.
- *Dispersion-shifted fiber* (DSF), where the parameter D has zero value at the 1550 nm wavelength and the dispersion slope of approximately 0.09 ps/km.nm^2. The chromatic dispersion parameter can take on both negative and positive values in the wavelength region belonging to C and L bands. This fiber type has been good for single-wavelength transmission, but is not suitable for WDM applications because of high penalties due to nonlinear effects.
- *Non-zero dispersion-shifted fibers* (NZDSF), where the parameter D has zero value shifted from the 1550 nm wavelength and the dispersion slope of approximately 0.03 ps/km.nm^2. The chromatic dispersion parameter has some minimal value in the wavelength region belonging to C and L bands, thus minimizing penalties due to nonlinear effects.

The influence of chromatic dispersion and the penalties related to it can be evaluated by assuming that the pulse spreading due to dispersion should be less than a fraction δ of the bit period T. For a 1-dB power penalty, $\delta = 0.306$; for a 2-dB penalty, $\delta = 0.491$. For a signal having a bit rate $B = 1/T$ and spectral linewidth $\Delta\lambda$, and transmitted over a distance L, this condition can be expressed as

$$\begin{aligned} \Delta\lambda |D| LB &< \delta \qquad \text{for direct modulation} \\ B\lambda [|D| L/2\pi c]^{1/2} &< \delta \qquad \text{for an external modulation} \end{aligned} \tag{4}$$

The influence of chromatic dispersion is a critical factor for higher bit rates and longer distances and should be suppressed by a proper dispersion compensation scheme. The dispersion compensation process is based on the following observation. While in single-mode optical fiber longer wavelengths impose more delay than shorter wavelengths, the dispersion compensating modules do just the opposite. As a result, signal delays over a specified wavelength band have been equalized. As for dispersion compensating modules, using dispersion compensation fibers (DCFs) with a negative dispersion coefficient is the most common method for dispersion compensation. Since there is an insertion loss introduced by DCF, the figure of merit, defined as the ratio of the absolute amount of dispersion divided by the insertion loss, is used to characterize DCF. Generally it is good if the figure of merit is better than 150 ps/nm/dB.

Optical fiber Bragg gratings can be used for chromatic dispersion compensation as well. The grating reflects different wavelengths at different points along its length, introducing different delays at different wavelengths. Delay introduced by the length of 10 cm is approximately 100 ps. Dispersion is inversely proportional to the bandwidth; that is, a large dispersion occurs over smaller bandwidth and vice versa. For example, 1000 ps/nm occurs over a 1 nm bandwidth, while 100 ps/nm occurs over a 10 nm bandwidth. Future applications, however, will require adaptive dispersion compensation modules that allow for adjustment of both the dispersion compensation value and the dispersion slope.

3.4. Polarization Mode Dispersion

Polarization mode dispersion (PMD) is characterized by two coefficients, D_{p1} and D_{p2}, reflecting so-called "first- and second-order" polarization mode dispersion, respectively. The extent of pulse broadening D_t is governed by the following relation:

$$D_t = D_{p1} L^{1/2} + D_{p2} L \tag{5}$$

where the coefficient D_{p1} presents the average differential group delay (DGD) between the two orthogonal states of polarization over length L, while D_{p2} measures the wavelength dependence of PMD. The contribution of D_{p2} is much smaller than the contribution of D_{p1}, and very often just the first term in Eq. (5) is considered. The value of the coefficient D_{p1} can vary from 0.01 ps/km$^{1/2}$ for new optical fibers to over 1 ps/km$^{1/2}$ for older fibers.

PMD is a stochastic process described by the Maxwellian distribution, which complicates the process of its control and compensation. The probability that actual delay will be 3 times larger than the average delay calculated by Eq. (5) is 4×10^{-5}. This is why we correlate the average delay expressed by Eq. (5) to the actual delay equal to three times the average delay. For differential delay equal to $0.3T$, the power penalty due to PMD will be less than 1 dB.

3.5. Nonlinear Effects

Nonlinear effects in an optical fiber are neither design nor manufacturing defects, but can occur regardless and can cause severe transmission impairments (unexpected loss and interference in the network). On the other hand, in some cases, they may be used to improve transmission characteristics (such as in soliton transmission).

Nonlinear effects are cumulative in nature and proportional to the lightwave pathlength L. Since signal power decreases with increasing lightwave pathlength, an effective length L_{eff} has been introduced to help with calculations. The effective length is defined as

$$L_{eff} = \frac{1 - \exp(-\alpha l)}{\alpha} M \tag{6}$$

where M is the number of fiber spans, each of length l. (Recall that one span is the distance between two amplifiers, therefore $l = L/M$.) In the wavelength region around 1.55 μm, and for links where $L > 1/\alpha$, L_{eff} is ~20 km (α is ~0.046 km^{-1}, or 0.2 dB/km). From the previous relation, it is clear that the effective length can be reduced by increasing the span length and by decreasing the number of amplifiers on the line. But what matters most is the product of the power launched from the amplifier, P, and the effective length L_{eff}. If amplifier spacing is increased, the launched power needs to be increased as well to compensate for additional fiber losses. This increase will be exponential: $P = \exp(\alpha l)$. Since the product increases with span length l, reducing the amplifier spacing can reduce the effect of nonlinearities.

The effects of nonlinearity are inversely proportional to the area of the fiber core. It is convenient to use an effective core area A_{eff} since the power is not uniformly distributed within the core section. This effective area is about 50 μm for a single-mode fiber with a core diameter of 8 μm, but for a dispersion compensating fiber (DCF) it is smaller (thus DCF tends to exhibit higher nonlinearities).

Nonlinear effects can be divided into two categories: the effects due to variations in the fiber refractive index, and the effects due to light scattering. Agraval has given a more detailed explanation of nonlinear effects [7].

Variations in the refractive index at high signal power are at the root of nonlinear effects classified as refractive-index phenomena: self-phase modulation (SPM), cross-phase modulation (XPM), and four-wave mixing (FWM). At low optical powers, an optical fiber's refractive index n is pretty constant [i.e., it is $n = n_1(\lambda)$ for specified wavelength λ]. Higher optical powers, however, cause a refractive index change as follows:

$$n(\lambda, E) = n_1(\lambda) + \frac{n_2 P}{A_{\text{eff}}} \tag{7}$$

where n_2 is the nonlinear refractive index ($n_2 \sim 3 \times 10^{-8}$ μm^2/W), and P is the optical signal power. Both SPM and XPM affect the optical signal phase in proportion to the nonlinear part of the refractive index and generate spectral broadening. Spectral broadening, in combination with chromatic dispersion, will contribute to signal distortion.

In *four-wave mixing* (FWM), new optical frequencies $\nu_{ijk} = \nu_i + \nu_j - \nu_k$ are generated whenever three wavelengths with frequencies ν_I, ν_j, and ν_k propagate through the fiber. The power of a resultant new wave is calculated as presented by Shibata et al. [8]

$$P_{ijk} = \frac{\alpha^2}{\alpha^2 + \Delta\beta^2}\left[1 + \frac{4\exp(-\alpha l)\sin^2(\Delta\beta l/2)}{[1 - \exp(-\alpha l)]}\right] \times \left(\frac{2\pi \nu_{ijk} n_2 d_{ijk}}{3cA_{\text{eff}}}\right)^2 P_i P_j P_k L_{\text{eff}}^2 \tag{8}$$

where $P_{ijk}(i, j, k = 1 \cdots N)$ is the power of the generated wave, n_2 is the nonlinear refractive index, and d_{ijk} is the so-called "degeneracy" factor. The value $\Delta\beta = \beta_i + \beta_j - \beta_k - \beta_{ijk}$ defines a phase condition or relationship among the propagation constants of the optical waves involved (a propagation constant is defined as $\beta = 2\pi n\lambda/c$, where n is the refractive index, λ is the wavelength, and c is the speed of light in a vacuum).

The total crosstalk due to FWM in a given channel is the sum of all generated waves according to Eq. (8) and can be analyzed as interchannel crosstalk [see Eq. (17)]. To alleviate the penalty introduced by FWM, the following measures could be taken: using unequal channel spacing, increasing channel spacing, using dispersion, or reducing the power of interacting channels. The most effective means is to use some amount of dispersion; this clarifies the need to shift the zero dispersion point from the 1550-nm-wavelength region.

Nonlinear effects that occur due to light scattering include *simulated Raman scattering* (SRS) and *stimulated Brillouin scattering* (SBS). For SBS, the acoustic phonons are involved in an interaction that occurs over a very narrow linewidth $\Delta\nu_{\text{SBS}}$($\Delta\nu_{\text{SBS}} = 20$ MHz at 1.55 μm). There is no such interaction if channel spacing is greater than 20 MHz. The SBS process depletes the signal and creates a strong backward signal if the incident power per channel is higher than some threshold value P_{th} expressed as

$$P_{\text{th}} = \frac{21 b A_{\text{eff}}}{g_B L_{\text{eff}}}\left(1 + \frac{\Delta\nu_L}{\Delta\nu_{\text{SBS}}}\right) \tag{9}$$

where g_B is the SBS gain coefficient equal to approximately 4×10^{-11} m/W, $\Delta\nu_L$ is the laser linewidth, while parameter b takes on a value between 1 and 2 depending on relative polarization of pump and Stokes waves. The worst case leads to $P_{\text{th}} \sim 1.3$ mW, since $\Delta\nu_L$ is approximately 20 MHz. The SBS penalty can be reduced by either keeping the power per channel below the SBS threshold or broadening the linewidth of the source using signal dithering. This method is commonly deployed in high-bit-rate systems.

Stimulated Raman scattering is a broadband effect, and its gain coefficient is a function of wavelength spacing. The gain coefficient peak is $g_R \sim 6 \times 10^{-14}$ m/W, which is much smaller than the gain coefficient peak for SBS. Channels up to 125 nm apart will be coupled by SRS, possibly in both directions. SRS coupling occurs only if both channels are at a logic 1 at that moment. The fraction of the power leaking from a particular channel to all other channels is given by

$$P_{\text{SRS}} = \frac{g_R \Delta\lambda_s P L_{\text{eff}} N(N-1)}{4\Delta\lambda_c A_{\text{eff}}} \tag{10}$$

where $\Delta\lambda_s \sim 125$ nm, $\Delta\lambda_c$ is the optical channel spacing, P is the power per channel, and N is the number of channels [7]. The SRS effect is reduced by dispersion, since different channels travel with different velocities and the probability of an overlap between pulses at different wavelengths is reduced. The penalty introduced by SRS can be alleviated by proper channels spacing and/or postequalization of optical channel powers. Some special techniques, such as polarization interleaving between the neighboring optical channels, can help as well.

4. OPTICAL TRANSPORT SYSTEM ENGINEERING

4.1. BER, Signal-to-Noise Ratio, and the *Q* Factor

The bit error rate (BER) is the most important parameter for measuring a digital signal transmission quality. It is

defined as

$$\text{BER}\,(Q) = \frac{1}{2\pi}\int_{Q}^{\infty} e^{-y^2/2}\,dy \approx \frac{1}{Q\sqrt{2\pi}} e^{-Q^2/2} \tag{11}$$

The so-called Q factor, introduced above, corresponds to the electrical signal-to-noise ratio:

$$Q = \frac{R(P_1 - P_0)}{\sigma_1 + \sigma_0} = \text{SNR} \tag{12}$$

where P_0 is the optical power during a "space bit," P_1 is the optical output power during a "mark bit," R is the responsivity of the photodiode, while σ_1 and σ_0 are standard deviations of the noise current during the 1 and 0 bits, respectively. The following practical values are mutually related: $\text{BER} = 10^{-15}$ with $Q = 8$, $\text{BER} = 10^{-12}$ with $Q = 7$, and $\text{BER} = 10^{-9}$ with $Q = 6$. In optical transport systems with cascades of optical amplifiers along the lightwave path, the following important relation between the Q factor and an optical signal-to-noise ratio can be established:

$$\text{OSNR} = \frac{P_1 + P_0}{4S_{\text{sp}}B_{\text{opt}}} \approx \frac{2Q^2\Delta f}{B_{\text{op}}} \tag{13}$$

Equations (12) and (13) are the basic ones since the impact of various impairments is not included.

4.2. Power Penalty Handling

If there are impairments involved, signal, noise-related values will be Q', P_0', P_1', σ_1', and σ_0', rather than Q, P_0, P_1, σ_1 and σ_0 respectively. Each impairment will contribute to a power penalty to the transport system. The total optical power penalty can be calculated as

$$\Delta P = -10\log\left(\frac{Q'}{Q}\right) \tag{14}$$

The biggest contribution to the total power penalty comes from the nonideal extinction ratio, imperfect dispersion compensation, nonlinear effects, and crosstalk:

- The power penalty due to a nonfinite extinction ratio r, defined as $r = P_1/P_0$, can be calculated in decibels as
$$\Delta P_{\text{ER}} = 10\log\left[\frac{r+1}{r-1}\right] \tag{15}$$
- The power penalty due intrachannel crosstalk involving N interfering signals is
$$\Delta P_{\text{intra}} = C\log\left(1 - 2\sum_{i=1}^{N}\sqrt{\delta_i}\right) \tag{16}$$
where the coefficient C takes on the value 10 for direct detection, and the value 5 forAPD/preamp detection, while δ_i is the crosstalk portion divided by the power of specified channel signal. If we allow a 1-dB crosstalk penalty, then the intrachannel crosstalk level should be just 1%, or 20 dB, below the specified channel signal.
- The power penalty due interchannel crosstalk involving N interfering signals is
$$\Delta P_{\text{inter}} = C\log\left(1 - \sum_{i=1}^{N}\delta_i\right) \tag{17}$$
with the same coefficient C as in relation (17). If we allow a 1-dB crosstalk penalty, then the intrachannel crosstalk level should be 13.5 dB below the desired signal. A more thorough treatment of crosstalk can be found in the article by Zhou et al. [9].
- As for power penalties due to imperfect dispersion compensation or nonlinear effects (FWM and SRS), Eq. (17) can be applied. The portion δ for a particular case can be calculated by Eqs. (4), (8), and (10).

4.3. Noise Accumulation

Recall that in an optical transport system a lightpath contains a number of optical amplifiers spaced l km apart. The length l defines the span length. If fiber attenuation is α, the span loss between two amplifiers is $\alpha_{\text{span}} = \exp(-\alpha l)$. Each optical amplifier amplifies an incoming optical signal to compensate for the loss at the previous span. At the same time, however, it generates some spontaneous emission noise. Both the signal and the spontaneous emission noise are then amplified by the following optical amplifiers.

If the gain G of an optical amplifier is larger than the span loss α_{span} the signal power will increase gradually throughout the amplifier chain. However, the output power from an optical amplifier is physically limited to a saturated value P_{sat}, which means that as input power increases the amplifier gain drops. Consequently, after some number of spans, amplifiers will enter into the saturation regime and the total gain will drop from its initial value G to a saturated value G_{sat}. Further along the lightwave path, a spatial steady-state condition will be reached, in which both the saturated output power P_{sat} and the gain G_{sat} remain the same from span to span. If there are N optical channels, the saturated output power will be equally divided among them. Therefore, the output power per channel will be $P_{\text{out}} = P_{\text{sat}}/N$.

The OSNR gradually decreases along the chain, since the accumulated ASE noise gradually makes up a more significant portion of the limited total power from an amplifier. The steady-state gain will be slightly smaller than the span loss, due to added noise at each amplifier point. Thus, the best engineering approach is to choose a saturated gain that is very close to the span loss. If we prescribe the OSNR for a lightwave path with total length L, and M amplifiers on the line ($M = L/l$), the following relation can be established:

$$\text{OSNR} = P_{\text{out}} - \alpha l - \Delta P - 10\log(M) - 10\log(F_n h\nu B_{\text{op}}) \tag{18}$$

where all except the last two terms are expressed in decibels. If we did not need to worry about impairments, we would neglect the power penalty term and either maximize

the power or decrease the span length to increase the OSNR in Eq. (18). However, the story is different when impairments cannot be neglected, since a power margin equal to ΔP needs to be allocated in advance to compensate for impairment power penalties.

5. OPTICAL TRANSPORT ENABLING TECHNOLOGIES AND TRADEOFFS

5.1. Enabling Technologies

Enabling technologies will continue to provide the means of increasing both transmission capacity and lightwave pathlength. There is a number of enabling technologies that are helpful in resolving the before-mentioned issues in optical transport systems, and in approaching a transmission capacity predicted by Mecozzi and Shtaif [10]. These include optical amplifiers, forward error correction, advanced coding techniques, and advanced dispersion compensators.

Optical amplifiers should provide enough gain for a specified number of optical channels, which suggests that an aggregate optical power should be >22 dB for systems with more than 100 optical channels. Next, the noise figure should approach its theoretical value of 3 dB. In addition, the gain profile should be equalized along the entire wavelength band, and this gain equalization should be dynamically adjustable.

Fiber doped optical amplifiers, such as erbium-doped fiber amplifiers (EDFAs) and thulium-doped fiber amplifiers (TDFAs) can serve to cover the entire low-loss optical fiber bandwidth. In addition, Raman amplifiers can be used to cover a wide range of wavelengths as well. The Raman based amplification is a newer technology based on the SRS nonlinear effect. In the Raman amplifier, the pump light is launched into the fiber at inline amplifier sites (or optical receiver sites), opposite the signal direction. As a result, the forward-propagating optical signals get some energy, and a low-noise preamplifier has been created. By combining several pumps, a fairly flat gain profile over a wide range of optical wavelengths can be achieved.

Advanced dispersion-compensating techniques are necessary to take full advantage of the improved optical amplifiers. First, the chromatic dispersion-compensating device (DCM) should not only incorporate dispersion compensation ability but slope compensation as well. Secondly, polarization mode dispersion compensation will be needed more often, but an efficient PMD compensator still needs to be introduced.

Forward error correction (FEC) is needed to push systems reach even further in future optical transport networks. For now, so-called Reed–Solomon 239–255 coding scheme remains widely used, but some other coding methods have been introduced as well. The final result of FEC application is BER enhancement for a lower signal-to-noise ratio.

Advanced modulation/transmission methods are emerging for use in high-speed optical transport systems. Some of them are

- *Solitons* or return-to-zero distortionless pulses, where spectral disorder at the trailing and leading edges that occurs due to self-phase modulation is corrected by another disorder caused by chromatic dispersion. The technique has shown very promising results when used in combination with fibers having a "prescribed dispersion map."
- *Advanced coding*, such as duobinary coding, where special filtering reduces the spectral width. Thus, the slowest and the fastest components are eliminated; the rest is more resistive to chromatic dispersion influence.
- *Coherent detection* where the weak input optical signal is mixed with a much stronger signal from the local laser. With this method the signal current takes on the value $I = 2RP_sP_{\mathrm{LO}}\cos[|\omega_s - \omega_L|t + \phi(t)]$, where R, P_s, and P_{LO} relate to receiver responsivity, incoming optical power, and local laser power, respectively. Because of P_{LO} contribution, the coherent receiver sensitivity is considerably enhanced. The detection process can either be heterodyne or homodyne. In the heterodyne detection scheme, the incoming optical signal frequency ω_s and the frequency ω_L of the local laser are slightly different, while in homodyne detection scheme both the optical frequencies and the phases of the signal and the local laser are completely matched. The demodulation process applied to the signal current depends on the modulation format of the incoming optical signal; this format could be amplitude shift keying (ASK), frequency shift keying (FSK), or phase shift keying (PSK). The realization of the coherent detection scheme involves the necessity of having a stable relationship between the phases and frequencies of an incoming optical signal and the local laser signal, which brings an additional complexity to the system design.

5.2. Transmission System Engineering Tradeoffs

Proper design of a transmission system is a big challenge, and some tradeoffs must be done. Generally speaking, the longer the distance, the smaller the transmission capacity, and vice versa. Overall design tradeoffs include

- *Fiber type selection* is applicable just for new fiber deployment. It is obvious that single-channel transmission favors DSF fibers, while NZDSF fiber should be, generally speaking, favorable for long-distance DWDM systems. Standard single-mode fibers (SMFs) might be the best choice in certain cases where either chromatic dispersion is not critical, or where SMF-based systems are less vulnerable to the influence of nonlinearities. Even low-cost multimode optical fibers can be considered for some short-reach and/or lower-bit-rate applications.
- *Spectral efficiency* versus the total optical bandwidth occupied is an important design issue in some cases. By increasing spectral efficiency with dense wavelength spacing, designers expose the system to greater susceptibility to degradation from nonlinear

effects. On the other hand, increasing the optical bandwidth occupied would lead to system cost increase.

- *Chromatic dispersion management* is essential for high-speed optical transmission systems. A novel transmission line design with proper dispersion management will provide conditions for ultra-high-capacity systems.
- *Optical power level* per optical channel is dependent on the output power level from optical amplifiers, nonlinear effects, crosstalk, and safety issues. It is always desirable to increase the power level from the SNR point of view, but the power penalty due to an increase in nonlinearity and amplifier noise will limit the signal power level, leading to an optimal in-between value.
- *Optical pathlength* is very important in transmission systems engineering. Design is more complex on longer optical paths since optical networking issues, such as crosstalk, wavelength misalignment, and cascaded filter effects, accumulate with increasing pathlength. Optical signal powers and the SNR among different paths that come together at the input of an optical amplifier or receiver should be equalized.

BIOGRAPHY

Milorad Cvijetic received his Ph.D. degree in electrical engineering from University of Belgrade in 1984. Dr. Cvijetic has experience in both academia (teaching at University of Belgrade and Carleton University), and industry (work in the area of high-speed optical transmission systems and optical networks). His research work related to quasi-single mode optical fibers, BER evaluation in soliton-based systems, and system performance evaluation in high-speed optical systems with external modulation, has been widely recognized.

He currently serves as the chief technology strategist for Optical Network Products with NEC America, Herndon, Virginia. Previously, he has been with Bell Northern Research (later NORTEL Technologies) in Ottawa, Canada, working in the Advanced Technology Laboratory. Dr. Cvijetic has published more than 40 technical papers and two books titled *Digital Optical Communications* and *Coherent and Nonlinear Lightwave Communications*. He has taken part in numerous telecommunications conferences and symposiums, in some as a session/conference chairman, technical committee member, or invited speaker. He is a member of IEEE Communications Society and LEOS.

OPTICAL WIRELESS LASER COMMUNICATIONS: FREE-SPACE OPTICS

Dennis Killinger
University of South Florida
Tampa, Florida

1. INTRODUCTION

Free-space optics (FSO) communication involves the use of modulated optical beams to send telecommunication information through the atmosphere from one location to another location, and has been the subject of a series of several conferences on FSO communication [1–3]. The concept of FSO light communication is not new, having been used by the Romans to transmit information via mirror reflected optical beams from one hill to another during ancient times. Indeed, Alexander Graham Bell in his photophone patent dated 1880 showed the use of an intensity modulated optical beam to transmit telephone signals 200 m through the air to a distant receiver. More recently, however, the tremendous growth in Internet traffic due to the use of high-bandwidth optical fiber transmission networks and the development of low-cost and high-power diode lasers has greatly increased the utility of transmitting information on an optical laser beam from one location to another through the air. Since 1996, the use of free-space optics has grown exponentially in the commercial market since it offers the potential to help connect the millions of telecom users within the "last mile" and at extremely high bandwidths of 1–10 gigabits per second (Gbps) or more. While cable (coax) offers 1-Gbps capability, it must be shared in bandwidth among different users and channels within a neighborhood or hub. T1 lines into offices carry a 1 Mbps (megabits per second) bandwidth, but are usually fiberoptic-coupled to a main hub. The more recent RF wireless 802.11b capability to link office and home computers wirelessly

to a common hub provides bandwidths of 11 Mbps, but can become crowded in capacity when many (say, 20–100) notebook computers are being used at the same time, such as within a campus library room. As such, future need and growth is anticipated for the development of individual higher bandwidth (0.1–1 Gbps per user) connectivity within all offices and homes in a metro (metropolitan) market. Optical access and FSO in particular may offer the optimal technical solution for such connectivity in the future since only optics offers such large bandwidths for each individual user. As the National Academy/NRC Committee on Optical Science and Engineering (COSE) report recently stated, "The Tera-bit/s era for information technology . . . includes the need for cost-effective networks of virtually unlimited bandwidth with local area networks operating at tens of gigabits/s" [4].

1.1. Historical Background and Current Technology Perspective

Historically, a significant amount of laser telecommunication and laser atmospheric propagation studies were conducted in the 1970s and 1980s as part of the development of military electrooptic instruments, laser radar systems, and secure communication data links. Much of the optical and laser science underlying these systems can be found in current optical handbooks. [5,6] Early Department of Defense (DoD) work involved the detailed analysis of the attenuation and scatter of a laser beam transmitted through the atmosphere, the common physical and parametric analysis of different types of visible and infrared detectors, and the intensity modulation and wavelength control of a wide range of lasers. For example, several laser FSO communication systems were developed in the 1980s for secure ship-to-ship communication and ground-to-aircraft applications. In addition, since the early 1990s, several secure laser communication systems for use between the ground and satellite-to-satellite have been developed and launched [7–9]. Most of these early or DoD FSO systems were designed to be used for long-range (5–1000 km) communication links and often used high-power (1–200-W) 10-μm-wavelength CO_2 lasers, 1.06-μm Nd:YAG, 0.85 μm GaAs, or 1.5-μm diode/erbium:fiber amplifier lasers. They often involved complex tracking systems, multiple detector receivers or adaptive optics to compensate for atmospheric turbulence, external modulators for the high-power lasers to place the communication signal on the laser intensity bitstream, and seldom were considered to eye-safe. Many of these systems had development costs on the order of several millions of dollars, although vehicle mounted systems have typical costs on the order of $100,000. The number of systems deployed is relatively small, ranging from one-of-a-kind satellite-to-satellite or ground-to-airborne systems, to unit numbers in the hundreds for small-size mobile systems. These DoD FSO systems and laser atmospheric studies are emphasized here since they provide much of the scientific groundwork in laser, propagation, signal processing, and detector technology in the context of current commercial FSO systems and for the design of future optical wireless communication systems.

Since 1996 there has been an explosion in commercial development of FSO systems that has been driven in part by several considerations from both technology and business viewpoints [10]. First and most importantly, the demand for high-bandwidth Internet connectivity within the last-mile market has driven the use of FSO systems in places where optical fiber is too expensive to use, especially within the urban metro market. Here, the price to lay fiber from one building to another building just across the street may cost $300,000 and take 6 months time to obtain a permit, if allowed at all. Second, the advent of directly modulated, moderate power diode lasers and light-emitting-diodes (LEDs) that are inexpensive and compact have allowed the development of low–moderate-cost FSO systems for short to moderate ranges. Initially, FSO commercial systems developed in the 1990s used higher-power (1–10-W) lasers to transmit a 0.1–1-GHz bandwidth signal at distances of 5–10 km. The systems were designed to provide point-to-point connectivity over a long distance, often used active tracking to compensate for building sway and atmospheric turbulence, and cost upwards of $100,000 [1]. Since the mid-1990s, the design of many commercial systems has gravitated toward shorter-range and lower-cost systems that use moderate power (10–100 mW) diode lasers or LEDs, and operate at shorter ranges (100–500 m) [3]. There are about 15 commercial companies currently selling FSO systems, ranging in price from $1000 per unit for 10-Mbps systems to about $20,000–$100,000 per system for advanced capabilities (1–10 Gbps). Several of these companies have installed or sold nearly 5000 FSO systems each, while some are implementing a complete networking capability in a point-to-multipoint or mesh-net configuration [3]. It is interesting to note, however, that most of the current commercial FSO systems operate at wavelengths of 0.8 or 1.5 μm, and use laser or optical technology derived mainly from the fiberoptic telecommunication community as opposed to the previously mentioned DoD laser sensor and atmospheric propagation community. This is due to two reasons: (1) the development of inexpensive and reliable laser and receiver/detectors near 0.8 μm (fiberoptic telecommunication in the 1980s) and 1.5-μm diode lasers with erbium:fiber amplifiers (fiberoptic telecommunication in the 1990s), and (2) the wish to remain compatible in optical format to the burgeoning fiberoptics telecommunications field and the wavelength and information requirements imposed by the standards adopted by the industry. FSO technology and deployment in the commercial sector may be viewed as being just in its infancy, with several marketing studies indicating that the current $200 million/year market could grow to $2 billion/year before the year 2007. As such, the reader should remember that the current growth in FSO may continue with advances along the current wavelength and devices used, or it may branch out to other wavelength regions (say, for instance, 3.5 or 9 μm) according to the technical needs of the market. If the last-mile, metro, or home market becomes the main focus of the telecommunications field in the future (say, 10 years from this writing), and if FSO plays a major role in its development, then the optimization of FSO last-mile technology at other wavelengths may

be more important than the demands to interface and use optical technology from the fiberoptic network legacy. It is beyond the scope of this article to speculate on the future of this area in light of some of these considerations, but such thoughts focus on the importance of covering the basic optical physics and technology behind FSO in this so that the reader can appreciate the different optical tradeoffs, technical limitations, and capabilities of FSO.

1.2. Technical Emphasis of Tutorial Overview

This article presents a brief overview of the optical science and technology involved in free-space optics communication. The emphasis will be on the basic physics and engineering aspects of FSO design mainly with an eye toward point-to-point communication for the commercial market. As such, the physics of laser atmospheric propagation, laser specifications, detector criteria, telescope design, eye safety, laser-beam tracking, and atmospheric turbulence and beam wander will be discussed. These are the main criteria for the design of current FSO systems and will probably determine the design of future systems. Most FSO systems are "modulation-tolerant" or "protocol-agnostic," which means that they faithfully reproduce the input modulation codes of a communication link. As such, they can be placed inside a wide range of different communication networks (Ethernet, FDDI, SONET, etc.) without changes being required as the system communication schemes are modified and updated in future years. Although some traditional copper data link formats such as T-1 and T-3 may require some data conversion. In addition, their use within a traditional network ring or multipoint configuration may also be independent of other communication parameters, however, this may not be the case if the FSO is not an add-on to an existing net but develops as the main net or "mesh-net" component. Since many of these latter topics on communication network topology and modulation or coding schemes are covered elsewhere, they will not be covered in this article on FSO except only as needed. The interested reader is directed toward these topics within this encyclopedia. It should be noted that there are several excellent overviews and technical articles on FSO that the reader may want to review, including the book on free-space optics communication by Willebrand and Ghuman that covers technical, marketing, and network issues; in-depth papers presented at several SPIE conferences; and specific research papers [1–3,10].

2. OVERVIEW OF A TYPICAL FREE-SPACE OPTICS COMMUNICATION SYSTEM

A typical free-space optics (FSO) communication system is depicted Fig. 1. It often consists of a small laser source that can be directly modulated in intensity at fairly high data rates, a beamshaping–transmitting telescope lens to transmit the laser through the atmosphere toward a distant point, a receiving lens or telescope to collect and focus the intercepted laser light onto a photodetector, and a receiver amplifier to amplify and condition the received communication signal. Figure 1 also shows the transmitted laser beam passing through the atmosphere and being partially collected by the receiver telescope. The laser or optical beam can be absorbed, scattered, or displaced by the atmosphere, depending on the atmospheric conditions and wavelength/linewidth of the laser source. If the laser beam has to transverse distances less than about 200–500 m or so, then finite movement and sway of the local buildings attached to the system may move the transmitted beam away from the receiving telescope aperture and outside the angular acceptance angle of the system. In this case or the case of high atmospheric turbulence, an active tracking device may have to be used to align the beam onto the receiver using a small gimbal mirror, lens translation stage, or detector/laser translation stage; active tracking may be eliminated if sufficient power is available by expanding the divergence of the beam or if the building and alignment is stable.

To give the reader a perspective of the size and shape of a typical FSO system, Fig. 2 is a photograph of a FSO indoor unit from PlainTree, Inc. (model 340) that uses a low-power (40-mW) 0.85-μm-wavelength light-emitting diode (LED) nonlaser (noncoherent) source for optical communication at short to moderate ranges (100–200 m) [11]. The transmitter lens is about 6.5 cm in diameter, the receiver telescope lens is about 13 cm

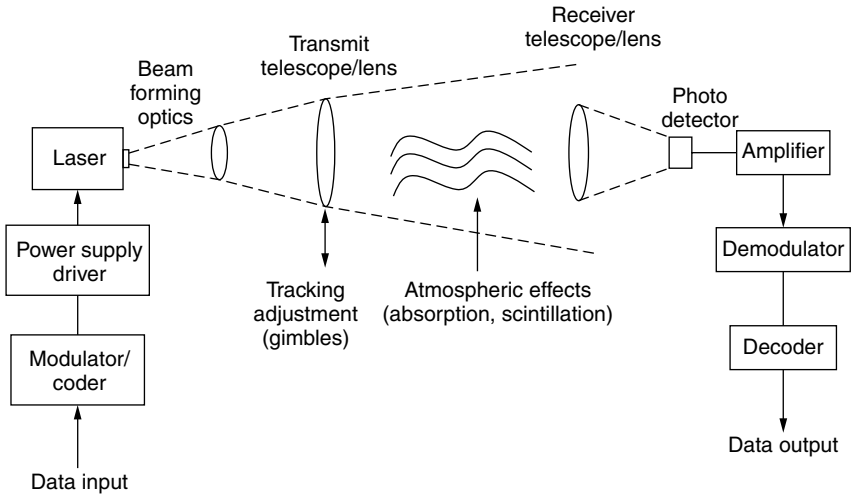

Figure 1. Pictorial schematic of free-space optics laser communication system for point-to-point applications. A typical FSO system has two of these optical channels for bidirection flow of the communication link.

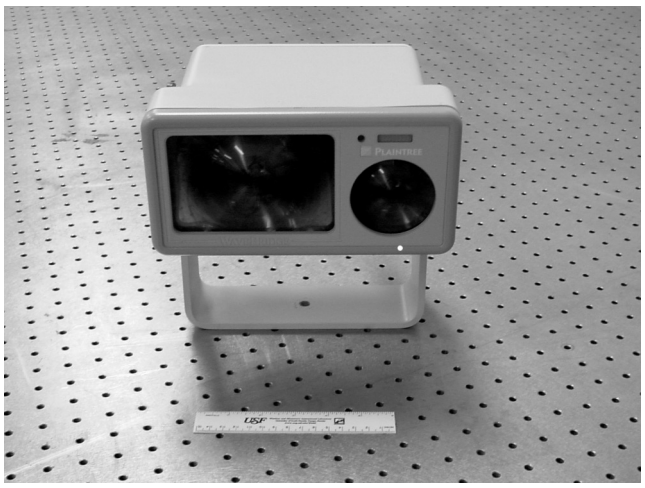

Figure 2. Photo of 0.85-μm noncoherent LED-based FSO system from PlainTree used for short/moderate indoor applications. Photo is that of a PlainTree Model 340 system.

Figure 3. Photo of 0.785-μm-wavelength diode laser FSO system from Optical Access that uses Four laser beams to reduce speckle fading and atmospheric turbulence effects.

in diameter, and the beam divergence is about 1° (0.0175 radians). The data rate is about 10 Mbps. Figure 3 shows a FSO system from Optical Access (model 155) that operates in the same near-IR wavelength region, but uses a 0.785-μm-diode laser and four laser beams to reduce fading and atmospheric turbulence effects. Here the laser output power is about 7 mW and the data rate is 155 Mbps [12].

Figure 4 shows a higher power and different wavelength system from fSONA, Inc. (model 622-M) that uses four separate 4-cm-diameter beams from 100-mW diode lasers operating at 1.55 μm that is able to transmit 622 Mbps information at ranges up to 2.5 km [13]. Here, the receiver telescope size is 20 cm and the four transmitted beams are used to reduce the effect of increased FSO signal fluctuations due to the effects of atmospheric turbulence at longer ranges and interference/speckle fluctuations associated with the use of a coherent laser. The four transmitter lasers also offer redundancy for the link.

Figure 4. Photo of 1.55-μm high-power diode laser FSO system from fSONA that uses Four laser beams to reduce signal fluctuations.

More sophisticated systems have also been developed that have been able to transmit data at rates beyond 40 Gbps at ranges of 5 km or more using multiple laser wavelengths, active atmospheric tracking, and multiple detectors and beams [14].

The detected FSO optical signal is usually converted to an electrical signal as shown in Fig. 1 and then sent to the communication network or individual hub. However, the optical detected signal can be redirected via mirrors to another location, or received by a router that will redirect it into a fiberoptic communication system. Of course, the optical signal received could also be amplified by another laser amplifier, as in the case of a 1.5-μm laser signal and an Er:YAG fiber amplifier. This is discussed later in Section 3 in this article.

As can be appreciated from Fig. 1, several important optics and laser spectroscopic issues need to be considered in the design and development of a FSO system. These include the availability and wavelength coverage of lasers and LED sources, the interaction and attenuation of the FSO optical beam as it traverses the atmosphere, the received light intensity collected by the receiver telescope, the sensitivity of the optical detectors, and the influence of atmospheric turbulence. These factors influence the relative SNR of the received laser signal and are depicted in the FSO range equation. These aspects are covered in the following sections.

3. LASER AND OPTICAL SOURCES FOR FSO

Most current FSO systems use either 0.8- or 1.5-μm lasers or LED sources. However, there are a wide range of other lasers and LED sources that have potential for use in a FSO system. For FSO applications, it is appropriate to look only at continuous-wave (CW) lasers as opposed to pulsed lasers since they can more often be intensity modulated at MHz or GHz rates. In this regard, Fig. 5 shows a plot of the output power of several CW lasers as a function of the wavelength covered [15–17]. As can

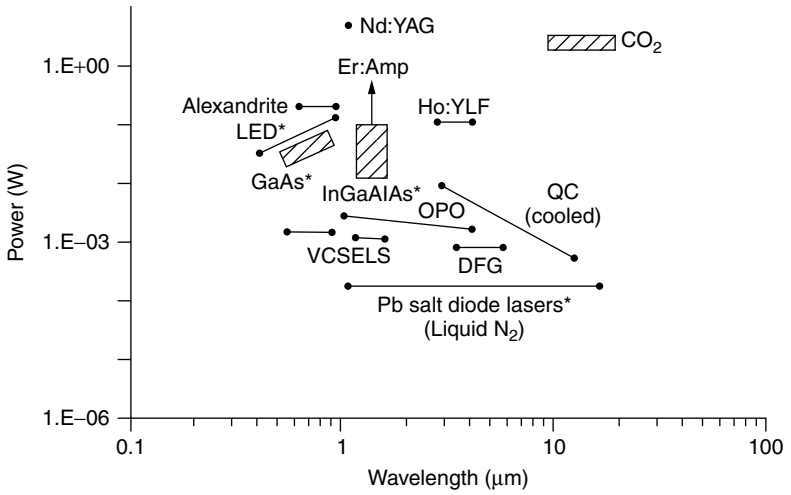

Figure 5. Typical laser output power in Watts as a function of wavelength for current lasers. Asterisks (∗) indicate direct modulation (10 MHz to 10 GHz); otherwise, external cavity modulation is used.

be seen, several high-power lasers such as the CO_2 and Nd:YAG laser operate only over a narrow wavelength range, while several lower-power lasers such as the optical parametric oscillator (OPO) and difference frequency generation (DFG) laser operate over a wider tuning range but at lower output power. The GaAs(Al) diode lasers operating near 0.8–0.9-μm wavelengths have CW power levels in the order of 0.01–0.1 W, while InGaAs(P) lasers near 1.5 μm operate with tens of mW power; the latter can be boosted by the use of Er:fiber laser amplifiers to levels of 1–10 W; governmental laboratory fiber lasers have reached levels of 100–200 W and higher, although problems with spectral mode hopping and spontaneous background emission require stringent cavity design and injection seeder laser-beam isolation. The vertical-cavity surface emitting lasers (VCSELs) are vertical layered semiconductor lasers that have output powers on the order of 1–10 mW and are tunable in some cavity arrangements. The quantum cascade (QC) laser offers potential for future FSO usage, especially with the development of 9-μm room-temperature lasers [18]. Also shown in Fig. 5 is the output power for a LED, which is a noncoherent light source but has wide utility as a FSO source. Of the lasers shown in Fig. 5, only the semiconductor diode lasers are directly modulated at rates up to 10 Gbps using the drive current of the laser or an internal loss material. The other lasers have to use external modulators (electrooptic, acoustooptic, or traveling-wave modulators) to reach Mbps–Gbps modulation rates. The LED modulation rate is generally 1–10 MHz, but newer models, including laboratory quasicavity LEDs, have modulation rates on the order of 100 MHz.

Some important output characteristics of these different CW lasers are tabulated in Table 1 [15–17]. As can be seen, the GaAs lasers and InGaAs lasers offer a significant combination of high output power and can be directly modulated via their drive currents. Some of the lasers have linewidths that are either single frequency (single longitudinal cavity mode) or consist of several laser modes within a group of lines, while an LED has a broad noncoherent emission spectrum. This can be seen in Fig. 6, which shows the spectral output measured by the author from three different optical sources as a function of wavelength or frequency. As can be seen in the figure, the output spectrum from the LED is broad, covering a range of 50 nm (about 500 cm^{-1} or 15,000 GHz), while the typical 1.33-μm diode laser shows multiple longitudinal modes covering a range of about 3 nm. The bottom portion of the figure shows the 50-kHz linewidth output spectrum of a single-frequency 1.55-μm distributed feedback (DFB) laser whose laser output has been controlled through use of Bragg reflection from imposed index variations along

Table 1. Output Characteristics of Several Currently Available CW Laser Sources[a]

Laser	λ (μm)	Power	Temperature	Modulation Rate	LineWidth[a]
GaAs	0.8	10–100 mW*	Room	100–500 MHz*	Multi/SF
VCSELs	0.8, 1.5	1–10 mW	Room	1 GHz*	SF
InGaAs	1.5	10–100 mW	Room/TE[b]	10 GHz*	Multi/SF
LED (nonlaser)	0.8	10–100 mW	Room	10–100 MHz*	50 nm
CO_2	10	1 W	Room	200 kHz*/20 GHz	$0.1cm^{-1}$/SF
Nd:YAG	1.06	1 W	Room	1 GHz	$0.1cm^{-1}$/SF
Quantum cascade	3–9	0.1–1 mW	77 K–room	?	$0.1cm^{-1}$/SF
Pb salt	2–10	0.1 mW	77 K	?	0.1–1 cm^{-1}

[b] Thermoelectrically cooled.
*indicates direct modulation of the laser intensity while other lasers use external cavity modulation.

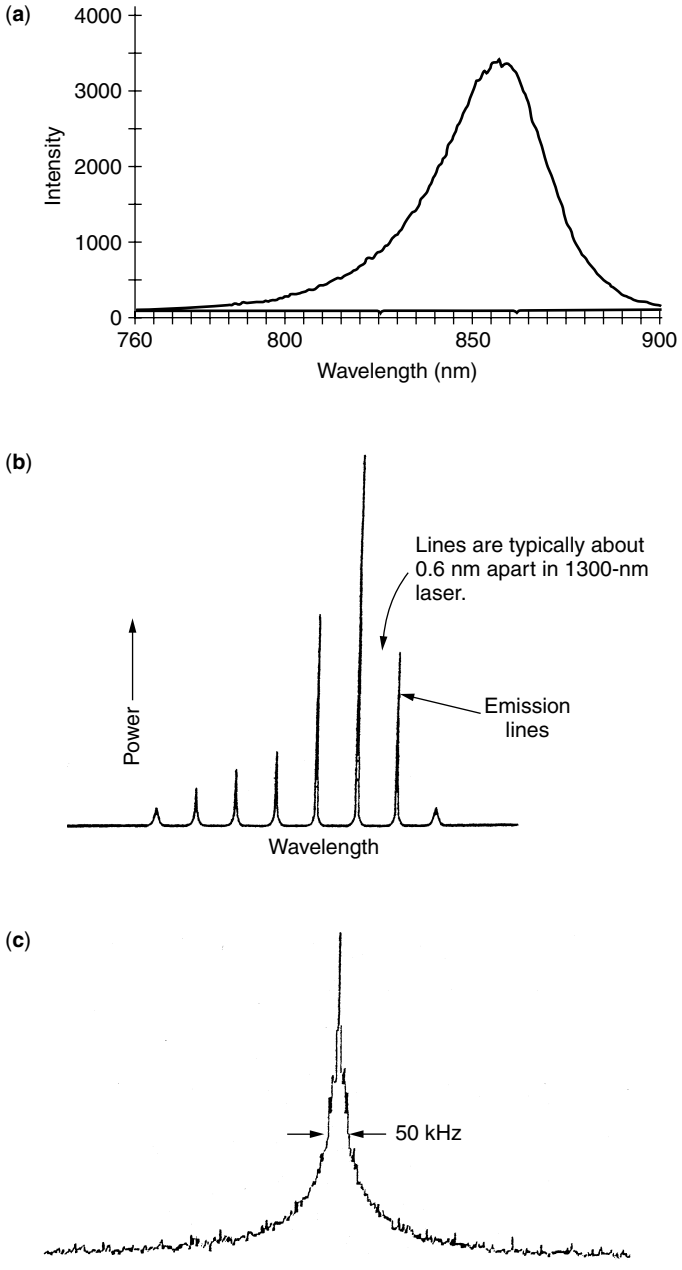

Figure 6. Spectral plots of the output power as a function of wavelength showing the spectral linewidth of a typical 0.86-μm LED source (**a**), 1.3-μm multimode diode laser (**b**), and a 1.55-μm single-frequency DFB diode laser (**c**).

the semiconductor laser cavity. Figure 6 is important in that the exact wavelength and linewidth of the laser can determine the absorption and scatter properties of a FSO laser beam as it propagates through the atmosphere. This will be seen more clearly in the next section.

It should be noted that many laser sources do not operate in a single spatial mode, but may have a divergence that is greater than the lowest-order (Gaussian) mode. A measure of this deviation is the M^2 parameter value, or mode structure parameter. For a Gaussian spatial beam, M^2 is equal to 1. However, for many short cavity lasers, the M^2 value may be closer to 2 or 3 for diode lasers, and as high as 20 to 50 for short cavity OPO lasers. An alternative to specifying the M^2 parameter value is to directly specify or measure the divergence of the laser in terms of milliradians. The divergence of the laser beam is equal to M^2 times the divergence of a Gaussian beam [19]. It is common in a FSO system for the divergence of the transmitted beam to be made larger than the diffraction minimum value so that the projected beam size is larger than the receiver optics and more tolerant of misalignment of the beam. This is discussed in Sections 6.1 and 6.2.

Finally, it should be added that Fig. 5 does not show an important third axis, which would be related to the cost of the laser system and modulation scheme. Such information is very important especially for commercial systems and influences the engineering trade-off design of the FSO system. To give the reader a ballpark value, typical costs range from a few dollars for a LED or low power GaAs laser to several $100K for an externally modulated CO_2 laser. Typical costs for moderate power 100 MHz 0.8 μm lasers are near $0.1K

to \$1K, with somewhat higher costs for 1.5 μm diode lasers, and approaching \$10K to \$20K for higher power Er doped amplifier lasers. Of course, these values are only approximate values amd will be reduced as technical progress is made in this area.

4. ATMOSPHERIC ATTENUATION AND SCATTER OF THE FSO BEAM

The attenuation of an optical beam as it propagates through a medium is given by the Beer–Lambert law as

$$I(x) = I_0 e^{-\alpha x} \tag{1}$$

where I_0 is the initial optical intensity in watts, $I(x)$ is the intensity after the beam has traveled a distance x meters, and α is the attenuation coefficient of the medium in reciprocal meters. The attenuation of the atmosphere can be due to several factors, including absorption of the beam via molecules in the atmosphere and scatter of the beam due to Rayleigh, Mie, and resonant scatter with molecules or aerosol particles in the air [20]. For most applications, the Mie Scatter (especially due to fog) is dominant.

The optical transmission of the normal atmosphere can be shown as in Fig. 7, which shows the low-resolution transmission spectrum of the atmosphere for a 2-km path near ground level [21]. The spectrum is that for a low-resolution spectrometer with a spectral resolution of about 20 cm^{-1}. As can be seen, there are several regions where water vapor and other gases absorb the optical beam, while there are large optical windows in the visible (0.4–0.7 μm) and at 1.5 μm and near 9–13 μm, where the beam is hardly absorbed. Of interest for FSO applications is the higher-resolution spectra for the atmosphere at regions that appear almost opaque in Fig. 7. Figure 8 is a calculated transmission spectrum of the atmosphere for a U.S. standard atmosphere for a path of 500 m over three different spectral regions of potential FSO interest near 0.85 μm, near 1.55 μm, and near 9 μm. As can be seen, the spectrums show individual absorption lines due to the vibrational–rotational absorption lines of water vapor, CO_2, CH_4, and other gases in the atmosphere. The individual lines all have a pressure-broadened linewidth of about 0.1 cm^{-1}, so that a tunable laser beam that has a linewidth on the order of 0.1 cm^{-1} or less can be absorbed if it is tuned online, or not absorbed if it is tuned in wavelength to the offline position. It is because of this close connection between the laser or optical source linewidth and wavelength and that of the atmosphere absorption lines, that careful selection of the laser wavelength can have a significant influence on the performance of a FSO system. It should be noted that the spectra in Fig. 8 were calculated using the HITRAN database and HITRAN-PC computer program since it has a spectral resolution better than 0.01 cm^{-1}, and usually produces spectral plots that have line centers with an accuracy of 0.001 cm^{-1} and line intensity accuracy of a few percent [22–24]. Other Air Force atmospheric spectral codes such as MODTRAN have a resolution of 2–20 cm-1 and may be valid for wide-linewidth LEDs and regions of little spectral absorption. However, in general, it is best to use the high-resolution capability of the Air Force FasCode program or HITRAN-PC, which uses the HITRAN spectral line database, and then convolute the overlap of the laser spectrum with that of the atmosphere. The HITRAN database has been developed by the U.S. Air Force since 1971 and is the compilation of over one million individual spectral lines of over 32 molecules in the atmosphere.

In addition to the absorption of molecules in the atmosphere, there is also the attenuation due to the scatter from aerosols and particles in the atmosphere. In this case, the fogs, clouds, and dust particles can add to the attenuation of the optical beam. For molecules and spatial scale changes in the index of refraction that are much smaller than the wavelength of light, the scatter is called Rayleigh scatter, named after Lord Rayleigh (1842–1919), who first quantified the effect. Rayleigh scatter attenuation coefficient can be given approximately for the standard atmosphere as [24,25]

$$\begin{aligned}\alpha_{\text{ray}} &= N\sigma_\pi = N\frac{8\pi}{3}\sigma_\pi \\ &= \frac{8\pi}{3}1.18 \times 10^{-8}\ [550\ \text{nm}/\lambda\ (\text{nm})]^4\ \text{cm}^{-1} \\ &= 1.1 \times 10^{-5}\ [550\ \text{nm}/\lambda\ (\text{nm})]^4\ \text{m}^{-1}\end{aligned} \tag{2}$$

where N is the number of molecules ($\sim 2.55 \times 10^{19}$ molecules/cm^3) in air and σ_π is the backscatter Rayleigh scatter cross section. Equation (2) is normalized to that for a wavelength of 550 nm. As can be seen, Rayleigh scatter increases in the short-wavelength or blue-wavelength regions, which is why sunsets appear red (most of the blue light has been scattered away from the viewing angle).

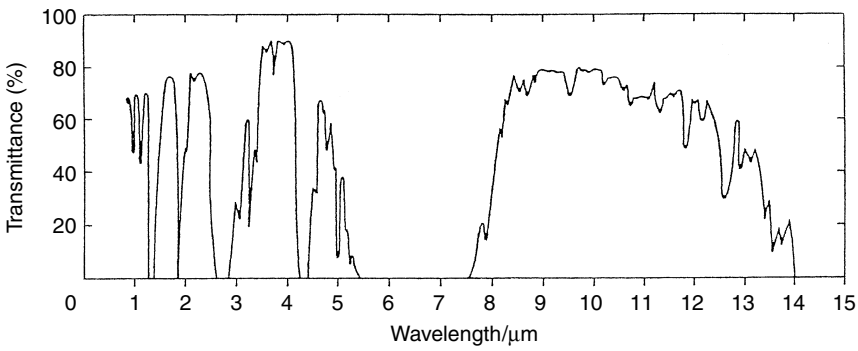

Figure 7. Calculated transmission spectrum of the standard atmosphere for a pathlength of 2 km. Strong absorption regions near 2.8μ m and 6–7 μ m are due mostly to water vapor.

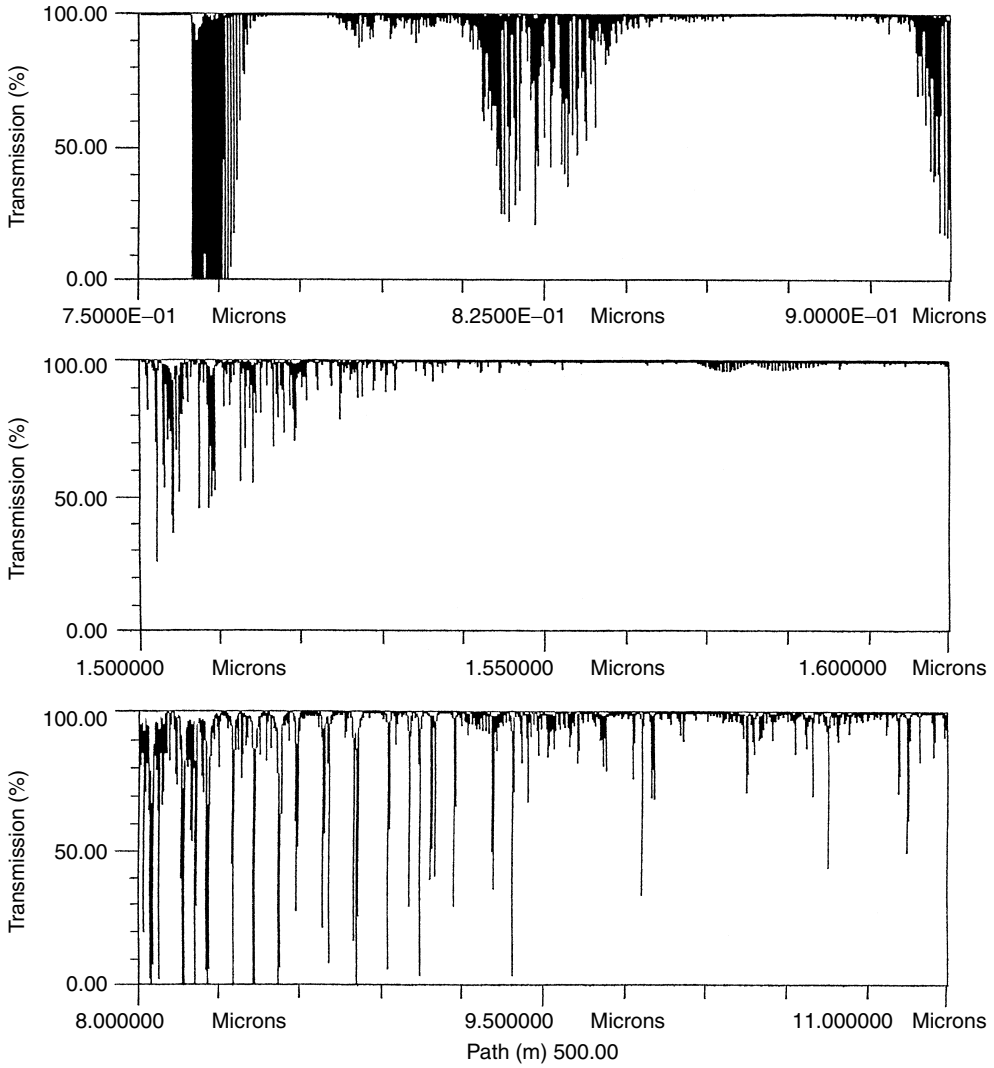

Figure 8. Calculated transmission spectrum of the atmosphere for a 500-m path near the wavelengths of 0.8, 1.55, and 9.5 μm. Most of the strong rotational–vibrational absorption lines seen are due to water vapor, CO_2, ozone, and oxygen.

When the scatter site is large or on the order of the wavelength of light then the scatter is a complex interference phenomenon with destructive and constructive interference lobes emanating outward from the particle. Such scatter is called *Mie scatter* and is highly dependent on angle, polarization, and wavelength/particle size. In theory, Mie scatter can be calculated for known particle sizes and orientation. However, it cannot be calculated a priori for complex shapes and orientations of particles such as those often found in the atmosphere. As such, the Mie scatter for the atmosphere is usually measured experimentally. Figure 9 shows the measured attenuation or extinction coefficient of the atmosphere as a function of wavelength for several different atmospheric conditions [25]. The values shown in Fig. 9 have error bars on the order of an order of magnitude dependent on atmospheric conditions.

Comparison of Figs. 8 and 9 suggests that at many laser wavelengths, the attenuation due to a strong absorption line in the atmosphere may be more dominant than that due to the normal background attenuation of the atmosphere such as that due to urban haze. In this case, FSO design is such that one chooses a laser wavelength that is offline of any strong absorption line in the atmosphere. After this choice, then the next dominant attenuation consideration is that due to clouds or heavy fog. For example, at a wavelength of about 1.51 μm, the extinction coefficient due to urban haze is about 0.9×10^{-4} m^{-1}, a value much smaller than that possible due to the molecular lines in Fig. 8. However, the attenuation due to absorption lines at 1.56 μm is negligible so that the Mie/Rayleigh or haze attenuation dominates.

Of more concern for a FSO system is the attenuation due to rain, snow, and fog. The Air Force MODTRAN and LOWTRAN computer programs have excellent attenuation calculations for rain and snow [22,23]. Under most cases with short ranges (<500 m), rain and snow attenuation may not be severe. However, fog can cause severe degradation in the signal. Figure 10 is a plot of the attenuation due to fog, rain, and snow as a function

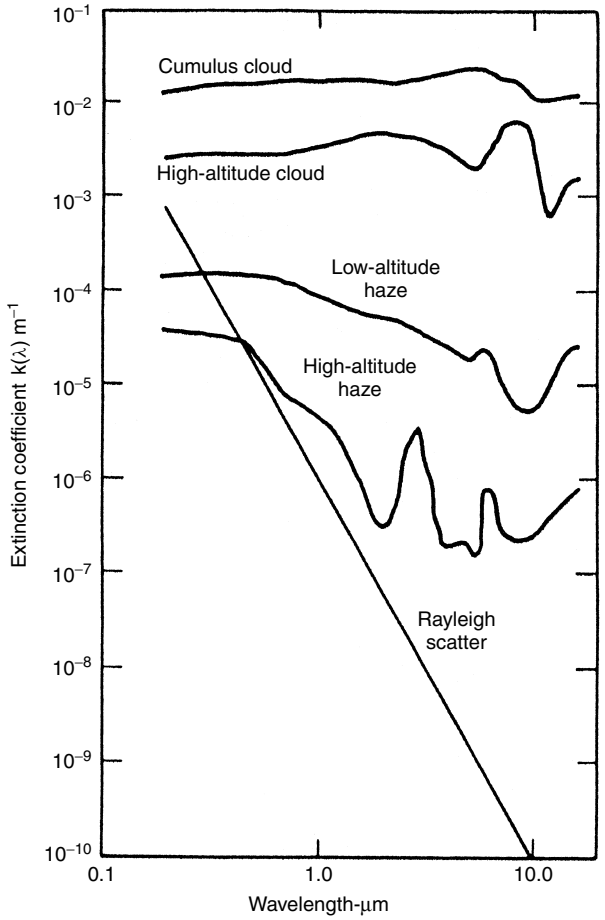

Figure 9. Approximate attenuation coefficient of the atmosphere as a function of wavelength for different atmospheric conditions. (Reproduced by permission of R. Measures, *Laser Remote Sensing*, John Wiley & Sons, New York, 1984.)

of the visibility [26]. As can be seen, thick fog can cause attenuation of up to 200 dB/km, or a reduction factor of 10^{-20} for a km path. Recent studies by Kim, McArthur, and Korevaar at 0.8 and 1.5 μm have indicated a refined equation for an approximation of the attenuation value, α, given by [26]

$$\alpha = \left(\frac{3.91}{V}\right)\left(\frac{\lambda}{550\text{ nm}}\right)^{-q}\ \text{km}^{-1} \qquad (3)$$

where V is the visibility (in km), λ is the wavelength in nm, and q depends on the size of the scattering particles, but is equal to 1.3 for average visibility and 0 for fog. In Eq. (3) α is given in units of km^{-1}.

It should be noted that in many reported studies, the attenuation values given in dB/km were extrapolated from short range studies on the order of several centimeters to meters, and were unable to take into account multipath scatter. The inclusion of multipath effects may decrease the overall attenuation value but also may spread out in time the modulated intensity waveform of the multiscattered beam [24].

Under normal conditions the first decision criterion for a FSO wavelength design is to reduce the atmospheric line spectra as shown in Fig. 8. Then the next consideration should be the reduction due to fog-type aerosols in the path. As can be seen in Fig. 9, the latter consideration may indicate that longer wavelengths near 9–10 μm may offer less attenuation due to fog and snow. As such, they may be considered for a backup system for a 0.8- or 1.5-μm FSO system, as opposed to the use of a microwave or RF backup system.

5. OPTICAL DETECTORS AND NOISE

Most current commercial FSO systems use the direct detection of the intensity-modulated laser beam. The optical detectors used are usually a small, high-bandwidth photodetector, either a Si photodiode or Si avalanche photodiode (APD) for wavelengths up to 1.1 μm, or a InGaAs photodiode or APD for the 1.5 μm wavelengths. To obtain the high speed required of 10 MHz up to 10 GHz, the size of the detector is kept small, on the order of 20–100 μm, to reduce capacitance and RC time constants. Table 2 shows a sampling of several optical detectors and some of their performance parameter values, including their size, electrical bandwidth, and noise equivalent power (i.e., minimum signal detected) [5,6,27]. As can be seen, they are small in size and have detection sensitivities ranging from a microwatt down to tens of nanowatts.

The overall science of optical detectors is covered in several excellent books, including that of R. Kingston, which covers photon counting, amplifier and background noise, and signal-dependent noise-limited performance of a FSO optical communication system [27,28]. In general, the detectors used in the visible to near-IR spectral region

Table 2. Typical NEP Values of Selected Detectors for Nighttime Conditions

	λ (μm)	Size (μm)	Bandwidth	Nighttime NEP (nW)
Si photodiode	0.9	2000	10 Mbps	200
Si APD	0.9	200	155 Mbps	20
InGaAS APD	1.5	50	2.5 Gbps	50
InGaAs APD	1.5	200	100 Mbps	20

[a]Daytime usage may require narrowband optical blocking filters to reduce background light. Typical daytime increase in NEP is ~2–8×.

are shot-noise-limited; that is, the dominant noise is the statistical fluctuations of the signal photons, which is essentially the square root of the number of photons in the signal. As such, the noise of the detector is usually stipulated in terms of a minimum detectable signal in decibels referenced to a milliwatt, or as a background current in the case of Johnson noise of the detector or amplifier combination. In the infrared spectral region, however, the background radiation or thermal emission of the 300-K world is often the dominant noise source. In the latter case, the detectors are background limited in their performance [i.e., background-limited infrared performance (BLIP)], and a different parameter related to the intrinsic sensitivity of the photodetector material is used to determine the system noise level. In this case, the detectivity, D^*, in units of Jones (i.e., cm $Hz^{1/2}$ W^{-1}), is a universal parameter for a particular material and is related to the noise equivalent power (NEP) in watts by

$$\text{NEP} = \frac{(A_D B)^{1/2}}{D^*} \tag{4}$$

where A_D is the area of the detector and B is the electrical bandwidth of the detector/amplifier combination [29]. The NEP is where the SNR in voltage equals 1 at the output terminals of the detector. The NEP is related to the term "sensitivity" as expressed in watts and used more often in the visible–near IR. "Sensitivity" is often used for a specified bit-error-rate and is about equal to 6 times NEP; this is explained in a later section.

With these concepts, one can compare different types of detectors at different wavelength ranges. Figure 11 shows a plot of the measured D^* for a range of infrared detectors along with that due to a S-20 photocathode photomultiplier tube (PMT), Si photovoltaic (pv) photodetector, and liquid nitrogen cooled HgCdTe for 10 μm wavelengths [30]. The influence of the 300-K background theoretical maximum thermal noise level shown by the doted line is given for both a photovoltaic detector and a photoconductor detector. As can be seen, the BLIP performance limit, due to the 300-K thermal background radiation that peaks near 8–10 μm in wavelength, is dominant for wavelengths greater than ~2 μm. Here, the D^* value was calculated for a bandwidth of 1 Hz for the PMT so that a comparison between the different detectors could be made. What are not shown in Fig. 11, however, are the signal bandwidth, lifetime, and cost of each detector. For example, many of the infrared detectors shown in Fig. 11 can operate at bandwidths

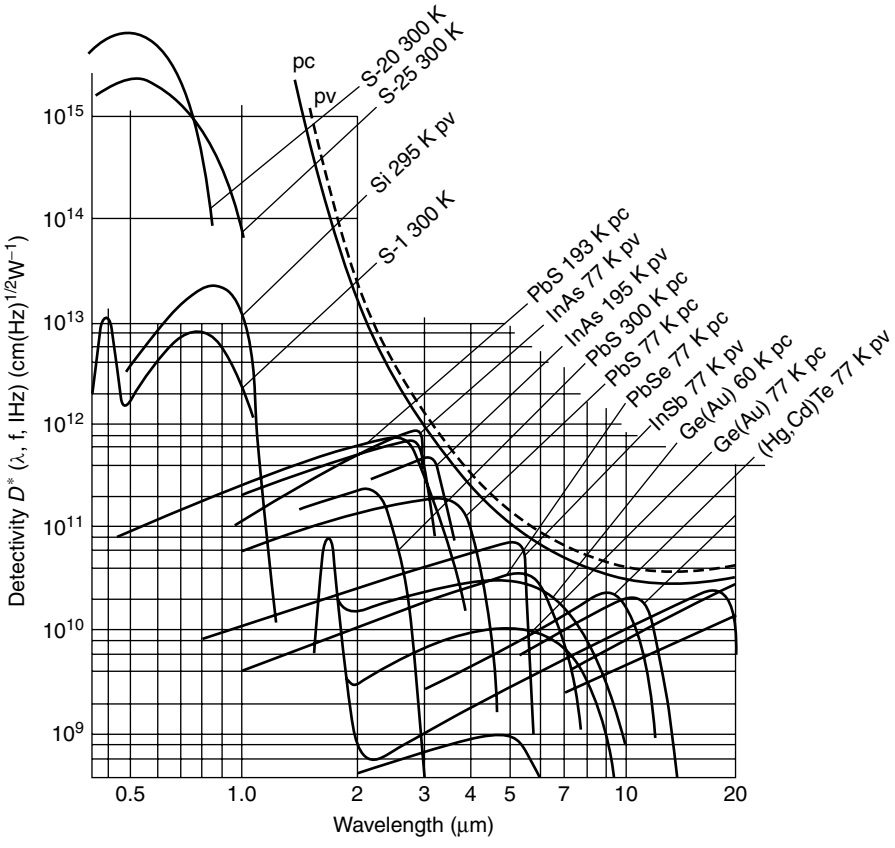

Figure 11. Detectivity, D^*, for selected detectors as a function of wavelength. (Adapted from P. R. Norton, *Handbook of Optics*, McGraw-Hill, New York, 1995, Chap. 15.)

of only 1–10 MHz or slower. On the other hand, cooled HgCdTe detectors have been operated at a wavelength of 10 μm in a heterodyne detection mode at speeds of ≤60 GHz.

Most communication systems use the bit error rate (BER) as a measure of the system sensitivity and level of signal-to-noise ratio in determining the probability of correctly decoding the bitstream in the signal [28,31]. The BER can be related to the signal-to-noise ratio (SNR) of the communication link and is a measure of the percentage of bits that are in error within a large ensemble of bits received. It is common for current FSO links to have a BER on the order of 10^{-9} to 10^{-10} for the case where no error correcting codes are used. The optical BER can be calculated as the integral of 1 minus the cumulative normal distribution function with argument $(\mathrm{SNR})_v/2$, where the SNR_v is the peak voltage SNR for a detector, which is the same as the returned peak power divided by the NEP of the detector. The average SNR power is half the peak SNR value. The "sensitivity" of a detector is defined for optical communication purposes as the average power required for a BER of 10^{-9}.

A plot of the BER value as a function of the voltage signal-to-noise ratio (returned optical power divided by NEP) is shown in Fig. 12 [28]. As can be seen, a BER of 10^{-9} requires a peak SNR of 12, which corresponds to a value of 6 for the average SNR value [28]. As such, the formula $\mathrm{SNR} = P_r/\mathrm{NEP} = 6$ is often used as the detection threshold for a FSO communication link; here, P_r is the average detected laser beam power by the receiver.

6. FSO RANGE EQUATION

The FSO range equation combines the attenuation and geometrical aspects of FSO in order to calculate the received optical power as a function of range and telescope aperture size. Before introducing the FSO range equation, some parameter values need to be defined and discussed.

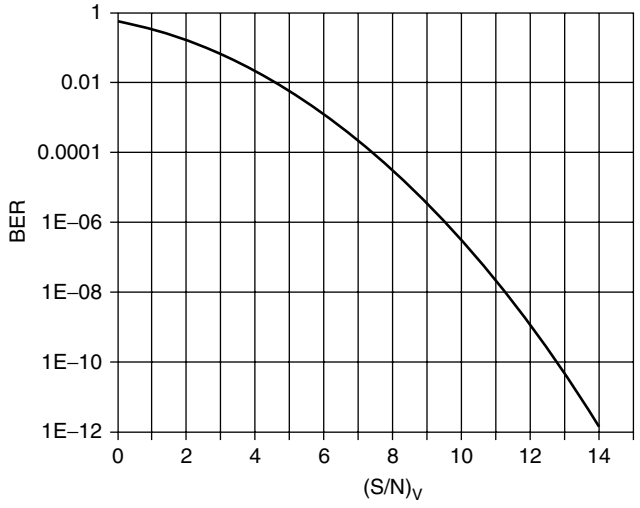

Figure 12. Bit error rate (BER) as a function of peak voltage signal-to-noise ratio (SNR), which is equal to the received power P_r, divided by the NEP of the detector. (Reproduced by permission of R. H. Kingston, *Optical Sources, Detectors, and Systems*, Academic Press, New York, 1995.)

6.1. Laser-Transmitted Beam Divergence

In the most simplistic case, the transmitted laser beam is divergent as a result of optical diffraction, where the angular spread, $\Delta\theta_1$ is equal to λ/D_1, where D_1 is the size of the initial laser beam. This is an approximate equation for the divergence of the lowest-order Gaussian spatial TEM_{00} mode for a Fabry–Perot laser cavity. Laser beams with higher-order spatial modes have greater diffraction than a Gaussian mode and will have a mode structure parameter, M^2, value greater than 1. In these cases, the divergence of the beam in one direction is equal to $M^2\Delta\theta_1$, or [19]

$$\Delta\theta_1 = \frac{(M^2)\lambda}{D_1} \tag{5}$$

The size of the projected laser beam at a distance of R meters will be equal to $D_1 + R\Delta\theta_1$. For example, a $M^2 = 10$ and 1 μm wavelength laser beam collimated through a 1 cm aperture will have an angular divergence of 10^{-2} radians (i.e., 0.57°) and will have a width of 10 m at a range of 1000 m.

Often, the beam divergence of a FSO system is made intentionally larger than the diffraction limit so that the projected beam size is larger than several times the size of the receiver telescope. This facilitates alignment of the two transmitter and receiver telescope optical axes. Beam divergence or beam spread is often made to be 0.1–1 mrad by slight defocusing of the transmitter telescope, as opposed to the normal Gaussian diffraction minimum of, say, 0.001–0.01 mrad.

Finally, the divergence of a semiconductor laser is often shaped by beamforming optics near the output facet of the diode laser. Normally, the output from a semiconductor laser has a beam divergence of, say, $3^\circ \times 15^\circ$. The beamshaping optics use a cylindrical lens to bring it down to a milliradian or so, in both axes.

6.2. Receiver Telescope Field of View

The receiver telescope field of view is the beam collection angle of the detector and telescope combination. Only light that falls or originates within this cone about the telescope optical axis will be focused onto the detector. The receiver telescope field-of-view angle, $\Delta\theta_r$, is given by

$$\Delta\theta_r = \frac{D_d}{f} \tag{6}$$

where D_d is the size of the detector and f is the focal length of the receiver telescope. Equation (6) does not usually influence the optical performance unless the optical axis of the receiver telescope–detector combination is aligned outside the receiver field of view, $\Delta\theta_r$. It should be noted that just because the receiver telescope intercepts a portion of the transmitted beam, the light collected would not be focused onto the detector unless the receiver telescope axis is pointed toward the transmitter location within $\Delta\theta_r$. For a typical detector size of 300 μm and a telescope focal length of 0.3 m, the field of view is about 10^{-3} radians.

6.3. FSO Range Equation Analysis

The FSO range equation can be given by inspection of Fig. 1, and the use of the Beer–Lambert law and Eq. (5). Under these simplifying assumptions, the FSO range equation is

$$P_R = P_T \frac{A_r}{(D_1 + R\Delta\theta_1)^2} T K e^{-\alpha R} \tag{7}$$

where P_R is the received optical signal power, P_T is the transmitted optical laser power, A_r is the area of the receiver telescope or collection lens, T is the transmission or efficiency of the receiver optical system, and the area of the beam at a range R is given by $(D_1 + R\Delta\theta_1)^2$. In Eq. (7) K is another loss factor that deviates from a normal value of 1 when a noncoherent light source is used, such as an LED. This latter parameter is equal to 1 for a laser source, and has a value equal to 1 or less for an LED source as

$$K = \frac{A_{\text{det}}}{A_{\text{LED}}} \tag{8}$$

if $A_{\text{det}} < A_{\text{LED}}$, and $K = 1$ otherwise, where A_{det} is the area of the detector and A_{LED} is the area of the LED source. The K factor takes into account the fact that a noncoherent optical source cannot be focused to an area smaller than that from which it originated due to thermodynamic reciprocity (brightness) considerations.

Equation (8) can be used to generate FSO SNR or power detection curves as a function of range. For example, Fig. 13 shows the calculated received power as a function of range for a case of a 10-Mbps bandwidth, low-power 0.85-μm LED FSO system with 40 mW power, 13 cm receiver, $T = 0.2$, and $K = A_{\text{det}}/A_{\text{LED}} = (0.28\text{ mm})^2/(0.5\text{ mm})^2 = 0.3$, divergence of $1^\circ = 0.0175$ radians, and NEP of the Si detector of 300 nW for daytime operation; these specifications are appropriate for a moderate power 0.85 μm LED FSO system and serves as a "strawman" for illustrative purposes only. Two atmospheric cases are shown for low α attenuation (10^{-4}/m, or 0.2 dB/km) due to low-altitude haze, and for moderate attenuation due to clouds (10^{-2}/m, or 20 dB/km) similar to light/moderate fog. As can be seen, the returned signal follows a $1/R^2$ dependence at close-in ranges, and follows the Beer–Lambert exponential decay at longer ranges. A threshold for the NEP of the detector at 300 nW is also shown, along with a value of the required SNR of 6 times greater than the NEP corresponding to a BER of 10^{-9}. As can be seen, the system should have good FSO communication capability at ranges out to 600 m for hazy conditions and out to 200 m under moderate/light fog conditions. These ranges would be even greater under nighttime conditions when the NEP of the detector would be less, or when operating under dry/no-fog conditions.

Another example is given in Fig. 14 for a 622-Mbps-bandwidth FSO "strawman" system appropriate for a higher power multi-beam 1.55 μm laser based FSO system. Here, the FSO parameters are approximately 1.55 μm wavelength, 400 mW power diode laser, $T = 0.2, K = 1$, 20 cm receiver telescope size, transmitted 1 mrad beam divergence, and a daytime NEP of 150 nW using two solar filters. Again, two attenuation cases are shown of 1.1×10^{-2}/m for light/moderate haze (cloud) and 0.7×10^{-4}/m for low-altitude haze. As can be seen the communication range is beyond 3 km for light haze and about 600 m under light/moderate fog. However, what is not shown in Fig. 14 are the deep fades due to constructive/destructive interference and atmospheric fluctuations in the beam. This will be mentioned in a later section of this article.

It should be added that the use of the FSO range equation is an approximation to give the reader some idea of the parameters and importance of there values. The calculated ranges are theoretical values, however, and are approximations subject to atmospheric conditions, which can cause errors in the attenuation as large as an order of magnitude or more. As such, it is important that the reader understand the usefulness and limitations in using the FSO range equation. Often, the values have to be modified by direct measurements under specific atmospheric conditions. This is why in so many cases extensive field tests of a FSO optical link have to be made under a wide range of weather conditions in order to accurately measure the system performance.

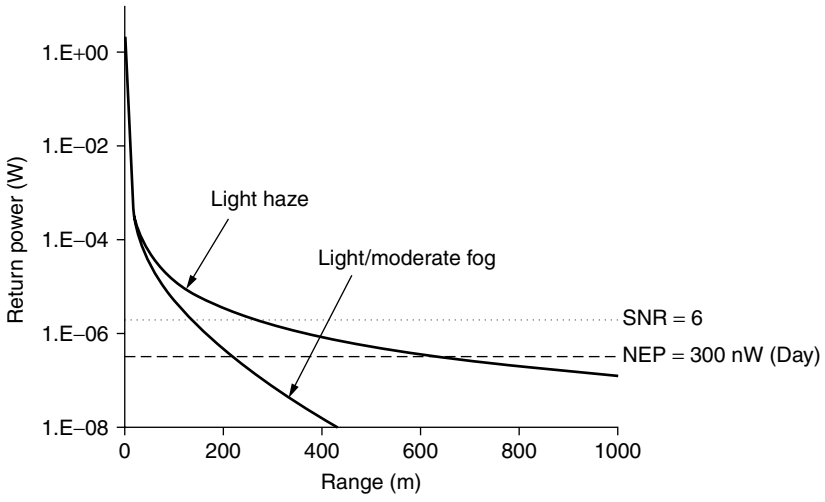

Figure 13. Calculated received optical signal as a function of range for "strawman" 0.85-μm LED FSO system. FSO range equation parameters included 40 mW power, 17 mrad beam divergence, and 13 cm telescope aperture.

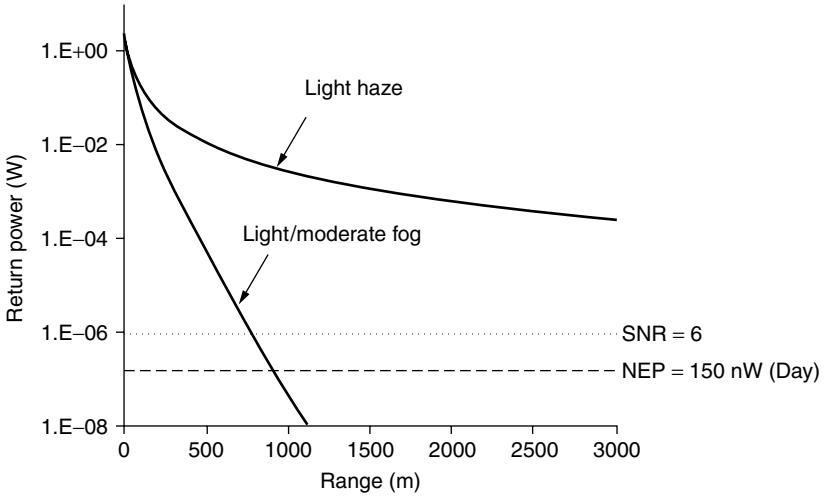

Figure 14. Calculated received optical signal as a function of range for "strawman" 1.55-μm high-power diode laser FSO system. FSO range equation parameters included 400 mW power, 1 mrad beam divergence, and 20 cm telescope aperture.

7. ATMOSPHERIC REFRACTIVE TURBULENCE

The most familiar effect of refractive turbulence in the atmosphere is the twinkling of the stars and the shimmer of the horizon on a hot day. The first of these is due to the random fluctuations in amplitude of the light, also known as *scintillation*. The second effect is the random change in the optical phase of the lightbeam that leads to a reduction in the resolution of an image. Other atmospheric effects are large-scale beam wander and breakup of the optical beam into smaller phase fronts or speckles. In the visible and near IR, these fluctuations are caused by small fluctuations in the temperature (0.01–0.1°) of the atmosphere on the spatial scale of 0.1 cm–10 m, which cause changes in the index of refraction of the atmosphere. These small-scale fluctuations can distort and break the laser beam into small turbulent cells. In the far IR spectral region, the influence of these temperature fluctuations is diminished, but large-scale spatial changes in the background absorption and concentration of water vapor can also cause large beam wander and fluctuations.

Extensive work by NOAA and DoD since the early 1960s, starting with the pioneering work of David Freed and Tatarskii, has been able to successfully clarify the phenomena of atmospheric refractive turbulence and yield predictive equations [24,32–34]. These atmospheric turbulence studies are valid for energy-conserving fluctuations in the atmosphere and have resulted in well-understood equations relating the optical beam fluctuations and the refractive-turbulence structure parameter, C_n^2. Figure 15 shows values of C_n^2 measured during a sunny day in Florida as a function of time using an optical beam intensity scintillometer instrument from NOAA [35]. As can be seen, the value of C_n^2 varies by several orders of magnitude, becoming largest during the middle part of the day.

The variation of C_n^2 with height above the ground is given approximately by [24]

$$C_n^2(h) = C_n^2(0)\, h^{-4/3} \tag{9}$$

where h is the height in meters above the ground and $C_n^2(0)$ is the value at ground level.

Fluctuations in the intensity or irradiance of the optical beam can be expressed approximately (for weak turbulence) as [24]

$$\sigma_r^2 = \exp(0.5\, k^{7/6} R^{11/6} C_n^2) - 1 \tag{10}$$

where σ_r^2 is the irradiance variance (normalized by the mean irradiance value), k is the optical wavenumber ($2\pi/\lambda$), and R is the range. This expression is modified slightly when the inner scale of the turbulence (smallest spatial fluctuation size) is greater than the square root of λR. There are several other expressions for σ_r^2 depending on the approach to saturation and the value of the inner

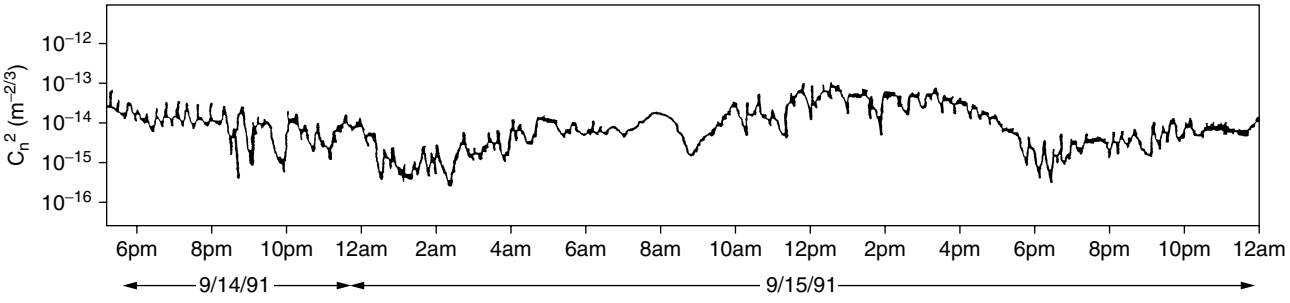

Figure 15. Measured atmospheric refractive-turbulence structure parameter, C_n^2, as a function of time throughout the day.

and outer scale values. The interested reader should consult the references for more detail [24,32–34].

The autocorrelation spectrum or power spectral density of the optical beam fluctuations gives the frequency or speed of the fluctuations. Experiments have shown that the decorrelation time of atmospheric refractive turbulence fluctuations is on the order of 1–10 ms, so that the frequency of the fluctuations is on the order of a few hundred hertz or less [36,37].

The influence of refractive turbulence is to break a Gaussian mode laser beam into smaller speckles or individual coherent wavefront groups. The effect can be given by the atmospheric turbulence field coherence length, ρ_0, which indicates the approximate size of the interference speckles within the laser beam, and is given by [24]

$$\rho_0 = (1.09\, k^2 R C_n^2)^{-3/5} \tag{11}$$

Equation (9) yields the size of the speckles within a beam front. It is an important parameter for a heterodyne detection or photon counting detection system since it places a limit as to the effective telescope aperture size (approximately $3\rho_0$) that can be used in a system [38]. However, for most current FSO systems that use direct detection of the beam, this will affect only the number of speckle modes to be aperture-averaged within the receiver, which will then affect the aperture-averaged SNR. The total system SNR will be a combination of all the fluctuation SNR values, power-limiting SNR considerations, and averaging effects within the communication decision time. Additional research is required in this area to better understand the tradeoffs in the area of signal averaging and atmospheric effects, including mitigation through the use of multiple wavelengths, beams, detectors, and temporal samples.

The beam wander due to refractive turbulence can be given by

$$\sigma_d^2 = 0.97 C_n^2 D^{-1/3} R^3 \tag{12}$$

where σ_d^2 is the variance in the displacement of the beam axis in m^2 and D is the diameter of the initial beam [39,40].

The preceding equations can be used to estimate the approximate level of fluctuations of a projected laser beam under controlled or laboratory conditions. Usually, the values for the standard deviation of the fluctuations σ are on the order of 0.05–0.7 (i.e., 5–70%), depending on the values of C_n^2 used. However, experience has shown that in many experimental and field-site cases complex windflow patterns exist (which are not energy-conserving) along with other atmospheric inhomogeneities that can cause beam drift and local absorption. As such, it is usually hard to accurately predict the fluctuation level in a particular setup. In this case, one has to resort to actual measurements of the fluctuation variance levels σ^2, in order to compare different experimental systems.

Under normal circumstances, the fluctuation variance level can be related to the information content signal-to-noise ratio (SNR) by [41]

$$\mathrm{SNR} = \frac{1}{\sigma^2} \tag{13}$$

where σ^2 represents the averaged or processed normalized variance measured over the time interval used to determine SNR of a decision period (possibly of one data bit or multiple bits for a coded word). Usually, if signal averaging is used, this has the effect of reducing the estimate of the variance by the square root of the number of samples averaged:

$$\mathrm{SNR}_n = \mathrm{SNR}_1\, n^{1/2} = \frac{n^{1/2}}{\sigma^2} \tag{14}$$

where n is the number of samples integrated, SNR_n is the SNR for n samples, and SNR_1 is the SNR for a single sample. Equation (14) is valid for an ergodic process that has random noise, but has to be reduced if nonrandom noise or processes are present [41]. This is true for large-scale attenuation processes in the infrared, where long-term temporal drifts in attenuation due to water vapor and other phenomena may be present. However, in the visible and near IR, the major noise sources are usually random.

Equation (14) is the general relationship for a signal detection process and helps relate the influence of increased fluctuation levels on SNR, which then directly affects the BER via Fig. 12. However, in the case of a FSO system, the fluctuation levels should more properly be measured only over the decision time of a bit. As such, the short-term variance measured over a time period of a data bit period may have to be used.

As can be seen in Eq. (14), the SNR can be improved through averaging multiple signals within the information decision period. This can be seen in an excellent research study by Kim et al., who studied the effect of refractive-turbulence fluctuations through the use of multiple laser beams [42]. Figure 16 shows the fluctuation levels measured over a 20-s time period for a 1.5-μm, 1.2-km FSO system that used one, two, and three separate laser beams. As can be seen, the use of several laser beams reduced the fluctuation levels that had the effect of increasing the measured SNR.

While the preceding equations indicate the level of fluctuations, it is customary in the FSO community for such an effect to be accounted for by introducing a fluctuation, fade, or link margin that is derived more from experimental measurements than from theory. Such a link margin may be on the order of 15–20 dB, although such a high value often includes the desired SNR for a specified BER compared to that for a SNR of 1. For example, for a system with a BER of 10^{-9} and a NEP of the detector of 20 nW, the BER value is related to a SNR of 6 [28]. In this case, a fade link margin could be 7 dB (factor of 5), so that the required SNR would be 6 times that due to 7 dB, specifically, a value of 30, or 15 dB. This is the equivalent of solving the range equation for a SNR of 1, but using a link margin of 15 dB. Both analysis types are used in the literature and are equivalent.

Finally, another atmospheric phenomena related to deep fades in the communication link has received considerable study [43,44]. For a FSO laser-based system transmitting over moderate to long ranges of 2–10 km, the fluctuations observed have the traditional refractive turbulence frequency fluctuations of up to a few hundred hertz, but long-term fades lasting 0.1 s to a few seconds are also observed. These are difficult to extract from similar effects due to tracking drifts or from building sway.

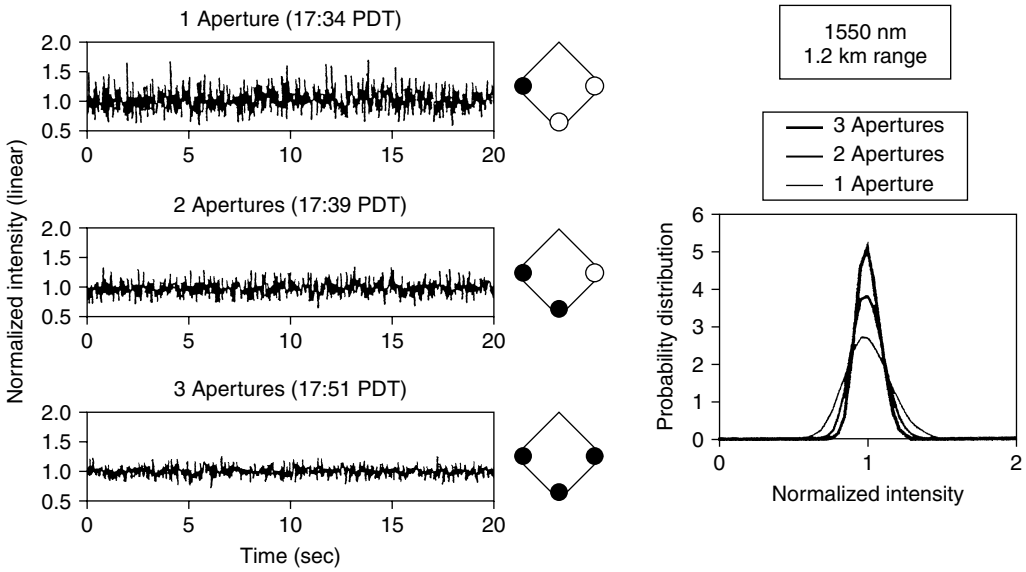

Figure 16. Intensity and fluctuation distribution measured for a 1.2-km FSO 1.55-μm system using one, two, and three laser beams. The reduction in signal fluctuations using three beams is easily seen. (Reproduced with permission of I. I. Kim, M. Mitchell, and E. Korevaar, SPIE Vol. 3850, 1999.)

However, some studies suggest that they may also be due to beam bending due to the presence of spatial localized concentrations of water vapor that move into the beam path. Such water vapor spatial clouds have been observed with high resolution Raman lidar (laser IR radar) systems, and indicate water vapor "clouds" of 10–100 m in diameter and movement times on the order of 1–100 s [45]. On the other hand, long-term fading can occur if the coherent beam produces a single speckle at the receiver and the optical alignment is such that destructive interference occurs (due to long-term building sway, beam wander, etc.). In this case, the intensity received is close to zero. Sometimes, these fades have values of up to 10–30 dB, suggesting partial destructive interference of the speckle. The effects of these fades can be mitigated through the use of multiwavelength, multispatial, or multitemporal samples within the link bit decision period in order to produce independent samples of the transmitted bit.

8. TELESCOPE DESIGN, TRACKING/ALIGNMENT DETECTORS, AND ENVIRONMENT

The telescope and receiver lens used in a FSO system is usually a compromise between the use of wide apertures for greater light gathering, short focal length for ease of handling, moderate field of view for ease of alignment, and optical coatings for narrow spectral filters for daytime use. This can be seen in Fig. 17, which shows several typical telescope configurations. Common configurations for a FSO system is either the use of a single lens and a

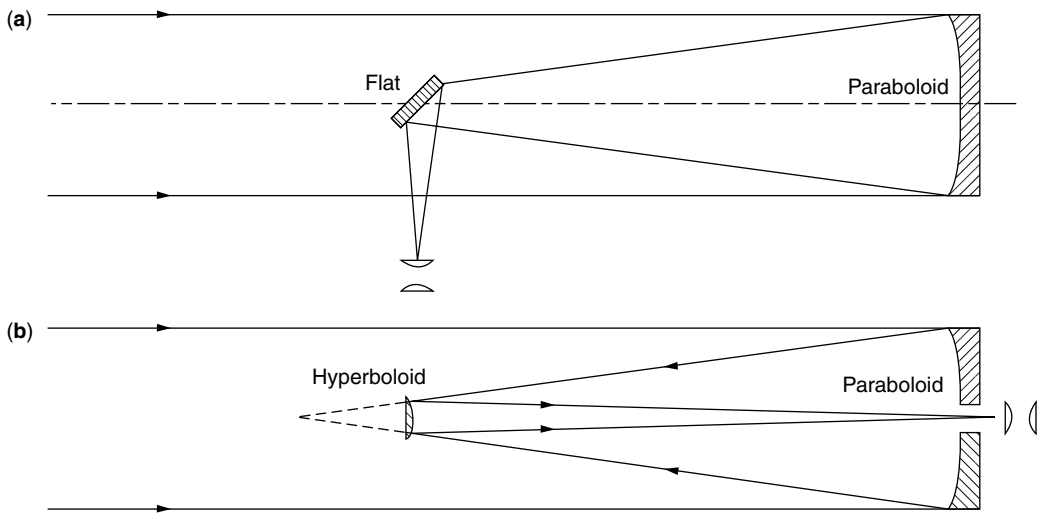

Figure 17. Schematic of Newtonian (**a**) and Cassegrainian (**b**) telescopes.

detector or the use of a Cassegrain telescope and a detector system that folds the beam path so that the telescope is shorter than that of a Newtonian configuration. An example of a short Cassegrain-type telescope used for FSO is one developed by Kaiser Electro-Optics in their f#/0.67 Hyperscope transceiver with an 8 in. aperture and 4 in. overall length. In this telescope a coated front reflecting window is used as the secondary mirror as in a Mangin mirror telescope configuration, which shortens the overall length of the telescope by a factor of ~2 [46,47].

Another method is to use a holographic lens or mirror arrangement to also ensure spectral and position placement that is similar to combining a diffraction grating with a lens [48]. Such a holographic lens is flat. Another possibility is that the holographic lens can be configured to displace or rotate the focused light around the perimeter of the lens as a function of input direction.

A common configuration for an inexpensive telescope systems is to use either a conventional optical lens or a flat Fresnel lens. In the latter case, the focal volume and resolution are not as good as with a conventional lens, but may be sufficient since in many cases the beam divergence and field of view of the transceiver have been enlarged to ease optical alignment of the system.

Alignment and tracking of the FSO system can be a difficult problem for longer-range systems. For short ranges under 200–500 m, the alignment and beam wander of the communication beam may be small enough that only coarse mechanical alignment is required during initial setup. For longer ranges, however, usually some form of active alignment and tracking is required. Two axis gimbals on the telescopes or the entire FSO unit are often used in this regard, as well as active positioning of the detector in the x–y image plane of the telescope. Fluctuation times on the order of 1–10 ms are required for atmospheric fluctuation, while building sway may have resonance times on the order of 1–10 s. Temperature- and wind-driven gross movement of buildings will have times on the order of hours. It is common to use quad (4) detectors and/or CCD cameras to monitor a separate alignment beam in order to actively track and compensate such movement.

Weather/environment protection of a FSO system is determined by the indoor or outdoor use of the system. Several systems are made for indoor use and require little environmental design. Some units are made for use behind the windows of an office and use the window and benign office conditions to separate them from harsher outside conditions. Outdoor use often entails hermetically sealing the FSO unit, with the placement of sunshields, rain canopies, and heaters on the telescope lens to reduce frost or condensation.

9. LASER EYE SAFETY

Any laser beam can cause damage to the human eye if it is operating with an irradiance (W/cm^2) that is above a certain level. The minimum permissible exposure level (MPE) is tabulated in the ANSI standards [49]. The standards are written for direct ocular view by the eye, and are given as a function of wavelength. This latter part is important because for wavelengths less than ~1.4 μm (~1400 nm), the optical radiation that enters the eye is focused and increased in irradiance onto the retina. For wavelengths longer than ~1.4 mm, the light is absorbed by the cornea and vitreous humor inside the eye. The reader should remember that it is possible for a coherent laser beam to be focused by a lens down to the diffraction limited spot size given by $f\#\,\lambda$, where the f-number, f#, of the lens is equal to the diameter of the lens (or pupil of the eye) divided by the focal length of the lens; as can be appreciated, for the human eye this spot size on the retina is close to the wavelength of light: about 1 μm in diameter. Such a focusing effect is already taken into effect by the ANSI standards.

While the reader should use the ANSI standards for each explicit situation, a general idea of the eye-safety values can be shown as in Table 3. Table 3 shows the direct ocular MPE values, and the approximate calculated maximum transmitted laser power levels for a FSO transmitter that delivers a 30 × 30-cm beam at a distant receiver where the ocular viewing would occur; this corresponds to the size of a 1° divergence laser beam after being transmitted 200 m through the atmosphere. The MPE is shown for a 10-s exposure. The maximum transmitted laser power is seen to be about 1 W for the 0.7-μm laser and about 90 W for the 1.55-μm system. Of course, these values are much lower if the eye is at a closer range and intercepts the beam where the beam is smaller and the irradiance is higher. In addition, the effect of atmospheric turbulence may increase the fluctuating intensity levels so that the values would need to be reduced appropriately. The eye safety for a LED is higher since it is a noncoherent source and will not be focused to a small diffraction-limited spot on the retina.

Most FSO systems are designed to be eye-safe, or to operate where a human will not intercept the beam. In the case where humans may intermittently intercept the beam, other warning systems such as the use of an inexpensive microwave radar system (e.g., marine radar) could be used to detect the presence of a human within the FSO beam path and shut down the system temporarily.

Finally, laser safety regulations and standards have been instituted as to the manufacturing classification of the laser, such as class IV or class IM, which covers the power levels and operational safety standards for the laser. The international organizations such as the International Electrotechnical Commission (IEC) and U.S.

Table 3. Approximate Maximum Permissible Exposure (MPE) Power in W/cm^2 for Direct Ocular (Eye) View for Several Different Wavelengths

λ (μm)	MPE (mW/cm^2)	P_t (Maximum Transmitted Power) – 200 m away (w)[a]
0.7	1	0.9
0.9	25	22
1.55	100	90
10	100	90

[a]The maximum transmitted laser power calculated is for the case of a beam size of 30 cm in diameter at the position of the eye (appropriate for a propagation distance of 200 m and beam divergence of 1 degree).

agencies (FDA, Laser Institute of America, and ANSI) have helped coordinate these classification schemes. For example, the IEC has expanded its coverage of TC 76/60825 part 12, Working Group 5 (WG5) to cover safety and transmission issues associated with laser and LED FSO communication [50]. The WG5 committee has been working on a draft titled *Part 12: Safety of Free Space Optical Communications Systems Using Directed Beams* to be released in 2003. The interested reader is encouraged to review this information in the references. They are not of concern for the scientific analysis of a FSO system, but are very important for the manufacturing and proper use of commercial FSO systems.

10. FSO SYSTEM AND ENGINEERING TRADE-OFFS

As can be seen from the above discussions, there are many scientific aspects of FSO design. In addition, there are a considerable number of system and engineering trade-offs that also have to be looked at. It is beyond the scope of this article to discuss this in detail, but some general aspects can be listed. Some of the trade-off parameters that need to be taken into account include (1) modulation of the laser or LED (direct modulation through the power supply or the need for an expensive external modulator), (2) detector bandwidth and cooling requirements in the case of IR detectors, (3) increased laser beam divergence and possible need to increase laser power versus increased cost of using active alignment of a narrow laser beam, (4) cost of laser or LED system at different wavelengths versus advantages of availability of cheaper detector components versus penetration of beam through fog or rain, and (5) eye safety versus laser beam size versus divergence of beam and beam size at detector telescope. As can be seen, there are a significant number of engineering trade-offs that have to be made in any FSO system. Although the above list of trade-offs seems formidable, it is not really as bad as it first appears. This is because there are many different ways to build a successful FSO system for a specified operating condition. As such, there is no "one" or ultimate maximized system, but rather several that are sufficient to provide the communication link required. The most basic, first-level trade-off studies are often conducted to provide a high level of reliability and link BER for the specified atmospheric conditions and system environmental conditions. Then, within these broad constraints, one finds that there are usually several approaches that will meet the requirements.

11. FUTURE TECHNICAL AND INDUSTRY CONSIDERATIONS

FSO is just starting to impact the Internet "last- mile" interconnectivity problem. It is felt that it may offer the unlimited bandwidth solution for this problem within the metro urban core involving downtown building-to-building communication, but may also be a major technology for home-to-home and office-to-office connectivity. As stated earlier, if the home/business last-mile connectivity becomes the main technical driving force for communication, then the optimization of the technical specifications for FSO may become more important than using laser wavelengths and transceivers as part of the current fiberoptic communication legacy. In that case, wavelength issues and tradeoffs between long-range point-to-point versus short-range mesh-net connectivity will be addressed and operational standards will be set by the industry. It is common to hear that FSO solves a technical problem at present, but that the industry does not yet recognize or fully understand the potential that FSO offers. As such, some of the current problems in the deployment of FSO is in the industry perception and marketing of this technology. FSO systems have now shown that they are reliable (99.9% to 99.999%) communication channels that have fast bandwidth, are easy to set up, and provide cost-effective solutions. The FSO community recognizes these concerns, and has launched the Free Space Optics Alliance organization [51]. The FSO Alliance currently consists of about 25 companies, and has a mission to educate and promote FSO technical information to the communication industry as a whole and the print and journal media sector. It is believed that through such industry wide education, that industry standards and proper growth of FSO technology will occur within the communication carrier industry.

It is believed by the author that FSO is on the verge of changing the basic communication medium and technology of the metro and last-mile network market. The challenges and importance of setting standards for FSO are becoming increasingly clear in order to help the field become a major component in the whole communication network. It is hoped that the reader has gained an appreciation of some of the technical challenges and opportunities that FSO offers in this regard.

Finally, the author would like to acknowledge several helpful discussions and suggestions from Drs. Issac Kim, David Rockwell, and John Schuster.

BIOGRAPHY

Dennis K. Killinger received the B.A. degree from the University of Iowa, M.A. degree from De Pauw University, and Ph.D. degree in Physics from the University of Michigan. He has conducted research on radar analysis and microwave atmospheric propagation while employed as a Research Physicist at the Naval Avionics Facility, and joined the research staff in Quantum Electronics at Lincoln Laboratory, Massachusetts Institute of Technology in 1978 conducting research in the development of new solid-state lasers and their application as spectroscopic lidar probes of the atmosphere. Since 1987 he has been a Professor of Physics at the University of South Florida and is a Distinguished University Professor and Director of the Laboratory for Atmospheric Lidar and Laser Communication Studies. Dr. Killinger is a Fellow of the Optical Society of America, Senior Member of the IEEE, past associate editor of *Applied Optics and Optics Letters*, past member of the NAS/NRC Committee on Optical Science and Engineering, and has served as chairman of several international conferences on lasers and applied spectroscopy. He has published over 200 technical papers, reports, and conference papers in laser remote sensing/lidar, applied laser spectroscopy, laser

physics, laser atmospheric propagation, and free-space optics (FSO) laser communication.

ORTHOGONAL FREQUENCY-DIVISION MULTIPLEXING

LEONARD J. CIMINI JR.
LARRY J. GREENSTEIN
AT&T Labs-Research
Middletown, New Jersey

1. INTRODUCTION

The permissible data rate of a digital communications link is limited by the available bandwidth and also by power and noise. The data rate can also be limited by phenomena in the communications medium (channel) between the transmitter and the receiver, especially by intersymbol interference (ISI) caused by time dispersion of the transmission medium, such as occurs on the multipath radio channel and the frequency-selective telephone channel.

As a general rule, the effects of ISI are small as long as the time extent of the channel impulse response is significantly shorter than the duration of a transmitted symbol. This implies that the symbol rate transmitted over a dispersive channel is practically limited by the channel's memory. However, mechanisms exist for countering ISI and thus extending symbol rates. These include receiver equalization, transmitter preequalization, and some forms of radio diversity. All are aimed at permitting the transmission of datastreams with symbol periods comparable to, or even smaller than, the channel's memory.

An alternative approach employs multiple carriers. In multicarrier transmission, the datastream to be transmitted is split into multiple parallel datastreams of reduced rate, and each of them is transmitted on a separate frequency (or *subcarrier*). Each subcarrier is modulated at a rate so low (or, equivalently, has a symbol period so long) that dispersion does not cause a problem. A given subcarrier, with its associated data signal, constitutes a *subchannel*. Ideally, the bandwidth of a subchannel would be so narrow as to preclude any ISI. More realistically, there will be *reduced* ISI on each subchannel, which can be either tolerated or easily corrected. Since the system's data throughput is the sum of the throughputs of the parallel subchannels, the data rate per subchannel is only a fraction of that of a single-carrier system having the same throughput. Thus we see that multicarrier transmission permits high data rates while maintaining symbol durations much longer than the channel's memory.

At the same time, the subchannels must be spaced, and spectrally shaped, to ensure that they do not interfere with each other. Such precautions can limit spectral efficiency, defined as the total bit rate divided by the total bandwidth. *Orthogonal frequency-division multiplexing* (OFDM) [1–4] is a special case of multicarrier transmission that permits the subchannels to overlap in frequency without mutual interference. In addition to improved spectral efficiency, this technique exploits digital signal processing technology to obtain a cost-effective means of implementation. Our primary aim here is to detail the theory and practice of this form of multicarrier transmission.

Before proceeding with the basics, we pause to note the numerous communications systems, past and present, that have used some form of multicarrier transmission. The first systems using this technique were designed in the late 1950s and early 1960s for military high-frequency radio applications [5,6]. These included the Kineplex and Kathryn systems. Since these early systems, multicarrier transmission (and in particular OFDM) has been used over many different communications media. Practical interest has increased partly as a result of enabling advances in signal processing and microelectronics, and partly because of the demand for ever-higher data-rate services over dispersive channels. Multicarrier modems have been standardized in different parts of the world for both wireline and wireless data applications, including digital audio/video broadcasting (DAB/DVB) [7,8]; digital transmission over copper wire, for example, digital subscriber loops (DSLs) [9]; wireless local-area networks (WLANs) [10]; and have been proposed for mobile radio applications [11].

2. BASIC CONCEPTS

2.1. Multicarrier Transmission

There are several techniques for realizing a multicarrier link. In the conceptually simplest approach, the total signal frequency band is divided into N ideally nonoverlapping (band-limited) frequency subchannels, employing N independent transmitter–receiver pairs. A block diagram description of how this can be done is given in Fig. 1. In the transmitter (Fig. 1a), an input stream of data, at rate R bits per second (bps), is divided into N

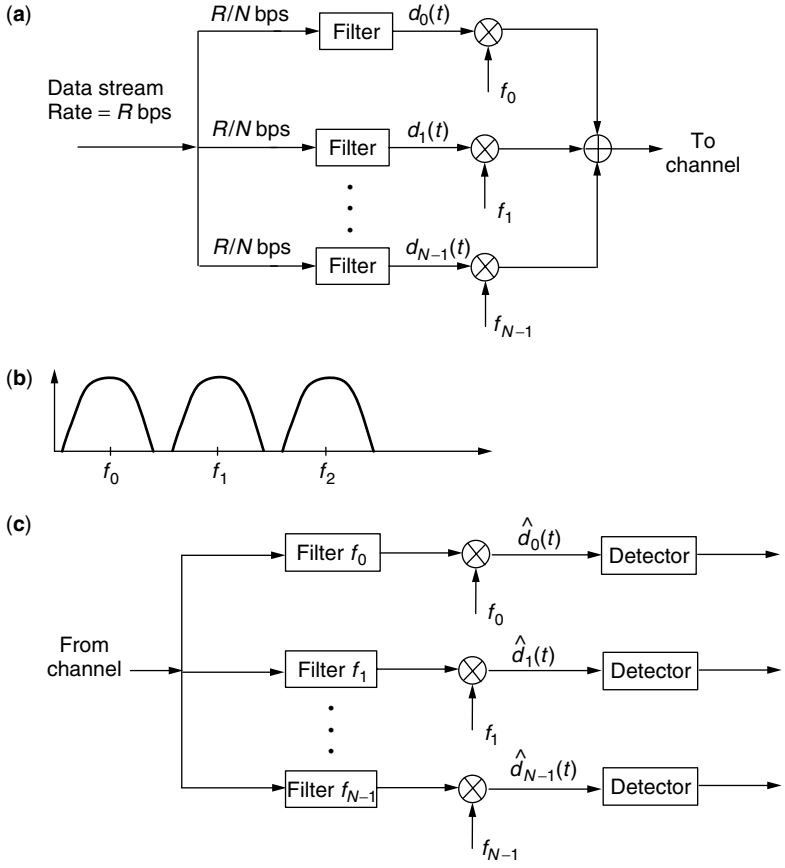

Figure 1. Multicarrier transmission system: (**a**) multicarrier transmitter; (**b**) transmit spectrum; (**c**) multicarrier receiver.

parallel substreams, each at data rate R/N bps. (The data values in the mainstream and the substreams are, in general, complex, and the real and imaginary components can be binary or multilevel.) Each substream is passed through a baseband pulseshaping circuit ("filter"), where we assume identical filters for all substreams. The kth filter output ($k = 0, 1, \ldots, N-1$) is then upconverted by a balanced mixer to frequency f_k. The result is a subcarrier with *quadrature amplitude modulation* (QAM). The N-QAM signals are combined (frequency-multiplexed) and sent over the channel. An example of the output signal spectrum is given in Fig. 1b. In the receiver, Fig. 1c, a set of bandpass filters centered on f_k, $k = 0, 1, \ldots, N-1$, is used to frequency-demultiplex the N subchannels, after which each subchannel is downconverted to baseband by a balanced mixer. Each substream is then applied to a detector, and the output data values are sent on for possible further processing. The spectral guard bands shown between subchannels in the figure are introduced so that easily realizable filters can be used in the receiver.

While the advantages of multicarrier transmission in terms of reduced sensitivity to dispersion are obvious, there are two major disadvantages to this particular realization. First, it is spectrally inefficient, since the signals must be sufficiently spaced in frequency to facilitate separation at the receiver. Second, a receiver with a large bank of filters may be prohibitive in terms of complexity and cost. The alternative approach (OFDM), using overlapping subchannels (to improve the spectral efficiency) and efficient digital signal processing techniques (to reduce the complexity and cost), is described next.

2.2. Basic OFDM

Orthogonal frequency-division multiplexing provides a solution to the disadvantages of conventional multicarrier transmission. In particular, a more efficient use of bandwidth can be obtained if the spectra of the individual subchannels are permitted to overlap, with specific orthogonality constraints imposed to facilitate separation of the subchannels at the receiver. Figure 2 shows the spectra for the two alternative forms of multicarrier transmission.

To analyze either form of multicarrier signal, we denote the symbol rate of the original data sequence by f_s, where $T_s = 1/f_s$ is the original symbol period. After serial-to-parallel conversion, there are N parallel data sequences, each with symbol rate f_s/N and symbol period $T = NT_s$. Thus, each subchannel is tolerant of N times as much time dispersion as would be the original datastream.

Now assume that, in a given symbol period $[0, T]$, the N subchannels carry data values $D_0, D_1, \ldots, D_k, \ldots, D_{N-1}$. We assume that D_k is two-dimensional, that is, $D_k = A_k + jB_k$, where A_k and B_k are real numbers representing the in-phase and quadrature data components, respectively. The set of discrete values possible for each component depends solely on the chosen data constellation, for example, $A_k = \pm 1$ and $B_k = \pm 1$ for four-level

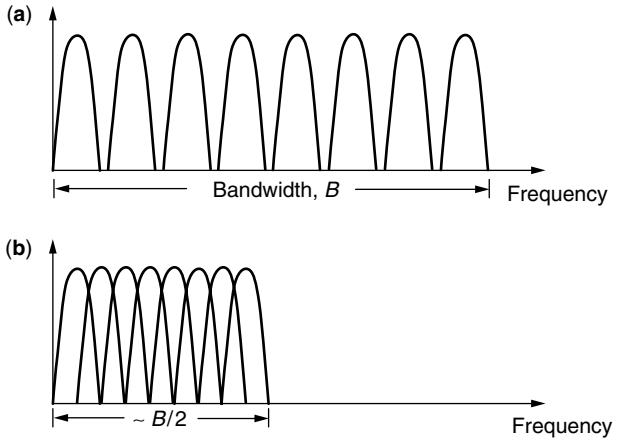

Figure 2. Transmit spectra of multicarrier and OFDM signals: (**a**) multicarrier spectrum; (**b**) OFDM spectrum.

quadrature amplitude modulation (4-QAM), also called *quadrature phase shift keying* (QPSK). Finally, assume initially that the data values are carried by rectangular pulses, that is, that the kth subchannel data value is carried by a pulse that is 1 on $[0, T]$ and 0 elsewhere. Then, the multicarrier signal transmitted on the given symbol interval can be represented as

$$s(t) = \mathrm{Re}\left\{\sum_{k=0}^{N-1} D_k e^{j\omega_k t}\right\}, \quad 0 \le t \le T \tag{1}$$

$$= \sum_{k=0}^{N-1} [A_k \cos \omega_k t - B_k \sin \omega_k t], \quad 0 \le t \le T \tag{2}$$

where the subcarrier radian frequency is $\omega_k = 2\pi f_k$, with $f_k = f_0 + k\Delta f$. The offset frequency, f_0, could represent the carrier frequency in a passband transmission system, such as one using a wireless channel, or could be adjusted for baseband transmission. Also, for baseband transmission, the data could be chosen in a symmetric fashion to guarantee a real output. This latter situation is discussed in Section 2.4. The parameter Δf represents the subcarrier spacing, which we discuss next.

The structure in Fig. 3 represents a general form of a multicarrier transmitter. For OFDM, the subchannels are permitted to spectrally overlap. To enable separation of these channels at the receiver, the data pulses for every pair of subchannels must be mutually orthogonal. For rectangular pulses, this can be achieved by relating the subcarrier spacing and the symbol duration via $\Delta f = 1/T$. Under these conditions, a simple correlation for each subchannel (i.e., multiplication by the appropriate waveform followed by integration over the symbol period) can separate out the subchannels. This receiver structure is shown in Fig. 4.

The power spectral density of the transmitted OFDM signal is the sum of the power spectral densities of N separate QAM signals at N subcarrier frequencies separated by the signaling rate. For rectangular symbol pulses, the Fourier transform of the symbol in each subchannel is a shifted version of $\sin x/x = \mathrm{sinc}(x)$, with nulls at the centers of the other subchannels. These and other spectral properties of an OFDM signal with rectangular symbol pulses are illustrated in Fig. 5. The Fourier transform of a single pulse in a single subchannel is shown in Fig. 5a; a set of Fourier transforms corresponding to eight subchannels ($N = 8$) is shown in Fig. 5b, and the OFDM power spectral density is shown in Fig. 5c for $N = 64$ and 256. (For convenience, we display the out-of-band portion in each case as the *envelope* of the actual lobe structure.) For large N, the total power spectral density is essentially flat in the bandwidth containing the subcarriers, and only the subchannels near the band edge contribute to the out-of-band power. Therefore, as the number of subcarriers becomes large, the spectral compactness approaches that of single-carrier modulation with rectangular bandpass filtering.

We now express the above ideas mathematically. Using the complex envelope of the transmitted signal, a single OFDM symbol can be represented as

$$S(t) = \sum_{k=0}^{N-1} D_k e^{j\omega_k t} \times \mathrm{rect}\left(\frac{t}{T}\right) \tag{3}$$

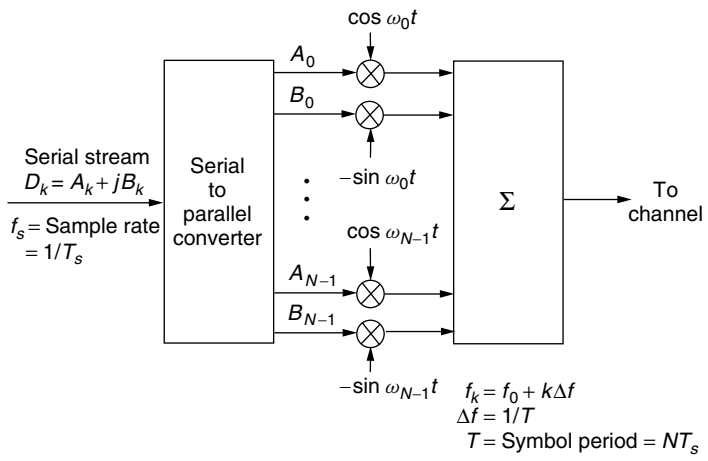

Figure 3. OFDM transmitter.

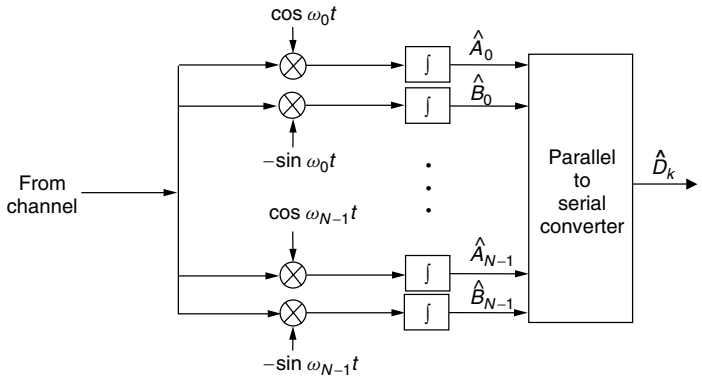

Figure 4. OFDM receiver.

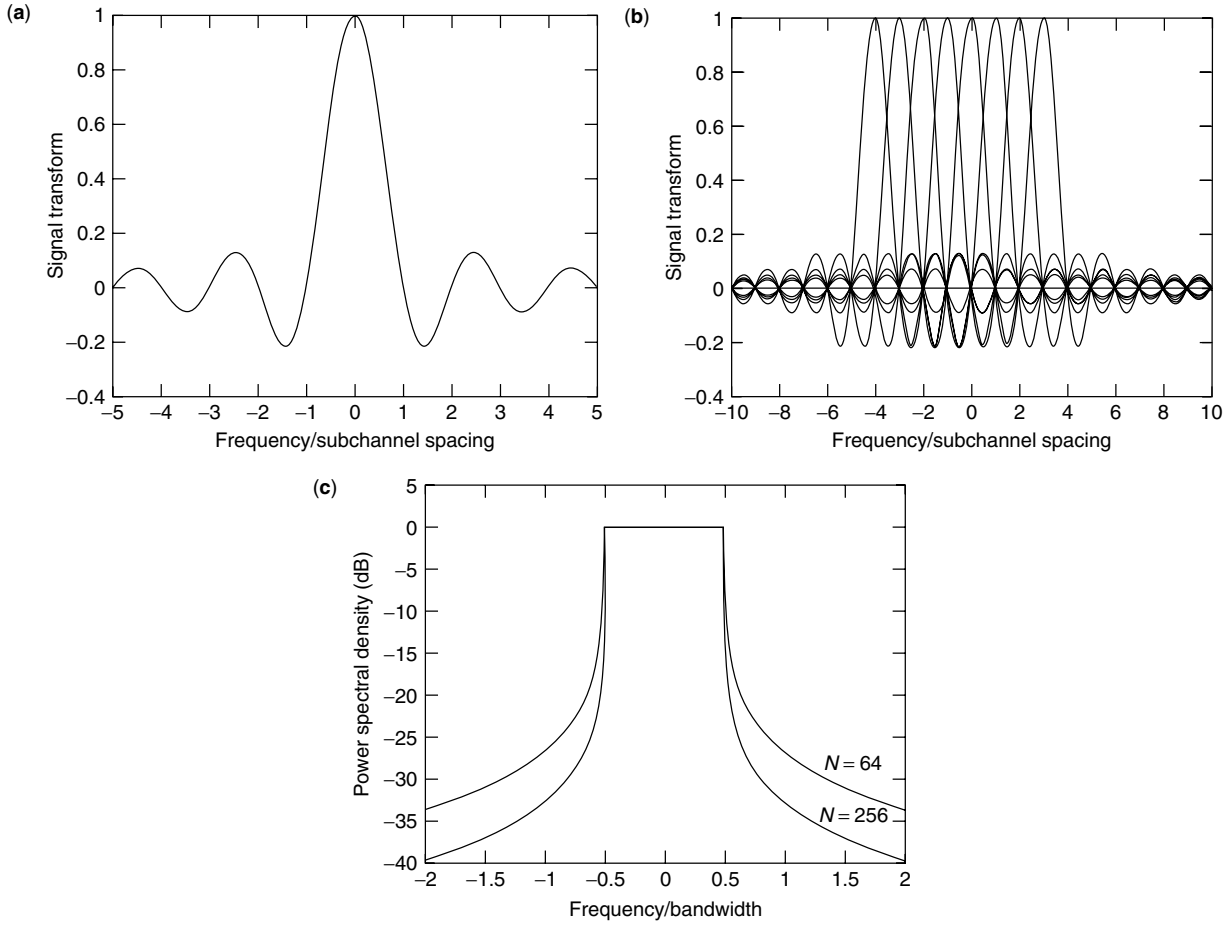

Figure 5. Spectral properties of an OFDM signal: (**a**) single channel; (**b**) eight individual subchannels; (**c**) Spectral power density (referred to center frequency).

where rect (x) is defined as having the value 1 on [0,1] and 0 elsewhere. The Fourier transform of $S(t)$ is thus given by

$$P(f) = T \sum_{k=0}^{N-1} D_k \frac{\sin \pi \left(\dfrac{f - f_k}{\Delta f} \right)}{\pi \left(\dfrac{f - f_k}{\Delta f} \right)} \tag{4}$$

If the data symbols are mutually independent (both among symbols and among subchannels), the power spectral density of the OFDM signal is $\overline{|P(f)|^2}/T$, where the overbar denotes averaging over the data. This formulation was used to obtain the results in Fig. 5c, where $f = 0$ corresponds to the center frequency of the OFDM spectrum. Note that the sharpness of the spectral falloff outside the main bandwidth increases with N.

We now show the orthogonality of the N transmitted pulses. Assuming, at this point, a perfect and noiseless channel, we can also regard $S(t)$ in Eq. (3) as the received signal. To detect the kth data value, D_k, $S(t)$ is multiplied by $e^{-j\omega_k t}$ and then integrated over $[0, T]$. The received data

symbols at the output of the kth correlator are

$$\hat{D}_k = \int_0^T S(t)e^{-j\omega_k t}\,dt = \sum_{l=0}^{N-1} D_l \int_0^T e^{j2\pi\Delta f(l-k)t}\,dt \tag{5}$$

For the case $\Delta f = 1/T$, it is easily shown that

$$\int_0^T e^{j2\pi\Delta f(l-k)t}dt = \delta(l-k) \tag{6}$$

where we use the Kronecker delta function, $\delta(l-k) = 1$ when $l = k$ and 0 otherwise. Therefore, $\hat{D}_k = D_k$, and, so, even though the subchannels overlap, they can be separated at the receiver with no interference among subchannels; that is, the subchannels are orthogonal.

We note that deriving the multicarrier transmitted signal from the data sequence, Eq. (5), and detecting that sequence from the received signal, Eq. (6), involves operations that resemble Fourier transforms. We will show more formally that the orthogonality that arises from setting $\Delta f = 1/T$ allows the use of the discrete Fourier transform (DFT) at both ends and thus the use of very efficient digital signal processing [12]. The combination of orthogonal pulses and efficient DFT processing constitutes the essence of OFDM. There are, of course, many details. The most important of these have to do with practical impairments in the transmission medium (notably, time dispersion and time variations) and in the system hardware (notably, frequency and timing errors in the receiver and amplifier nonlinearities in the transmitter). Discussions of basic implementation, channel and system impairments, and their remedies occupy most of the remaining sections.

2.3. DFT Implementation

We show here how the DFT and the inverse DFT (IDFT) can be used to implement OFDM. In most cases, these transforms can be done very efficiently by using the fast Fourier transform (FFT) algorithm. In this discussion, the number of subchannels and the FFT size are the same, N. (Later, we show why the FFT size is generally greater.) If N is a power of 2, the number of operations is on the order of $N\log_2 N$, as opposed to N^2 for conventional DFTs, leading to substantial savings for large N. For example, the number of FFT operations for $N = 1024$ is about 10^4, as opposed to about 10^6 with conventional processing, for a reduction of 100 to 1. Thus, completely digital implementations can be built around special-purpose hardware performing the FFT and its inverse (IFFT), replacing the banks of oscillators, mixers, and filters shown in Fig. 1.

Consider a discrete-time version of the complex envelope of the transmitted OFDM symbol in Eq. (3). Assuming $f_0 = 0$, without loss of generality, and sampling at times $t_n = nT_s$, Eq. (3) becomes

$$S_n = \sum_{k=0}^{N-1} D_k e^{j2\pi k\Delta f n T_s}, \quad 0 \le n \le N-1 \tag{7}$$

With the imposed orthogonality condition, $\Delta f = 1/T = 1/NT_s$, this becomes

$$S_n = \sum_{k=0}^{N-1} D_k e^{j2\pi kn/N}, \quad 0 \le n \le N-1 \tag{8}$$

which is simply the IDFT of the input data sequence, $D_0, D_1, \ldots, D_{N-1}$. With N suitably chosen, the transmitted signal samples can then be generated using the efficient IFFT algorithm.

The receiver correlation operations can also be performed in this fashion. Specifically, suppose that the block of received signal samples, $\{S_n\}$, is transformed in the receiver using a DFT. This yields

$$\begin{aligned}\hat{D}_k &= \frac{1}{N}\sum_{n=0}^{N-1} S_n e^{-j2\pi kn/N} \\ &= \frac{1}{N}\sum_{n=0}^{N-1}\sum_{l=0}^{N-1} D_l e^{j2\pi n(l-k)/N} \\ &= \frac{1}{N}\sum_{l=0}^{N-1} D_l \sum_{n=0}^{N-1} e^{j2\pi n(l-k)/N} \\ &= \frac{1}{N}\sum_{l=0}^{N-1} D_l N\delta(l-k) \\ &= D_k\end{aligned}$$

Thus, the correlation operations can also be efficiently implemented using the FFT algorithm.

We should mention at this point that there are several alternative forms of OFDM, that is, orthogonality can be achieved in various ways [13–15]. In particular, several of the early forms of OFDM were based on band-limited signaling, using specially designed pulses or special signaling patterns to guarantee orthogonality. Nevertheless, the form of OFDM described here is the most popular and the one proposed or implemented for all OFDM-based standards.

Finally, it is important to note how the sequence of IDFT samples in the transmitter, $\{S_n\}$, is converted into a continuous analog signal for transmission over the medium. The N samples, spaced in time by $1/N\Delta f = T_s$, are passed through a digital-to-analog converter (DAC) and then applied to a band-limiting filter. The spectrum of a discrete-time waveform such as the S_n sequence is periodic, with period $N\Delta f$. The purpose of the band-limiting filter is to pass one such period (the *primary spectrum*) and suppress all others. The burden on this filter can be severe if the primary spectrum has significant content at the band edges, as is generally the case (Fig. 5). This situation is avoided, and the filtering problem eased, by "padding" the original block of data values, $\{D_k\}$, with zeros before and/or after the actual data values; that is, zero-valued subcarriers are added to the data-carrying subcarriers. Thus, the band-limiting filter does not require as sharp a cutoff characteristic. This padding creates a difference between the number (N) of data-carrying subcarriers and the total number (N') of subcarriers

processed by the FFT. The FFT size, N', can readily be chosen to be a power of 2; we will assume hereafter that this is the case, so that the central transmitter and receiver processings are IFFTs and FFTs, respectively. Note that the bandwidth to be transmitted is still $N\Delta f$, but the samples in time, S_n, are now spaced by $1/N'\Delta f$ (oversampling) and the spectrum period is $N'\Delta f > N\Delta f$.

2.4. Baseband versus Passband Representations

For a given block of data values $\{D_k\}$, the complex envelope of the OFDM signal is $S(t)$ in Eq. (5). For passband transmissions (as, e.g., in wireless applications), a stage of modulation is needed to convert $S(t)$ to a real passband signal. For baseband transmission (as in wireline applications like DSL), no modulation is needed but $S(t)$ must be a real baseband signal. This can be done by converting the N-symbol stream $\{D_k\}$ to a stream of $2N$ symbols according to the following rule:

$$D'_k = \begin{cases} \mathrm{Re}(D_0) & k = 0 \\ D_k & k = 1, 2, \ldots, N-1 \\ \mathrm{Im}(D_0) & k = N \\ D^*_{2N-k} & k = N+1, \ldots, 2N-1 \end{cases} \tag{9}$$

where $*$ denotes complex conjugate. It is easy to show that a DFT or an IDFT applied to this sequence will produce a sequence of real numbers. This requires that D'_0 and D'_N be real, so these symbols are used in the above rule to carry the real and imaginary parts of D_0. Note that all the data are contained in the first $N+1$ terms (D'_0 through D'_N). The rest are used to ensure a real baseband signal at the IDFT output in the transmitter.

Since the input to the IDFT in the baseband case has twice as many samples, so must the output. For the same OFDM symbol length, T, this means the samples of $S(t)$ are now spaced by $T/2N$ (not T/N), thus requiring a baseband bandwidth of about $2N/T$ Hz. This is the same as the bandwidth required for the passband case.

2.5. Guard Interval Considerations

Even with a large symbol duration, channel time dispersion will cause consecutive symbols (also called *OFDM blocks*) to overlap, resulting in some residual ISI that could degrade performance. This residual ISI can be eliminated, at the expense of spectral efficiency, by using guard time intervals, between OFDM symbols, that are at least as long as the maximum extent of the channel impulse response. Samples of the received signal lying in the guard interval are discarded in the receiver and the demodulated OFDM symbol is generated from the remaining N samples.

The guard interval could be filled at the transmitter with null signal samples (zeros). However, in the case where there is dispersion, the receiver FFT processing will truncate the spread signal, so that each detected data value, $\hat{D}_k$, will consist of D_k plus interchannel interference (ICI) from the other data values.[1] In particular, if the signal has length NT_s and the impulse response of the channel is of length LT_s, the signal at the output of the channel is the linear convolution of the channel and the transmitted signal and is therefore of length $(N+L)T_s$. In the receiver, however, the FFT processes only N samples; this is the truncation that causes ICI. Putting it an alternative way, an FFT preserves orthogonality between tones only when the convolution in time is a *cyclic* convolution, rather than the linear convolution that occurs in a real channel.

One widely used solution to this problem is to cyclically extend the OFDM block by an amount longer than the expected time extent of the channel impulse response [16]. Specifically, to create a periodic received signal for the FFT to process (and thereby eliminate ICI), M' time samples are copied from the end of the original OFDM sequence and appended as a prefix; and, M'' time samples are copied from the beginning of the original OFDM sequence and appended as a suffix, where $M = (M' + M'') \geq L$. In some systems only a prefix is used ($M'' = 0$) and the processing window position is adjusted accordingly. An example is shown in Fig. 6. At the receiver, the samples of the cyclic extension are discarded before FFT processing. Clearly, the need for a cyclic extension in time-dispersive environments reduces the efficiency of OFDM transmissions by a factor of $N/(N+M)$. In most OFDM designs, a guard interval of not more than 10% to 20% of the symbol duration is employed.

2.6. Windowing

In some OFDM applications, compactness of the transmitted spectrum is important. A case in point is wireless systems, where spectrum is precious and multiple systems are closely spaced in frequency. The sharpness with which the signal spectrum falls off outside the allocated bandwidth is then of great interest.

In the OFDM systems described so far, a rectangular symbol pulse has been assumed. In other words, all samples of the IFFT output and the cyclic extension (if used)

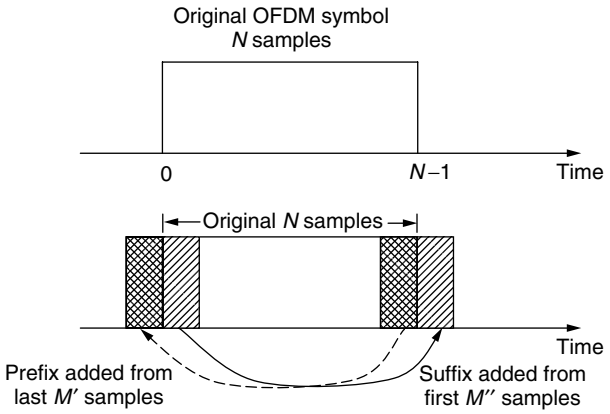

Figure 6. Cyclic extension.

between symbols in the same subchannel. Other causes of ICI, besides the one cited above, are channel time variations, frequency offset, and phase noise (Section 3).

[1] *ICI* refers, generally, to the interference between subchannels in the same symbol period. By contrast, *ISI* refers to interference

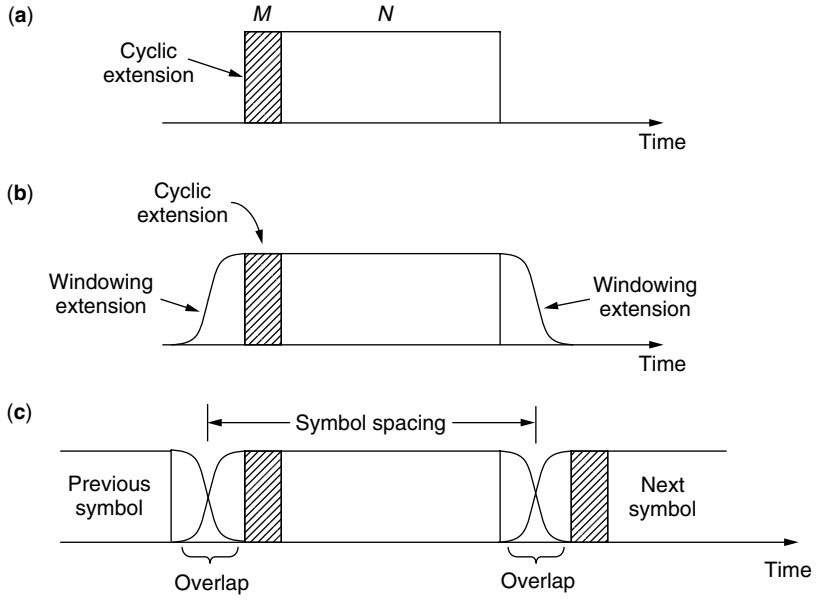

Figure 7. Windowing: (**a**) OFDM symbol; (**b**) windowed OFDM symbol; (**c**) sequence of windowed OFDM symbols.

are unweighted, which corresponds to having a rectangular symbol pulse, at each tone, of length $(N + M)T_s$. This is depicted in Fig. 7a. The spectral properties of the rectangular pulse shape (high sidelobes that decay slowly) lead to poor out-of-band spectral falloff [see Fig. 5c for $M = 0$, $N \leq 64$ or $(M + N) \leq 64$].

A simple way to improve the spectrum is to increase the periodic extension of $\{S_n\}$ even further and to taper the additional extension. This is called *windowing*. An example is shown in Fig. 7b. A commonly used shape is the cosine rolloff function. Although the total symbol duration is thus enlarged, the symbol *spacing* can be smaller than this duration, because adjacent symbols can overlap in the (unprocessed) rolloff region. This is shown in Fig. 7c.

To see the improvement possible with even a small extension, note the power spectral density plots of Fig. 8 for $N = 64$ ($M = 0$ for these computations). The parameter in the plots is the cosine rolloff factor, β, and the fractional

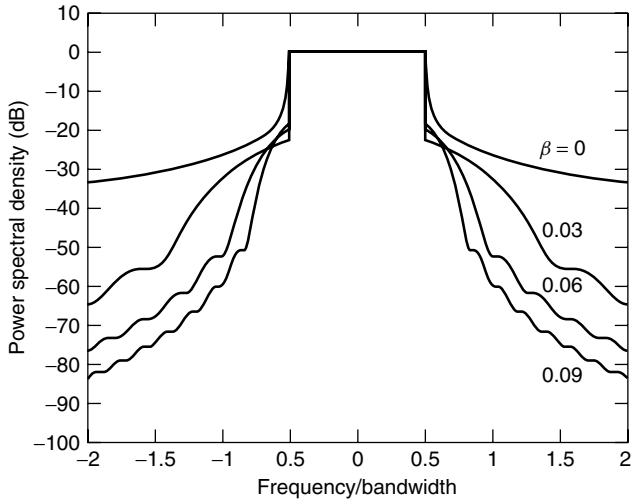

Figure 8. Power spectral density for windowed OFDM signal.

increase in symbol spacing can be shown to be $\beta/(1 - \beta)$. Thus, the curves show that an increase of only 3% in symbol spacing can produce dramatic benefits in out-of-band spectral falloff.

2.7. Coding

Because of the frequency-selective nature of the typical wideband channel (which is the main motivation for using OFDM), the OFDM subchannels generally have different received powers. Variations in the channel gain with frequency may cause some groups of received subcarriers to be much weaker than others, or even completely lost. Therefore, even though most subcarriers may be detected without errors, overall performance will be dominated by the performance of the few subcarriers with the lowest SNR (signal-to-noise ratio). As a result, satisfactory performance cannot be achieved without the addition of some form of error correction coding. By using coding across the subcarriers, errors in weak subcarriers can be corrected, up to a limit that depends on the code and the channel. Coding in OFDM systems has an additional dimension: it can be implemented in both the time and frequency domains, so that both dimensions can be utilized to achieve immunity against channel variations.

2.8. A Sample Design

The processing steps discussed above are all reflected in the simplified block diagrams of Fig. 9. We will present a

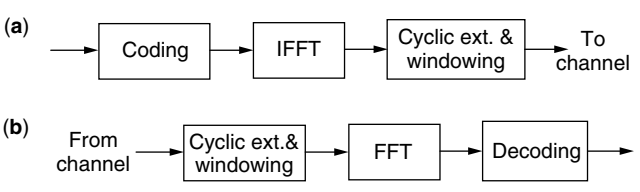

Figure 9. OFDM transmitter and receiver: (**a**) OFDM transmitter processing; (**b**) OFDM receiver processing.

sample design here, highlighting the factors influencing the choices of key parameters. It will be seen that OFDM system design involves tradeoffs among various, often conflicting, requirements. For example, to minimize the effects of time dispersion, a long symbol duration is required, meaning a large number of subchannels. However, if the channel is time-varying, as in a mobile radio environment, the variations during a long symbol period could be significant, causing possible ICI. The design parameters of interest are (1) the number of subcarriers, N; (2) the size of the FFTs, N'; (3) the guard time, T_g; the OFDM symbol duration, T; and (4) the subcarrier spacing, Δf. These are influenced by the assigned bandwidth, the desired bit rate, the time extent of the channel impulse response, and the rate of the channel time variations.

As an example, consider a wireless system that requires a bit rate of 1.2 Mbps (megabits per second) in a bandwidth of 800 kHz. Assume that the system must operate in an environment with a channel delay span of 20 μs, corresponding to wide-area transmission. A guard time, T_g, of 40 μs should be more than enough to guarantee that there is no ISI. (In this example, the guard time is assumed to be sufficient to handle the channel dispersion as well as any additional extension for windowing.) The OFDM symbol duration, T, is then chosen large enough to ensure that the efficiency loss due to the guard interval is small and to guarantee that the subchannel bandwidth is narrow enough to suffer only flat fading. In this case, we consider an OFDM symbol interval $T' = T + T_g = 200$ μs. This is five times the size of the guard interval, resulting in a 20% guard time overhead. The subcarrier spacing is then $\Delta f = 1/T = 6.25$ kHz. At a carrier frequency of 2 GHz and assuming a vehicle speed of no more than 100 km/h, the maximum Doppler spread is about 200 Hz, which is small enough compared to 6.25 kHz that ICI should be acceptably small. This choice of spacing allows for at most 128 subchannels in the 800 kHz bandwidth. Assuming QPSK modulation (i.e., 2 bits per symbol) and four guard subchannels at either end of the OFDM spectrum (to facilitate filtering), the resulting bit rate is

$$R_b = \frac{120 \text{ data subchannels} \times 2 \text{ bits per subchannel}}{200\ \mu s} = 1.2 \text{ Mbps}$$

With a half-rate code, this results in an information rate of 600 kbps. Finally, as discussed in Section 2.3, zero-valued subcarriers can be added to the data set $\{D_k\}$, to facilitate transmit filtering, so that the FFT size, N', is greater than the number of subcarriers, N. A typical choice for this design example might be $N' = 4N = 512$.

3. CHANNEL AND SYSTEM IMPAIRMENTS

3.1. Introduction

Noise and the channel frequency (or impulse) response largely determine the performance of an OFDM system. In addition, several phenomena can significantly degrade the performance. Time variations in the channel, as well as frequency offset, phase noise, and timing errors, can impair the orthogonality of the subchannels [17]. Also, the large amplitude fluctuations characteristic of a multicarrier signal can be a serious problem when transmitting through a nonlinearity, such as the transmit power amplifier. We discuss all these issues here.

3.2. Noise and Interference

The ultimate limit on system performance, even without other impairments, is the combination of thermal noise and interference. In the case of OFDM, we can assume that there are N independent subchannels, each with its own signal-to-interference-plus-noise ratio (SINR). The usual methods of analysis can be used to compute the performance (bit error rate, block error rate, etc.) of each subchannel as a function of SINR. Typical approaches for maximizing the performance of a given subchannel are power control and coding, as in other systems. The difference in OFDM is that power control and coding can be applied across subchannels as well as within subchannels.

In the case of an additive white Gaussian noise (AWGN) channel (no frequency or time selectivity), all subchannels have the same performance. Moreover, the total system performance is identical to that of a single-carrier system having the same modulation, bandwidth, and power.

3.3. Channel Time Dispersion

Channel time dispersion can produce deep fades at one or more subchannel frequencies, causing performance degradation. However, the problems of ISI and ICI due to dispersion can be avoided using guard times and a cyclic extension (see Section 2.5). To put this mathematically, let the channel impulse response be expressed in discrete-time form by the finite set $\{h_l, 0 \le l \le L\}$, where T_s is the spacing between samples and LT_s is the maximum delay. The channel response at the subcarrier frequency $f_k = k/N$ is

$$H_k = H\left(\frac{2\pi k}{N}\right) = \sum_{l=0}^{L} h_l e^{-j2\pi lk/N} \tag{10}$$

Assuming that the channel is time-invariant, each h_l is constant. Given suitable choices for the length of the OFDM symbol and the guard time, and the use of a cyclic extension to avoid ICI, the demodulated sequence may be expressed as

$$X_k = H_k D_k + \eta_k \tag{11}$$

where η_k is additive Gaussian noise in the kth subchannel. Note that the noise components for different subcarriers are generally uncorrelated, that is, $E[\eta_k \eta_l^*] = \sigma_k^2 \delta(k - l)$.

If the communication channel is time-invariant, its effect on each subchannel is seen to be represented by a single complex-valued coefficient. Therefore, correcting for the channel response can be accomplished by following the receiver FFT with a single complex gain adjustment at each subcarrier frequency. Estimation to correct for the channel is discussed in Section 4, along with the possibility of matching (adapting) the transmitted signal to the channel frequency response.

3.4. Channel Time Variations

Channel and system time variations over a symbol result in spectral spreading of the individual subchannels, which causes ICI. We now show this analytically for one type of variation. Specifically, assume that the composite effect of the channel and system time variations can be represented as a multiplicative complex factor, so that the received signal's complex envelope is $\gamma(t)S(t)$. The factor $\gamma(t)$ could represent a frequency-independent gain variation, as might be encountered in a narrowband mobile radio channel. Let the nth received sample be $R_n = \gamma_n S_n$. Then, we find the kth data value at the receiver output is

$$\begin{aligned}\hat{D}_k &= \frac{1}{N}\sum_{n=0}^{N-1}\gamma_n S_n e^{-j2\pi kn/N} \\ &= \frac{1}{N}\sum_{n=0}^{N-1}\sum_{l=0}^{N-1}\gamma_n D_l e^{j2\pi n(l-k)/N} \\ &= \sum_{l=0}^{N-1} D_l \frac{1}{N}\sum_{n=0}^{N-1}\gamma_n e^{j2\pi n(l-k)/N} \\ &= D_k\Gamma_0 + \sum_{\substack{l=0\\ l\neq k}}^{N-1} D_l\Gamma_{l-k} \end{aligned} \tag{12}$$

where the sequence $\{\Gamma_l\}$ is the DFT of the sequence $\{\gamma_n\}$. If $\gamma_n = 1$ for all n (a time-invariant channel), then $\Gamma_{l-k} = \delta(l-k)$ and $\hat{D}_k = D_k$; otherwise, there is ICI, namely, a complex-weighted average of the other data values. In addition, the desired signal term is attenuated and rotated via the complex factor Γ_0. In a channel that is both time-dispersive and time-varying, the mathematics is more complicated, but the basic concept is the same.

3.5. Frequency Offset

Before an OFDM receiver can demodulate subcarriers, it has to perform at least two synchronization tasks: (1) it must locate the symbol boundaries and derive the optimal timing instants, so as to minimize the effects of ICI and ISI; and (2) it must estimate and correct for carrier frequency errors due to frequency offset and phase noise. We discuss these in the next three subsections, starting with frequency offset. A number of techniques have been devised for estimating and correcting timing and carrier frequency errors at the OFDM receiver, and these are discussed in Refs. 1 and 3.

The usual source of frequency offset in OFDM is a static frequency recovery error in the receiver. To analyze the impact, we can use Eq. (12), where $\gamma(t)$ can now be modeled simply as $e^{j2\pi\delta ft}$, with δf representing the difference between the transmitter and receiver carrier frequencies. In this case, the received data symbol again suffers from ICI, as in Eq. (12), with

$$\Gamma_0 = \frac{\sin\pi\left(\dfrac{\delta f}{\Delta f}\right)}{\pi\left(\dfrac{\delta f}{\Delta f}\right)} e^{j\pi\delta f/\Delta f} \tag{13}$$

and

$$\Gamma_{l-k} = \frac{\sin\pi\left(l-k-\dfrac{\delta f}{\Delta f}\right)}{\pi\left(l-k-\dfrac{\delta f}{\Delta f}\right)} e^{j\pi[l-k-\delta f/\Delta f]} \tag{14}$$

If the frequency error is a multiple, I, of the subcarrier spacing, then the received subcarriers are shifted in frequency by $\delta f = I\Delta f$. The subcarriers remain orthogonal in this case (all still have an integer number of cycles within the FFT processing window), but the recovered data have the wrong index values. This can be seen from Eqs. (12)–(14); if $\delta f = I\Delta f$, with $I \neq 0$, then Γ_0 will be 0 and so will every Γ_{l-k} except for $l = k + I$. Thus, the detected data for the kth subchannel will be $\hat{D}_k = D_{k+I}$, meaning that all data values are detected but are associated with the wrong subchannels. In general, *all* offsets of magnitude $\Delta f/2$ or more will lead to subchannel ambiguity, where the strongest component of $\hat{D}_k$ is that of a subchannel other than the kth. The first task of receiver frequency correction, then, is a coarse acquisition that brings δf within the range $\pm\Delta f/2$.

Assuming that δf lies within this range following initial acquisition, the number of cycles within the processing window will be a noninteger for all subchannels, and ICI will result, [Eq. (14)]. (This is analogous to the ISI in a single-carrier system caused by timing offset.) Also, the desired component will be reduced in magnitude by a factor $\text{sinc}(\delta f/\Delta f)$, as given by Eq. (13).

3.6. Phase Noise

A problem related to frequency offset is phase noise: a practical oscillator does not produce a carrier at exactly one frequency, but rather a carrier that is phase modulated by random noise. As a result, the receiver's recovered frequency, which is the time derivative of its phase, is never perfectly constant. Thus, phase noise produces a *dynamic* frequency error, whereas frequency offset is a static one. The result, in both cases, is ICI. The problem is more serious in OFDM than in a single-carrier system because the subchannels are so close in frequency and, in addition, their spectra overlap.

Although OFDM is more susceptible to phase noise and frequency offset than are single-carrier systems, there are techniques for keeping this degradation to a minimum. First, phase noise in the local oscillator is common to all subcarriers. If the oscillator linewidth (i.e., the spread of the oscillator tone due to phase noise) is much smaller than the OFDM symbol rate, which is usually the case, the common phase error is strongly correlated from symbol to symbol and from tone to tone; thus, tracking or differential detection (Section 4.2) can be used to minimize its effects. Second, the impact of phase noise grows monotonically with the ratio of the linewidth to the subcarrier spacing. Therefore, control of this ratio in choosing oscillators and subcarrier spacings can control the ICI.

3.7. Timing Errors

To achieve time synchronization (as well as frequency synchronization) with a minimum of processing at the

receiver, and also a minimum of redundant information added to the data signal, the synchronization process is normally split into an acquisition phase and a tracking phase. This is possible if the general characteristics of the timing (and frequency) errors are known. In the acquisition phase, an initial estimate of the errors is acquired, perhaps using more complex algorithms and more overhead; then, the follow-on tracking algorithms only have to correct for small short-term deviations.

With respect to timing offsets, OFDM is relatively robust; in fact, the symbol timing offset may vary over an interval equal to the guard time without causing ISI or ICI. This is because, for timing offsets smaller than the guard interval, the impact is just a phase shift; that is, for a timing offset δt, the received sample for the kth subcarrier is

$$\hat{D}_k = D_k e^{j2\pi f_k \delta t} \tag{15}$$

Thus, no ICI results; just a phase error which grows with f_k. If differential detection between tones is used, the impact of the timing error can be controlled by just ensuring that the root mean square (RMS) value of $\delta t/T$ is sufficiently small, say, 0.01 or less. The precise requirement depends on the modulation, the target bit error rate, and other such factors. Of course, if δt exceeds the guard time, the receiver's FFT window spans samples from two consecutive OFDM symbols and ISI occurs.

3.8. Transmitter Nonlinearities

An OFDM signal is the superposition of many modulated subcarrier signals and thus may exhibit a high signal peak relative to the average signal level. If the transmitter processing is not linear over the full range of the signal variation, nonlinear distortion will occur. This is manifested in two ways: (1) in-band intermodulation products, causing interference to each subchannel; and (2) out-of-band spectral spreading, potentially causing adjacent-channel interference (ACI) to other systems. Avoiding these problems requires a degree of transmitter linearity that can be costly.

One possible metric for characterizing signal peaking is the ratio of the peak signal power to the average signal power, or the *peak-to-average power ratio* (PAPR). This quantity can be taken over an OFDM symbol, in which case it varies from symbol to symbol, or over all time, in which case it is a single number. Either way, this metric must be used with care. The most extreme peaking occurs when all of the subcarrier signals line up in their peak amplitudes at the same time instant. It is easy to show that, for N subcarriers having equal average powers and using BPSK or QPSK (binary and quadrature phase shift keying) modulation, the PAPR defined as above (and taken over all time) is N. Thus, the PAPR would be 12 dB for $N = 16$ and 21 dB for $N = 128$. It may therefore seem that signal peaking progressively worse as N increases. However, worst-case signal peaking becomes less probable as N increases, so it is necessary to look at peaking in a *statistical* way. For N sufficiently large, the complex envelope converges to a complex Gaussian process, meaning that the squared envelope approximates an exponential variate. This approximation is used in Fig. 10, which shows the complementary cumulative distribution function for the ratio of the instantaneous power to the average power, taken over all time. If we redefine PAPR as the value not exceeded more than 0.001% of the time, the proper value to use is about 10.6 dB. This result, which holds for all realistic N and all modulations, is large enough to raise concerns about transmitter nonlinearities.

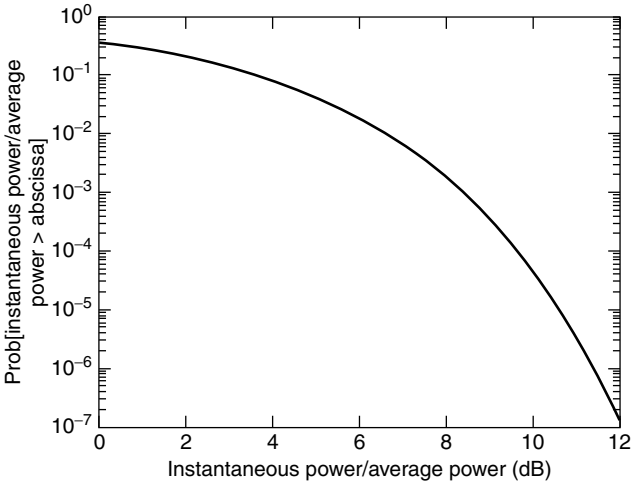

Figure 10. Complementary cumulative distribution function of PAPR of an OFDM signal.

To transmit signal peaks without major distortion, the transmitter's DAC must use a sufficient number of bits to accommodate these peaks, which is a cost/technology issue. More importantly, the power amplifier must remain linear over an amplitude range that includes the peaks, which leads to both high amplifier cost and high power consumption (low power efficiency). Several techniques have been proposed to mitigate the peaking problem, and they divide basically into three categories: (1) *signal distortion* techniques, which reduce the peak amplitudes by nonlinearly distorting the OFDM signal at or around the peaks. (e.g., clipping and filtering, peak windowing, peak cancellation); (2) *coding* techniques, involving special codes that exclude OFDM symbols with high peaking; and (3) *scrambling* techniques, that is, scrambling each OFDM symbol with different sequences and selecting the one that gives the least peaking. Details and the relative performances of these techniques can be found in Refs. 1, 2, 18, and 19.

4. OTHER MAJOR ISSUES

4.1. Introduction

We have seen that, to get the most value out of OFDM, special techniques have been devised such as cyclic extension and windowing. These relate primarily to how the signal is prepared at the transmitter to be sent over the channel. Equally important are methods of data detection and channel estimation at the receiving end and methods for adapting both transmission and reception to the frequency selectivity of the channel so as to maximize data efficiency. We explore these topics here.

4.2. Detection Techniques

In general, the data constellation of each subcarrier will show a random phase shift and amplitude change. These are caused by carrier frequency offset, timing recovery offset, and the frequency selectivity of the channel, as discussed in the previous section. To cope with these unknown changes, two classes of detection techniques exist. The first is *coherent detection*, using estimates of the channel response to derive reference values for the amplitude and phase correction for each subchannel. Spectrally efficient use of this approach requires reliable techniques for channel estimation that, at the same time, do not require excessive overhead, as discussed in the next section.

The second technique is *differential detection*, which does not require absolute reference values but accounts only for the phase and/or amplitude differences between two data symbols. In OFDM, differential detection can be done in the time domain or in the frequency domain. In the first case, each subcarrier is compared with the same subcarrier of the previous OFDM symbol; in the second case, each subcarrier is compared with the adjacent subcarrier within the same OFDM symbol. In contrast to coherent detection, differential detection does not require channel estimation, thereby saving complexity and gaining overhead efficiency. The cost is a degraded performance because of the noisy references that are effectively being used.

If differential detection is used within each subchannel, symbols must be highly correlated in time; performance can thus degrade if the channel response has significant time variation. Similarly, if differential detection is done between subchannels, symbols must be highly correlated in frequency; performance can thus degrade if the channel response has significant frequency variation.

4.3. Channel Estimation and Correction for Coherent Detection

In the kth OFDM subchannel, the data component appears at the detector input with a complex amplitude scaling, H_k, plus Gaussian noise, η_k, as in Eq. (11). Coherent detection of this sample amounts to comparing it against all points in the data constellation and choosing the point closest to it. To do this optimally, it is necessary to undo the amplitude scaling $|H_k|$ and the phase rotation $\mathrm{Arg}(H_k)$. Doing this individually for all frequency components of the FFT output is called *frequency-domain equalization*; broadly speaking, it consists of scaling each subchannel with a complex multiplier $1/\hat{H}_k$, where $\hat{H}_k$ is an approximation to H_k.

A conventional approach to implementing this equalization is to initially estimate the subchannel gains (e.g., by transmitting a known modulated sequence in each subchannel) and to then handle time variations via either periodic updates or decision-directed tracking. An alternative approach, ideally suited to OFDM, is pilot-aided estimation. Pilots are unmodulated tones, lasting for one or more symbols at a time, that are inserted by the transmitter and processed by the receiver to estimate channel gains. They can be distributed in time and frequency in any number of ways, one example of which is shown in Fig. 11. The two competing goals in placing pilots are that they should occupy a small fraction of the time–frequency slots, and their frequency of occurrence in each direction should be high enough to adequately sample the channel.

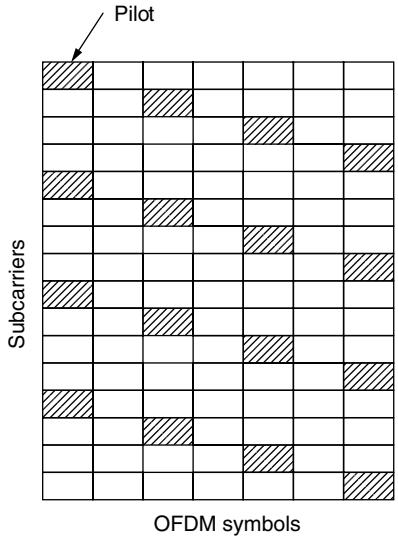

Figure 11. Typical pilot pattern.

Pilots are used for channel correction as follows. First, the receiver estimates channel gains at all times and frequencies where pilots have been transmitted. Then the channel gains at all other time–frequency positions can be estimated using two-dimensional interpolation filtering. Equalization then consists of setting the scaling to $1/\hat{H}_k$ for each data-carrying subchannel, where $\hat{H}_k$ is the gain estimate or some modification to account for additive noise.

To accurately interpolate the channel estimates from the available pilots, the pilot spacing in each dimension must satisfy the Nyquist sampling theorem. This means that there exist both a minimum necessary subcarrier spacing and a minimum necessary symbol spacing between pilots. To determine these spacings, two quantities must be known or estimated, namely, the double-sided bandwidth, $B_{\max}$, of the channel gain's time variations; and the full time extent, $\tau_{\max}$, of the channel's impulse response. The requirements for the pilot spacings in time and frequency, Δt_p and Δf_p, are then $\Delta t_p < 1/B_{\max}$ and $\Delta f_p < 1/\tau_{\max}$. In order to get a degree of noise reduction by filtering, the pilot symbol spacing should be smaller than half these values (oversampling) but not so small that the fraction of pilots is excessive.

Many solutions based on both pilot-aided estimation and decision-directed scaling are described in the references (e.g., see Refs. 1 and 3). The proper choice among pilots, training sequences, and decision-directed tracking, and the "best" design of whichever methods are used, depend on such factors as channel variability, type of traffic (e.g., continuous voice, packet data), and performance and cost objectives. For example, in the case of high-speed packet transmission to low-mobility users, as in wireless LAN applications, the most appropriate approach seems to be the use of a preamble consisting of one or more known OFDM symbols. The choice of the number of training

symbols is a tradeoff between short training time (better spectral efficiency) and good estimation performance.

4.4. Adaptive Loading

The frequency selectivity of an OFDM channel provides both challenges and opportunities. One way to address the problem of weak subchannels is to code across tones (thereby exploiting the frequency selectivity that causes the problem), as noted in Section 2.7. Another is to adaptively turn off weak subchannels, that is, to send no data at frequencies where the received SNR is below some threshold. To better exploit frequency selectivity and realize a spectral efficiency benefit, the data constellation used in each subchannel can be adaptively sized to its SNR [20]. This process, called *adaptive loading*, recognizes the fact that, in media where some subchannels are weaker than average, others are stronger. Thus, for example, each subchannel could use QPSK, 16-QAM, or 64-QAM (equivalently, 2, 4, or 6 bits per symbol), depending on the frequency response (gain) for that subchannel. This optimum form of OFDM is used for DSL applications and is called *discrete multitone* (DMT) [21]. A sample variation of the channel frequency response across the OFDM subchannels is illustrated in Fig. 12.

For the case of fixed transmit power, P, in each subchannel, the SNR in the kth subchannel would be

$$SNR_k = \frac{P}{N_0/T}|H_k|^2 \tag{16}$$

where N_0 is the noise power density at the receiver input. Assume that SNR is accurately measured in the receiver for every subchannel and communicated to the transmitter over a feedback channel. For a specified bit error rate, each such measurement can be used to select a data constellation size; specifically, the bits per symbol for the kth subchannel can be matched to the subchannel gain, $|H_k|^2$. To be effective, this approach requires an accurate SNR measurement in the receiver, a reliable feedback channel to the transmitter, and a means for changing constellations at the transmitter and efficiently notifying the receiver. If the same carrier frequency is used for both transmit and receive, as in Time-Division Duplexing, the over-the-air feedback channels is not required.

An additional degree of freedom is power control, that is, adaptively changing the transmit power, P_k, in the kth subchannel in accordance with its gain, subject to a total power constraint. If the power and constellation size are jointly distributed among subchannels in the most optimal way, the overall spectral efficiency of OFDM matches that of a single-carrier system with ideal decision feedback equalization [22].

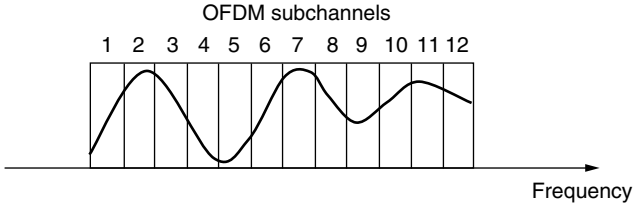

Figure 12. A channel response that justifies adaptive loading.

5. CONCLUSION

OFDM is a very attractive technique for high-bit-rate data transmission over a dispersive communication channel. However, to realize an OFDM system, many practical issues must be addressed, including high signal peaks, frequency offset, timing mismatch, and channel variation. Promising solutions have been devised for all these problems, but most solutions contribute to a "nibbling away" of the spectral efficiency. Even so, OFDM can attain the same spectral efficiency as an equalized single-carrier system and has the virtue of flexibility and a processing complexity that grows gracefully with channel dispersion.

Multicarrier modulation has been used in modems for both radio and telephone channels, as well as for digital audio and video broadcasting. The digital audio broadcasting (DAB) standard was, in fact, the first OFDM-based standard. The main reasons to choose OFDM for this system, which also applies to digital video broadcasting (DVB), are the possibility to provide a single frequency network and the efficient handling of multipath delay spread. A particularly suitable application of multicarrier modulation is in digital transmission over copper wire subscriber loops, as exemplified in high-speed digital subscriber loop (DSL) systems. In addition, the major high-bit-rate wireless LAN standards (IEEE 802.11a, HIPERLAN/2, and MMAC) use OFDM to overcome the bit-rate limitations caused by delay spread.

While much effort on OFDM is focused on critical implementation issues, there is also research on new variations and applications. Examples include *orthogonal frequency-division multiple access* (OFDMA); OFDM combined with *code-division multiple access* (CDMA); and OFDM combined with *multiple-input/multiple-output* (MIMO) antenna techniques. In OFDMA, multiple access is realized by providing each user with a fraction of the total number of subcarriers [23]. It is similar to conventional FDMA, except that it avoids the usual guard bands and exploits the power of FFT processing. OFDM-CDMA techniques (of which there are several variants) provide alternative ways to achieve multiple access while still combating frequency selectivity with moderate processing complexity [24]. OFDM-MIMO techniques exploit the power of array processing to increase wireless system capacity [25]. In all these applications, the need for time-domain equalization or RAKE reception is avoided because of the use by OFDM of narrow subchannels. Thus, powerful signal processing techniques like the FFT and adaptive arrays can be used instead to achieve high levels of performance.

BIOGRAPHIES

Leonard J. Cimini, Jr., received his B.S., M.S., and Ph.D. degrees in electrical engineering from the University

of Pennsylvania in 1978, 1979, and 1982, respectively. Over a 20-year AT&T career, starting at Bell Labs and then at AT&T Labs, he conducted research on lightwave and wireless communications systems. His main emphasis has been on devising techniques for overcoming the bit-rate limitations imposed by communications channels. In this context, he pioneered the application of Orthogonal Frequency Division Multiplexing to the emerging field of wireless communications. Dr. Cimini has been very active within the IEEE, including serving on several editorial boards and on the board of governors of the IEEE Communications Society. He was also the founding editor in chief of the IEEE J-SAC: Wireless Communications Series. Dr. Cimini is an adjunct professor in the Electrical Engineering Department of the University of Pennsylvania where he teaches a graduate-level course in wireless systems. He was elected a fellow of the IEEE in 2000 for contributions to the theory and practice of high-speed wireless communications.

Larry J. Greenstein received his B.S., M.S., and Ph.D. degrees in electrical engineering from Illinois Institute of Technology, Chicago, Illinois, in 1958, 1961, and 1967, respectively. From 1958 to 1970 he was with IIT Research Institute, working on radio frequency interference and anti-clutter airborne radar. He joined Bell Laboratories, Holmdel, New Jersey, in 1970. Over a 32-year AT&T career, he conducted research in digital satellites, point-to-point digital radio, lightwave transmission techniques, and wireless communications systems. For 21 years during that period (1979–2000), he led a research department renowned for its contributions in these fields. His research interests in wireless communications have included measurement-based channel modeling, microcell system design and analysis, diversity and equalization techniques, and system performance analysis and optimization. He recently retired from AT&T Labs–Research, Middletown, New Jersey, as a technology leader. Dr. Greenstein is an AT&T fellow and an IEEE fellow, has won two best paper awards, and has been a guest editor, senior editor, and editorial board member for numerous publications.

ORTHOGONAL TRANSMULTIPLEXERS: A TIME-FREQUENCY PERSPECTIVE

ALI N. AKANSU
HUSREV T. SENCAR
New Jersey Institute of Technology University Heights
Newark, New Jersey

1. INTRODUCTION

Orthogonality of carriers has been widely utilized in communications as the way to share available common resources by multiple users [1–3]. The most popular multiuser communication systems use one of the three modulation techniques. Namely, the frequency division multiple access (FDMA), the time division multiple access (TDMA), and code division multiple access (CDMA). The orthogonality of the user signature functions or carriers in a multiuser communication scenario is the underlying feature. The basic difference between these modulation techniques comes from the domain where the orthogonality conditions of the carrier functions are emphasized. In other words, an FDMA system aims to minimize the interaction of its multiple carriers in the frequency domain. Similarly, a TDMA system tries to reduce the time domain overlaps or correlations of its carrier or modulation functions. In contrast, a CDMA system prefers maximized overlaps of its signature functions both in the time and frequency domains while keeping their orthogonality features as the most vital requirement.

The fundamentals of signal and transform theories help us to better understand the multiple user or multicarrier communication systems where the time-frequency and orthogonality properties of the carrier functions are the defining issues. Therefore, we will briefly describe them in the following section.

2. MATHEMATICAL PRELIMINARIES

2.1. Time-Frequency Measures for a Discrete-Time Function

The time and frequency domain energy spread of a function has been a classical topic in signal processing field. The celebrated "uncertainty principle" states that no function can be concentrated simultaneously in both the time and frequency domains [4]. The time domain spread of a discrete-time function $\{h_0(n)\}$ is defined as [5],

$$\sigma_n^2 = \frac{1}{E}\sum_n (n-\overline{n})^2 |h_0(n)|^2 \tag{1}$$

The energy E and time center $\overline{n}$ of the function $\{h_0(n)\}$ are expressed as

$$E = \sum_n |h_0(n)|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi} |H_0(e^{jw})|dw, \tag{2}$$

$$\overline{n} = \frac{1}{E}\sum_n |h_0(n)|^2 \tag{3}$$

where its Fourier transform is given as

$$H_0(e^{jw}) = \sum_n h_0(n)e^{-jwn}x \tag{4}$$

Similarly, we define the frequency domain spread of a discrete-time function with $\overline{w} = 0$ as follows

$$\sigma_w^2 = \frac{1}{2\pi E}\int_{-\pi}^{\pi} (w-\overline{w})^2 |H_0(e^{jw})|^2 dw \tag{5}$$

where its center in the frequency domain is given as

$$\overline{w} = \frac{1}{2\pi E}\int_{-\pi}^{\pi} w|H_0(e^{jw})|^2 dw \tag{6}$$

Figure 1 illustrates time-frequency properties of a discrete-time function $\{h_0(n)\}$ using spreading measures defined above. This representation is also called time-frequency tile of a function. The shape and location of the tile can be defined by properly designing the time and frequency features of the function under construction. This interpretation of functions can be further extended in the case of orthogonal basis design. In addition to shaping time-frequency tiles, the orthogonality requirements are also imposed on the basis functions.

For any real signal with $\overline{w} = 0$ and $\overline{n} = 0$ the lower bound for the product of *time-frequency spread* $\sigma_n\sigma_w$ is given as [6]

$$\sigma_n\sigma_w \geq \frac{|1-\mu|}{2} \tag{7}$$

where

$$\mu = \frac{|H_0(e^{jw})_{w=\pi}|^2}{E} \tag{8}$$

Similar time-frequency spreading measures for band-pass signals with peak frequency responses $\overline{w} \neq 0$ are also introduced in Ref. 6.

2.2. Orthogonal Function Sets

2.2.1. Orthogonal Block Transforms. Orthogonal block transforms like discrete Fourier transform (DFT) and

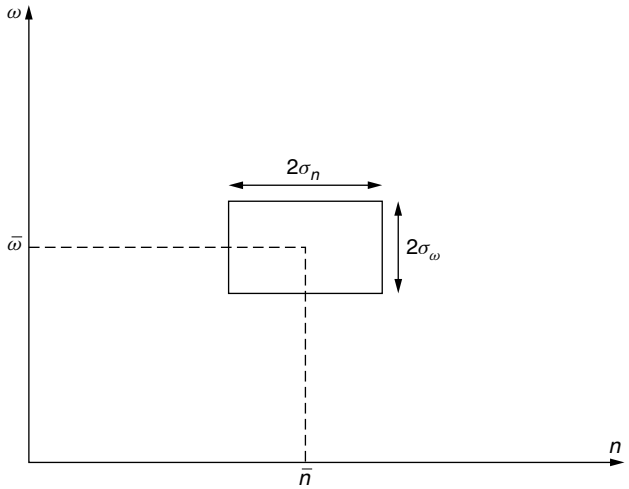

Figure 1. Time-frequency plane illustrating time-frequency properties of discrete time function $\{h_0(n)\}$.

discrete cosine transform (DCT) have been widely used in many engineering applications. The basis of an orthogonal block transform consists of functions $\{h_k(n)\}$ with the orthogonality property as

$$\sum_{n=1}^{N} h_k(n)h_l(n) = \delta_{k-l} \tag{9}$$

where δ_{k-l} is the Kronecker delta sequence given as

$$\delta_{k-l} = \begin{cases} 1, & k-l=0 \\ 0, & \text{otherwise.} \end{cases} \tag{10}$$

Note that the length of basis functions and number of functions in the set are the same in block transforms. Therefore, the main emphasis in block transforms has been the orthogonality requirements along with implementation efficiency since there is not much freedom in the design to adjust the time and frequency properties of the functions in the set.

Figure 2 displays DCT basis functions in the time and frequency domains for $N = 8$. Due to the short time durations of these functions it is observed that their frequency selectivity is somehow limited and they overlap significantly. They perform like a filter bank with poor frequency selectivity. The time-frequency measures of these functions are presented in Table 1.

The only way to improve the frequency localizations of orthogonal basis functions is to increase their durations in the time domain. Due to the time-frequency duality property of functions, the localization of a function in one domain can be improved at the expense of its localization in the other domain. This property paved the way for filter banks and subband transforms that we introduce in the next section.

One can use orthogonal transforms for analysis of a given function or signal through an operation called forward transform. Let real orthonormal sequences $\{h_r(n)\}$ be the rows of a transformation matrix, $H(r, n)$,

$$H = [H(r, n)], \quad r, n = 1, \ldots, N \tag{11}$$

Orthonormality of the matrix H assures that its inverse matrix

$$H^{-1} = H^T \tag{12}$$

where ^{T} indicates a matrix transpose. Hence,

$$HH^T = I \tag{13}$$

where I is an $N \times N$ identity matrix.

The forward transform of an input vector $\underline{x}$ of size N is written in a matrix notation as

$$\theta = Hx \tag{14}$$

where θ is the transform coefficient vector of size N. Therefore, x can be perfectly reconstructed through the inverse transform operation as

$$x = H^T\theta \tag{15}$$

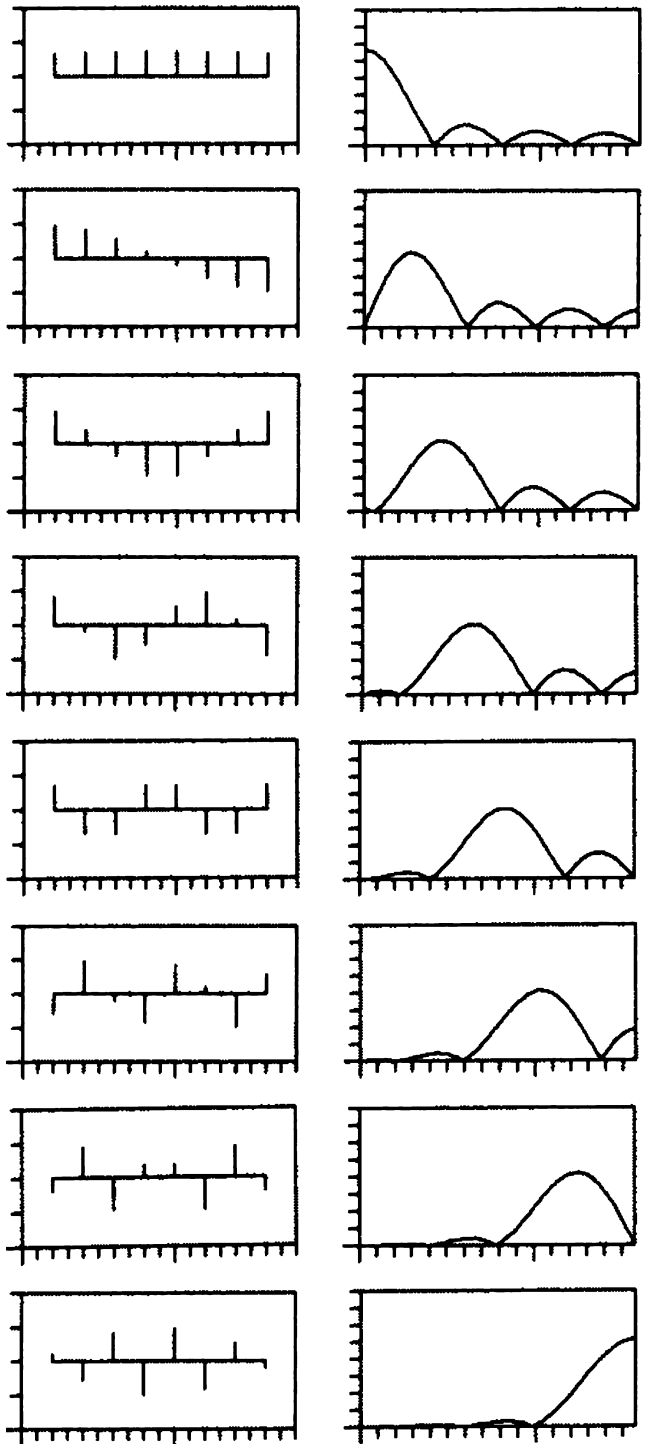

Figure 2. DCT basis functions in time and frequency domains for $N = 8$.

This defines a pair of forward/inverse transform operators where the input x is mapped onto the transform space as vector θ and perfectly recovered from θ through the inverse transform operator.

In contrast, one could synthesize the signal vector x by transforming the given input signal θ onto the inverse transform space as

$$x = H^T\theta \tag{16}$$

Table 1. Time-Frequency Localization of DCT for $N = 8$

$\overline{w}$	$\overline{n}$	σ_w^2	σ_n^2	$\sigma_w\sigma_n$
0	3.5	0.3447	5.25	1.3452
0.74	3.5	0.3021	8.4054	1.5935
1.02	3.5	0.2413	5.9572	1.1989
1.36	3.5	0.1957	5.4736	1.0350
1.71	3.5	0.1488	5.25	0.8839
2.08	3.5	0.1206	5.0263	0.7786
2.45	3.5	0.0797	4.5428	0.6017
π	3.5	0.1388	2.0955	0.5393

where H^T is the inverse transform matrix. It is a straightforward operation to perfectly reconstruct θ from x through a forward transform operation on x as

$$\theta = Hx \tag{17}$$

This is a sequence of inverse/forward transform operators that serves as the foundation for *orthogonal transmultiplexers* in multiple access communications. Fourier transform basis has been widely used in telecommunication applications for many decades utilizing the concept of transmultiplexers. As mentioned earlier, the frequency selectivity of these carrier functions, DFT basis, are not very good although their implementation in a real-time transmultiplexer structure is efficient. Therefore, they have been quite popular [7].

2.2.2. M-Band Filter Banks with Perfect Reconstruction. A maximally decimated M-band finite impulse response (FIR) perfect reconstruction quadrature mirror filter (PR-QMF) bank analysis/synthesis configuration is displayed in Fig. 3a. The output of this filter bank is the delayed version of its input as

$$y(n) = x(n - n_0) \tag{18}$$

where n_0 is a delay constant. In a paraunitary filter bank solution, the synthesis and analysis filters are related as

$$g_r(n) = h_r^*(p - n) \tag{19}$$

where p is a time delay. Hence, the PR-QMF conditions can be imposed on the analysis filters in the time domain

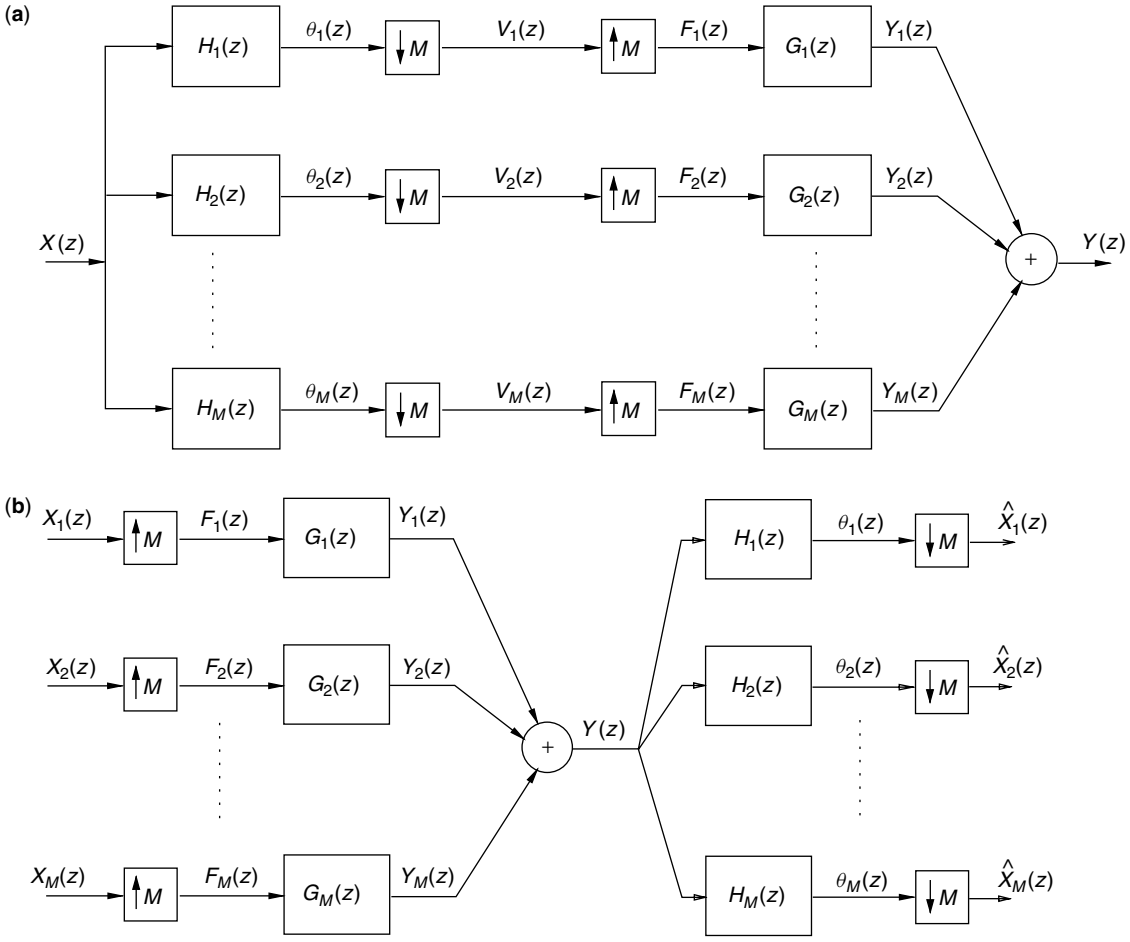

Figure 3. (**a**) Maximally decimated M-band FIR PR-QMF bank structure (analysis/synthesis filter bank configuration). (**b**) M-band Transmultiplexer structure (synthesis/analysis filterbank structure).

as [6]

$$\sum_n h_r(n)h_r(n+Ml) = \delta(l), r = 1, \ldots, M \quad (20)$$

$$\sum_n h_r(n)h_s(n+Ml) = 0, \text{ for all } l \quad (21)$$

Analysis/synthesis filter bank configurations are widely used in image or video processing, speech or audio processing, interference cancellation, and other applications [8–9].

In contrast, Fig. 3b depicts a synthesis/analysis filter bank where there are M inputs and M outputs of the system. It is shown that if the synthesis $\{g_r(n)\}$ and analysis $\{h_r(n)\}$ filters satisfy the PR-QMF conditions of Eqs. (19)–(21), synthesis/analysis filter bank configuration gives equal input and output for its all branches as

$$\hat{x}_r(n) = x_r(n - n_0) \quad r = 1, \ldots, M \quad (22)$$

where n_0 is a time delay. The synthesis/analysis PR-QMF bank with equal inputs and outputs at all branches has been used as orthogonal transmultiplexers in communications applications for single user and multiuser scenarios [6,10].

3. COMMUNICATION APPLICATIONS OF ORTHOGONAL TRANSMULTIPLEXERS

The unified framework for orthogonal transmultiplexers along with time-frequency tools allowing some design flexibilities for the application at hand was given in the previous sections of the article. The main engineering challenge in this context is to design the most suitable transform basis $\{h_r(n)\}$ for a given application. Applications using orthogonal multiplexers vary from single-user communication scenarios to multiuser communication systems. These applications might require to utilize frequency localized or time-localized orthogonal carriers depending on the system requirements including channel properties. The orthogonal block transforms like DFT has been widely used in a synthesis/analysis filter bank configuration (inverse/forward block transform sequence of operators) as a transmultiplexer in multicarrier (single and multiuser) communication systems. Although the frequency selectivity of DFT basis functions is not very good, except at the bin frequencies of the orthogonal carrier functions, the ease of its implementation has been very attractive for real-time applications.

An examination of M-band orthogonal transmultiplexer structure displayed in Fig. 3b helps us to interconnect time-frequency properties of carrier (modulation) basis with the type of communication system under consideration. The most popular types are FDMA, TDMA, and CDMA. We discuss these orthogonal modulation types further from a time-frequency perspective in the following sections.

3.1. FDMA

Figure 4a displays an ideal filter bank that consists of brick-wall frequency functions without any interbrand energy leakage. The frequency localizations of these orthogonal carriers are perfect although their time-localization is extremely poor. Since they are noncausal functions with infinite time durations they are not implementable. In practice, finite length (FIR) orthogonal carriers are used. Therefore, interbrand (cross-carrier) energy leakage (interference) is of a great concern in communication applications. As mentioned earlier, DFT basis has been used in many applications including the popular digital subscriber line (DSL) communications. The other applications like digital audio broadcasting (DAB) and low probability of intercept (LPI) communication also employ orthogonal transmultiplexers with properly selected filter banks or carrier basis [8,9].

3.2. TDMA

Similarly, Fig. 4b displays the ideal orthogonal carriers (basis functions) for a TDMA configuration. Note that each carrier is a unit sample function in the time domain with a perfect localization. In contrast, those functions completely overlap in the frequency domain. In this case, a perfect orthogonality is imposed in the time domain. Practical TDMA systems use nonideal time pulses or symbols where intercarrier energy leakage (interference) is inevitable.

3.3. CDMA

CDMA is a marked departure from the traditional FDMA and TDMA systems where the spreading of orthogonal carrier functions (signatures) in both domains (time and frequency) is aimed. Note that the orthogonal transmultiplexer configuration of Fig. 3b is still applicable even for the CDMA systems. The optimal code design problem for CDMA can also be handled by the PR-QMF requirements of Eqs. (19)–(21) with the addition of maximizing the joint time-frequency spread, $\sigma_n\sigma_w$, of the codes in the design. Figure 5 displays frequency spectra of a 32-length spread spectrum PR-QMF along with 31-length Gold Codes. It is observed from this figure that the functions used in orthogonal transmultiplexers for CDMA are not selective in either domain. Although filter banks have been mostly used for spectral analysis/synthesis problems the underlying theory is also applicable for any time-frequency shaped function sets.

4. CONCLUSIONS

The synthesis/analysis configurations of filter banks (transmultiplexers) have been widely employed in many popular communications applications. Conversely, the time-frequency shaping of orthogonal functions has been well tied to the optimal filter bank design in the signal processing literature. We highlighted those developments in the context of orthogonal transmultiplexers that serve as the foundation in single and multiple user communication systems.

P

PACKET-RATE ADAPTIVE RECEIVERS FOR MOBILE COMMUNICATIONS

STELLA N. BATALAMA
State University of New York
at Buffalo
Buffalo, New York

1. INTRODUCTION

The effectiveness of a receiver designed for a rapidly changing multiple-access (multiuser) communications environment depends on the following design attributes: (1) system adaptivity under limited data support, (2) multiple-access-interference resistance, and (3) low computational complexity. Short-data-record adaptive designs appear as the natural next step for a matured discipline that has extensively addressed the other two design objectives, 2 and 3, in ideal setups (perfectly known or asymptotically estimated statistical properties). System adaptivity based on short data records is necessary for the development of practical adaptive receivers that exhibit superior signal-to-interference-plus-noise ratio (SINR) or bit error rate (BER) performance when they operate in rapidly changing communications environments that limit substantially the input data support available for adaptation and redesign.

In modern packet data transmission systems where the basic information flow unit is the packet (a group of bits that includes the actual information bits as well as other coding and network control bits), the main measure of link quality is the throughput (either packet throughput or information throughput) that which is directly related to the packet error rate (PER). Real-time voice communications impose stringent delay constraints and require a guaranteed upper bound on PER of about 10^{-2}. On the other hand, data packets can tolerate reasonable delays but may require a lower PER bound [1,2]. Packet throughput improvements can be achieved as a result of BER improvements. On the other hand, BER improvements can be achieved by means of advanced receiver designs that exploit both the characteristics of the transmitted signal and the current state of the environment (these "raw" BER values can be further improved through channel coding (forward error correction)). In dynamic environments, adaptive receiver designs can react to variations as opposed to static receivers that remain unchanged regardless of the changes in the environment. Inherently, a major consideration in the design of successful adaptive receivers is the fact that their adaptation rate must be commensurate to the rate of change of the environment.

An example of a system that can benefit from modern advanced adaptive receiver technology is the direct-sequence code-division multiple-access (DSCDMA) radiofrequency (RF) system. In such a system, the transmitted signal is a spread-spectrum (SS) signal obtained by multiplying each information bit by a unique code (or signature) waveform dedicated to each user. The SS characteristics of the transmitted signal allow intelligent temporal (code) processing at the receiver (unmasking of the signature). During RF transmission, the signal in general undergoes a process known as *multipath-fading* dictated by the physical characteristics of the communication channel. As a result, the received signal consists of multiple faded and delayed copies of the transmitted signal. At the receiver, the multiple copies, instead of being discarded as interference, can be processed in an advantageous manner (a procedure known as RAKE processing). Further performance improvements can be obtained by exploiting the spatial characteristics of the transmitted signal; such processing requires that antenna-array ("smart antenna") technology is employed at the receiver. DSCDMA systems equipped with antenna arrays offer the opportunity for jointly effective spatial (array) and temporal (code) noise suppression. Primary noise sources include additive white Gaussian noise (AWGN) usually due to the receiver front-end electronics as well as interference from other users who transmit similar signals at the same time and in the same frequency spectrum [CDMA systems allow such channel accessing as opposed to time-division multiple-access (TDMA) or frequency-division multiple-access (FDMA) systems]. This general DSCDMA signal model example will be revisited many times throughout our discussion, and a complete adaptive antenna-array DSCDMA receiver will be developed as an illustration.

Returning to the main topic of our discussion, an adaptive receiver consists of a set of building blocks that are a reevaluated (or estimated) every time there is a significant change in the statistics of the environment. The design of each building block is initially formulated mathematically as a solution to an optimization problem under the assumption that all statistical quantities are perfectly known. This is known as the *ideal* or *optimum* solution. Then, the statistical quantities that are present in the optimum solution are substituted by corresponding estimates that are based on the actual received data (observations). This is known as an *estimate* of the optimum solution. It is the latter estimates that need to be adapted according to the changes of the environment, justifying this way the term "adaptive receiver." For example, a popular class of DSCDMA receivers utilizes minimum mean-square-error (MMSE) linear (discrete-time) filters as a means to suppress multiple-access interference (MAI) and AWGN. In other words, the receiver consists of a linear filter that operates on a discrete sequence of spacetime (ST) received signal samples and the optimum filter solution is found by minimizing the mean-square error between the output of the linear filter and a pilot information bit sequence. Several adaptive MMSE filtering algorithms are known and include the sample matrix inversion (SMI), the least-mean-square (LMS) and the recursive-least-square (RLS) algorithms, which will be discussed in detail in subsequent sections. As a general comment, these algorithms/adaptive

filters outperform significantly the popular static ST RAKE filter when a sufficiently large number of data is made available to them [4–9]. Unfortunately, the time-varying nature of the channel frequently necessitates fast (short-data-record) adaptive ST optimization through the use of small input data sets that can "catch up" with the channel variations.

To motivate the developments presented in this article, let us consider a DSCDMA system with 5-element antenna-array reception, system processing gain 64, and, say, 3 resolvable multipaths for the user signal of interest (usually the number of resolvable multipaths is between 2 and 4 including the direct path if any [10]). For such a system, we will see later that jointly optimal S-T processing at the receiver under the MMSE criterion requires processing in the $5(64+3-1)=330$ space-time product space. That is, filter optimization needs to be carried out in the complex $\mathbb{C}^{330}$ vector space. We know that adaptive SMI implementations of the MMSE filter solution require data samples many times the space-time product to approach the performance characteristics of their ideal counterpart (RLS/LMS implementations behave similarly) [11,12]. In fact, theoretically, system optimization with data samples less than the spacetime product may not even be possible, as we will explain later in our discussion. With CDMA chip rates at 1.25 MHz [10], processing gain 64, and typical fading rates of $\geq$70 Hz for vehicle mobiles [13], the fading channel fluctuates decisively at least every 280 data symbols. In this context, conventional SMI/RLS/LMS adaptive filter optimization in the $\mathbb{C}^{330}$ vector space becomes an unrealistic objective.

The goal of our presentation is to first introduce and then elaborate on the underlying principles of short-data-record adaptive filter estimation. Through illustrative examples from the mobile communications literature, we will observe that short-data-record (e.g., packet-rate) filter estimation results in improved channel BER, which translates to higher packet success probability and higher user capacity for a given PER upper bound quality-of-service (QoS) constraint. This ensures an improvement in terms of packet throughput and delay characteristics of a network system that satisfies the QoS constraint. Additional performance improvements can and must be pursued through synergistic use of channel coding (FEC).

While our target applications are all time-critical communications problems, the theoretical developments that will be presented herein may touch many aspects of multidisciplinary engineering that are hampered by the "curse of dimensionality" and could benefit from adaptive filtering and/or adaptive system optimization through limited input data.

2. BASIC SIGNAL MODEL

For illustration purposes, we consider throughout this presentation a multiuser communications system where binary antipodal information symbols from user0, user1, ..., user $Q-1$ are transmitted at a rate $1/T$ by modulating (being multiplied by) a signal waveform $d_q(t)$ of duration T, $q=0,\ldots,Q-1$, that uniquely identifies each user and is assumed to be approximately band-limited or have negligible frequency components outside a certain bandwidth. If H_1 (H_0) denotes the hypothesis that the information bit $b_0=+1$ ($b_0=-1$) of the user of interest, say, user 0, is transmitted during a certain bit period T, then the corresponding equivalent lowpass composite received waveform over the bit interval T may be expressed in general as

$$\begin{aligned} H_1&: x(t)=(+1)\sqrt{E_0}v_0(t)+z(t) \quad \text{and} \\ H_0&: x(t)=(-1)\sqrt{E_0}v_0(t)+z(t), \quad 0\leq t\leq T \end{aligned} \tag{1}$$

With respect to the user of interest, user 0, E_0 denotes transmitted energy per bit, $v_0(t)$ represents the channel processed version of the original waveform $d_0(t)$ [w.l.o.g. the signal waveform $d_0(t)$ is assumed to be normalized to unit energy over the bit period T], and $z(t)$ identifies comprehensively the channel disturbance and includes one, some, or all of the following forms of interference: (1) MAI, (2) intersymbol interference (ISI), and (3) additive Gaussian or non-Gaussian noise.

The continuous-time waveform $x(t)$ is "appropriately" sampled and the discrete samples are grouped to form vectors of "appropriate" length P (both the sampling method and the length value P are pertinent to the specifics of the application under consideration). Let $\mathbf{x}$ denote such a discrete-time complex, in general, received signal vector in $\mathbb{C}^P$:

$$\begin{aligned} H_1&: \mathbf{x}=+\sqrt{E_0}\mathbf{v}_0+\mathbf{z} \quad \text{and} \\ H_0&: \mathbf{x}=-\sqrt{E_0}\mathbf{v}_0+\mathbf{z}, \quad \mathbf{x},\ \mathbf{v}_0,\ \mathbf{z}\in\mathbb{C}^P \end{aligned} \tag{2}$$

where P identifies the dimension of the discrete-time complex observation space, $\mathbf{v}_0$ is the signal vector that corresponds to $v_0(t)$, and $\mathbf{z}$ denotes the discrete-time comprehensive disturbance vector [14]. Our objective is to detect b_0 (i.e., to decide in favor of H_1 or H_0) by means of a linear filter $\mathbf{w}$ as follows:

$$\hat{b}_0=\text{sgn}(\text{Re}\{\mathbf{w}^H\mathbf{x}\}) \tag{3}$$

where $\text{sgn}(\cdot)$ is the ±1 hard-limiter, $\text{Re}\{\cdot\}$ extracts the real part of a complex number, and $(\cdot)^H$ denotes the Hermitian operation. In other words, we fix the structure of the receiver to that given by Fig. 1. Our discussion will be focused on the design of the linear filter $\mathbf{w}$ according to the MMSE or minimum-variance distortionless response (MVDR) optimization criteria we present in the section that follows.

The specific illustrative example of a multipath fading AWGN DS-CDMA packet data communication link with narrowband linear antenna-array reception that we considered earlier, is certainly covered by the above general basic signal model. The transmitted signal waveform of a particular user is obtained as follows. The user is assigned a unique binary antipodal signature (code)

Figure 1. General receiver structure for the (one-shot) detection of binary antipodal information symbols of the user of interest.

sequence, that is a sequence with elements $+1$ or -1 of length L (L is also called *system processing gain*). The bits of the user code multiply a basic signal pulse (e.g., square pulse or raised cosine) of duration T_c, known as *chip*. This way we obtain the signature waveform $d_q(t)$ of duration $T = LT_c$. The transmitted signal waveform that corresponds to a single information bit is the product of the information bit itself and the signature waveform. The corresponding received waveform is the convolution of the transmitted waveform and the impulse response of the multipath fading channel (when the latter is modeled as a linear filter) and is assumed to be band-limited by the chip rate. Discretization of the continuous received waveform at each antenna element of the array can be achieved by chip-matched filtering of the received waveform and sampling at the chip rate (or by lowpass filtering, commensurate Nyquist sampling, and chip-rate accumulation) over the multipath-extended symbol period. The discrete vector outputs from all antenna elements are stacked together (one on top of the other) to create a supervector known as the *spacetime* (ST) received vector. In this way the data are prepared for processing by the linear filter $\mathbf{w}$, extraction of the real part of the filter output and finally sign detection as shown in Fig. 1, a process termed "one shot" detection: detection on a symbol-by-symbol (information bit) basis, as opposed to simultaneous detection of all information bits of the user of interest. If M is the number of antenna elements of the array, L is the length of the signature (code) vector, and N is the number of resolvable multipaths (w.l.o.g. we assume that N is the same for all users) then the discretetime, ST complex received vector $\mathbf{x}$ is of dimension $M(L+N-1)$; where $L+N-1$ is exactly the length of what we referred to earlier as the multipath-extended symbol period. "Inside" $\mathbf{x}$ in (2), $\mathbf{v}_0$ corresponds to the channel-processed (also known as "effective") ST signature vector of the user of interest, while $\mathbf{z}$ corresponds to the discrete-time disturbance vector that accounts for MAI, ISI, and AWGN. Specifically, $\mathbf{v}_0$ can be expressed as a function of the transmitted signal, channel and receiver structure parameters:

$$\mathbf{v}_0 = \sqrt{\frac{E_0}{L}} \sum_{n=0}^{N-1} c_{0,n} \left[\underbrace{0 \ldots 0}_{n} \quad \mathbf{d}_0^T \quad \underbrace{0 \ldots 0}_{N-n-1} \right]^T \odot \mathbf{a}_{0,n} \tag{4}$$

where $c_{0,n}, n = 0, \ldots, N-1$, denote the path coefficients of the channel of the user of interest. The coefficients $c_{0,n}, n = 0, \ldots, N-1$, are frequently modeled as independent zero-mean complex Gaussian random variables (that exhibit Rayleigh distributed amplitude and uniformly distributed phase that fits experimental measurements) and are assumed to remain constant over the entire packet duration. In a realistic environment the coefficients may vary approximately every 300 symbols [15]. Thus, keeping the packet size less than 300 validates the assumption of constant multipath coefficients over the duration of a packet. In (4), $\mathbf{d}_0 = [\mathbf{d}_0[0], \ldots, \mathbf{d}_0[L-1]]^T$ is the binary signature vector (spreading sequence) of the user of interest, $\mathbf{d}_0[l] \in \{\pm 1\}, l = 0, \ldots, L-1$, $\mathbf{a}_{0,n}$ is the array response vector that corresponds to the nth path of the user of interest, and $\odot$ denotes the Krönecker tensor product. The array response vector of the nth path of the user of interest is defined by

$$\mathbf{a}_{0,n}(m) = e^{j2\pi(m-1)\frac{d}{\lambda}\sin\theta_{0,n}}, \quad m = 1, 2, \ldots, M \tag{5}$$

where $\theta_{0,n}$ identifies the angle of arrival of the corresponding path, λ is the carrier wavelength, and d is the element spacing of the antenna array (usually $d = \lambda/2$). More details on the DSCDMA ST received signal model in (4) and the operational characteristics of an antenna-array system can be found elsewhere in the literature [5,16]. Finally, the noise vector $\mathbf{z}$ represents the comprehensive disturbance effect of AWGN and all other user signal contributions that are again of the form of (4), yet with different in general energy values, signature vectors, multipath coefficients, and angles of arrival.

3. FILTERING WITH KNOWN INPUT STATISTICS

3.1. Optimum MMSE/MVDR Filter

Minimum-variance distortionless response (MVDR) *receiver design* refers to the problem of identifying a linear finite-impulse response filter that minimizes the variance at its output, while at the same time the filter maintains a "distortionless" response toward a specific input vector direction of interest. In mathematical terms, if $\mathbf{x}$ is a random, *0*-mean (without loss of generality) complex input vector of dimension P, $\mathbf{x} \in \mathbb{C}^P$, that is processed by a P-tap filter $\mathbf{w} \in \mathbb{C}^P$, then the filter output variance is $E\{|\mathbf{w}^H\mathbf{r}|^2\} = \mathbf{w}^H\mathbf{R}\mathbf{w}$, where $\mathbf{R} = E\{\mathbf{x}\mathbf{x}^H\}$ is the input autocorrelation matrix ($E\{\cdot\}$ denotes the statistical expectation operation). The MVDR filter minimizes $\mathbf{w}^H\mathbf{R}\mathbf{w}$ and simultaneously satisfies an equation of the form $\mathbf{w}^H\mathbf{v}_0 = \rho$, where $\mathbf{v}_0$ is the given input signal vector direction to be protected. In this setup, MVDR filtering is a standard linear constraint optimization problem and the conventional Lagrange multipliers constraint optimization technique leads to the solution (the Lagrange multipliers optimization technique is presented in detail elsewhere [16])

$$\mathbf{w}_{\text{MVDR}} = \rho^* \frac{\mathbf{R}^{-1}\mathbf{v}_0}{\mathbf{v}_0^H\mathbf{R}^{-1}\mathbf{v}_0} \tag{6}$$

where $(\cdot)^*$ denotes conjugation. Extensive tutorial treatments of MVDR filtering can be found in many sources [e.g., 16,17], along with historical notes on the early work by Capon [18] and Owsley [19].

MVDR filtering has long been a workhorse for blind (unsupervised) communications and signal processing applications where a desired (pilot) scalar filter output $y \in \mathbb{C}$ cannot be identified or cannot be assumed available for each input $\mathbf{x} \in \mathbb{C}^P$. Prime examples include radar and array processing problems where the constraint vector $\mathbf{v}_0$ is usually referred to as the "target" or "look" direction of interest. It is interesting to observe the close relationship between the MVDR filter and the MMSE ("Wiener") filter. Indeed, if the constraint vector $\mathbf{v}_0$ is chosen to be the statistical cross-correlation vector between the desired output y and the input vector $\mathbf{x}$; that is, if $\mathbf{v}_0 = E\{\mathbf{x}y^*\}$,

then the MMSE filter obtained by minimizing the mean-square (MS) error between the filter output $\mathbf{w}^H\mathbf{x}$ and the desired output y is given by

$$c\mathbf{R}^{-1}\mathbf{v}_0, \quad c > 0 \tag{7}$$

that is, the MMSE filter becomes a positive scaled version of the MVDR filter and exhibits identical output SINR performance. For this reason in the rest of our discussion we refer comprehensively to both filters as MMSE/MVDR filters as [16,17].

Conventionally, the computation of the MMSE/MVDR filter in (6) or (7) begins with the calculation of the inverse of the ideal input autocorrelation matrix $\mathbf{R}^{-1}$ (assuming that the Hermitian matrix $\mathbf{R}$ is strictly positive definite, hence invertible). The calculation of the inverse is usually based on numerical iterative diagonalization linear algebra procedures [20]. Then, the matrix $\mathbf{R}^{-1}$ is used for the linear transformation (left multiplication) of the constraint vector $\mathbf{v}_0$, followed by $\mathbf{v}_0^H\mathbf{R}^{-1}\mathbf{v}_0$ normalization, as necessary.

Linear transformations that involve the inverse of a high-dimension matrix are computationally intensive. In addition, and most importantly, severe complications arise at the adaptive implementation stage when the estimate of such a high-dimension matrix is inverted (particularly when the estimate is based on a small set of data/observations and is obtained, possibly, by some form of sample averaging). One extreme example of such a complication is the fact that the inverse may not even exist. Thus, when the data that are available for adaptation and redesign are limited, use of inverses of (sample average) estimated high-dimension matrices is not viewed favorably (this issue will be discussed in detail in the next section). In such cases, it is preferable to proceed with alternative methods that *approximate* the optimum solution and, hopefully, avoid implicit or explicit use of inverses. Then, at the adaptive implementation stage, we may utilize estimates of the approximate solutions. Algorithmic designs that aim at approximating the optimum MMSE/MVDR filter include (1) the generalized sidelobe canceler (GSC) and its variations, (2) the auxiliary vector (AV) filter, and (3) the orthogonal multistage filter (also "called nested Wiener filter"). The relative performance of these methods in limited data support environments is examined in Section 4.

3.2. Generalized Sidelobe Canceler (GSC)

For a given (not necessarily normalized) constraint vector $\mathbf{v}_0 \in \mathbb{C}^P$, any "distortionless" linear filter $\mathbf{w} \in \mathbb{C}^P$ that satisfies $\mathbf{w}^H\mathbf{v}_0 = \rho$ can be expressed/decomposed as $\mathbf{w} = (\rho^*/\|\mathbf{v}_0\|^2)\mathbf{v}_0 - \mathbf{u}$ for some $\mathbf{u} \in \mathbb{C}^P$ such that $\mathbf{v}_0^H\mathbf{u} = 0$, as shown in Fig. 2 (this decomposition is an application of the projection theorem in linear algebra). There are two general approaches for the design of the filter part $\mathbf{u}$: (1) eigen-decomposition-based approaches and (2) non-eigendecomposition-based approaches.

Algorithmic eigendecomposition-based designs that focus on the MMSE/MVDR filter part $\mathbf{u}$, which is orthogonal to the constraint vector, or "look" direction $\mathbf{v}_0$, include the Applebaum–Howells arrays, beamspace partially adaptive processors, or generalized sidelobe cancelers

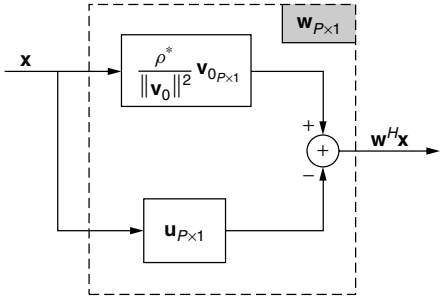

Figure 2. General decomposition of a linear filter $\mathbf{w}$ that satisfies $\mathbf{w}^H\mathbf{v}_0 = \rho$ to two orthogonal components ($\mathbf{u}^H\mathbf{v}_0 = 0$).

(GSCs). More recent developments have been influenced by principal-components analysis (PCA) reduced-rank processing principles. The general goal of these designs is to approximate the MMSE/MVDR filter part $\mathbf{u}$ by utilizing different rank-reducing matrices as explained below [16,17,21–26]. The approximation is of the general form (Fig. 3)

$$\mathbf{u}_{P\times1} \simeq \mathbf{B}_{P\times(P-1)}\mathbf{T}_{(P-1)\times p}\mathbf{w}_{p\times1}^{\mathrm{GSC}} \tag{8}$$

where $\mathbf{B}$ is a matrix that satisfies $\mathbf{B}^H\mathbf{v}_0 = \mathbf{0}_{P-1}$ and is, thus, called "blocking matrix" since it blocks signals in the direction of $\mathbf{v}_0$ ($\mathbf{B}$ is a full column-rank matrix that can be derived by Gram–Schmidt orthogonalization of a $P \times P$ orthogonal projection matrix such as $\mathbf{I} - (\mathbf{v}_0\mathbf{v}_0^H/\|\mathbf{v}_0\|^2)$, where $\mathbf{I}$ is the identity matrix). $\mathbf{T}$ is the rank-reducing matrix with $1 \le p < P-1$ columns that have to be selected and $\mathbf{w}^{\mathrm{GSC}}$ is a vector of weights of the p columns of $\mathbf{T}$ that is designed to minimize the variance at the output of the "overall" filter $\mathbf{w}$, $E\left\{\left|\left(\frac{\rho^*}{|\mathbf{v}_0|^2}\mathbf{v}_0 - \mathbf{u}\right)^H\mathbf{x}\right|^2\right\}$. The solution to the latter optimization problem (assuming that $\mathbf{T}$ is given) is

$$\mathbf{w}^{\mathrm{GSC}} = \frac{\rho^*}{\|\mathbf{v}_0\|^2}[\mathbf{T}^H\mathbf{B}^H\mathbf{R}\mathbf{B}\mathbf{T}]^{-1}\mathbf{T}^H\mathbf{B}^H\mathbf{R}\mathbf{v}_0 \tag{9}$$

We note that the rank-reducing matrix $\mathbf{T}$ "reduces" the dimension of the linear filter (number of parameters to be designed) from P (filter $\mathbf{w}$) to p (filter $\mathbf{w}^{\mathrm{GSC}}$), $1 < p < P-1$. The p columns of the rank-reducing matrix $\mathbf{T}$ can be chosen in various ways. We can choose the p columns to be the eigenvectors that correspond to the P maximum eigenvalues of the *disturbance-only* autocorrelation matrix [27]. This choice is mean-square (MS) optimum under the assumption that the disturbance-only eigenvectors are not rotated by the

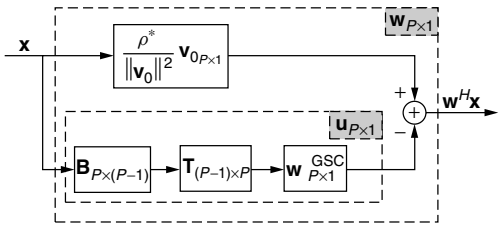

Figure 3. Generalized sidelobe canceler structure.

blocking matrix being used (i.e., when the disturbance subspace is orthogonal to the constraint vector $\mathbf{v}_0$), which is not valid in general. We can address this concern by choosing alternatively the p columns of $\mathbf{T}$ to be the eigenvectors that correspond to the p maximum eigenvalues of the *blocked* data autocorrelation matrix $\mathbf{B}^H\mathbf{R}\mathbf{B}$ [28,29]. If, however, the columns of the rank-reducing matrix $\mathbf{T}$ *have to be* eigenvectors of the blocked-data autocorrelation matrix (there is no documented technical optimality to this approach), then the best way in the minimum output variance sense is to choose the p eigenvectors $\mathbf{q}_i$ of $\mathbf{B}^H\mathbf{R}\mathbf{B}$ is to choose the p eigenvectors $\mathbf{q}_i$ with corresponding eigenvalues λ_i that maximize the ratio $\dfrac{|\mathbf{v}_0^H\mathbf{R}\mathbf{B}\mathbf{q}_i|^2}{\lambda_i}$, $i = 1, \ldots, p$ [30]. This algorithm is also known as "cross-spectral metric" reduced-rank processing [31]. Non-eigendecomposition-based alternatives for the synthesis of $\mathbf{u}$ include the auxiliary vector (AV) filters and the orthogonal multistage filters (also called "nested Wiener filters") [5,32–41].

3.3. Auxiliary Vector (AV) filters

Auxiliary vector (AV) filters are non-eigendecomposition-based filters that approximate the optimum MMSE/MVDR solution [5,32–38]. The AV algorithm is a statistical optimization procedure that generates a sequence of filters (AV filters). Each filter in the sequence has the general structure described in Fig. 2, where the vector $\mathbf{u}$ is approximated by a weighted sum of auxiliary vectors that maintain orthogonality *only* with respect to the distortionless direction $\mathbf{v}_0$ (and they are, in general, *nonorthogonal* to each other). The number of auxiliary vectors used to approximate the filter part $\mathbf{u}$ in Fig. 2 is increasing with the filter index in the sequence. Both the auxiliary vectors and the corresponding weights are subject to design (they are designed according to the maximum cross-correlation and minimum-variance criteria, respectively, as explained in detail below). An important characteristic of the AV algorithm (besides the nonorthogonality of the auxiliary vectors) is that it is a conditional optimization procedure; that is, each filter in the sequence is a function of the previously generated filter. Furthermore, AV filters do not require any explicit or implicit matrix inversion, eigendecomposition, or diagonalization. Finally, under ideal setups (perfect known input autocovariance matrix) the AV filter sequence converges to the MMSE/MVDR optimum solution, [33,34].

A pictorial presentation of generation of the sequence of AV filters is given by Fig. 4a. The sequence is initialized at the appropriately scaled constraint vector $\mathbf{w}_0 = \dfrac{\rho^*}{\|\mathbf{v}_0\|^2}\mathbf{v}_0$, which is MMSE/MVDR optimum only when the vector inputs are white (i.e., when $\mathbf{R} = \sigma^2\mathbf{I}$, $\sigma > 0$). Next, we incorporate in $\mathbf{w}_0$ an "auxiliary" vector component $\mathbf{g}_1$ that is orthogonal to $\mathbf{v}_0$, and we form $\mathbf{w}_1 = \mathbf{w}_0 - \mu_1\mathbf{g}_1$, where $\mathbf{g}_1 \in \mathbb{C}^P - \{\mathbf{0}\}$, $\mu_1 \in \mathbb{C}$, and $\mathbf{g}_1^H\mathbf{v}_0 = 0$. We assume for a moment that the orthogonal auxiliary vector $\mathbf{g}_1$ is arbitrary but nonzero and fixed, and we concentrate on the selection of the scalar μ_1. The value of μ_1 that minimizes the variance of the output of the filter $\mathbf{w}_1$ can be found by direct differentiation of the variance $E\{|\mathbf{w}_1^H\mathbf{x}|^2\}$ or simply as the value that minimizes the MS error between $\mathbf{w}_0^H\mathbf{x}$ and $\mu_1^*\mathbf{g}_1^H\mathbf{x}$. This leads to $\mu_1 = \mathbf{g}_1^H\mathbf{R}\mathbf{w}_0/\mathbf{g}_1^H\mathbf{R}\mathbf{g}_1$.

Since $\mathbf{g}_1$ is set to be orthogonal to $\mathbf{v}_0$, the expression of μ_1 shows that if the vector $\mathbf{R}\mathbf{w}_0$ happens to be "on $\mathbf{v}_0$" [i.e., if $\mathbf{R}\mathbf{w}_0 = (\mathbf{v}_0^H\mathbf{R}\mathbf{w}_0)\mathbf{v}_0$ or equivalently $(\mathbf{I} - \mathbf{v}_0\mathbf{v}_0^H)\mathbf{R}\mathbf{w}_0 = \mathbf{0}$], then $\mu_1 = 0$. Indeed, if $\mathbf{R}\mathbf{w}_0 = (\mathbf{v}_0^H\mathbf{R}\mathbf{w}_0)\mathbf{v}_0$, then $\mathbf{w}_0$ is *already* the MMSE/MVDR filter. To avoid this trivial case and continue with our presentation, we assume that $\mathbf{R}\mathbf{w}_0 \neq (\mathbf{v}_0^H\mathbf{R}\mathbf{w}_0)\mathbf{v}_0$. By inspection, we also observe that for the MS-optimum value of μ_1 the product $\mu_1\mathbf{g}_1$ is independent of the norm of $\mathbf{g}_1$. Hence, so is $\mathbf{w}_1$. At this point, we set the auxiliary vector $\mathbf{g}_1$ to be a normalized vector that maximizes the magnitude of the cross-correlation between $\mathbf{w}_0^H\mathbf{x}$ and $\mathbf{g}_1^H\mathbf{x}$ (i.e., $\mathbf{g}_1 = \arg\max_{\mathbf{g}} |\mathbf{w}_0^H\mathbf{R}\mathbf{g}|$) subject to the constraint that $\mathbf{g}_1^H\mathbf{v}_0 = 0$ and $\mathbf{g}_1^H\mathbf{g}_1 = 1$. For the sake of mathematical accuracy, we note that both the criterion function $|\mathbf{w}_0^H\mathbf{R}\mathbf{g}|$ to be maximized as well as the orthogonality constraint are phase-invariant. Without loss of generality, to avoid any ambiguity in our presentation and to have a uniquely defined auxiliary vector, we choose the one and only auxiliary vector $\mathbf{g}_1$ that satisfies the maximization problem and places the cross-correlation value on the positive real line ($\mathbf{w}_0^H\mathbf{R}\mathbf{g}_1 > 0$).

The general inductive step is as follows. At step $k+1$, we define the AV filter $\mathbf{w}_{k+1} = \mathbf{w}_k - \mu_{k+1}\mathbf{g}_{k+1}$, where $\mathbf{g}_{k+1}$ and μ_{k+1} are to be *conditionally* optimized given the previously identified AV filter $\mathbf{w}_k$. The auxiliary vector $\mathbf{g}_{k+1}$ is chosen as the vector that maximizes the magnitude of the cross-correlation between the output of the previous filter $\mathbf{w}_k$ and the output of $\mathbf{g}_{k+1}$ (Fig. 4a), again subject to $\mathbf{g}_{k+1}$ being orthonormal to $\mathbf{v}_0$ *only* (we note that the choice of the norm does not affect the solution since $\mu_k\mathbf{g}_k$, $k = 1, 2, \ldots$, is $\mathbf{g}$-norm-invariant; we also emphasize that $\mathbf{g}_1, \mathbf{g}_2, \mathbf{g}_3, \mathbf{g}_4 \ldots$, *are not* necessarily orthogonal to each other). The value of μ_{k+1} minimizes the output variance of $\mathbf{w}_{k+1}$ given $\mathbf{w}_k$ and $\mathbf{g}_{k+1}$ (or equivalently minimizes the MS error between $\mathbf{w}_k^H\mathbf{x}$ and $\mu_{k+1}^*\mathbf{g}_{k+1}^H\mathbf{x}$). The solution for $\mathbf{g}_{k+1}$ and μ_{k+1} is given below, while the iterative algorithm for the generation of the infinite sequence of AV filters $\mathbf{w}_0, \mathbf{w}_1, \mathbf{w}_2, \ldots$ is presented in Fig. 4b (we note that in Fig. 4b we dropped the unnecessary normalization of $\mathbf{g}_1, \mathbf{g}_2, \ldots$ since $\mu_k\mathbf{g}_k$ is independent of the norm of $\mathbf{g}_k$):

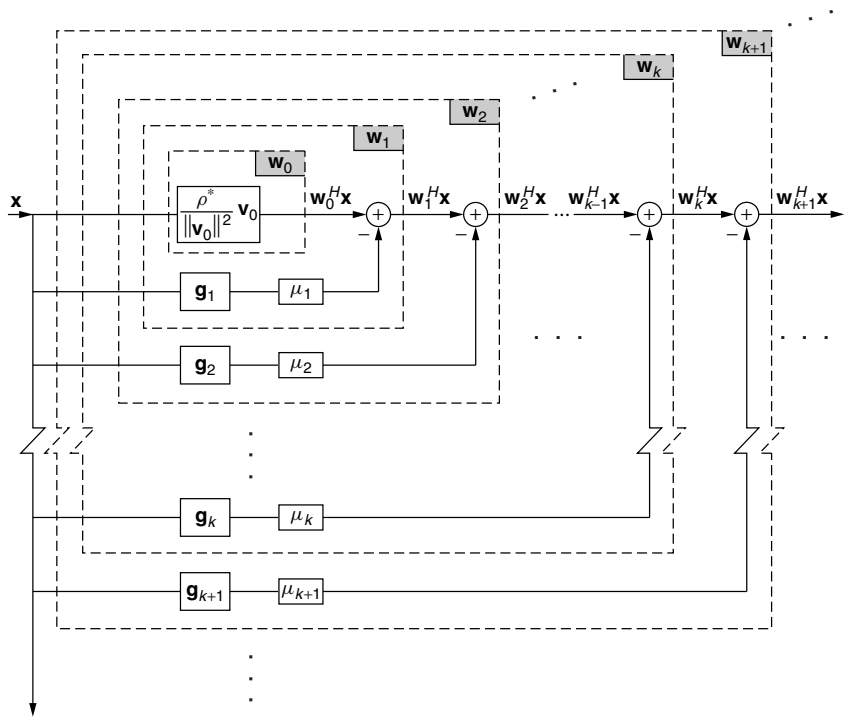
1. The scalar μ_{k+1} that minimizes the variance at the output of $\mathbf{w}_{k+1}$ or equivalently minimizes the MS error between $\mathbf{w}_k^H\mathbf{x}$ and $\mu_{k+1}^*\mathbf{g}_{k+1}^H\mathbf{x}$ is

$$\mu_{k+1} = \frac{\mathbf{g}_{k+1}^H\mathbf{R}\mathbf{w}_k}{\mathbf{g}_{k+1}^H\mathbf{R}\mathbf{g}_{k+1}}, \quad k = 0, 1, 2, \ldots \tag{10}$$

2. Suppose that $\left(\mathbf{I} - \dfrac{\mathbf{v}_0\mathbf{v}_0^H}{\|\mathbf{v}_0\|^2}\right)\mathbf{R}\mathbf{w}_k \neq \mathbf{0}$ ($\mathbf{w}_k \neq \mathbf{w}_{\text{MVDR}}$). Then, the auxiliary vector

$$\mathbf{g}_{k+1} = \frac{\mathbf{R}\mathbf{w}_k - \dfrac{\mathbf{v}_0^H\mathbf{R}\mathbf{w}_k}{\|\mathbf{v}_0\|^2}\mathbf{v}_0}{\left\|\mathbf{R}\mathbf{w}_k - \dfrac{\mathbf{v}_0^H\mathbf{R}\mathbf{w}_k}{\|\mathbf{v}_0\|^2}\mathbf{v}_0\right\|}, \quad k = 0, 1, 2, \ldots \tag{11}$$

(**a**)



(**b**)

Auxiliary-Vector (AV) algorithm

Input:

Autocovariance matrix $\mathbf{R}$, constraint vector $\mathbf{v}_0$,

desired response $\mathbf{w}^H\mathbf{v}_0 = \rho$.

Initialization:

$$\mathbf{w}_0 := \frac{\rho^*}{\|\mathbf{v}_0\|^2}\mathbf{v}_0.$$

Iterative computation:

For $k = 1, 2, \ldots$ do

begin

$$\mathbf{g}_k := \left(\mathbf{I} - \frac{\mathbf{v}_0\mathbf{v}_0^H}{\|\mathbf{v}_0\|^2}\right)\mathbf{R}\,\mathbf{w}_{k-1}$$

if $\mathbf{g}_k = 0$ then EXIT

$$\mu_k := \frac{\mathbf{g}_k^H\mathbf{R}\,\mathbf{w}_{k-1}}{\mathbf{g}_k^H\mathbf{R}\,\mathbf{g}_k}$$

$$\mathbf{w}_k := \mathbf{w}_{k-1} - \mu_k\mathbf{g}_k$$

end

Output:

Filter sequence $\mathbf{w}_0, \mathbf{w}_1, \mathbf{w}_2, \ldots$.

Figure 4. (**a**) Block diagram representation and (**b**) algorithmic description/generation of the auxiliary vector (AV) filter sequence $\mathbf{w}_1, \mathbf{w}_2, \ldots$.

maximizes the magnitude of the cross-correlation between $\mathbf{w}_k^H\mathbf{x}$ and $\mathbf{g}_{k+1}^H\mathbf{x}$ (which is equal to $|\mathbf{w}_k^H\mathbf{R}\mathbf{g}_{k+1}|$), subject to the constraints $\mathbf{g}_{k+1}^H\mathbf{v}_0 = 0$ and $\mathbf{g}_{k+1}^H\mathbf{g}_{k+1} = 1$. In addition, $\mathbf{w}_k^H\mathbf{R}\mathbf{g}_{k+1}$ is real positive ($\mathbf{w}_k^H\mathbf{R}\mathbf{g}_{k+1} > 0$).

With respect to the convergence of the filter sequence $\mathbf{w}_0, \mathbf{w}_1, \mathbf{w}_2, \ldots$ to the MVDR filter $\rho^*\dfrac{\mathbf{R}^{-1}\mathbf{v}_0}{\mathbf{v}_0^H\mathbf{R}^{-1}\mathbf{v}_0}$, we can show that [33]

1. The generated sequence of auxiliary vector weights $\{\mu_k\}, k = 1, 2, \ldots,$ is real-valued, positive, and bounded: $0 < \dfrac{1}{\lambda_{\max}} \le \mu_k \le \dfrac{1}{\lambda_{\min}}$, $k = 1, 2, \ldots$, where $\lambda_{\max}$ and $\lambda_{\min}$ are the corresponding maximum and minimum eigenvalues of $\mathbf{R}$
2. The sequence of auxiliary vectors $\{\mathbf{g}_k\}, k = 1, 2, \ldots,$ converges to the $\mathbf{0}$ vector: $\lim_{k\to\infty}\mathbf{g}_k = \mathbf{0}$

3. The sequence of AV filters $\{\mathbf{w}_k\}, k = 1, 2, \ldots,$ converges to the MVDR filter: $\lim_{k\to\infty} \mathbf{w}_k = \rho^* \dfrac{\mathbf{R}^{-1}\mathbf{v}_0}{\mathbf{v}_0^H \mathbf{R}^{-1}\mathbf{v}_0}$.

3.4. Orthogonal Multistage Filters

An alternative mechanism to approximate the optimum MMSE/MVDR solution can be obtained through the use of the orthogonal "multistage" filter decomposition procedure [39,40] (also called "nested Wiener filter"). It can be shown theoretically that the l-stage filter in [39,40], $\mathbf{w}_{l-\text{stage}}$, $0 \le l \le P-1$, is equivalent to the following structure. First, change the auxiliary vector generation recursion in (11) or Fig. 4b to impose orthogonality with respect not only to the constraint vector $\mathbf{v}_0$ but also to *all previously defined* auxiliary vectors that we denote now as $\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_{k-1}, k \le P-1$:

$$\mathbf{y}_k = \left(\mathbf{I} - \frac{\mathbf{v}_0\mathbf{v}_0^H}{\|\mathbf{v}_0\|^2} - \sum_{i=1}^{k-1} \frac{\mathbf{y}_i\mathbf{y}_i^H}{\|\mathbf{y}_i\|^2}\right)\mathbf{R}\mathbf{w}_{k-1} \tag{12}$$

Next, terminate the recursion at $k = l$, $0 \le l \le P-1$, and organize the l (orthogonal to each other and to $\mathbf{v}_0$) vectors $\mathbf{y}_1, \ldots, \mathbf{y}_l$ in the form of a blocking matrix $\mathbf{B}_{P\times l} = [\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_l]$. Then

$$\mathbf{w}_{l-\text{stage}} = \frac{\rho^*}{\|\mathbf{v}_0\|^2}\mathbf{v}_0 - \mathbf{B}_{P\times l}\vec{\boldsymbol{\alpha}}_{l\times 1} \tag{13}$$

where

$$\vec{\boldsymbol{\alpha}} = \frac{\rho^*}{\|\mathbf{v}_0\|^2}[\mathbf{B}^H\mathbf{R}\mathbf{B}]^{-1}\mathbf{B}^H\mathbf{R}\mathbf{v}_0 \tag{14}$$

is the MS *vector*-optimum set of weights of the vectors $\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_l$ [5,37]. We note that "vector-optimum" implies that the elements of the vector $\vec{\boldsymbol{\alpha}}$ (weights of the columns of $\mathbf{B}$) are designed/optimized jointly (and *not* in a conditional one-by-one manner). The multistage decomposition algorithm [39,40] is a computationally efficient procedure for the calculation of the weight vector $\vec{\boldsymbol{\alpha}}$ tailored to the particular structure of $\mathbf{B}^H\mathbf{R}\mathbf{B}$ (tridiagonal matrix); the calculation incorporates an implicit matrix inversion operation [in view of (14)]. The same computational savings can be achieved by the general forward calculation algorithm of Liu and Van Veen [42] that returns all intermediate stage filters along the way, up to the stage of interest l.

We conclude this section with a few comments on the relative merits and characteristics of the structures presented so far. From a general input space synthesis/decomposition point of view, the main distinguishing features of the AV algorithm with respect to the multistage algorithm are the *non-orthogonal* AV synthesis approach and the *conditional statistical optimization* procedure. Nonorthogonal synthesis allows the designer to grow an *infinite* sequence of AV filters on a "best effort" basis that takes into account the whole interference space at every step. Conditional optimization results in estimators that do not require any implicit or explicit matrix inversion or decomposition operation and, thus, plays a key role in developing superior adaptive filtering schemes in short-data-record environments, as illustrated in the next section.

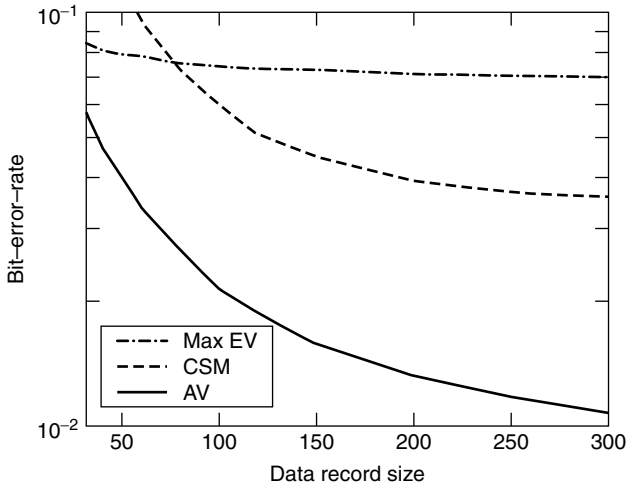


Figure 5. BER as a function of the data record size for the AV, "maximum eigenvector" (MaxEV), and "cross-spectral metric" (CSM) receivers of the same order (3 auxiliary vectors, 3 eigenvectors). *Operational environment*: synchronous DS-CDMA system, user of interest at 12 dB, 12 interferers at 10–14 dB, processing gain $L = 32$, and arbitrary normalized signatures (cross-correlation with the signature of the user of interest ~0.2).

Figure 5 presents an illustrative example of the relative merits of various receiver designs in terms of BER. The example is based on a simple single-path synchronous DSCDMA signal model ($P = L$). The BER performance of the receiver $\mathbf{w}_3$ (that utilizes three auxiliary vectors $\mathbf{g}_1, \mathbf{g}_2$, and $\mathbf{g}_3$) is compared with the BER performance of the "maximum eigenvector" (Max EV) [28,29] receiver and the "cross-spectral-metric" (CSM) [30,31] receiver (both of which use three eigenvectors). As a numerical example that illustrates the convergence of the AV-filter sequence to the ideal MMSE/MVDR solution under perfectly known (ideal) autocorrelation matrix $\mathbf{R}$, in Fig. 6 we plot the squared norm error between the AV filter of the user of interest $\mathbf{w}_k$ and $\mathbf{w}_{\text{MMSE/MVDR}}$ as a function of k (i.e., the number of auxiliary vectors used or equivalently the index of the AV filter in the sequence).

4. ADAPTIVE FILTER ESTIMATION

4.1. Known Channel

4.1.1. SMI, GSC, Auxiliary Vector, and Multistage Estimators. We recall that the MMSE/MVDR filter is a function of the *true* input autocorrelation matrix $\mathbf{R}$ and the *true* constraint vector, $\mathbf{v}_0$. However, in almost every practical adaptive filtering application neither $\mathbf{R}$ nor $\mathbf{v}_0$ is known to the receiver. In this section (4.1) we present various estimates of the optimum MMSE/MVDR filter when $\mathbf{R}$ is unknown and sample average estimated from a data packet (data record) of size J, that is, $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{J-1}$:

$$\hat{\mathbf{R}}(J) = \frac{1}{J}\sum_{j=0}^{J-1} \mathbf{x}_j\mathbf{x}_j^H \tag{15}$$

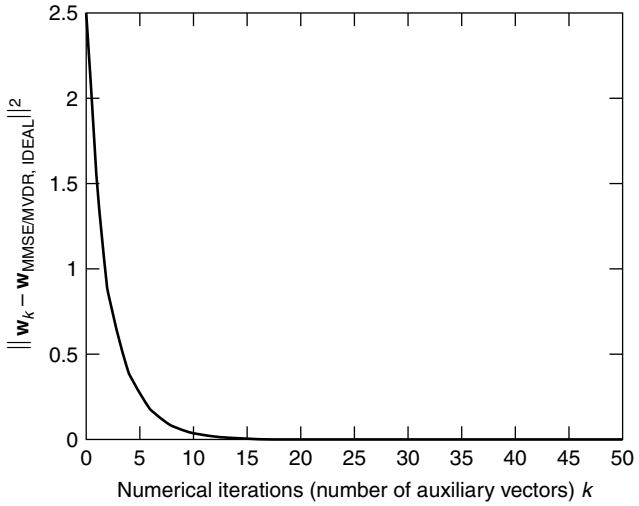

Figure 6. Convergence of the AV filter sequence to the ideal MMSE/MVDR solution as a function of the number of iterations k in Fig. 4b. The sequence of *conditionally optimized* AV filters (that utilize *nonorthogonal* auxiliary vectors) converges to the $\mathbf{w}_{\mathrm{MMSE/MVDR}}$ optimum solution for a perfectly known input autocorrelation matrix $\mathbf{R}$.

Throughout this (4.1) section, $\mathbf{v}_0$ is assumed to be known (since $\mathbf{v}_0$ is a function of the channel parameters we label this section as the "known channel" case); a procedure for the estimation of $\mathbf{v}_0$ from the same data packet (data record) $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{J-1}$ will be presented in the Section 4.2 ("unknown channel").

When $\mathbf{R}$ is unknown, the most widely used MMSE/MVDR filter estimator is obtained from (6) by using the sample average estimate $\hat{\mathbf{R}}(J)$ in place of $\mathbf{R}$. This estimator is known as the sample matrix inversion (SMI) filter. If we choose to work with the approximate solutions presented in Section 3 and utilize the sample average estimate of the autocorrelation matrix $\hat{\mathbf{R}}(J)$ instead of $\mathbf{R}$ in Eqs. (9)–(14), we obtain a GSC, AV, or multistage-type estimator of the MMSE/MVDR solution, respectively. We note that, for Gaussian inputs, $\hat{\mathbf{R}}(J)$ is a maximum-likelihood (ML), consistent, unbiased estimator of $\mathbf{R}$. On the other hand, the inverse of $\hat{\mathbf{R}}(J)$, which is utilized explicitly by the SMI filter and implicitly by both the GSC and the orthogonal multistage decomposition estimator, is not always defined. We can guarantee (with probability 1) that $\hat{\mathbf{R}}(J)$ is invertible only when the number of observations J is greater than or equal to the dimension of the input space (or filter dimension) P and the input distribution belongs to a specific class of multivariate elliptically contoured distributions that includes the Gaussian [43–46]. On the basis of the convergence properties of the AV filter sequence discussed in the previous section we can show that the corresponding sequence of AV filter estimates $\hat{\mathbf{w}}_k(J)$ converges, as $k \to \infty$, to the SMI filter [33]:

$$\hat{\mathbf{w}}_k(J) \xrightarrow[k\to\infty]{} \hat{\mathbf{w}}_\infty(J) = \hat{\mathbf{w}}_{\mathrm{SMI}} = \rho^* \frac{[\hat{\mathbf{R}}(J)]^{-1}\mathbf{v}_0}{\mathbf{v}_0^H[\hat{\mathbf{R}}(J)]^{-1}\mathbf{v}_0} \tag{16}$$

4.1.2. Properties of the Sequence of AV Estimators. The AV filter sequence of estimators begins with $\hat{\mathbf{w}}_0(J) = \frac{\rho^*}{\|\mathbf{v}_0\|^2}\mathbf{v}_0$, which is a zero-variance, fixed-value, estimator that may be severely biased ($\hat{\mathbf{w}}_0(J) \neq \mathbf{w}_{\mathrm{MMSE/MVDR}}$) unless the input is white (i.e., $\mathbf{R} = \sigma^2\mathbf{I}$, for some $\sigma > 0$). In the latter trivial case, $\hat{\mathbf{w}}_0(J)$ is already the perfect MMSE/MVDR filter. Otherwise, the next filter estimator in the sequence, $\hat{\mathbf{w}}_1(J)$, has a significantly reduced bias due to the optimization procedure employed, at the expense of nonzero estimator (co)variance. As we move up in the sequence of filter estimators $\hat{\mathbf{w}}_k(J)$, $k = 0, 1, 2, \ldots$, the bias decreases rapidly to zero[1] while the variance rises slowly to the SMI [$\hat{\mathbf{w}}_\infty(J)$] levels [cf. (16)]. To quantify these remarks, we plot in Fig. 7 the norm-square bias $\|E\{\hat{\mathbf{w}}_k(J)\} - \mathbf{w}_{\mathrm{MMSE/MVDR}}\|^2$ and the trace of the covariance matrix $E\{[\hat{\mathbf{w}}_k(J) - E\{\hat{\mathbf{w}}_k(J)\}][\hat{\mathbf{w}}_k(J) - E\{\hat{\mathbf{w}}_k(J)\}]^H\}$ as a function of the iteration step (filter index) k, for the same signal model as in Fig. 6 and data packet (data record) size $J = 256$. Bias and covariance trace values are calculated from 100,000 independent filter estimator realizations for each iteration point k; that is, we generate 100,000 independent data packets (J received random vectors per packet). For each packet we evaluate $\hat{\mathbf{w}}_1(J), \hat{\mathbf{w}}_2(J), \ldots$. Then, we evaluate expectations as sample averages over 100,000 data packets.

Formal, theoretical statistical analysis of the generated estimators $\hat{\mathbf{w}}_k(J), k = 0, 1, 2, \ldots$, is beyond the scope of this presentation. We do note, however, that for multivariate Gaussian input distributions, an analytic expression for the covariance matrix of the SMI estimator $\hat{\mathbf{w}}_\infty(J)$ can be found in [46]

$$E\{[\hat{\mathbf{w}}_\infty(J) - E\{\hat{\mathbf{w}}_\infty(J)\}][\hat{\mathbf{w}}_\infty(J) - E\{\hat{\mathbf{w}}_\infty(J)\}]^H\} = \frac{|\rho|^2}{(\mathbf{v}_0^H\mathbf{R}^{-1}\mathbf{v}_0)(J-P+1)}\left(\mathbf{R}^{-1} - \frac{\mathbf{R}^{-1}\mathbf{v}_0\mathbf{v}_0^H\mathbf{R}^{-1}}{\mathbf{v}_0^H\mathbf{R}^{-1}\mathbf{v}_0}\right) \tag{17}$$

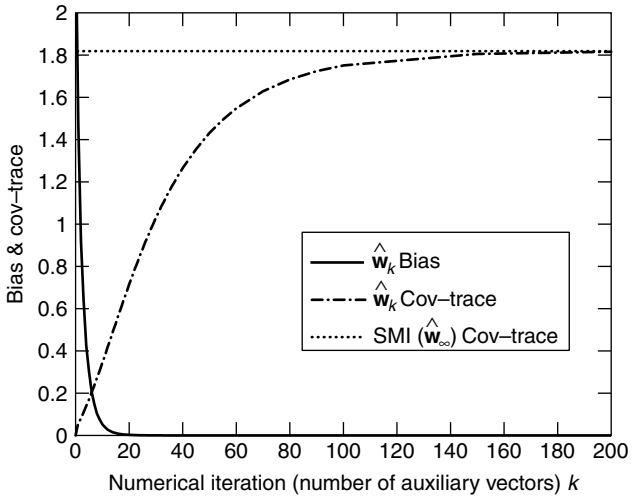

Figure 7. Norm-square bias and covariance trace for the sequence of estimators $\hat{\mathbf{w}}_k(J), k = 0, 1, \ldots$. The signal model is as in Fig. 6; data record size $J = 256$.

[1] The SMI estimator is unbiased for multivariate elliptically contoured input distributions [46,47]: $E\{\hat{\mathbf{w}}_\infty(J)\} = \mathbf{w}_{\mathrm{MMSE/MVDR}} = \rho^*\frac{\mathbf{R}^{-1}\mathbf{v}_0}{\mathbf{v}_0^H\mathbf{R}^{-1}\mathbf{v}_0}$.

Since under these input distribution conditions $\hat{\mathbf{w}}_\infty(J)$ is unbiased, the trace of the covariance matrix is the MS filter estimation error. It is important to observe that the covariance matrix and, therefore, the MS filter estimation error depend on the data record size J, the filter length P, as well as the specifics of the signal processing problem at hand (actual $\mathbf{R}$ and $\mathbf{v}_0$). It is also important to note that when the input distribution is not Gaussian (e.g., for the CDMA signal model example considered earlier in our discussion, the input is Gaussian-mixture-distributed), then the analytic result in (17) is not directly applicable and can be thought of as only an approximation (a rather close approximation for DSCDMA systems). From the results in Fig. 7 for $J = 256$, we see that the estimators $\hat{\mathbf{w}}_1(J), \hat{\mathbf{w}}_2(J), \ldots,$ up to about $\hat{\mathbf{w}}_{20}(J)$ are particularly appealing. In contrast, the estimators $\hat{\mathbf{w}}_k(J)$ for $k > 20$ do not justify their increased covariance trace cost since they have almost nothing to offer in terms of further bias reduction.

We emphasize that since the AV filters $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3, \ldots$ can be considered as approximations of the MMSE/MVDR optimum filter under idealset-ups, the AV-filter estimates $\hat{\mathbf{w}}_1(J), \hat{\mathbf{w}}_2(J), \hat{\mathbf{w}}_3(J), \ldots$ have been viewed so far not only as estimates of the filters $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3, \ldots$ but also, and most importantly, as estimates of the MMSE/MVDR optimum filter in (6) and (7). In this context, the mean-square estimation error expression $E\{\|\hat{\mathbf{w}}_k(J) - \mathbf{w}_{\mathrm{MMSE/MVDR}}\|^2\}$ captures the bias/variance balance of the individual members of the estimator sequence $\hat{\mathbf{w}}_k(J)$, $k = 0, 1, 2, \ldots$. In Fig. 8 we plot the MS estimation error as a function of the iteration step k (or filter index) for the same signal model as in Fig. 6, for $J = 256$ [part (a)] and $J = 2048$ [part (b)]. As a reference, we also include the MS-error of the constraint LMS estimator and the RLS estimator.

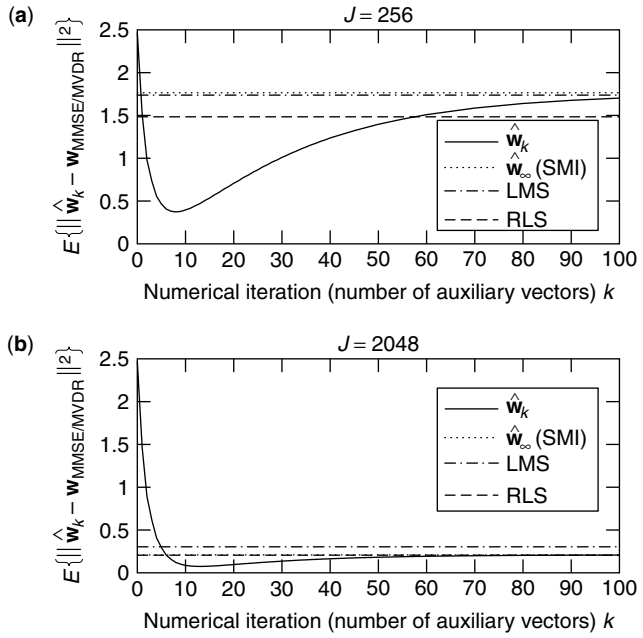

Figure 8. MS estimation error for the sequence of estimators $\hat{\mathbf{w}}_k(J)$, $k = 0, 1, \ldots$: (**a**) data record size $J = 256$; (**b**) $J = 2048$.

The constraint LMS estimator is given by the following recursion:

$$\hat{\mathbf{w}}_{\mathrm{LMS}}(j) = \left(\mathbf{I} - \frac{\mathbf{v}_0\mathbf{v}_0^H}{\|\mathbf{v}_0\|^2}\right)\left[\hat{\mathbf{w}}_{\mathrm{LMS}}(j-1) - \mu\mathbf{x}_j\mathbf{x}_j^H\hat{\mathbf{w}}_{\mathrm{LMS}}(j-1)\right] + \frac{\rho^*}{\|\mathbf{v}_0\|^2}\mathbf{v}_0, \quad j = 1, \ldots, J \tag{18}$$

with $\hat{\mathbf{w}}_{\mathrm{LMS}}(0) = \dfrac{\rho^*}{\|\mathbf{v}_0\|^2}\mathbf{v}_0$ and some $\mu > 0$. The recursion of the RLS estimator can be obtained from the SMI formula in (16) by utilizing the following iterative estimation of $\mathbf{R}^{-1}$ that is based on the matrix inversion lemma:

$$\hat{\mathbf{R}}^{-1}(j) = \hat{\mathbf{R}}^{-1}(j-1) - \frac{\hat{\mathbf{R}}^{-1}(j-1)\mathbf{x}_j\mathbf{x}_j^H\hat{\mathbf{R}}^{-1}(j-1)}{1 + \mathbf{x}_j^H\hat{\mathbf{R}}^{-1}(j-1)\mathbf{x}_j}, \quad j = 1, \ldots, J \tag{19}$$

where $\hat{\mathbf{R}}^{-1}(0) = \dfrac{1}{\varepsilon_0}\mathbf{I}$ for some $\varepsilon_0 > 0$. Theoretically, the LMS gain parameter $\mu > 0$ has to be less than $\dfrac{1}{2 \cdot \lambda_{\max}^{\mathrm{blocked}}}$, where $\lambda_{\max}^{rmblocked}$ is the maximum eigenvalue of the "blocked data" autocorrelation matrix $\left(\mathbf{I} - \dfrac{\mathbf{v}_0\mathbf{v}_0^H}{\|\mathbf{v}_0\|^2}\right)\mathbf{R}\left(\mathbf{I} - \dfrac{\mathbf{v}_0\mathbf{v}_0^H}{\|\mathbf{v}_0\|^2}\right)$. While this is a theoretical upper bound, practitioners are well aware that empirical, data-dependent "optimization" or "tuning" of the LMS gain $\mu > 0$ or the RLS initialization parameter $\varepsilon_0 > 0$ is necessary to achieve acceptable performance (in our study we set $\mu = \dfrac{1}{200 \cdot \lambda_{\max}^{\mathrm{blocked}}}$ and $\varepsilon_0 = 20$, respectively) [8,9,48–51]. This data-specific tuning frequently results in misleading, overoptimistic conclusions about the short-data-record performance of the LMS/RLS algorithms. In contrast, when the AV filter estimators $\hat{\mathbf{w}}_k(J)$ generated by the algorithm of Fig. 4b are considered, tuning of the real-valued parameters μ and ε_0 is virtually replaced by an integer choice among the first several members of the $\{\hat{\mathbf{w}}_k(J)\}$ sequence. In Fig. 8a, for $J = 256$ all estimators $\hat{\mathbf{w}}_k(J)$ from $k = 2$ up to about $k = 55$ outperform in mean-square error (MSE) or their RLS, LMS, and SMI $[\hat{\mathbf{w}}_\infty(J)]$ counterparts. $\hat{\mathbf{w}}_8(J)$ ($k = 8$ auxiliary vectors) has the least MSE of all (best bias/variance tradeoff). When the data record size is increased to $J = 2048$ (Fig. 8b), we can afford more iterations and $\hat{\mathbf{w}}_{13}(J)$ offers the best bias/variance tradeoff (lowest MSE). All filter estimators $\hat{\mathbf{w}}_k(J)$ for $k > 8$ outperform the LMS/RLS/SMI $[\hat{\mathbf{w}}_\infty(J)]$ estimators. For such large data record sets ($J = 2048$), the RLS and the SMI $[\hat{\mathbf{w}}_\infty(J)]$ MSE are almost identical. Figure 9 offers a three-dimensional plot of the mean-square estimation error as a function of the sample support J used in forming $\hat{\mathbf{w}}_k(J)$ and the number of auxiliary vectors k (or filter index). The dark line that traces the bottom of the MS estimation error surface identifies the best number of auxiliary vectors (or the index of the best filter) for any given data record size J.

4.1.3. How to Choose the Best AV Estimator. We recall that, when the autocovariance matrix is sample-average-estimated, the sequence of AV estimators converges

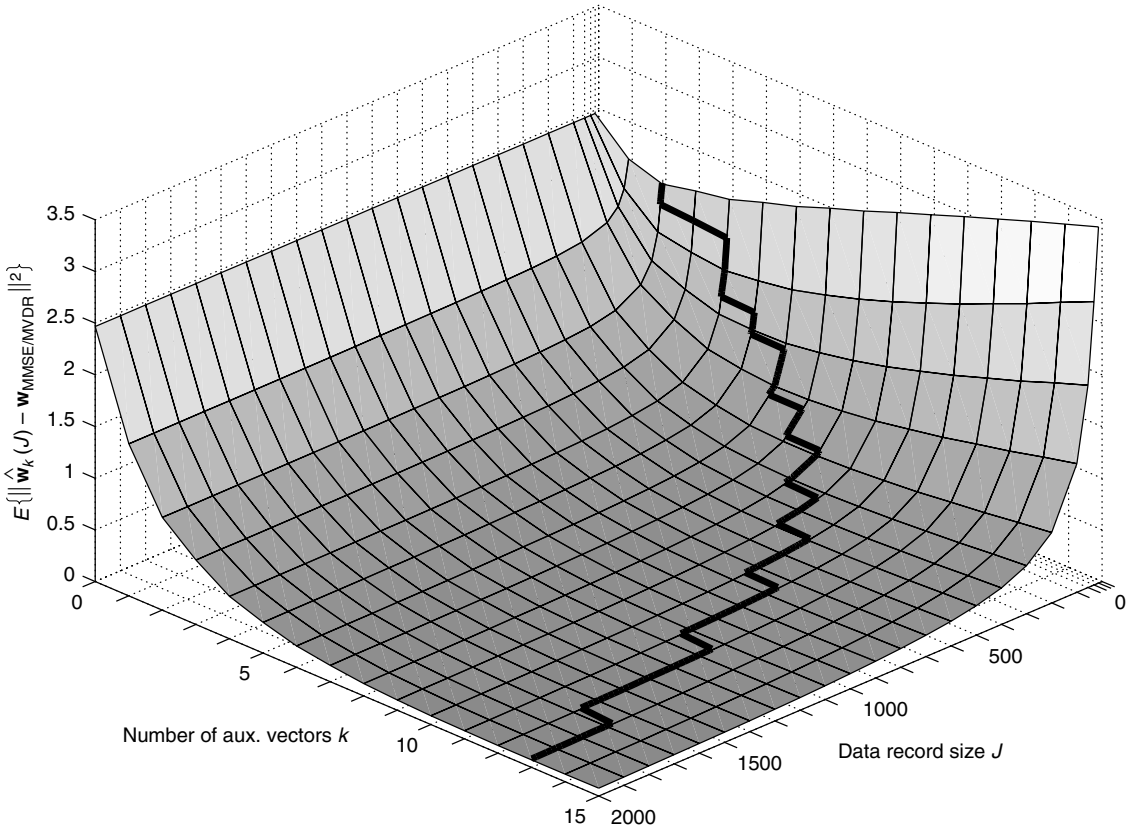

Figure 9. MS estimation error versus number of auxiliary vectors k and sample support J (the signal model is the same as in Fig. 6).

to the SMI filter. Evidently, the early, nonasymptotic elements of the sequence offer favorable bias/variance balance characteristics and outperform in mean-square filter estimation error, as we have seen in Figs. 7–9, the unbiased SMI filter estimator as well as the (constraint) LMS, RLS. We will later see that they also outperform the orthogonal multistage decomposition, and diagonally loaded (DL) SMI filter estimators. In the context of digital wireless communication receivers, superior mean-square filter estimation error translates to superior BER performance under short-data-record receiver adaptation. Selecting the most successful (in some appropriate sense) AV estimator in the sequence for a given data record is a critical problem. Below we present two data-dependent selection criteria [52,53]. The first criterion minimizes the cross-validated sample average variance of the AV filter output and can be applied to general filter estimation problems; the second criterion maximizes the estimated $\mathcal{J}$ divergence of the AV filter output conditional distributions and is tailored to general hypothesis testing (detection) applications.

In particular, the *cross-validated minimum output variance* (CVMOV) rule is motivated by the fact that minimization of the output variance of filters that are constrained to be distortionless in the vector direction of a signal of interest is equivalent to maximization of the output SINR. Cross-validation is a well-known statistical method. In the context of AV filtering, cross-validation is used to select the filter parameter of interest (number of auxiliary vectors k) that minimizes the output variance, which is estimated on the basis of the observations (training data) that have not been used in the process of building the filter itself. A particular case of this general method used in this presentation is the "leave one out" method [54]. The following criterion outlines the CVMOV AV filter selection process.

Criterion 1. For a given data packet (data record) of size J, the cross-validated minimum-output-variance AV filter selection rule chooses the AV filter estimator $\hat{\mathbf{w}}_{k_1}(J)$ that minimizes the cross-validated sample average output variance:

$$k_1 = \arg\min_k \left\{ \sum_{j=1}^{J} \hat{\mathbf{w}}_k(J\backslash j)^H \mathbf{x}_j \mathbf{x}_j^H \hat{\mathbf{w}}_k(J\backslash j) \right\} \tag{20}$$

where $(J\backslash j)$ identifies the AV filter estimator that is evaluated from the available data record after removing the jth sample.

While the CVMOV criterion can be applied to general filter estimation problems, the second criterion, the *maximum $\mathcal{J}$-divergence* criterion, is tailored to applications that can be formulated as binary hypothesis testing problems on AV-filtered data. For any scalar binary hypothesis testing problem, if f_0 and f_1 denote the conditional distributions of the detector input under

hypothesis H_0 and H_1, respectively, then the $\mathcal{J}$-divergence distance between f_0 and f_1 is defined as the sum of the Kullback–Leibler (KL) distances between f_0 and f_1 [55]

$$\mathcal{D}(f_0, f_1) \triangleq \mathcal{KL}(f_1, f_0) + \mathcal{KL}(f_0, f_1) \tag{21}$$

where the KL distance of f_1 from f_0 is defined as $\mathcal{KL}(f_1, f_0) \triangleq \int_{-\infty}^{\infty} f_1(x) \log \frac{f_1(x)}{f_0(x)}\, dx$.

The choice of the output $\mathcal{J}$ divergence as one of the underlying rules for the selection of the AV filter is motivated by the fact that the probability of error of the optimum (Bayesian) detector for any scalar binary hypothesis testing problem is lower bounded by

$$P_e \geq \pi_0 \pi_1 \exp\left\{\frac{-\mathcal{D}(f_0, f_1)}{2}\right\} \tag{22}$$

where π_0 and π_1 are the a priori probabilities of H_0 and H_1, respectively. The right-hand side of (22) is a monotonically decreasing function of the $\mathcal{J}$ divergence between the conditional distributions of the detector input. When the conditional distributions under H_0 and H_1 are Gaussian with the same variance, (22) is satisfied with equality. The latter implies that the larger the $\mathcal{J}$ divergence, the smaller the probability of error or, equivalently, the larger the $\mathcal{J}$ divergence, the easier the detection problem. Thus, maximization of the $\mathcal{J}$ divergence implies minimization of the probability of error. Because of the above mentioned properties and their relationship to the probability of error of the optimum detector, $\mathcal{J}$ divergence has been extensively used in the detection literature as a hypothesis discriminant function. In the context of AV filtering, we denote the AV scalar filter output conditional distributions under H_0 and H_1 by $f_{0,k}(\cdot)$ and $f_{1,k}(\cdot)$, respectively, where the index k indicates the dependence of the distributions on the specific AV filter $\hat{\mathbf{w}}_k$ used from the available sequence $\hat{\mathbf{w}}_1, \hat{\mathbf{w}}_2, \ldots$. Then, the $\mathcal{J}$ divergence between $f_{0,k}(\cdot)$ and $f_{1,k}(\cdot)$ is also a function of k; for this reason, in the rest of our presentation it will be denoted as $\mathcal{D}(k)$. To the extent that the conditional distributions of the AV filter output under H_0 and H_1 are approximated by Gaussian distributions with opposite means and equal variances (which is a reasonable, in general, assumption), we can show in a straightforward manner that

$$\mathcal{D}(k) \approx \frac{4E^2\{b_0 \mathrm{Re}[\hat{\mathbf{w}}_k^H(J)\mathbf{x}]\}}{\mathrm{Var}\{b_0 \mathrm{Re}[\hat{\mathbf{w}}_k^H(J)\mathbf{x}]\}} \tag{23}$$

where $\mathrm{Var}(\cdot)$ denotes variance. The following criterion outlines the $\mathcal{J}$-divergence AV-filter selection process.

Criterion 2. For a given data packet (data record) of size J, the $\mathcal{J}$ divergence AV filter selection rule chooses the AV filter estimator $\hat{\mathbf{w}}_{k_2}(J)$ that maximizes the estimated $\mathcal{J}$ divergence $\hat{\mathcal{D}}(k)$ between the AV filter output conditional distributions:

$$k_2 = \arg\max_k \{\hat{\mathcal{D}}(k)\} \tag{24}$$

If we substitute b_0 in (23) by $\hat{b}_0 = \mathrm{sgn}(\mathrm{Re}[\hat{\mathbf{w}}_k^H(J)\mathbf{x}])$ and evaluate expectations by sample averaging, then we can obtain a blind estimate of the $\mathcal{J}$ divergence:

$$\hat{\mathcal{D}}_B(k) = \frac{4\left[\frac{1}{J}\sum_{j=1}^{J} |\mathrm{Re}[\hat{\mathbf{w}}_k^H(J)\mathbf{x}_j]|\right]^2}{\frac{1}{J}\sum_{j=1}^{J} |\mathrm{Re}[\hat{\mathbf{w}}_k^H(J)\mathbf{x}_j]|^2 - \left[\frac{1}{J}\sum_{j=1}^{J} |\mathrm{Re}[\hat{\mathbf{w}}_k^H(J)\mathbf{x}_j]|\right]^2} \tag{25}$$

where the subscript B identifies the blind version of the $\mathcal{J}$-divergence function. Then, we can evaluate $k_2 = \arg\max_k \{\hat{\mathcal{D}}_B(k)\}$. We recall that in (25) $\mathbf{x}$ denotes the received signal vector of the general form $\mathbf{x} = b_0\sqrt{E_0}\mathbf{v}_0 + \mathbf{z}$ where [cf. (2)] $\mathbf{v}_0 \in \mathbb{C}^P$ is a known deterministic signal vector, $E_0 > 0$ represents the unknown energy scalar, $\mathbf{z} \in \mathbb{C}^P$ is a zero-mean disturbance vector (i.e., it may incorporate ISI, MAI, and additive noise effects), and b_0 is $+1$ or -1 with equal probability. We also recall [cf. (3)] that the decision on $H_0(b_0 = -1)$ or $H_1(b_0 = +1)$ is based on the real part of the AV filter output $\mathrm{Re}[\hat{\mathbf{w}}_k^H(J)\mathbf{x}]$, where $\hat{\mathbf{w}}_k(J)$ is the AV estimator that utilizes k auxiliary vectors.

4.1.4. Properties of the Multistage and the DL-SMI Estimators. A *finite set* of P filter estimators with varying bias/variance balance can be obtained through the use of the orthogonal "multistage" filter decomposition procedure [40]. In the context of filter estimation from a data record of size J, $\hat{\mathbf{w}}_{0-\mathrm{stage}}(J)$ is the matched filter and $\hat{\mathbf{w}}_{(P-1)-\mathrm{stage}}(J)$ is the SMI estimator. In Fig. 10b we plot the MS estimation error of $\hat{\mathbf{w}}_{l-\mathrm{stage}}(J)$ as a function of l, $0 \leq l \leq P-1 = 31 (J = 60)$. We identify the *best* multistage estimator ($l = 3$ stages), and in Fig. 10c we compare against the AV estimator sequence. We see that all AV estimators $\hat{\mathbf{w}}_k(J)$ from $k = 3$ to 8 outperform in MSE the best multistage estimator ($l = 3$ stages).

An alternative bias/variance trading mechanism through real-valued tuning is the diagonally-loaded (DL) SMI estimator obtained by adding an amount (Δ) to each element of the diagonal of $\hat{\mathbf{R}}(J)$ in the SMI formula (16) [56] [in this way we ensure the invertibility of $\hat{\mathbf{R}}(J)$]

$$\hat{\mathbf{w}}_{\mathrm{DL-SMI}}(\Delta) = \rho^* \frac{[\hat{\mathbf{R}}(J) + \Delta\mathbf{I}]^{-1}\mathbf{v}_0}{\mathbf{v}_0^H[\hat{\mathbf{R}}(J) + \Delta\mathbf{I}]^{-1}\mathbf{v}_0} \tag{26}$$

where $\Delta \geq 0$ is the diagonal loading parameter. We observe that $\hat{\mathbf{w}}_{\mathrm{DL-SMI}}(\Delta = 0)$ is the regular SMI estimator, while $\lim_{\Delta\to\infty} \hat{\mathbf{w}}_{\mathrm{DL-SMI}}(\Delta) = \frac{\rho^*}{\|\mathbf{v}_0\|^2}\mathbf{v}_0$, which is the properly scaled matched filter. In Fig. 10a we plot the MS estimation error of the DL-SMI estimator as a function of the diagonal loading parameter $\Delta (J = 60)$. We identify the *best possible* diagonal loading value $\Delta \simeq 3.45$ (at significant computational cost), and in Fig. 10c we compare the best DL-SMI estimator against the AV estimator sequence for which *no* diagonal loading is performed. Interestingly, $\hat{\mathbf{w}}_k(J)$ from $k = 4$–7 outperform in MSE the best possible DL-SMI estimator ($\Delta \simeq 3.45$). In Fig. 11 we plot the MS error of the $\Delta = 3.45$ DL-SMI estimator together with the MS error of the *best* multistage and AV estimators over the data support

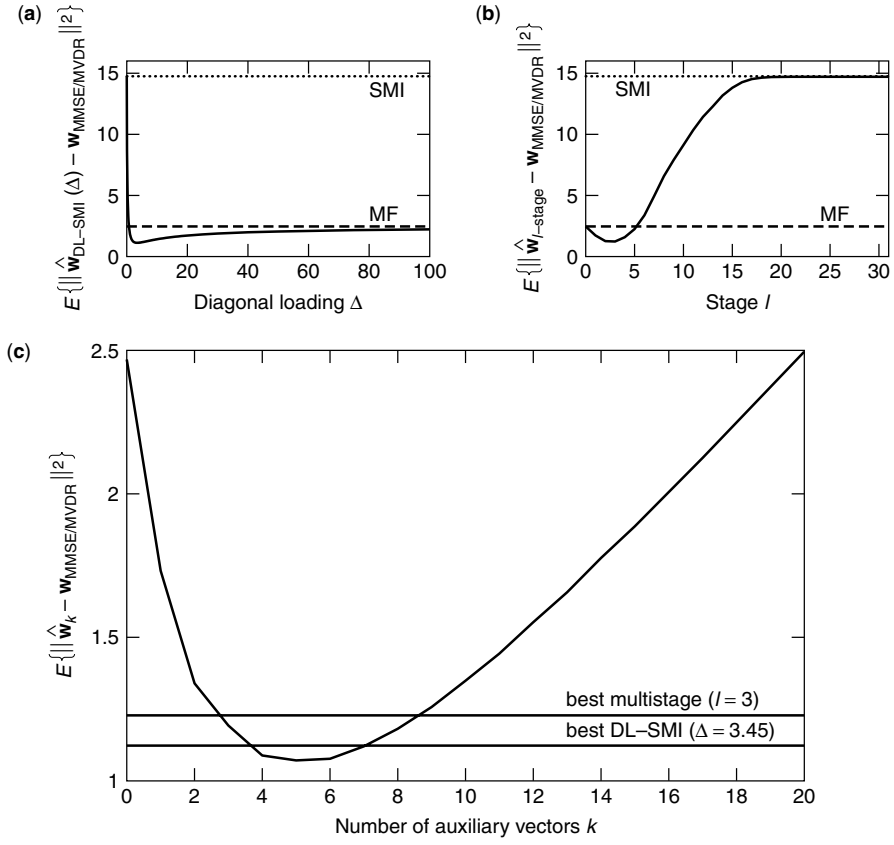

Figure 10. MS estimation error studies for (**a**) diagonally loaded SMI, (**b**) multistage (also called "nested Wiener"), and (**c**) auxiliary vector estimators (the signal model is the same as in Fig. 6 and $J = 60$).

(packet size) range $J = P/2 = 16$ to $J = 3P = 96$. The total computational complexity of the multistage algorithm is of order $O((J + l)P^2)$. The AV algorithm has computational complexity $O((J + k)P^2)$, where k is the desired number of auxiliary vectors $\mathbf{g}_1, \ldots, \mathbf{g}_k$. All intermediate AV filters are returned. The computational complexity of DL-SMI is of order $O((J + P)P^2)$. Estimators of practical interest have $l \ll J$ or $k \ll J$. Therefore, the complexity of all algorithms is dominated by $O(JP^2)$, which is required for the computation of $\hat{\mathbf{R}}(J)$ (the computational complexity of the RLS estimator is, similarly, of the order $O(JP^2)$, the complexity of the GSC estimator is $O(JP^2 + P^3)$, while the complexity of LMS estimator — with no data recycling — is of order $O(JP)$). In terms of performance, the *explicit* or *implicit* matrix inversion that the SMI and the multistage algorithm (at any given stage) performs, respectively, affects adversely their behavior under short-data-record adaptation.

4.1.5. Performance Illustrations. We illustrate the overall short-data-record adaptive filter performance in Figs. 12 and 13 for a multipath fading DSCDMA system that employs antenna array reception. We consider processing gain 31, 20 users, 5 antenna elements, and 3 resolvable multipaths per user with independent zero-mean complex Gaussian fading coefficients of variance 1. The maximum cross-correlation between the assigned user signatures reaches 30%. The total SNR's (over the three paths) of the 19 interferers are set at $\mathrm{SNR}_{2-6} =$ 6 dB, $\mathrm{SNR}_{7-8} = 7$ dB, $\mathrm{SNR}_{9-13} = 8$ dB, $\mathrm{SNR}_{14-15} = 9$ dB, $\mathrm{SNR}_{16-20} = 10$ dB. The spacetime product (filter length) is

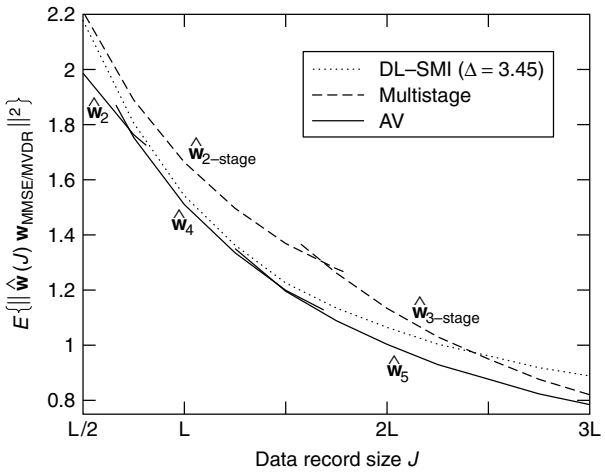

Figure 11. MS estimation error for the *best* multistage and AV estimators over the data support range $J = P/2 = 16$ to $J = 3P = 96$. The MS estimation error of the $\Delta = 3.45$ DL-SMI estimator is also included as a reference (the signal model is the same as in Fig. 6).

$P = (31 + 2)5 = 165$. The experimental results are averages over 1000 runs (100 different channel realizations and 10 independent data record generations per channel). In Fig. 12, we plot the BER[2] of the AV estimators

[2] The BER of each filter under consideration is approximated by $Q(\sqrt{\mathrm{SINR}_{\mathrm{out}}})$, since the computational complexity of the BER

$\hat{\mathbf{w}}_{k_1}(J)$ and $\hat{\mathbf{w}}_{k_2}(J)$ as a function of the SNR of the user of interest for data records of size $J = 230$. We also plot the BER curve of the "genie" assisted BER-optimum filter $\hat{\mathbf{w}}_{k_{\text{opt}}}(J)$ as well as the corresponding curves of the ideal MMSE/MVDR filter $\mathbf{w}_{\text{MMSE/MVDR}}$, the SMI filter estimator $\hat{\mathbf{w}}_{\infty}(J)$, the S-T RAKE matched-filter (MF) $\hat{\mathbf{w}}_0(J)$, and the multistage filter (with the preferred number of stages[3] $l = 7$). We observe that both $\hat{\mathbf{w}}_{k_1}(J)$ and $\hat{\mathbf{w}}_{k_2}(J)$ are very close to the "genie" BER-optimum AV filter estimator choice and outperform significantly the SMI filter estimator, the multistage filter estimator, and the matched filter. We also observe that for moderate to high SNR of the user of interest, the $\mathcal{J}$-divergence selection rule is slightly superior to the CVMOV selection rule. Figure 13 repeats the study of Fig. 12 as a function of the data record size. The SNR of the user of interest is fixed at 8 dB.

Concluding our discussion in this section (4.1), we note that the key for a successful solution (in the sense of superior filter output SINR or BER performance) to the problem of adaptive receiver design under limited data support is to employ receivers with varying bias/variance characteristics and to effectively control these characteristics in a data-driven manner. For this reason, operations and filter design/optimization criteria that suffer from "data starvation" (e.g., implicit or explicit matrix inversion and/or eigendecomposition) should be avoided. From a general input space synthesis/decomposition point of view, the *nonorthogonal* synthesis and the conditional statistical optimization are two principles that allow to grow an *infinite* sequence of AV filters on a "best effort" basis that takes into account the whole interference space at each step. These two features play a key role, leading to superior adaptive filtering performance in short-data-record environments. In particular, under

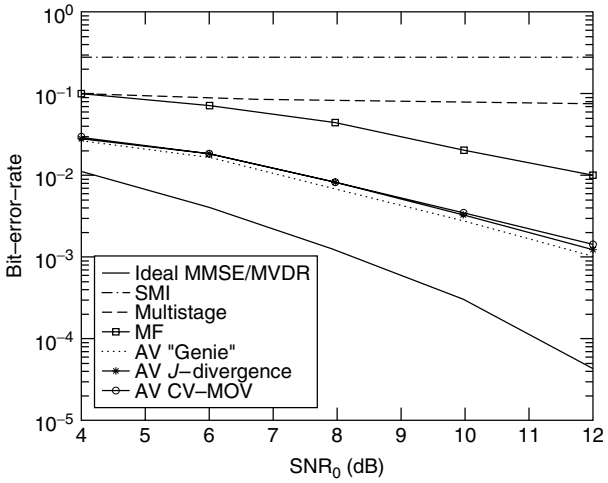

Figure 12. BER versus SNR for the user signal of interest for a multipath fading antenna array received signal model ($L = 31$, $K = 20, M = 5, N = 3$) with $P = 165$ and $J = 230$.

expression for this antenna-array CDMA system prohibits exact analytic evaluation [57].

[3] Honig and Xiao [41] argued that $l = 7$ ($D = 8$ in their notation [41]) stages is "nearly optimal over a wide range of loads and SNRs."

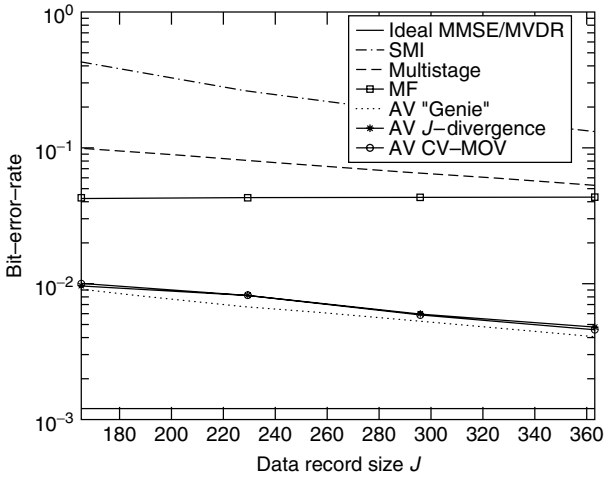

Figure 13. BER versus data record size (the signal model is the same as in Fig. 12, and $\text{SNR}_0 = 8$ dB).

short-data-record adaptation, the early, non-asymptotic elements of the sequence of AV estimators are mildly biased but exhibit much lower variance than other alternatives (for digital communications applications, the latter implies superior BER performance). As the available data record increases we can afford to go higher and higher in the sequence of generated estimators. In the limit, if we are given infinitely many input data, we can go all the way up to the convergence point of the algorithm, which is the ideal MMSE/MVDR receiver. The significant role of conditional statistical optimization in short-data-record adaptive filtering is evident even when *orthogonal* vectors are utilized. For example, it has been seen that the nonconditional (vector-optimum) scheme that utilizes orthogonal vectors with vector-optimum weights (12)–(14) (or, equivalently, the filter obtained by the algorithm of Goldstein et al. [40] that performs implicitly a matrix inversion) exhibits inferior short-data-record performance than does the structure that utilizes orthogonal vectors and conditionally optimized weights [5]. As a few concluding notes, an online version of the AV algorithm has been presented [58,59]. Application of AV filtering to the problem of rapid synchronization and combined demodulation of DSCDMA signals has been considered [60–62]. Detailed results on data record size requirements to achieve a given output SINR (or BER) performance level can be found in earlier studies [63,64].

4.2. Unknown Channel

The second part of this section is devoted to the estimation of the channel-processed constraint vector $\mathbf{v}_0$ from the same data packet (data record) $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{J-1}$. To be consistent with our discussion and illustrative studies presented in the previous sections, we consider the general case of ST DSCDMA signal model described by (1)–(5). We recall that Q, L, N, M, and J denote the number of active users in the system, the processing gain, the number of paths experienced by the transmitted signal of each user, the number of antenna elements, and the data packet (data record) size, respectively. We also recall that $\mathbf{v}_0$ is the ST

RAKE filter of the user of interest (user 0), defined by $\mathbf{v}_0 \triangleq E_{b_0}\{\mathbf{x}b_0\}$, where the statistical expectation operation $E_{b_0}\{\cdot\}$ is taken with respect to the bit of the user of interest b_0 only. Clearly, $\mathbf{v}_0$ consists of shifted versions of the ST matched filter multiplied by the corresponding channel coefficients [cf. (4)]:[4]

$$\mathbf{v}_0 = \sum_{n=0}^{N-1} c_{0,n} \begin{bmatrix} \underbrace{0 \ldots 0}_{n} & \mathbf{d}_0^T & \underbrace{0 \ldots 0}_{N-n-1} \end{bmatrix}^T \odot \mathbf{a}_{0,n} \qquad (27)$$

Hence, $\mathbf{v}_0$ is a function of the binary signature vector (spreading sequence) of the user of interest $\mathbf{d}_0$, the channel coefficients $c_{0,0}, c_{0,1}, \ldots, c_{0,N-1}$, and the corresponding angles of arrival $\theta_{0,0}, \theta_{0,1}, \ldots, \theta_{0,N-1}$ [cf. (5)]. While the spreading sequence is assumed to be known to the receiver, the channel coefficients and the angles of arrival are in general unknown.

4.2.1. Subspace Channel and Angle-of-Arrival Estimation. In this section we explain how the channel coefficients $\mathbf{c}_0 \triangleq [c_{0,0}, c_{0,1}, \ldots, c_{0,N-1}]^T$ and the angles of arrival $\boldsymbol{\theta}_0 \triangleq [\theta_{0,0}, \theta_{0,1}, \ldots, \theta_{0,N-1}]^T$ for the user of interest, user 0, can be estimated by subspace-based techniques from the ST data packet (data record) $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{J-1}$ [65,66]. We note that while adaptive subspace (eigendecomposition)-type MMSE/MVDR filtering is not a favorable approach under limited data support (the resulting estimates exhibit high variance), subspace-type channel estimation techniques do not suffer from "data starvation" as illustrated later.

Let the binary data of each user be organized in identically structured packets of J bits. The channel estimation procedure that we employ utilizes J_p pilot bits (bits that are known to the receiver). Thus, the qth user data packet, $\{b_q(0), b_q(1), \ldots, b_q(J-1)\}, q = 0, 1, \ldots, Q-1$, contains $J - J_p$ information bits and J_p pilot bits. The J_p known bits will be utilized later for the supervised recovery of the phase of the subspace channel estimates since blind second-order channel estimation methods return phase-ambiguous estimates. An example of the data packet structure is shown in Fig. 14, where the J_p pilot bits appear as a *midamble* in the transmitted packet [67]. Without loss of generality, we assume that each user transmits one data packet per slot and the slot duration is T_s seconds. Therefore, the data packet size J is the number of information bits transmitted by each user in one time slot, $T_s = JT$, where T is the duration of each information bit transmission.

The rank r_s of the *signal subspace* of the received data vectors $\mathbf{x}$ can be controlled by considering one-sided or two-sided truncations of $\mathbf{x}$ (the latter eliminates ISI). The possible values of r_s, depending on the data format of choice, are as follows:

1. *No truncation*: data dimension $= M(L+N-1)$, $2Q+1 \le r_s \le 3Q$.
2. *One-sided truncation*: data dimension $= ML$, $2Q \le r_s \le 3Q-1$.
3. *Two-sided truncation*: data dimension $= M(L-N+1)$, $Q \le r_s \le 2Q-1$.

To have a guaranteed minimum rank of the *noise subspace* of $M(L-N+1)-(2Q-1)$, we choose to truncate $\mathbf{x}$ from both sides (case (3)) as shown in Fig. 15, and we form the "truncated" received vector $\mathbf{x}^{\text{tr}}$ of length $M(L-N+1)$ as follows:

$$\mathbf{x}^{\text{tr}} = \begin{bmatrix} \mathbf{x}((N-1)T_c) \\ \mathbf{x}(NT_c) \\ \vdots \\ \mathbf{x}((L-1)T_c) \end{bmatrix}$$

Then, with respect to the jth information bit of user 0, $\mathbf{x}_j^{\text{tr}}$ can be expressed as

$$\mathbf{x}_j^{\text{tr}} = b_0(j)\frac{\sqrt{E_0}}{L}\mathbf{A}_0\mathbf{B}(\boldsymbol{\theta}_0)\mathbf{c}_0 + \text{MAI}_j + \mathbf{n}_j \qquad (29)$$

where MAI_j accounts comprehensively for multiple-access interference of rank $r_s - 1$, $\mathbf{B}(\boldsymbol{\theta}_0)$ is a block diagonal matrix of the form $\mathbf{B}(\boldsymbol{\theta}_0) \triangleq \text{diag}(\mathbf{a}_{0,0}, \mathbf{a}_{0,1}, \ldots, \mathbf{a}_{0,N-1})$, and $\mathbf{A}_0 = \mathbf{A}_0^s \odot \mathbf{I}_M$, where $\mathbf{I}_M$ is the $M \times M$ identity matrix, and

$$\mathbf{A}_0^s = \begin{bmatrix} d_0[N-1] & d_0[N-2] & \ldots & d_0[0] \\ d_0[N] & d_0[N-1] & \ldots & d_0[1] \\ \vdots & \vdots & & \vdots \\ d_0[L-1] & d_0[L-2] & \ldots & d_0[L-N] \end{bmatrix} \qquad (30)$$

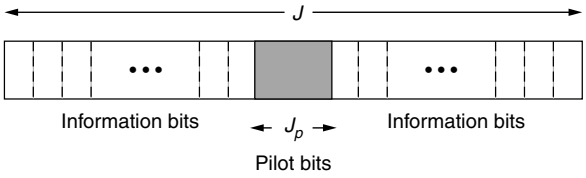

Figure 14. Data packet structure of total length J bits that contains a midamble of J_p pilot bits.

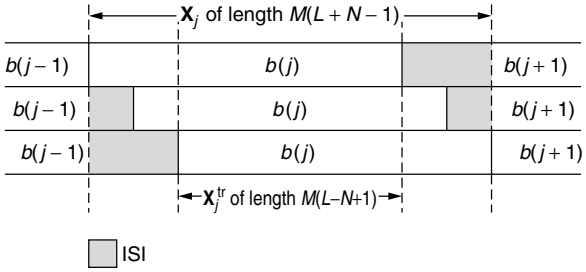

Figure 15. Data collection and ISI trimming.

[4] For the sake of mathematical accuracy

$$\mathbf{v}_0 = \sqrt{\frac{E_0}{L}} \sum_{n=0}^{N-1} c_{0,n} \begin{bmatrix} \underbrace{0 \ldots 0}_{n} & \mathbf{d}_0^T & \underbrace{0 \ldots 0}_{N-n-1} \end{bmatrix}^T \odot \mathbf{a}_{0,n}$$

The positive multiplier $\sqrt{\frac{E_0}{L}}$ is dropped in (27) as inconsequential.

Let $\mathbf{R}_{\text{tr}} = E\{\mathbf{x}^{\text{tr}}\mathbf{x}^{\text{tr}H}\}$ be the autocorrelation matrix of $\mathbf{x}^{\text{tr}}$. We form a sample-average estimate

$$\hat{\mathbf{R}}_{\text{tr}} = \frac{1}{J}\sum_{j=0}^{J-1}\mathbf{x}_j^{\text{tr}}\mathbf{x}_j^{\text{tr}H} \tag{31}$$

based on the truncated J available input vectors $\mathbf{x}_j^{\text{tr}}, j = 0, 1, \ldots, J-1$. If $\hat{\mathbf{R}}_{\text{tr}} = \hat{\mathbf{Q}}\hat{\mathbf{\Lambda}}\hat{\mathbf{Q}}^H$ represents the eigendecomposition of $\hat{\mathbf{R}}_{\text{tr}}$, where the columns of $\hat{\mathbf{Q}}$ are the eigenvectors of $\hat{\mathbf{R}}_{\text{tr}}$ and $\hat{\mathbf{\Lambda}}$ is a diagonal matrix consisting of the eigenvalues of $\hat{\mathbf{R}}_{\text{tr}}$, then we use the eigenvectors that correspond to the $M(L-N+1)-(2Q-1)$ smallest eigenvalues to define our estimated noise subspace. Let the matrix $\hat{\mathbf{U}}_n$ of size $[M(L-N+1)] \times [M(L-N+1)-(2Q-1)]$ consist of these "noise eigenvectors." We estimate $\mathbf{c}_0$ and $\boldsymbol{\theta}_0$ indirectly through an estimate of the $MN \times 1$ vector

$$\mathbf{h}_0 \triangleq \mathbf{B}(\boldsymbol{\theta}_0)\mathbf{c}_0 \tag{32}$$

We estimate $\mathbf{h}_0$ as the vector that minimizes the norm of the projection of the signal of the user of interest, user 0, $\mathbf{A}_0\mathbf{h}_0$, onto the estimated noise subspace $\hat{\mathbf{U}}_n$:

$$\hat{\mathbf{h}}_0 = \arg\min_{\mathbf{h}_0} \|(\mathbf{A}_0\mathbf{h}_0)^H\hat{\mathbf{U}}_n\| \quad \text{subject to} \quad \|\hat{\mathbf{h}}_0\| = 1 \tag{33}$$

The solution to this constrained minimization problem is the eigenvector that corresponds to the minimum eigenvalue of $\mathbf{A}_0^H\hat{\mathbf{U}}_n\hat{\mathbf{U}}_n^H\mathbf{A}_0$. After obtaining $\hat{\mathbf{h}}_0$, we may extract the desired vectors $\hat{\mathbf{c}}_0$ and $\hat{\boldsymbol{\theta}}_0$ by applying least-squares (LS) fitting to $\hat{\mathbf{h}}_0$. Then, the estimate $\hat{\mathbf{v}}_0$ is completely defined by (27).

Since the channel estimation method described above is based on a blind second-order criterion, the phase information is absorbed, which means that the estimate $\hat{\mathbf{v}}_0$ is phase-ambiguous. Inherently, adaptive filter estimators that utilize a phase-ambiguous estimate of $\mathbf{v}_0$ are also phase-ambiguous. Next, we consider the recovery (correction) of the phase of linear filters when the vector $\mathbf{v}_0$ is known within a phase ambiguity.

4.2.2. Phase Recovery. Without loss of generality, let $\tilde{\mathbf{v}}_0$ denote a phase ambiguous version of $\mathbf{v}_0$

$$\tilde{\mathbf{v}}_0 e^{j\psi} = \mathbf{v}_0 \tag{34}$$

where ψ is the unknown phase. We consider the class of linear filters $\mathbf{w} \in \mathbb{C}^{M(L+N-1)}$ that are functions of the ST RAKE vector $\mathbf{v}_0$ and share the following property:

$$\mathbf{w}(\mathbf{v}_0) = \mathbf{w}(\tilde{\mathbf{v}}_0)e^{j\psi} \tag{35}$$

Such filters include (1) the ST RAKE filter itself, $\mathbf{v}_0$, (2) the ST MMSE/MVDR filter of (6), and (3) the auxiliary vector sequence of ST filters $\{\mathbf{w}_k\}$.

As seen in (35), for this class of filters the phase ambiguity of $\tilde{\mathbf{v}}_0$ leads to a phase ambiguous linear filter $\mathbf{w}(\tilde{\mathbf{v}}_0)$. Phase ambiguity in digital communications can be catastrophic since it may result in receivers that exhibit BER equal to 50%. Given $\tilde{\mathbf{v}}_0$, we attempt to correct the phase of $\mathbf{w}(\tilde{\mathbf{v}}_0)$ as follows. As a selection criterion for the phase correction parameter ψ we consider the minimization of the mean-square error (MSE) between

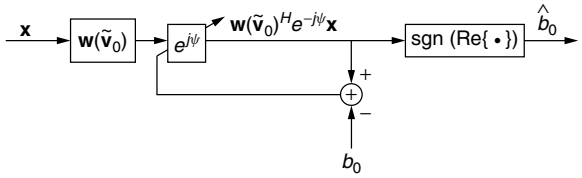

Figure 16. Supervised (pilot-assisted) phase correction for the spacetime linear filter $\mathbf{w}(\tilde{\mathbf{v}}_0)$.

the output of the phase corrected filter $[\mathbf{w}(\tilde{\mathbf{v}}_0)e^{j\psi}]^H\mathbf{x}$ and the desired information bit b_0 (Fig. 16):

$$\hat{\psi} = \arg\min_{\psi} E\{|[\mathbf{w}(\tilde{\mathbf{v}}_0)e^{j\psi}]^H\mathbf{x} - b_0|^2\}, \quad \psi \in [-\pi, \pi) \tag{36}$$

The optimum phase correction value according to this criterion is given by

$$\hat{\psi} = \text{angle}\{\mathbf{w}(\tilde{\mathbf{v}}_0)^H E\{\mathbf{x}b_0\}\} \tag{37}$$

Essentially, (37) suggests to project the phase ambiguous $\mathbf{w}(\tilde{\mathbf{v}}_0)$ filter onto the ideal ST RAKE filter $\mathbf{v}_0 = E\{\mathbf{x}b_0\}$. However, $E\{\mathbf{x}b_0\}$ is certainly not known. Since we have assumed that a pilot information bit sequence of length J_p is included in each packet, the expectation $E\{\mathbf{x}b_0\}$ can be sample-average-estimated by $\frac{1}{J_p}\sum_{j=1}^{J_p}\mathbf{x}_j b_0(j)$, where $b_0(j), j = 1, 2, \ldots, J_p$, is the jth *pilot* information bit and $\mathbf{x}_j$ is the corresponding input data vector. Then, the phase-corrected adaptive filter estimate is given by

$$\mathbf{w}(\hat{\mathbf{v}}_0, \hat{\mathbf{R}})e^{j\hat{\psi}}, \quad \hat{\psi} = \text{angle}\left\{\mathbf{w}(\hat{\mathbf{v}}_0, \hat{\mathbf{R}})^H\left[\sum_{j=1}^{J_p}\mathbf{x}_j b_0(j)\right]\right\} \tag{38}$$

Since J represents the packet size of the DSCDMA system and J_p is the number of midamble pilot information bits per packet, then the ratio J_p/J quantifies the wasted bandwidth due to the use of the pilot bit sequence. Ideally, J_p/J is to be kept small. As we will see in the next section, a few pilot bits (on the order of 5 bits) are sufficient for effective recovery of the filter phase. As a numerical example, when the packet size is set at $J = 256$ and $J_p = 5$ is chosen, then $J_p/J \simeq 2\%$ only.

5. PACKET ERROR RATE, CAPACITY, AND THROUGHPUT ANALYSIS

5.1. Packet Error Rate

So far, we have concentrated on the design/estimation of the receiver filter $\mathbf{w}$ in (3). The filter estimate is generated adaptively on an individual packet-by-packet basis. All J received vectors of the packet are utilized for the design of $\mathbf{w}$ (estimation of $\mathbf{R}$, $\mathbf{v}_0$, and the number of auxiliary vectors k_1 or k_2), while J_p of them are also used for supervised phase correction (estimation of ψ). Then, the $J - J_p$ information bits of user 0 associated with the remaining $J - J_p$ received vectors are detected by (3).

The effectiveness of the filter is characterized statistically by the probability distribution of the number of bit errors in a packet:

$$p(i) \triangleq \Pr\{i \text{ bit errors in the packet}\}, i = 0, 1, \ldots, J - J_p. \tag{39}$$

Without loss of generality, we define the bit error rate (BER) as the probability of erroneous detection of $b_0(0)$ (the first bit of user 0 in the packet):

$$\begin{aligned}\text{BER} &\triangleq \Pr\{\hat{b}_0(0) \neq b_0(0)\} \\ &= \sum_{i=0}^{J-J_p} \Pr\{\hat{b}_0(0) \neq b_0(0) \mid i \text{ bit errors in the packet}\} p(i) \\ &= \sum_{i=0}^{J-J_p} \frac{i}{J-J_p} p(i) = \frac{1}{J-J_p} \sum_{i=0}^{J-J_p} i p(i)\end{aligned} \tag{40}$$

It is interesting to note at this point that if the filter $\mathbf{w}$ were independent of the information bit stream $b_0(0), b_0(1), \ldots$, then the BER could have been expressed analytically as a weighted sum of the value of the error function $Q(x) = \dfrac{1}{\sqrt{2\pi}} \displaystyle\int_x^\infty \mathrm{e}^{t^2/2}\, dt$ evaluated at 2^{K-1} different points (interfering bit combinations) weighted by the probability of each point $2^{-(K-1)}$. However, this independence assumption does not hold true in our system since the data packet (data record) $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{J-1}$, which includes the information bits $b_0(0), b_0(1), \ldots, b_0(J-1)$ to be detected, is directly utilized for the calculation of $\mathbf{w}$. Therefore, performance cannot be evaluated using the analytic BER expression; instead, we can only rely on (40).

A data packet is received successfully within a single time slot if the number of errors in the detection of the $J - J_p$ information bits is less than or equal to the maximum number of (correctable) bit errors allowed by the forward error correction (FEC) module. If no FEC is present, then the packet is successfully received when all $J - J_p$ information bits are detected correctly. The packet error rate (PER) is defined as the probability of receiving an uncorrectable packet within a single time slot and is given by

$$\begin{aligned}\text{PER}(h) &\triangleq \Pr\{\text{more than } h \text{ bit errors in the packet}\} \\ &= \sum_{i=h+1}^{J-J_p} p(i) = 1 - \sum_{i=0}^{h} p(i)\end{aligned} \tag{41}$$

where h is the maximum number of correctable bit errors per packet. By setting $h = 0$ we obtain the PER of a system without FEC:

$$\text{PER}(0) = \sum_{i=1}^{J-J_p} p(i) = 1 - p(0) \tag{42}$$

To examine the PER performance of the general DSCDMA system described in (1)–(5) equipped with the packet-rate adaptive ST AV filter receiver, we proceed with an illustration. We consider a Q-user system with Gold signatures of length $L = 31$. We fix the packet size at $J = 256$ bits and use $J_p = 5$ of them as pilot midamble bits. Each user signal experiences $N = 3$ independent Rayleigh fading paths with equal average received energy per path and independent angles of arrival uniformly distributed in $\left(-\dfrac{\pi}{2}, \dfrac{\pi}{2}\right)$. We consider averages over 20,000 independently drawn multipath Rayleigh fading ST channels. The receiver antenna array consists of $M = 4$ elements. With these numbers, the multipath extended ST product (or, equivalently, the length of the adaptive filter) is $M(L + N - 1) = 132$. The total received predetection SNRs of each user, namely, the sum of the received SNRs over all paths defined as $2E_q \displaystyle\sum_{n=0}^{N-1} E\{|c_{q,n}|^2\}/N_0$, $q = 0, 1, \ldots Q-1$, is set to 11 dB (we recall that $\dfrac{N_0}{2}$ is the AWGN power spectral density assumed to be identical for every spatial channel/antenna element).

In Fig. 17a, we plot the PER as a function of the number of active users Q using (41) for various receivers: (1) ST RAKE, (2) SMI, (3) auxiliary vector, (4) and the orthogonal multistage decomposition filter (also known as "nested Wiener filter") with the preferred number of stages $l = 7$. We also add to this study the multistage filter with $l = 1$ stages, which we found empirically to be the best number of stages for this specific problem. No FEC is assumed ($h = 0$). In a rather more interesting study, Fig. 17b shows the PER under $h = 4$ FEC.

5.2. Capacity

System BER/PER performance improvements due to the use of the AV receiver allow us to accommodate more users for a set quality-of-service (QoS) PER constraint (or reduce the transmitting power of the handset or increase the range/coverage of the base-station transceiver for a preset maximum number of active users). The QoS constraint is based strictly on the specific user application requirements and determines the *user capacity* of the system. Let us express the PER as a function of both the FEC capabilities h and the number of active users Q, $\text{PER}(h, Q)$. Then, we define the user capacity $C(h)$ as the maximum number of users under which the QoS constraint is not violated:

$$C(h) \triangleq \max\{Q: \text{PER}(h, Q) \leq \lambda_{\text{QoS}}\} \tag{43}$$

where λ_{QoS} is the QoS constraint threshold.

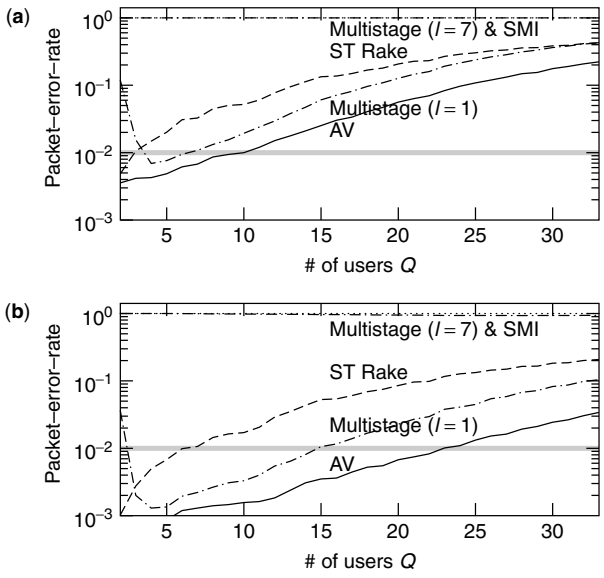

Figure 17. PER versus number of users Q for a system with (**a**) no FEC and (**b**) 4-bit FEC.

We return to Fig. 17 to examine the user capacity of the system for the adaptive receivers under consideration. We set the QoS constraint threshold to $\lambda_{\text{QoS}} = 10^{-2}$. From Fig. 17a we conclude that in the absence of FEC the user capacity of the AV system is 10 and the capacity of the RAKE system is 2. Significant capacity improvement is achieved with 4-bit FEC (Fig. 17b). The AV system supports 23 users, while the RAKE scheme supports only 6 users. Neither the $l = 7$ multistage nor the SMI receiver can meet the QoS constraint for any number of users $Q \geq 1$, with or without FEC. The best multistage ($l = 1$) receiver can support 4–6 users when no FEC is considered and 3–14 users with 4-bit FEC. However, it cannot meet the QoS requirement when $Q \leq 2$. We conclude that we have two viable solutions: the AV and plain ST RAKE receiver systems. The AV system allows up to $\frac{23}{31} \simeq 74\%$ loading for this Gold-coded system with processing gain $L = 31$ and 4-bit FEC (with $M = 4$ antenna elements and multipath fading reception with 11 dB total predetection SNR per user).

5.3. Throughput

If a packet is received with only correctable errors, a positive acknowledgment (ACK) is sent back to the user over a different downlink channel (FDD). Once an uncorrectable error is detected in the packet, a negative acknowledgment (NAK) is sent back to the mobile which then retransmits after waiting for a random number of time slots. If packet arrival is modeled as Poisson-distributed, then the probability of the arrival of Q new messages during a time-slot interval T_s is given by

$$A(Q) = \frac{{G_N}^Q e^{-G_N}}{Q!}, \qquad Q \geq 1 \tag{44}$$

where $G_N \triangleq (\lambda T_s / L)$ is the normalized offered traffic load (we recall that L is the system processing gain) and λ is the packet arrival rate. *Packet throughput* is defined as a measure of the ratio of the average number of successful transmissions to the number of transmission attempts made in a particular time slot. Let $\text{PSR}(h, Q)$ be the packet success rate (that is the probability that a packet is received successfully within a single time slot) with h-bit FEC in the presence of Q users. Then, $\text{PSR}(h, Q) = 1 - \text{PER}(h, Q)$ and the *normalized* packet throughput of the system S_N under slotted ALOHA accessing can be expressed as

$$\begin{aligned} S_N(h) &= \frac{1}{L} \sum_{Q=1}^{C(h)} Q A(Q) \text{PSR}(h, Q) \\ &= \frac{1}{L} \sum_{Q=1}^{C(h)} Q A(Q)(1 - \text{PER}(h, Q)) \end{aligned} \tag{45}$$

In Fig. 18a we plot the normalized packet throughput S_N versus the offered traffic G_N without FEC ($h = 0$). As a reference, we add the familiar packet throughput

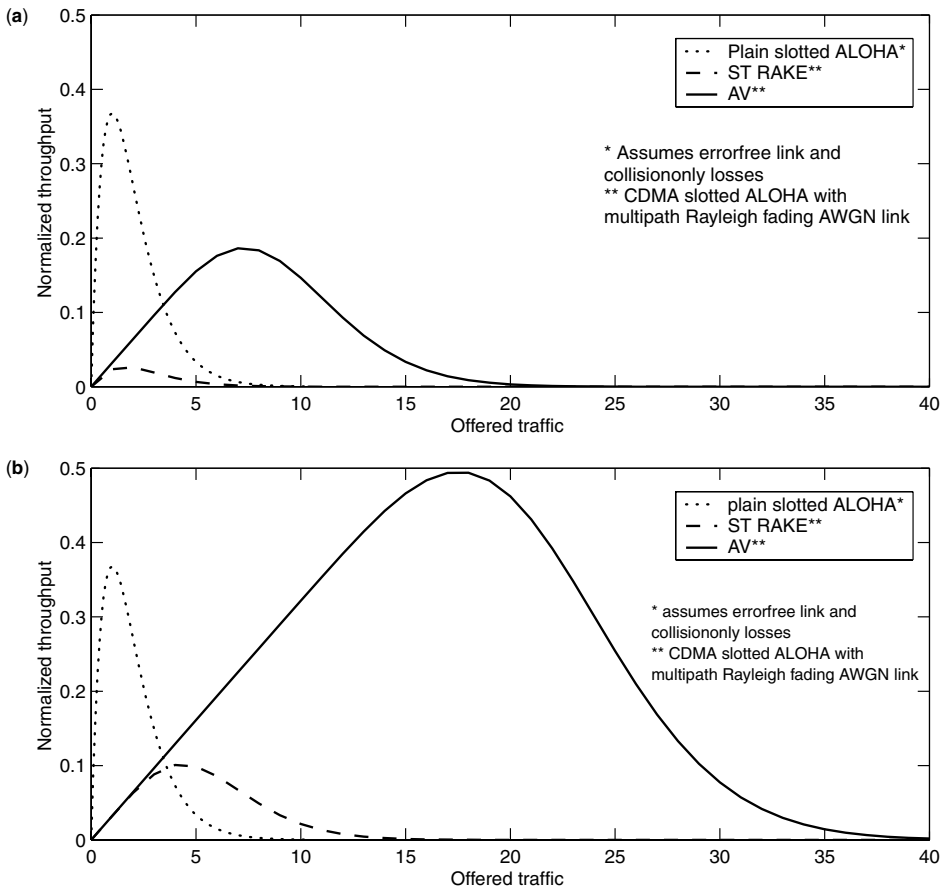

Figure 18. Normalized throughput versus offered traffic for a system with (**a**) no FEC and (**b**) 4-bit FEC.

curve for a plain slotted ALOHA system that assumes an *ideal error-free* link and *collision-only* packet losses. As one might expect, the CDMA slotted ALOHA (RAKE or AV) system with a multipath fading AWGN link and no FEC exhibits a lower maximum achievable throughput value than the plain ALOHA system with an error-free link. However, enhancing the system with FEC (Fig. 18b) gives rise to a significant improvement of the AV system whose throughput performance at higher traffic loads now overshoots the ideal-link plain slotted ALOHA which allows only one user per slot for successful transmission. We observe that with the adaptive AV filter receiver we can achieve up to 0.4938 throughput when we have FEC capability of $h = 4$ bits.

6. CONCLUDING REMARKS

Wireless cellular and personal communication service (PCS) networks have experienced significant growth driven by a strong market interest for highly mobile, widely accessible, two-way voice and data communications. Current research efforts are focusing on system improvements to meet future demand and quality of service requirements. User capacity increase may be sought in the form of a synergy of effective multiple accessing schemes and advanced receiver technology (e.g., code-division multiple access with adaptive antenna arrays). Manageable complexity (hardware and software) at the physical layer can be achieved by means of linear equalizers as opposed to more complex structures. Improved receiver output SINR and BER performance may be sought in the form of intelligent modulation techniques as well as intelligent signal processing at the receiver end of the communications link. However, realistically, receiver output SINR and BER improvements in rapidly changing channel environments can be achieved only by means of adaptive short-data-record-optimized receiver designs (as opposed to designs based on ideal asymptotic optimization solutions).

This article focused on linear MMSE/MVDR adaptive filtering with applications to adaptive receiver designs for mobile communications. We presented three alternative methods that approximate the optimum solution under perfectly known input statistics (input autocorrelation matrix and input/desired-output cross-correlation vector): (1) The generalized sidelobe canceler, (2) the auxiliary vector filters, and (3) the multistage filters. When the input statistics are unknown and estimated, these three approximate solutions provide estimates of the optimum solution with varying performance levels (output SINR and BER). When estimation is based on a short data record, that is, when system adaptation and redesign has to be performed with limited data support (which is the case for most systems of practical interest), then the performance differences become even more pronounced. In mobile packet data communications, for example, the size of the data record that is available for receiver adaptation and redesign is limited by the coherence time of the communication link and may be of the order of 300 data symbols or less in practical situations. In this context, for a given system transmission bit rate, the packet size may be designed to be sufficiently small to conform with the coherence time of the link. Then, packet-rate adaptive receiver designs may be pursued.

A viable solution for adaptive MMSE/MVDR system designs under limited data support is provided by the auxiliary vector (AV) algorithm. AV estimators exhibit varying bias/covariance characteristics — the bias of the generated estimator sequence decreases rapidly to zero while the estimator covariance trace rises slowly from zero (for the initial, fixed-valued, matched-filter estimator) to the asymptotic covariance trace of the SMI filter. Sequences of practical estimators that offer such control over favorable bias/covariance balance points are always a prime objective in the estimation theory literature. Indeed, under quasistatic fading over the duration of a packet and packet-rate adaptation, members of the generated sequence of AV estimators outperform in MS estimation error LMS/RLS-type, SMI and diagonally loaded SMI, and orthogonal multistage decomposition filter estimators. In addition, the troublesome, data-dependent tuning of the real-valued LMS learning gain parameter, the RLS initialization parameter or the SMI diagonal loading parameter, is replaced by an integer choice among the first several members of the estimator sequence. In that respect, we presented two data-driven criteria for the selection of the best AV filter estimator in the sequence.

As a representative application throughout this article we considered a wireless multiuser multipath fading AWGN link with direct-sequence spread-spectrum signaling and slotted ALOHA accessing. We developed a complete adaptive antenna-array CDMA linear filter receiver design that adapts itself and detects the transmitted information bits on an individual packet-by-packet basis. The receiver incorporated seamlessly packet-rate blind subspace-based spacetime channel estimation and supervised recovery of the spacetime channel phase through the use of a few packet midamble pilot bits. Illustrative examples showed that very limited midamble pilot signaling (on the order of $\frac{5}{256} \simeq 2\%$) can be sufficient for phase recovery and effective adaptive receiver design. Therefore, differential modulation to overcome the phase ambiguity problem is not absolutely necessary.

Bit error rate, packet error rate, and user capacity studies and comparisons were also included. Through the development of the probability mass distribution of the bit errors in a packet, we can translate these findings to packet throughput results. Interestingly, the adaptive AV receiver designed for a CDMA system in multipath Rayleigh fading and AWGN that assumed a modest 11 dB total received predetection SNR per user, four antenna elements, and 4-bit FEC, offers a $\frac{0.4938 - 0.3679}{0.3679} 100\% \simeq 34\%$ improvement in terms of normalized maximum packet throughput over plain (non-CDMA) slotted ALOHA with an *error-free* link. In this context, the packet-rate adaptive receiver design using the AV filtering principles coupled with FEC techniques seems to provide a viable solution in improving the performance of DS-CDMA mobile communication links.

BIOGRAPHY

Stella N. Batalama received the Diploma degree in computer engineering and science from the University of Patras, Greece in 1989 and the Ph.D. degree in electrical engineering from the University of Virginia, Charlottesville, in 1994.

From 1989 to 1990 she was with the Computer Technology Institute, Patras, Greece. From 1990 to 1994 she was a Research Assistant in the Communication Systems Laboratory, Department of Electrical Engineering, University of Virginia. In 1995 she joined the Department of Electrical Engineering, State University of New York at Buffalo, where she is presently an Associate Professor. During the summers of 1997–2002 she was Visiting Faculty in the U.S. Air Force Research Laboratory, Rome, New York. Her research interests include small sample support adaptive filtering and receiver design, adaptive multiuser detection, robust spread-spectrum communications, supervised and unsupervised optimization, and distributed detection.

Dr. Batalama is currently an associate editor for the *IEEE Transactions on Communications* and the *IEEE Communications Letters*.

Holmdel, New Jersey

1. INTRODUCTION

Packet-switched networks are becoming the dominant method of communication, replacing earlier schemes based on the telephone-type circuit-switched networks. With the increasing popularity of the World Wide Web, electronic mail (email), and multimedia applications, the traditional role of a data network as a means of transmitting data between computers is expanding. The same integrated network is now used by applications such as teleconferencing, distance education, real-time video and voice, email, Facsimile (fax), and distributed systems. At the same time, link speeds are experiencing dramatic increases, and the number of users is growing exponentially.

Telephone networks are based on the idea of *circuit switching* (Fig. 1). The dominant application supported by the circuit-switching architecture is voice, and it is assumed that the bandwidth required between two users is determined by the bandwidth needed for transmitting good-quality analog voice, or 8 kHz. The network establishes a dedicated bidirectional path between end nodes (i.e., telephones), and while the call is active, end users can continuously use this path to transmit information. The network is responsible for allocating enough resources throughout the communication path so that data can be transmitted as a continuous flow. Once the resources are allocated, they cannot be reused by another user, until the call is complete. This allocation is usually done by using either time-division multiplexing (TDM) or frequency-division multiplexing (FDM).

One of the most important properties of circuit-switched networks is that the sum of the capacities required by all the active communication paths cannot exceed the capacity of the link. The network must perform *admission control* and cannot accept new connections once the sum of the capacities needed by the active connections reaches a maximum threshold. When the network cannot admit any more connections, new requests by end users receive a "busy signal" similar to the one encountered in phone networks (or the *call is blocked*). Because of the requirement for admission control, establishing a connection and allocating resources (i.e., initiating a new phone call) is a relatively expensive operation that is tackled by a set of distributed computers.

The ideas of voice switching can be extended to the context of data communications by assuming that the two end nodes are computers exchanging data. The network offers a dedicated communication path between the two computers, and once a path is established, it may remain active for a long time period. However, nodes do not constantly transmit data during this period, but they may remain idle for some long intervals of time. Consider, for example, the case where one of the nodes is a desktop computer and the other is a file server. The computer will issue a request to the file server for some data, and once the data are received, the computer will begin to process them. When processing is complete, it will write the data back to the file server. While the computer is processing the data, no information is exchanged on the communication path.

Several data applications may exhibit a similar *bursty* behavior, where they use the bandwidth for some intervals of time and remain idle for others. File access and the World Wide Web (WWW) are prominent examples of such applications. Furthermore, the notion of burstiness can be extended to real-time applications such as voice or video. During a voice call, communicating parties do not always talk, but might have long periods of silence, during which a voice signal corresponding to silence does not need to be transmitted over the network.

If multiple users reserve bandwidth that is needed only during short intervals of time, valuable resources are wasted. In the example of Fig. 1, let us assume that only one session can be active at any time at the central link. Assume that user A places a phone call to user B, and they start talking. Although all the bandwidth of the critical link is reserved for this communication, user A only talks half of the time, and thus the link is 50% utilized. Now let us assume that user C tries to place a phone call to user D. The network cannot accept this call, since the bandwidth

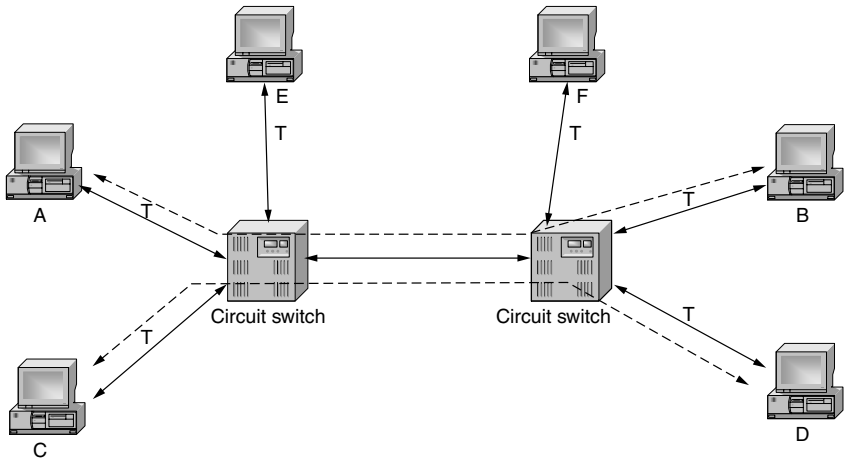

Figure 1. Circuit-switched network.

of the critical link is already allocated to the other phone call. Therefore, when an dedicated path is set up between bursty applications, the bandwidth might not be properly utilized.

Now assume that we could have a network where the path is set up when the link is actually needed and the resources are released when no information is transmitted. In this case, user A would use the critical link while talking to user B. The rest of the time the critical link would be free and user C could also transmit information. Both calls would take place at the same time, and resources would be shared in a more efficient manner.

Unfortunately, this is not easy to achieve in a circuit-switched network, since establishing a communication path requires the configuration of several nodes in the network. However, it is exactly this observation that led to the idea of packet-switched networks, also referred to as *store-and-forward networks*.

2. PACKET-SWITCHED NETWORKS

Communication between two users can be thought of as an exchange of *messages*. For example, when two people talk to each other, they form sentences, and each sentence can be considered as a message. When an end user browses the Web, he/she reads several pages of information, and each page can be considered as a message. A message can have variable sizes and the size of any given message is not bounded. For this reason, the concept of a *packet* is introduced. A packet can be part of a message or it can encapsulate several messages. However, depending on the technology, the packet size is either constant or bounded. For example, packets in a local network based on Ethernet technology are no more than 1500 bytes [1].

When two users communicate, they form a series of messages (and thus packets) and transmit them to one another. Referring to the network of Fig. 2, when user A talks, a packet is created and it is transmitted over the access link. The packet arrives at the intermediate node (referred to as *packet switch* or *router*), and assuming that the link is free, it is transmitted to user B. At a later time a packet from node C is transmitted to the intermediate node and through the critical link to user D. Information from the two users is *multiplexed* on the link on a packet-by-packet basis.

A problem arises when packets from both users arrive at a packet switch at the same time, but only one of the packets can be transmitted at the core link. The packet switch must store in some local memory the packet received from one of the two users (let us say user A) and transmit the packet from the other user. When the transmission is complete, it will retrieve the packet that originated from user A and transmit this packet over the link. It is exactly this concept, that is the foundation of *packet-switched* or *store-and-forward* networks.

Although packet networks may operate efficiently in most cases, *congestion* may degrade their performance during some time periods. Congestion occurs when during a period of time, the bandwidth needed for transmitting all arriving packets exceeds the capacity of the outgoing link. When this happens, the memory in the packet switches may overflow and messages might get lost. In order for packet switched networks to avoid or prevent congestion, they must support a range of mechanisms that control the end user behavior.

3. STATISTICAL MULTIPLEXING

Let us consider again the network of Fig. 2 and assume that the capacity of all the links between users and network nodes is equal to 2 packets per second, and thus, the time to transmit a packet is equal to half a second. Let us also assume that users transmit information half of the time. For example, user A transmits 10 packets and then waits for 5 s before transmitting more packets. If both users transmit their packets at exactly the same time, some of these packets must be buffered at the packet switch.

Let us now assume that the capacity of the core link is equal to the sum of the capacities of the input links, or 4 packets per second. Note, that this is also equal to the capacity needed from a circuit-switched network if both calls are active at the same time. In this scenario, both packets can be transmitted on the link without any delay (Fig. 3). A packet is transmitted over this link within 0.25 s and the link remains idle for half of the time. The maximum queueing delay of any packet is bounded by 0.25 s.

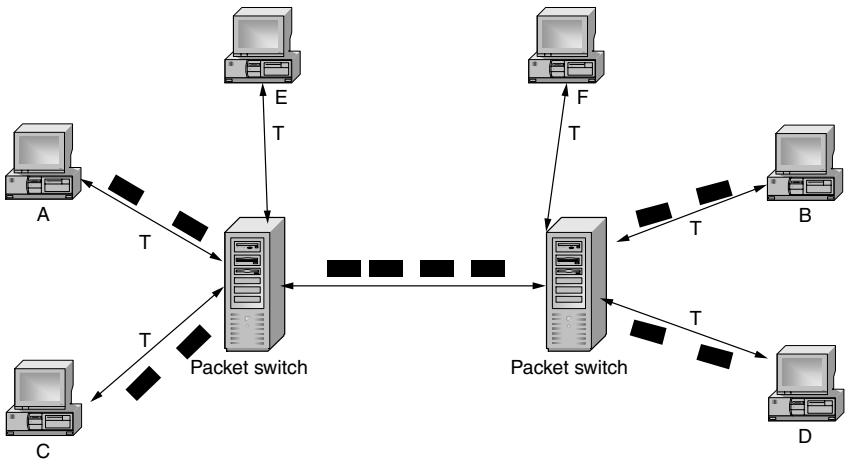

Figure 2. Packet-switched network; information transmitted in terms of packets.

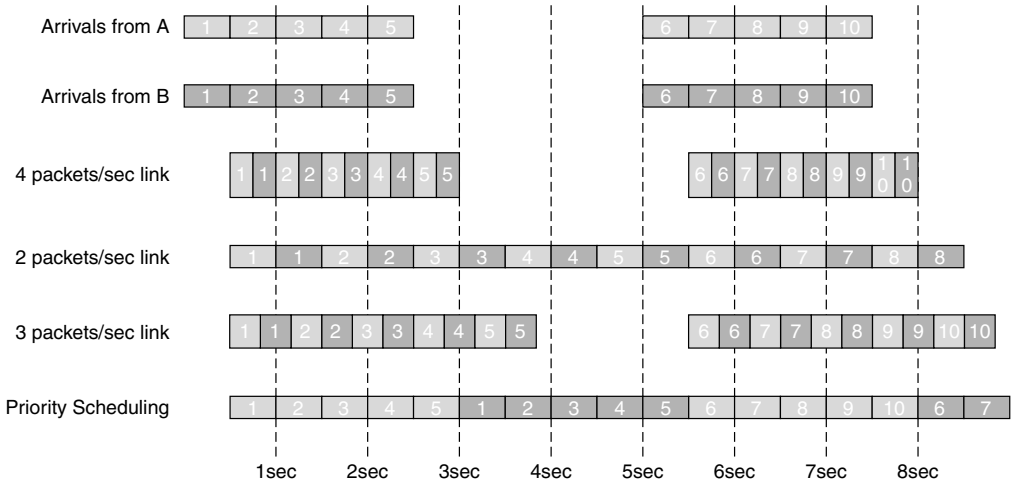

Figure 3. Sequence of packet arrivals and transmissions by a packet switch for different link capacities and scheduling disciplines.

If we set the capacity of the core link to 2 packets per second, some packets are delayed by as much as 2 s (or 4 packet transmission times) and the packet switch must maintain a buffer of at least 4 packets. However, the utilization of the core link is 100%. If we set the capacity of the core link equal to 3 packets per second, no packet will see a delay longer than 0.33 s and the utilization of the core link is 66%.

We can observe in the example above that by modifying the capacity of the core link, we can trade off link utilization for delays and buffers in the core switches. This is exactly the concept of statistical multiplexing. The ratio derived as the sum of the incoming link capacities divided by the outgoing link capacity is referred to the *statistical multiplexing gain* [2]. For example, when we set the core link capacity equal to the access link capacity, the statistical multiplexing gain is $\frac{4}{2}$ or 2.

The concept of statistical multiplexing can be viewed from a different perspective. If we assume that the buffers and link capacities at the core node are fixed (and thus, the maximum delay we can afford is fixed), we need to determine whether traffic from a particular source will not encounter excessive losses. This leads to the *effective bandwidth theory* [3]. If some statistical model for the arrival traffic is available, we can determine the loss probability of different sources.

3.1. Timescales

The concept of statistical multiplexing is not unique to data networks, but it was actually developed within the context of circuit switching. The main difference between the two approaches is in terms of times of interest or, *timescales*. In circuit switching it is assumed that end nodes use the network mostly for phone-calls. The main concept behind engineering voice networks is that not all users will initiate a call at the same time. Thus, a large number of users can share the same resources on a *call-by-call* basis. Statistical models are used to describe how often users actually initiate a call (*call arrival rate*) and how long is the call duration (*call holding time*). Based on these parameters, one can estimate the link capacities required to reduce the probability that the network will reject a call because of lack of resources. This was the original concept of statistical multiplexing of resources among a large number of users.

When we move to packet-switched networks, multiplexing is done on a *packet-by-packet* basis as opposed to a call-by-call basis. The lengths of times (timescales) of interest are much shorter. The reason for our interest in these shorter timescales is derived from the nature of data applications. Users would like to have a constant high-speed connection to the network and transmit very fast only for short intervals of time. Consider the operation of the Web (WWW). Users access Webpages, process the received data (i.e., read the context), and make decisions about accessing more data (i.e., follow links). The response time of the network is critical, and the duration of the connection to the Internet might be very long.

During the late 1990s, when many users were connecting to the Internet using modems and their telephone lines, the phone network was constantly overloaded. The traffic models used to engineer the network assumed that the call holding time is around 3 min. These models were failing to capture the actual behavior of end users however, since an increasing number of users kept their phone lines busy for hours when connected to the Internet. Although the network would reject calls, the bandwidth of the lines was not fully utilized.

3.2. Traffic Scheduling

Since packet-switched networks are used for a variety of end-user applications, it is reasonable to expect that different applications might have different requirements from the network. For example, email messages might be stored in the routers for several seconds without any problem. On the other hand, messages that carry voice must be delivered immediately since they are part of an interactive communication. Similarly, some applications might be able to afford information loss, whereas for other applications the network must support mechanisms that will guarantee that all information is delivered without packet losses.

Let us consider the network of Fig. 2, and let us assume that the core link capacity is 2 packets per second. In the previous case (Fig. 3), we assumed that packets are served in an first come–first served order (FCFS or FIFO) (where packets are transmitted in the same order as they were received). If traffic from user A is real-time traffic and requires minimum possible delays, whereas traffic from user C is email traffic, we can modify the way packets are selected for transmission. When packets from both users are buffered in the switch, it will always transmit packets from node A first (*static priority* order). The sequence of departures is also shown in Fig. 3. Real-time packets see no delay, whereas email packets see a maximum delay of 2 s. Thus, the method used for selecting packets for transmission (or *traffic scheduling discipline*) can determine the maximum and average queueing delays of different users. Notice however, that if the scheduler always transmits packets when packets are available in its queues, the average delay of *all* packets does not depend on the traffic scheduling discipline. Interested readers are referred to Zhang [4] for an overview of various traffic scheduling mechanisms.

4. CONNECTION-ORIENTED VERSUS CONNECTIONLESS NETWORKS

There is one main taxonomy of packet-switched networks, which is based on the method used to decide how packets are forwarded (or *routed*), and how resources are allocated [5].

In the previous examples we concentrated on a switch where traffic from all input links is multiplexed on a specific output link. This type of a switch is also known as a *multiplexer*. In the more general case, however, a packet switch might receive traffic from several interfaces and forward the packets to different interfaces. A large network will consist of multiple packet switches as shown in Fig. 4. When a packet arrives in such a switch a decision must be made as to which is the outgoing interface.

There are two main philosophies or methods used to resolve this question:

1. *Connection-Oriented* or *Virtual Circuit Switched Networks*. In these networks a virtual circuit is established between the source and destination nodes before any communication starts. The establishment of the virtual circuit does not necessarily lead to an explicit resource allocation as in the case of circuit-switched networks. However, some state information is associated with each switch that determines how all packets that belong to this connection must be forwarded. When a packet is created, a unique connection identifier is attached to it. All intermediate nodes will use this connection identifier to determine the output interface for this packet. The path that all packets of the connection follow is determined a priori during the connection setup phase. Technologies such as *asynchronous transfer mode* (ATM) [6] and *multiprotocol label switching* (MPLS) [7] are based on this principle.
2. *Connectionless Networks*. In these networks no explicit path is established a priori. Every end node in the network is associated with some address, and every switch or router has a "view" of the topology of the network. In other words, a *forwarding table* is stored in every switch with an entry corresponding to every other node. This table determines on a packet-by-packet basis, the interface that must be

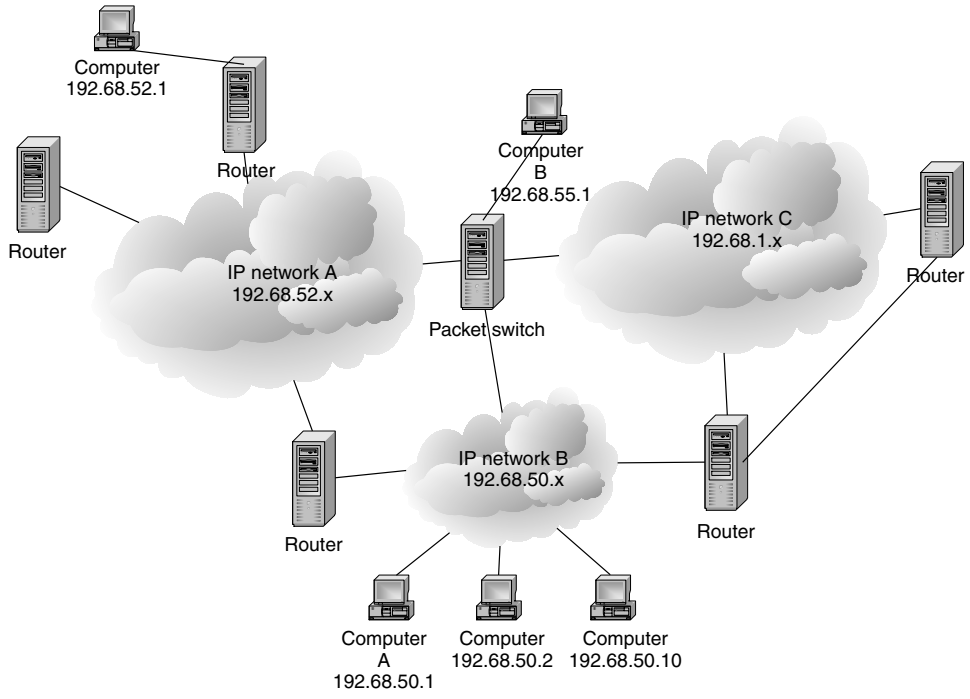

Figure 4. Global Internet architecture as an interconnection of multiple networks.

used in order to reach specific end nodes. Packets carry a *destination address* that identifies the end nodes, and switches use only this information to decide how to forward them. The network supports the mechanisms that allow individual switches to discover the topology of the network and create this forwarding table. Networks based on the *Internet Protocol* use this approach.

A connectionless network operates very much like regular mail and the post office. Senders address letters to specific recipients and the post office uses the address to forward the letters from one city to another and finally to the recipient. The originating post office cares only about the destination town or state. Local post offices make decisions about street addresses and apartment numbers. Similarly, in a packet network, routers in the middle of the network need to know only the router that is closest to the destination user. Only the final (or *edge*) router needs to know about specific users.

An important feature of connectionless networks is that packets between two end nodes can be routed through multiple paths of the network at the same time. For example, subsequent packets from workstation A to workstation B in Fig. 4 might take different paths. It is exactly this feature of connectionless networks, however, that makes them extremely reliable. If one of the nodes fails, packets can be still forwarded to their destination through a different path. This is known as the *shelf-healing* property of IP networks. On the other hand, in a connection-oriented network if a node or a link fails, a completely new path must be established from scratch. Since establishing a path might take a long period of time, traffic may be interrupted during this period and packets may get lost. For this reason connection oriented networks support techniques where multiple paths are reserved a priori.

Note that, depending on the path delays of a connectionless network, it is possible for packets that use different paths arrive to their destination out of order (i.e., if packet p1 is transmitted before packet p2 from node (workstation) A, it is not guaranteed to arrive at node B before packet p2). For this reason, the network must support mechanisms that will reorder packets at the end node.

In addition to these differences, which are related mainly to how the forwarding decisions are made, there is another fundamental distinction between the two philosophies. In connection-oriented networks, that are very similar to traditional phone networks, the end user must notify the network in advance of the bandwidth and the type of service he/she wants to use. The network uses this information to *admit* the user, avoid congestion, and offer different services. In connectionless networks the user transmits the packet to the network and hopes that enough capacity is available for the packet to be delivered to its destination. The network does not promise to any node that packets will be delivered after a predetermined delay, but it does its best (*best-effort networks*). The user is responsible for adapting his/her bandwidth requirements based on feedback received by the network, in order to prevent congestion.

5. PROTOCOLS AND LAYERING

During the design of networks (both packet-switched and circuit-switched), it became apparent that a large number of technologies and architectures must work together. For example, packet networks might work on top of Ethernet, and Ethernet is defined to work either over copper using electrical signals or over fiber using optical signals. The Ethernet network can also interchange information with a wireless network or a network using strictly optical signals [like a SONET (synchronous optical network)].

In order to allow a variety of transmission media to interwork with a variety of networking architectures and physical links, the notion of protocol layering was introduced [8]. First, a *protocol* can be considered as a set of rules, messages, and behaviors, that allows two end nodes to communicate to each other. Networks are built using a layered architecture of protocols.

To understand the concept of layering, let us consider the case of the voice network. End users know only about telephone numbers. When they want to communicate with other users, they dial a number on their phone, which can be considered as a *module*. The telephone will interact with the telephone network, that is another module, to establish a connection and the end users can begin talking. The user does not need to know how the telephone works, and the telephone does not to know how exactly the telephone network establishes a connection. However, the user expects a behavior from the phone, and the phone expects a behavior from the network.

In other words, each module in the network follows a set of rules to communicate with another module and expects a prespecified behavior. In the case of packet-networks, there are different modules in the network architecture that decide how packets are formed and how delivery is guaranteed. These modules expect a specific behavior from modules downstream, and finally from the links that are used to interconnect network nodes.

Figure 5 illustrates the most commonly accepted layer architecture as defined by the reference model of the Open Systems Interconnection (OSI) model developed by the International Standards Organization (ISO). Most networks follow this model. A description of the different layers follows.

5.1. Physical Layer

The physical layer defines the electrical, optical, electromagnetic or other properties of actual physical links. Examples are electrical signal voltages, signal frequencies, coding schemes, clock recovery and distribution schemes, and error correction schemes. Layers above the physical layer do not need to worry about such details, and they expect usually a low loss transmission of information among nodes.

5.2. Data-Link Layer

The data-link layer provides a variety of mechanisms that offer a logical communication path between two nodes. Mechanisms defined are packet formats, error checking, and retransmission mechanisms. A commonly used data-link layer is encountered in Ethernet networks. The basic

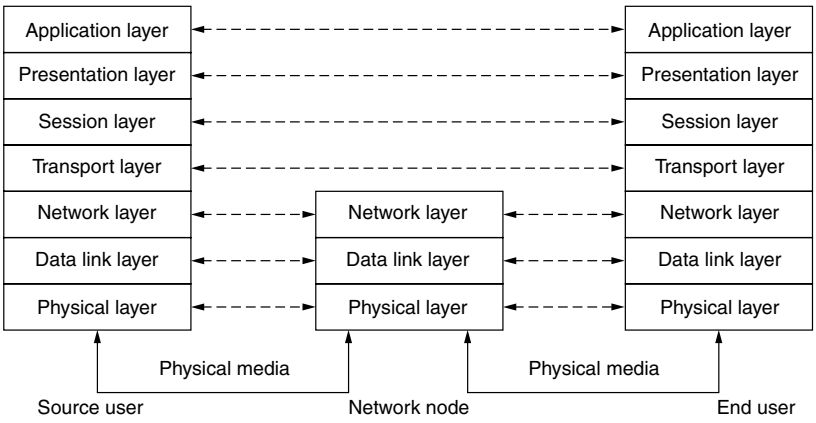

Figure 5. Network protocol layers.

principle of Ethernet (or any *multiple-access network* in general) is that several nodes are connected through the same physical media. Each node broadcasts information on the media, and only the destination node actually uses this information. The data-link layer will designate the source and destination nodes, and it will resolve contentions that appear when multiple nodes try to use the media at exactly the same time. The operation of this layer might involve retransmission of packets if communication fails. The data-link layer is limited to communication between two neighboring network nodes only.

5.3. Network Layer

The main function of the network layer is to determine where and how packets must be forwarded. When a packet arrives to this layer, the network layer uses local information to determine whether this packet is destined for some local process or it must be transmitted to another node. For packets arriving from higher layers, the network layer will format the packet in such a way that it will be recognized by other nodes in the network. The network layer does not care for the method used to transmit a packet to a neighboring node, and it assumes that the data-link and physical layers will provide this communication path. The *Internet Protocol* (IP) is an example of a network-layer protocol.

In some networks, the network layer might also assist with flow control. It might provide mechanisms that will avoid or reduce the probability of congestion. For example, if a downstream node is congested, information might be provided to the upstream nodes to reduce their transmission rate. The nodes might pick a different path to transmit traffic or they might propagate this information all the way back to the end user.

5.4. Transport Layer

The transport layer is responsible for establishing a logical connection between two end nodes. Connections might have properties such as bidirectional or unidirectional, or error-free. The transport layer will receive information from higher layers, packetize it, and pass it to the network layer. The transport layer might also verify that information is delivered correctly to the other application, by adding error checking mechanisms and defining the end-to-end protocol for retransmissions that will fix errors. In connectionless networks the transport layer will also guarantee in-order delivery of packets. The Transport Control Protocol (TCP) and User Datagram Protocol (UDP) encountered in the Internet are examples of transport-layer protocols.

5.5. Session Layer

The session layer is the user–network interface. It translates a user request to a request from the network. Users do not need to know how the network establishes connections and how it guarantees packet delivery. The session layer maps user requirements to network functions. If the application needs an error-free communication, the session layer will interface to a transport protocol like TCP. If the application needs an one-way transmission of information, where error-free delivery is not required, the session layer will interface to a transport protocol like UDP.

The session layer might also assist with resolving names to addresses that are recognized by the network. For example, end users do not really know about numeric addresses used by the transport and network layers (like IP addresses), but mostly remember mnemonics (like World Wide Web addresses).

5.6. Presentation Layer

The presentation layer might apply specific transformations on the data when they are delivered across the network. For example, data might be encrypted to prevent any other users from receiving the information. Sometimes data might be compressed in order to provide a speedier delivery. The presentation layer will also determine issues like ordering of bytes in big-endian or little-endian formats.

5.7. Application Layer

The application layer consists of end-to-end applications that use the network as a means of providing a service. An example of an application layer protocol is HTTP, which is the protocol used between a Web browser and a Web server.

5.8. Assigning Tasks to Layers

Although in the previous sections we gave some definitions of layers, depending on the network technology some of the functions can be moved to different layers. Flow control

is a clear example of such a function. In the case of ATM networks, flow control or congestion control is a part of the network layer definition, and *all* nodes in the network are responsible for assisting in this task. On the other hand, in IP networks, congestion control is a transport-layer function, and intermediate nodes do not interfere. The basic concept of TCP is that end nodes will detect packet losses, and will use these losses as an indication of congestion (i.e., several packets were queued on the same node and some packets had to be dropped). When congestion is detected the rate of data transmission of the end nodes is decreased. One can easily notice that if the data-link and physical layers do not guarantee error-free transmission, when a packet is lost because of link quality, it will be misinterpreted by TCP as an indication of congestion. This can lead to performance problems that have been the focus of several studies [9].

6. INTERNET AND TCP/IP

In this section we briefly discuss the principles of the most popular packet-switched network, the Internet. The basic architecture follows the principles of connectionless networks as described earlier [10] (Fig. 4). Data are forwarded in terms of packets of variable size, and the maximum packet size is 64K bytes (64 kilobytes). A header is associated with every packet that includes among other fields the addresses for the source and destination nodes of the packet. Routers use this header to determine how packets must be forwarded.

One can imagine the Internet as being composed of a large number of independently controlled networks without centralized control. Each network consists of three basic components:

1. A global assignment of addresses to nodes
2. Routers that forward packets to different interfaces and run the protocols that allow them to decide how to forward packets (*routing protocols*)
3. End nodes that use the TCP/IP protocol stack

6.1. Addressing

The Internet architecture provides a global means for assigning addresses to end nodes or routers, and once an address is assigned to a node, it is unique across the Internet. Whenever another user wants to communicate with this node, it must forward packets toward this address. IP version 4[1] addresses are 32 bits or 4 bytes. A decimal notation of four numbers separated by a dot is used to represent these addresses. For example 192.68.52.1 is an IP address that maps to the 32-bit number *C*0443401 (Fig. 6).

In order to minimize administrative overheads a hierarchical method of address assignment, was developed. Several end nodes that can be accessed through similar paths are assigned addresses within a specific range. Take for example, the networks in Fig. 4. Networks A and B

[1] We will refer to IP version 4 address within this text. There are newer versions of the IP protocol (IPv6) that use a slightly different address space.

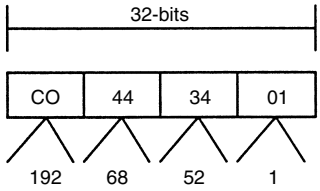

Figure 6. Representation of IP addresses.

are two global networks that can span the same country or continent. There are only two routers connecting networks A and B, and the IP addresses assigned to nodes on network A can be all aggregated together in a single number 192.68.52.x. This means that every node in network A has an address between 192.68.52.0 and 192.68.52.255. Similarly, IP addresses within network B are aggregated as 192.68.50.x. When any node in network B wants to communicate with a node in network A, the packets must go through one of the paths that interconnect networks A and B.

Note, that even though two nodes might be located in the same area they might connect to the Internet using a different network. Their IP address is determined by the network they connect to and not by their physical location. This is contrary to the method used in the telephone network, where address assignment is based on geographic boundaries (i.e., all telephone numbers within the same area have the same area code).

The IP addresses in these examples can be thought of as consisting of two components: (1) the *network number*, which is the 24 most significant bits, and identifies the network where a host resides; and (2) the *host or interface address*, which is the 8 less significant bits, which identify individual hosts within the network. The maximum number of hosts in a given network depends on the number of bits that are used to identify the network.

Originally, the IP address space was partitioned into four *static* classes of addresses (classes A–D) with different number of bits assigned to the network number. For example, a class A address uses 8 bits for the network number and 24 bits for hosts. Only a small number of networks (127) can have a class A address, and they were assigned to large organizations. The problem with this approach is that if an organization does not need all these addresses, a significant portion of the address space is wasted. For example, if a network is assigned a class A address, it can have up to 2^{24} interface addresses. If the network needs only a quarter of them, the rest will remain unused.

As the popularity of the Internet increased, it became apparent that the address space must be utilized properly, and that wasting address space resources can limit the scalability of the network. The new version of IP (version 6) is designed to address this problem, and it introduces 128-bit addresses. In the meantime, however, the concept of classless interdomain routing (CIDR) was introduced to allow a more efficient use of the address space [11]. Each network is now identified by two numbers: (1) an IP address and (2) a mask that determines the number of most significant bits of the address that identify the network. For example, a network might be identified with an address of 192.128.0.0/9, which means that the 9 most

significant bits correspond to the network number, and the 23 less significant bits identify hosts within this network. This method allows a variable number of hosts in any given network, and the address space is utilized more efficiently.

6.2. Routing

The second component is routing. This is a set of protocols run by the IP routers that allow them to construct a local view of the topology of the network. The routers must know which interface to use in order to reach a specific IP address in the network. However, routers do not need to maintain a distinct entry for each individual address. Because of the aggregation method described earlier, routers in network A can maintain a single entry for all nodes in network B, since they are all reachable through the same path [12]. This is actually the main benefit of the hierarchical address assignment. Routers at the core of the network must only maintain state information that determines how different networks are reached. Routers at the edge of the network must maintain state information on individual hosts.

In order for the routers to discover the network topology, they exchange information. Such information might include the list of neighboring routers or information learned from other routers in the network. For example, router R1 knows that one of its interfaces is connected to network A. It will thus notify the routers or end nodes in network B that if they want to reach network A, they must forward packets toward R1.

Once the network topology is discovered, most routing protocols assume that the network is represented by a graph, and routing is the task of finding the shortest path between any two nodes in this graph. Other criteria, such as finding the least-congested path, might be used in order to optimize network performance. Routing protocols are distributed among the various routers, and there is no centralized place that decides how packets must be forwarded. Each router makes independent decisions, and it is crucial that the routing algorithms lead to a stable network configuration and do not create loops. Assume two routers A and B and a destination C. Let us assume that router A views that in order for a packet to reach destination C, it must send the packet to node B. If router B has also an entry that says that if a packet is destined to destination C, it must be forwarded to node A, then any packet destined to node C will be constantly transmitted between nodes A and B.

As we mentioned earlier, the Internet can be considered as an interconnection of various networks. Each of these individually managed networks is called an *autonomous system* (AS). Routers that belong to the same AS use an *interior gateway protocol* (IGP) to exchange information, and forwarding is mostly based on shortest-path criteria. Routing between ASes uses an *exterior gateway protocol* (EGP), that is based mainly on policies determined by contracts between network operators.

6.3. TCP/IP Stack

The third component is that all end nodes must follow the TCP/IP protocol stack. This means that they must encapsulate packets using the IP headers and use the correct destination IP addresses. Most IP traffic uses one of two basic transport protocols. When a reliable end-to-end communication is required without any packet losses, the TCP protocol is used. TCP allows end users to open a logical "connection" to another end user. Once the connection is established, TCP enables the transmission of data between the end users and guarantees reliable delivery. For example, if a packet is lost in the network, TCP will take care of retransmissions.

TCP is also an important part of the congestion control mechanisms of IP networks. The basic principle is that end users must adapt their transmission rate to the bandwidth that is available from the network. Users start with a low transmission rate and increase the rate periodically. When losses are detected, they are interpreted as an indication of congestion and the rate is dropped. This process is constantly repeated, and allows TCP to calibrate the transmission rate to the available resources. One can consider this as a *closed-loop* flow control protocol, since information from the network is used to adjust the rate of the transmitter [13].

When nonreliable communication is sufficient, the User Datagram Protocol (UDP) can be used. UDP establishes an simplex connection between two users and allows delivery of data without flow control or error recovery. UDP is especially useful in real-time streaming applications, like video or voice, where small data losses are acceptable.

6.4. Domain Name Servers

There is an additional layer, handled by the *domain name servers*, that maps mnemonic addresses to IP addresses and can be regarded as a directory service. Most users are aware of World Wide Web (WWW) addresses such as *www.wiley.com.* These addresses must be translated to actual IP addresses before a communication can start. End nodes first send a request to a DNS asking for the IP address of the mnemonic address of the destination. The DNS will translate the WWW address to an IP address. When the address is resolved, the end node can use the IP protocol to communicate with the desirable destination. Note that the DNS address itself is statically configured by the end user.

7. HISTORY OF PACKET-SWITCHED NETWORKS

The first theoretical work in packet switching appeared in L. Kleinrock's Ph.D. thesis in 1962, and it is still considered as forming the theoretical foundation [14]. Around the same time Baran invented the fundamental concepts behind store-and-forward switching [15]. Among others, Baran's work developed the concepts of packets or messages, adaptive routing based on failures, and decoupling between logical and physical addresses. Similar concepts were developed independently in the Cyclades packet-switched network in France [16].

The telecommunications industry did not pay much attention to these concepts until the U.S. Department of Defense Advanced Research Project Agency (DARPA) sponsored a research program for the development of ARPAnet. The ARPAnet was mainly developed in order to provide a reliable and low cost communication network

among timesharing systems scattered throughout the country. This can be considered as the first wide-area packet-switched network, that was demonstrated by 1969. By 1972 the ARPAnet had 4 hosts, expanding to 23 by 1973.

From that point on the expansion of the Internet has been exponential, and it entered our everyday lives with the development of the World Wide Web in the early 1990s. Currently millions of hosts are interconnected in the Internet through a maze of networks without any centralized control, and data traffic is increasing exponentially.

BIOGRAPHY

Dimitrios Stiliadis received his Ph.D and M.S. degrees in computer engineering from the University of California at Santa Cruz, in 1996 and 1994, respectively. Prior to that he received the Diploma in computer engineering from the University of Patras, Greece, in 1992. Since 1996, he has been with the High-Speed Networks Research Department of Bell Laboratories, where he is currently a distinguished member of technical staff. During these years he has been leading the architecture of several generations of packet switching equipment. His recent research has been in issues related to traffic management, switch scheduling, and applications of optical technologies to packet networks. He is a corecipient of the 1998 IEEE Fred W. Ellersik Award.

PAGING AND REGISTRATION IN MOBILE NETWORKS

CHRISTOPHER ROSE
Rutgers WINLAB
Piscataway, New Jersey

1. INTRODUCTION

A communications network routes messages from senders to recipients. In *fixed* networks where units are not mobile, the terminal (such as a telephone handset, computer, video display, or a host of other possible devices) resides at a fixed physical location which rarely changes. In contrast, a *mobile communication network* routes messages between senders and receivers who may often change location. The seemingly simple addition of terminal mobility to the networking problem complicates it in both obvious and subtle ways.

We will start by exploring conceptually simple methods for accommodating mobility and then examine the deeper implications of these methods on network organization and design. However, rather than plunging directly into what could easily become an opaque technicalese treatise, it is easiest to use an analogy that we will expand as needed. So, consider a postal address, 536 West 145th Street, Apartment 21 in New York City — the author's childhood residence. Any messages for the author would be delivered to this address via a mail carrier or through a specific set of copper wires running from a central office to this address. The "address" of the telephone was (212) AU1-4676, which could be reached from anywhere in the "developed" world at that time. This basic fixed scenario was the dominant communications network structure — static identifiers corresponding to fixed physical locations for the terminal equipment, and tacitly, for the reams of equipment necessary to carry traffic between arbitrary addresses. For the postal service this would include postoffices and the city streets along which mail carriers traveled. For telephone service this would mean central switching offices and the cables that threaded their way under and around the city between central offices and homes.

Of course, people move about in their day to day lives, and the fixed scenario could only awkwardly accommodate mobility. A mail carrier arriving before August 6, 1970 would have been able to properly deliver mail to the author. After that date, without a *forwarding address*, the mail would remain undelivered or marked "Return to sender." Likewise, a telephone call that arrived while the

author was in school across the street at PS 186 would be missed, or the caller would have to be given a new number corresponding to the new physical location. At the time there was no (inexpensive) method to guarantee delivery of messages to a recipient in motion.

This simple analogy illustrates that having fixed terminals associated with fixed physical locations makes routing information through any sort of network a relatively straightforward task in principle. Certainly there are details such as communications link congestion/availability that the service provider must handle, but the basic notion of network topology stasis remains intact.

Now, suppose that units require messages to be delivered wherever they happen to be. The network needs to know exactly where the unit is — or in the parlance of the mobility management field — the unit's *point of network attachment*. There are two ways the network can ascertain the unit's location: (1) the network can search for the unit in likely places (paging) or (2) the unit can tell the network where he/she is (registration) — and we have thus provided an en passant definition of paging and registration as basic building blocks (or *primitives*) for handling mobility in communications networks.

The basic ideas of paging and registration lead to a variety of techniques that we will explore more carefully in Section 2. However, before proceeding we pause here to note that "units" need not be rigidly defined. In the Internet age where computer programs such as *Web crawlers* might autonomously search the Web for information, a *unit* could in principle be a *program*. Conceptually, paging and registration for such programs is not a big leap; however, from the network management standpoint one must consider that such programs could change their physical location *much* more rapidly than any "physically realized" unit such as a person or a piece of hardware and this could lead to unique stresses on the network.

Finally, suppose that in addition to keeping track of mobile units, the actual network topology were labile. By analogy, imagine the perplexity of a mail carrier who found not only that had the author moved from 536 West 145th Street but also that the connecting avenues and streets had changed relative locations as well! The analog to this somewhat nightmarish scenario might be the rule rather than the exception in some types of ad hoc network architectures where the communication infrastructure is *composed* of mobile nodes communicating wirelessly as opposed to the usual sets of fixed location equipment such as cables, microwave towers, and switching centers.

Interestingly (and perhaps obviously), all these scenarios can be handled by suitably abstracted versions of the basic paging and registration paradigm. We therefore carefully describe paging and registration along with their associated costs for conventional mobile networks in following sections and later apply the concepts to the more exotic scenarios which will almost certainly arise in the future.

2. PAGING AND REGISTRATION

The key idea behind paging and registration is that routing messages to a unit is a cooperative affair where the network makes an effort to find the unit through paging and the unit, who needs to be found, registers its location with the system. The optimization problem arises since both paging and registration require some sort of communication, and communication bandwidth is a valuable commodity — thus, there are *costs* associated with paging and registration.

Specifically, it is obvious that a unit could always be immediately located by the system if that unit always registered each change in location, and in response the system updated its global routing databases. However, the network cost of such updates, especially for units whose point of network attachment changed often could be prohibitive [1–6]. Thus, mobile networks trade unit localization delay against the cost of perfect location information available through constant registration. In other words, some uncertainty in the actual unit point of attachment is tolerated and is resolved by seeking the unit through paging — which requires time and some cost in communications bandwidth. In addition, the unit concurrently offers periodic updates on location within cost constraints, or alternatively, the system actively seeks a unit when paging cost exceeds some threshold. Finally, if a unit never receives calls, then there is little need to ever register location since the system will never need to find that unit. All these issues combined form the paging/registration problem.

2.1. Paging in a Typical Cellular System

Consider a cellular telephone system where units can reside in one of N possible locations as in Fig. 1. These locations might be associated with cellular base stations or be *location areas* composed of many cells associated with a mobile telephone switching office (MTSO). If the unit location is uncertain, then the system must find the unit when an incoming call arrives. To do so, in a wireless system, paging messages are sent to possible unit locations. The paging message uniquely specifies the desired mobile terminal and thus requires passage of information, which further implies use of bandwidth — the most precious resource in a wireless system. The system could page a unit in all possible locations simultaneously and could in principle find a unit almost immediately.

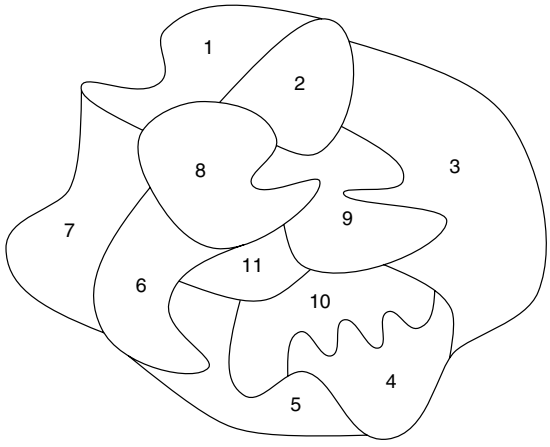

Figure 1. Possible locations associated with a mobile unit.

However, paging a single unit in all locations precludes paging more than one unit simultaneously, and in systems where signaling channels and traffic channels are shared, consumes resources everywhere, which can actually increase the average delay in finding a unit [7,8] and/or degrade quality of service (QoS).

Thus, if some delay can be tolerated in finding a unit, sequential paging of a unit starting with the most likely location will minimize the expected amount of paging bandwidth used. If some delay bound must be met, then groups of locations can be paged simultaneously and in this way various points on a paging delay/cost performance curve can be achieved. Regardless, in all such paging problems, the key result is that locations should be searched in order of the *a priori* probability of unit residence [9].

For such *unit-centric* approaches to mobility management, the unit location probability distribution plays a key role in minimizing the system cost of paging; the problem of assembling and maintaining such information has been carefully examined [10,11]. Specifically, it was shown how the Lempel–Ziv empirical sequence coding method could be applied to constructing and maintaining compact mobility profiles for different users.[1] In addition, the tradeoff between paging group size and paging delay for multiple unit systems has been considered [7,8].

Of course, some practical issues must be mentioned.[2] There is the possibility that a unit, owing to the propagation environment, will not receive a page. Thus, paging messages may be repeated up to some system-specified number of retries before a failure is declared at a given location. This somewhat complicates the analysis, but the basic premise (search most likely first) still holds. It should also be noted that most current systems do not bother to maintain a dynamic register of likely unit locations, even though it could significantly reduce paging channel use [12] since the complexity of implementation is thought to exceed the benefit.

2.2. Registration

Classically, registration strategies have used the previously mentioned concept of a *location area* — groups of (usually) contiguous locations. These areas can be global in the sense that they are identical for all mobile units, or personal in that each unit has its own location area. The two concepts are illustrated in Figs. 2 and 3.

Under the classical scenario, a service area is partitioned into groups of locations. Incoming calls result in page requests at all locations in the appropriate location area. When a mobile unit crosses a group boundary, a registration is mandated. Location area boundaries are chosen based on incoming call rates, aggregate mobility patterns, and the relative cost of paging and registration.

[1] The papers by Bhattacharya and Das [10,11] received top prize at ACM MobiCom'99 and are required reading for anyone who studies mobility management

[2] Details about paging message structure and protocols for current systems can be found in (for example) the paper by Goodman et al. [7].

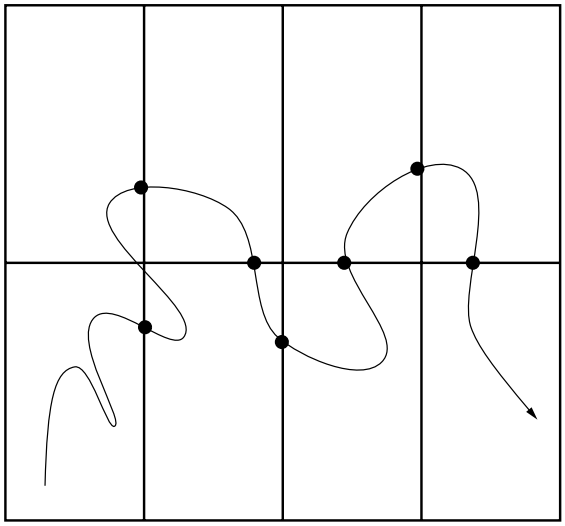

Figure 2. Illustration of classical registration strategy with geographically fixed location areas. Registration occurs at location area boundary crossings (denoted by solid dots). The arrival of an incoming call triggers polling requests over all locations contained in the current location area.

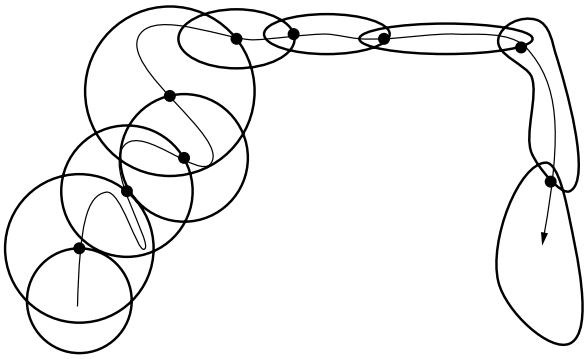

Figure 3. Illustration of personal location areas, recalculated after every contact with system. The location area shape may change with time depending on the mobility characteristics of the unit. For example, the mobile unit in this example might first be driving around a city and then enter a high-speed thoroughfare. The location areas change shape to accommodate the changed mobility. Registration points are denoted by solid dots.

Unfortunately the simple classical strategy suffers from spurious registrations since mobile units that dwell near boundaries can "pingpong" between location areas. Furthermore, since mobile units may have different mobility characteristics, designing location areas for the aggregate can be inefficient.

A key element of the registration problem is the rate at which calls arrive to the mobile unit. If calls never arrive, then the unit need never register since paging cost is always zero. Likewise, if calls arrive regularly then registration might not often be necessary because the network has reasonably accurate location information. Thus, the procedure used depends both upon the mobility process and the incoming call rate as well as the relative cost of registration.

Using these ideas, the concept of personal location areas was proposed [13,14] where each mobile unit contact with

the system results in the calculation of a new location area, centered around the current location. Since the boundaries are reset after each registration, this method does not suffer from spurious location updates, and since location areas can be designed for each unit, the problem of designing for the aggregate does not exist.

However, as with the classical scheme, all locations in a location area are paged in response to an incoming call even if the call arrives shortly after a previous call has terminated. Furthermore, since the boundaries of these location areas are fixed, high-velocity mobile units must register more frequently or require larger location areas, both of which tend to increase cost.

2.3. Paging/Registration Using Optimal Paging and the Mobility Index

Suppose a unit follows a brownian motion pattern[3] in which case the cost of paging is proportional to $(\mathcal{D}t)^{n/2}$, where n is the number of degrees of freedom in unit motion, τ is the time since the unit location was known exactly, and $\mathcal{D}$ is a constant [15]. It is useful to further define a *mobility index* as $\rho = \mathcal{D}/\lambda$, where λ is the incoming call rate. The inverse of ρ is known as the *call to mobility ratio* [16,17]. The paging cost can then be written as $(\rho t)^{n/2}$, where the new variable t, the time since last sighting, is measured in units of average call interarrival times $1/\lambda$. The utility of the mobility index lies in its explicit inclusion of the frequency with which a unit is contacted. For example, if the unit is often paged, then its whereabouts are better known to the system, thereby decreasing the unit mobility index.

These basic notions have been applied to registration strategies based on time and/or place [18]. Other work has also considered versions of this basic problem, for example, the paper by Bar-Noy et al. [19]. It is assumed that the mobile unit knows the paging method employed by the network and thereby knows the cost (or expected cost) to be incurred at the current point in (time, place). Assuming Poisson arrivals of paging requests makes for a relatively straightforward optimization.

When only time information is used by the mobile unit, a deadline registration policy is appropriate. Thus, the mobile unit should register at time τ^* after the time of last contact with the network, where τ^* depends on the mobility index and the relative costs of registration and paging. Intervening call initiations or received calls reset the timer. With both time and place information, however, optimality is an open question.

Application of the timer-only registration method leads to an improvement over simpler place-based methods [13], especially at higher mobile unit velocities since the optimal paging algorithm is affected only by location uncertainty and not directly by the unit velocity. Suboptimal registration methods based on time *and* place have been explored [20,21], and similar to an optimal method based on distance from last sighting derived for the random walk with drift velocity zero [22], threshold rules for registration were obtained. It was found that the (time, place)-based method performed only slightly better than the timer-alone method over a range of conditions. The primary improvement afforded by spatial information was a reduction in cost variance.

[3] Brownian motion is the simplest and most often used mobility model. In certain ways it constitutes a worst-case mobility scenario since for finite location variance (a surrogate for average energy expended in moving an object), the location uncertainty (entropy) is maximum.

3. PAGING, REGISTRATION, AND INFORMATION THEORY ABSTRACTIONS

3.1. Entropy and Paging Cost

Since paging amounts to issuing queries about unit location and these queries require signaling messages, two obvious questions arise:

How much information does the network need to resolve a mobile unit location at a given point in time?

What is the relationship of this information to the amount of signaling required?

The obvious simple answer to the first question is *the entropy of the location distribution*. Likewise, considering that locations vary with time, we see that the average information *rate* necessary to completely specify unit location for all time is the entropy rate of the motion process [23,24]. However, the structure of allowable queries about location profoundly affects the relationship between information content and the necessary signaling in the paging problem.

For example, consider the game of "Guess my number," where a number n is chosen between 1 and J according to some probability distribution p_j [25,26]. Using the standard information-theoretic formulation, the minimum average number of yes/no questions necessary to identify n is the entropy of the probability distribution. However, in a mobile communications system, each polling event at a given location requires signaling in the network, and possibly use of a radio channel as well in the case of a wireless system. Thus, from a signaling standpoint, the appropriate queries are of the form "Is your *number* (*location*) *k*?" This leads to problems with relying solely on entropy as a measure of location uncertainty. Specifically, one can easily describe distributions whose entropies exist and are finite, but for whom the paging cost is infinite [27].

3.2. Beyond Paging and Registration

We have so far considered only the effort associated with finding a given mobile unit through paging and registration; that is, the unit location was not known exactly. Here we take a slightly different view and assume that the location of every unit is known somewhere. Now we ask how much signaling effort is necessary to efficiently disseminate the location information over the network.

Consider then the *universal phone number* (UPN), where a single number is used to identify each mobile unit and route the call appropriately. At the heart of the UPN problem is a question similar to that which arose in the paging/registration context: *Who needs to know?* Thus, the frequency with which a given UPN routing entry is used is the primary index of the importance of maintaining its accuracy.

Let us assume that the answer to this question is given by the rate, r_{ij}, at which unit i calls unit j. This concept of calling rate, coupled to a view of mobility as a set of time-varying location distributions, allows a simple lower bound on the amount of information that must be disseminated over the network.

Specifically, let a random variable τ_{ij} describe a renewal process for the time between calls from unit i to unit j. We assume that τ_{ij} has a density function $f_{\tau_{ij}}(t)$ with mean $1/r_{ij}$. At the initiation of a call at time t, from the perspective of unit i, the location uncertainty of unit j is given by the location probability distribution $p_j(t, t_0, x_j(t_0))$, where $x(t_0)$ was the position of unit j at time t_0.[4] In information-theoretic terms, however, the entropy of this distribution represents the average amount of information required to exactly specify the location of unit j to unit i at time t.

Define $H_{ij}(t)$ with $t \geq t_0$ as the entropy in bits of the location distribution $p_j(t, t_0, x_j(t_0))$. The average number of bits needed by unit i to specify the location of unit j just before the next call is

$$\overline{H}_{ij} = \int_0^\infty f_{\tau_{ij}}(t') H_{ij}(t')\, dt' \tag{1}$$

and by renewal theory [28], the *absolute minimum* average number of bits per second needed by unit i to determine the location of unit j is simply $\overline{H}_{ij}/E[\tau_{ij}] = r_{ij}\overline{H}_{ij}$.

The minimum necessary aggregate network signaling load can then be determined by considering the average number of hops [29]; that is, location information from unit j must be routed to unit i and must traverse some number of nodes. As a simple example, assume M mobile units. With uniformly distributed mobile unit locations, we define γ as the mean number of hops from any node to the rest of the network. Therefore, the aggregate signaling rate associated with location information dissemination is

$$\mathcal{R} = \gamma \sum_{ij} r_{ij}\overline{H}_{ij} \tag{2}$$

The generality of this approach allows connection rates between *any* two entities to be defined; thus, not only "mobile units" but possibly routing tables as well — harkening back to the perplexed postman from the introduction who must travel streets that rearrange themselves from day to day. Possibly, this basic method can be extended to derive lower bounds for signaling costs associated with any mobility management scheme on any given network.

4. MOBILITY MANAGEMENT AND THE FUTURE

When considering mobility in present-day communications systems, what usually comes to mind is a person, conveyance, or mobile computer. However, in future networks, programs as well as physical objects might also be mobile. For example, suppose that you are an investment banker and seek financial market information distributed over the network. Specifically, you might wish to exploit small price differences over numerous "cybermarkets" — analogous to but more extensive than current arbitrage practices.

If the processing and communication capacity of the machines and network were infinite or there were no competing units, it would be a relatively simple task to spawn search processes on all machines in the network and have them report back information in some fashion. However, capacity constraints allow only a small number of programs to be launched into the network and run on other machines. For efficient search or to execute trades, the programs should be able to communicate and modify their behavior as information is gathered. For effective search, the programs should be able to relocate themselves to appropriate databases or markets. Such migrant programs charged with ferreting out information are generically called *mobile agents* [30–33].

The need for communication between agents implies a need for registration and paging since the agents are effectively mobile units to which calls may be routed. In motion processes that involve movement of mass, there are inherent constraints on motion between physical locations. Mobile agents, however, suffer few such constraints since their motion processes are influenced primarily by the location of contacts relevant to the search. Thus, one instant an agent could be active at a host in Los Angeles, and when done relocate to a suggested host in Madras.

For a simple random walk in n dimensions, paging cost is proportional to $(\rho t)^{n/2}$, where, once again, ρ is the mobility index and t is the time elapsed since last contact with the system (measured in units of intercall arrival). The intrinsic lack of constraints on both mobility index (how fast and far) and motion dimensionality (how many choices) for mobile agents suggests that groups of intercommunicating agents moving rapidly over a network of effective dimension $n \geq 3$ could severely stress signaling resources. Under this not-too-futuristic scenario, efficient mobility management could easily become the principal issue in network design.

5. CONCLUSIONS

The concept of mobility management based on time-varying mobile unit location probability distributions was introduced. Mobile units could be cellular telephone units, mobile computers or even mobile computer programs such as mobile agents. Regardless, the problem of finding mobile units boils down to the intuitively pleasing problem of searching for units in the most likely places as characterized by a unit location probability distribution.

Since location uncertainty is at the heart of the mobility management problem and information theory is the lingua franca of uncertainty, it is tempting to apply information theory to the paging problem, but sometimes unilluminating since even if the entropy of the location distribution is finite, it could still require infinite paging effort to find the unit on average. Thus, it is safest to rely directly on the ordered location probability function (ordered from most likely to least likely locations).

[4] Paging and registration are done by the *system* as opposed to the caller. Thus, the only a priori information available to the caller is the location distribution $p_j(t, t_0, x_j(t_0))$, which is independent of the registration/paging method used to track unit j.

We outlined various simple paging/registration procedures based on location probability distributions and compared them to more classical methods. A byproduct of this study was the definition of a *mobility index*, which is a useful reification of mobile unit location uncertainty and its growth as a function of time since the last contact. We then showed how paging/registration cost varies as a function of the mobility index.

We also showed how this cost varies with the dimensionality of the motion process which led to a consideration of non-classical mobility: groups of mobile programs ranging over a network in a coordinated way seeking out information. One could imagine agents that roam the network for information [33] or to buy and sell goods [31]. The results suggest that severe stress could be placed on a communication network by widespread use of such programs.

In the networks context, we then suggested ways in which time-varying location probability distributions for mobile units might be used to underbound the amount of signaling traffic necessary for distributing location information. In this case, an information theoretic approach *is* helpful.

BIOGRAPHY

Dr. Christopher Rose received the B.S. (1979), M.S. (1981), and Ph.D. (1985) degrees all from the Massachusetts Institute of Technology in Cambridge, Massachusetts, Dr. Rose joined AT&T Bell Laboratories in Holmdel, New Jersey, as a member of the Network Systems Research Department in 1985 and in 1990 moved to Rutgers University, where he is currently an Associate Professor of Electrical and Computer Engineering and Associate Director of the Wireless Networks Laboratory. He is Editor for the *Wireless Networks* (ACM), *Computer Networks* (Elsevier), and *Transaction on Vehicular Technology* (IEEE) journals and has served on many conference technical program committees. Dr. Rose was Technical Program Co-Chair for MobiCom'97 and Co-Chair of the WINLAB Focus'98 on the U-NII, the WINLAB Berkeley Focus'99 on Radio Networks for Everything and the Berkeley WINLAB Focus 2000 on Picoradio Networks. Dr. Rose, a past member of the ACM SIGMobile Executive Committee, is currently a member of the ACM MobiCom Steering Committee and has also served as General Chair of ACM SIGMobile MobiCom 2001 (Rome, July 2001). In December 1999 he served on an international panel to evaluate engineering teaching and research in Portugal.

His current technical interests include mobility management, short-range high-speed wireless (Infostations), and interference avoidance methods for unlicensed band networks.

PARABOLIC ANTENNAS

ALESSANDRO ORFEI
CNR, Istituto di
Radioastronomia
Bologna, Italy

1. INTRODUCTION

The aim of this article is to introduce the important tutorial matters related to the specific field of parabolic antennas and to give an overview as complete as possible on the key parameters and factors to understand the operation of this widely used tool to transmit and receive radiowaves. Parabolic antennas can be designed in various ranges of radiofrequencies, spanning from ~100 MHz to 100 GHz, and a many applications take advantage of this well-established and versatile technology. Whether very small parabolas are used for commercial links or large reflectors are needed to detect faint signals coming from the sky, the fundamentals are the same; the particular application will address which aspects among others have to be taken into account.

2. ANTENNA PARAMETERS AND CHARACTERISTICS

There are many parameters characterizing the operation and performance of parabolic antennas. Their importance in designing a system is dependent on the application; for instance, large antennas have to be carefully designed with respect to structural and mechanical constraints, because induced deformations, arising from gravity, wind, and temperature, dictate most of the performances. On the other hand, simple small parabolas used in receiving satellite TV signals need reasonable design, but the cost and ease of effective mass production are of primary importance.

2.1. Geometry of Used Configurations, Primary Focus-Fed Parabola

The simplest way to collect electromagnetic energy is to use a paraboloidal mirror only. Exploiting the geometric definition, a plane wave incoming at different points of the parabolic surface will be focused at the focus (called *primary focus*) of the parabola. If the phase center of a *feed* (or *illuminator*) coincides with the focus, the energy will be collected by the waveguide and then transformed in an electric signal (Fig. 1). A paraboloidal surface is obtained simply by rotating a parabola about its *focal axis*, that is the axis joining the *vertex* of the paraboloid and the primary focus. The distance between these two points is called *focal length*.

2.2. Geometry of Used Configurations, Cassegrain/ Gregorian System

Collection of electromagnetic energy could also be achieved by adding a portion of a hyperbolic shape as a second mirror. Exploiting the geometrical definition of hyperbola the energy will be focused at one of the hyperbole foci if the other one coincides with the paraboloidal primary focus. In this case the first one is called a *secondary focus* (F2) of the paraboloid and the phase center of the feed is placed to coincide with it. Again, the hyperboloid is obtained by revolution of an hyperbola about its axis. This kind of configuration is called *Cassegrain* system (Fig. 2a). The goal is also achieved if the second mirror is a portion of an ellipsoid (Fig. 2b). In this case the configuration is called a *Gregorian* system. In both systems the *secondary mirror* is also called a *subreflector*.

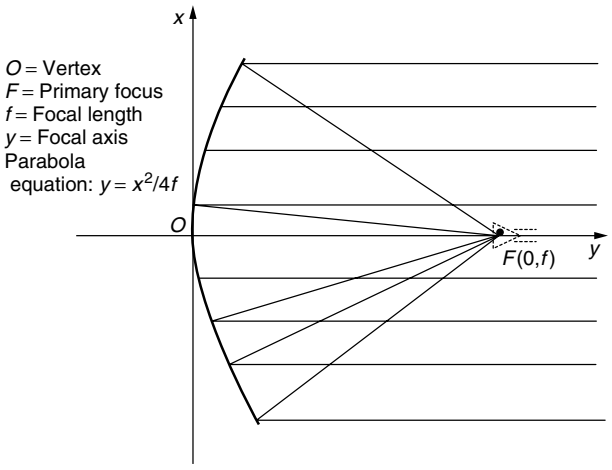

Figure 1. Primary focus-fed system.

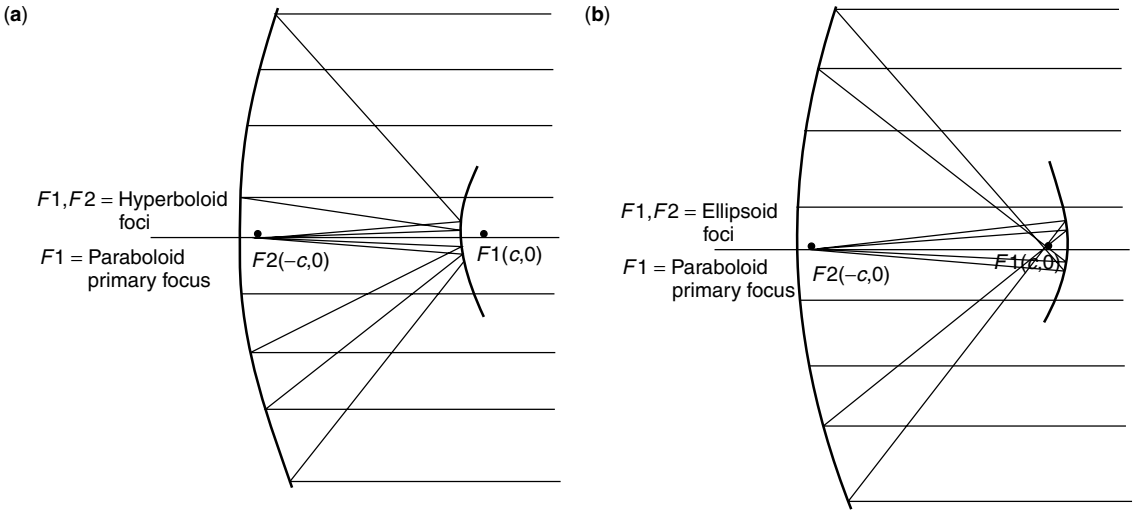

Figure 2. (**a**) Cassegrain system; (**b**) Gregorian system.

In applications where very high antenna efficiency and very particular antenna illumination are necessary, both mirrors have a shape that slightly deviates from a perfect parabolic/hyperbolic or parabolic/elliptic pair. In this case the configuration is called a *shaped* system. A shaped form of the illumination function can have a dip in the central portion of the mirror because that surface is obscured by the primary focus arrangement and so it is not useful in picking up a signal. The central dip also improves the return loss of the system, avoiding a standing wave.

2.3. Geometry of Used Configurations, Offset System

The *offset* system can be built starting with one of the three classic configurations shown in Figs. 1 and 2. Let's imagine that we remove part of the paraboloidal surface, keeping only the subsurface that collects the electromagnetic energy that doesn't interfere with either the feed or the secondary mirror (Fig. 3). This particular and very difficult-to-design configuration avoids the efficiency loss for the blockage effect due to the obstruction of the feed or secondary mirror. An impressive realization of this configuration is the GBT (Green Bank Telescope, Green Bank WV), a radiotelescope with the primary dish of 100 m in diameter.

2.4. Geometric Parameters

Referring to Fig. 4, seven parameters are used to describe and design the optics of the parabolic system:

D = diameter of the primary mirror
d = diameter of the secondary mirror
f = focal length
Φ_p = primary mirror edge half-angle
Φ_s = secondary mirror edge half-angle
L = secondary mirror depth
F = secondary mirror focal length

For describing the Cassegrain/Gregorian system, only four of them have to be fixed/the other ones are dependent by the following three equations:

$$\tan\frac{\Phi p}{2} = \pm\frac{D}{4f}\begin{cases}+\text{Cassegrain;}\\ -\text{Gregorian}\end{cases} \tag{1}$$

$$\frac{1}{\tan\Phi p}+\frac{1}{\tan\Phi s}=\frac{2F}{d} \tag{2}$$

$$1-\frac{\sin\left(\frac{\Phi p-\Phi s}{2}\right)}{\sin\left(\frac{\Phi p+\Phi s}{2}\right)}=\frac{2L}{F} \tag{3}$$

One of the most representative parameter for the design is the ratio f/D, because many of the electromagnetic characteristics have mathematical dependence on it.

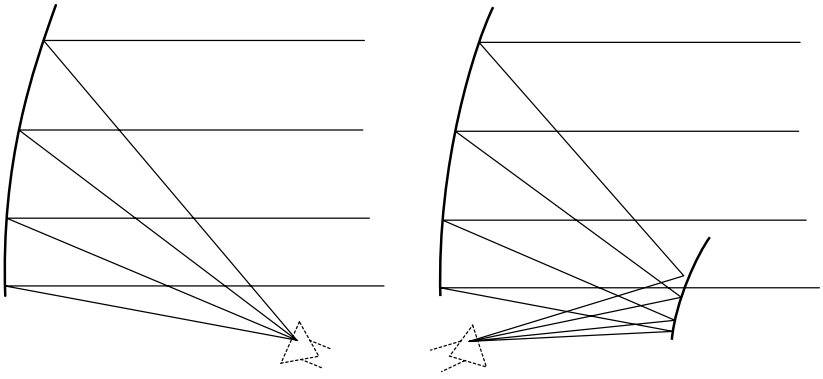

Figure 3. Offset configurations.

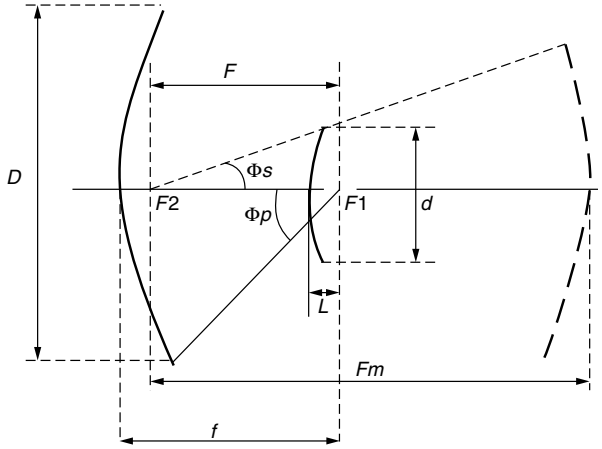

Figure 4. Antenna parameters.

Figure 4 also shows the concept of an *equivalent parabola*, which is useful in introducing the term known as *magnification* M, defined as the ratio between the focal length of the equivalent parabola and the focal length of the real system

$$M = \pm\frac{Fm}{f} = \frac{\tan\dfrac{\Phi p}{2}}{\tan\dfrac{\Phi s}{2}} (+\text{Cassegrain}, -\text{Gregorian}) \qquad (4)$$

The equivalent parabola has the same diameter and feed of the real system but is a paraboloid of different curvature. Its property is to focalize the incoming rays at the same point of the real dual-mirror system. This concept is useful in appreciating that a dual-mirror system gives a longer focal length, avoiding any lengthening of the mechanical structure in front of the primary mirror.

2.5. Electromagnetic Characteristics of Parabolic Antennas

2.5.1. Pattern. The combination of each geometry previously described and the illuminator gives the properties by means of which the antenna can irradiate or receive an electromagnetic signal. The first characteristic to be considered is the *pattern*. The antenna pattern relates the spatial distribution of the transmitted or received power [power pattern, $P(\theta, \phi)$]. Similarly, the pattern gives the value of the electric field at every point in space [field pattern, $E(\theta, \phi)$]. Usually the patterns are functions of spherical coordinates and often are normalized values with respect to the maximum of the function. The simplest pattern refers to an isotropic antenna, namely, an antenna that radiates the same amount of power in all directions. However, an isotropic antenna is inappropriate in cases where the antenna must pick up signals from a specific direction at a time while avoiding spurious signals coming from the ground (increasing *antenna noise temperature*) or unwanted other transmitters (interference). If the useful signal is to be transmitted to or received from different directions, the antenna can be pointed in the desired direction. In this way the antenna is directive and the *antenna gain* will be much higher than an isotropic one, but only at specific desired directions in space. Therefore, from Fig. 5a–c, many electromagnetic parameters can be defined.

The range of angles of maximum propagation are referred as the *main lobe* and numerically are within the half-power beamwidth (HPBW), namely, all the directions between the maximum power received (or transmitted) and its half-power. HPBW is often called the antenna *beam* and the following equation holds:

$$\text{HPBW} = k_i \frac{\lambda}{D} \qquad (5)$$

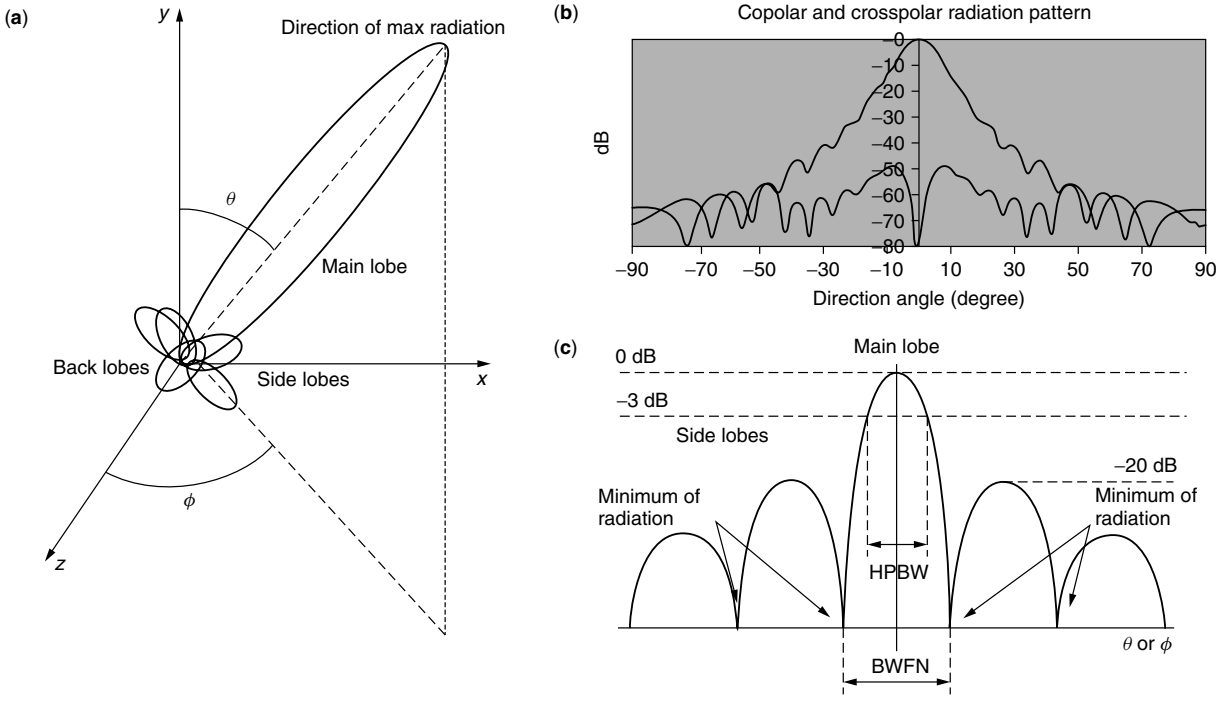

Figure 5. Antenna pattern.

where λ is the operating wavelength, D is the diameter of the antenna aperture, and k_i is a factor, always near unity, depending on which kind of function the feed illuminates in the mirror of the antenna. Often HPBW is also considered a measure of the antenna *resolution*; that is, its capability to discriminate two closely spaced objects in space. To clarify this statement, in Fig. 5c, note that the distance between the direction of max pick up and the first minimum is half of beamwidth between first nulls (BWFN). This means that two objects spaced at these locations are distinguishable because from one point the pickup is maximum while the other one is null. It could be shown that HPBW is approximately equal to BWFN/2.

Figure 5c represents a cut in either the θ or Φ plane (see Fig. 5a) and shows how low the near sidelobes are with respect to the main lobe. This is indicated as -20 dB. This illustration could be viewed as a zoom of the more complete polar pattern in Fig. 5b. In this figure the relative amount of power radiated (or received) as a function of angle is shown (polar or *copolar pattern*) together with the radiation in a perpendicular direction where, ideally, the radiation should be zero (*cross-polar pattern*).

2.5.2. Gain and Aperture Efficiency. It can be shown that the antenna gain has a direct relation to the collecting area of the antenna:

$$G = \eta \frac{4\pi}{\lambda^2} Ag \tag{6}$$

Although G is a dimensionless quantity, often given in decibels by simply taking $10 \log_{10}(G)$, there are application fields, such as radio astronomy, in which the antenna gain assumes the meaning of how much the antenna temperature is increased when the antenna surface receives a given amount of power density per unit bandwidth. In this case the dimension of gain is kelvins over jansky, where jansky is a unit defined as

$$1 \text{ Jy} = 10^{-26} \frac{W}{\text{m}^2 \cdot \text{Hz}} \tag{7}$$

and the antenna gain can be calculated in the following way:

$$G_R = 10^{-26} \eta \frac{Ag}{2k} \tag{8}$$

where k is the Boltzmann constant. The two ways to express the antenna gain are equivalent; what simply changes is the measurement unit. If G_R is known, we can calculate η and use Eq. (6) to get G; conversely, if G is available, we can calculate η and then get G_R from (8).

Ag is the geometric area of the aperture of the parabolic antenna. *Aperture* is the cross section subtended by the dish, and for parabolic antennas it is a circle with diameter D. λ is the wavelength at which the gain is to be calculated or measured, and η is called the aperture efficiency. The *aperture efficiency* is a number less than one and acts in reducing the real area that is effective in collecting the electromagnetic energy coming into the aperture. η originates from many causes, each of them described by an appropriate efficiency parameter, and in general depends on a lot of variables, including the frequency, direction of pointing, structural deformations of the antenna due to gravity, temperature and wind, and type of function by which the feed illuminates the dish. Trying to clarify as simply as possible, we could start by stating (9), which relates the causes that most affect the efficiency:

$$\eta = \eta_b \eta_x \eta_{\text{ph}} \eta_{\text{sp}} \eta_{\text{diff}} \eta_{\text{ill}} \eta_{\text{surf}} \eta_{f\text{loss}} \eta_{\text{vswr}} \eta_{s\text{loss}} \tag{9}$$

η_b is the *blocking efficiency*. It comes from the obstruction of the feed or subreflector, and the supporting legs raise at the incoming electromagnetic energy. Practical values span from 0.85 to 0.95, except for the antenna offset solution. A rule of thumb to get the order of magnitude of η_b is to compute the ratio of the total blocked area A with the area of the antenna aperture Ag, then

$$\eta_b = \left(1 - \frac{A}{Ag}\right)^2 \approx 1 - 2\frac{A}{Ag} \tag{10}$$

η_x is the *cross-polarization efficiency*. It arises when the polarization of the incoming wave doesn't match the polarization of the antenna. The extreme example should be a dipole sensitive at the horizontal polarization: η_x is zero for vertical polarized waves, so they cannot be detected. Parabolic antennas have a high degree of symmetry, so they are sensitive to both linear and circular polarizations and η_x has very high values (0.99 or better), particularly if the feed is circular and designed so that the amplitude and phase patterns are equal in the two orthogonal planes of maximum radiation (E and H planes). The situation worsens if the antenna components are not perfectly aligned to each other or the feed is not symmetric. In the case that the antenna is an offset system, a very careful design must be developed if a low cross-polarization level is needed.

η_{ph} is the *phase efficiency*. If all rays (see Figs. 1–3) don't arrive in phase (e.g., because the mirror deforms under structural loads or because the feed is not able to perfectly illuminate in phase all directions), a small amount of power can be lost. This term is generally negligible for classic parabolic antennas, 0.99 or so, but it could be very low for shaped antennas when used with primary focus receivers, because the equalizing effect of the subreflector is absent. However, in this case, the effect is very frequency-dependent, putting a limit on the highest usable frequency of receivers placed at the primary focus.

η_{sp} is the *spillover efficiency*. When a feed illuminates the primary or secondary mirror of the antenna, the energy at the edges cannot go sharply to zero. Thus, a fraction of the total illumination energy will be lost: the ratio between this fraction and the total energy is called "spillover efficiency". This term is generally the result of a compromise, as the illumination is far from uniform, the higher is η_{sp} but the lower is the effective area. Normally antennas have an illumination function different from uniform, so a certain amount of tapering is used. The *taper* is how much the function is lower at the edge with respect to its maximum value. This is one of the design parameters for the feed and is evaluated at the angle Φp or Φs depending on which geometry is chosen, and usually the tapering is higher in the primary focus configuration than the secondary. The reason is that a primary mounting of the feed "sees" the ground at angles greater than Φp,

so it picks up an unwanted noise temperature at about 300 K that must be attenuated. Instead, by illuminating the subreflector, the feed "sees" the atmosphere at angles greater than Φs, that it is cooler than the ground.

η_{diff} originates from *diffraction* due to edge effects for both primary and secondary mirrors.

η_{ill} is the *illumination efficiency* and accounts for the fact that the illumination function is not uniform over the aperture, so it is a measure of the reduction of gain due to tapering.

η_{surf} is the *surface efficiency*. The rays colliding on the antenna surface find a nonideal shape. The subreflector and primary mirror surfaces have roughness. Furthermore, large-diameter antennas have a primary mirror consisting of a lot of aluminum panels drawn close, which also means that their relative alignment is a concern. Sometimes larger subreflectors are made by panels as well. Antennas suffer important deformation due to gravitational and wind effects as their dimensions increase; also temperature-induced deformation of the surfaces must be taken into account. The net result is that incident rays are reflected by nonperfect surfaces, resulting in phase errors that reduce the gain. Manufacturing errors of the panels and surface, temperature, and wind effects on the mirrors and on the antenna supporting structure, and also gravitational deformations, are treated like random errors. Therefore the parameter indicating the departure from the ideal shape is the RMS (root-mean-squared) value of the real surface with respect to the ideal one. Because of the many the causes, the RMS values must be combined to obtain the *total surface* RMS σ. Usually σ is the RSS (root sum squared) of the RMS values:

$$\sigma = \sqrt{\sigma_1^2 + \sigma_2^2 + \cdots + \sigma_n^2} \tag{11}$$

The surface efficiency follows a Gaussian function depending on the σ/λ ratio:

$$\eta_{\text{surf}} = e^{-[4\pi(\sigma/\lambda)]^2} \tag{12}$$

$\eta_{f\text{loss}}$ is the *feed loss efficiency*. When the electromagnetic energy passes through the feed, the waveguide attenuates a small amount of power, so the power for illuminating the aperture is slightly less than the supplied one. The insertion losses are generally low — let's say in the range 0.1–0.4 dB, which means that $\eta_{f\text{loss}} = 0.91 \div 0.98$.

η_{vswr} is the feed *return loss efficiency*. Together with the insertion loss mentioned previously, the feed loses power because a part goes back due to a nonperfect impedance matching. Return losses less than -15 dB are easily obtained, so $\eta_{\text{vswr}} \geq 0.97$.

$\eta_{s\text{loss}}$ is the *surface loss efficiency*. The surface of the mirrors are conducting electric currents; thus ohmic losses due to material resistivity arise. The effect is low, $\eta_{s\text{loss}} = 0.99$.

To conclude this section, it is worthwhile to mention other possible causes that reduce the antenna gain. Up to now a perfect geometric alignment of the three antenna components — the primary mirror, the secondary mirror, and the feed — were assumed. In the case that either the feed or the subreflector are not well positioned on the focus in the direction of its axes, a *defocusing* effect occurs. Defocusing exists in a movable antenna also if it were properly aligned. In fact, the alignment holds for a single position of the antenna, because the antenna deformation, as the elevation changes, will move the focus so that the feed or subreflector will be defocused. If a proper tracking of the focus movement is necessary to recover that amount of loss, a mechanical facility must be added in the antenna design in order to move the feed or subreflector.

Another useful concept is the *field of view* (*FOV*). It is related to a displacement of the feed with respect to the focus position outside the focal axis. If this is the case, a reduction of gain, together with an increase of sidelobe level and cross-polar pattern, will be experienced. The field of view could be defined as the space region where the feed can be displaced losing no more than a fixed amount of gain. Of course, FOV is not an absolute parameter, but it depends on the amount of gain loss that is considered acceptable. Generally it has an angular dimension, but it could also be expressed as HPBW times or as a multiple of wavelength. The FOV concept suggests that in the real world the focus of an antenna must not be viewed as a point just outside of which the system doesn't completely work. Instead a "focal surface" exists where the performance of the antenna worsens with the distance that the feed is placed with respect to the focus. The FoV can be exploited to use the antenna with more than one frequency by placing receivers working at different wavelengths, or using feed arrays (many identical feeds working at the same frequency).

2.6. Structural and Mechanical Aspects of Parabolic Antennas

Small parabolic and stationary dishes don't give particular structural and mechanical problems. They are mounted on a lattice or on a mast, pointed in a fixed direction, and their performances are not affected by temperature, wind stress, or operating environment. On the other hand, some applications call for the antenna to be protected from all these causes, and thus it is completely enclosed in a *radome*, a microwave transparent dielectric housing protecting the antenna from adverse environmental conditions.

Between these two extremes a lot of applications use parabolic antennas without radomes, that experience all weather conditions and, because of their dimension and weight, also gravitational deformations both for the dish and the supporting framework. The general characteristics of a movable and large reflector antenna are described in the following text. The following structural and mechanical elements are shown in Fig. 6.

- A *concrete foundation* with pillars, which is embedded some meters in the ground.
- A *track* over which the *wheels* move. This is a very common solution to allow the rotation of the antenna in the azimuth direction.
- The *alidade*, which is the supporting structure of the antenna.
- The *elevation wheel*, which allows the antenna to rotate in the elevation direction.
- The *backup structure*, which supports the primary mirror.

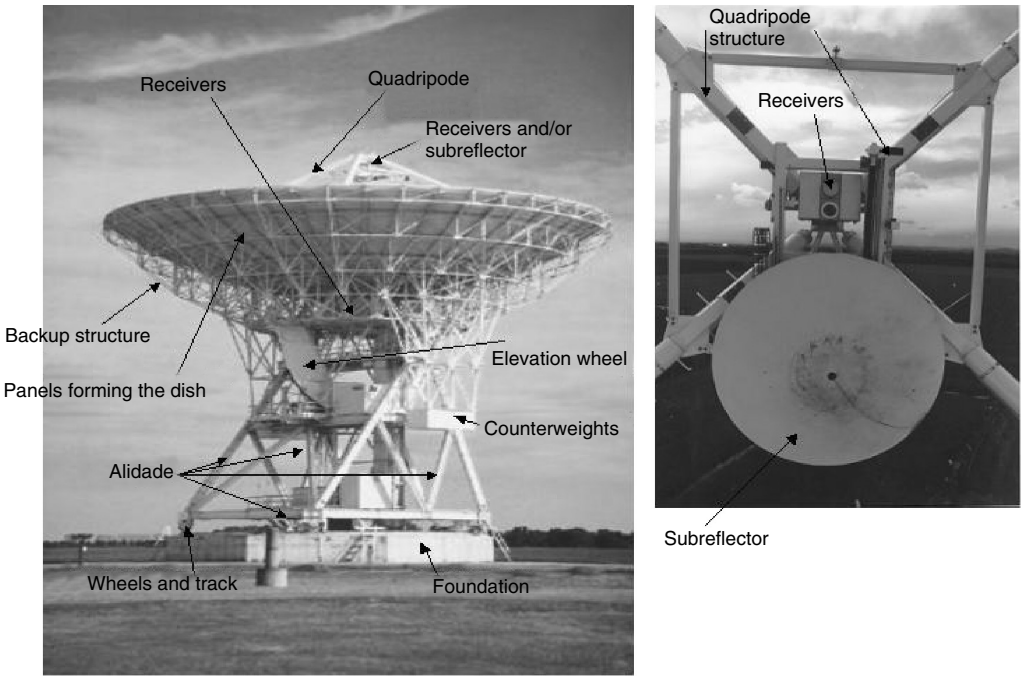

Figure 6. Elements of a parabolic antenna (Medicina observatory radiotelescope, Bologna, Italy).

The *quadripode*, usually three or four legs, which supports the secondary mirror and primary focus receivers.

The *panels*, which form the primary mirror of the antenna.

The right side of Fig. 6, a zoom of the primary mirror location, shows a very particular arrangement of the mechanical coexistence of the subreflector and the primary focus receivers. This allows a fast change among receivers placed at both the primary and secondary focus.

The wheels and track are made of iron alloy, and this is interfaced with the concrete foundation by means of either a suitable grout solution or, better, iron plates over which the track is bolted and grout under the plates. The plates are bolted in the concrete by anchor bolts. The alidade, elevation wheel, and backup and quadripode structure consist of large steel beams, trusses, frames, and brackets. The panels are made of aluminum, covered by a highly reflective white paint, the dimension and quantity of which are determined by the diameter of the dish; to give an idea, a mirror with a diameter around 30 m needs 200 or more panels, with an area of 3–5 m^2 each. The specifications regarding the panels are given in terms of manufacturing error and deformation under gravity, temperature, and wind. All of these are RMS values with respect to the ideal parabolic contour and they contribute, together with the RMS value of the subreflector surface, the RMS deformation of the structure and the mirrors alignment error, to the total surface accuracy σ [see formula (11)]. σ is said to determine the minimum operating wavelength of the antenna by means of the conventional relation

$$\sigma = \frac{\lambda \min}{20} \tag{13}$$

The subreflector can be made of fiberglass or, if the dimension is too large, by aluminum panels. Usually, the dimension for the subreflector is around $D/10$, where D is the diameter of the primary dish. It results as a compromise by taking the blockage at minimum values together with an efficient illumination of the paraboloid. The shaping of the antenna may instead require a subreflector diameter higher than $D/10$.

Sun exposure heats in a nonuniform way all the elements of the structure, both deforming the shape of the mirror and changing the direction of pointing. Further, in these heavy antennas (a 30-m antenna can weigh 200 tons or more), gravity takes a great role in deforming the backup structure. The departure from a true parabolic shape changes with respect to the elevation. To overcome the gravitational effect, some antennas adopt a structural design called *homology*; the mirror maintains a parabolic shape, changing the focal length only (i.e., the mirror opens or closes, maintaining the symmetry). By focusing the subreflector, the focal length can be tracked for each elevation. This design results in a much heavier antenna and significantly increases the cost.

2.7. Pointing

2.7.1. Overview. This subject is rarely taken into account in most applications and books, but it is worthwhile to mention both for completeness and for those applications that need a precise tracking of a target.

In Section 2.5 the term *beam* and the acronym HPBW were introduced, indicating a measure of the angular size where most of the radiation is contained. If the antenna has to point at a target and, above all, has to track it, the response of the antenna servosystem to the target coordinates must be within the pointing performance, to maintain the target inside the antenna beam. It is easily

recognized here that a pointing error can be viewed as a loss of power. It acts like the antenna efficiency terms, multiplying by a factor of <1 the amount of power received (transmitted) from (to) the target. To give a quantitative example, suppose that the antenna main lobe is Gaussian so it can be expressed in terms of HPBW by the following equation (see also Fig. 7):

$$\eta_{\text{point}} = e^{-(1.665*\theta/\text{HPBW})^2} \tag{14}$$

η_{point} is unity for perfect pointing, but rapidly decreases if errors occur. If the pointing error $\theta = \text{HPBW}/2$, half of the power is lost and an error of equal to one-fifth of the beam is enough to loose 10% of power.

Pointing errors can be divided into two classes: systematic and nonsystematic. *Systematic* errors are repeatable errors, and a mathematical model can be predicted. Gravitational deformations induce a pointing error. The erection of the antenna leaves unavoidable errors such as a slight nonorthogonality between the azimuth and elevation axis, nonperfect horizontal azimuth plane, and a mechanical axis of the mirror different from the electromagnetic direction of maximum pickup. All these factors induce systematic pointing errors that can be measured or derived from the best-fitting technique.

Nonsystematic errors are random errors and are due to temperature effects on all the elements of the antenna structure, for example unevenly expanding alidade trusses, and wind forces acting so that average wind and its gusts slightly move the antenna. These are not predictable and environment-dependent, in the sense that the pointing accuracy is a function of the amount of wind, absolute temperature, and its drift. Generally the antenna is said to work in three possible conditions — precision, normal, and extreme operation, indicating worsening of performance as wind and temperature effects increase.

2.7.2. Beam Deviation Factors. In Section 2.5 the case of a displaced feed was reported, listing the effects on the antenna pattern. A feed displacement gives pointing displacement as well. Generally speaking, the movements of all elements forming the antenna geometry, primary or secondary focus feed, subreflector, or primary mirror, cause pointing errors. These movements can be the translation or rotation of the element that originates a misalignment angle α, causing a pointing angle error β: the ratio between these angles is called the *beam deviation factor* (BDF), which is a function of the antenna parameters, namely, focal length f, diameter D, magnification M, and secondary mirror focal length F and for most cases its value ranges from 0.7 to 0.9. In the following, a survey of possible situations is presented,

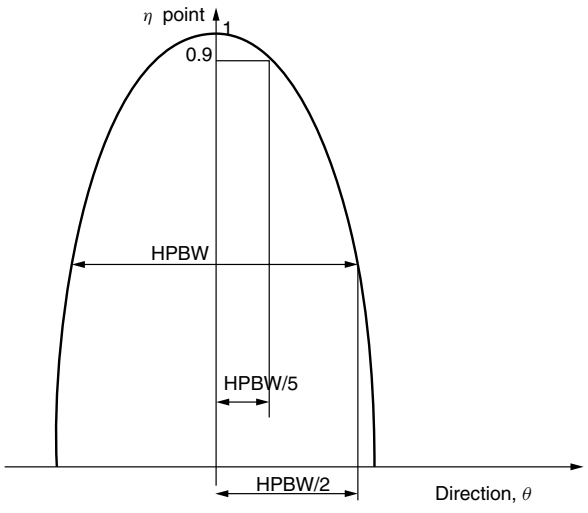

Figure 7. Pointing error.

- Primary feed lateral displacement (Fig. 8a):

$$\text{BDF} = \frac{\beta}{\alpha_p} = \frac{\beta}{\tan^{-1} d/f} = \frac{\sin^{-1}\left[\dfrac{d*\left(1+k_i(D/4f)^2\right)}{f*\left(1+(D/4f)^2\right)}\right]}{\tan^{-1} d/f} \tag{15}$$

k_i is the same factor appearing in Eq. (5). In the case $d \ll f$, so that $\tan^{-1}$ and $\sin^{-1}$ are equal to their argument, a more practical and usual relation can be used:

$$\text{BDF} = \frac{1 + k_i * (D/4f)^2}{1 + (D/4f)^2} \tag{16}$$

- Secondary feed lateral displacement (Fig. 8b):

$$\text{BDF} = \frac{\beta}{\tan^{-1}\left(\dfrac{d}{M*F}\right)} \tag{17}$$

- Subreflector rotation (Fig. 8b):

$$\text{BDF} = \frac{\beta}{\tan^{-1}\left(\dfrac{F}{f}*\dfrac{2\alpha_s}{M+1}\right)} \tag{18}$$

- Subreflector displacement (Fig. 8b):

$$\text{BDF} = \frac{\beta}{\tan^{-1}\left(\dfrac{h}{f}*\dfrac{M-1}{M}\right)} \tag{19}$$

The situation is such that by moving an element to one side, the beam is deviated to the opposite side (as shown in Fig. 8a), so to recover the right pointing, the antenna must be moved according to the element. BDF values allow us to understand the pointing error sensitivity of the antenna with respect to misalignments or effects due to the stiffness of the antenna elements.

2.8. Antenna Noise Temperature

Regardless of whether the antenna is receiving, or transmitting the wanted signal, a certain amount of noise power is picked up by its pattern. The amount of noise power is expressed as an equivalent resistor at temperature T_a, called the *antenna noise temperature*, which, when matched at the antenna receiver input in place of the antenna, gives the same amount of noise power. It is recalled here that the relation between power and temperature is

$$P = kT_aB \tag{20}$$

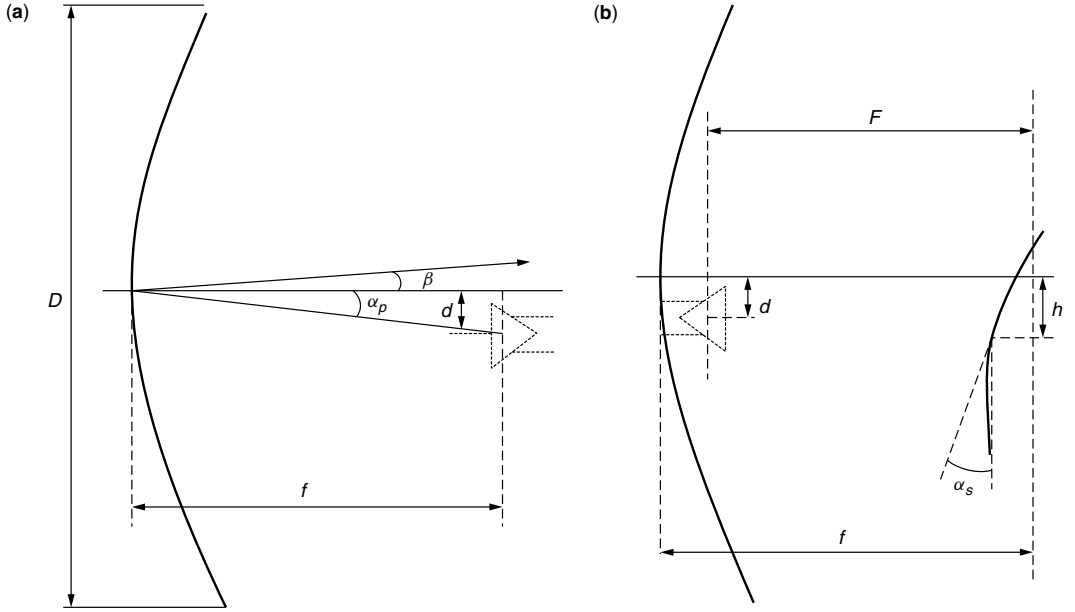

Figure 8. Beam deviation factors: (**a)** primary and (**b)** secondary feed lateral displacement, subreflector rotation and lateral displacement.

where k is the Boltzmann constant, B is the bandwidth, and T_a is the equivalent temperature.

The noise power comes from different origins:

- Noise power picked up from ground (conventionally at a physical temperature equal to 290 K) by backlobes or by antenna spillover.
- Noise power coming from cosmic sources, from the sky or planets and received by either the mainlobe or sidelobes. At least the antenna receives the big bang remnant, 2.73 K, which is uniformly distributed over all the sky and not dependent on frequency. Galaxies or other sky objects emit signals in the form of noise. The same could be said for planets and the sun of our solar system. The amount of noise power picked up depends strongly on frequency, on the object, and on how the antenna lobes point toward the object.
- Noise power from the atmosphere. The atmosphere is an absorbing medium, so it acts like an attenuator producing noise. The atmosphere noise varies with frequency and with the elevation angle at which the antenna is pointing. Low elevation angles give a higher amount of noise because the radio path is longer than that at high elevation.

2.9. G/T

By adding the antenna noise temperature to the receiver noise temperature, the so called *system temperature* T is obtained; that is, the overall noise of the complete antenna receiving system proportional to the inferior limit on the detection of signals. In any case, the detection of signals also depends on the antenna gain; the larger the reflector, the higher is the amount of power received, but this also holds for antenna noise. The ratio between T and the antenna gain G, the term G/T, gives a figure on the capability of the antenna to detect small signals. G/T can also be used to compare different antenna receiving systems; if a larger antenna has a very noisy receiver, its performance can be worse than a smaller antenna having a receiver, at the state of the art, with very low noise.

3. APPLICATIONS

Parabolic antennas have many applications in various fields requiring very different performance. Depending on the application, the design will encompass all or part of the characteristics described in Section 2.

3.1. Radio Astronomy

This relatively young science uses many large reflector antennas located all over the world to receive signals from many different natural sky objects such as galaxies, quasars, stars, and planets. The nature of the received signals is generally noise or plenty of spectral lines. If an object has to be resolved, the interferometry technique is used. This means that many parabolic antennas are used in observing the same object at the same time. In that case the value D of the interferometer is the distance among the antennas that can span from some kilometers to thousands of kilometers. This last case is called a *very-long-baseline-interferometry* (VLBI) technique and allows us to reach angular resolution as low as milliarcseconds at microwave frequencies [by applying Eq. (5)].

The parabolic antennas used in radio astronomy are of all types described in Sections 2.1 to 2.3, and operative frequencies span from about 300 MHz to 30 GHz for centimetric wave antennas to hundreds of gigahertz for millimeter and submillimeter antennas.

This field of application often needs a very careful design for all the antenna characteristics described in Section 2.

3.2. Microwave Relay Link

A microwave relay link is intended as a link that transmits and receives the radio signal (e.g., the broadcasting of

analog and/or digital signals) between parabolic antennas many tens of kilometers in distance and on a line-of-sight path. The diameters of the antennas used are a few meters, and the operative frequency range is in the microwave region from about 2 to 20 GHz. The Friis formula addresses the design of the link:

$$\mathrm{Pr} = \frac{\mathrm{Pt} * \mathrm{Gt} * \mathrm{Gr}}{(4 * \pi * r)^2} * \lambda^2 \tag{21}$$

P_r = received power
P_t = transmitted power
G_t, G_r = gain of transmitting and receiving antenna
r = distance of the link
λ = operating wavelength in free space of the transmitted and received signal

3.3. Satellite Communication

Most of the earth stations in a satellite communication system are parabolic antennas of all types described in Section 2. Both single feed and feed array configurations are used. In this last case, displaced location of the feeds with respect to the reflector are used to get different pointing directions in order to receive signals from different satellites. The used frequencies span from a few gigahertz to over 12 GHz. The diameter of the antennas can range well over 10 m.

3.4. Remote Sensing

Parabolic antennas can be used in the microwave range for radiometric measurements of the atmosphere parameters and earth and sea surface characteristics. Also in this case, scanning beam techniques and multifrequency measurements call for use of a feed array.

BIOGRAPHY

Alessandro Orfei received his degree in 1983 from Bologna University, Department of Electronic Engineering. He worked for three years at the G. Marconi Foundation Laboratories in the field of the fiber optics, and then for three years in a private company as a design engineer in the field of telecommunication. Since 1989, he has been a researcher at the Istituto di Radioastronomia–Consiglio Nazionale delle Ricerche (Italy). He is in charge of all work concerning the VLBI (very-long-baseline interferometry) 32m antenna at the Medicina Radio Observatory (Bologna, Italy).

PARTIAL-RESPONSE SIGNALS FOR COMMUNICATIONS

Apostolos Rizos
AWARE, Inc.
Bedford, Massachusetts

1. INTRODUCTION

Partial-response signals are those where intentional controlled intersymbol interference (ISI) is introduced between successive symbols, either for channel-matching or bandwidth-efficiency purposes. In contrast to a partial response signal, a *full-response signal* does not introduce any intentional ISI between successive symbols.

To explain these definitions in more detail, let us remember the basic representation of a linear digital modulation technique [1]

$$s(t) = \sum_{n=0}^{\infty} I_n g_T(t - nT) \tag{1}$$

A binary sequence d_n with values $\{0, 1\}$ is mapped to an information-bearing sequence I_n, which is typically an amplitude value that will scale the transmitting filter output $g_T(t)$ (the subscript T refers to the transmitter and not the symbol rate $1/T$). For binary PAM (pulse amplitude modulation), I_n will take values $A, -A$, so that a binary 1 will be transmitted using pulse $A \cdot g_T(t)$ and a binary 0 will be transmitted using the inverse pulse $-A \cdot g_T(t)$.

Note that for higher-order modulations (e.g., 4-PAM), k bits of the binary sequence are mapped into a 2^k-level information symbol I_n. The information sequence I_n may also be complex-valued, which corresponds to a QAM (quadrature amplitude modulation) scheme that needs to be modulated onto a carrier; the real part of the information signal will modulate the cosine of the carrier, while the imaginary part will modulate the sine (which is orthogonal to the cosine, and hence, can be distinguished from it). Without loss of generality, we will assume the information sequence to take values $\{1, -1\}$, and the cascade of the information sequence and the transmitting filter $g_T(t)$ to give a total energy $\mathcal{E}_b$ for each transmitted bit.

Assuming a linear transmission channel with impulse response $c(t)$, and a receiving filter with impulse response $g_R(t)$, then the output of the receiver filter will be

$$r(t) = \sum_{n=0}^{\infty} I_n x(t - nT) + v(t) \tag{2}$$

where $v(t)$ is the noise from the channel and $x(t)$ is the combined effect of $g_T(t), c(t), g_R(t)$. Its frequency representation (Fourier transform) will be the product of the Fourier transforms of its components

$$X(f) = G_T(f)C(f)G_R(f) \tag{3}$$

By sampling the output of the receiving filter every T seconds, we obtain the decision variables that are used for the estimation of the information sequence

$$r_m = x(0)I_m + \sum_{n=0, n\neq m}^{\infty} I_n x(mT - nT) + v(mt) \tag{4}$$

We see that the mth received sample r_m depends on the mth information symbol I_m, but also [depending on the values of $x(nT), n \neq 0$] on the adjacent symbols $I_n, n \neq m$. This is called *intersymbol interference* (ISI). A full-response

signal is designed in such a way that the combination of transmit and receiver filters will give no ISI

$$x(n) = \begin{cases} 1, & n = 0 \\ 0, & n \neq 0 \end{cases} \tag{5}$$

while a partial-response signal is designed in such a way that the combination of transmit and receive filters will give controlled ISI, $x(n) \neq 0$ (but equal to predetermined values) for more than one sample n. The controlled ISI amount in a PR system is chosen in such a way so as to satisfy the system requirements, such as small bandwidth or no DC spectral component.

An example of a full-response signal is shown in Fig. 1. The basic transmitting pulse is a rectangular pulse $p(t)$ of duration T, and we assume that both the channel and the receiver filter introduce no change to the signal: $C(f) = G_R(f) = 1, \forall f$. We see that each symbol does not interfere with adjoining symbols.

There is a problem with a signal such as this rectangular pulse; it is not bandwidth-limited; that is, its Fourier transform $P(f)$ is nonzero for a nonbounded frequency range. Nonband-limited signals pose problems in communications for two reasons. First, the characteristics of the transmission medium (and the transmitter and receiver components) usually result in some form of nonideal frequency response and bandwidth limitation for the signal — the signal has to be of limited bandwidth to be able to be transmitted without significant frequency content loss or distortion from the channel. The second reason is that in order to accommodate many channels in large-capacity trunks, most telecommunication standards impose some form of frequency-division multiplexing (FDM), whereas each individual channel has to satisfy a bandwidth constraint in order to be multiplexed and not interfere with adjacent channels.

For the remainder of this discussion we will assume that the channel characteristics are such that it is an ideal channel of bandwidth W, with

$$C(f) = \begin{cases} 1, & |f| \leq W \\ 0, & |f| > W \end{cases} \tag{6}$$

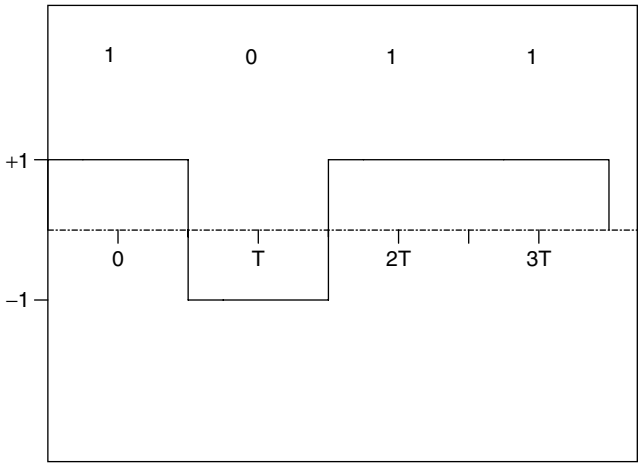

Figure 1. An example of a full-response signal.

Dealing with a channel that, besides the bandwidth limitations, also introduces amplitude or phase distortion to the transmitted signal is a subject of channel equalization.

Hence, the problem of designing full-response signals [i.e., signals that satisfy Eq. (5)] that also have a limited bandwidth W, having $G_T(f)G_R(f) = 0$ for $|f| \geq W$, arises. The pioneering work on this was done by Nyquist [2]. He established the condition (*Nyquist condition*) that $X(f)$ has to satisfy in order to have zero ISI in the received samples.

The major result of the Nyquist condition is that in order to transmit without ISI a signal with symbol rate $1/T$, there is a minimum bandwidth requirement of $W \geq 1/2T$. The resulting maximum symbol rate of $1/T = 2W$ is called *Nyquist rate*. It is interesting to note the duality with sampling theory, where it is known (again by Nyquist) that in order to uniquely sample a bandlimited signal, one has to use a sampling rate (frequency) of at least $2W$; a higher rate results in correlation (i.e., ISI, from a communications point of view) between successive samples.

A family of pulses that satisfy the Nyquist criterion for zero ISI is the one with a *raised cosine spectrum*. The bandwidth occupancy B of this pulse is determined by the rolloff factor α, which takes values $0 \leq \alpha \leq 1$, giving

$$B = \left(\frac{1}{2T}\right) \cdot (1 + \alpha) \tag{7}$$

An example of two pulses with raised-cosine spectrum, with rolloff factors $\alpha = 0, 0.5$ is shown in Fig. 2. We notice that the pulses have zero value at multiple integers of the symbol interval $t = nT, n \neq 0$, which is the non-ISI criterion of Eq. (5). Thus, superimposing shifted versions (by nT) of these pulses leads to a combined signal where only one constituent pulse contributes in the value of the signal at a specific sampling instant $t = mT$.

The limiting case of pulses with the raised-cosine spectrum is when the rolloff factor is $\alpha = 0$. Then the spectrum has an ideal rectangular characteristic with the smallest possible bandwidth $B = 1/2T$ for no ISI. The resulting pulse is the sinc( ) function

$$x(t) = \frac{\sin(\pi t/T)}{\pi t/T} = \text{sinc}\,\frac{t}{T} \tag{8}$$

However, filters that have such a sharp frequency response are practically nonrealizable. For the filter to be causal (i.e., to have its impulse response to the right of the $t = 0$ axis in Fig. 2a), the truncation of its impulse response must be of a reasonable length and a plus a delay function is required. Since the tails of the sinc( ) function decay quite slowly (proportionally to $1/t$) the truncation length has to be extremely large, to avoid the significant loss of the signal characteristics, and this makes the filter realization very difficult. Another detrimental effect of the heavy tails of the sinc( ) pulse is that a mistiming error (sampling at a time slightly off the multiples of T) results in a nonconverging (due to the $1/t$ decay) series of ISI components.

Hence, usually for a realizable full-response system a raised-cosine spectrum characteristic with $\alpha >$

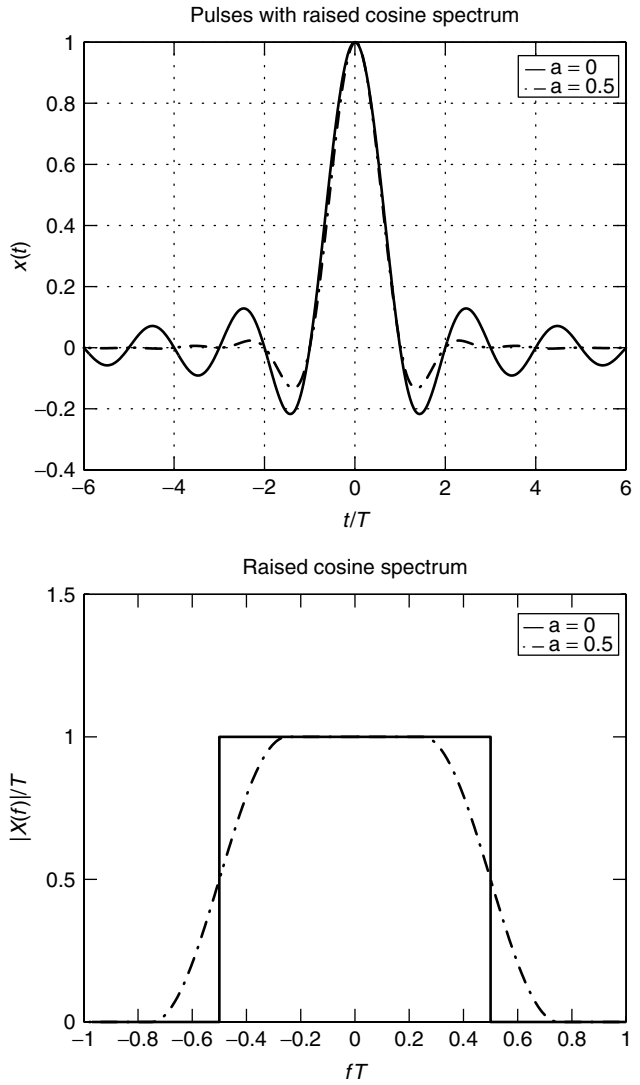

Figure 2. Pulses with raised-cosine spectrum: (**a**) $x(t)$ in the time domain; (**b**) frequency response $X(f)$.

0 is chosen. This leads to a filter with a more realistic truncation length requirement. However, this also results to a signal bandwidth occupancy that is larger than the optimum $(1/2T)$ one, typically by 15–25%.

2. SIMPLE PARTIAL-RESPONSE SIGNALS

In the previous section we noticed that the Nyquist limit on the transmission rate over band-limited channels $1/T = 2W$ is practically nonrealizable with full-response signaling. However, if one relaxes the zero-ISI condition and allows for a controlled amount of ISI, then one can obtain realizable filters that have the Nyquist bandwidth $W = 1/2T$. This was first observed by Lender [3] and later extended by Kretzmer [4], Kobayashi [5], and Pasupathy [6].

Let's examine the simplest case of a partial-response signal, one that has a composite response $x(n)$ [as given by Eq. (3)] with values[1]

$$x(n) = \begin{cases} 1, & n = 0 \\ 1, & n = 1 \\ 0, & \text{otherwise} \end{cases} \tag{9}$$

It is easily shown that for $W = 1/2T$ the actual corresponding pulse is

$$x(t) = \text{sinc}\left(\frac{t}{T}\right) + \text{sinc}\left(\frac{t}{T} - \frac{1}{T}\right) \tag{10}$$

with frequency response

$$X(f) = 2Te^{-j\pi fT}\cos(\pi fT),\ |f| < \frac{1}{2T}(0 \text{ otherwise}) \tag{11}$$

This is the first partial-response pulse that was examined and is called a *duobinary* pulse. We notice that it is equivalent to a digital FIR filter with coefficients [1 1] followed by a filter with an ideal rectangular frequency response [to which $\text{sinc}(t/T)$ corresponds]. We mentioned above that the ideal rectangular filter is not practically realizable on its own; however, the pulse given by Eq. (9) and shown in Fig. 3a is much more easily realizable since its tails decay rapidly and its frequency response (shown in Fig. 3b) decays smoothly toward zero.

Another simple partial-response scheme is the *modified duobinary pulse*, which is characterized by the following composite response:

$$x(n) = \begin{cases} 1, & n = -1 \\ -1, & n = 1 \\ 0, & \text{otherwise} \end{cases} \tag{12}$$

The modified duobinary pulse and its spectrum are given by the following relationships and are shown in Fig. 4; also

$$x(t) = \text{sinc}\left(\frac{t+T}{T}\right) - \text{sinc}\left(\frac{t-T}{T}\right) \tag{13}$$

$$X(f) = j \cdot 2T\sin(\pi f 2T),\ |f| < \frac{1}{2T}(0 \text{ otherwise}) \tag{14}$$

We notice that the modified duobinary spectrum has a null at DC ($f = 0$), which makes it suitable for channels that don't pass DC (e.g., circuits with transformer couplings) or for SSB modulation. Currently, the most significant application of the modified duobinary pulse is in magnetic recording systems. From Fig. 4a, we notice that the modified duobinary pulse is similar to the read-back signal response to a pulse in a magnetic recording system. On the basis of this observation, one can shape with minimal equalization the combined magnetic channel into a modified duobinary system response, and use maximum-likelihood decoding (explained in the next subsection) to estimate the data sequence. The use of these ideas in magnetic recording systems [7] (labeled as PRML, from

[1] One should notice that the given sample values result in a higher energy per bit with respect to a zero-ISI system with $x(0) = 1$, and this should be taken into account when one calculates the SNR of the signal and its bit error probability.

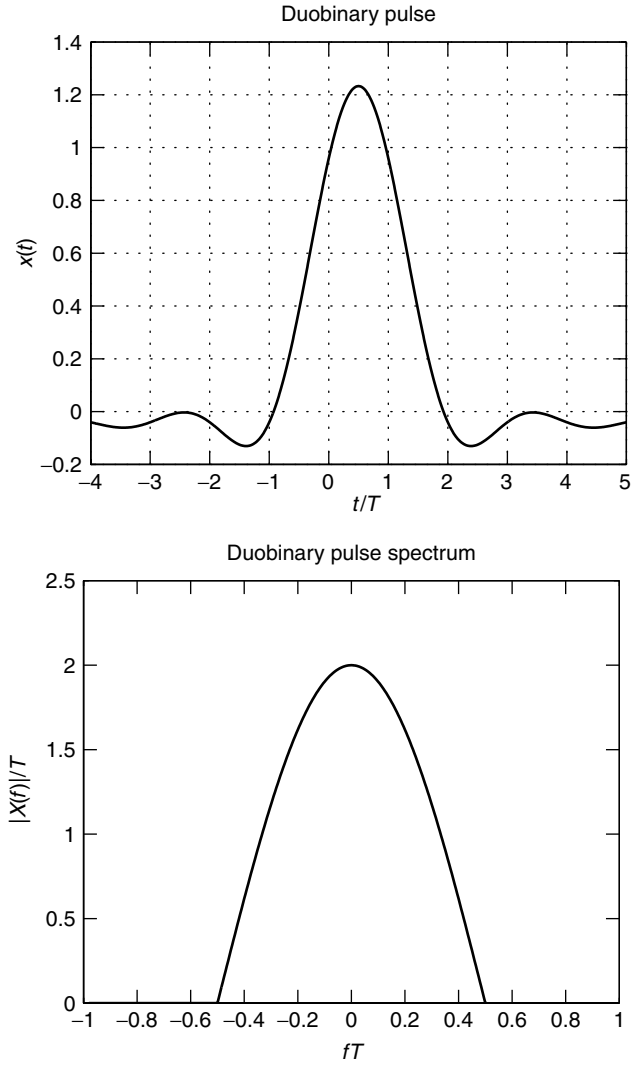

Figure 3. Duobinary pulse: (*a*) $x(t)$ in the time domain; (*b*) frequency response $X(f)$.

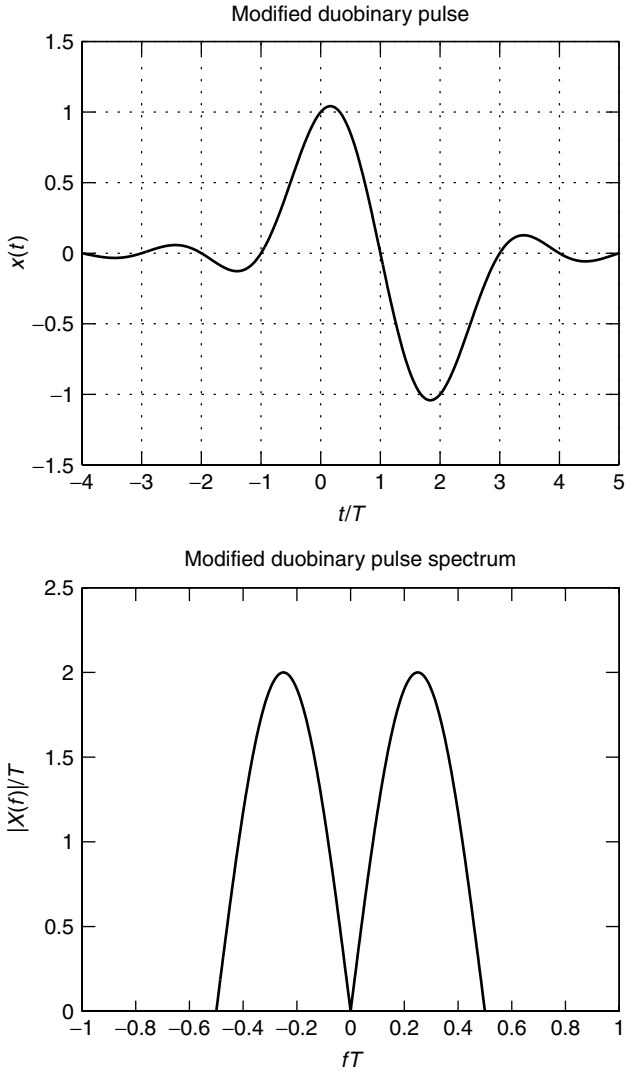

Figure 4. Modified duobinary pulse: (**a**) $x(t)$ in the time domain; (**b**) frequency response $X(f)$.

partial-response maximum likelihood) was one of the main reasons in the impressive increase of recording density, and hence capacity, of the hard disks in the last decade.

2.1. Detection of Partial-Response Signals

Let's examine the detection methods that may be employed for the simplest duobinary partial response signal. From Eqs. (4) and (9) we see that the output of the sampler, which is used as the decision variable, is

$$r_m = I_m + I_{m-1} + v_m$$

If I_{m-1} has already been detected with value I'_{m-1}, then its effect on r_m may be eliminated through subtraction, and hence I_m may be estimated from

$$I'_m = \text{sgn}(r_m - I'_{m-1})$$

where sgn() denotes the sign function, since in a binary scheme the detection rule for a signal with possible values $\{1, -1\}$ is $x > 0?1 : -1$, for zero-mean Gaussian noise. The detected value I'_m can then be used for the detection of I_{m+1} and so on. However, the use of this method can lead to serious error propagation: an error (because of the noise) in the estimate of a particular symbol will adversely affect the estimate of the next symbol and so on.

A technique that may be used to eliminate the dependence on the previous symbol estimate is *precoding*. The binary source sequence d_n is transformed to a new binary sequence p_n through the precoding operation

$$p_n = d_n \ominus p_{n-1} \tag{15}$$

where $\ominus$ denotes modulo-2 subtraction (equivalent to modulo-2 addition). Then the precoded sequence p_n is mapped into the information sequence, $I_n = 2p_n - 1$, that is used for transmission using the duobinary pulse. Using the relationship between d_n, p_n, I_n, and r_n, one can show

Table 1. Example of Precoding for Duobinary Signal

Binary sequence d_n		0	1	1	1	0	0	1	0
Precoded sequence p_n	1	1	0	1	0	0	0	1	1
Information sequence I_n	1	1	−1	1	−1	−1	−1	1	1
Duobinary signal r_n		2	0	0	0	−2	−2	0	2
Estimate d'_n		0	1	1	1	0	0	1	0

that the estimate of d'_m may be obtained as

$$d'_m = \frac{r_m}{2} - 1(\text{modulo } 2) \tag{16}$$

directly from r_m, without any use of the previous symbols. The (noiseless) example presented in Table 1 demonstrates this detection operation. We notice that, according to Eq. (16), values of $r_m = \pm 2$ (which occur with probability $\frac{1}{4}$ each) map to a binary 0 in the original binary source sequence, and the value $r_m = 0$ (which occurs with probability $\frac{1}{2}$) maps to a binary 1. In the case where noise affects the sample r_m the corresponding decision regions will be $|r_m| \geq 1$ and $-1 < r_m < 1$ respectively.

In a similar way, the modified duobinary signal can be detected on a symbol-by-symbol basis, without any dependence on the previous decisions, and hence without any error propagation, by using the precoding operation of

$$p_n = d_n \oplus p_{n-2}$$

The abovementioned precoding techniques may be extended directly from a binary to an M-ary ($M = 2^k$) modulation scheme, by using modulo-M instead of modulo-2 operations.

It can be shown [8] that the performance of a duobinary or modified duobinary scheme that employs a symbol-by-symbol detector is approximately 2.1 dB worse than the performance of a full-response scheme with the same constellation size. However, the symbol-by-symbol detector does not exploit a significant property of the partial-response signal: its memory. As an example, we notice that two consecutive received samples of a valid duobinary signal cannot have the values $2, -2$ or $-2, 2$. However, the symbol-by-symbol detector will not factor this in and will decode the preceding received samples according to the rule of Eq. (16), which will lead to at least one binary error.

There is an estimation method that does factor in the memory present in communication signals and gives the sequence of symbols with the minimum probability of error. This is the maximum-likelihood sequence estimator (MLSE), which can be implemented efficiently using the Viterbi algorithm [9]. This algorithm was first proposed for the decoding of convolutional codes, where the output depends on a finite number of previous inputs, and its use was later extended for systems with finite ISI, either unintentional (channel distortion) or intentional (partial response signals). It uses the squared distance[2] between the received samples and the possible valid sequences, and declares as detected sequence the one having the smallest total squared distance from the received one.

It can be shown that a duobinary or modified duobinary signal with MLSE detection at the receiver has the same performance as a full-response signal. So the MLSE detector does not have the 2.1-dB performance degradation that characterizes the symbol-by-symbol detector. As a side note, we should mention that there were research efforts after the introduction of partial response signaling to evaluate the free Euclidean distance of a *faster-than-Nyquist* scheme [10]. This name has been used for transmission schemes that employ a sinc( ) pulse with zero crossings at $1/T$ (and a bandwidth of $W = 1/2T$), but which are spaced at $T' < T$ (i.e., have a higher baud rate than does the pulse designed for zero ISI). This closer spacing of the sinc pulses leads to ISI, since the sample points for successive symbols no longer correspond to the zero crossing of the pulse. However, it was proved that the minimum Euclidean distance of such a scheme is the same as that of a full-response (no-ISI) system, as long as $T' > 0.802 \cdot T$. Since the use of the ideal rectangular spectrum is not practically realizable and the receiver will have to deal with an infinite series of ISI terms in order to estimate the received sequence, these ideas were just a form of mathematical exercise. However, the underlying principle of the existence of PR schemes that have bandwidth less than the Nyquist rate with a free distance that is the same as a full-response system led to additional research for bandwidth-efficient implementable PR techniques.

3. PARTIAL RESPONSE FOR BANDWIDTH EFFICIENCY

The duobinary and modified duobinary systems that we outlined above were designed with the goal of achieving the Nyquist rate of $W = 1/2T$, with practically implementable filters. Still, one can achieve even better bandwidth efficiency by using a partial response scheme. Since partial response can be viewed as just one form of filtering, one may use a longer filter $x(n)$ to achieve better bandwidth characteristics.

The disadvantage of this approach is the increased intersymbol interference between symbols, due to the longer $x(n)$ that spans $L + 1$ successive samples, where by L we denote the memory of the partial-response scheme.

As noted in a previous section, for received sequences coming from a channel/system with finite memory, the MLSE detector is the optimum one. We noted that the major determining factor for its performance is the minimum Euclidean distance $d_{\min}$ between any two valid sequences.

It can be shown [8] that any partial response system has minimum distance $d_{\min}$ less or equal to a full-response system of the same constellation size and transmitted energy level. Hence, the goal of the partial response scheme is to lose as little performance as possible, while maximizing the bandwidth efficiency. Said and Anderson [8] offered an optimization framework for finding the best partial-response scheme for a certain memory length L; given a constraint on the bandwidth B,

[2] For the case of linear modulation in AWGN the likelihood of a received sample r depends on its squared distance $|r - s|^2$ from the nominal value s to be received.

the partial-response scheme $x(n)$ with the best (largest) $d_{\min}$ would be found; or, given a certain $d_{\min}$ (i.e., a given performance level) the partial-response scheme $x(n)$ with the best bandwidth characteristics B would be found.

Besides the potential loss in $d_{\min}$, there is a second disadvantage associated with such a partial-response scheme, namely, the complexity of its receiver. An MLSE, implemented through a Viterbi algorithm (VA), has complexity quite bigger than the slice-and-quantize operation of a full-response receiver for an M-ary PAM. The MLSE complexity grows proportionally to the number of states in the finite memory system to which the PR scheme is equivalent. The number of states is equal to 2^{ML}, where L is the memory of the PR scheme and M is the constellation size. So for large constellation sizes (where the advantages of a smaller-bandwidth scheme are more easily exhibited), or for longer filters $x(n)$ (which give better bandwidth efficiency), the complexity issue makes implementation problematic. To overcome this disadvantage, reduced-complexity schemes, such as *reduced-state sequence estimation* (RSSE) [11,12], were proposed. These schemes were originally proposed for the traditional channel ISI problem, of which partial response is a special case. It was shown that with careful design and state reduction choices these schemes can offer performance very close to MLSE with significant computational cost savings.

Using these ideas, practical PR schemes were found [13], with bandwidth occupancy $B \approx 0.35 \cdot 1/T$ (roughly half of the bandwidth of a realizable full-response system), which exhibits a performance penalty of $<2-3$ dB compared to an equivalent (same constellation size) FR scheme. However, because of its much better bandwidth characteristics, the symbol (baud) rate of the PR scheme can be increased w.r.t. (with respect to) to the FR scheme, while still satisfying spectral occupancy constraints. If the bandwidth of the full-response scheme is $B_{\mathrm{FR}} = 0.7 \cdot 1/T_{\mathrm{FR}} = 1.4 \cdot 1/2T_{\mathrm{FR}}$ (raised cosine with 40% rolloff), and the bandwidth of the PR scheme is $B_{\mathrm{FR}} = 0.35 \cdot 1/T_{\mathrm{PR}}$, then the symbol rate of the PR scheme can be increased to twice that of the full response scheme: $1/T_{\mathrm{PR}} = 2 \cdot 1/T_{\mathrm{FR}}$. This will allow the use of PR scheme with a constellation size of $M^{1/2}$, if the full-response scheme is M-ary, which for moderate to large M more than compensates — due to the increased distance, and hence noise immunity, between energy levels — for the performance penalty paid for the ISI between symbols.

4. LINE CODING: MODULATION SIGNALS WITH MEMORY

A more generalized form of partial-response signaling is employed in modulation systems that are used mainly for high-speed baseband transmission, and their purpose is to shape the spectrum of the transmitted signal to match the spectral characteristics of the channel. The way to shape the spectrum is typically through the introduction of restrictions, namely, memory, on the generator pulse. These techniques are usually called *transmission line coding* or *modulation coding*. We should make the distinction here between the above type of coding, where correlation between transmitted symbols is introduced, and the more usual notion of coding that involves an increase in the bit rate between the source data sequence and the line sequence. In the latter case, the code typically encodes k source bits into n transmitted bits (code rate $R = k/n < 1$), and the receiver use this redundancy to detect and correct errors. These are called *channel coding* or *error correction* techniques, and they are different from modulation coding techniques.

Focusing on transmission line codes, we depict in Fig. 5, some of the most commonly employed ones.

The first, and probably simplest, modulation scheme for baseband transmission is the *non-return-to-zero* (NRZ) method. In NRZ a binary $d_k = 1$ is mapped into a square waveform of amplitude +A, and a binary $d_k = 0$ is mapped into a square waveform of amplitude −A. Actually, this scheme is a memoryless system, equivalent to binary PAM transmission. It does not pose any demodulation problems, but it is not suitable for spectrum shaping because of its lack of correlation between symbols. Furthermore, it does not offer another desirable property for baseband transmission — it does not guarantee a minimum rate for pulse transitions, since a sequence of multiple 1s (or 0s) leads to a constant voltage signal throughout its duration. Pulse transitions are necessary for deriving timing and synchronization from the received signal at the receiver.

Numerous slight variations of the NRZ scheme exist. The system that is described above is also called by some authors a *(bi)polar NRZ scheme*, to distinguish it from a unipolar NRZ scheme, where the two amplitude levels are $[+A, 0]$ instead of $[+A, -A]$ of bipolar NRZ. The unipolar NRZ scheme has a more pronounced DC component than the bipolar one, and is used less in practise.

Another memoryless system is the *return-to-zero* (RZ) method. In this system, the basic square pulse (of amplitude $[+A, -A]$, for binary $d_k = 1$, 0 respectively) returns to 0 for the second half of the symbol duration, so it has a 50% duty cycle. The return to 0 guarantees voltage transitions at a rate of $2/T$, thus eliminating

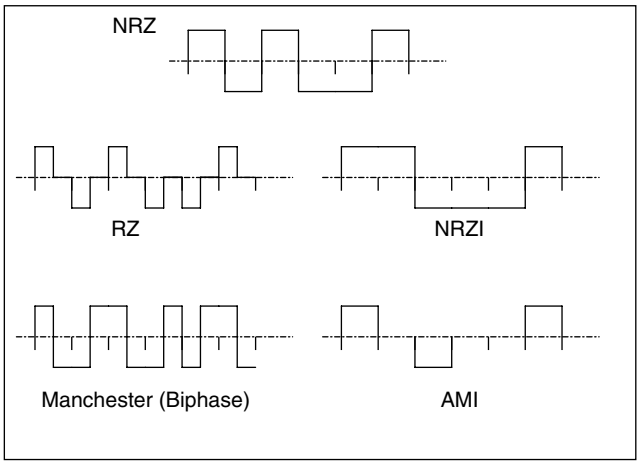

Figure 5. Examples of line coding techniques: NRZ, RZ, Manchester, NRZI, AMI (all mapping the binary information sequence [1, 0, 1, 0, 0, 1]).

the timing/synchronization problems that an NRZ scheme might have. However, its narrower pulses occupy a larger bandwidth, and this is a serious disadvantage for an RZ scheme.

Similar to the RZ scheme is biphase (or Manchester) encoding, which employs a square wave of period T that transitions from $+$A to $-$A (instead of to 0, like the RZ scheme) at the middle of the symbol interval. The abovementioned pulse is used for a binary $d_k = 1$, while its antipodal pulse is used for 0. Although relatively bandwidth-inefficient, the Manchester scheme is used in some practical systems, including some Ethernet and TTY applications, because of its lack of DC, and timing information provision.

A line code that employs memory in its waveform generation is the *non-return-to-zero, inverse* (NRZI) scheme. This employs the same basic pulse as the NRZ scheme, but with the transitions from one amplitude level to the other happening when the information bit is $d_k = 1$, and the previous symbol level is retained when $d_k = 0$. NRZI can be directly generated from NRZ, if the actual data sequence is passed through a precoder of the form $p_k = p_{k-1} \oplus d_k$, and then p_k is used to generate the transmitted waveform through NRZ. NRZI is used in magnetic recording systems, since it has good bandwidth characteristics and no DC component. However, it presents the usual problem of no guaranteed timing information, if many consecutive 0's appear in the data sequence.

Finally, another line coding technique with memory is *alternate mark inversion* (AMI). An AMI waveform employs zero voltage/amplitude for a binary 0, while it employs a square pulse of alternating amplitude for binary 1s, so if the previous 1 bit were sent using $-$A voltage, the next 1 bit would be sent using a pulse with $+$A voltage. AMI has good bandwidth characteristics and no DC component, and its memory offers some elementary error detection capabilities, since two consecutive pulses of the same sign (with any number of zero-voltage symbols in between them) mean that an error has occurred. Although AMI might present the receiver with timing/synchronization problems when multiple consecutive 0s exist in the transmitted sequence, it is a widely employed scheme, especially in T1/T3 trunklines.

The problem of the transmitted waveform being constant for many symbols, if multiple consecutive 0s are being transmitted, that practical NRZI and AMI schemes face is addressed in two ways.

1. The first one is to introduce codes that operate on the binary source sequence and generate a channel sequence with a restriction in the maximum number of successive zeros. Typically this technique is used in conjunction with NRZI in magnetic recording systems. These codes usually impose an additional restriction in the minimum number of 0s between two 1s in a sequence, and this is used to increase the distance (and, hence, reduce interference) between pulse transitions. These codes are known as *runlength-limited codes* (RLL codes), and have a code rate of less than 1; that is, they introduce redundancy. A good tutorial paper on them has been written by Immink [22].
2. The second technique to address the consecutive 0s problem is used in conjunction with AMI. We have seen that AMI offers some basic error detection, since two successive (ignoring intermediate 0s) pulses of the same polarity do not correspond to a valid input sequence. The idea for the second technique is to replace a string of consecutive zeros with a string that violates the AMI principle (and contains pulse transitions). The receiver will detect the "error" condition, and, since the received string has a predetermined pattern, it will substitute the original string of all zeros in its place. This way both sufficient timing information is available, and the original data are not lost.

The class of these codes is usually denoted as *binary bipolar with n zero substitution* (BnZS). A common one is B8ZS: a pattern of 8 zeros is replaced by a string where the bits 4 and 7 violate the bipolar principle. Let's take as an example the string $+(00000000)0-\cdots$, where $+$ stands for amplitude A, $-$ stands for amplitude $-$A (both correspond to 1s in the information sequence), and 0 is zero amplitude (0s in the information sequence). This string is a valid bipolar sequence, since the two consecutive nonzero pulses have opposite polarity. The B8ZS code replaces the constant string of 8 zeros (inside parentheses) by the string with the two bipolar violations (BPV) resulting in the transmitted string of $+(000+-0-+)0-\cdots$. The receiver, on detecting the two BPVs at the specified locations, replaces the 8 bits with all zeros, and the original sequence is restored. If the most recent pulse sign before the 8-zero string is negative, then the replacement string will be $(000-+0+-)$ in order to give the two BPVs at bits 4 and 7. The B8ZS scheme is employed by many commercial carriers. A similar, but simpler, scheme is the B6ZS code, where 6 consecutive 0s are replaced by a string with bipolar violation at the second and fifth bits (i.e., the B8ZS scheme, without the two first initial zero bits).

Another two members of the BnZS family are the B3ZS and B4ZS codes, which are very similar. Let's examine B4ZS [which is widely used, and is also called *high-density bipolar 3* (HDB3)]. Here, a string of four zeros is replaced by the string B00V or 000V, where B stands for a pulse that satisfies the bipolar rule, while V is a pulse violating the rule. The choice between these two strings is made such that the number of pulses satisfying the bipolar rule between violations is odd. As an example, suppose that we have the string $+(0000)0-0+\cdots$, and the number of valid pulses after the last (not shown) violation is even. Then, the marked four 0s will be replaced by B00V, because the first bit (valid pulse) will make for an odd number of valid pulses between the last violation and the current one. Hence, the transmitted string will be $+(-00-)0+0-\cdots$. Note that, contrary to B8ZS, the B4ZS code does affect the polarity of the subsequent nonzero pulses. The B3ZS scheme is the same as B4ZS, but with three consecutive zeros replaced by either B0V or 00V patterns (again, with an odd number of valid B pulses between successive V violations).

5. NOTES ON THE LITERATURE

Partial-response systems were first proposed by Lender [3], and later extended by Kretzmer [4], Pasupathy [6], and others. Faster-than-Nyquist signaling was investigated by Mazo [15], Foschini [10], and Hajela [16].

The combination of partial response with TCM encoding was investigated by Wolf and Ungerboeck [17], Ketchum [18], and Forney and Calderbank [19].

The use of partial-response shaping in magnetic recording systems is covered in various papers. As an example we mention the papers by Cideciyan et al. [7], and Tyner and Proakis [20], where additional references in the evolution of PRML systems can be found. Typically nowadays, the target response in a PRML system is a *generalized* partial-response scheme, which is the product of the modified duobinary with a system of the form $(1+D)^n$. A tutorial paper on the general issue of coding for magnetic recording channels was written by Immink et al. [21].

A paper that surveys the use of modulation coding in copper wire subscriber lines was published by Lechleider [22], while a good reference for BnZS and other currently employed line coding techniques is the one by Bellamy [23].

The correlation between a PR system and precoding techniques to combat ISI in a decision feedback equalization scheme can be found in the paper by Forney and Eyuboglu [24] and references cited therein. A paper that covers the state of partial response signaling is the one by Said and Anderson [8], while a typical implementation of a PR system for a copper cable channel is given in [25].

BIOGRAPHY

Apostolos D. Rizos received the B.S. degree in physics from the University of Athens, Athens, Greece, and the M.S.E.E. and Ph.D. degrees in electrical engineering from Northeastern University, Boston. Since 1999, he has been with AWARE Inc., Bedford, Massachusetts, where he is a Senior DSP Engineer, working on algorithms for DSL modems. Before that, he was a technical consultant with Delphi Communication Systems, Maynard, Massachusetts, working on underwater acoustic modems. His interests lie in modulation and coding for communication systems, and computationally efficient algorithm implementations.

PATH LOSS PREDICTION MODELS IN CELLULAR COMMUNICATION CHANNELS

H. L. BERTONI

Brooklyn, New York

1. INTRODUCTION

Modern wireless services involve two-way transmission of individual signals, rather than one-way broadcast of the same signal to many listeners. In order to accommodate many users for such services in an allocated frequency band, the concept of spatial frequency reuse was developed. The simplest implementation of frequency reuse involves spatial separation of the simultaneous use of the same frequency channel linking subscribers with their nearest access point (or base station). By keeping the interference just low enough to achieve a desired quality of service, the subscribers can be accommodated with a minimum of physical infrastructure. In other words, using the smallest distance possible between cochannel cells allows for the most channels per base station. The conflicting requirements of achieving radio coverage, while maintaining the desired limit to interference, places a premium on accurate methods for prediction of the received radio signal strength and other channel characteristics. A survey of many of the characteristics can be found in Refs. 1 and 2.

One approach to understanding the channel characteristics is to make measurements over a wide range of system parameters, such as frequency and bandwidth, antenna height, and distance between antennas [3–5]. The measurement results can be reduced to best-fit formulas that give the system parameter dependence in a way that is simple to use in prediction software [6–8]. Because most subscribers live in cities, it is important to measure these quantities in different building environments. An alternative approach is to use theoretical methods for predicting radiowave propagation; the most common are ray optics and the uniform theory of diffraction (UTD). In this article we discuss only the theoretical methods for predicting the path loss (or path gain), and compare them with measurement-based models. The prediction of other channel characteristics can be found elsewhere [1,9].

Path gain PG is defined as the ratio of the received signal strength to the total radiated power. The commonly used term "path loss" refers to the reciprocal of path gain, and is usually expressed in decibels. As an example, for antennas located in free space the path gain is given by

$$PG_0 = \left(\frac{\lambda}{4\pi R}\right)^2 g_1 g_2 \tag{1}$$

where R is the separation between antennas, λ is the wavelength, and g_1 and g_2 are the directive antenna gains. It is often convenient to consider the path gain between idealized isotropic antennas for which $g_1, g_2 = 1$. Provided that the carrier frequency is the same, reciprocity of Maxwell's equations implies that the path gain is the same, no matter which end of the wireless link is the transmitter and which is the receiver.

2. RAY CONCEPTS FOR UNDERSTANDING AND PREDICTING PROPAGATION

Modern wireless systems use UHF (300 MHz–3 GHz) and microwave radiolinks to connect base station antennas and subscribers located between the buildings, or even inside buildings. Thus the buildings have a major influence on the received signal. Since the wavelength λ at these frequencies is small compared to the building size, it is appropriate to think of the radiowaves as traveling along rays radiated in all directions by the source. The rays travel along straight lines until they encounter the buildings or ground where they are reflected according to the laws of geometric optics (GO). A ray incident on a building edge or corner creates a family of diffracted rays propagating away from the edge in a cone whose half-angle is equal to the angle between the incident ray and the edge, as described by the uniform theory of diffraction (UTD) [10]. The influence of each interaction on the ray fields is contained in a reflection or diffraction coefficient, together with an algebraic dependence on the length of the ray segments that conserves energy within a tube of neighboring rays. Subsequent ray encounters with buildings act in cascade. Thus, rays connecting base station antenna and subscriber may be multiply reflected by the building walls, and/or diffracted at the corners and rooftops, as suggested in Fig. 1 for propagation from the base station antenna to the subscriber.

The ray segments reaching the subscriber come from all directions in the horizontal plane, and a wedge of angles in the vertical direction. Reciprocity of Maxwell's equations implies that the same ray paths, with arrows reversed, apply for propagation from the subscriber to the base station antenna. For an elevated base station, as shown in Fig. 1, the arriving rays come from limited wedge of angles. However, base station antennas located below the rooftops will receive rays coming from all directions in the horizontal plane.

Each ray carries a copy of the transmitted symbol bit $p(t)$ that is delayed by the path length L_j divided by the speed of light c, and has complex amplitude A_j. The received voltage at location x along a street is the sum of

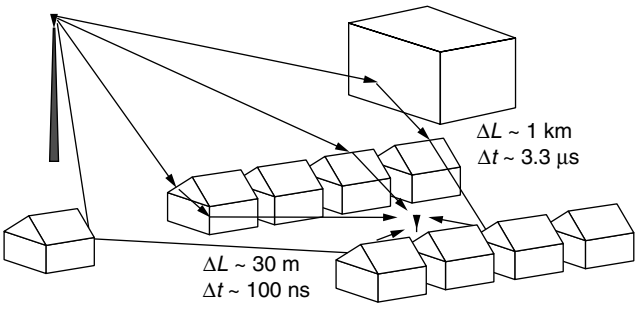

Figure 1. Multiple ray paths by which signals propagate from an elevated base station to a subscriber at street level. (©2002 by H. L. Bertoni.)

the ray contributions

$$V(x)e^{j\omega t} = \sum_j A_j p(f - L_j/c)e^{j\omega(t-L_j/c)} \qquad (2)$$

where c is the speed of light and $\omega = 2\pi f$. Because the differences in path length ΔL of the various rays reflected from objects near to the mobile are on the order of the street width, which is on the order of 30 m, the time difference for this cluster of rays is on the order of 100 ns. In addition, rays from the base station may be reflected from large structures at a greater distance before arriving at the building in the vicinity of the subscriber. Such paths may have delays on the order of 1 μs, followed by additional delays due to scattering in the vicinity of the subscriber, which results in another cluster of rays arriving at the subscriber. Figure 2 is an example of the time-delay profile of the signal received during wideband pulsed measurements made in Paris at 890 MHz with an omnidirectional receiving antenna and a system time resolution of 0.1 μs [11]. Echos with significant amplitude are received with time delays up to about 5 μs.

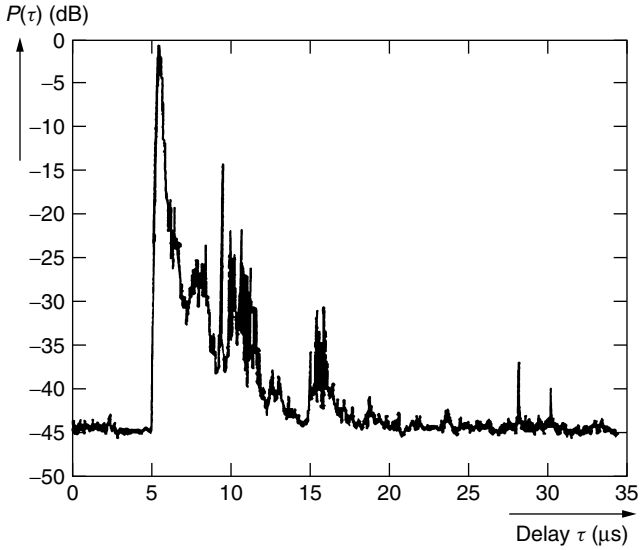

Figure 2. Time-delay profile of a pulsed signal in the 890-MHz band measured in Paris showing significant arrivals at up to 5 μs. (From Ref. 11, with permission.)

For systems whose bandwidth BW is small enough so that individual ray signals overlap in time ($1/BW \gg \Delta L/c$), all terms in (2) can be approximated using $p(t - L_j/c) \approx p(t - R/c)$, where R is the distance from the base station. In this case the rays arriving in all directions at the subscriber add coherently and generate a standing wave or interference pattern in space. The rapidly varying curve in Fig. 3 is a plot of the total received power as a function of the position x of a vehicle that is non-line-of-sight (NLoS) of the base station [12]. The amplitude is seen to undergo variations of up to 20 dB over distances on the order of one half the wavelength λ, which at 910 MHz is about $\frac{1}{3}$ m. In a moving vehicle, this spatial variation is perceived as a rapid time variation, which has led to the term "fast fading." Taking a sliding average of the received power over a distance of about 10–20λ smooths out the rapid fluctuation, as shown in Fig. 3, and is known as the small-area average.

The small average in Fig. 3 is seen to vary by about ±6 dB from the overall average, and variation has a scale length of 5–10 m. This variation is often referred to as "slow fading" or "shadow loss" since it results from shadowing by buildings, trees, and other objects. Finally, for outdoor or indoor links, the signal amplitude shows a systematic dependence on the distance or range R between base station and subscriber. Typically, measurements of the small-area average are plotted in dB against $\log R$, and a linear regression line is fit to the measurements. The regression fit gives the range dependence, as discussed in a later section, while the deviation from the regression line is interpreted as the shadow fading.

The sliding average of power is proportional to the spatial average $\langle |V(x)|^2 \rangle$ of the voltage in Eq. (2). Since the ray amplitudes A_j are slowly varying functions of distance x, and since the pulse duration ($1/BW$) is typically long compared to the time difference over the averaging interval of about $20\lambda/c = 20/f$, the sliding average is therefore

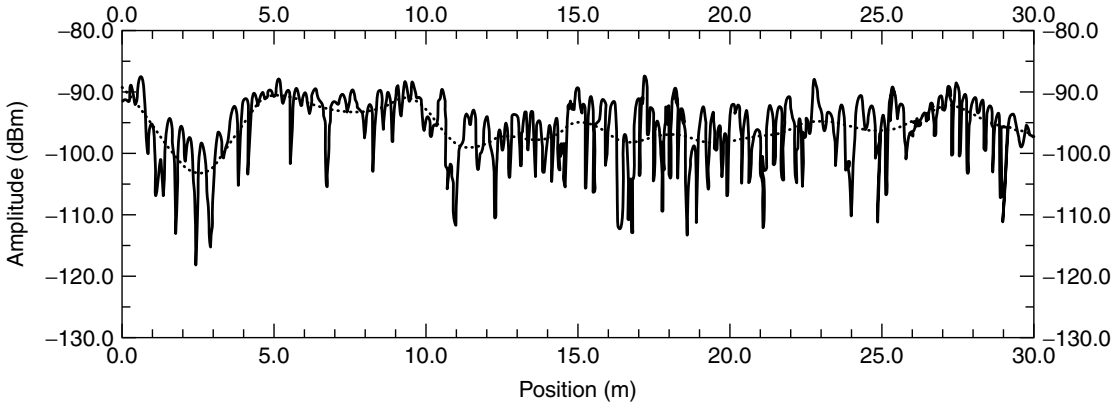

Figure 3. Narrowband [continuous-wave (CW)] measured signal variation, and the sliding average, as a function of distance along a street for non-LOS conditions. (From Ref. 12, with permission.)

given by

$$\langle |V(x)|^2 \rangle = \sum_{j,k} A_j A_k^* p(t - L_j/c) p^*(t - L_k/c) \langle e^{-j\omega(L_j - L_k)/c} \rangle$$
$$\approx \sum_j |A_j|^2 |p(t - L_j/c)|^2 \quad (3)$$

The final approximation in this equation is obtained by recognizing that the phase differences $\omega(L_j - L_k)/c$ for $j \neq k$ go through 2π variations due to changes in the pathlengths L_j with distance x along the street. As a result, the spatial average of the exponential vanishes for $j \neq k$. Thus the spatial average power is equal to the sum of the ray powers. For each symbol bit, the total received energy is found by integrating (3) over time, and is seen to be proportional to $\sum |A_j|^2$. Thus the total bit energy is proportional to the sum of the ray powers. Again for narrow band systems $|p(t - L_j/c)|^2 \approx |p(t - R/c)|^2$ and the time variation can be taken outside of the summation in (3).

3. TWO-RAY MODEL FOR FLAT EARTH

The simplest propagation environment occurs when there is only flat earth between the base station and the subscriber. In this case the received signal can be computed from the two-ray model consisting of a direct ray and a ground-reflected ray, as shown in Fig. 4. Because the two ray paths are of nearly equal length, it is necessary to add the ray fields coherently, and not simply add the ray powers [13]. For isotropic antennas the path gain of the two-ray model is given by [13]

$$PG = \left(\frac{\lambda}{4\pi}\right)^2 \left| \frac{e^{-jkr_1}}{r_1} + \Gamma(\theta) \frac{e^{-jkr_2}}{r_2} \right|^2 \quad (4)$$

where r_1 is the direct distance from the transmitter to the receiver, r_2 is the distance through reflection point. The Fresnel reflection coefficient $\Gamma(\theta)$ depends on the angle of incidence θ and the polarization, and is given by

$$\Gamma(\theta) = \frac{\cos\theta - a\sqrt{\varepsilon_r - \sin^2(\theta)}}{\cos\theta + a\sqrt{\varepsilon_r - \sin^2(\theta)}} \quad (5)$$

Here $a = 1/\varepsilon_r$ for vertical polarization and $a = 1$ for horizontal polarization, where ε_r is the relative dielectric constant of the ground. For average ground, the relative dielectric constant is $\varepsilon_r = 15 - i60\sigma\lambda$, and the conductivity σ is around 0.005 mho/m [13]. As the distance between the transmitter and receiver increases, the angle θ approaches 90°, the reflection coefficient Γ approaches -1 and r_2 approaches r_1.

Measured path loss between vertically polarized dipoles and between vertically polarized bicones is shown in Fig. 5 when the antennas are located along a flat road whose only features are low vegetation and wooden telephone poles [13]. For comparison, the dashed curve in Fig. 5 is a plot of the signal predicted by (4) for vertical polarization. For small horizontal separation $R < 10$ m, the antenna patterns have an influence on the measurements. However, for $R > 10$ m, only the antenna gains are important and they result in a vertical offset of the curves (the signal for dipoles is few decibels greater than for isotropic antennas, and for bicones it is a few decibels smaller).

Using a logarithmic scale for the horizontal separation R, as in Fig. 5, the received power is seen to vary about straight lines having two distinct slopes separated by a breakpoint R_B. Before the R_B, the radio signal oscillates severely as a result of alternating regions of destructive and constructive combination of the two rays, while after the R_B it decreases more rapidly with distance. The breakpoint lies near the last peak in the two-ray model, at a distance $R_B = 4h_1h_2/\lambda$, where h_1, h_2 are the antenna heights [1]. Well beyond the breakpoint distance the path gain of (4) reduces to

$$PG = \frac{h_1^2 h_2^2}{4R^4} \quad (6)$$

so that the received signal decreases more rapidly than the $1/R^2$ dependence of free space.

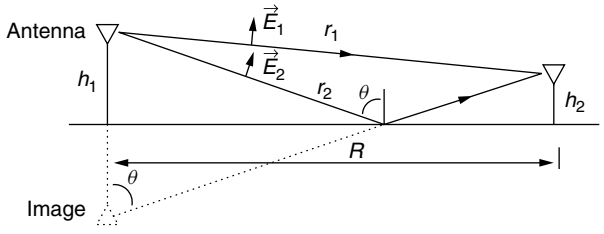

Figure 4. Propagation over flat earth as described by the two ray model. The ground reflected ray appears to come from the image of the source. For large R, the fields of both rays are nearly parallel.

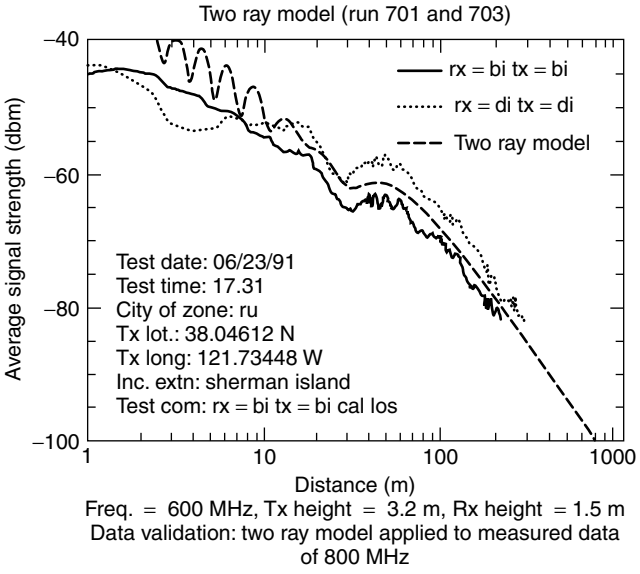

Figure 5. Measured and predicted variations of the received signal for propagation over flat earth for antennas of height 3.2 and 1.6 m at 800 MHz. (From Ref. 13, with permission.)

The two-ray model also serves as a basis for understanding the received signal when the two antennas are located within a line of sight along a street in an urban environment. In this case the direct and ground reflected rays give the dominant contributions, while additional contributions come from rays that are reflected by the buildings lining the streets. Building-reflected rays result in additional rapid variations about the simple two-ray model, but do not change the overall variation. Accounting for a single reflection in the building walls and ground reflection leads to the six-ray model, which has been used to obtain the plot of Fig. 6. Similar results are obtained from measurements in urban environments [1,14].

4. PROPAGATION OVER BUILDINGS IN RESIDENTIAL ENVIRONMENTS

In residential sections of cities, and in suburban regions, the buildings are of more or less uniform height, and the propagation may take place past many rows of buildings between the base station and subscriber. For base station antennas near to or above the rooftops, the radiowaves to a subscriber will propagate primarily over the rooftops, except for subscribers on the few streets aligned with the base station. Signals propagating through the buildings are highly attenuated by the exterior and interior walls. Except in the distant suburbs, the gaps between buildings are small and are seldom aligned with the base station, or aligned from row to row.

To predict the range dependence of the spatial average path gain for macrocells, the individual buildings in a row are replaced by a continuous smooth obstacle, as seen in the end view in Fig. 7. All rows are assumed to have the same height, and each row of buildings is separated by the same distance d. Using this model of the buildings, the mean path gain PG is the product of three factors [1]:

$$PG = (PG_0)(Q^2)(PG_2) \tag{7}$$

Here, PG_0 is the free-space path gain given by Eq. (1). The term Q in (7) is the reduction of the fields arriving at the buildings near to the mobile as a result of diffraction past the previous rows of buildings. The term PG_2 represents the signal resulting from diffraction from the rooftops down to ground level. These two terms are discussed in more detail below.

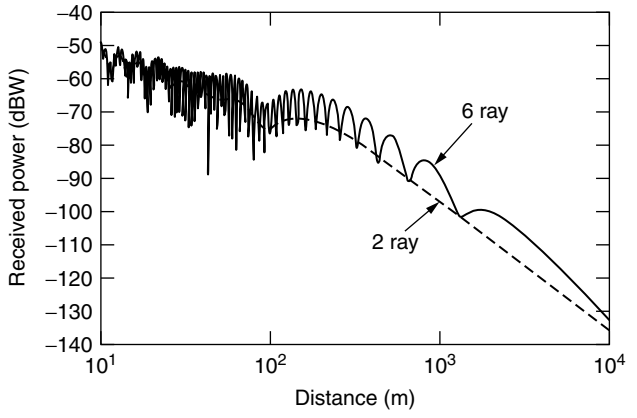

Figure 6. Comparison of the predictions of the two-ray model and the six ray model accounting for reflections form the buildings lining a street, as well as reflections from the ground. (© 1999 by H. L. Bertoni.)

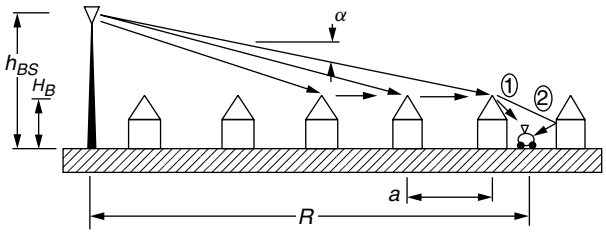

Figure 7. Side view of propagation over the rooftops to the last building before the subscriber and subsequent diffraction down to street level.

4.1. Q: Reduction of the Rooftop Fields

Except close to the base station, the horizontal distance from the base station to the buildings around the subscriber is large compared to the elevation of the base station antenna above the average building height. As a result, the glancing angle α shown in Fig. 7 is given by

$$\alpha = \tan^{-1}\left(\frac{h_{BS} - H_B}{R}\right) \approx \frac{h_{BS} - H_B}{R} \tag{8}$$

where h_{BS} is the base station height and H_B is the average building height. Provided that α is small, the radiowave propagating from the base station to the rooftops near the subscriber will undergo a cascade of multiple diffraction events at all of the previous rows of buildings. The mathematical treatment of multiple diffraction can be found in Ref. 1, while the simpler results are presented here.

A simple case occurs when the rooftops are all of the same height, the rows of buildings are all separated by the same distance d, and the base station antenna is at the same height as the rooftops. In this case the additional loss of the field reaching the Mth row of buildings from the base station is $Q = 1/M$ [1]. Because $M \approx R/d$, when (1) and $Q = 1/M$ are substituted into (7), the path gain is found to vary with distance as $PG \propto 1/R^4$, which is like the dependence for large separations of antennas above a flat earth. However, the proportionality constant for PG, and its dependence on frequency and antenna height will be different in the two cases.

When the base station antenna is well above the rooftops, as is the case for macrocellular applications, relatively simple expressions can again be found for Q. In this case the number of rows of buildings crossed by the radiowave is large and the glancing angle α is small. For example, in older cities the row separation is $d = 50$ m, so that 40 rows are crossed when the signal propagates to a distance of $R = 2$ km. In this case the reduction of the rooftop fields due to diffraction by previous rows of buildings can be expressed in terms of the parameter g_p, which is defined by

$$g_p = \alpha\sqrt{\frac{d}{\lambda}} \tag{9}$$

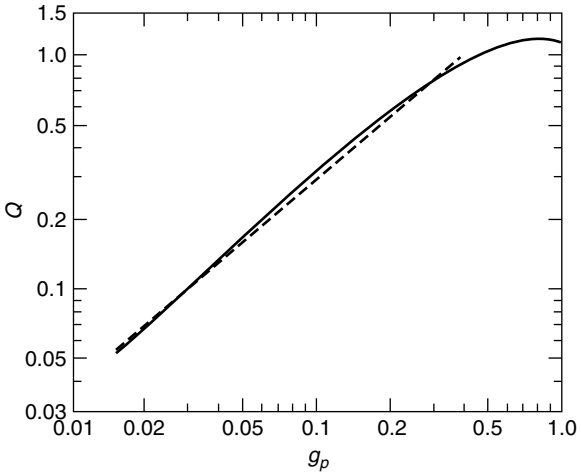

Figure 8. Dependence of the reduction of the rooftop fields Q on the dimensionless parameter g_p. The dashed line gives the simple approximation. (From Ref. 15, with permission.)

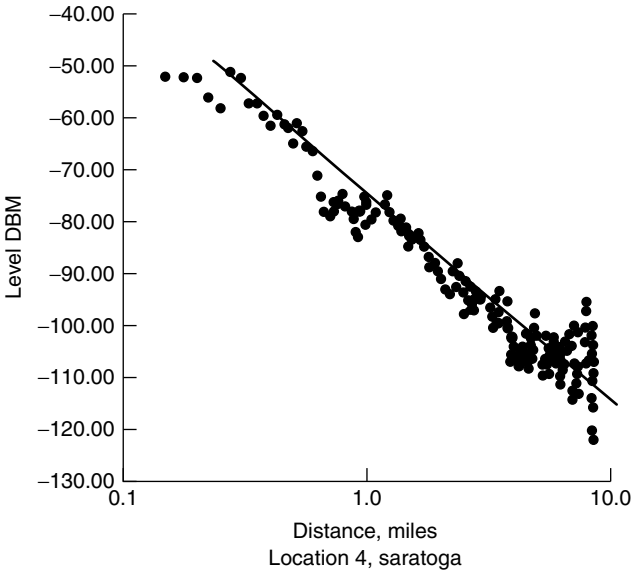

Figure 9. Measured small-area average power in dBm (dots) plotted versus R on a logarithmic scale. The solid line represents the theoretical prediction. (From Ref. 15, with permission.)

for propagation perpendicular to the rows of buildings. The variation of $Q(g_p)$ with g_p is plotted in Fig. 8 [15], and can be expressed in terms of a third order polynomial.

For large angles α, such as on satellite links, $g_p > 1$ and $Q(g_p) \approx 1$ so that only the last row of buildings before the mobile affects the received signal. A simple approximation to $Q(g_p)$ is given by the straight line shown dashed in Fig. 8. This approximation is given by

$$Q(g_p) = 2.35\, g_p^{0.9} \tag{10}$$

and is accurate to within 0.8 dB over the range $0.01 < g_p < 0.4$ [1].

4.2. PG_2: Diffraction from Rooftop to Ground Level

Many diffraction paths exist whereby the waves above the buildings reach ground level. In Fig. 7 the two rays giving the major contribution are as shown. The first of these is diffracted from the rooftop of the building nearest the mobile in the direction of the base station, while the second is reflected from the face of the building across the street. The field resulting from diffraction at the building edge is in the form of a cylindrical wave, with the edge acting as an equivalent line source. Because of the rapid spatial variation resulting from the interference of the two waves, the spatial average power will be the sum of the individual ray powers. With the foregoing assumptions, the spatial average received power is given by

$$PG_2 = \left[\frac{1}{\rho_1}|D(\theta_1)|^2 + |\Gamma|^2\frac{1}{\rho_2}|D(\theta_2)|^2\right] \tag{11}$$

where Γ is the reflection coefficient of the building opposite to the mobile, $k = 2\pi/\lambda$ and $D(\theta_i)$ is the diffraction coefficient.

For a receiver in the middle of the street, the distances ρ_1 and ρ_2 in from the diffracting edge (Fig. 9) are given by

$$\begin{aligned}\rho_1 &= \sqrt{(H_B - h_m)^2 + x^2}\\ \rho_2 &= \sqrt{(H_B - h_m)^2 + (2d - w - x)^2}\end{aligned} \tag{12}$$

while the angles θ_i for $i = 1, 2$ are

$$\theta_i = \arcsin\frac{(H_B - h_m)}{\rho_i} \tag{13}$$

In these expressions, H_B is the building height, h_m is the mobile height, w is the front-to-back dimension of the building, and x is the distance of the receiver from the diffracting edge of the building just before the mobile.

The diffraction coefficient $D(\theta_i)$ in Eq. (11) depends on the boundary condition at the rooftop edge of the building, which is rarely known. However, for diffraction angles θ_i away from 90°, the diffraction coefficient is not very sensitive to the boundary conditions. Thus we may use the diffraction coefficient for an absorbing edge, which for propagation perpendicular to the rows of buildings is [1]

$$D(\theta_i) = \frac{1}{\sqrt{2\pi k}}\left(\frac{1}{\theta_i - \alpha} + \frac{1}{2\pi + \theta_i - \alpha}\right) \approx \frac{1}{\sqrt{2\pi k}}\frac{1}{\theta_i} \tag{14}$$

We can simplify (11) by accounting for Γ, which for common building materials is $\Gamma \approx 0.3$. The value of Γ compensates for the differences in sizes of $D(\theta_1)/\sqrt{\rho_1}$ and $D(\theta_2)/\sqrt{\rho_2}$, so that the second term is close to the first term. The near equality of the two terms is seen from the deep fades observed in the fast fading pattern. Thus, the path gain for diffraction down to street level can be rewritten as

$$PG_2 \approx \frac{2}{\rho_1}[D(\theta_1)]^2 \approx \frac{1}{\pi k}\frac{1}{\rho_1\theta_1^2} \approx \frac{1}{\pi k}\frac{d/2}{(H_B - h_m)^2} \tag{15}$$

The variation of (11) with x has been validated by measurements in Japan [16] and England [17].

4.3. Path Gain for Macrocells

Macrocells in cities have $h_{BS} - H_B \sim 10$ m and 1 km $< R <$ 10 km. Since $d \approx 50$ m, the value of g_p falls in the range

0.015–0.15 at 900 MHz and 0.021–0.21 at 1800 MHz, so that we may use expression (12) for $Q(g_p)$. Combining expressions (1), (8), (9), (12), and (15) into (7), the path gain for isotropic antennas can be expressed in decibels as

$$PG_{dB} = 10\log\left(\frac{\lambda}{4\pi R}\right)^2 + 10\log\left[(2.35)^2\left(\frac{h_{BS}-H_B}{R}\right)^{1.8} \times \left(\frac{d}{\lambda}\right)^{0.9}\right] + 10\log\left[\frac{d/(2\pi k)}{(H_B-h_m)^2}\right] \quad (16)$$

Substituting $k = 2\pi/\lambda$ and $\lambda = c/f$, combining the various constant terms in (14) and expressing the frequency f_M in megahertz, the range R_k in kilometers, the path gain, can be written as

$$PG_{dB} = -92.5 - 21\log f_M + 10\log\left[\frac{d^{1.9}(h_{BS}-H_B)^{1.8}}{(H_B-h_m)^2}\right] - 38\log R_k \quad (17)$$

It is seen from (15) that the R dependence of Q combines with the free-space path to give the overall range dependence of 38 log R_k, corresponding to a range index $n = 3.8$ that is close to values measured in North American cities [4]. As a result of the near cancellation of the frequency dependence in Q^2 and PG_2, the path gain is seen to vary inversely with frequency to the 2.1 power, which is nearly that of the free-space path gain.

The predictions given by (17) for the received signal are shown in Fig. 9 superimposed on the small area average received power (dots) measured in Philadelphia [4]. The horizontal range is plotted on a logarithmic scale, for which (17) plots as a straight line. Excellent agreement is seen with the slope index of propagation and the average signal level. The deviations of the small area averages in Fig. 9 from the straight line correspond to the shadow fading. This deviation can be modeled in terms of the differences in building height along the rows; gaps between buildings, including street intersections; and the presence of trees [1,17].

4.4. Measurement-Based Models

In designing the original CMR systems, extensive measurements of the small-area average power versus R were made by various groups around the world. Okumura et al. [3] made an extensive set of measurements in and around Tokyo. Their work examined the effects of base station antenna height, frequency, building environment, terrain roughness, and other factors on the range dependence of the received signal, which was presented as curves of median received field strength (proportional to voltage) versus R for various parameters. Subsequently, Hata [4] fitted curves with simple formulas based on the slope intercept form $L = -10\log A + 10n\log R$ for the path loss L in decibels between isotropic antennas. Recall that the path loss in decibels is the negative of PG_{dB}. Hata's formulas were made to fit the measurements over the range of parameters: $150 \le f_M \le 1{,}500$ MHz, $1 \le R_k \le 20$ km, $30 \le h_{BS} \le 200$ m, and $1 \le h_m \le 10$ m. Over this range the result for urban areas is

$$L = 69.55 + 26.16\log f_M - 13.82\log h_{BS} - a(h_m) + (44.9 - 6.55\log h_{BS})\log R_k \quad (18)$$

The term $a(h_m)$ gives the dependence of path loss on subscriber antenna height, and is defined such that $a(1.5) = 0$.

To compare the predictions of (17) with (18), assume that $f_M = 1000$ MHz, $H_B = 10$ m (3 stories), $h_m = 1.5$ m, and $d = 50$ m. If we further assume that $h_{BS} = 20$ m, which is somewhat below the range of the Hatta model but consistent with practice, then the path loss obtained from (17) and (18) is

$$\text{Theory:}\quad L = 123.8 + 38\log R_k$$
$$\text{Hatta:}\quad L = 130.9 + 36.4\log R_k \quad (19)$$

The close agreement of the theory and measurements shown in this equation is a further substantiation of diffraction as a key process in the propagation from an elevated base station to subscribers at street level.

4.5. Range Dependence for Microcells

Microcellular systems make use of base station antennas located at about the height of three-story buildings, or on lampposts, to cover cells of radius 1 km or less. In a high-rise building environment, this placement is well below the building so that propagation is around the buildings rather than over them. For residential areas, this base station antenna height will be near to, or below the rooftops. In both environments, the location of the base station antenna relative to the buildings needs to be taken into accounted. Over microcells, the street grid likely to be rectangular, and line-of-sight (LoS) streets are a more significant fraction of all the streets in a cell, calling for their separate treatment. Measurement models appropriate to such antenna placement have been proposed for high-rise and residential environments [7,18]. Theoretical models have also been evaluated for predicting path loss, as discussed, for example, in Ref. 1.

5. 3D RAYS FOR SITE-SPECIFIC PREDICTIONS

Computer codes have been written to compute the ray paths and the ray fields working from databases of buildings and ground elevation. An example of a building database is shown in Fig. 10, which represents a simplified view of the high rise section of Rosslyn, Virginia [19]. In creating a building database there are tradeoffs that limit useful fidelity. The cost of creating the database increases with the detail included, as does the running time of the ray code. However, accuracy of the ray predictions does not continue to increase as more detail is added. The Rosslyn database of Fig. 4 shows the shape of the major geometric components of the buildings, but omits many smaller features, such as windows, balconies and decorative masonry.

Because almost all buildings have vertical sides, building databases are usually constructed with this assumption in order to reduce computation time. It is common to take the roofs to be flat, and some computer codes assume the ground to be flat. The most inexpensive databases describe each building using a polygon to represent its footprint, and a single building height. The more elaborate database of Fig. 10 stacks individual building elements, each of which has a polygonal base, while the height at each corner of the polygon can be different to accommodate slanting roofs.

In practice it is difficult to create a building database with position accuracy better than 0.5 m, or to include the architectural detail that can introduce phase shift in the reflection coefficients. For these reasons it is not possible to accurately compute the phases of the individual rays that would be needed to predict the spatial interference pattern for narrowband signals. Although the exact fading pattern cannot be predicted, its statistical properties can. The most important parameter is the small-area average received power, which corresponds to the sliding average in Fig. 2. This average, which is found by spatially averaging the power or field magnitude squared, can be computed by adding ray powers, as discussed in the text following Eq. (3).

The primary problem when using GO and UTD is to find the rays connecting the transmitter and the receiver. Even in simple environments there are a very large, and possibly infinite, number of such rays to be found. Geometric optical (GO) rays that undergo only reflections at the building walls and the ground are found using either the image method or the shooting–bouncing ray approach, which is most commonly employed for outdoor environments. It has been found that five to seven reflections must be accounted for to ensure accurate predictions [20].

In the shooting–bouncing ray (SBR) approach, rays starts from the transmitter in all directions over a sphere at incremental angular separations. For each ray from the transmitter, the first intersection with a building surface is computed. Using the laws of geometric reflection, the reflected ray is traced to the point of intersection with the first building surface, and so on. Because the rays have finite angular separation, there is a vanishing probability that a ray will pass through a predefined receiver point. To overcome this problem, the receiver is given a finite cross section whose diameter is equal to the product of the angular separation and the total pathlength. This procedure replaces the actual ray to the receiver by a single neighboring ray that undergoes reflections at the same building surfaces.

Diffracted rays are found by tracing the GO rays to the edge, and then treating the diffracting edge as a secondary source of rays that are traced using GO. An example of rays diffracted at a corner of one building and at the roof of another is shown in Fig. 11. The ray incident at one point along the edge excites diffracted rays that leave the edge in a Keller cone whose half-angle is equal to the angle between the incident ray and the edge [10]. Since the cone angle will vary along the edge, the edge is divided into small segments and a secondary ray trace is carried out from each segment. Moreover, each ray incident on an edge segment will, in general, have a different cone angle, hence requiring a separate ray trace.

Because each edge initiates a series of ray traces for each ray family that illuminates the edges, the three-dimensional (3D) ray trace is very time consuming, and can only accommodate rays that undergo no more than two diffraction events. In order to speed the code and to account for more diffraction events at the rooftops, the vertical plane launch (VPL) approximation has been proposed [19,21]. This approximation is involves replacing the Keller cone for diffraction at horizontal edges by the vertical planes. For the common case when the horizontal displacement of the rays is larger than the vertical displacement, the distortion of the ray path will be small with this approximation. When viewed from above, the rays diffracted in the forward direction lie in the plane of incidence, while rays diffracted backwards lie in the plane of reflection.

The VPL approximation allows the ray paths to be constructed by first carrying out a 2D ray trace in

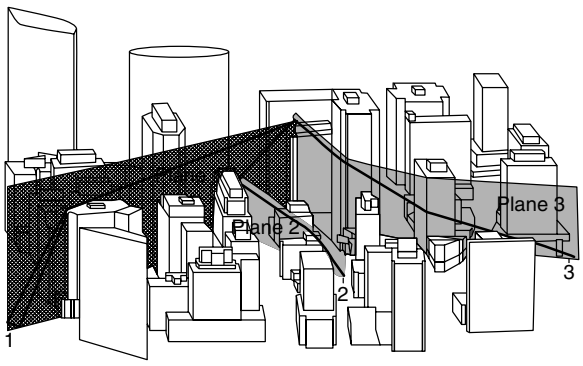

Figure 10. Building database of Rosslyn, Virginia, showing the vertical planes launched from a base station atop a building. The ray paths in the planes are those found from the VPL approximation. (From Ref. 19, with permission.)

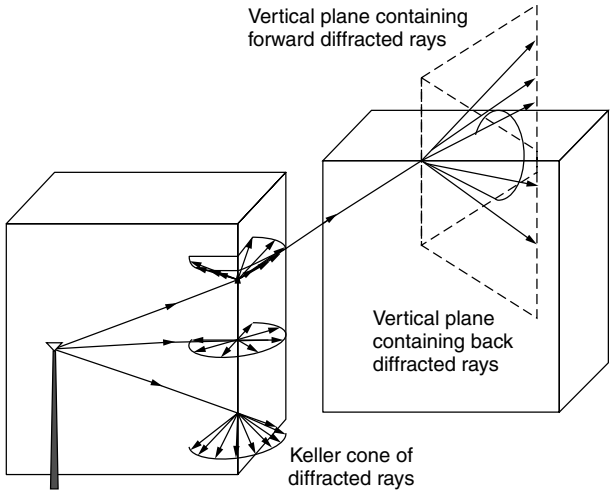

Figure 11. Rays diffracted at an edge lie in the Keller cone, whose half-angle is equal to that between the incident ray and the edge. In the VPL approximation, the cone for diffraction at horizontal edges is unrolled into the vertical planes. (© 2002 by H. L. Bertoni.)

the horizontal plane, followed by a simpler analytic determination of the ray paths in the vertical dimension. The procedure, in effect, traces vertical planes launched by the transmitter as they pass over and are reflected from building surfaces, as suggested in Fig. 10. These planes may also diffract at vertical building corners. After unfolding the vertical plane for each ray, the path in the vertical plane is determined by accounting for possible reflection or diffraction at horizontal edges. Because the shooting and bouncing ray method needs be used in only two dimensions, much less computer time is required. Moreover, by using analytic methods in the vertical plane, many more diffraction events at horizontal edges can be accommodated. An example of the VPL prediction of the spatial average received power in Rosslyn is shown in Fig. 12 [22]. The transmitter is located atop the building shown in Fig. 10, while the receiving locations are spaced approximately 5 m apart along a 2-km drive path on six different streets. For comparison with these predictions, measurements were made as the receiving van was driven along all the streets. The predictions are generally in good agreement with the measurements, except for 1360 receiver numbers and higher, which are on a street at the edge of the database. When compared to measurements, the error of ray predictions typically has an average of 1–2 dB and a standard deviation of 6–8 dB.

6. SUMMARY

Measurements and theory give complementary ways of predicting path loss and other statistical properties of the radio channel. Given the highly variable nature of the path loss, theoretical predictions are in good agreement with measurements. When validated against a set of measurements, the theoretical models allow for the variation of system parameters, such as frequency and antenna height, and building geometry. Thus a good theoretical model increases the value of a set of measurements by carrying it to a much larger range of parameters and building environments. Although we have discussed only a few aspects of path loss prediction in this article, theoretical models can be used to predict other channel characteristics. For example, computation of the ray fields via GO and UTD directly gives the directions of departure and arrival at both ends of the link, time delay of the ray, and the contribution of the ray fields to the received voltage. By making predictions for many mobile locations, the ray codes can be used for Monte Carlo simulation of statistical channel parameters, such as delay spread or angle spread.

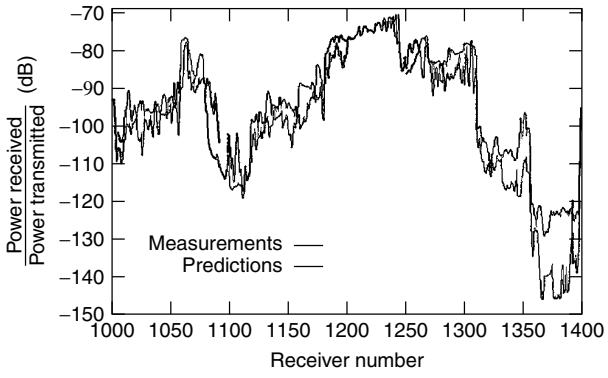

Figure 12. Comparison of measurements and predictions of the small-area path gain from a rooftop base station and mobiles at approximately 5-m intervals along six different streets in Rosslyn for a frequency of 900 MHz.

BIOGRAPHY

Henry L. Bertoni is on the faculty of Polytechnic University in Brooklyn, serving as head of the ECE Department (1990–95, 2001–present), and as vice provost of graduate studies (1995–96). His research has dealt with theoretical aspects of wave phenomena in electromagnetics, ultrasonics, acoustics, and optics. He has authored or coauthored over 80 journal papers and nine book chapters on these topics. Four journal articles have received best paper awards. His current research deals with characterizing the radio channel for modern wireless application, and the theoretical prediction of these characteristics. He and his students were the first to explain the physical mechanisms underlying characteristics observed in the measurements of cellular mobile radio signals. Much of this work is described in his recent book *Radio Propagation for Modern Wireless Systems*, Prentice Hall PTR, 2000. Dr. Bertoni is a fellow of the IEEE. He was the first chairman of the Technical Committee on Personal Communications of the IEEE Communications Society, and was IEEE representative to, and chairman of, the Hoover Medal Board of Award. He is a member of the International Scientific Radio Union and the Radio Club of America. From 1998 to 2001 he was a distinguished lecturer of the IEEE Antennas and Propagation Society.

1. INTRODUCTION

OFDM techniques have been proposed for digital TV broadcasting and high-speed wireless networks over multipath channels [1]. OFDM is commonly implemented using discrete Fourier transform (DFT) techniques and has been adopted, or is being investigated, for wireless LANs, wireless ATM, digital audio broadcasting [2], terrestrial digital videobroad-casting [3], and the broadband wireless local loop. OFDM offers many advantages such as resistance to multipath and excellent performance under noisy conditions.

With OFDM, the single carrier wave is replaced by simultaneous transmission of the signal on multiple, equally spaced subcarriers [4]. A baseband version of OFDM is called *discrete multitone transmission* (DMT). OFDM systems require the calculation of discrete Fourier transforms (DFTs). It is the availability of technology that allows for the implementation of fast transform (FFT) algorithms on integrated circuits at a reasonable price, that has made OFDM and DMT the modulation method of choice for the commercial applications given above [5].

Unfortunately, there are a number of difficulties with implementing OFDM and DMT:

- When the sinusoidal signals of the N subcarriers add constructively, the peak power can be N times the mean power; that is, the peak-to-average power ratio (PAR) of the transmitted signal can as large as N.
- Radiofrequency amplifiers are used to achieve the linearity over the entire signal. This causes high battery demand in mobile/wireless applications.
- The allocation of the radio spectrum for radio LANs limits the isotropically radiated peak envelope power. If the output peak is clipped, this generates out of band radiation due to intermodulation distortion as well as in-band distortion.

The first difficulty listed above is in fact the cause of the second and third. These problems limit the usefulness of OFDM for some applications.

2. PEAK-TO-AVERAGE POWER RATIO OF OFDM

The complex baseband OFDM signal may be represented as

$$s(t) = \frac{1}{\sqrt{N}} \sum_{n=-\infty}^{\infty} \sum_{k=0}^{N-1} a_{k,n} e^{j2\pi k \Delta f t} g[t - k(T + T_g)] \qquad (1)$$

where $j^2 = -1$, N is the total number of subcarriers, and $a_{k,n}$ is the data symbol for the k subcarrier and the nth OFDM symbol (i.e., N subcarrier OFDM system transmits a block of N data symbols per OFDM symbol). The frequency separation between any two adjacent subcarriers is $\Delta f = 1/T$. The unit rectangular pulse $g(t)$ is of duration $T + T_g$, where T_g is known as the "guard interval."

Because there is no overlap between different OFDM symbols, for the PAR problem it is sufficient to consider a single OFDM symbol ($n = 0$). In practice, filtering can cause some degree of intersymbol interference, which will be neglected here. The guard interval is used to repeat parts of each OFDM signal, but has no effect on the PAR. Therefore we may set $T_g = 0$. Since only $n = 0$ is sufficient

for the problem at hand, $a_{k,n}$ may be replaced by a_k. Thus, for PAR considerations, the complex baseband signal may be represented as

$$s(t) = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} a_k e^{j2\pi k \Delta f t}, \quad 0 \le t < T \tag{2}$$

Note that all the subcarriers are mutually orthogonal. Each modulated symbol a_k is chosen from the set $F_q = \{\lambda_1, \lambda_2, \ldots, \lambda_q\}$ of q distinct elements. The set F_q is called the *signal constellation* of the q-ary modulation scheme. While several modulation schemes are in use it should be noted that the statistical distribution of the PAR is largely independent of the signal constellation. In most applications, one uses phase shift keying (PSK) signaling in which

$$F_q = \{1, \zeta, \zeta^2, \ldots, \zeta^{q-1}\} \tag{3}$$

where $\zeta = e^{j2\pi/M}$. For example, for binary PSK (BPSK) $F_q = \{1, -1\}$ and for quaternary PSK (QPSK), $F_q = \{1, j, -1, -j\}$. Another popular modulation technique is quadrature amplitude modulation (QAM), for which

$$F_q = \{m + jn\} \tag{4}$$

where m and n are selected integers.

Note that for any PSK constellation F_q for any $u \in F_q$, $|u|^2 = 1$, and this condition does not hold for QAM constellations. In general, all elements in F_q occur with equal probability $1/q$.

We shall write an ordered N-tuple $\mathbf{a} = (a_0, a_1, \ldots, a_{N-1})$ and let $(F_q)^N$ denote the set of all ordered N-tuples where each $a_k \in F_q$. We shall refer to any member of the set $(F_q)^N$ as a *data frame*. Note that each a_k carries $\log_2 q$ data bits. Normal values are $q = 2, 4, 8$, and so on. Each OFDM symbol thus carries $N \log_2 q$ data bits. The instantaneous envelope *power* of the signal is the real-valued function $P_a(t) = |s(t)|^2$. We define the peak-to-average power ratio (PAR) as

$$\mathrm{PAR}(\mathbf{a}) = \frac{\max_t P_a(t)}{E(P_a(t))} \tag{5}$$

where $E(\cdot)$ denotes the time average. For a PSK constellation, this value is unity. Strictly speaking, this definition should be called the peak-to mean envelope power ratio (PMEPR), because $s(t)$ is the envelope but not the transmitted signal itself. As such, this is also called the *baseband* PAR. The actual transmitted signal is modeled as

$$S(t) = \Re(s(t)e^{j2\pi f_c t}) \tag{6}$$

where f_c is the carrier frequency and $\Re(z)$ denotes the real part of z. The definition of PAR would now be

$$\mathrm{PAR}(\mathbf{a}) = \frac{\max_t |\Re(s(t)e^{j2\pi f_c t})|^2}{E(|S(t)|^2)} \tag{7}$$

which is also known as the *passband* PAR. It is often easier to work with definition (5) rather than (7). Further, if f_c is large (i.e., $f_c \gg N/T$), which is the case in practice, this is approximately 3 dB higher than the baseband PAR. This difference is more or less fixed. Consequently, we will be using the baseband PAR without any loss of generality or applicability.

The PAR is a function of the data frame, and recall that there are q^N distinct data frames. For any input data frame, we have

$$1 < \mathrm{PAR}(\mathbf{a}) \le N \tag{8}$$

For example, for $N = 256$ the PAR can be as high as 24 dB $[10 \log_{10}(256)]$. Fortunately, very high PAR values are very rare. For example, with BPSK, only four sequences $0000\ldots, 1111\ldots, 0101\ldots$, and $1010\ldots$ achieve $\mathrm{PAR}(\mathbf{a}) = N$. For randomly distributed data, the probability of an occurrence of this is $4/2^N = 2^{2-N}$. This probability is negligible when N is large - as is the case in practice.

The PAR of a sequence is closely related to its out-of-phase aperiodic autocorrelation (APA) values. The APA coefficients of $\mathbf{a}$ are

$$\rho(k) = \sum_{n=0}^{N-1-k} a_{n+k} a_n^* \quad \text{for} \quad k = 0, \ldots, N-1 \tag{9}$$

The PAR is bounded as

$$\mathrm{PAR}(\mathbf{a}) \le 1 + \frac{2}{N} \sum_{k=1}^{N-1} |\rho(k)| \tag{10}$$

This shows that binary or polyphase sequences with low out-of-phase APA values [i.e., small $\rho(k)$ for $k \ge 1$] can be used to construct low PAR signals. Conversely, Schroeder, [6] notes that sequences that have low PAR also have low APA values. The problem of constructing sequences with low APA values (i.e., similar to an impulse function) is a longstanding problem. The general problem of finding sequences that minimize the PAR seems just as difficult.

Example 1. Consider $\mathbf{a} = (1, 1, 1, -1, 1)$, which is a Barker sequence. Its APA is $\{5, 0, 1, 0, 1\}$. Hence applying (10) gives $\mathrm{PAR}(\mathbf{a}) \le 1 + \frac{4}{5}$; thus, the PAR is less than 2.55 dB. By computing (5), the PAR is exactly 2.55 dB. In this case, the upper bound coincides with the exact.

Example 2. Using (10), we can immediately device a simple PAR reduction code. For an information sequence $p_0 = (m_0, m_1, \ldots, m_{n-1})$, where $m_k \in \{1, -1\}$, the encoder output is given by $p_e = (m_0, \ldots, m_{n-1}, -m_{n-2}, m_{n-3}, -m_{n-4}, \ldots, -m_0)$. This code rate is $n/(2n-1)$ and length $N = 2n - 1$. For k odd, $\rho(k)$ of p_e is zero. For example, when $n = 3$, then $\rho(1) = \rho(3) = 0$ and $|\rho(2)| \le 3$ and $|\rho(4)| = 1$. Thus our bound gives PAR ≤ 2.6, almost a 3-dB reduction. For large N, the coding rate is almost $\frac{1}{2}$. The sum of $|\rho(k)|$ for k even is bounded by $(N-1)^2/4$. Thus, the peak is bounded as $\mathrm{PAR} \le 1 + (N-1)^2/(2N)$, a 3 dB reduction.

3. STATISTICAL PROPERTIES OF PAR

3.1. CCDF of the PAR

Since the input data are randomly distributed in many applications (if not, they can be made so by the use of a

suitable scrambling operation), PAR(**a**) itself is a random variable. The complementary cumulative distribution function (CCDF), the probability that the PAR of an OFDM symbol exceeds a certain threshold, is useful for many purposes. The CCDF is defined as

$$F(\zeta) = \Pr(\text{PAR}(\mathbf{a}) \geq \zeta) \tag{11}$$

The CCDF is shown for $N = 32$, 64, 128, and 256 in Fig. 1. For 256 subcarriers, the maximum PAR is 24 dB. To reach this, however, all the subcarriers need to be in phase at some instant in time, and therefore produce an amplitude peak equal to the sum of the amplitudes of the individual subcarriers. This occurs with extremely low probability for large N. For example, the PAR exceeds 12.5 dB for 1 in 10^5 of all the possible transmitted OFDM symbols.

3.2. Gaussian Approach

An exact expression for $F(\zeta)$ is not yet known because computing PAR(**a**) requires the time instances for which the derivative of the envelope power $P_a(t)$ equals zero. This is a root-finding problem for a nonlinear equation and as such there are no analytic formulas for the roots. However, as a way around this difficulty, we make the following assumptions:

A1. $s(t)$ is a complex Gaussian process.
A2. N samples of $s(t)$ given by $s_n = s(nT/N)$ for $n = 0, 1, \ldots, N-1$ are independent and identically distributed complex Gaussian random variables.
A3. The maximum of $|s_n|^2$ is equal to $\max_t = P_a(t)$.

A1 becomes quite accurate as N increases. The independence assumption in A2 is never exact because we know that the N samples must satisfy Parseval's theorem. A3 is never exactly true. Nevertheless, we define random variables (RVs):

$$Y_n = |s_n|^2 \quad n = 0, \ldots, N-1 \tag{12}$$

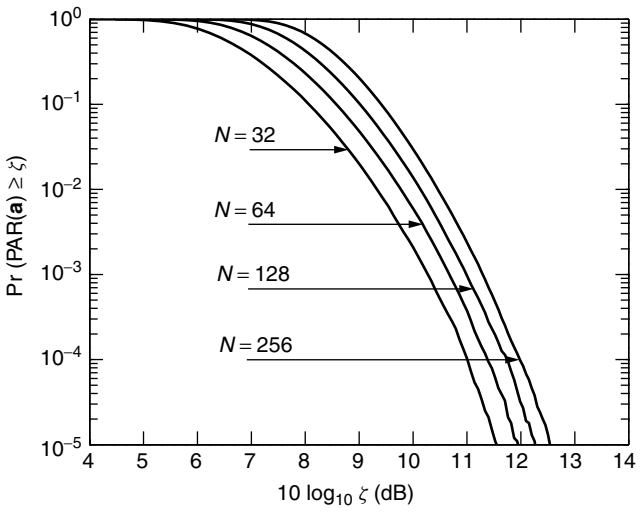

Figure 1. The CCDF for N QPSK subcarriers.

Since the real and imaginary parts of s_n are independent (provided no oversampling is used), with mean zero and the same variance, Y_n approaches a chi-squared distribution with two degrees of freedom. The Y_n values hence are i.i.d. and exponential RVs. Their cumulative density function (CDF) is given by

$$F(y) = \Pr(Y_n \leq y) = 1 - e^{-y} \tag{13}$$

The statistical properties of the maximum of Y_n can be readily derived. We see that the CDF of the maximum is given by

$$\begin{aligned} F_{\max}(y) &= \Pr\{Y_{\max} \leq y\} \\ &= \Pr\{\text{all } Y_n \leq y\} \\ &= (1 - e^{-y})^N \end{aligned} \tag{14}$$

The CDF of the PAR is then obtained as

$$F(\zeta) = 1 - (1 - e^{-\zeta})^N \tag{15}$$

Despite the three assumptions that may not always hold, this result is useful for quick analysis of the statistics of PAR and for determining the achievable PAR reduction for some schemes.

3.3. Asymptotic Results

The statistical behavior of PAR(**a**) for large N is important, and in some practical applications, N can be as large as 2048 or more. We can show that PAR(**a**) grows as $\ln N$; that is, for a randomly picked data sequence, PAR(**a**) is unlikely to be significantly less than $\ln N$. From Eq. (14), we get

$$\begin{aligned} \Pr\{\text{PAR}(\mathbf{x}) \leq \alpha \ln N + h\} &= (1 - e^{-(\alpha \ln N + h)})^N \\ &\simeq e^{-N^{(1-\alpha)}e^{-h}} \text{ for } N \to \infty \end{aligned} \tag{16}$$

where $\alpha \geq 1$. This follows readily from fact that $\lim_{n\to\infty}(1 - \theta/n)^n = e^{-\theta}$. If $\alpha = 1$ and $h = -h$ in (16), we see that

$$\Pr\{\text{PAR}(\mathbf{x}) \leq \ln N - h\} \simeq e^{-e^h} \tag{17}$$

This is the formal mathematical equivalent of our statement above. This also elicits information about clipping and coding for PAR reduction. *Clipping* is a method used to deal with high peak amplitude excursions at the transmitter output. This is necessary because the D/A converter has a limited resolution (i.e., the number of bits) and the power amplifier cannot be linear over an amplitude range that includes the peak amplitudes. A clip occurs when the signal amplitude exceeds a predefined threshold, and hence clipping is described as follows:

$$s_c(t) = \begin{cases} s(t) & \text{if } |s(t)| \leq s_{\text{clip}} \\ s_{\text{clip}} e^{j\angle s(t)} & \text{if } |s(t)| > s_{\text{clip}} \end{cases} \tag{18}$$

where $s_{\text{clip}} > 0$ is the clipping threshold. The probability of clipping is the number of clips per unit time. Of course, each clip introduces symbol errors and out-of-band noise.

Equation (17) shows that for a normal OFDM system, if the clipping threshold is set below $\ln N$, then the clipping probability will be unity for large N. Likewise, (16) suggests if the clipping threshold is set above αN, then the clipping probability can be arbitrarily reduced. Here the right-hand side (RHS) of (16) explicitly shows that the decay rate depends on both α and h.

Additionally, coding seems unnecessary for PAR reduction of $\alpha \ln N$ or higher as clipping will not occur very often. In contrast, keeping the PAR at a level significantly below $\ln N$ using clipping will introduce significant distortion. At this point coding becomes interesting. Consider coding to reduce the PAR to h below $\ln N$, where $|h|$ is small compared to $\ln N$. Assume a binary modulation [i.e., $x_k \in (+1, -1)$]. From (17), the achievable coding rate is

$$R(h) = \frac{\log_2(2^N e^{-e^h})}{N} = 1 - \frac{e^h}{N \log_2 e} \tag{19}$$

As h increases, the achievable coding rate tends to zero. Similarly, if h is negative, the achievable coding rate tends to one, suggesting that the PAR can be limited to a level above $\ln N$ with very little redundancy. Moreover, the required amount of redundancy decays exponentially with the difference between the target PAR and $\ln N$. It appears that any family of good codes (i.e., of nonvanishing coding rate) must have a PAR bound of around $\ln N$.

3.3.1. Code Rate. Consider QPSK modulated N subcarriers, which can accommodate $2N$ information bits at most. Suppose that we need a code rate $R = 1 - K/(2N)$ to limit the PAR to ζ. Thus we have

$$\Pr(\text{PAR} \le \zeta) = \frac{2^{2N-K}}{2^{2N}} \tag{20}$$

which can be rearranged as

$$R = 1 + \frac{1}{2N} \log_2 \Pr(\text{PAR} \le \zeta) \tag{21}$$

This probability term can be estimated by simulation. Figure 2 shows the required code rate to limit the PAR. For $N = 128$, to reduce PAR to 7 dB from 21 dB for the uncoded case, the required code rate is 0.98. This suggests that the PAR can be much reduced by a small amount of redundancy. Unfortunately, it has thus far not been possible to discover such a code.

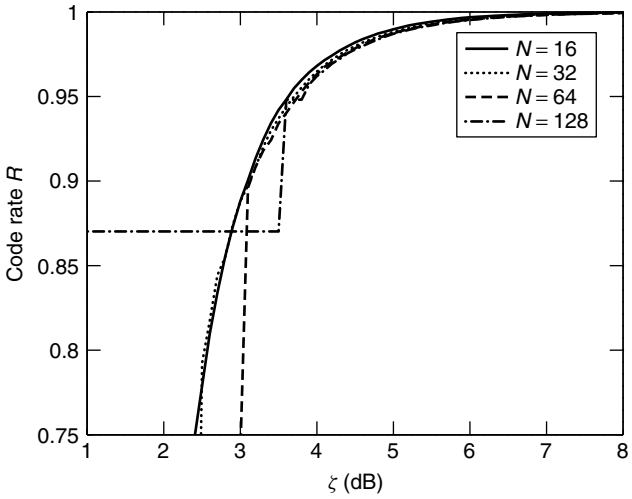

Figure 2. Code rate for limiting the PAR.

4. COMPUTATIONAL METHODS FOR PAR

4.1. Discrete-Time PAR

In order to compute PAR($\mathbf{a}$) exactly, we need all the roots of the equation

$$\frac{dP_{\mathbf{a}}(t)}{dt} = 0 \tag{22}$$

which is difficult to solve, especially for higher-order modulation formats. Most PAR reduction techniques are concerned with reducing PAR($\mathbf{a}$) [Eq. (5)]. However, since most systems employ discrete-time signals, the maximum amplitude of LN samples of $s(t)$ is used to approximate it, where L is the oversampling factor. The sampling can be implemented by an inverse discrete Fourier transform (IDFT). Hence consider the IDFT of length LN of $\mathbf{a}$ expressed as

$$A_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} a_k e^{i2\pi nk/LN} \quad n = 0, 1, \ldots, LN-1 \tag{23}$$

It is seen that A_n are the samples of the waveform [Eq. (2)]. The discrete-time PAR is thus defined as

$$\text{PAR}(\mathbf{a})_{\text{dis}} = \max_{0 \le n < LN} |A_n|^2 \tag{24}$$

$L > 1$ corresponds to oversampling. Of course, if $L \gg 1$, the discrete-time PAR should approach the (continuous-time) PAR. It is therefore clear that

$$\text{PAR}(\mathbf{a})_{\text{dis}} \le \text{PAR}(\mathbf{a}) \tag{25}$$

Moreover [7] has shown that $\text{PAR}(\mathbf{a}) \le 2\text{PAR}(\mathbf{a})_{\text{dis}}$ if $L = \lceil 2\pi \rceil$. In practice, samples of (2) are generated by means of an inverse fast Fourier transform (IFFT), and fed to a digital-to-analog converter followed by an antialiasing lowpass filter. Quite often an oversampling factor of 4 is sufficiently accurate. For BPSK modulated subcarriers, this fact can be verified because the continuous-time PAR can be computed exactly. The most common method to compute PAR($\mathbf{a}$) is to use the discrete-time PAR. Note that we will simply use the term PAR, except when we are concerned about the difference between the discrete- and continuous-time values.

4.2. Using the Infinity Norm

This method was suggested by Van Eetvelt. The peak of a continuous function $s(t)$ is given by the L_∞ norm defined as

$$\max |s(t)| = L_\infty(s(t)) = \lim_{n \to \infty} \left[\frac{1}{T} \int_0^T |s(t)|^n dt \right]^{1/n} \tag{26}$$

To compute the L_∞ norm, we can use the result that for increasing p the L_p norm is nondecreasing. So in practice, taking a sufficiently large power allows the peak value to be approximated as closely as required. However, as computing this integral is not that easy, the use of the discrete-time PAR is much more convenient.

4.3. Computation of Continuous-Time PAR: BPSK case

To compute the continuous-time PAR, the roots of the derivative of the envelope power function (EPF) are required. At first, finding the required roots appears very difficult, since this derivative consists of sinusoidal functions. As such, the problem suggests a general root finding algorithm for nonlinear functions. Fortunately, this difficulty can be avoided for the BPSK case. Using an inverse cosine based transformation, the EPF can be converted to a sum of Chebysev polynomials. Moreover, the required roots are now trapped within the interval from 0 to 1. So the original root finding problem is reduced to a root finding problem for a polynomial. Reliable algorithms for finding all roots of a polynomial (a polynomial of order n will have n roots) are well known. Consequently, using this approach, the absolute peak of the EPF can be evaluated exactly. In this case, we have $a_k \in \{1, -1\}$. It is easy to show that [8,9]

$$P_a(t) = \sum_{k=0}^{N-1} \beta_k \cos(2\pi k t) \tag{27}$$

where

$$\beta_k = \begin{cases} 1 & k = 0 \\ \dfrac{2}{N} \displaystyle\sum_{n=0}^{N-1-k} a_n a_{n+k} & k = 1, 2, \ldots, N-1 \end{cases} \tag{28}$$

To compute PAR($\mathbf{a}$) exactly, the roots of $\dfrac{dP_a(t)}{dt} = 0$ are needed. Let us define

$$Q_a(t) = P_a\left[\frac{\cos^{-1} t}{2\pi}\right] = \sum_{k=0}^{N-1} \beta_k T_k(t) \tag{29}$$

where $T_k(t) = \cos(k \cos^{-1} t)$ is the kth order Chebysev polynomial (Ref. 10, p. 1054). Note that $T_0(t) = 1, T_1(t) = t, T_2(t) = 2t^2 - 1$ and so on (explicit expressions for the coefficients of $T_n(t)$ for any N are available). Since $Q_{\mathbf{a}}(t)$ is a polynomial of degree $(N-1)$, its first derivative is a polynomial of degree $(N-2)$. Recall that a polynomial of degree n will have n roots. These roots can be real or complex and many algorithms exist with which one can find all the roots of a polynomial. For example, a companion matrix can be constructed whose eigenvalues are the desired roots. Since

$$\frac{dP_{\mathbf{a}}(t)}{dt} = \frac{dQ_{\mathbf{a}}(\cos(2\pi t))}{dt} = -2\pi \sin(2\pi t) \frac{dQ_{\mathbf{a}}[\cos(2\pi t)]}{d\cos(2\pi t)} \tag{30}$$

the derivative vanishes both at $t = 0, \frac{1}{2}$ and at the transforms of the real roots of $\dfrac{dQ_a(t)}{dt}$ that lie between -1 and $+1$. Let those roots be $\xi_1, \xi_2, \ldots, \xi_M$ where $M \le N-2$. Define the set

$$\Lambda = \left\{0, \frac{1}{2}, \frac{\cos^{-1}\xi_1}{2\pi}, \ldots, \frac{\cos^{-1}\xi_M}{2\pi}\right\} \tag{31}$$

It is clear that all the required roots of the derivative of $P_a(t)$ are in this set. Note that $P_{\mathbf{a}}(t)$ is a periodic function and only the roots between 0 to 1 need to be considered. Therefore, the continuous-time PAR is obtained by

$$\text{PAR}(\mathbf{a}) = \max_{t \in \Lambda} P_{\mathbf{a}}(t) \tag{32}$$

5. PAR REDUCTION METHODS

We next describe some of the techniques that have been proposed to reduce the effects of high PAR.

5.1. Multiple Signal Generation

The basic idea behind this approach is to generate multiple, independent OFDM symbols to represent an input data frame and select the minimum PAR symbol for transmission. There are several techniques based on this idea and these primarily differ in the way they generate the multiple symbols. Another issue with this approach is the need for side information to tell the receiver which one of the signals has been used. Suppose that $M \ge 1$ independent OFDM symbols are generated for an information sequence. The CCDF of the minimum of these is given by

$$\Pr(\text{PAR}_{\min} \ge \zeta) = [1 - (1 - e^{-\zeta})^N]^M \tag{33}$$

Figure 3 shows this CCDF for $M = 1, 2, \ldots, 16$ and $N = 128$. $M = 1$ is the ordinary OFDM. Even for $M = 4$, a PAR reduction of about 4 dB occurs at a probability of 10^{-6}.

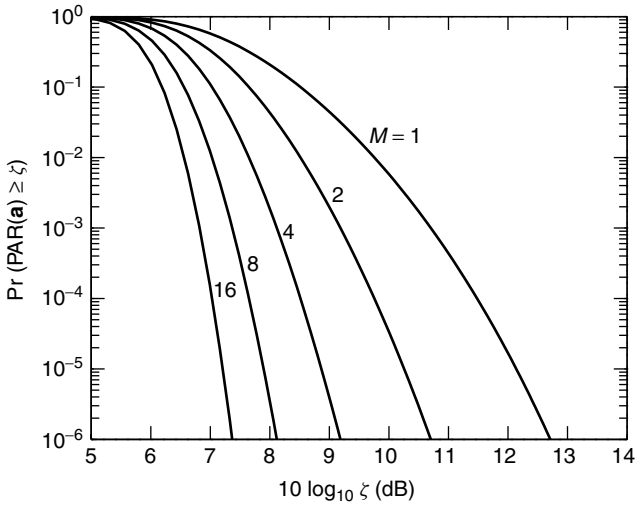

Figure 3. CCDF for the lowest PAR out of M statistically independent signals.

5.1.1. Partial Transmit Sequences. We shall write the input data block as a vector, $\mathbf{X} = [X_0, \ldots, X_{N-1}]^T$. For the PTS approach, the input data vector $\mathbf{X}$ is partitioned into disjoint subblocks, as $\{\mathbf{X}_m | m = 1, 2, \ldots, M\}$, and these are combined to minimize the PAR. While several subblock partitioning schemes do exist, we assume the simplest scheme for which the subblocks consist of a contiguous set of subcarriers and are of equal size. Now, suppose that for $m = 1, \ldots, M$, $\mathbf{A}_m = [A_{m1}, A_{m2}, \ldots, A_{m,LN}]^T$ is the zero-padded IFFT of $\mathbf{X}_m$. These are the partial transmit sequences. The objective is thus to combine these with the aim of minimizing the PAR. The signal samples at the output of the PTS combiner can be written as

$$\mathbf{S} = \begin{bmatrix} A_{11} & A_{21} & \ldots & A_{M1} \\ A_{12} & A_{22} & \ldots & A_{M2} \\ \ldots & \ldots & \ldots & \ldots \\ A_{1LN} & A_{2LN} & \ldots & A_{MLN} \end{bmatrix} \begin{bmatrix} e^{j\phi_1} \\ e^{j\phi_2} \\ \vdots \\ e^{j\phi_M} \end{bmatrix} \tag{34}$$

where $\mathbf{S} = [S_1(\Phi), \ldots, S_{LN}(\Phi)]^T$ contains the optimized signal samples. We shall write the phase factors as a vector, $\Phi = [\phi_1, \phi_2, \ldots, \phi_M]^T$. The phase factors $\{\phi_k\}$ are chosen to minimize the peak of the signal samples $|S_k(\Phi)|$. So the minimum PAR is related to the problem

$$\begin{aligned} &\text{Minimize} \quad \max_{0<k\le LN} |S_k(\Phi)| \\ &\text{subject to} \quad 0 \le \phi_m < 2\pi, m = 1, \ldots, M \end{aligned} \tag{35}$$

Suppose $\hat{\phi}_m$ to be the global optimal solution to this problem. Unfortunately, there appears to be no simple way to obtain $\hat{\phi}_m$ analytically. For coherent demodulation, it is necessary to send $\hat{\phi}_m$ to the receiver as side information. When $\hat{\phi}_m$ is a continuous value, an infinite number of bits will be required as side information. The solution to this problem is to limit $\hat{\phi}_m$ to a level from a finite number of predetermined levels (quantization). For differential demodulation, it is not necessary to send $\hat{\phi}_m$ to the receiver, but $M - 1$ subcarriers at the subblock boundaries have to be set aside as reference carriers.

The phase factors are restricted to a finite set of values and hence (35) is approximated by the problem

$$\begin{aligned} &\text{Minimize} \quad \max_{0<k\le LN} |S_k(\Phi)| \\ &\text{subject to} \quad \phi_m \in \left\{ \frac{2\pi l}{W} | l = 0, \ldots, W-1 \right\} \end{aligned} \tag{36}$$

If the number of rotation angles W is "sufficiently" large, the solution of (36) will approach that of (35). Furthermore, ϕ_1 can be fixed without any performance loss. Now, there are only $M - 1$ free variables to be optimized and hence W^{M-1} distinct phase vectors, Φ_i, need to be tested. As such, (36) is solved using W^{M-1} iterations; the ith iteration involves computing LN signal samples, each of which is denoted by $S_k(\Phi_i)$, using (34) and choosing the maximum $|S_k(\Phi_i)|$ value. At the end of each iteration, the phase vector is retained if the current value of max $|S_k(\Phi_i)|$ is less than the previous maximum. The phase vector that is retained after all the iterations are completed will be an approximation to the global optimal solution of (35).

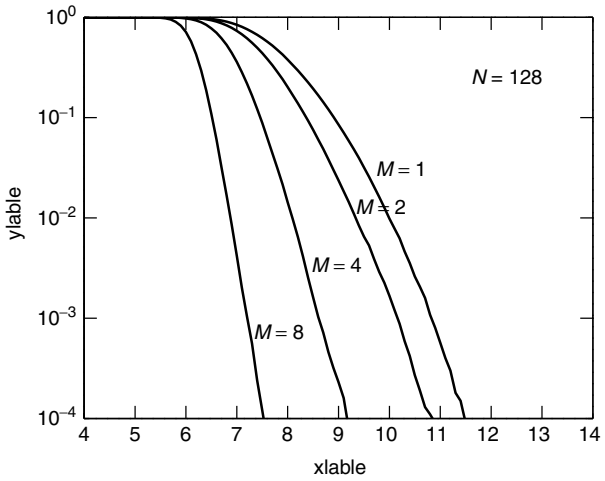

Figure 4. PTS performance for several M for $N = 128$ QPSK subcarriers.

In most reported studies, $W = 2$. In some cases, the use of more rotation angles ($W > 2$) has been found to yield diminishing returns. Figure 4 shows the PAR distribution for this method for varying M, with normal OFDM being $M = 1$. For $M = 8$, the PAR can be reduced by about 4 dB at a probability of 10^{-6}.

5.1.2. Selected Mapping (SLM) Approach. For a given M-PSK sequence, one generates M independent M-PSK sequences by multiplying by M fixed vectors and choosing the sequence with lowest PAR for transmission. This method is simple and very impressive. However, it needs M FFTs to select the best sequence among L. Suppose that we have M fixed phase vectors $\underline{P}_k = (p_k^0, p_k^1, \ldots, p_k^{N-1})$ for $k = 1, \ldots, M$, where $p_k^n \in \{0, 1, \ldots, M-1\}$ for $\forall n, k$. Without loss of generality, $p_1^n = 0$ $\forall n$. For an input data sequence $\mathbf{a}$, we generate M independent' sequences

$$A_k = \mathbf{a} \oplus \underline{P}_k \quad k = 1, \ldots, M \tag{37}$$

where $\underline{u} \oplus \underline{v}$ is the componentwise modulo M addition of $\underline{u}$ and $\underline{v}$. Originally, it was suggested to use the following selection function [9,11]: transmit A_l for $1 \le l \le L$ if

$$\text{SF} = \begin{cases} \text{PAR}(A_l) & \text{Baüml} \\ |W_H - N|^2 + |R_1|^2 & \text{Van Eetvelt} \end{cases} \tag{38}$$

is minimized. Here

$$R_1 = \sum_{k=1}^{N-1} A_{l:k} A_{l:k+1}^*$$

and W_H is the binary Hamming weight of the length N binary sequence. The performance of Baüml's SF is quite good, but requires multiple FFTs per input data frame.

5.1.3. Interleaving Approach. In this approach $K - 1$ interleavers are used at the transmitter [12]. These interleavers produce $K - 1$ permuted frames of the input

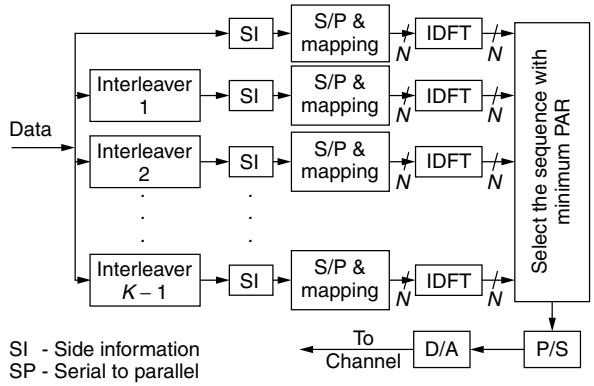

Figure 5. System model.

data before mapping into QPSK symbols. The 4 times oversampled IDFT of each frame (including the uncoded frame) is used to compute its PAR. The minimum PAR frame of all the K frames is selected for transmission. The identity of the corresponding interleaver is also sent to the receiver as side information. Figure 5 describes an OFDM transmitter with interleavers to reduce the PAR. The PAR reduction achievable with this method is similar to that of the PTS method.

5.2. Coding Techniques

5.2.1. Constructing Sequence Families with Low PAR and High Distance. Some definitions: A M-ary code $\mathcal{C}$ is a given set of sequences of symbols where each symbol is chosen from a set $F_M = \{\lambda_1, \lambda_2, \ldots, \lambda_M\}$ of M distinct elements. The set F_M is often taken to be the set $Z_M = \{0, 1, 2, \ldots, M-1\}$, with $M = 2^h$ for positive integer h. We will denote a codeword as an N-tuple $(b_0, \ldots, b_{N-1})$ by $\mathbf{b}$. The Hamming distance between two sequences or codewords is defined as

$$d_H(\mathbf{a}, \mathbf{b}) = \sum_{n=0}^{N-1} \delta(a_n - b_n)$$

where $\delta(\cdot)$ is the Krönecker delta function. A critical parameter of a code $\mathcal{C}$ is the minimum Hamming distance, or just minimum distance, which measures how good it is at error-correcting. This is defined to be the smallest of the distances between any two distinct codewords:

$$d_{\min} = \min\{d_H(\mathbf{a}, \mathbf{b}) | \mathbf{a}, \mathbf{b} \in \mathcal{C}, \mathbf{a} \neq \mathbf{b}\}$$

The PAR of a code $\mathcal{C}$ is defined as

$$\mathrm{PAR}_{\max} = \max\{\mathrm{PAR}(\mathbf{a}) | \forall \mathbf{a} \in \mathcal{C}\}$$

Finally, the code rate of a code $\mathcal{C}$ is defined as

$$R = \frac{\log_2 \#(\mathcal{C})}{N \log_2 M}$$

where $\#(S)$ denotes the number of elements of set S. The following notation will be used where necessary. An $[n, k, d_{\min}, \eta]$ code is a code of length n, containing k information symbols, with minimum distance $d_{\min}$ and $\mathrm{PAR}_{\max} \eta$.

5.2.2. Golay Complementary Sequences and Reed–Muller Codes. One of the earliest low-PAR code constructions was that proposed by Jones et al. [13], with parameters [4,3,2,1.75]. This was based on a table of low-PAR codewords. Several authors noted that low-PAR codes can be constructed using complementary sequences. A pair of sequences $\mathbf{a}$ and $\mathbf{b}$ is complementary if

$$\rho_{\mathbf{a}}(k) + \rho_{\mathbf{b}}(k) = 2\delta(k) \qquad k = 0, 1, \ldots, N-1$$

Taking the Fourier transform of this, we have

$$P_{\mathbf{a}}(t) + P_{\mathbf{b}}(t) = 2.$$

Hence it is clear the PAR of $\mathbf{a}$ and $\mathbf{b}$ must be less than or equal to 2. Recently, Davis and Jedwab made a significant breakthrough by identifying the relationship between complementary sequences and Reed–Muller codes [14]. Further important results have been found [7,15]. The rth-order Reed–Muller code $\mathrm{RM}(r, m)$ has length $n = 2^m$, minimum Hamming distance $d = 2^{m-r}$, and the number of information bits $k = \sum_{i=0}^{r} \binom{m}{i}$. For example, RM(1,5) is (32,6,16), a low rate linear code.

5.2.3. Constructing Single Sequences with Low PAR. Although OFDM requires the transmission of a large family of sequences with low PAR, it is helpful to also consider the special case where the family size is 1. These single sequences can form the kernel of larger families of sequences with low PAR. The periodic autocorrelation (PA) of a length N sequence, $\mathbf{a}$, is given by

$$\rho_p(k) = \sum_{n=0}^{N-1} a_{n+k} a_n, \quad \text{for } k = 0, 1, \ldots, N-1$$

where all indices are taken, mod N. We can upper bound the PAR of the N-point DFT of $\mathbf{a}$ using,

$$\mathrm{PAR}_p(\mathbf{a}) \leq 1 + \frac{2}{N} \sum_{k=1}^{(N-1)/2} |\rho_p(k)|, \; N \text{ odd} \tag{39}$$

and a similar expression for N even.

Similarly, the negaperiodic autocorrelation (NA) of a length N sequence, $\mathbf{a}$, is given by

$$\rho_n(k) = \sum_{n=0}^{N-1} (-1)^{\left\lfloor \frac{n+k}{N} \right\rfloor} a_{n+k} a_n, \quad \text{for } k = 0, 1, \ldots, N-1$$

where all indices are taken, mod N. We can upper bound the PAR of the N-point negaperiodic DFT of $\mathbf{a}$ using

$$\mathrm{PAR}_n(\mathbf{a}) \leq 1 + \frac{2}{N} \sum_{k=1}^{(N-1)/2} |\rho_n(k)|, \; N \text{ odd} \tag{40}$$

and a similar expression for N even.

Figure 6 shows the continuous power spectrum of an m-sequence, where the N periodic DFT points are bounded by the PA, and interleaved with the N negaperiodic DFT points that are bounded by the NA. There are numerous constructions for sequences with low PA in the literature (e.g., m sequences, trace sequences, Legendre sequences,

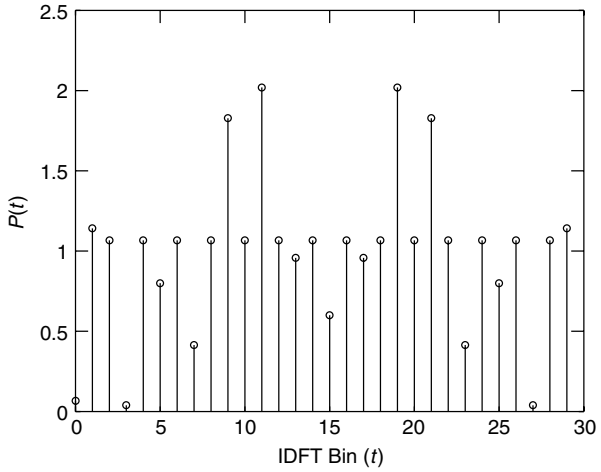

Figure 6. 30-point IDFT power spectrum for length $N = 15$ binary m-seq: 001001101011110.

and cyclotomic constructions). For instance, a binary m sequence guarantees $\rho_p(k) = -1, \forall k, k \neq 0$. Substituting back into (39) gives an upper bound on PAR_p (**a**) of $\dfrac{2N-1}{N}$, which is not particularly tight as the true PAR_p of a binary m sequence is $\dfrac{N+1}{N}$. Sequences with low PA are often proposed for code-division multiple access, but the spectral power peak of a sequence in between N IDFT points can rise considerably. Figure 6 illustrates this fact for a length 15 m sequence which has a low N-point IDFT, but not such a low $2N$-point IDFT. The periodic and negaperiodic N-point IDFTs are bins 0, 2, 4, ..., 26, 28, and bins 1, 3, ..., 27, 29, respectively, of Fig. 6.

Unlike the periodic case, the NA of a sequence has not been studied in such great detail. This is partly because there is a certain overlap between construction techniques for sequences with low PA and low NA, respectively. For instance, for BPSK, if **a** has odd length and low PA, then $\mathbf{a} \oplus 010101\cdots$ has equally low NA. However, the constructions are distinct for the even-length case. The APA and associated PAR upper bound were given in Eqs. (9) and (10). The APA can be viewed as the sum of PA and NA as follows:

$$\rho(k) = \frac{\rho_p(k) + \rho_n(k)}{2}, 0 \leq k < N,$$

$$\rho(k) = \frac{\rho_p(N-k) - \rho_n(N-k)}{2}, -N < k < 0$$

It follows that if a sequence has low PA *and* low NA, then it has low APA and a low upper bound on PAR. Finding constructions that have both low PA and low NA is a difficult problem.

Sequences with low APA are often parameterized by their merit factor (MF), where

$$\mathrm{MF}(\mathbf{a}) = \frac{N^2}{2\sum_{k=1}^{N-1} |\rho(k)|^2} \tag{41}$$

and high MF implies low APA. Finding sequences with highest MF is closely related to the APA problem, and has been studied by a few authors [16,17]. The BPSK sequence with highest known MF is of length 13 and has an MF of 14.08. This sequence has $\max_{k>0} |\rho(k)| = \max_{k>0} |\rho_p(k)| = \max_{k>0} |\rho_n(k)| = 1$. In words, the optimum periodic and negaperiodic properties of **a** guarantee its aperiodic optimality. Although BPSK sequences have been found with MF $\simeq$ 9.0 up to length 117, these sequences are the result of optimized computer search. *Very few* infinite constructions for high MF sequences are known. The best-known are the offset Legendre, twin prime, and (modified) Jacobi constructions. These constructions generate sequences with optimally low PA, moderately low NA, and with MF $\to$ 6.0 as $N \to \infty$, and this is the highest asymptote known for BPSK. A more recent Legendre-type infinite construction has generated sequences with optimally low NA, moderately low PA, and again with MF $\to$ 6.0 as $N \to \infty$. In contrast, both the m sequence and length 2^m complementary sequence have an asymptotic MF of 3.0 [17]. Finally we note that if an infinite construction could be found such that $|\rho_p(k)| \leq c_p, |\rho_n(k)| \leq c_n$, where c_p, c_n are constants, and $k > 0$, then, as $N \to \infty$, the construction would have asymptotically infinite MF. The existence of such a sequence construction is extremely unlikely.

5.2.4. Golay–Davis–Jedwab Codes. Many of the early code proposals were comprehensively generalized by Davis and Jedwab when they proposed an infinite family of binary Golay complementary sequences with parameters $[2^m, \log_2(m!) + m, 2^{m-2}, 2.0]$, and defined them as certain Reed–Muller (RM) RM(2, m) cosets of RM(1, m). We call this family *DJ*, where *DJ* comprises codewords, $c(\mathbf{x})$, with algebraic normal form

$$c(\mathbf{x}) = \sum_{i=0}^{m-2} x_{\pi(i)} x_{\pi(i+1)} \oplus \sum_{i=0}^{m-1} g_i x_i \oplus h\mathbf{1}$$

where $g_i, h \in (0, 1)$, $\mathbf{1}$ is the all-ones vector, π is a permutation of the integers $\{0, 1, \ldots, m-1\}$ and the x_i are binary variables representing length 2^m binary sequences such that element t of x_i is $\left\lfloor \dfrac{t}{2^i} \right\rfloor$, mod 2. The DJ construction was also generalized to higher alphabets and to PARs that are a multiple of 2. The construction is optimal for low N. For instance, for $m = 3$ and binary sequences we can construct an optimal $[8, \log_2(48), 2, 2.0]$ DJ code. There are only 16 more sequences with PAR $\leq$ 2.0, which are not included in the DJ set, and the inclusion of any of these sequences would reduce d from 2 to 1. Unfortunately the rate, k/N, of the DJ construction vanishes rapidly for $N > 32$. Therefore the DJ construction is practically useful only in the context of OFDM for systems requiring no more than 32 subcarriers. It remains an open problem to discover low PAR error-correcting code constructions for $N > 32$ with an acceptable rate. Unfortunately, many OFDM systems require anything from 8 to 8192 subcarriers.

5.2.5. Rudin–Shapiro Recursion and Its Generalizations. The DJ construction can be viewed as Rudin–Shapiro recursion [18]. Let length N sequences, $\mathbf{a_i}$ and $\mathbf{b_1}$ satisfy $P_{\mathbf{a}}(t) + P_{\mathbf{b}}(t) \leq Q$ so that both **a** and **b** have PAR $\leq Q$. Then

it can be shown that sequence concatenations $\mathbf{a_{i+1}} = \mathbf{a_i} \mid \mathbf{b_i}$ and $\mathbf{b_{i+1}} = \mathbf{a_i}|\overline{\mathbf{b_i}}$ both have PAR $\leq Q$, where "|" means concatenation, and "$\overline{*}$" means negation of every component of *. When $Q = 2$, the recursive definition, along with swapping the places of $\mathbf{a}$ and $\mathbf{b}$, and varying the position of the negation, gives the complete DJ binary codeset. This is the case when $\mathbf{a_0}, \mathbf{b_0} \in \{1, -1\}$. More generally, $\mathbf{a_0}$ and $\mathbf{b_0}$ can be any length N_1 pair of sequences, where we wish Q to be as close to 2.0 as possible. Then we can construct a Rudin–Shapiro-type code from this 'seed pair' with parameters $[N_1 2^m, \log_2(m!) + m, d_s 2^{m-2}, Q]$, where $d_s = \min(d_H(\mathbf{a_0}, \mathbf{b_0}), d_H(\mathbf{a_0}, \overline{\mathbf{b_0}}))$.

For N_1 small these codes are roughly the same size as the DJ code with marginally worse PAR. Moreover one can form the union of codes constructed this way, where the distance of the combined codeset is dependent on the set of seed pairs, and the PAR is governed by the constituent code with highest Q. However, as Rudin–Shapiro recursion generates a quadratic extension of an arbitrary-degree seed, the rate of the construction still vanishes as N increases, as quadratics constitute a vanishingly small part of the whole space of 2^N sequences. We can devise higher-degree constructions by viewing the parameters of the Rudin–Shapiro construction as arising from orthogonality of the matrix $\mathbf{R} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$, where $\mathbf{v_{i+1}} = \begin{pmatrix} \mathbf{a_{i+1}} \\ \mathbf{b_{i+1}} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} \mathbf{a_i} \\ \mathbf{b_i} \end{pmatrix}$, where addition is replaced by concatenation (more generally *tensor sum*). Let $[N_i, k_i, d_i, \eta_i]$ be the code parameters at iteration i of the recursion. Let r and c be the number of rows and columns of the associated matrix, $\mathbf{R}$, respectively, and δ be the number of rows and columns of the associated matrix, $\mathbf{R}$, respectively, and δ be the Hamming distance between rows of $\mathbf{R}$. Then, using matrix $\mathbf{R}$ along with permutation and negation to define the recursion, we get

$$\begin{aligned} N_{i+1} &= cN_i & k_{i+1} &= c\tbinom{r}{c}k_i \\ d_{i+1} &= \min(\delta(N_i - d_i) + (c-\delta)d_i, \delta d_i \\ &\quad + (c-\delta)(N - d_i)) & \eta_{i+1} &= f(\eta_i, i) \end{aligned}$$

where $N_0 = T, k_0 = r, d_0 = d_T, \eta_0 = \eta_T$, and where f is some function determined by the closeness to orthogonality of the matrix $\mathbf{R}$. If $\mathbf{R}$ is orthogonal then $f(\eta_i, i) = \eta_i$. The rate can be improved (as is the case with the DJ code) at the price of distance by including all tensor permutations of the construction. It is possible to increase the rate still further, at the price of distance, by including further permutations of v_i in between iterations. Thus there are a vast number of currently unexplored recursive constructions based on orthogonal and near-orthogonal matrices of various dimensions. Near-orthogonal constructions are of particular interest as they provide a moderate increase in PAR while also providing a large number of rows to maintain rate as N increases.

5.3. Other Techniques

The tone reservation approach has been proposed for the reduction of PAR of OFDM signals by Tellado and Cioffi [19]. In this method, both the transmitter and receiver agree on reserving a small subset of tones for generating PAR reduction signals. The transmitter does not send data on these reserved tones. The complex baseband signal may now be represented as

$$s(t) = \sum_{k \in I_{\text{info}}}^{N-1} c_k e^{j2\pi k \Delta f t} + \sum_{k \in I_{\text{tones}}}^{N-1} b_k e^{j2\pi k \Delta f t}, 0 \leq t \leq T \qquad (42)$$

where I_{info} and I_{tones} are two disjoint tone-index sets such that

$$I_{\text{info}} \cup I_{\text{tones}} = \{0, 1, \ldots, N-1\}$$

The values $b_k, k \in I_{\text{tones}}$, will be called PAR reduction tones (PRTs). The redundancy for this method is

$$R = \frac{|I_{\text{tones}}|}{N} \qquad (43)$$

Parallel combinatory OFDM [20] reduces the PAR without reducing the bandwidth efficiency and without increasing the bit error probability. An OFDM system with N subcarriers using q-PSK can transmit q^N different OFDM symbols. PC-OFDM is based on expanding the q-PSK signal constellation with one extra, zero-amplitude, point. With this expanded signal constellation, the number of different OFDM symbols increases to $(q+1)^N$. A subset of these modified OFDM symbols may be chosen with lower PAR. The authors show that this method will have at least the same bandwidth efficiency, and lower bit error probability, when compared to the original OFDM system.

Another PAR reduction method, and the simplest, is to deliberately clip the OFDM signal before amplification. In particular, since the large peaks occur with very low probability, clipping could be an effective technique for PAR reduction. However, clipping is a nonlinear process and may cause significant in-band distortion, which increases the bit error rate, and out-of-band noise, which reduces the spectral efficiency. Filtering after clipping can reduce the spectral splatter but may also cause some peak regrowth. Peak regrowth can however be reduced by oversampling the OFDM signal and clipping [21,22].

Henkel and Wagner [23] develop a trellis shaping technique for PAR reduction. In this method, a valid code sequence of a convolutional code is added (modulo 2) to a data sequence. The code sequence is chosen to reduce the PAR. If H is the parity-check matrix of the convolutional code, then for a valid code sequence y we have $yH^T = 0$. This property can be used to eliminate the added code sequence at the receiver side. However, it is necessary to precode the information sequence with the left inverse $(H^T)^{-1}$.

BIOGRAPHIES

C. Tellambura received his B.Sc. degree with honors from the University of Moratuwa, Sri Lanka, in 1986, his M.Sc. in electronics from the King's College, UK, in 1988, and his Ph.D. in electrical engineering from the University of Victoria, Canada, in 1993. He was a postdoctoral research fellow with the University of Victoria and the University of Bradford. Currently, he is a senior lecturer at Monash University, Australia. He is an editor for the *IEEE Transactions on Communications* and the *IEEE Journal on Selected Areas in Communications* (Wireless

Communications Series). His research interests include coding, communications theory, modulation, equalization, and wireless communications.

Matthew G. Parker received a B.Sc. in electrical and electronic engineering in 1982 from University of Manchester Institute of Science and Technology, U.K. and, in 1995, a Ph.D. in residue and polynomial residue number systems from University of Huddersfield, U.K. From 1995 to 1998 he was a postdoctoral researcher in the Telecommunications Research Group at the University of Bradford, U.K., researching into coding for peak factor reduction in OFDM systems. Since 1998 he has been working as a postdoctoral researcher with the Coding and Cryptography Group at the University of Bergen, Norway. He has published on residue number systems, number-theoretic transforms, complementary sequences, sequence design, quantum entanglement, coding for peak power reduction, factor graphs, linear cryptanalysis, and VLSI implementation of Modular arithmetic.

PERMUTATION CODES

EMANUELE VITERBO
Politechnico di Torino
Torino (Turin), Italy

1. INTRODUCTION

Permutation codes were proposed by David Slepian in 1965 [12]. In the quest for efficient codes for the band-limited Gaussian channel, permutation codes are among the first attempts to solve the problem taking into account both coding gains and decoding efficiency. Permutation codes are multidimensional spherical signal constellations with the desirable property that they possess a very simple maximum-likelihood (ML) decoding algorithm. Slepian used the term *permutation modulation* for his permutation codes.

A *variant I* permutation modulation is the set of codewords obtained by taking all permutations of an initial vector in the n-dimensional Euclidean space. A *variant II* permutation modulation is the set of codewords obtained by taking all permutations and sign changes of the components of an initial vector in the n-dimensional Euclidean space. Trivial examples of variant I and variant II modulations are orthogonal and biorthogonal codes,

respectively. Also pulse code modulation (PCM), pulse position modulation (PPM), and simplex codes can be viewed as permutation modulations.

Good permutation modulations may be designed by appropriately selecting the initial vector. Permutation modulations may be very efficiently decoded by essentially applying a sorting algorithm to the received signal vector. Permutation modulations are very special cases of group codes for the band-limited channel proposed by Slepian [10,13].

Karlof later proposed the term *permutation code* for a generalization of permutation modulations [6]. In particular, he studied the group codes obtained from subgroups of the symmetric group (the group of permutations of n objects). The resulting spherical codes may be seen as particular subsets of the corresponding permutation modulation. We can think of permutation modulation as a "full rate" permutation code. In this case the initial vector selection problem and the decoding algorithm are much harder [6–8].

Here, we will focus on permutation codes according to Slepian's definition. This article is organized as follows. The next section introduces the notation and gives detailed definition of permutation modulation. Performance in terms of error probability and the ML decoding algorithm are also presented. Section 3 gives some examples of permutation codes and discusses some application issues.

2. THEORY

Digital transmission over the band-limited additive white Gaussian noise (AWGN) channel is commonly modeled in the n-dimensional Euclidean space $\mathbf{R}^n$ as $\mathbf{y} = \mathbf{x} + \mathbf{n}$, where $\mathbf{y}$ is the received signal vector, $\mathbf{x}$ is the transmitted signal vector (or codeword) taken from a finite signal constellation (or codebook) $\mathcal{S}$, and $\mathbf{n} \sim \mathcal{N}(\mathbf{0}, \sigma^2\mathbf{I})$ is a real Gaussian random vector with i.i.d. (independent, identically distributed) components. The space dimension n is related to the time–bandwidth product through the sampling theorem, namely, if T is the signal duration and W the occupied bandwidth, then $n = 2WT$.

Letting $M = |\mathcal{S}|$ be the number of points in the constellation, we define the spectral efficiency as

$$\frac{R}{W} = \frac{2}{n}\log_2 M \text{ bps/Hz} \tag{1}$$

Let $r = \log_2 M$. If we are interested in transmitting binary information, we simply label $2^{[r]}$ codewords by distinct binary vectors of length $[r]$ and disregard the remaining $M - 2^{[r]}$ codewords.[1]

The average signal power of $\mathcal{S} = \{\mathbf{x}_i\}_0^{M-1}$ is given by

$$\mathcal{P} = \frac{1}{nM}\sum_{i=0}^{M-1}\|\mathbf{x}_i\|^2 \tag{2}$$

where $\|\cdot\|$ denotes the Euclidean norm in $\mathbf{R}^n$.

The maximum-likelihood (ML) receiver gives an estimate $\hat{\mathbf{x}}$ of the transmitted codeword $\mathbf{x}$ according to the minimum distance criterion

$$\hat{\mathbf{x}} = \arg\min_{\mathbf{x}_i \in \mathcal{S}} \|\mathbf{y} - \mathbf{x}_i\|^2 \tag{3}$$

[1] Where $[x]$ denotes the greatest integer smaller than x.

We note that the complexity of the ML receiver depends greatly on the structure of the code $\mathcal{S}$. In the worst case a total of M Euclidean distances must be computed. For large values of M this may be impractical; hence it is common to trade some of the performance for a reduced decoding complexity. Many classical forward error-correcting (FEC) codes have been selected for applications because they have simple decoding algorithms.

The average codeword error probability with ML detection is given by

$$P(e) = \frac{1}{M}\sum_{i=0}^{M-1} P(e \mid \mathbf{x}_i) = \frac{1}{M}\sum_{i=0}^{M-1}\int_{\overline{\mathcal{R}_i}} \frac{e^{-\|\mathbf{x}-\mathbf{x}_i\|^2/(2\sigma^2)}}{(2\pi\sigma^2)^{n/2}}\,d\mathbf{x} \tag{4}$$

where $\overline{\mathcal{R}_i} = \mathbf{R}^n \backslash \mathcal{R}_i$ is the complement of the decision region corresponding to the codeword $\mathbf{x}_i$, defined as

$$\mathcal{R}_i = \{\mathbf{z} \in \mathbf{R}^n : \|\mathbf{z} - \mathbf{x}_i\| < \|\mathbf{z} - \mathbf{x}_j\|, \quad \forall j \neq i\} \tag{5}$$

These regions are also known as *minimum-distance* or ML regions.

Good codes should be designed in order to minimize $P(e)$, given the parameters M, n, $\mathcal{P}$, and σ. Shannon showed that the codeword error probability decreases exponentially with n and gave the famous asymptotic result that, for given R, W, and $\mathcal{P}/\sigma^2$, the $P(e)$ can be made arbitrarily small as $n \to \infty$, provided that $R < C$, where

$$C = W\log_2\left(1 + \frac{\mathcal{P}}{\sigma^2}\right) \tag{6}$$

On the contrary, if $R > C$, then $P(e) \to 1$ as $n \to \infty$.

Explicit construction of optimal codes is an open problem and has been analyzed in some very special cases only [1,15].

2.1. Definitions

Let $\{\mu_1, \ldots, \mu_k\}$ be a set of distinct real numbers with $\mu_1 < \mu_2 < \cdots < \mu_k$, and let $\{m_1, \ldots, m_k\}$ be a set of positive integers such that

$$n = \sum_{j=1}^{k} m_j \tag{7}$$

Consider the initial vector with components sorted in ascending order:

$$\mathbf{x}_0 = (\underbrace{\mu_1, \ldots, \mu_1}_{m_1}, \underbrace{\mu_2, \ldots, \mu_2}_{m_2}, \ldots, \underbrace{\mu_k, \ldots, \mu_k}_{m_k}) \tag{8}$$

A variant I permutation code consists of the set of vectors obtained by permuting the components of the initial vector $\mathbf{x}_0$. The total number of codewords in such a code is

$$M_I = \frac{n!}{m_1!m_2!\cdots m_k!} \tag{9}$$

The variant I code with $k = 2$, $m_1 = n - 1$, $m_2 = 1$, and $\mu_1 = 0$ is the well-known PPM or orthogonal modulation.

A variant II permutation code consists of the set of vectors obtained by permuting and applying all possible sign changes to the components of the initial vector $\mathbf{x}_0$. Without loss of generality, we may assume

$$0 \leq \mu_1 < \mu_2 < \cdots < \mu_k \tag{10}$$

The total number of codewords in this code is

$$M_{\mathrm{II}} = \frac{2^h n!}{m_1! m_2! \cdots m_k!} \tag{11}$$

where $h = n - m_1$, if $\mu_1 = 0$ and $h = n$, if $\mu_1 > 0$.

The variant II code with $k = 2$, $m_1 = n - 1$, $m_2 = 1$, and $\mu_1 = 0$ results in the well-known biorthogonal modulation. The variant II code with $k = 1$, $m_1 = n$, and $\mu_1 \neq 0$ yields an n-bit PCM. In this case the points of $\mathcal{S}$ correspond to the 2^n vertices of an n-dimensional hypercube of edge length $2\mu_1$.

It is clear that all codewords of both variant I and II codes lie on a hypersphere of radius $\sqrt{n\mathcal{P}}$ centered at the origin and

$$\mathcal{P} = \frac{1}{n} \sum_{j=1}^{k} m_j \mu_j^2 \tag{12}$$

2.2. Decoding

Let us consider ML decoding of variant I codes. We need to find the minimum of the quantities

$$\|\mathbf{y} - \mathbf{x}_i\|^2 = \|\mathbf{y}\|^2 + \|\mathbf{x}_i\|^2 - 2(\mathbf{y}, \mathbf{x}_i) = \|\mathbf{y}\|^2 + n\mathcal{P} - 2(\mathbf{y}, \mathbf{x}_i), \quad i = 0, \ldots, M-1 \tag{13}$$

where $(\mathbf{y}, \mathbf{x}_i)$ denotes the scalar product of the two vectors. Since $\|\mathbf{y}\|$ is independent of i, the ML decoder may simply maximize the scalar product between the received vector and the codewords:

$$\hat{\mathbf{x}} = \arg \max_{\mathbf{x} \in \mathcal{S}} \sum_{k=1}^{n} x_k y_k \tag{14}$$

This maximization problem may be solved as follows. Given the received vector $\mathbf{y}$, replace the smallest m_1 components by the values μ_1, replace the smallest m_2 remaining components with μ_2, and so on until all the components have been replaced.

It is interesting to show the very simple and elegant proof of the optimality of this decoding algorithm given by Slepian. In particular, we want to show that the sum

$$x_{i_1} y_1 + x_{i_2} y_2 + \cdots + x_{i_n} y_n \tag{15}$$

is maximized by the permutation of indices $(i_1, i_2, \ldots, i_n)$, which pairs the largest x to the largest y, the second largest x to the second largest y, and so forth.

For $n = 1$ it is trivially true; then we proceed by induction. For some $n > 1$, let $\overline{x}$ and $\overline{y}$ denote the largest x and the largest y. If $\overline{x}$ is not paired with $\overline{y}$ in (15), then the sum contains the two terms $\overline{x}y' + \overline{y}x'$ for some $x' \leq \overline{x}$ and $y' \leq \overline{y}$. If we swap x' with $\overline{x}$, the sum (15) will decrease; in fact

$$(\overline{x}\overline{y} + x'y') - (\overline{x}y' + \overline{y}x') = (\overline{x} - x')(\overline{y} - y') \geq 0 \tag{16}$$

Hence, pairing $\overline{x}$ with $\overline{y}$ maximizes the sum (15). We now delete $\overline{x}\overline{y}$ from the sum and proceed by induction on the $n - 1$ terms; pairing the second largest x to the second largest y does not reduce the $n - 1$ term sum, and so on.

For variant II codes ML decoding can be performed as follows:

1. Take the absolute value of the components of the received vector $\mathbf{y}$; that is, let
$$\mathbf{y}' = (|y_1|, |y_2|, \ldots, |y_n|)$$
2. Apply the decoder of variant I codes to $\mathbf{y}'$ to make a first decision $\mathbf{x}'$.
3. The final decision is given by
$$\hat{\mathbf{x}} = (\mathrm{sgn}(y_1)x'_1, \mathrm{sgn}(y_2)x'_2, \ldots, \mathrm{sgn}(y_n)x'_n)$$
where $\mathrm{sgn}(x) = +1$, if $x \geq 0$ and $\mathrm{sgn}(x) = -1$, if $x < 0$.

It can be shown that this algorithm is equivalent to solving the maximization problem (14).

The complexity of these decoding algorithms is rather small if compared to the brute-force exhaustive search. In particular, it is enough to perform a sorting algorithm on the n components of the received vector and to keep track of the final index permutation. This permutation uniquely identifies the ML decoded codeword, and the corresponding information bit label may be easily recovered. Sorting can be performed with a complexity of $O(n \log(n))$, whereas exhaustive decoding requires Mn multiplications and $M(n-1)$ additions.

2.3. Decision Regions and Error Probability

Evaluation of the average codeword error probability [4] for permutation codes can be simplified by the following argument. Consider the collection $\mathcal{C}$ of all $n \times n$ permutation matrices, that is, matrices having a single entry equal to one in each row and column and zeros in the remaining positions. When a permutation matrix is applied to the vectors of the codebook of a variant I code, it simply maps the codebook back into itself. In $\mathcal{C}$ we can find a permutation matrix A_{ij} that maps any codeword $\mathbf{x}_i$ into the codeword $\mathbf{x}_j$.

The permutation matrices are also orthogonal matrices so that, when they operate on $\mathcal{S}$, they preserve the distances between the points. Since the decision regions are defined in (5) in terms of distances, the permutation matrix A_{ij} also sends $\mathcal{R}_i$ into $\mathcal{R}_j$. Thus all the decision regions of a variant I code are congruent, and (4) reduces to $P(e) = P(e \mid \mathbf{x}_i)$, which is independent of i.

For variant II codes, a similar argument also enables us to conclude that $P(e) = P(e \mid \mathbf{x}_i)$ is independent of i. In particular, it is enough to replace the collection $\mathcal{C}$ by the collection $\mathcal{O}$ of $2^n n!$, $n \times n$ matrices having a single nonzero entry equal to $+1$ or -1 in each row and column.

We note that this simplification is similar to the one that can be used in evaluating the codeword error probability of linear codes, where it is convenient to consider the case where the all-zero codeword is transmitted. For permutation codes we will focus on $P(e \mid \mathbf{x}_0)$.

Let us now consider in detail the average codeword error probability of variant I codes. First observe that the received vector components have independent Gaussian distributions. The first m_1 components have mean μ_1 and variance σ^2, the next m_2 components have mean μ_2 and variance σ^2, and so on.

Assume that the codeword $\mathbf{x}_0$ was transmitted. To understand when a decoding error appears, let us split the received vector components into k runs of length m_j each:

$$\mathbf{y} = (y_1^{(1)}, y_2^{(1)}, \ldots, y_{m_1}^{(1)}, y_1^{(2)}, y_2^{(2)}, \ldots, y_{m_2}^{(2)}, \ldots, y_1^{(k)}, y_2^{(k)}, \ldots, y_{m_k}^{(k)}) \tag{17}$$

The correct decision will be made if the first m_1 components are smaller than the following m_2 components, the next m_2 components are smaller than the following m_3 components, and so forth. Then we can write

$$P_{\mathrm{I}}(e) = P_{\mathrm{I}}(\mu_1, \mu_2, \ldots, \mu_k) = 1 - P\{\eta_1 \le \xi_2 \le \eta_2 \le \xi_3 \le \cdots \le \eta_{k-1} \le \xi_k\} \tag{18}$$

where, for $j = 1, \ldots, k$

$$\xi_j = \min(y_1^{(j)}, y_2^{(j)}, \ldots, y_{m_j}^{(j)})$$

$$\eta_j = \max(y_1^{(j)}, y_2^{(j)}, \ldots, y_{m_j}^{(j)})$$

and the n independent Gaussian random variables $y_i^{(j)}$ have mean μ_j and variance σ^2.

Note that $P_{\mathrm{I}}(e)$ depends only on the differences of the μ values; thus, for all δ

$$P_{\mathrm{I}}(\mu_1 + \delta, \mu_2 + \delta, \ldots, \mu_k + \delta) = P_{\mathrm{I}}(\mu_1, \mu_2, \ldots, \mu_k) \tag{20}$$

Let $\beta_1 = \mu_1$ and $\beta_i = \mu_i - \mu_{i-1}$, for $i = 2, \ldots, k$. Let

$$\phi(z) = \frac{1}{\sqrt{2\pi}\sigma} e^{-z^2/(2\sigma^2)} \tag{21}$$

be the probability distribution function of a zero-mean Gaussian random variable with variance σ^2 and

$$\Phi(x) = \int_{-\infty}^{x} \phi(z)\, dz \tag{22}$$

the corresponding cumulative distribution function.

Slepian [12] has shown that for both variants I and II it is possible to bound $P(e)$ as

$$B - \frac{B^2}{2} \le P(e) \le B \tag{23}$$

For variant I codes, we obtain

$$B = B_{\mathrm{I}} = \sum_{i=2}^{k} P_{m_i, m_{i-1}}(\beta_i) \tag{24}$$

and

$$P_{m,n}(\alpha) = P_{n,m}(\alpha) = n \int_{-\infty}^{\infty} \phi(z)[1 - \Phi(z)]^{n-1} \times [1 - \Phi^m(z + \alpha)]\, dz \tag{25}$$

For variant II, when $\mu_1 = 0$, we have

$$B = B_{\mathrm{II}} = \overline{P}_{m_1, m_2}(\beta_i) + \sum_{i=3}^{k} P_{m_i, m_{i-1}}(\beta_i) \tag{26}$$

where

$$\overline{P}_{m,n}(\alpha) = 2m \int_{0}^{\infty} \phi(z)[1 - 2\Phi(-z)]^{m-1} \times \{1 - [1 - \Phi(z - \alpha)]^n\}\, dz \tag{27}$$

and when $\mu_1 \neq 0$

$$B = B_{\mathrm{II}'} = 1 - [1 - \Phi(-\beta_1)]^{m_1} + \sum_{i=2}^{k} P_{m_i, m_{i-1}}(\beta_i) \tag{28}$$

3. EVALUATION

We are now able to consider the problem of selecting good permutation codes for a fixed dimension n. We want to optimize the choice of k, the μ values, and the m values. From (1), (9), and (11) we see that R is independent of the μ values and depends only on k and the m values.

It is natural to fix k and the m values (i.e., fix R) and choose the μ values to minimize $\mathcal{P}$ for some fixed value of $P(e)$.

For variant I codes, the first optimization step to reduce the average signal power is to center the signal constellation $\mathcal{S}$ around its barycenter, by selecting

$$\sum_{j=1}^{k} m_j \mu_j = 0 \tag{29}$$

By imposing this condition to PPM, we obtain the simplex modulation. For variant II codes, $\mathcal{S}$ is already centered around its barycenter.

The optimization problem has been solved numerically [12], and some optimal codes are presented for various n, m values, and k for two values of $P(e) = 10^{-3}$ and $P(e) = 10^{-5}$. A simplified version of the code optimization problem was solved analytically by Biglieri and Elia [2] and independently by Ingemarson [9]. They selected the μ values in order to maximize the minimum Euclidean distance $d_{\min}$, among the points of $\mathcal{S}$, for a fixed average power $\mathcal{P}$. Here, we report the optimal codes for $P(e) = 10^{-5}$ in Table 1.

Figures 1–4 show the codeword error probability of the codes in Table 1 as a function of E_b/N_0, where $E_b = n\mathcal{P}/r$ and $N_0 = 2\sigma^2$. These figures may be interpreted as follows. Given the system constraints T (maximum acceptable

Table 1. Optimized Codes at $P(e) = 10^{-5}$ Found by Slepian [12]

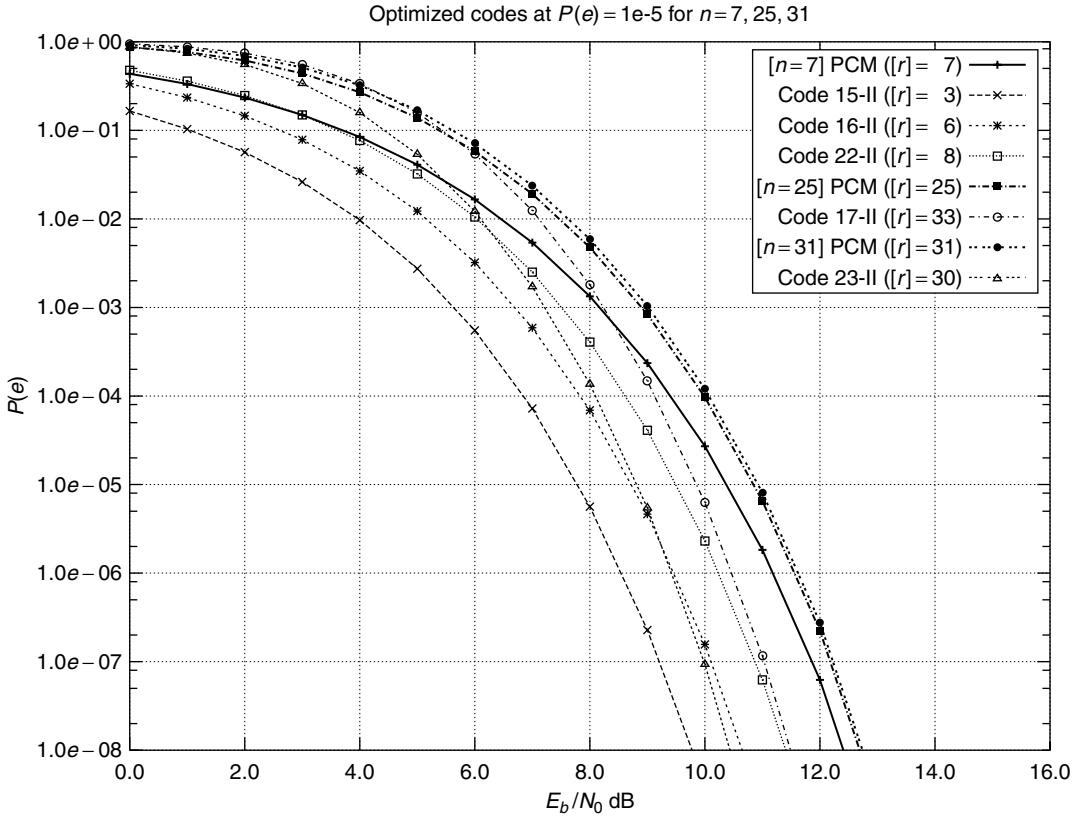

Figure 3. Optimized codes at $P(e) = 10^{-5}$ for $n = 7, 25, 31$.

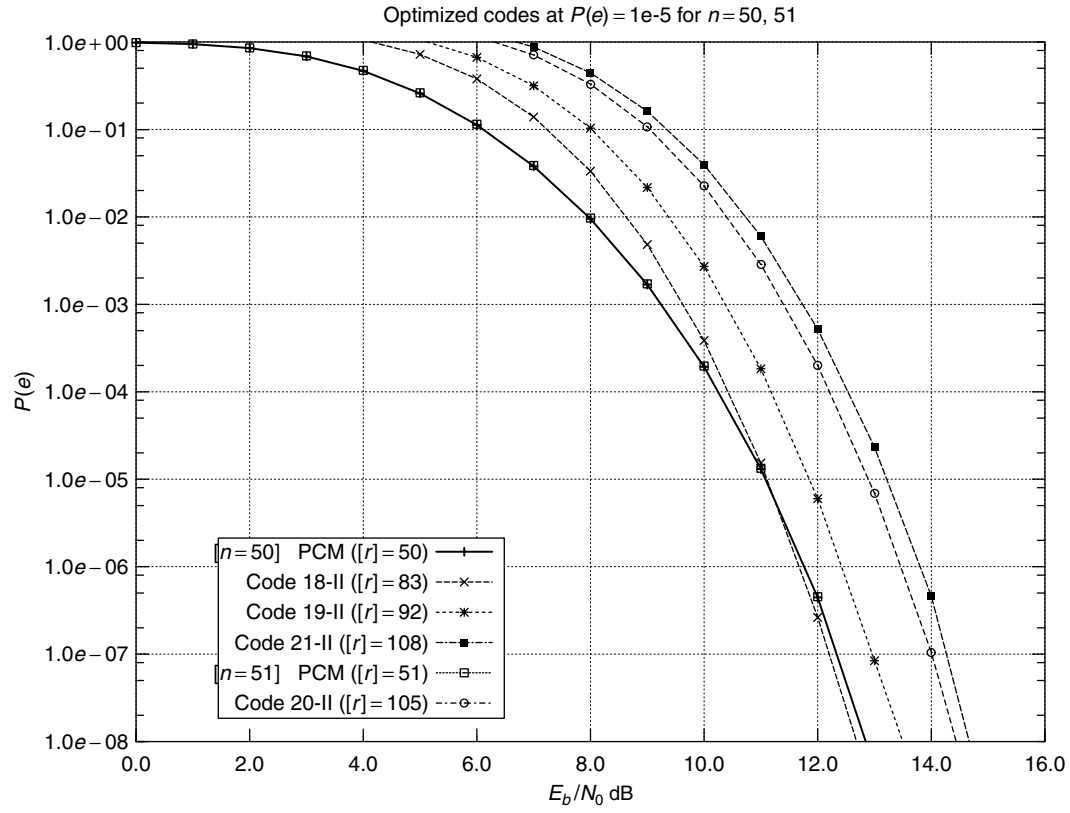

Figure 4. Optimized codes at $P(e) = 10^{-5}$ for $n = 50, 51$.

delay) and W (available bandwidth), we have n; then we can chose among the codes of different rate the one that satisfies our packet error rate $P(e)$ requirement.

For example, code 3 for $n = 5$ enables us to transmit at the same rate of the 5-bit PCM with a lower $P(e)$, corresponding to an asymptotic gain of 1.2 dB (see Fig. 1). Code 10 enables us to transmit at 0.9 the rate of PCM with an asymptotic gain of 2.2 dB (see Fig. 2). Code 23 enables us to transmit at almost at the same rate of PCM with an asymptotic gain of 2.9 dB (see Fig. 3).

Figure 5 shows the performance of the optimal codes given by Slepian [12] at $P(e) = 10^{-3}$. Comparison with Fig. 1 shows that their performance in almost identical in both cases, so we may conclude that the optimization is quite insensitive to the value $P(e)$.

Given an n-dimensional code, we define its asymptotic coding gain with respect to an n bit PCM as

$$\gamma = \frac{d^2_{\min}/E_b}{d^2_{\min,\mathrm{PCM}}/E_{b,\mathrm{PCM}}} \tag{30}$$

We report γ in decibels in the last column of Table 1. These asymptotic values can be approximately verified in all figures at $P(e) = 10^{-8}$, with an accuracy of about 0.5 dB.

We conclude with a few comments on the possible application of permutation codes. In order to implement the transmitter, we need to define an orthonormal basis $\{\psi_j(t)\}_1^n$ of the signal space so that each transmitted signal is given by

$$x(t) = \sum_{j=1}^{n} x_j \psi_j(t) \tag{31}$$

The basis functions must be approximately time- and band-limited. For example, we can select the strictly bandlimited functions

$$\psi_j(t) = \frac{\sin(2\pi Wt - j\pi)}{2\pi Wt - j\pi} \quad j = 1, \ldots, n \tag{32}$$

or the strictly time-limited functions for $0 \le t \le T$

$$\psi_{2j-1}(t) = \sin\left(\frac{2\pi jt}{T}\right)$$
$$\psi_{2j}(t) = \cos\left(\frac{2\pi jt}{T}\right) \quad j = 1, \ldots, \frac{n}{2} \tag{33}$$

Other choices are also possible [e.g., 3–5,11]. The receiver can be implemented using a bank of matched filters, matched to the basis functions in order to obtain the components of the received vector $\mathbf{y}$.

Although permutation codes have a very long history and some very promising coding gains, to the author's knowledge, they have never been used in applications. Nevertheless, we can be expect that they may be exploited in the future for high-speed transmission, due to their very simple decoding algorithm.

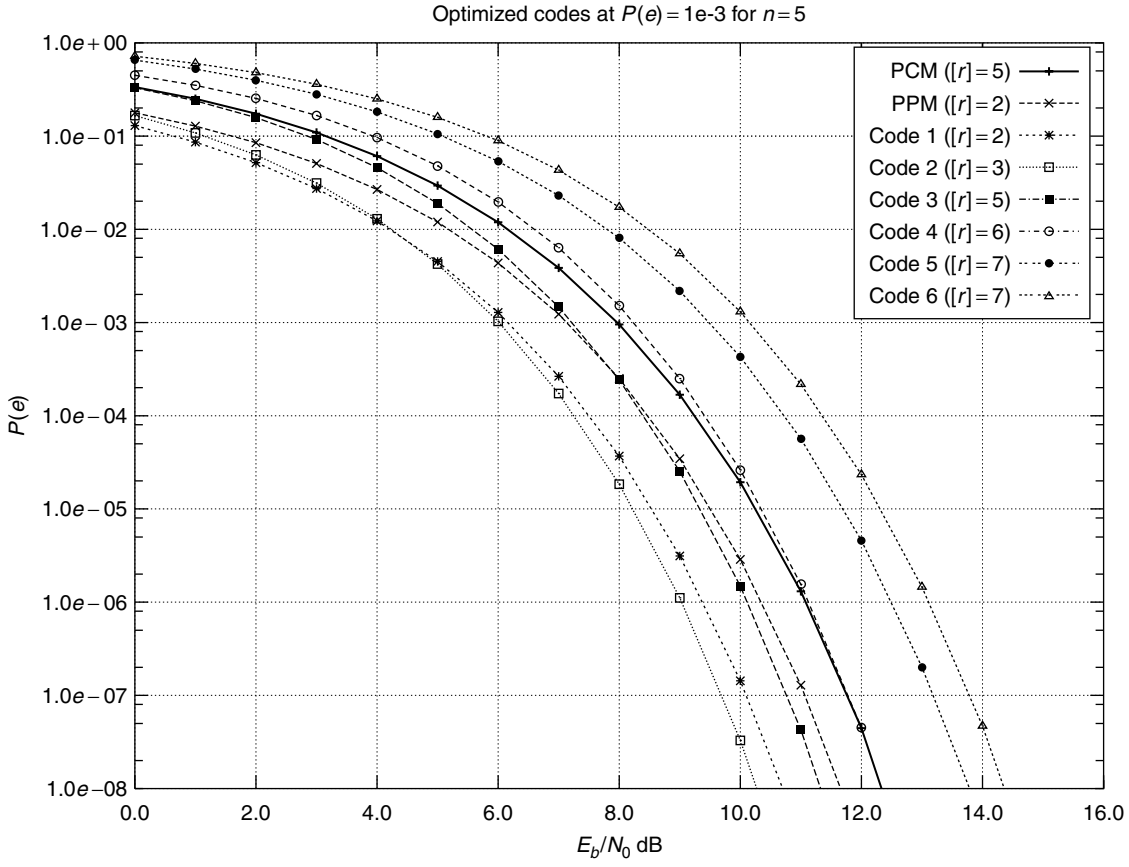

Figure 5. Optimized codes at $P(e) = 10^{-3}$ for $n = 5$.

BIOGRAPHY

Emanuele Viterbo was born in Torino (Turin), Italy, in 1966. He received his baccalaureate degree (Laurea) in Electrical Engineering in 1989 and his Ph.D. in 1995 in Electrical Engineering, both from the Politecnico of Torino, Torino, Italy. From 1990 to 1992 he was with the European Patent Office, The Hague, The Netherlands, as a patent examiner in the field of dynamic recording and in particular in the field of error-control coding. Between 1995 and 1997 he held a postdoctoral position in the Dipartimento di Elettronica of the Politecnico di Torino in Communications Techniques over Fading Channels. Between 1997 and 1998 he was Visiting Researcher in the Information Sciences Research Center of AT&T Research, Florham Park, New Jersey. Since 1998, he has been Assistant Professor at Politecnico di Torino, Dipartimento di Elettronica. Dr. Emanuele Viterbo was awarded a NATO Advanced Fellowship in 1997 from the Italian National Research Council. His current research interests are in lattice codes for the Gaussian and fading channels, algebraic coding theory, digital terrestrial television broadcasting, and digital magnetic recording.

PHOTONIC ANALOG-TO-DIGITAL CONVERTERS

BARRY L. SHOOP
United States Military Academy
West Point, New York

1. INTRODUCTION

Analog-to-digital (A/D) conversion is the process by which an analog signal that is continuous in both time and amplitude is converted to a digital signal that is discrete in time and amplitude. The A/D converter is an important component in any electronic or photonic system that senses the natural environment and processes, stores, displays, or communicates the information using digital techniques. Since the vast majority of signals encountered in nature are analog and the preferred method of processing, storing, and transmitting signals is digital, this interface is generally considered to be the most critical and challenging part of the overall signal acquisition and processing system. Recent advances in both electronics and telecommunication markets as well as continued improvements in sensor resolution has renewed interest in the pursuit of high-speed, high-resolution A/D converters and has focused attention on photonic techniques to provide improvements in this technology area.

In general, the process of A/D conversion can be characterized by the four distinct functional blocks shown in Fig. 1. The analog input signal $x(t)$ is first band-limited to the range $0 \le f_x \le f_B$ (Hz) by a lowpass analog filter with cutoff frequency f_B to protect against aliasing that could occur during the subsequent sampling operation. The sampling operation in a conventional Nyquist rate A/D converter is chosen to satisfy the minimum Nyquist criterion: $f_S = f_N = 2f_B$, where f_S is the sampling frequency, f_N is the Nyquist frequency, and f_B is the constrained signal bandwidth. There are also other alternatives to sampling frequency depending on the specific application. Subsampling below the Nyquist rate is acceptable if the input signal is known to be periodic. Oversampling is another alternative in which $f_S \gg f_N$ and signal processing techniques are subsequently used to achieve improved amplitude resolution through a technique called *spectral noise shaping*. The output from the sampler is $x_n \equiv x(nT_S)$, where T_S is the uniform sampling period $T_S = 1/f_S$. Scalar quantization then maps each continuous-amplitude input x_n to one value in a discrete-amplitude ensemble $q_n \equiv q(nT_S)$. On the basis of the results of this mapping, the digital processor generates a digital codeword that most closely approximates the input analog signal value. The output $y_n \equiv y(nT_S)$ is then the multibit, digital word representing the input analog input value.

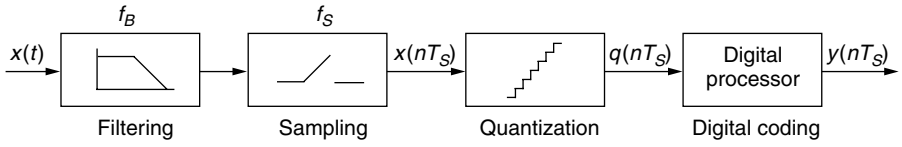

Figure 1. Generic analog-to-digital converter block diagram.

A complete coverage of the subject of photonic A/D conversion can be found in the 2001 book *Photonic Analog-to-Digital Conversion* [1]. For additional background and information on the general subject of A/D conversion, Refs. 2–5 provide an excellent overview.

1.1. Motivation for Photon-Based A/D Conversion

Photonic approaches to A/D conversion provide some distinct performance advantages over their electronic counterparts. Nonlinear optoelectronic devices have demonstrated ultrahigh switching speeds that can be applied to the quantization functionality required in the A/D converter. Mode-locked lasers provide high-speed and accurate optical pulses in the range of 0.5 ps–50 fs that can be used for precision clocks and sampling. These optical clocks provide the capability for ultrafast sampling with extremely low clock jitter. Another advantage specifically associated with optical sampling techniques is the decoupling of the sampled and sampling signals, achieved when the sampling signal is optical and the sampled signal is electronic. Mach–Zehnder interferometers that can be used for optical sampling and modulation have been demonstrated with modulation bandwidths of up to 120 GHz. Photonic techniques also bring the potential for utilization of the full two-dimensional (2D) nature of optics. Many other applications have successfully converted from temporal approaches to spatial approaches and, applying the 2D nature of optical processing, extended the performance of the specific application. Many current approaches to photonic A/D conversion are leveraging this higher dimensionality in an effort to extend converter performance bounds. Many photonic approaches to A/D conversion also produce output digital codes that are Gray codes directly, eliminating the need for additional hardware to produce these coding schemes.

2. HISTORICAL PERSPECTIVE

The application of photonic techniques to the problem of A/D conversion began with optical sampling. In 1970, Steigman and Kuizenga [6] first proposed the use of a mode-locked laser for optical sampling of an electronic signal. Later, in 1975, Taylor [7] applied optical sampling using mode-locked laser pulses to the first optical A/D converter. This optical A/D converter integrated Mach–Zehnder interferometers, avalanche photodetectors, and electronic comparators. In the early 1980s this basic approach was further developed by a group at the Massachusetts Institute of Technology (MIT) Lincoln Laboratory, demonstrating a 4-bit electrooptic A/D converter operating at a sampling frequency of 1 GHz [8]. Jalali and Xie extended this electrooptic A/D converter using a folding architecture [9].

In the early 1990s, Shoop and Goodman proposed the first optical approach to oversampling A/D conversion [10]. This work resulted in a proof-of-concept experimental demonstration of an optoelectronic oversampled A/D converter based on multiple quantum well modulators [11]. Later this work was extended to low-resolution photonic A/D conversion for digital image halftoning based on spatial oversampling and error diffusion using smart pixel technology [12]. A newer approach to photonic A/D has been developed that integrates spatial oversampling, an error diffusion neural algorithm, and spectral noise shaping for high-resolution A/D conversion applications [13,14]. Pace has investigated an alternate approach to photonic oversampled A/D conversion based on a fiber lattice accumulator [15,16].

In the late 1990s, there was renewed interest in photonic A/D conversion, particularly for high-speed A/D applications. The majority of these architectures relied on channelization or interleaving techniques that partition the wide-bandwidth input into N-parallel channels, each operating at $1/N$ of the original sampling rate. This approach allows integration of high-speed optical sampling and lower-speed conventional electronic quantization, taking advantage of each technology's strengths. Twichell and colleagues at MIT Lincoln Laboratory have applied phase-encoded optical sampling and a time-interleaving architecture to wideband photonic A/D conversion, demonstrating a 505-MS/s (megasample/second) system providing 8 bits of resolution [17,18]. Clark and colleagues at the Naval Research Laboratory have investigated time- and wavelength-interleaving for photonic A/D conversion [19,20]. Another interesting approach that falls within the context of a channelized architecture is based on time-stretch preprocessing using an optically dispersive element [21].

Since the mid-1970s, other approaches to photonic A/D converters have also been investigated. Most were novel approaches that were ultimately limited by speed, complexity, or resolution. The interested reader can find details of several of these other approaches to optical A/D conversion in the literature [22–29].

3. REPRESENTATIVE PHOTONIC A/D CONVERTER ARCHITECTURES

There are a variety of different approaches to photonic A/D conversion differing in the fundamental architectures as well as the photonic components used. The following examples of photonic A/D converters are not intended to be inclusive but rather provide an introduction to several representative approaches to the application of photonic architectures and devices to the problem of A/D conversion.

3.1. Electrooptic A/D Conversion

Probably the best known optical A/D conversion technique to date was developed by Taylor in 1975 [7]. He was the

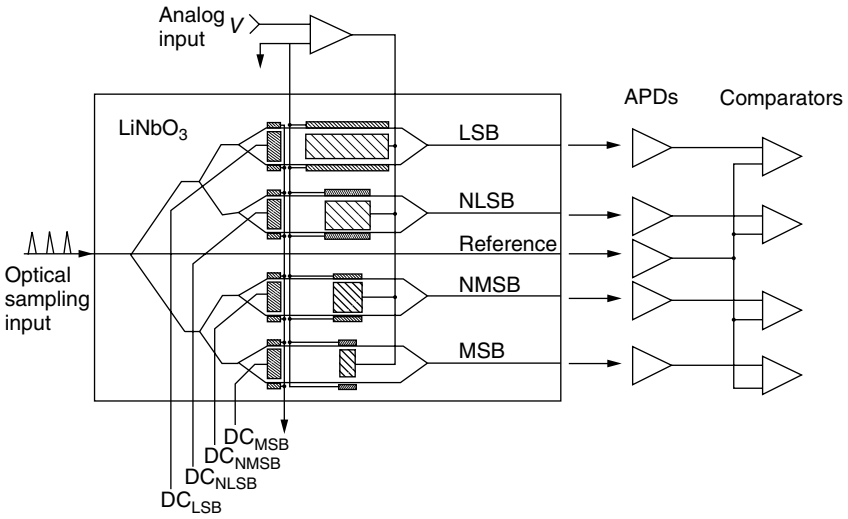

Figure 2. Schematic diagram of a 4-bit electrooptic A/D converter. (Reprinted with permission from B. L. Shoop, *Photonic Analog-to-Digital Conversion*, Springer Series in Optical Sciences, Vol. 81 [1], Fig. 5.1, p. 124. Copyright 2001, Springer-Verlag GmbH & Co. KG.)

first to recognize the relationship between the periodicity of the output of an interferometric electrooptic modulator with applied voltage and the periodic variation of a binary representation of an analog quantity. A 4-bit implementation of this concept is shown in Fig. 2 [8].

The basic optical element used in this architecture is a planar waveguide version of a Mach–Zehnder interferometric modulator. The interferometer consists of an electrooptic crystal containing a single-mode input optical waveguide that branches at a "Y" to split the optical power into two equal components. The light in the two paths then travels an equal distance before recombining at the second Y and exiting the crystal. The input analog voltage is applied to one arm of the interferometer through coplanar electrodes. In the absence of an applied electric field, the light from the two paths recombines in phase and produces a maximum in the output intensity. With an electric field applied to the electrode, the phase velocity of the light propagating in that arm is changed as a result of the linear electrooptic effect. The output intensity of a single interferometer can be shown to vary as

$$I = I_0 \cos^2\left(\frac{\phi}{2} + \frac{\psi}{2}\right) \tag{1}$$

where ψ is the static phase difference between the two paths and ϕ is the net electrooptic phase difference between the light propagating in the two guides

$$\phi = 2\pi L\left(\frac{\Delta n}{\lambda}\right) = kLV \tag{2}$$

Here, Δn is the refractive index change, V is the applied voltage, L is the modulator length, and k is a constant that depends on the electrooptic parameters of the crystal, the electrode spacing, and optical wavelength. The use of a three-electrode configuration, one between the two waveguides and two outside the waveguides produces an opposite phase shift in the two waveguides and therefore doubles the magnitude of the parameter k. An important parameter of a Mach–Zehnder interferometer is the voltage, which yields a phase shift of $\phi = \pi$

$$V_\pi = \frac{\pi}{kL} \tag{3}$$

In Fig. 2, the analog input signal V is applied in parallel to one arm of each of the four modulators, one for each bit of resolution. The sampling of the analog signal is performed optically, using a series of short optical pulses derived from a pulsed laser source. The optical output from each waveguide modulator is detected by an avalanche photodiode (APD) which converts the optical signal to an electronic signal and also provides amplification. The electronic signal from each modulator is then compared to a reference signal, obtained from the common light source. The output of each comparator is either a binary "1" or "0", depending on whether the modulator output intensity is greater or less than $I_0/2$, respectively. The output of the top modulator represents the least significant bit (LSB) in the digital word, and that of the bottom modulator is the most significant bit (MSB). The output intensity, the threshold, and the corresponding binary representation for each modulator are shown in Fig. 3. The Gray-code representation in Fig. 3 is achieved by controlling the static phase difference in each modulator by applying the appropriate DC biases, labeled as DC_{LSB}, DC_{NLSB}, DC_{NMSB}, and DC_{MSB} in Fig. 2.

In this Gray-code approach, the voltage quantization step size V_Q is equal to one-half the value of V_π for the LSB channel, or

$$V_Q = \frac{\pi}{2kL_N} \tag{4}$$

for an N-bit comparator where L_N is the electrode length for the LSB channel. For each subsequent significant bit, the value of V_π increases by a factor of 2 and therefore the electrode length L_n decreases by a factor of 2. Therefore

$$L_n = 2^{n-N} L_N \tag{5}$$

where $n = 1$ corresponds to the MSB and $n = N$ corresponds to the LSB. The maximum input analog voltage

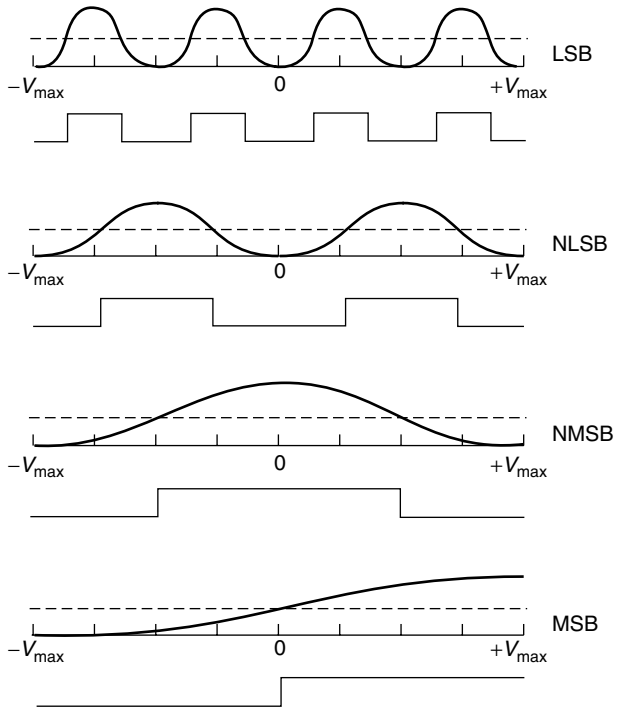

Figure 3. Intensity versus voltage for a 4-bit electro-optic A/D converter with a Gray-code output (the dashed-lines represent the threshold level in each of the four channels). (Reprinted with permission from B. L. Shoop, *Photonic Analog-to-Digital Conversion*, Springer Series in Optical Sciences, Vol. 81 [1], Fig. 5.2, p. 125. Copyright 2001, Springer-Verlag GmbH & Co. KG.)

that can be converted in this architecture is

$$V_{\max} = 2^{N-1} V_Q \tag{6}$$

This electrooptic A/D converter provides several distinct advantages. This photonic A/D converter is linear in complexity, requiring one additional Mach–Zehnder interferometer for each additional bit of resolution. Another important advantage is the decoupling of the analog sampled signal from the optical sampling signal. This eliminates the distortion effects common to diode bridge sampling circuits, which tend to couple the sampling signal into the converter circuitry. A limitation of this type of converter is that each additional bit of resolution requires a doubling of the electrode length of the LSB modulator. In $LiNbO_3$, this produces a transit-time limitation on performance of approximately 6 bits at 1 GHz. Other electrooptic crystals exist that produce larger refractive index changes and therefore could improve the performance of this transit-time limit. However, most of these crystals also have larger loss mechanisms and therefore would produce loss-limited performance instead.

3.1.1. An Optical Folding-Flash A/D Converter. Jalali and Xie [9] proposed an extension to the electrooptic A/D converter based on a folding architecture. This approach eliminates the geometrical scaling of V_π with amplitude resolution by incorporating an analog encoding technique. Figure 4 is a block diagram of a 4-bit optical folding-flash A/D converter. In contrast to the previous electrooptic A/D converter, the electrode lengths of all the Mach–Zehnder interferometers are identical. An analog encoding scheme is used in this approach to bias all these individual Mach–Zehnder interferometers at different points on the interferometer transfer characteristic.

The optical folding-flash A/D converter provides a solution to the V_π and subsequent electrode length scaling problem of the original electrooptic A/D converter; however, it also introduces some alternate challenges. In this approach, the MSB is susceptible to noise for extreme values of the input. Furthermore, this approach relies on the ability to accurately bias each interferometer in the architecture at several different points on the sinusoidal interferometer transfer characteristic. Hardware complexity is another limitation in this approach. The optical folding-flash A/D converter architecture is exponential in complexity with the number of interferometers

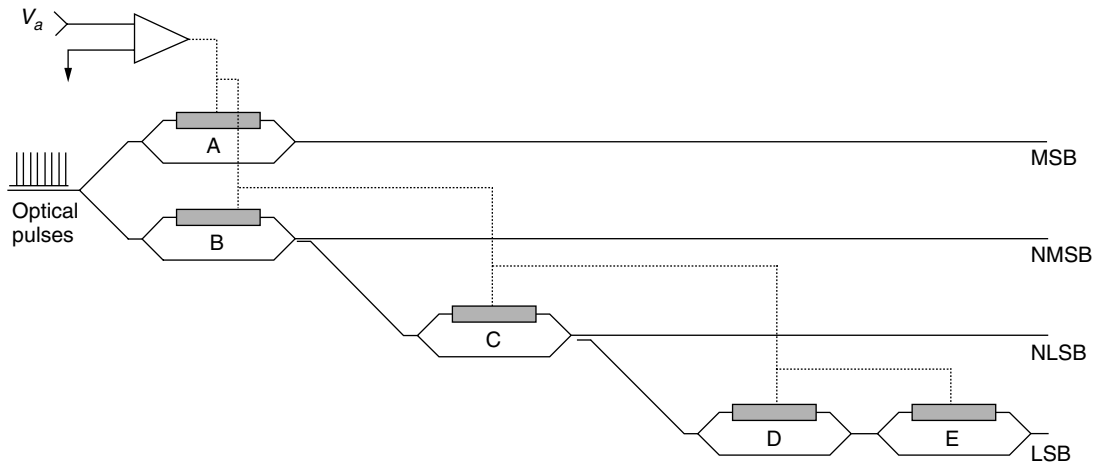

Figure 4. Block diagram of the optical folding-flash A/D converter. (Reprinted with permission from B. L. Shoop, *Photonic Analog-to-Digital Conversion*, Springer Series in Optical Sciences, Vol. 81 [1], Fig. 5.3, p. 127. Copyright 2001, Springer-Verlag GmbH & Co. KG.)

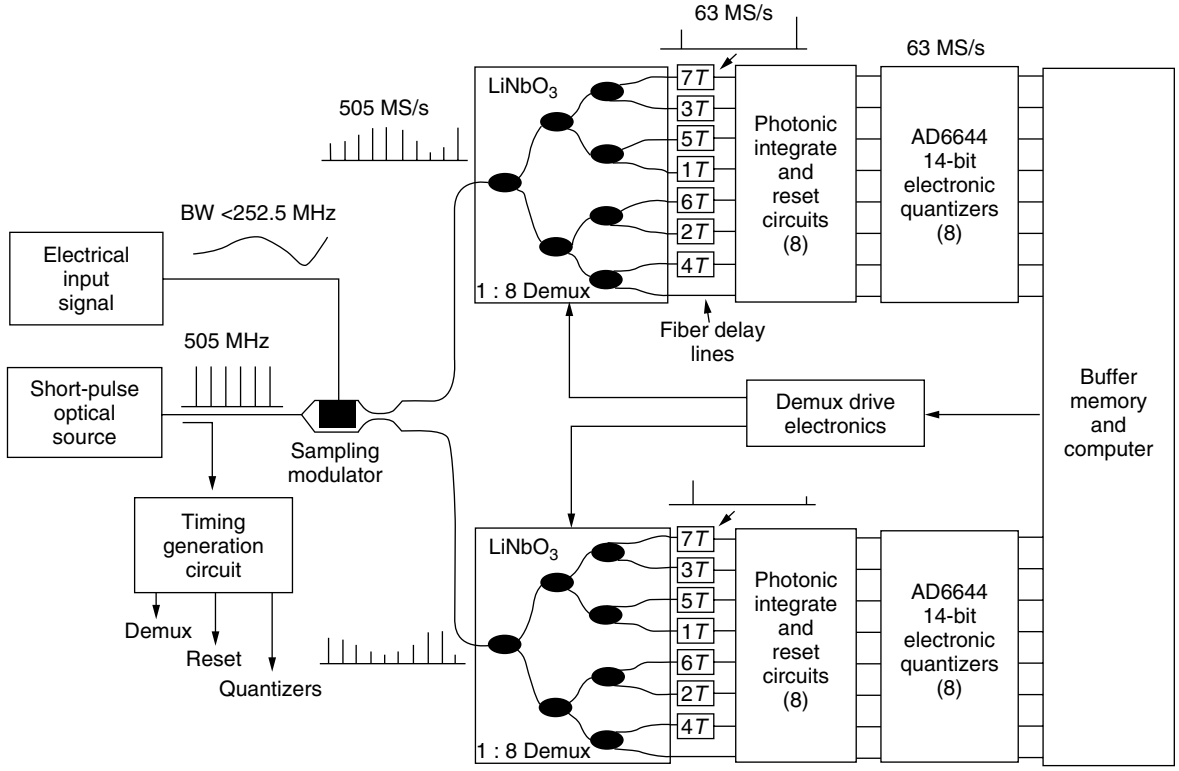

Figure 5. Block diagram of 505-MS/s optically sampled A/D converter.

scaling as $2^{(b-2)} + 1$, where b is the number of bits in the desired resolution.

3.2. Channelized Photonic A/D Conversion

Channelized or interleaved A/D converter architectures partition the input sampled signal into N-parallel channels, each of which operates at $1/N$ of the original sampling rate. In this approach, high-speed optical sampling can be integrated with N-electronic A/D converters in a common architecture that extends the bandwidth performance of the overall photonic A/D converter beyond that of the individual electronic A/D converters.

Mach–Zehnder interferometers can be used for wideband electrooptic modulation and as electrooptic switches for optical demultiplexing. One popular approach to achieving optical time interleaving is to use a tree-structured Mach–Zehnder switching architecture in which an array of Mach–Zehnder interferometric switches is used to provide the demultiplexing functionality. Using 1×2 electrooptic switches, each subsequent stage of the optical time-division demultiplexer is driven by a clock with a switching frequency that is one-half that of the previous stage. Unlike classic Mach–Zehnder interferometers that have a single output, the 1×2 electrooptic switch has a two-channel output. By modulating the refractive index of the interferometer, the output can be switched between the two output channels. Each output channel of the photonic demultiplexer can then be followed by a photodetector stage and an electronic quantizer stage to complete the time-interleaved A/D architecture.

An 8-channel time-interleaved photonic A/D converter operating at 505 MS/s has been demonstrated that employs a wideband electrooptic modulator and 1×2 electrooptic switches to accomplish the 1 : 8 optical demultiplexing [30]. Figure 5 is block diagram of this system [18]. Because the range over which linear modulation occurs in a Mach–Zehnder interferometer is relatively small, this architecture uses a new phase encoding technique [31] to produce linear modulation over a much wider dynamic range. This new approach combines the complimentary outputs from a dual-output electrooptic modulator to improve the linearity of the output.

In the architecture in Fig. 5, the optical source produces 25-ps pulses at the 505-MHz sampling rate that are used to sample the analog electrical input signal. Phase-encoded optical sampling is performed by the dual-output $LiNbO_3$ Mach–Zehnder modulator. The complimentary output of the sampling modulator is then fed to a pair of $LiNbO_3$ 1 : 8 optical time division demultiplexers to distribute the output pulsestreams to an array of photonic integrate and reset circuits and subsequently to electronic quantizers. In this architecture, the 14-bit electronic quantizers operate at 63 MS/s, which is one-eighth of the sampling rate. Fiber delay lines are used to time-align the pulses at the input to the photonic integrate and reset circuits to simplify timing.

The 1 : 8 optical demultiplexers were Ti-indiffused $LiNbO_3$ and employed a high-extinction design to minimize crosstalk between the parallel channels. Each demultiplexing stage consisted of a 1×2 electrooptic switch with an additional extinction modulator at each

output arm. The extinction for a single stage ranged between 36 and 46 dB. The bandwidth of a stage was 600 MHz and the insertion loss for a channel ranged between 6.8 and 8.4 dB. This photonic A/D architecture demonstrated SNR in the Nyquist bandwidth of 51 dB or 8.2 bits of resolution. The spur-free dynamic range (SFDR) was limited to 61 dB by channel-to-channel mismatch and crosstalk errors [32].

Although this approach holds promise for high-speed and high-resolution photonic A/D conversion, a number of technical challenges remain. Incomplete isolation between the individual demultiplexed channels can lead to channel-to-channel crosstalk, which, in turn, will result in undesirable spectral tones in the output frequency spectrum [33]. Consequently, each switch must be accurately designed and fabricated to ensure that optical crosstalk between channels is minimized. Also, the individual clock signals that control the switching of each electrooptic switch must be accurate and synchronous. Inaccuracies in clock timing between channels produce jitter in the demultiplexer which will also contribute to additional mismatch distortion.

3.3. Oversampling Photonic A/D Conversion

Oversampled A/D converters derive their name from the fact that the sampling rate is routinely chosen to be much higher than that required to satisfy the Nyquist criterion. This type of A/D converter trades bandwidth for improved amplitude resolution. In this type of converter, a low-resolution quantizer is embedded in a feedback architecture in an effort to reduce the quantization noise through spectral noise shaping. Here, a large error associated with a single sample is diffused over many subsequent samples and then linear filtering techniques are applied to remove the spectrally shaped noise, thereby improving the overall performance of the converter. Figure 6 shows a generalized block diagram of an oversampled A/D converter.

The analog signal $x(t)$ is again bandlimited to the range $0 \le f_x \le f_B(Hz)$ by an antialiasing filter and is then sampled at a rate $f_S \gg f_N$, where f_S is the sampling frequency, $f_N = 2f_x$ is the Nyquist frequency of the sampled signal, and $f_B \le f_S/2$ is the constrained signal bandwidth. The output of the sampler is then applied to a modulator that provides coarse amplitude quantization and spectral shaping of the quantization noise. The digital postprocessor, which consists of a digital lowpass filter (LPF) and a decimator, removes the quantization noise that was spectrally shaped by the modulator, provides antialiasing protection, and reduces the rate to the original sampled signal's Nyquist rate by trading word rate for word length.

3.3.1. The Modulator. The function of the modulator is to quantize the analog input signal and reduce the quantization noise within the signal baseband. This is accomplished through the use of a low-resolution quantizer, oversampling, negative feedback, and linear filtering.

One common type of modulator used in photonic oversampled A/D architectures is the recursive error diffusion modulator, shown in Fig. 7. Here, $H(z)$ represents the z transform of a causal, unity-gain filter and z^{-1} is a unit sample delay.

For a first-order modulator in which $H(z) = 1$, the modulator output can be shown to be

$$q(u_n) = \underbrace{x_n}_{\text{signal}} + \underbrace{\varepsilon_n - \varepsilon_{n-1}}_{\text{quantization error}} \tag{7}$$

Here, the quantity ε_n is the quantization error that would be seen at the modulator output *if there were no feedback loop*. However, as a result of the negative feedback, the first-order difference or discrete-time derivative of the error, $\varepsilon_n - \varepsilon_{n-1}$, appears at the output instead. By design, this difference signal is concentrated at high frequencies and can be removed by the digital LPF in the postprocessor.

3.3.2. The Digital Postprocessor. The function of the digital postprocessor is to digitally filter and decimate the output of the modulator so that the quantization noise that was spectrally shaped by the modulator is removed through lowpass filtering and the output digital signal is decimated to the Nyquist rate of the original sampled signal. An ideal LPF with cutoff frequency f_B is generally used to characterize upper-bound performance. Since the ideal LPF can be only approximated in practice, other practical filters have been investigated for this application [34]. With more recent advances in microlithography and silicon VLSI (very-large-scale integration technology), the digital postprocessor has

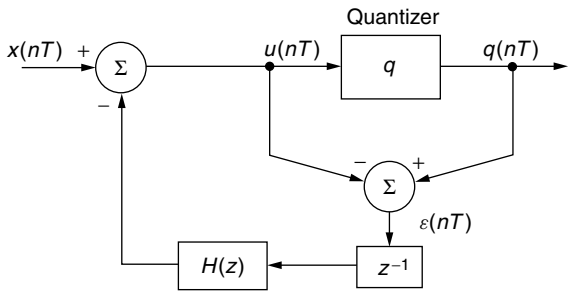

Figure 7. Block diagram of recursive error diffusion modulator.

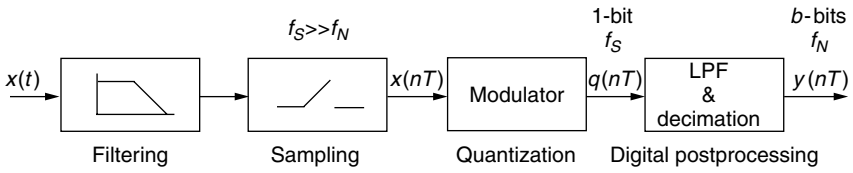

Figure 6. Generalized block diagram of an oversampled A/D converter.

become extremely sophisticated, routinely allowing the realization of filters with orders in excess of 100th-order.

3.3.3. Performance Analysis. Assuming white quantization noise characteristics, an ideal LPF with cutoff frequency f_B, and an Nth-order modulator with a noise shaping characteristic described by

$$H_{\text{ns}}(z) = (1 - z^{-1})^N \tag{8}$$

the spectral distribution of the quantization noise after shaping is the product of the filter shaping function and the spectral density of the quantizer error

$$S_\varepsilon(f) = \underbrace{[|H_{\text{ns}}(z)|^2_{z=e^{j2\pi fT}}]}_{\text{noise shaping}} \cdot \underbrace{\left[\frac{S_q}{f_S}\right]}_{\text{noise power density}} \tag{9}$$

If the quantizer step size is assumed to be Δ and the input signal is sinusoidal with a full-scale input range of $\pm\Delta/2$, the maximum signal-to-quantization noise ratio ($\text{SQNR}_{\max}$) can be computed as

$$\text{SQNR}_{\max}(M, N) = \frac{3}{2} \cdot \left[\frac{2N+1}{\pi^{2N}}\right] \cdot M^{2N+1} \tag{10}$$

where M is the oversampling ratio

$$M = \frac{f_S}{f_N} \tag{11}$$

For comparison, the $\text{SQNR}_{\max}$ of a conventional Nyquist rate uniform quantizer with b-bits resolution can be shown to be

$$\text{SQNR}_{\max}(b) = 3 \cdot 2^{2b-1} \tag{12}$$

Figure 8 shows the theoretical $\text{SQNR}_{\max}(M, N)$ and equivalent resolution for first- through fourth-order oversampled modulators as a function of oversampling ratio. The case of no noise shaping represents the $\text{SQNR}_{\max}$ that can be expected if the same quantizer, embedded in the feedback loop of the oversampled modulator, were simply oversampled and digitally filtered. The slope of this curve is 3 dB per octave and is included only for comparison. The slope of the $N = 1$ curve is 9 dB per octave and that of the $N = 2$ curve is 15 dB per octave, showing the significant advantage achieved by using a noise shaping modulator.

3.3.4. Spectral Characteristics. To better understand the relationship between the spectral shaping of the quantization noise and the input signal, the power spectrum for a fourth-order oversampling modulator output is shown in Fig. 9. This power spectrum assumes a half-scale sinusoidal input and an oversampling ratio of $M = 32$. Here, spectral noise shaping in the low frequencies of the power spectrum improves the A/D converter SNR performance.

3.3.5. The Error Diffusion Neural Network. The concept of spectral noise shaping can be extended to spatial dimensions and can be formulated in the context of a 2D symmetric error diffusion architecture. This extension requires each state variable in Fig. 7 to be represented in matrix–vector notation and can be described in terms of a specialized neural network.

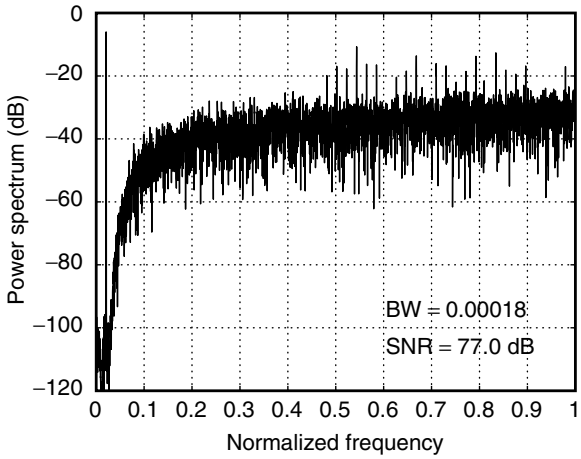

Figure 9. Power spectrum of the output data sequence for a fourth-order oversampling modulator.

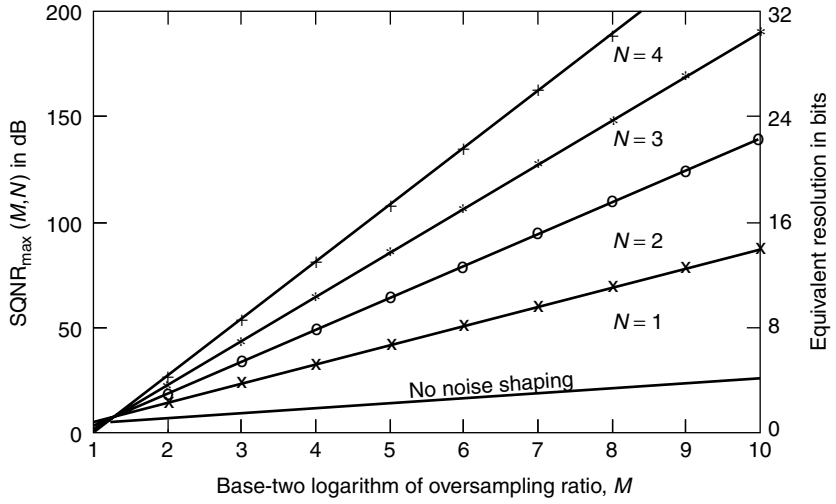

Figure 8. Maximum signal-to-quantization noise ratio of Nth-order modulators.

In equilibrium, the error diffusion neural network satisfies

$$\mathbf{u} = \mathbf{W}(\mathbf{y} - \mathbf{u}) + \mathbf{x} \tag{13}$$

For an $N \times N$ image, $\mathbf{W}$ is an $N^2 \times N^2$ sparse, "circulant without wrapping" matrix derived from the error diffusion filter weights $w_{i,j}$.

An equivalence to the classic Hopfield network can be described by

$$\mathbf{u} = \mathbf{A}(\mathbf{W}\mathbf{y} + \mathbf{x}) \tag{14}$$

where $\mathbf{A} = (\mathbf{I} + \mathbf{W}^{-1})$ and $\mathbf{I}$ is the identity matrix. Effectively, the error diffusion neural network includes a prefiltering of the input image $\mathbf{x}$ by the matrix $\mathbf{A}$ while still filtering the output image $\mathbf{y}$ but now with a new matrix, $\mathbf{AW}$.

The energy function of the error diffusion neural network can be shown to be a quadratic function

$$E(\mathbf{x}, \mathbf{y}) = [\mathbf{B}\underbrace{(\mathbf{y} - \mathbf{x})}_{\text{error}}]^T[\mathbf{B}\underbrace{(\mathbf{y} - \mathbf{x})}_{\text{error}}] \tag{15}$$

where $\mathbf{y} \in \{-1, 1\}$ is the output vector of quantized states with one element per pixel and $\mathbf{A} = \mathbf{B}^T\mathbf{B}$. As the error diffusion neural network converges and the energy function is minimized, so, too, is the error between the output and input images.

The error diffusion neural network represents an important class of A/D converter that applies to digital image halftoning. In digital halftoning [35], a continuous-tone input image is converted to a binary output image for purposes of printing, storage, or display.

3.3.6. A Distributed Mesh Feedback Approach to Photonic A/D Conversion. A relatively new approach to photonic A/D conversion uses spatial oversampling techniques, an error diffusion neural network, and a smart pixel [12] hardware implementation. This approach converts a 1D temporal signal to a 2D spatial representation in an effort to leverage the 2D nature of a photonic A/D architecture. In this approach, the input signal is first sampled at a rate higher than that required by the Nyquist criterion and then presented spatially as the input to a 2D error diffusion neural network consisting of $N \times N$ neurons, each representing a pixel in the image space. The neural network processes the input oversampled analog image and produces an $N \times N$ pixel binary or halftoned output image. Decimation and lowpass filtering techniques, common to conventional 1D oversampling A/D converters, digitally sum and average the $N \times N$ pixel output binary image using high-speed digital electronic circuitry. By employing a 2D neural approach to oversampling A/D conversion, each pixel constitutes a simple oversampling modulator, thereby producing a distributed A/D architecture. Spectral noise shaping across the array diffuses the quantization error, thus improving overall SNR performance. The matrix $\mathbf{A}$ in Eq. (14) describes the interconnectivity of the network resulting from local connections through the error diffusion filter. Since $\mathbf{A}$ is full-rank, the network is fully connected. Therefore each quantizer within the $N \times N$ network is embedded in a fully connected, distributed mesh feedback loop that spectrally shapes the overall quantization noise, thereby significantly reducing the effects of component mismatch typically associated with parallel or channelized A/D approaches.

3.3.7. Spectral Characteristics. A representative power spectrum of the output halftoned image of this fully connected distributed mesh feedback architecture is shown in Fig. 10. The input signal used was an $N \times N$ sinusoid with period 2 in both spatial dimension, and the error diffusion filter was a LPF with a 25×25 region of support designed using a Kaiser window with $\alpha = 5$. Approximately 30 dB of low-frequency noise suppression is achieved in this specific approach resulting in approximately a 54-dB SNR. Larger in-band noise suppression has also been achieved with other filter designs.

3.3.8. A Photonic Implementation of the Error Diffusion Neural Network. The functionality necessary to implement the error diffusion neural network consists of a one-bit quantizer, two differencing nodes, and the interconnection and weighting of the error diffusion filter. One photonic implementation of the error diffusion neural algorithm uses smart pixel technology [36]. Smart pixels integrate both electronic processing and individual optical devices on a common chip to take advantage of the complexity of electronic processing circuits and the speed of optical devices. Arrays of these smart pixels bring the advantage of parallelism that optics provides.

The electronic circuitry, used for quantization, weighting, and summation functions, was fabricated in a 0.5 μm complementary metal oxide semiconductor (CMOS) process. In a subsequent processing step, self-electrooptic effect device (SEED) multiple-quantum-well (MQW) modulators are integrated with the CMOS VLSI circuitry using a flip-chip bonding process. The MQW modulators are used in this implementation to provide optical input and output

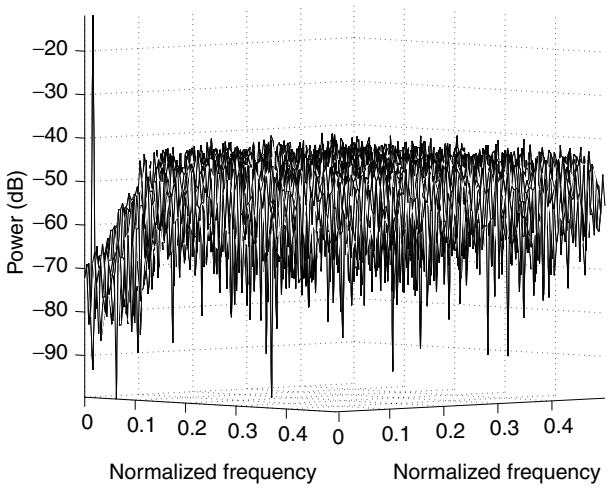

Figure 10. 3D perspective plot of one quadrant of the power spectrum of the fully connected distributed mesh feedback architecture generated with a 2D sinusoidal input of period 2 and a Kaiser error diffusion filter.

functionality. Using this approach, a 5×5 proof-of-concept photonic error diffusion neural network was fabricated.

The electronic circuitry for this CMOS-SEED error diffusion neural network consists of six distinct circuits associated with a single neuron. The standard neuron contains a total of 152 transistors with 23 dedicated to the neural functionality and 3 used for the output SEED driver. The error weighting circuitry for weights 1–5 contain the remaining 126 transistors with weights 1–5 accounting for 22, 20, 20, 28, and 36 transistors, respectively. This photonic implementation of the error diffusion neural network has been experimentally characterized and performed as predicted by both theory and simulation.

Figure 11 shows a photomicrograph of a single neuron of the CMOS-SEED photonic error diffusion neural network. The long rectangular features are the SEED MQW modulators and the background features are the CMOS VLSI transistors and interconnect metallization.

The challenges associated with this distributed approach to photonic A/D conversion include achieving large 2D arrays of smart pixel devices, the speed of convergence of the neural algorithm, and the integration with the electronic digital postprocessing circuitry.

3.4. Time Stretching Using Dispersive Optical Elements

Time stretching utilizes linear group velocity dispersion, most often in optical fibers, to frequency-downshift a signal that has been modulated onto optical pulses. In many of the more recent demonstrations, two long fiberoptic spools of lengths L_1 and L_2 are used with the modulator positioned between the two spools. The stretch factor M is defined as the width of the pulse exiting L_2 compared to that exiting L_1. If the pulsewidth exiting the source is defined as τ_0, and if δ_{τ_1} and δ_{τ_2} are defined as the additional broadening resulting from fiber spools L_1 and L_2, respectively, the stretch factor can be shown to be [37]

$$M = \frac{\tau_0 + \delta_{\tau_1} + \delta_{\tau_2}}{\tau_0 + \delta_{\tau_1}} \approx 1 + \frac{L_2}{L_1} \tag{16}$$

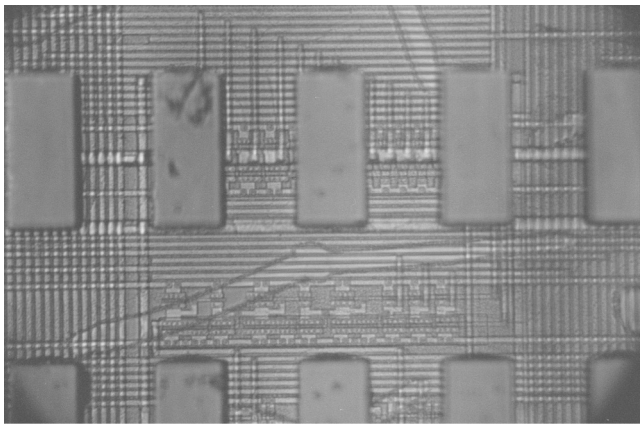

Figure 11. Photomicrograph of a single neuron of the 5×5 error diffusion neural network. (Reprinted with permission from B. L. Shoop, *Photonic Analog-to-Digital Conversion*, Springer Series in Optical Sciences, Vol. 81 [1], Fig. 8.4, p. 220. Copyright 2001, Springer-Verlag GmbH & Co. KG.)

if $\tau_0 \ll \delta_{\tau_1}$. In experimental demonstrations to date, L_1 and L_2 have generally been several kilometers in length.

Photonic time-stretch preprocessing techniques have also been proposed as a method to extend the performance of electronic A/D converters [21]. This technique is based on the premise that if an analog signal can be stretched in time, then the effective sampling rate and consequently the input bandwidth of a conventional electronic A/D converter can be increased. This specific technique is best suited to the class of *time-limited signals* such as those used in pulsed radar applications. Figure 12 shows the general concept of time stretching. Here, a modulated optical carrier is introduced to an optically dispersive element that subsequently stretches the modulated envelope of the signal. In Fig. 12, the vertical lines represent individual samples and the sampling interval T that would be required of the original signal is modified by the stretch factor M after the signal passes through the dispersive element. The optically dispersive element can be in a waveguide structure or a fiber. Time stretching using an array waveguide that is a wavelength dispersive element has been applied to photonic A/D conversion [37] and a 30-Gsps, 4-bit time-stretched photonic A/D converter using an 8-Gsps electronic digitizer has been reported [38].

One of the challenges associated with this particular approach to wide-bandwidth A/D conversion is distortion introduced by the nonuniform spectrum of the nonlinear dispersion. Nonuniformities in the spectrum result in temporal modulation of the carrier, which is mixed with the input signal during modulation. This nonuniformity results in a broadband distortion that limits the bandwidth and resolution of this particular approach to A/D conversion.

4. TRENDS IN PHOTON-BASED A/D CONVERSION

In general, trends in photonic A/D conversion can be categorized within the context of individual device and component development and investigation of new and novel architectures.

Individual photonic device development continues to be an active area of research interest. Improving the linearity, dynamic range, insertion loss, and speed of photonic components such as the electrooptic interferometers used for modulation and switching in current photonic A/D converters will directly improve the performance of these converters. Low-noise clock sources are an important part of any photonic A/D converter architecture. In high-speed, high-resolution applications, these sources require low timing and amplitude jitter, high repetition rate, and

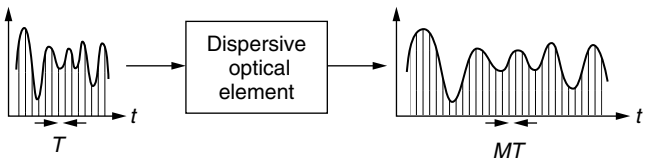

Figure 12. Concept of time stretching using a dispersive optical element.

short pulsewidth. For WDM applications, the clock source also requires large spectral width. For high-speed, high-resolution A/D applications, the clock source specifications are particularly challenging. Because of the importance of low-noise optical clock sources to both photonic A/D converters and other high-speed sampling applications, these sources also continue to be the focus of numerous research efforts.

New approaches and novel architectures continue to be developed to improve both the electronic and photonic contributions to the overall photonic A/D converter performance. Various forms of interleaving architectures will continue to be investigated and improved for application to wideband photonic A/D converters. As optical sampling speeds continue to increase, oversampling architectures will undoubtedly be considered for high-resolution applications. Distributed approaches to photonic A/D conversion can also be expected to be the focus of continued development because of their potential modularity and tolerance to fabrication errors.

A number of other promising approaches are currently under investigation. Details of several of these can be found in Refs. 39–41.

Photonics technology has generally been described as an enabling technology, supporting many of the functions provided by electronics technology. As both electronic and photonic technologies continue to mature, we can expect continued application and improvements to photonic A/D converter technology.

BIOGRAPHY

Barry L. Shoop is an associate professor in the Department of Electrical Engineering and Computer Science at the U.S. Military Academy, West Point, New York. He received his B.S. from the Pennsylvania State University, University Park, Pennsylvania, in 1980, an M.S. from the U.S. Naval Postgraduate School, Monterey, California, in 1986, and a Ph.D. from Stanford University, Stanford, California, in 1992, all in electrical engineering. His research interests are in the area of photonic A/D conversion, optical information processing, image processing, and smart pixel technology. He is a fellow of the OSA, a senior member of the IEEE, and a member of SPIE, Phi Kappa Phi, Eta Kappa Nu, and Sigma Xi.

POLARIZATION MODE DISPERSION MITIGATION

HENNING BÜLOW
Optical Systems
Stuttgart, Germany

With the increase of channel bit rate to 10 and 40 Gbps (gigabits per second) and in conjunction with unrepeated link lengths of hundred of kilometers and beyond, polarization mode dispersion (PMD) might become visible as a degrading property of the transmission link. Since PMD effects are drifting with time and differ for each wavelength channel, various dynamically adapting PMD compensators (PMDC) have been proposed that process either the optical signal field at link output or the electrical signal in the receiver after detection.

1. IMPACT OF PMD ON TRANSMISSION

The PMD of the optical transmission link arises mainly as a result of the residual optical birefringence varying along the fiber length, which is induced during the production of or cabling of the fiber. Nevertheless, other optical components or subsystems within the optical signal path such as optical amplifiers, dispersion-compensating fiber modules, or wavelength multiplexers might also add to the link PMD.

The effect of all these cascaded birefringences can again be regarded as an optical birefringence having a pair of principal states of polarization (PSP) e_- and e_+, which are orthogonally polarized and exhibit different group delays τ_- and τ_+. Unlike the scenario with fixed birefringence, they vary with the optical frequency ω. The difference of the group delay between fast and slow PSP is denoted by the differential group delay (DGD) $\Delta\tau = \tau_+ - \tau_-$ (see Fig. 1). The PMD is described by the dispersion vector $\Omega(\omega) = \Delta\tau e_-$, which has the length $\Delta\tau(\omega)$ and is oriented into the direction of the Stokes vector $e_-(\omega)$, which represents the state of polarization on the Poincaré sphere of the fast PSP at the output of the link [1]. Evaluation of Ω around the signal center frequency ω_0 exhibits that, as long as the signal bandwidth $\Delta\omega_S$ is sufficiently narrow with respect to the link PMD, the transmitter signal spreads among fast and slow PSP and thus suffers from a dual-path propagation due to the DGD (see Fig. 1). This leads to a temporal broadening of the bit beyond a bit period T and thus to intersymbol interference (ISI).

Since the DGD as well as the PSP vary with both wavelength and time (see Fig. 2), PMD is quantified by

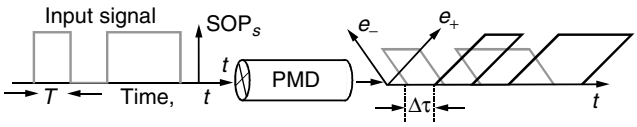

Figure 1. Optical data signal at input and output of a fiber having a first-order PMD with a DGD $\Delta\tau$.

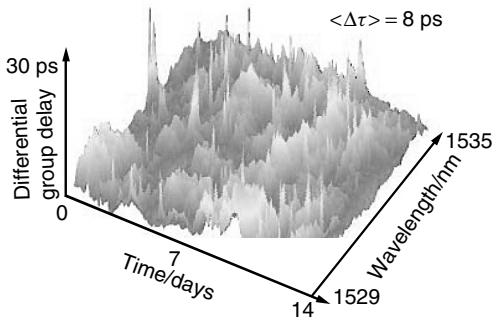

Figure 2. DGD of an installed fiber (246 km length, 8 ps PMD) measured over a timespan of 14 days and a wavelength range of 6 nm.

statistical means: the mean value of the DGD $\langle\Delta\tau\rangle$ and the probability density function of the actual DGD $\Delta\tau$, which is given by the Maxwellian distribution

$$\rho(\Delta\tau) = \sqrt{\frac{6}{\pi}}\frac{3\Delta\tau^2}{\langle\Delta\tau\rangle^3}\exp\left[-\frac{3\Delta\tau^2}{2\langle\Delta\tau\rangle^2}\right]$$

Thus, an actual DGD $\Delta\tau$ of beyond 3.1 $\langle\Delta\tau\rangle$ occurs with a probability of 10^{-5}. As indicated by the autocorrelation function (ACF) of PMD, which decays below 0.5 for $\Delta\omega > 2/\langle\Delta\tau\rangle$, the PMD cannot be considered as constant anymore within increasing signal bandwidth $\Delta\omega_S$ and increasing link PMD $\langle\Delta\tau\rangle$. Then the probability of a signal distortion due to second- and higher-order PMD increases. Second-order PMD denotes a constant variation $d\Omega/d\omega$ of the PMD vector, and higher orders $(n+1)$ denote nonvanishing derivatives $d^n\Omega/d\omega^n$ at the signal center frequency. The impact of second-order PMD on the signal is a depolarization proportional to $de_-/d\omega$ and to $\Delta\tau$ [2], which denotes a cross coupling of signal fields between the orthogonal PSPs, and the PMD-induced chromatic dispersion proportional to $\pm 0.5 d\Delta\tau/d\omega$. The induced dispersion exhibits opposite signs in both PSPs and adds to the chromatic dispersion of the link. A signal distortion induced by PSP rotation $de_-/d\omega$ has the highest likelihood of the two second-order contributions. It generates distortions similar to over- and undershoots in the data signal detected by the receiver photodiode [2].

Variations of $\Delta\tau$ and e_- with time are induced mainly by environmental temperature changes that lead to a variation of the signal distortion and thus to a fluctuating bit error rate (BER). The BER limit that is tolerated, such as 10^{-12} or for forward error correction (FEC) support 10^{-4},

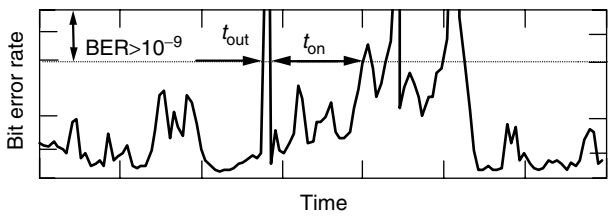

Figure 3. Temporal BER evolution for the transmission over a fiber link with PMD (14-day timespan).

might be exceeded (see Fig. 3). Times of poor BER mean an outage for the transmission system. An outage event has a duration t_{out}. Because of the statistical nature of PMD, the impact on a transmission system is quantified by the cumulative probability (CP) for a PMD-induced outage. CP can be defined by the ratio of accumulated outage time and system operation time for long observation timespans. Besides the outage probability, the mean outage duration $\langle t_{out}\rangle$ and the mean time between outages $\langle t_{on}\rangle$ have been proposed to describe the impact of PMD on a system. That is 56 min for $\langle t_{out}\rangle$ and 2.56 years (outage rate 0.39 yea^{-1}) for $\langle t_{on}\rangle$ have been deduced from PMD measurements of buried fiber [3]. On the other hand, PMD fluctuations, also on the timescale of a few milliseconds, have been observed for aerial cables or fiber exposed to mechanical vibrations. If these fast fluctuations need to be compensated, they determine the upper speed limit of a PMDC.

Alternatively, the robustness of a transmission system to PMD can be quantified by the PMD limit $\langle\Delta\tau\rangle_{lim}$, which is the maximum PMD that leads to a specific outage probability CP given that the system operates with a certain optical signal-to-noise ratio (OSNR) margin. Typical values for CP and margin are 10^{-5} and 2 dB, respectively. $\langle\Delta\tau\rangle_{lim}$ amounts to about ~15% of the bit period T for a non-return-to-zero (NRZ) signal.

In order to assess the relevance of PMD for a transmission system, the value of the length-related PMD, the PMD coefficient τ', needs to be related to $\langle\Delta\tau\rangle_{lim}$ and the link length L. Fiber PMD $\langle\Delta\tau\rangle_{fiber}$ and all component and subsystem PMDs $\langle\Delta\tau\rangle_i$ contribute to the total link PMD$_{tot}$ according to $\langle\Delta\tau\rangle_{tot}^2 = \langle\Delta\tau\rangle_{fiber}^2 + \Sigma\langle\Delta\tau\rangle_i^2$. The maximum link length is $L < (\langle\Delta\tau\rangle_{lim}^2 - \Sigma\langle\Delta\tau\rangle_i^2)/\tau'^2$. With more recently manufactured fiber having a low PMD coefficient of $\leq$0.08 ps/$\sqrt{}$km, and assuming a dispersion compensation fiber PMD coefficient of 0.15 ps/$\sqrt{}$km, an amplifier PMD of 0.5 ps and 80 km amplifier spacing, 40 Gbps transmission over long-haul distances is affected by PMD beyond 1400 km. In fiber production PMD received only minor attention until the mid-1990s. Therefore links incorporating older fibers might exhibit PMD coefficients of $\geq$0.5 ps/$\sqrt{}$km. This means that a few hundreds of kilometers of link might reach the PMD limit even at 10 Gbps.

2. PMD COMPENSATION

A slight improvement in the robustness of PMD can be obtained by keeping the receiver threshold in the middle of the eye diagram degraded by ISI. This automatic threshold adjustment leads to the abovementioned PMD limit of $0.15T$. Moreover, specific modulation formats such as return to zero (RZ) tolerate a slightly higher bit broadening due to PMD and thus increase the limit to approximately $0.18T$. The tolerance to PMD can further be increased if there is room to allocate a power margin (OSNR margin) for PMD of much more than 1 or 2 dB. This margin can be obtained by reducing span loss or by incorporating forward error correction (FEC).

However, in general only a limited margin will be reserved for PMD, and a higher PMD limit must be overcome. Therefore several active compensation

techniques have been proposed to mitigate the degrading effect of PMD. The majority of these approaches can be classified as either optical or electrical compensation techniques that apply optical signal processing within an optical PMD compensator unit, or postdetection electronic signal processing of the photodiode signal by an electrical equalizer within the receiver. Commonly the dynamic adaptation of the compensator unit to the drifting signal distortion is accomplished by three elements arranged in a feedback scheme (see Fig. 4): a signal processing element to reduce the distortion, an element at its output to measure the signal quality and to provide a feedback signal, and an adaptation control algorithm implemented in an electronic processor that tunes the parameters of the signal processor into direction of optimum feedback signal and thus to reduced signal distortion.

3. OPTICAL COMPENSATION

The signal processing element of the simple optical PMD compensator is formed by an electrically tunable polarization controller (PC) based, for example, on the electrooptic effect in lithium niobate, on the elastooptic effect used in fiber squeezer devices, or on liquid crystal technology. A constant optical birefringence [e.g., polarization-maintaining fiber (PMF)] is attached at its output (see Fig. 4). A typical value of the PMF's DGD is $\Delta\tau_C = 0.6T$. The principle of operation of this basic PMDC is to modify the dispersion vector of the total PMD $\Omega_{\text{tot}} = \Omega_L + \Omega_C$ formed by the link PMD Ω_L and the compensator PMD Ω_C (see Fig. 5), by tuning of the PC in such a way that the signal degradation at compensator output is a minimum [4]. The PC modifies the orientation of Ω_C ($|\Omega_C| = \Delta\tau_C$). Factoring in these dispersion vectors and the Stokes vector SOP_S representing the signal input state of polarization on the Poincaré sphere, all

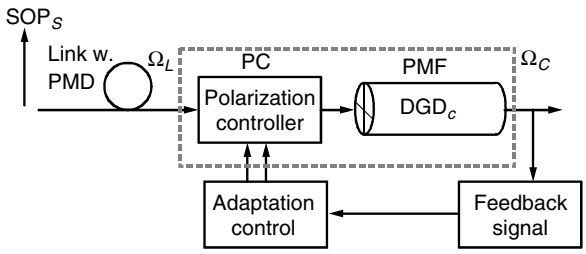

Figure 4. Basic optical PMD compensator.

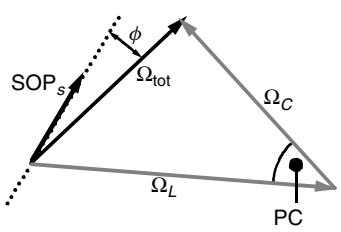

Figure 5. PMD dispersion vectors Ω and the signal state of polarization SOP_S observed at the output of the basic PMD compensator. Ω_L and Ω_C represent the link PMD and compensator PMD, respectively, at signal center frequency.

transformed to PMDC output, the PMD conditions for compensation of first-order PMD at the center frequency can be explained. During operation the compensator will either minimize the total DGD $|\Omega_{\text{tot}}|$ (case A) or the angle ϕ between SOP_S and the total PMD Ω_{tot} (case B). In both cases the degradation effects are minimized: in case A due to minimum delay $|\Omega_{\text{tot}}|$ and in case B due to single-path propagation in one PSP only. A more detailed analysis shows that by detuning of the PC from these ideal first-order conditions — to some extent — higher-order PMD can be mitigated too.

During operation of a PMDC under conditions of drifting link PMD, the adaptation control keeps the signal processor in an extremum of the feedback signal. In this simple PMD compensator structure the decay of a global maximum of the feedback signal to a local maximum limits the efficiency.

Calculations indicate that with the basic PMD compensator, the PMD limit can be extended to about $0.30T$ (2 dB power margin, 10^{-5} outage) for non-return-to-zero (NRZ) signals.

A feedback signal (FS) must satisfy the following the requirements: (1) good correlation with the receiver BER and (2) sufficient sensitivity to detect a detuning of the signal processor from the optimum setting or a variation of the link PMD. As a feedback signal the measurement of signal properties can be used, either in the optical domain such as the degree of polarization (DoP) or, after detection, in the electrical domain, including "spectral line" or eye opening. The DoP is measured at the compensator output by a polarimeter setup. The PMD-induced pulse splitting results in a time-varying state of polarization along the bit pattern, which reduces the measured DoP [5]. The spectral line feedback denotes the analysis of the electrical spectrum at a photodiode illuminated by the compensator output signal. Since PMD generates a notch in the electrical spectrum at the frequency $0.5/\Delta\tau$, the maximization of spectral power measured at, for instance, $0.5/T$ or $0.25/T$ or the weighted sum of both indicate a decreasing residual PMD distortion after compensation and thus an improved receiver BER [6]. A very good correlation between BER and the feedback signal is provided by an electronic performance monitor, also referred to as an "eye monitor" [7]. It extracts a quality measure of the actual eye diagram by bit-synchronous sampling at decision time t_0 and is thus strongly correlated with the BER. The sampling demands a valid clock that might not always be extractable from the signal during times of strong signal distortion as might occur during startup of the compensator when the accommodation to the actual distortion is not completed.

4. HIGH-ORDER PMD COMPENSATION

In basic PMD compensator with a PMD limit of about $0.30T$, the adaptation control has to optimize the 2 degrees of freedom (DoF) of the polarization controller. An improvement of this basic structure can be achieved by replacing the fixed DGD by an continuously tunable DGD that is also tuned by the adaptation control. With this increase of the number of DOFs to 3, the PMD limit

is slightly improved [4]. The main advantage of a variable DGD is that the decay of the global optimum to a less efficient local optimum can be avoided during tracking of the drifting link PMD. Realizations of a variable group delay are based on beam optics with mechanically variable gaps or stacks of birefringent elements with electrically controlled polarization switches in between.

In order to address higher orders of PMD and increase the PMD limit of the compensator, improved optical signal processing can be achieved by a cascade of two or more basic compensators [6]. This leads to structures with ≥ 4 DoF controlled by maximization of one single feedback signal. The increase of the PMD limit beyond $0.40T$ was calculated for a two stage structure [4,8]. However, in general an increasing number of DoFS improves the effectiveness of a PMDC, but it seems that the sensitivity of the feedback signal to the variation of an individual tuning parameter decreases. This slows down the accommodation time for a changing PMD. Moreover, with increasing number of DoFs, the danger of being trapped in suboptimal local maxima increases. Therefore the search for efficient high-order PMDC is continued [8].

5. ANALYSIS OF COMPENSATION

For experimental or numerical assessment of compensator performance, the statistics of the system-relevant quality parameter degradation (BER, power penalty or OSNR penalty) have to be determined. Several hundreds or some thousands of statistically independent samples of actual PMD values of a given PMD $\langle \Delta\tau \rangle$ are applied at a transmission system with PMDC and the BER or power penalties are determined. These PMD samples are generated either in a PMD emulator or in a computer model with all relevant orders. Their occurrence should obey the PMD statistics of a real link (or it should be possible to convert them to the appropriate statistics). The set of BER or penalty values exhibits the same statistics that one would obtain from measurements at a real link after many months or years. For analysis, the relative occurrence that a specific BER or penalty value is exceeded is plotted against this limit (see Fig. 6). Thus, the resulting curves show that with PMDC, specific degradations are exceeded with a lower likelihood than without it and that an improved PMDC (two stages) leads to further reductions of the likelihood. The curves can be extrapolated to more relevant 10^{-5} outage, and a set of curves for different PMDs $\langle \Delta\tau \rangle$ allows us to interpolate the PMD limit $\langle \Delta\tau \rangle_{\text{lim}}$.

6. ELECTRICAL COMPENSATION

Postdetection electronic signal processing is also discussed and applied for PMD mitigation. Adaptive electrical signal processing schemes, well established in lower-rate communications for compensation of channel degradation, are also implemented in an optical receiver. The equalization schemes that are in the scope of application are a feedforward equalizer (FFE) followed by a decision feedback equalizer (DFE). The FFE superimposes differently delayed and weighted replica of the input signal and the

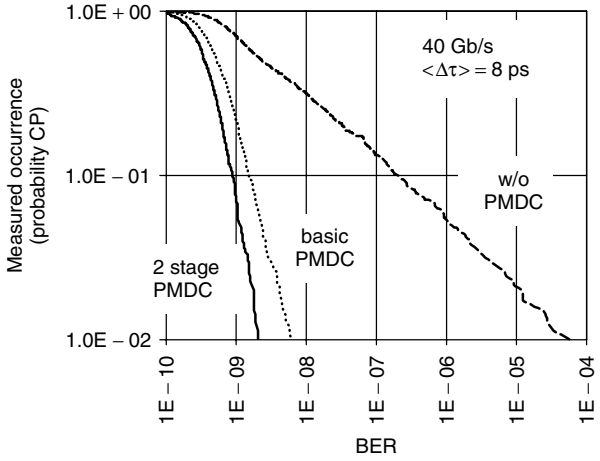

Figure 6. Relative occurrence (y axis; ordinate) of measured system bit error ratios beyond a BER limit (x axis; abscissa) for some hundred transmissions over a statistically changing PMD emulator. The experiments were performed without and with optical PMD compensators.

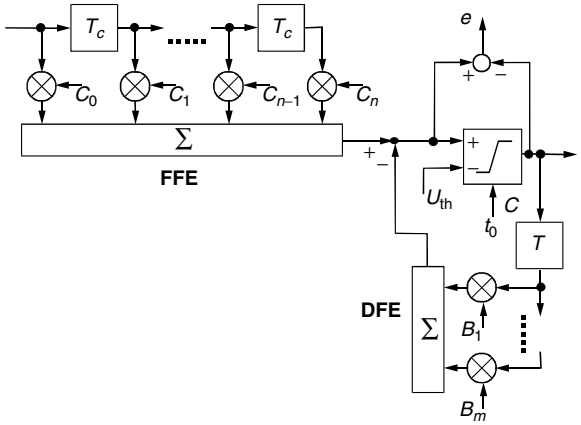

Figure 7. Electronic equalizer for electrical PMD compensation. The electronic signal processing is performed by a feedforward equalizer (FFE) and a decision feedback equalizer (DFE), which also provides an error signal e for the adaptation control.

DFE subtracts the weighted and delayed signal appearing at the decision gate output from the input signal provided by the FFE (see Fig. 7). Tuning to the actual PMD distortion is achieved by adjusting the FFE weights (C_i), also referred to as "tap coefficients," and the DFE feedback weights (B_i). FFE and DFE suitable for 10-Gbps operation have been realized as integrated analog signal processing circuits in high-speed technologies such as SiGe, InP, or GaAs [9]. An alternative realization in a digital signal processing (DSP) scheme based on digitally processing of the signal in an integrated electronic circuit [complementary metal oxide semiconductor integrated circuit (CMOS IC)] after analog-to-digital conversion of bit-synchronous signal samples is also discussed.

Besides these equalization techniques that perform the decision on a bit-by-bit basis, there also exists a concept of optimum detection based on data decisions that are most likely to be correct when utilizing the entire

received signal and the knowledge of the characteristics of the transmission channel. Since in the case of PMD the characteristics are neither known nor stable in time, adaptive mechanisms also have to be applied. The performance limits of this maximum-likelihood sequence estimation (MLSE) under realization constraints for the optical channel is currently under investigation [10]. Constraints are high-speed electronic realization for 10-Gbps signals with reduced complexity, processing of truncated sequences, nonstationary noise, and nonlinear channel due to optical nonlinearity of the fiber and to square-law detection of the photodiode. Preliminary results confirm the potential for an improved performance for PMD compensation compared to the FFE and a DFE equalizer (see Fig. 8). The MLSE detector will be realized as DSP scheme. The processing is based on the Viterbi algorithm, which is an efficient way to organize the computations of the signal samples.

Different adaptation schemes for the FFE, DFE, and clock-phase alignment are under consideration. Similar to the optical compensator, the eye monitor can be used at the FFE output in conjunction with a gradient algorithm that consecutively tunes the equalizer taps. The implementation of the least-mean-square (LMS) algorithm, well established at lower rates, has also been discussed. An error signal e at the decision time t_0 is generated for adaptation purpose by subtracting the signal at the decision gate output, serving as reference, from the signal at the equalizer output (see Fig. 7). The multiplication of this error signal with samples of signals at different positions within the equalizer generates different independent feedback signals for each FFE tap or DFE feedback tap. This allows for simultaneous adaptation of all tap weights. Moreover, the feedback signals are bipolar and thus automatically indicate the direction of tuning to the optimum. Therefore very fast adaptation within some hundreds of bits is possible in principle. An alternative realization of the LMS scheme is possible in conjunction with channel coding used for forward error correction (FEC). By comparing the uncorrected and the corrected data sequences launched into and appearing at the output of the FEC decoder, respectively, the observed errors can be correlated with specific bit constellations. The error count for a specific constellation provides a measure for the error e.

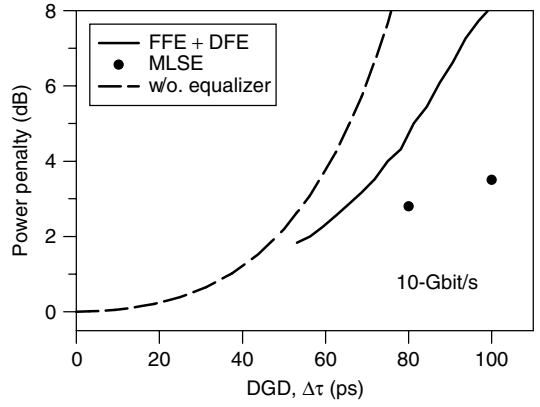

Figure 8. Power penalty (OSNR penalty) of a 10-Gbps optical receiver versus a first-order PMD distortion quantified by the DGD. The penalties are determined numerically for a receiver both without (dashed line) and with (solid line) an equalizer for electrical PMD compensation.

7. OPTICAL VERSUS ELECTRICAL COMPENSATION

Optical PMD compensation by a cascade of two ($0.4T$ PMD limit) or more basic compensators has been demonstrated experimentally. Theoretically, zero penalty can be achieved for an ideal exact compensation of the PMD and operation at bit rates of $\leq$160 Gbps has already been shown in the laboratory. In contrast to these findings, electrical equalization exhibits a residual penalty in the presence of strong PMD distortion and operation has been demonstrated at $\leq$10 Gbps as a result of the speed limits of electronic realization. The remaining penalty is due to the loss of polarization and phase information after square-law detection by the receiver photodiode (see Fig. 8). Mitigation by FFE and DFE is accompanied by a residual penalty of 7 dB for a first-order PMD distortion with a DGD of one bit period and beyond (equal excitation of both PSPs) and in the presence of signal-dependent optical noise (signal independent thermal noise leads to approximately half-residual penalty). This is too high for target applications such as long-distance transmission, which is strongly limited by noise and where only approximately $\leq$2 dB can be allocated for PMD. In this case the FFE and DFE exhibit a reasonable low penalty only if the DGD remains well below a bit period. This value corresponds to a PMD limit in the range of $0.25T$. An improvement is possible by applying MLSE schemes, with the first numerical results indicating a residual penalty in the range of 4 dB [9,10].

Nevertheless, postdetection electronic signal processing improves the receiver performance not only in the presence of PMD but also for ISI stemming from chromatic dispersions or optical nonlinearity such as self-phase modulation (SPM). In addition, it has the potential for effecting a seamless and cost-effective integration in the receiver electronics.

More recent numerical and experimental results have indicated that the efficiency of PMD compensation might be degraded when being used in a WDM environment [11]. As a result of the birefringence induced by other wavelength channels via the Kerr effect of the fiber, a fast polarization modulation can occur at high channel power that is not compensated by current PMDC schemes.

BIOGRAPHY

Henning Bülow received the Dipl.-Ing. degree in electrical engineering in 1985 from the University of Dortmund, Germany, and the Dr. degree in electrical engineering from the University of Berlin in 1988. He joined the Research Center of Alcatel in Stuttgart, Germany, in 1990 as a Research Engineer. At Alcatel he has been studying different aspects of optical communication systems, focusing mainly on erbium-doped fiber amplifiers, optical end electrical time-multiplexed 40-Gbps transmission systems, and assessment of data

transmission in the presence of polarization mode dispersion of the fiber. Since 1998, Dr. Bülow has headed a research team investigating the dynamic mitigation of transmission distortions at 10, 40, and 160 Gbps by adaptive electrical and optical signal processing. He holds over 20 patents in the area of optical communications, has authored or co-authored more than 60 journal and conference publications, and serves on the technical program committee of the Optical Fiber Communication Conference (OFC).

1. INTRODUCTION

Sequences have played an important role in the history of communication systems, especially as the spreading sequences in spread-spectrum (SS) code-division multiple access (CDMA) systems used widely for the most recent personal cellular communications. Among the systems using the SS technique, the direct-sequence (DS) CDMA system expands the bandwidth of a signal by directly multiplying an information symbol by a spreading sequence uniquely assigned to each user, so that a number of users in a cell can share the same frequency band simultaneously. The DSCDMA system is usually preferred over the other SS techniques because it has low implementation cost, can be used with coherent demodulation, and can provide a large capacity in addition to such usual benefits of the SS systems as interference rejection/suppression, multipath mitigation, and security [1–5].

Cellular DSCDMA systems have adopted the multiple or two-layered spreading sequence allocation for flexible system deployment and operation [6]. Orthogonality can be achieved by first multiplying each user's information symbol by a short spreading sequence that is orthogonal to that of any other user in the same cell. This first spreading is followed by a multiplication of a long spreading sequence, which is cell-specific but common to all users in the same cell in the forward link and user-specific in the reverse link. It is possible to provide waveform orthogonality among all users in the same cell while maintaining only mutual randomness between users in different cells. The short spreading sequences are called *channelization sequences* and the long spreading sequences, *scrambling sequences*.

Since different base stations (different mobile users) use different timeshifts of the same sequence in the forward (reverse) link in intercell synchronous operation, the long scrambling sequences are required to have good autocorrelation (AC) properties. The AC property of a sequence is said to be perfect when the AC value is N for the in-phase component and zero for the out-of-phase components, where N is the length of the sequence. This property can support fast symbol synchronization, low multipath interference (MPI), and low intercell interference (ICI). In the intercell asynchronous operation, each cell is assigned to a unique long sequence, which is thus required to have good AC property for fast symbol synchronization and low MPI and to have good crosscorrelation (CC) property for low ICI.

The short spreading sequences in a cell play an important role not only in spreading and despreading but also in the identification of a desired user from interfering users. This is the reason why the short spreading sequence is alternatively called the *signature sequence*. Because the whole frequency band is being used all the time, the bandwidth can be utilized more efficiently (i.e., with narrower equivalent bandwidth per user) in the DSCDMA system than in the conventional systems. The number of users that a system can accommodate is determined by the required signal-to-noise ratio (SNR), which is in turn determined by system design requirements. Note that there is a stringent limitation on the maximum number of users in the time-division multiple access (TDMA) and

frequency-division multiple access (FDMA) systems. On the other hand, the capacity of a CDMA system is softly limited; that is, the maximum number of users is not a clear-cut number. Instead, as more users share the same CDMA channel, the signal quality degrades gradually until it is unacceptable. The acceptable number of users depends on many aspects, including the CC property of the signature sequences in DSCDMA systems. The CC property of signature sequences is linked directly with the multiple access interference (MAI), and consequently with the capacity of the cell. Thus, for low MAI and a large channel capacity, it is desired that the CC value is always (close to) zero.

Traditionally, the cellular DSCDMA systems have utilized the binary maximal length (m) and Gold sequences as the scrambling sequences and Walsh sequences as the channelization sequences. The m sequences have been chosen because they possess the desired randomness and are easily generated via linear feedback shift registers. Gold sequences are an important subclass of the m sequences that can provide good periodic (even) CC. The maximum magnitudes of the periodic AC and CC of Gold sequences are 1 and $1 + 2^{\lfloor (m+2)/2 \rfloor}$, respectively, which is optimum in the sense of the Sidelnikov lower bound for binary sequences. Here, $m \geq 3$ is an integer not equal to a multiple of 4, the length of the sequence is $N = 2^m - 1$, and $\lfloor x \rfloor$ denotes the largest integer less than or equal to x [7]. The Walsh sequences are generated by mapping $\{0, 1\}$ onto $\{-1, 1\}$ for codeword rows of square Hadamard matrices.

In order to obtain sequences having better correlation properties, a number of polyphase sequences have been suggested [8–29]. Using the phase diversity in a chip, polyphase sequences can be so designed as to be more suitable for than binary (two-phase) sequences channelization and scrambling sequences in cellular DSCDMA systems [30,31].

2. SOME PRELIMINARIES

Figure 1 shows the correlation of two sequences in asynchronous DSCDMA systems when the chip synchronization is assumed to be perfect, where k_1 and k_2 denote the user index and $x_j^{(k_i)}$ denotes the jth chip of the k_i(th) sequence. For M-ary phase shift keying (MPSK) systems, the general correlation function [32–34] between two polyphase sequences $\mathbf{x}^{(k_1)}$ and $\mathbf{x}^{(k_2)}$ of length N is

$$\theta_\gamma(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) = C(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) + \gamma C^*(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l - N) \tag{1}$$

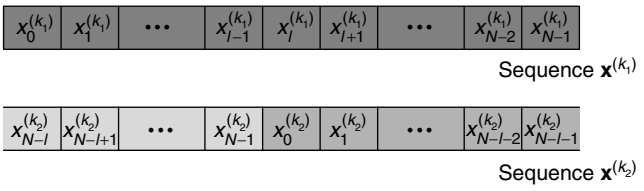

Figure 1. Correlation of two sequences.

where

$$C(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) = \begin{cases} \sum_{i=0}^{N-1-l} x_i^{(k_1)} \{x_{i+l}^{(k_2)}\}^*, & 0 \leq l \leq N-1 \\ \sum_{i=0}^{N-1+l} x_{i-l}^{(k_1)} \{x_i^{(k_2)}\}^*, & 1-N \leq l < 0 \\ 0, & |l| \geq N \end{cases} \tag{2}$$

is the partial correlation

$$\gamma \in \{W_M^t \mid t = 0, 1, \ldots, M-1\} \tag{3}$$

$$W_A^k = e^{2\sqrt{-1}\pi k/A} \tag{4}$$

and A is a natural number with $*$ denoting the complex conjugate. For binary ($M = 2$) phase shift keying (BPSK) systems, we have two important functions, the *even correlation* (EC)

$$\theta(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) = C(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) + C^*(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l - N) \tag{5}$$

and the *odd correlation* (OC)

$$\hat{\theta}(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) = C(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) - C^*(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l - N), \tag{6}$$

from Eq. (1). When $k_1 = k_2$, Eqs. (5) and (6) are called the "even AC (EAC)" and "odd AC (OAC)," respectively, and when $k_1 \neq k_2$, Eqs. (5) and (6) are called the "even CC (ECC)" and "odd CC (OCC)," respectively.

In order to completely analyze the performance of asynchronous DSCDMA systems using a particular class of sequences in an environment of multiple simultaneous users, we should consider not only the EC properties but also the OC properties of sequences. The OC function affects the output of the correlator when the information symbols change over one integration interval, while the EC function affects the output when the information symbols do not change. Thus, when the binary information symbols are equiprobable, both the EC and OC functions are equally important in the system design and performance analysis. Designing sequences with good OC properties is a difficult problem, as observed by other authors [35–37].

3. POLYPHASE SEQUENCES FOR CELLULAR DSCDMA SYSTEMS

3.1. Polyphase Sequences with Perfect EAC

We first consider several polyphase sequences that have perfect EAC properties. Since the good AC properties of such sequences guarantee low interference among the different timeshifts, they are useful as the long scrambling sequences in intercell synchronous cellular DSCDMA systems:

Frank sequence [22] — the sequence of length $N = M^2$ is defined by

$$x_{nM+k} = W_M^{nk}, \quad n, k \in \{0, 1, \ldots, M-1\} \tag{7}$$

Golomb sequence [18,23] — the Golomb sequence of length N is defined by

$$x_n = W_N^{n(n+1)/2}, \quad n = 0, 1, \ldots, N-1 \tag{8}$$

P1 sequence [11] — the P1 sequence of length $N = M^2$ is defined by

$$x_{nM+k} = W_{2M}^{-(M-2n-1)(nM+k)}, \quad n, k \in \{0, 1, \ldots, M-1\} \tag{9}$$

Px sequence [25] — the Px sequence of length $N = M^2$ is defined by

$$x_{nM+k} = \begin{cases} W_{4M}^{(M-2n-1)(M-2k-2)}, & M \text{ even}, \\ W_{4M}^{(M-2n-1)(M-2k-1)}, & M \text{ odd}, \end{cases}$$
$$n, k \in \{0, 1, \ldots, M-1\}. \tag{10}$$

P3 sequence [12] — the P3 sequence of length N is defined by

$$x_n = W_{2N}^{n^2}, \quad n = 0, 1, \ldots, N-1 \tag{11}$$

P4 sequence [13] — the P4 sequence of length N is defined by

$$x_n = W_{2N}^{n(n-N)}, \quad n = 0, 1, \ldots, N-1 \tag{12}$$

In Eqs. (7–12), M and N are natural numbers. The EAC properties of all the sequences listed above are perfect:

$$\theta(\mathbf{x}, \mathbf{x})(l) = \begin{cases} N, & l = 0 \\ 0, & l \neq 0 \end{cases} \tag{13}$$

For example, we obtain Table 1 when $N = 16$. When the length of sequences is 16, the numbers of phases of the Frank, P1, Golomb, Px, P3, and P4 sequences are 4, 8, 16, 16, 32, and 32, respectively. For the sequences shown in Table 1, we have calculated the normalized EAC and OAC functions as shown in Fig. 2; thus we can clearly confirm the perfect EAC property of the sequences. Although each of the six sequences has its own unique defining equation, the EAC properties of the sequences are all the same (at least in the sense of magnitude) and the OAC properties are quite similar to each other. The Frank sequence has the same AC function as the P1 sequence, whose normalized maximum magnitude of the out-of-phase OAC value is 0.1768. The Golomb sequence has the same AC function as do the P3 and P4 sequences, whose normalized maximum magnitude of the out-of-phase OAC value is 0.2310. The maximum magnitude of the out-of-phase OAC value of the Px sequence is the same as that of the Frank sequence, although the OAC functions of these two sequences are different. The peak : second-peak ratio of the Frank, P1, and Px sequences is better than those of the Golomb, P3, and P4 sequences. In addition, the mainlobe : total sidelobe energy ratio of the Px sequence is the lowest among the six sequences.

3.2. Polyphase Sequences with Optimum or Near-Optimum EC

Let $\theta_a = \max_{\mathbf{x}} \max_{l \neq 0} \theta(\mathbf{x}, \mathbf{x})(l)$ and $\theta_c = \max_{\mathbf{x} \neq \mathbf{y}} \max_l \theta(\mathbf{x}, \mathbf{y})(l)$, where $\mathbf{x}$ and $\mathbf{y}$ denote members in a class of polyphase sequences. Then, we have [35]

$$\max\{\theta_a, \theta_c\} \geq \sqrt{N} \tag{14}$$

Thus, if a set of sequences satisfies $\theta_a \leq \sqrt{N}$ and $\theta_c \leq \sqrt{N}$, the sequence is called *optimum* in the sense of the lower bound for polyphase sequences. We now consider some polyphase sequences whose EC functions are (nearly) optimum. These (near) optimum sequences are useful as the long scrambling sequences in intercell asynchronous cellular DSCDMA systems.

3.2.1. Four-Phase Sequence. The generating polynomial of four-phase sequences [16] is a primitive basic irreducible polynomial in $\mathbb{Z}_4[t]$, whose modulo 2 projections are primitive irreducible polynomials in $\mathbb{Z}_2[t]$. If $g(t)$ is a primitive basic irreducible polynomial of degree m, the set of four-phase sequences has period $N = 2^m - 1$ and size $N + 1$. Let the generating polynomial of degree m for the four-phase sequence be

$$g(t) = g_m t^m + g_{m-1} t^{m-1} + \cdots + g_1 t + g_0 \tag{15}$$

where $g_i \in \{0, 1, 2, 3\}$, $g_m \neq 0$, and $g_0 \neq 0$. Then, the recurrence condition of the quaternary sequence $\mathbf{s} = [s_0\, s_1\, \cdots\, s_{N-1}]$ is

$$s_{i+m} = g_{m-1} s_{i+m-1} + g_{m-2} s_{i+m-2} + \cdots + g_1 s_{i+1} + s_i \pmod 4, \text{ for } i \geq 0 \tag{16}$$

and the four-phase sequence $\mathbf{x} = [x_0\, x_1\, \cdots\, x_{N-1}]$ can be obtained from $x_i = W_4^{s_i}$. For example, let $m = 3$ and $g(t) = t^3 + 3t^3 + 2t + 3$. Then, $N = 2^m - 1 = 7$ and the recurrence condition is $t^3 = -3t^2 - 2t - 3 = t^2 + 2t + 1 \pmod 4$. There are $4^m - 1 = 63$ possible nonzero initial

Table 1. Examples of Some Sequences with Perfect EAC When Sequences Length Is 16

Sequence	Value of A in W_A^i (number of phases)	Value of i in W_A^i															
Frank	4	0	0	0	0	0	1	2	3	0	2	0	2	0	3	2	1
P1	8	0	5	2	7	4	3	2	1	0	1	2	3	4	7	2	5
Golomb	16	0	1	3	6	10	15	5	12	4	13	7	2	14	11	9	8
Px	16	9	3	13	7	3	1	15	13	13	15	1	3	7	13	3	9
P3	32	0	1	4	9	16	25	4	17	0	17	4	25	16	9	4	1

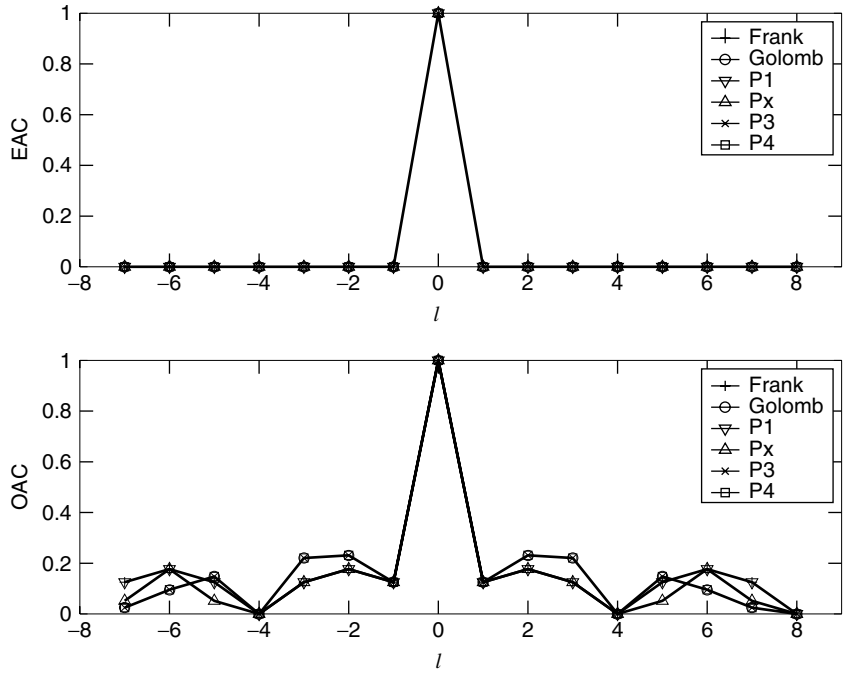

Figure 2. Normalized magnitudes of the AC functions of the sequences in Table 1.

loadings for the mod 4 shift register circuit, but only a collection of $(4^m - 1)/N = N + 2 = 9$ of them will yield cyclically distinct sequences. One of the 9 quaternary sequences is $\mathbf{s} = [1001132]$, and the corresponding four-phase sequence is

$$\mathbf{x} = [W_4^1\ W_4^0\ W_4^0\ W_4^1\ W_4^1\ W_4^3\ W_4^2] \tag{17}$$

The maximum nontrivial correlation magnitude of the four-phase sequence is

$$\max\{\theta_a, \theta_c\} \le 1 + \sqrt{N+1} \tag{18}$$

As in the case of the (binary) Gold sequence, the exact distribution of EC values of the four-phase sequence is known.

3.2.2. Frank–Zadoff–Chu (FZC) Sequence. Let p denote the smallest prime divisor of an odd number N and M_k denote the multiplicative inverse of k mod N, $k = 1, \ldots, p-1$. Then the set $\{\mathbf{x}^{(k)}; k = 1, \ldots, p-1\}$ of $p-1$ FZC sequences [8,10] is defined by

$$\begin{aligned} x_n^{(k)} &= (-1)^{nM_k} W_{2N}^{M_k n^2} \\ &= W_{2N}^{nM_k(n+N)}, \quad n = 0, \ldots, N-1 \end{aligned} \tag{19}$$

When N is prime, there can be as many as $N-1$ FZC sequences. An example of the FZC sequence, when $N = 7$ and $k = 1$, is

$$\mathbf{x}^{(1)} = [W_7^0\ W_7^4\ W_7^2\ W_7^1\ W_7^1\ W_7^2\ W_7^4] \tag{20}$$

The correlation properties of the FZC sequence include

$$\theta(\mathbf{x}^{(k)}, \mathbf{x}^{(k)})(l) = \begin{cases} N, & l = 0 \\ 0, & l \ne 0 \end{cases} \tag{21}$$

for the EAC function, and

$$\theta(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) \le \sqrt{N}, \quad k_1 \ne k_2 \tag{22}$$

for the ECC function.

3.2.3. Generalized Chirplike (GCL) Sequence. Let $\{b_0, b_1, \ldots, b_{m-1}\}$ be a set of m complex numbers all having absolute value 1, and let $\{a_0, a_1, \ldots, a_{N-1}\}$ be a set of $N = sm^2$ numbers defined by

$$a_n = \begin{cases} W_N^{-n^2/2-qn}, & N \text{ even} \\ W_N^{-n(n+1)/2-qn}, & N \text{ odd} \end{cases} \tag{23}$$

where q is an integer and m and s are natural numbers. Then, the GCL sequences [17–21] $\mathbf{x}^{(k)}$, $k = 0, 1, \ldots, N-1$, are defined by

$$x_n^{(k)} = W_N^k a_n b_{n \bmod m}, \quad n = 0, 1, \ldots, N-1. \tag{24}$$

For example, when $s = 2$, $m = 2$ (i.e., $N = 8$), $q = 0$, $k = 0$, and $b_0 = b_1 = 1$, we have

$$\mathbf{x}^{(0)} = [W_{16}^0\ W_{16}^{15}\ W_{16}^{12}\ W_{16}^7\ W_{16}^0\ W_{16}^7\ W_{16}^{12}\ W_{16}^{15}] \tag{25}$$

The EAC function of the GCL sequence is

$$\theta(\mathbf{x}^{(k)}, \mathbf{x}^{(k)})(l) = \begin{cases} N, & l = 0 \\ 0, & l \ne 0 \end{cases} \tag{26}$$

The ECC between two GCL sequences of odd length N, obtained from the two different primitive Nth roots $W_N^{k_1}$ and $W_N^{k_2}$ of unity, is constant if $k_1 - k_2$ is relatively prime to N:

$$\theta(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) = \sqrt{N}, \quad N \text{ odd} \tag{27}$$

3.2.4. Lüke Sequence. The construction of the family of Lüke sequences [15] starts with a q-ary m sequence (see Section 3.4) $\mathbf{c} = [c_0\, c_1 \cdots c_{N-1}]$ of length $N = q^r - 1$, where q is prime and $r \geq 2$ is an integer. The Lüke sequence can then be generated by

$$x_n^{(k)} = W_{qN}^{Nc_n + knq}, \quad n, k \in \{0, 1, \ldots, N-1\} \tag{28}$$

For example, when $q = 3$, $r = 2$, $N = 8$, $k = 1$, and $\mathbf{c} = [12022101]$, we have

$$\mathbf{x}^{(1)} = [W_{24}^{8}\ W_{24}^{19}\ W_{24}^{6}\ W_{24}^{1}\ W_{24}^{4}\ W_{24}^{23}\ W_{24}^{18}\ W_{24}^{5}] \tag{29}$$

The EAC function of the Lüke sequence is two-level in magnitude and nearly perfect:

$$\theta(\mathbf{x}^{(k)}, \mathbf{x}^{(k)})(l) = \begin{cases} N, & l = 0 \\ 1, & l \neq 0 \end{cases} \tag{30}$$

Interestingly, the ECC function is also two-level in magnitude:

$$\theta(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) = \begin{cases} 0, & l = 0, \\ \sqrt{N+1}, & l \neq 0, \end{cases} \tag{31}$$

for $k_1 \neq k_2$.

3.3. Polyphase Sequences with Perfect ECC

We now consider some polyphase sequences that have perfect ECC properties and are useful as the signature (channelization) sequences in cellular DSCDMA systems.

3.3.1. Park–Park–Song–Suehiro (PS) Sequence. Let $\mathbf{b} = [b_0\, b_1 \cdots b_{N_b-1}]$ be a sequence of length N_b with elements $b_i \in \{W_M^0, \ldots, W_M^{M-1}\}$, $i = 0, 1, \ldots, N_b - 1$, where M is a natural number. Then, the PS sequence [28] $x^{(k)}$ of length $N = KN_b^2$ is defined by

$$x_n^{(k)} = W_N^{nk} \sum_{p=0}^{N_b-1} b_p W_{N_b^2}^{np} \delta(R(n + mp, N_b)) \qquad n = 0, 1, \ldots, N-1, \quad k = 0, 1, \ldots, K-1 \tag{32}$$

where $\delta(\cdot)$ is the Kronecker delta function, K is a natural number, $R(a, b)$ is the remainder when a is divided by b, and m is a natural number less than N_b. If N_b is prime, we have

$$x_n^{(k)} = b_{p_s} W_N^{n(k + Kp_s)} \tag{33}$$

where p_s is the number in $\{0, 1, \ldots, N_b - 1\}$ such that $R(n + mp_s, N_b) = 0$. For example, when $N_b = 2$, $K = 2$, $m = 1$, $k = 1$, and $\mathbf{b} = [W_2^0\ W_2^1]$, we have

$$\mathbf{x}^{(1)} = [W_8^0\ W_8^7\ W_8^2\ W_8^5\ W_8^4\ W_8^3\ W_8^6\ W_8^1] \tag{34}$$

3.3.2. Song–Park (SP) Sequence. The SP sequence [29] of length $N = 2(L + 1)$ is defined by

$$x_n^{(k)} = (-1)^n W_{L+1}^{nk}, \quad n = 0, 1, \ldots, N-1, \tag{35}$$

where the even integer L is the size of the SP sequence. For example, when $L = 2$ and $k = 1$, we have

$$\mathbf{x}^{(1)} = [W_6^0\ W_6^5\ W_6^4\ W_6^3\ W_6^2\ W_6^1] \tag{36}$$

The ECC functions of these two sequences [Eqs. (32) and (35)] are perfect:

$$\theta(\mathbf{x}^{(k_1)}, \mathbf{x}^{(k_2)})(l) = 0, \quad k_1 \neq k_2 \tag{37}$$

In order to compare the OCC properties of the PS and SP sequences, we show the cumulative frequencies of the normalized maximum magnitude of the OCC (MMO) values in Fig. 3 when the lengths of sequences are almost the same (the lengths of the PS sequence are 36, 126, and 513 and those of the SP sequence are 30, 126, and 510). The distribution curves are obtained by evaluating the MMO for all possible ${}_SC_2$ pairs of sequences, where S is the number of sequences (which depends on N). For example, when $N = 126$, the cumulative frequency for the PS and SP sequences in Fig. 3b is obtained from ${}_{14}C_2$ and ${}_{62}C_2$ values of the MMO, respectively. In this figure, we can clearly see that the MMO of the SP sequence is smaller than that of the PS sequence with high probability. In addition, the cumulative frequency for the SP sequence converges to 1 at a much faster rate than that for the PS sequence.

3.4. Other Polyphase Sequences

Among the other interesting polyphase sequences are the q-phase m sequences, equal OC and EC (EOE) sequences, and generalized Barker sequences.

3.4.1. *q*-Phase *m* Sequences. q-phase m sequences are obtained by expanding the number of phases of binary m sequences. The q-phase m sequence $\mathbf{x}$ of period $N = q^m - 1$ can be defined by $x_i = W_q^{c_i}$, where $\mathbf{c} = [c_0\, c_1 \cdots c_{N-1}]$ is called the "q-ary m sequence." When q is prime, the generating polynomial

$$g(t) = g_m t^m + g_{m-1} t^{m-1} + \cdots + g_1 t + g_0 \tag{38}$$

for q-ary m sequences is a primitive polynomial of degree m. Here, $g_i \in \{0, 1, \ldots, q-1\}$, $g_m \neq 0$, and $g_0 \neq 0$. The recurrence condition of q-ary m sequences $\mathbf{c}$ is

$$c_{i+m} = g_{m-1} c_{i+m-1} + g_{m-2} c_{i+m-2} + \cdots + g_1 c_{i+1} + c_i \pmod q, \text{ for } i \geq 0 \tag{39}$$

For example, let $q = 3$, $m = 2$, and $g(t) = t^2 + 2t + 2$. Then, the recurrence becomes $t^2 = -2t - 2 = t + 1 \pmod 3$. Using the initial loading of 21 in the registers yields the ternary sequence of period $N = 3^2 - 1 = 8$ as $\mathbf{c} = [c_0\, c_1 \cdots c_{N-1}] = [12022101]$, and a three-phase m sequence can be obtained as

$$\mathbf{x} = [W_3^1\ W_3^2\ W_3^0\ W_3^2\ W_3^2\ W_3^1\ W_3^0\ W_3^1] \tag{40}$$

The EAC function of q-phase m sequences is

$$\theta(\mathbf{x}, \mathbf{x})(l) = \begin{cases} N, & l = 0 \\ -1, & l \neq 0 \end{cases} \tag{41}$$

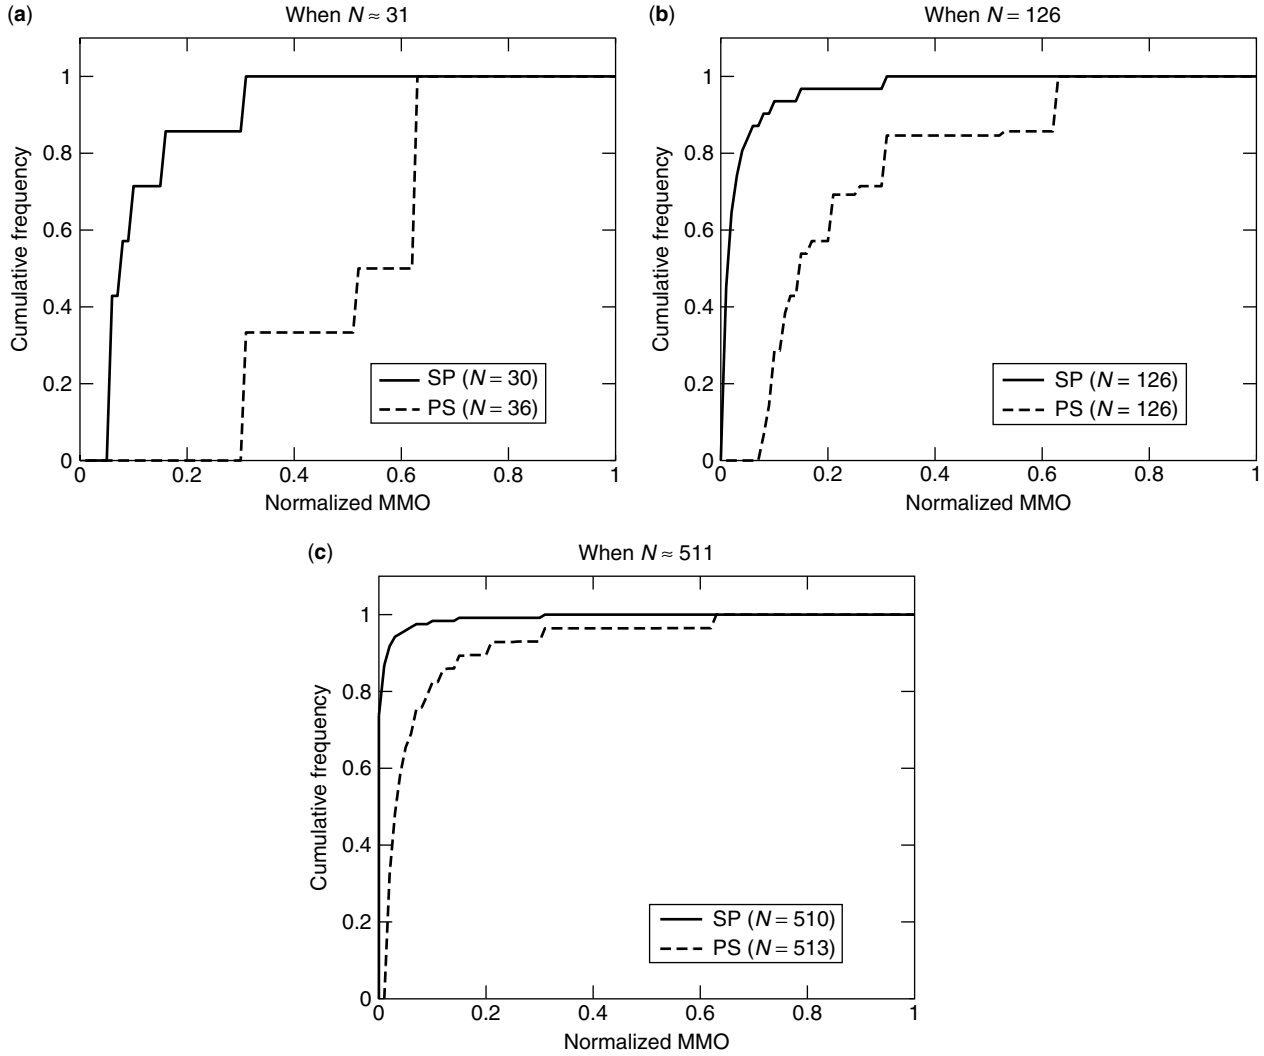

Figure 3. Cumulative frequency of the normalized MMO values of the PS and SP sequences.

3.4.2. EOE Sequences. When $\mathbf{u} = [u_0\, u_1 \cdots u_{N-1}]$ is an arbitrary real-valued sequence of period N,p is an odd integer and β is a real constant satisfying $0 \le \beta < 2\pi$, the complex-valued sequence $\mathbf{x} = [x_0\, x_1 \cdots x_{N-1}]$ defined by

$$x_n = u_n e^{\sqrt{-1}\beta} W_{4N}^{pn}, \quad n = 0, 1, \ldots, N-1 \tag{42}$$

is an EOE sequence [20]. For example, when $N = 7, p = 7$, $\beta = 0$, and $\mathbf{u} = [1\ -1\ -1\quad 1\ -1\ 1\ 1]$ is a Gold sequence, an EOE–Gold sequence with length 7 can be obtained as

$$\begin{aligned}\mathbf{x} &= [W_4^0\ -W_4^1\ -W_4^2\ W_4^3\ -W_4^0\ W_4^1\ W_4^2] \\ &= [W_4^0\ W_4^3\ W_4^0\ W_4^3\ W_4^2\ W_4^1\ W_4^2]\end{aligned} \tag{43}$$

The magnitudes of the OC and EC functions of these sequences are equal:

$$|\theta(\mathbf{x}, \mathbf{y})(l)| = |\hat{\theta}(\mathbf{x}, \mathbf{y})(l)| \tag{44}$$

In addition, we have

$$|\theta(\mathbf{x}, \mathbf{y})(l)| = |\hat{\theta}(\mathbf{x}, \mathbf{y})(l)| \le \max\{\theta(\mathbf{u}, \mathbf{v})(l), \hat{\theta}(\mathbf{u}, \mathbf{v})(l)\} \tag{45}$$

where $\mathbf{y} = [y_0\, y_1 \cdots y_{N-1}]$ denotes an EOE sequence defined with $\mathbf{v} = [v_0\, v_1 \cdots v_{N-1}]$:

$$y_n = v_n e^{\sqrt{-1}\beta} W_{4N}^{pn}, \quad n = 0, 1, \ldots, N-1 \tag{46}$$

3.4.3. Generalized Barker Sequences. A polyphase sequence $\mathbf{x}$ is called a "generalized Barker sequence" [9,24] if the partial AC function satisfies $C(\mathbf{x}, \mathbf{x})(l) \le 1$ for $l \ne 0$. Generalized Barker sequences are widely used as a synchronization sequence because the partial AC property is so good. Let $\mathbf{y} = [y_0\, y_1 \cdots y_{N-1}]$ be a p-phase sequence of length N. Then the q-phase generalized Barker sequence $\mathbf{x}$ of length N is defined by

$$x_n = y_n W_M^n \tag{47}$$

where M is a nonzero integer and q is the least common multiple of p and M. It is easy to see that the partial AC of $\mathbf{x}$ is

$$C(\mathbf{x}, \mathbf{x})(l) = W_M^{-n} C(\mathbf{y}, \mathbf{y})(l), \quad \text{for all } l \tag{48}$$

In particular, we have $|C(\mathbf{x},\mathbf{x})(l)| = |C(\mathbf{y},\mathbf{y})(l)|$ for all l as well as $|x_n| = |y_n|$ since $|W_M^{-n}| = 1$. As a special case, if $|C(\mathbf{y},\mathbf{y})(l)| \le 1$ for all l and $y_n \in \{1,-1\}$, we can obtain a polyphase generalized Barker sequence of length N from a binary Barker sequence of length N. For example, using a binary Barker sequence $\mathbf{y} = [1\ 1\ 1\ -1\ -1\ 1\ -1]$ with length 7, we obtain a four-phase generalized Barker sequence with length 7 as

$$\mathbf{x} = [W_4^0\ W_4^1\ W_4^2\ W_4^1\ W_4^2\ W_4^1\ W_4^0] \tag{49}$$

It has been shown that the binary Barker sequences with odd length $N > 13$ and even length $4 < N < 189884$ do not exist: on the other hand, polyphase sequences of length $N > 13$ satisfying the Barker condition can be found; for example, the 180-phase generalized Barker sequence with length 36 has been reported [24].

4. CONCLUSION

In this article, we have reviewed some polyphase sequences and described their applications to cellular DSCDMA systems based on the correlation properties. The Frank, Golomb, P1, Px, P3, and P4 sequences have a perfect EAC property so that they can be used as scrambling sequences in intercell synchronous cellular DSCDMA systems. The four-phase, FZC, GCL, and Lüke sequences, whose EC functions are (near) optimum in the sense of the lower bound for polyphase sequences, are useful as the scrambling sequences in intercell asynchronous cellular DSCDMA systems. Next, the PS and SP sequences are suitable for the short signature (channelization) sequences in cellular DSCDMA systems because of their perfect ECC properties. Some other polyphase sequences such as the q-phase m, EOE, and generalized Barker sequences are also described briefly.

BIOGRAPHIES

So Ryoung Park received the B.S. degree in Electronics Engineering from Yonsei University, Seoul, Korea, in 1997, and the M.S.E. and Ph.D. degrees in Electrical Engineering from Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea, in 1999 and 2002, respectively. She was a Research Assistant at the Department of Electrical Engineering, KAIST, from 1997 to 2001 and is now a Research Scientist at the Statistical Signal Processing Laboratory, Department of Electrical Engineering and Computer Science, KAIST. She was the recipient of a Gold Prize at the Samsung Humantech Paper Contest in 2001. Her current research interests are in mobile communications and statistical signal processing with emphasis on spread-spectrum communications.

Iickho Song received the B.S.E. (magna cum laude) and M.S.E. degrees in Electronics Engineering from Seoul National University, Seoul, Korea, in 1982 and 1984, respectively, and the M.S.E. and Ph.D. degrees in Electrical Engineering from University of Pennsylvania, Philadelphia (USA), in 1985 and 1987, respectively. In 1988, he joined KAIST, as an Assistant Professor, where he has been a full Professor since 1998. He is a Fellow and Chartered Engineer of the Institution of Electrical Engineers, and a Senior Member of the Institute of Electrical and Electronics Engineers. He has coauthored a book (Advanced Theory of Signal Detection, Springer, 2002) and more than 150 papers in the area of signal detection and estimation and of code design and acquisition for CDMA systems. He received a number of awards, including the Young Scientists Award presented by the President of the Republic of Korea and four Academic Awards from the Korean Institute of Communication Sciences. He has been listed in many "who's who" books, including *Marquis Who's Who in the World* and *Marquis Who's Who in Science and Engineering*. His research interest include detection and estimation, statistical signal processing, and CDMA communications.

POWER CONTROL IN CDMA CELLULAR COMMUNICATION SYSTEMS

MATTI RINTAMÄKI
Helsinki University of Technology
Helsinki, Finland

1. INTRODUCTION

Transmitter power control (TPC) is vital for capacity and performance in cellular communication systems, where high interference is always present as a result of frequency reuse. The basic intent is to control the transmitter powers in such a way that the interference power from each transmitter to other cochannel users (users that share the same radio resource simultaneously) is minimized while preserving sufficient quality of service (QoS) among all users. Cochannel interference management is important in any system employing frequency reuse. However, in CDMA there are interfering users both inside and outside a cell, which makes CDMA interference limited. Thus efficient TPC is essential in CDMA,[1] especially in the uplink (from mobile to base station communication).

Consider the situation depicted in Fig. 1. Mobile stations MS1 and MS2 share the same frequency band, and their signals are separable at the base station (BS) by their unique spreading codes. The link attenuation of MS2 a particular time instant might be several tens of decibels greater than that from MS1 to BS. If power control is not applied, the signal of MS1 will overpower the signal of MS2 at the base station. This is called the *near–far effect*. To mitigate this effect, power control aims to set the

[1] This applies to direct-sequence CDMA (DS-CDMA). In frequency-hopping CDMA (FHCDMA) the intracell interference can be made very small. In this article we concentrate on DS-CDMA, where transmitter power control is more critical. Thus throughout the rest of the text, DS-CDMA is referred to simply as CDMA.

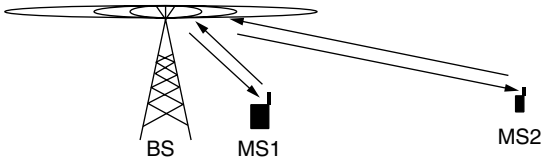

Figure 1. Near–far effect.

transmitter powers of MS1 and MS2 so that both signals are received at the same power level at the base station.

1.1. Radio-Link Attenuation

The attenuation of a radio signal can be modeled as a product of three effects: path loss, shadowing, and multipath fading. *Path loss* is the large-scale distance-dependent attenuation in the average signal power, which can be modeled as r^{-d}, where r is the distance in meters and d is the path loss exponent with typical values ranging from 2 to 5. *Shadowing* is the medium-scale attenuation, which is caused by diffraction and shielding phenomena emanating from terrain variations. This results in relatively slow variations in the mean signal power over a distance of a few tens of wavelengths, caused by reflections, refractions, and diffractions of the signal from buildings, trees, rocks, and other objects. It can be modeled as a lognormally distributed random variable with zero decibels mean and a standard deviation of typically 4–12 dB. *Multipath fading* is the rapid fluctuation in the received signal power that is caused by the constructive and destructive addition of the signals that propagate through different paths with different delays from the transmitter to the receiver. This is usually modeled as a complex Gaussian process, resulting in a Rayleigh-distributed envelope and a classic Doppler spectrum. If a line-of-sight signal is present, the Rice distribution is a better model. Also Nakagami distribution has been widely used to model multipath fading.

With all the three effects included, the attenuation g of the signal power in linear scale can be modeled as

$$g = r^{-d} \times 10^{\zeta/10} \times A_f \tag{1}$$

where ζ is a Gaussian random variable with zero mean and a standard deviation of 4–12 and A_f is a random variable such that $(A_f)^{1/2}$ is either Rayleigh-, Rice- or Nakagami distributed with a classic Doppler spectrum.

As can be understood from above, the signal attenuation is a random variable. Thus, when power control is applied, it must adapt to the changing attenuation of the desired signals, as well as the changing interference conditions, since the attenuations of the cochannel users' signals are also changing, and those signals are power-controlled as well.

1.2. Uplink Versus Downlink Power Control

In CDMA the uplink transmission creates a near–far situation if power control is not used. This occurs because the signals of the different mobile stations propagate through different paths before reaching their serving base station. The task of power control is thus to vary the transmitter powers in order to compensate for the varying channel attenuations, so that the signals from the different mobile stations are received with equal powers at the base station. The requirement of the dynamic range of uplink power control can be of the order of 80 dB.

In downlink there is no near–far situation, since all signals transmitted by a base station propagate through the same path before reaching a mobile station. These signals can be made essentially orthogonal by using proper spreading codes. However, unnecessary high powers can be provided to mobile users near the cell border, thus creating unnecessarily high interference to the neighboring cells. Therefore, downlink power control is used to reduce this interference. The dynamic range of downlink power control is usually much smaller than in uplink, typically on the order of 20–30 dB. This limitation is because a high dynamic range could produce a near–far situation for the mobile stations, since the signals cannot be made perfectly orthogonal.

1.3. Quality Measures for Power Control

A great deal of the work on power control in CDMA cellular systems has focused on how to set the transmitter powers so that all users in the system have acceptable *bit energy-to-interference spectral density ratios* (E_b/I_0). This approach is based on the fairly reasonable assumption that the bit error probability (BEP) at a receiver is a strictly monotonically decreasing function of E_b/I_0. For instance, BEP in an *additive white Gaussian noise* (AWGN) channel decreases very quickly with increasing E_b/I_0. E_b/I_0 is closely related with another measure, namely, the *signal-to-interference ratio* (SIR), such that

$$\frac{E_b}{I_0} = \mathrm{SIR}\frac{W}{r} \tag{2}$$

where W is the transmission bandwidth in hertz and r is the data rate in bits per second (bps). The quantity W/r is called the *processing gain*. When the data rate is fixed, the SIR differs from E_b/I_0 by merely a scaling factor.

In digital communication systems the information to be transmitted is arranged in strings of bits called *frames*, and error correction coding is applied to each frame to further decrease the BEP after decoding. A frame is useless if there are still bit errors in the frame after decoding, and it must be discarded. Hence, depending on the service, a sufficiently low frame erasure rate (FER) must be guaranteed. However, long time delays are needed to obtain reliable estimates of BEP or FER. Since the channel conditions can change very rapidly, these delays might be unacceptably long in practice. Hence most of the attention in the power control field has been on SIR-based algorithms. Also algorithms based on received signal strength have been used, but it has been shown that SIR-based power control offers better performance [1]. The FER information can be used to adjust the target SIR, which a fast TPC algorithm is trying to achieve. This increases system capacity, since a worst-case setting of the SIR target is not required.

In addition to the SIR and FER requirements, the delay or *latency* requirements must be taken into account. For instance, a voice service tolerates a certain amount of data loss but is delay-critical, whereas file downloads do not tolerate bit errors at all (erroneous frames must be retransmitted), but the transmission need not be continuous and must only satisfy some delay limit on the average. The delay tolerances can be taken advantage of in the design of power control algorithms for non-real-time services.

2. THE SIR BALANCING PROBLEM

A widely studied approach to transmitter power control is the SIR balancing problem, namely, how to set the transmitter powers so that all users in the system have equal SIRs. This method is applicable for circuit-switched real-time services such as voice, where the data rate is fixed.

Figure 2 illustrates a simple two-cell CDMA system. We consider only uplink, but the same analysis applies in downlink. The mobile stations MS1 $\cdots$ MS3 share a common frequency band, and their signals are separable at the base stations by their unique spreading codes. The link attenuation from mobile j to base station i is denoted by g_{ij} and is assumed to be fixed in the analysis. In this "snapshot" approach [2,3], it is assumed that the link attenuations change slowly enough compared to the power control dynamics, and can thus be assumed constant. This assumption is reasonable if multipath fading is neglected, but generally leads to optimistic results.

Define a base station assignment function $b(i)$ so that $k = b(i)$ if mobile i is served by base station k. Then the uplink SIR requirement for user i can be expressed as

$$\gamma_i = \frac{g_{b(i)i}p_i}{\sum_{j=1, j\neq i}^{N} g_{b(i)j}p_j + \eta_i} = \frac{p_i}{\sum_{j=1, j\neq i}^{N} \frac{g_{b(i)j}}{g_{b(i)i}}p_j + \frac{\eta_i}{g_{b(i)i}}} \geq \gamma_i^t \qquad (3)$$

where γ_i is the SIR at the receiver of mobile station i, p_i is the transmission power of mobile i, N is the number of mobile stations using the same channel including the intracell and intercell users, η_i is the receiver noise power, and γ_i^t is the uplink SIR requirement for user i. Define the vectors $\mathbf{p} = \{p_i\}$ and $\boldsymbol{\eta} = \{\gamma_i^t \eta_i / g_{b(i)i}\}$ and matrix $\mathbf{H} = \{H_{ij}\}$ with elements $H_{ij} = \gamma_i^t g_{b(i)j}/g_{b(i)i}$ when $i \neq j$ and $H_{ii} = 0$. Now we can put (3) in matrix form:

$$(\mathbf{I} - \mathbf{H})\mathbf{p} \geq \boldsymbol{\eta} \qquad (4)$$

where $\mathbf{I}$ denotes the identity matrix and the inequality holds componentwise. A minimum-power solution corresponds to the case where (4) is satisfied with equality. This is desirable, as it saves energy and thus prolongs the mobile station battery life.

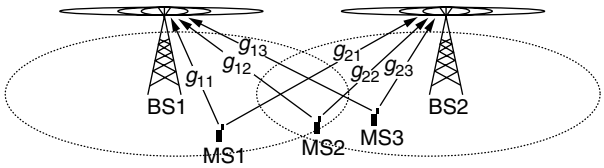

Figure 2. Illustration of a two-cell CDMA system with three mobile stations.

Definition 1. The problem is said to be feasible if there exists a nonnegative power vector $\mathbf{p}$ such that condition in (4) is satisfied.

It has been shown that balancing the SIRs and making the balanced SIR as high as possible maximizes the minimum SIR in all links. Consider the power control problem in (4) with $\gamma_i^t = \gamma^t$. Define matrix $\mathbf{A}$ so that $\mathbf{H} = \gamma^t \mathbf{A}$. If the interference in the receiver is sufficiently high that the receiver noise can be neglected, the problem can be identified as an eigenvalue problem:

$$\mathbf{p} = \mathbf{H}\mathbf{p} \Leftrightarrow \frac{1}{\gamma^t}\mathbf{p} = \mathbf{A}\mathbf{p} \qquad (5)$$

The maximum possible value for γ^t (denoted by γ^*) is equal to the inverse of the maximum (real) eigenvalue of $\mathbf{A}$. The corresponding positive eigenvector $\mathbf{p}^*$ is the power vector achieving this maximum.

If receiver noise cannot be neglected, the optimal power vector is a solution to a set of linear equations:

$$\mathbf{p}^* = \mathbf{H}\mathbf{p}^* + \boldsymbol{\eta} \qquad (6)$$

Proposition 1 [5]**.** The power control problem in (6) is feasible if the largest eigenvalue of the matrix $\mathbf{H}$, denoted by $\rho(\mathbf{H})$, is less than or equal to one.

Note that the case $\rho(\mathbf{H}) = 1$ can only be met if the receiver noise is zero, otherwise infinite transmitter power would be required. Moreover, in practice there always exists an upper limit for the transmitter power.

Using the optimal power vector $\mathbf{p}^*$ results in all users in the system having the same SIR. If the power control problem is not feasible, this results in the disastrous case that none of the users achieve the SIR requirement. To prevent this, a removal strategy must be employed, which removes transmitters from the channel until the power control problem becomes infeasible. The problem is to determine which transmitters to remove. An intuitive approach is to remove those transmitters that produce largest interference, that is, transmitters having the worst link quality. Several removal strategies have been investigated in the literature [4]. Note that a removal of a transmitter from a channel does not necessarily mean that the connection is broken, but it can be handed over to another channel.

3. DISTRIBUTED POWER CONTROL

Solving (6) directly is a centralized method, since it requires the information of all the link attenuations and receiver noise values in the system. This is generally not suitable in real implementations, since it would require extensive signaling overhead. However, it is valuable in determining upper bounds for the performance of distributed algorithms that can be implemented in practice.

A distributed algorithm uses only local measurements to update the transmitter powers. Hence it is more suitable for practical implementation than a centralized algorithm. Since in this case a user does not know the link attenuations, the problem must be iteratively solved. It is thus necessary to find an iteration that depends only on local measurements, and converges to the optimal solution reasonably soon (sooner than the link gains change). Fast convergence can be achieved in two ways: by making the iteration time step smaller, and by designing an iteration with faster convergence property.

A general iterative algorithm to solve the problem in (6) can be found from numerical linear algebra, and is given by [5]

$$\mathbf{p}(k+1) = \mathbf{M}^{-1}\mathbf{N}\mathbf{p}(k) + \mathbf{M}^{-1}\boldsymbol{\eta}, \quad k = 0, 1, \ldots \tag{7}$$

where $\mathbf{M}$ and $\mathbf{N}$ are matrices such that $\mathbf{p}^* = \mathbf{M}^{-1}\mathbf{N}\mathbf{p}^* + \mathbf{M}^{-1}\boldsymbol{\eta}$. By selecting $\mathbf{M}$ and $\mathbf{N}$ properly, the iteration in (7) will converge so that $\lim_{k\to\infty} \mathbf{p}(k) = \mathbf{p}^*$. For example, if we select $\mathbf{M} = \mathbf{I}$ and $\mathbf{N} = \mathbf{H}$, we get

$$\mathbf{p}(k+1) = \mathbf{H}\mathbf{p}(k) + \boldsymbol{\eta}, \quad k = 0, 1, \ldots \tag{8}$$

Looking at this equation componentwise, we have

$$\begin{aligned} p_i(k+1) &= \gamma_i^t \left(\sum_{j=1, j\neq i}^{N} \frac{g_{b(i)j}}{g_{b(i)i}} p_j(k) + \frac{\eta_i}{g_{b(i)i}} \right) \\ &= \frac{\gamma_i^t}{\gamma_i(k)} p_i(k), \quad k = 0, 1, \ldots \end{aligned} \tag{9}$$

where $\gamma_i(k)$ and $p_i(k)$ are the received SIR and transmission power of transmitter i at iteration k, respectively. This is referred to as the *distributed power control* (DPC) algorithm. It was proposed by Foschini and Miljanic [6]. It is totally distributed, since it depends only on local measurements of the SIR.

3.1. Convergence of the Iterative Algorithm

A necessary and sufficient condition for the iteration in (7) to converge is the following [5]. Let $\alpha_1, \alpha_2, \ldots$ be the eigenvalues of the matrix $\mathbf{M}^{-1}\mathbf{N}$. Then the iteration converges if and only if $\max_k |\alpha_k| < 1$. Consider the DPC algorithm in (9). In this case we have $\mathbf{M}^{-1}\mathbf{N} = \mathbf{H}$. Hence the dominant eigenvalue of $\mathbf{H}$, $\rho(\mathbf{H})$, should be less than one. By proposition 1, this ensures that the SIR requirements are satisfied for all users. Hence DPC converges to $\mathbf{p}^*$ whenever the SIR requirements can be satisfied.

The speed of the convergence is very important, since the link attenuations are changing all the time. For the iteration in (7), it can be shown that the smaller the $\rho(\mathbf{M}^{-1}\mathbf{N})$, the faster the convergence. Hence the task is to find $\mathbf{M}$ and $\mathbf{N}$ such that $\rho(\mathbf{M}^{-1}\mathbf{N}) < 1$ and as small as possible.

3.2. Convergence Using Standard Interference Functions

A different way of proving convergence of iterative algorithms was developed by Yates [7] and extended by Huang and Yates [8]. There the iteration is formulated by defining an *interference function* $I(\mathbf{p})$ such that

$$\mathbf{p}(k+1) = I(\mathbf{p}(k)) \tag{10}$$

The standard interference function framework gives a *sufficient* but not *necessary* condition for convergence of the iteration in (7). The following definition and proposition summarize this framework.

Definition 2 [7]**.** An interference function $I(\mathbf{p})$ is called "standard" if for all nonnegative power vectors

$$\begin{aligned} &I(\mathbf{p}) > 0 \\ &\mathbf{p} \geq \mathbf{p}' \Rightarrow I(\mathbf{p}) \geq I(\mathbf{p}') \\ &\forall \alpha > 1, \quad \alpha I(\mathbf{p}) > I(\alpha\mathbf{p}) \end{aligned} \tag{11}$$

Proposition 2 [7]**.** If the power control problem is feasible and $I(\mathbf{p})$ is a standard interference function, then for any initial nonnegative power vector $\mathbf{p}$ the iteration in (10) converges to the unique nonnegative fixed point $\mathbf{p}^*$.

3.3. Distributed Constrained Power Control

In all practical systems the transmitter powers are limited so that

$$\mathbf{0} \leq \mathbf{p} \leq \mathbf{p}_{\max} \tag{12}$$

where $\mathbf{0}$ is a vector with all-zero elements and $\mathbf{p}_{\max} = [p_i^{\max}, p_2^{\max}, \ldots, p_N^{\max}]^T$ denotes the maximum transmitter power of each transmitter. To take these limitations into account, the distributed constrained power control (DCPC) algorithm was suggested by Grandhi et al. [9]. It is defined by

$$p_i(k+1) = \min\left(p_i^{\max}, \frac{\gamma_i^t}{\gamma_i(k)} p_i(k) \right), \quad k = 0, 1, \ldots \tag{13}$$

where $p_i^{\max}$ is the maximum allowed transmitter power of transmitter i. With DCPC some transmitters can transmit with the maximum power, thus producing maximum interference to other users, but still not achieving their SIR target. Therefore it might be beneficial to lower the transmission power when link quality is poor. With this in mind, a following more general algorithm has been proposed (see Ref. 5 and the references cited therein) that has DCPC as a special case:

$$p_i(k+1) = \begin{cases} \dfrac{\gamma_i^t}{\gamma_i(k)} p_i(k) & \text{if, } \dfrac{\gamma_i^t}{\gamma_i(k)} p_i(k) \leq p_i^{\max} \\ p_i' & \text{if, } \dfrac{\gamma_i^t}{\gamma_i(k)} p_i(k) > p_i^{\max} \end{cases} \tag{14}$$

where $0 \leq p_i' \leq p_i^{\max}$. It can be shown that this algorithm converges to the optimal power vector $\mathbf{p}^*$ provided that the system in (6) has the optimal solution $\mathbf{p}^*$ in the power range given by (12).

3.4. A Two-User Example

Consider a system with only two mobile stations MS1 and MS2 and two base stations BS1 and BS2. Assume that

MS1 is connected to BS1 and MS2 is connected to BS2. In this case the power control problem is the following:

$$\begin{cases} \gamma_1 = \dfrac{g_{11}p_1}{g_{12}p_2 + \eta_1} \geq \gamma_1^t \\ \gamma_2 = \dfrac{g_{22}p_2}{g_{21}p_1 + \eta_2} \geq \gamma_2^t \end{cases} \Rightarrow \begin{cases} p_1 \geq \gamma_1^t \left(\dfrac{g_{12}}{g_{11}} p_2 + \dfrac{\eta_1}{g_{11}} \right) \\ p_2 \geq \gamma_2^t \left(\dfrac{g_{21}}{g_{22}} p_1 + \dfrac{\eta_2}{g_{22}} \right) \end{cases} \quad (15)$$

This situation is depicted in Fig. 3. The feasible region is shaded in the figure, and the optimal (minimum power) solution $\mathbf{p}^*$ is in the intersection of the two lines. Since $\mathbf{p}^*$ is within the maximum power limits, the problem is feasible. Consider that user 1 raises its target SIR γ_1^t while the link attenuations remain unchanged. It is then necessary for it to also raise its transmitter power as seen from (15). This, in turn, forces user 2 to raise its transmitter power. Thus it can happen that the optimal point $\mathbf{p}^*$ moves outside the maximum power limits, thereby making the problem unfeasible.

4. PRACTICAL ISSUES ON POWER CONTROL

A number of practical issues limit the implementation of the theoretical algorithms:

- *SIR Estimation*. The received SIR is not known exactly at a receiver, but it must be estimated, and thus there will always be some estimation error.
- *TPC Update Rate*. In CDMA one has to deal with the near–far situation, and thus the update rate of the power control algorithm must be sufficiently high that the variations in the link attenuation can be tracked. Typical update rates are from 800 Hz (used in the IS95 system [11]) to 1500 Hz (used in WCDMA [10]).
- *Feedback Information Accuracy*. The information of the SIR at the receiver should somehow be communicated to the transmitter. An accurate representation of the SIR measurement requires several bits, but this requires more signaling overhead. A usual case in practice is that only one bit is used to inform the transmitter to either increase or decrease its transmitter power by a fixed amount, typically by 1 dB (e.g., in IS95).
- *Loop Delay*. The loop delay greatly affects the performance of a power control algorithm. This delay comes from the SIR measurement process, the transmission of the SIR information over the radio channel, the processing of the SIR information to calculate and adjust the transmission power, and the propagation time after which the new transmission power affects the next SIR measurement. Therefore the power update is based on outdated information of the received SIR. If the channel variation is fast in comparison to the loop delay, the TPC algorithm cannot track the variations.
- *Errors in the Transmission of Feedback Information*. To minimize the loop delay, the TPC command bits are sent without error correction coding. Hence the probability of receiving an erroneous command can be relatively high (e.g., 5–10%).

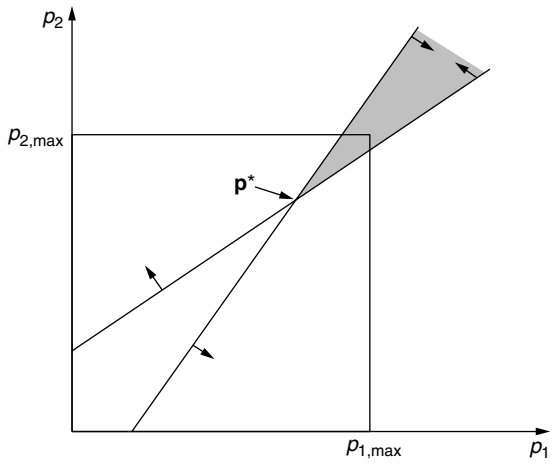

Figure 3. Power control problem for two-user case.

4.1. Open-Loop, Closed-Loop, and Outer-Loop Power Control

Because of the limitations mentioned above, TPC in CDMA is implemented in a slightly different way than the theoretical algorithms.

An intuitive way to compensate for the channel attenuation in the uplink would be to measure the strength of a pilot signal from the downlink, and adjust the transmitter power proportionally to the inverse of this measurement. Since the pilot signal is transmitted at constant power, the variation of its strength gives information of the downlink link attenuation. This is called *open-loop power control*. Unfortunately the center frequencies allocated to up- and down-link transmissions are usually widely separated, and thus the correlation between up- and down-link attenuations is generally weak. Therefore, the transmitter power update of a mobile must be based on feedback information of the received SIR at the base station, forming a closed loop between them. This *closed-loop power control* aims to keep the received uplink signal power level at a specified target. Moreover, the target must also be varied, because the SIR requirement for a given BER is not constant, but depends on the radio propagation conditions. This is the task of the *outer-loop power control*.

Open-loop TPC is generally used for initial power setting, when the two-way communication link is not yet established and closed loop is not possible. *Closed-loop TPC* aims to keep the received SIR at a target value. This is what is happening in the DPC algorithm given in Eq. (9). However, in practice only one bit is used to signal the received SIR information at a fast rate to track the channel variations. The transmitter is commanded to increase its power by a fixed step if the received SIR is below the target, and decrease otherwise. This kind of algorithm is used in IS95. In WCDMA there are some more degrees of freedom, for instance, the possibility to signal a "no change" command when the received SIR is reasonably close to the target, thus reducing the "bang-bang"-effect around the target.

The outer-loop control adjusts the SIR target so that a desired FER is guaranteed. A typical way to do this in practice is to raise the target by a larger step Δ_{up} when a frame is discarded, and to decrease the target with a smaller step Δ_{down} when a frame is correctly received. The relation between the step sizes gives the resulting average FER as $\text{FER} = \Delta_{\text{down}}/(\Delta_{\text{up}} - \Delta_{\text{down}})$ [10].

5. POWER CONTROL IN REAL-TIME VERSUS NON-REAL-TIME AND MULTIRATE SERVICES

The SIR balancing concept has the goal of maximizing the number of users in the system. If the users are real-time users requiring constant bit rates, this is a good strategy for maximizing capacity. However, as the cellular systems evolve to the next generation, the variety of services will be considerably different from those in the previous systems. In addition to the familiar real-time voice, there will be both real-time and non-real-time services with different data rates. Hence, maximizing the data throughput instead of the number of users might be more interesting from the operator's point of view. Of course the delay requirements must be fulfilled, as merely maximizing throughput would be achieved by just letting the user with the best instantaneous link quality to transmit.

Since CDMA is interference-limited, any decrease in the transmission power of one user is directly advantageous for other users because of decreased interference. If the link quality between a transmitter and a receiver is poor, high transmitter power is needed to satisfy the SIR requirements. This produces high interference to other receivers, and their serving transmitters must also increase their powers in order to cope with the increased interference.

In non-real-time services the data rate must only be satisfied on the average sense, and therefore the instantaneous data rate can be considerably varied. This allows the TPC algorithm even to cut off the transmission when the link quality is bad, and to transmit at a high data rate when the link quality is good. Thus, the situation as compared to conventional TPC designed for real-time services is reversed — the transmission power should be small when link quality is low, and vice versa. Since the time dimension can be utilized in the optimization, there is potential for significant capacity gain by minimizing the total transmitted *energy* instead of power. This can be accomplished by scheduling the data transmissions properly [12].

To elaborate, consider a set of users requiring individual data rates. Using (2) and (3), we write the effective data rate of user i as

$$r_i = \frac{W}{(E_b/N_0)_i}\gamma_i(\mathbf{p}) \tag{16}$$

where $\gamma_i(\mathbf{p})$ is the received SIR of user i with the power vector $\mathbf{p}$ and $(E_b/N_0)_i$ is the E_b/N_0 requirement for user i for achieving the data rate r_i. Let the maximum transmission power vector for the users be $\mathbf{p}_{\max} = (p_1^{\max}, p_2^{\max}, \ldots, p_N^{\max})$.

Definition 3 [5,12]**.** A rate vector $\mathbf{r}(\mathbf{p}_{\max}) = (r_1, r_2, \ldots, r_N)$ is instantaneously achievable if there exists a nonnegative power vector $\mathbf{p} \le \mathbf{p}_{\max}$ such that $r_i \le \dfrac{W}{(E_b/N_0)_i}\gamma_i(\mathbf{p})$ for all $1 \le i \le N$.

Definition 4 [5,12]**.** A rate vector $\mathbf{r}^*(\mathbf{p}_{\max}) = (r_1^*, r_2^*, \ldots, r_N^*)$ is achievable in the average sense if it may be expressed as $\mathbf{r}^* = \sum_k \lambda_k r_k$, where $\lambda_k \in [0, 1]$, $\sum_k \lambda_k = 1$, and all the r_k are instantaneously achievable rate vectors.

Thus, different rate vectors can be assigned a fraction of time (or frequency) yielding the required rate vector on the average. Assume that each link i requires a minimum data rate $r_i^{\min}$. Any excess data rate is potentially consumed, and thus paid for, by the user. It is the interest of the operators then to provide as much excess data rate as possible. For non-real-time services, therefore, the following optimization problem is of interest:

$$\begin{aligned} &\max \sum_{i=1}^{N} r_i^*(\mathbf{p}_{\max}) \\ &\text{subject to } r_i^*(\mathbf{p}_{\max}) \ge r_i^{\min}, \forall i \end{aligned} \tag{17}$$

6. POWER CONTROL AND OTHER RADIO RESOURCE MANAGEMENT (RRM)

Optimizing power control alone is not always the best way to enhance capacity. By understanding the relations between power control and other RRM functions, one can design more efficient algorithms by combining them in an ingenious way. For instance, base station assignment is closely related to the power control problem. For the SIR balancing problem, if the mobile stations could always be connected to the base station to which the link quality is optimal, the total transmission power would be minimized. Combined power and rate control is interesting for services with heterogeneous bit rates and quality requirements as discussed in the last section. Other methods that have been considered jointly with power control include smart antennas and beamforming, where there are more degrees of freedom in the optimization of the algorithms. An interested reader is directed to the articles in the Further Reading list for more details.

7. DISCUSSION AND VIEWS INTO THE FUTURE

The ultimate goal of radio resource management is to maximize the network capacity without unduly sacrificing the satisfaction of the users. Efficient transmitter power control is essential in CDMA cellular systems for achieving these goals. The efficiency of TPC depends on its ability to control the interference inherent in wireless multiuser systems. However, there are other methods for combating the multiple access interference in CDMA. One of these methods is *multiuser detection* (MUD). An optimal MUD-based receiver would theoretically eliminate the need for power control completely! In practice,

however, an optimal MUD receiver would be too complex, and suboptimal solutions must be used that are not completely resistant to interference, and TPC can still provide additional gain. Using only TPC provides a much cheaper way of controlling interference. This situation might change in the future, as the microtechnology evolves very rapidly and more efficient chips become available.

BIOGRAPHY

Matti J. Rintamäki received an M.S. degree in electrical engineering from Helsinki University of Technology, Finland, in 2000. Since then he has been a research scientist at Signal Processing Laboratory at HUT, where he has been working on power control algorithms for CDMA systems. His areas of interest are adaptive control and signal processing algorithms, and the design of radio resource management algorithms for wireless communications.

POWER SPECTRA OF DIGITALLY MODULATED SIGNALS

JOHN G. PROAKIS
Northeastern University
Boston, Massachusetts

1. INTRODUCTION

In the design of digital communication systems for transmitting digital information through a channel, the spectral characteristics of the information-bearing signals is an important element. The communication system designer must ensure that the signals used for transmitting the information do not violate the bandwidth constraint imposed by the channel or some governmental agency. In this article, the spectral characteristics of several types of digitally modulated signals are described.

In describing the spectral characteristics of digitally modulated signals, it is desirable to classify such signals into two different categories, namely, linearly modulated signals and nonlinearly modulated signals. The class of linearly modulated signals include pulse amplitude modulation or amplitude shift keying (PAM or ASK),

phase shift keying (PSK), and quadrature amplitude modulation (QAM). The class of nonlinearly modulated signals includes continuous-phase modulation (CPM) and the special form of CPM called *continuous-phase frequency shift keying* (CPFSK). CPM and CPFSK are constant-amplitude signals; hence, they are well suited for radiocommunications, where the transmitted signals can be amplified by power amplifiers that can be driven into saturation without introducing nonlinear distortion in the signals.

The spectral characteristics of linearly modulated signals are considered in the next section. Nonlinearly modulated signals are treated in the subsequent section.

2. POWER SPECTRA OF LINEARLY MODULATED SIGNALS

Linear digital modulation methods that include PAM (ASK), PSK, and QAM can be treated in a unified manner. The digitally modulated signals for these methods are usually generated as lowpass signals, which may be expressed mathematically as

$$v(t) = \sum_n I_n g(t - nT) \tag{1}$$

and then translated to bandpass, for transmission over the bandpass channel, by a frequency translation. Hence, the bandpass signal is

$$s(t) = \mathrm{Re}[v(t)e^{j2\pi f_c t}] \tag{2}$$

where f_c is the carrier frequency. In the expression for the lowpass signal given by Eq. (1), the data sequence $\{I_n\}$ has values taken from either a PAM, PSK, or QAM signal-point constellation. In particular, if the modulated signal is M-level PAM, the sequence $\{I_n\}$ takes on values from the set $\{\pm 1, \pm 3, \pm 5, \ldots, \pm(M-1)\}$. When the modulated signal is M-phase PSK, the data sequence $\{I_n\}$ takes values from the set $\{\exp(2\pi m/M), m = 0, 1, \ldots, M-1\}$. A QAM signal is basically a combined amplitude/phase-modulated signal, so the data sequence takes an values from the set $\{A_m e^{j\theta_m}, m = 0, 1, \ldots, M-1\}$. Finally, the signal $g(t)$ in Eq. (1) is a signal pulse that is used to shape the spectrum of the transmitted signal. The rate at which data symbols are transmitted is $1/T$, where T defines the symbol interval.

The digitally modulated signal $v(t)$ is a random process because the data sequence $\{I_n\}$ is random. The power spectrum of $v(t)$ will be determined by first obtaining the autocorrelation function of $v(t)$ and then computing its Fourier transform. The power spectrum of the bandpass signal $s(t)$ is simply obtained from the power spectrum of $v(t)$ by a simple frequency translation. Thus, the autocorrelation function of the bandpass signal $s(t)$, denoted as $\phi_{ss}(\tau)$ is related to the autocorrelation function of the equivalent lowpass signal $v(t)$ through the expression

$$\phi_{ss}(\tau) = \mathrm{Re}[\phi_{vv}(\tau)e^{j2\pi f_c \tau}] \tag{3}$$

where $\phi_{vv}(\tau)$ is the autocorrelation function of the equivalent lowpass signal $v(t)$. The Fourier transform of Eq. (3) yields the desired expression for the power density spectrum $\Phi_{ss}(f)$ in the form

$$\Phi_{ss}(f) = \tfrac{1}{2}[\Phi_{vv}(f - f_c) + \Phi_{vv}(-f - f_c)] \tag{4}$$

where $\Phi_{vv}(f)$ is the power density spectrum of $v(t)$. It suffices to determine the autocorrelation function and the power density spectrum of the equivalent lowpass signal $v(t)$.

The autocorrelation function of $v(t)$ is defined as

$$\begin{aligned}\phi_{vv}(t + \tau; t) &= \frac{1}{2}E[v^*(t)v(t + \tau)] \\ &= \frac{1}{2}\sum_{n=-\infty}^{\infty}\sum_{n=-\infty}^{\infty} E[I_n^* I_m]g^*(t - nT)g(t + \tau - mT)\end{aligned} \tag{5}$$

It is assumed that the sequence of information symbols $\{I_n\}$ is wide-sense stationary with mean μ_i and autocorrelation function

$$\phi_{ii}(m) = \tfrac{1}{2}E[I_n^* I_{n+m}] \tag{6}$$

Hence Eq. (5) can be expressed as

$$\begin{aligned}\phi_{vv}(t + \tau; t) &= \sum_{n=-\infty}^{\infty}\sum_{m=-\infty}^{\infty}\phi_{ii}(m - n)g^* \\ &\quad \times (t - nT)g(t + \tau - mT) \\ &= \sum_{m=-\infty}^{\infty}\phi_{ii}(m)\sum_{n=-\infty}^{\infty} g^*(t - nT)g \\ &\quad \times (t + \tau - nT - mT)\end{aligned} \tag{7}$$

The second summation in Eq. (7), namely

$$\sum_{n=-\infty}^{\infty} g^*(t - nT)g(t + \tau - nT - mT) \tag{8}$$

is periodic in the t variable with period T. Consequently, $\phi_{vv}(t + \tau; t)$ is also periodic in the t variable with period T:

$$\phi_{vv}(t + T + \tau; t + T) = \phi_{vv}(t + \tau; t) \tag{9}$$

In addition, the mean value of $v(t)$, which is

$$E[v(t)] = \mu_i \sum_{n=-\infty}^{\infty} g(t - nT) \tag{10}$$

is periodic with period T. Therefore, $v(t)$ is a random process having a periodic mean and autocorrelation function. Such a process is called a *cyclostationary process* or a *periodically stationary process in the wide sense*.

In order to compute the power density spectrum of a cyclostationary process, the dependence of $\phi_{vv}(t + \tau; t)$ on the t variable must be eliminated. This can be

accomplished simply by averaging $\phi_{vv}(t+\tau;t)$ over a single period:

$$\begin{aligned}\overline{\phi}_{vv}(\tau) &= \frac{1}{T}\int_{-T/2}^{T/2}\phi_{vv}(1+\tau;t)\,dt \\ &= \sum_{m=-\infty}^{\infty}\phi_{ii}(m)\sum_{n=-\infty}^{\infty}\frac{1}{T}\int_{-T/2}^{T/2}g^*(t-nT)g \\ &\quad\times(t+\tau-nT-mT)\,dt \\ &= \sum_{m=-\infty}^{\infty}\phi_{ii}(m)\sum_{n=-\infty}^{\infty}\frac{1}{T}\int_{-T/2-nT}^{T/2-nT}g^*(t)g(t+\tau-mT)\,dt\end{aligned} \tag{11}$$

We interpret the integral in this equation as the time autocorrelation function of $g(t)$ and define it as

$$\phi_{gg}(t) = \int_{-\infty}^{\infty}g^*(t)g(t+\tau)\,dt \tag{12}$$

Consequently Eq. (11) can be expressed as

$$\overline{\phi}_{vv}(\tau) = \frac{1}{T}\sum_{m=-\infty}^{\infty}\phi_{ii}(m)\phi_{gg}(\tau-mT) \tag{13}$$

The Fourier transform of the relation in Eq. (13) yields the (average) power density spectrum of $v(t)$ in the form

$$\Phi_{vv}(f) = \frac{1}{T}|G(f)|^2\Phi_{ii}(f) \tag{14}$$

where $G(f)$ is the Fourier transform of $g(t)$, and $\Phi_{ii}(f)$ denotes the power density spectrum of the information sequence, defined as

$$\Phi_{ii}(f) = \sum_{m=-\infty}^{\infty}\phi_{ii}(m)e^{-j2\pi fmT} \tag{15}$$

The result in Eq. (14) illustrates the dependence of the power density spectrum of $v(t)$ on the spectral characteristics of the pulse $g(t)$ and the information sequence $\{I_n\}$. Thus, the spectral characteristics of $v(t)$ can be controlled by design of the pulseshape $g(t)$ and by design of the correlation characteristics of the information sequence.

Whereas the dependence of $\Phi_{vv}(f)$ on $G(f)$ is easily understood on observation of Eq. (14), the effect of the correlation properties of the information sequence is more subtle. First, we note that for an arbitrary autocorrelation $\phi_{ii}(m)$ the corresponding power density spectrum $\Phi_{ii}(f)$ is periodic in frequency with period $1/T$. In fact, the equation [Eq. (15)] relating the spectrum $\Phi_{ii}(f)$ to the autocorrelation $\phi_{ii}(m)$ is in the form of an exponential Fourier series with the $\{\phi_{ii}(m)\}$ as the Fourier coefficients. As a consequence, the autocorrelation sequence $\phi_{ii}(m)$ is given by

$$\phi_{ii}(m) = T\int_{-1/2T}^{1/2T}\Phi_{ii}(f)e^{j2\pi fmT}\,df \tag{16}$$

Second, let us consider the case in which the information symbols in the sequence are real and mutually uncorrelated. In this case, the autocorrelation function $\phi_{ii}(m)$ can be expressed as

$$\phi_{ii}(m) = \begin{cases}\sigma_i^2+\mu_i^2 & (m=0)\\ \mu_i^2 & (m+0)\end{cases} \tag{17}$$

where σ_i^2 denotes the variance of an information symbol. When Eq. (17) is used to substitute for $\phi_{ii}(m)$ in Eq. (15), we obtain

$$\Phi_{ii}(f) = \sigma_i^2+\mu_i^2\sum_{m=-\infty}^{\infty}e^{-j2\pi fmT} \tag{18}$$

The summation in Eq. (18) is periodic with period $1/T$. It may be viewed as the exponential Fourier series of a periodic train of impulses with each impulse having an area $1/T$. Therefore Eq. (18) can also be expressed in the form

$$\Phi_{ii}(f) = \sigma_i^2+\frac{\mu_1^2}{T}\sum_{m=-\infty}^{\infty}\delta\left(f-\frac{m}{T}\right) \tag{19}$$

Substitution of Eq. (19) into Eq. (14) yields the desired result for the power density spectrum of $v(t)$ when the sequence of information symbols is uncorrelated:

$$\Phi_{vv}(f) = \frac{\sigma_i^2}{T}|G(f)|^2+\frac{\mu_1^2}{T^2}\sum_{m=-\infty}^{\infty}\left|G\left(\frac{m}{T}\right)\right|^2\delta\left(f-\frac{m}{T}\right) \tag{20}$$

The expression in Eq. (20) for the power density spectrum is purposely separated into two terms to emphasize the two different types of spectral components. The first term is the continuous spectrum, and its shape depends only on the spectral characteristic of the signal pulse $g(t)$. The second term consists of discrete frequency components spaced $1/T$ apart in frequency. Each spectral line has a power that is proportional to $|G(f)|^2$ evaluated at $f=m/T$. Note that the discrete frequency components vanish when the information symbols have zero mean: $\mu_i=0$. This condition is usually desirable for the digital modulation techniques under consideration, and it is satisfied when the information symbols are equally likely and symmetrically positioned in the complex plane. Thus, the system designer can control the spectral characteristics of the digitally modulated signal by proper selection of the characteristics of the information sequence to be transmitted.

As an example that illustrates the spectral shaping from $g(t)$, consider the rectangular pulse shown in Fig. 1. The Fourier transform of $g(t)$ is

$$G(f) = AT\frac{\sin\pi fT}{\pi fT}e^{-j\pi fT}$$

Hence

$$|G(f)|^2 = (AT)^2\left(\frac{\sin\pi fT}{\pi fT}\right)^2 \tag{21}$$

This spectrum is illustrated in Fig. 1. Note that it contains zeros at multiples of $1/T$ in frequency and that it decays inversely as the square of the frequency variable. As a consequence of the spectral zeros in $G(f)$, all except one of

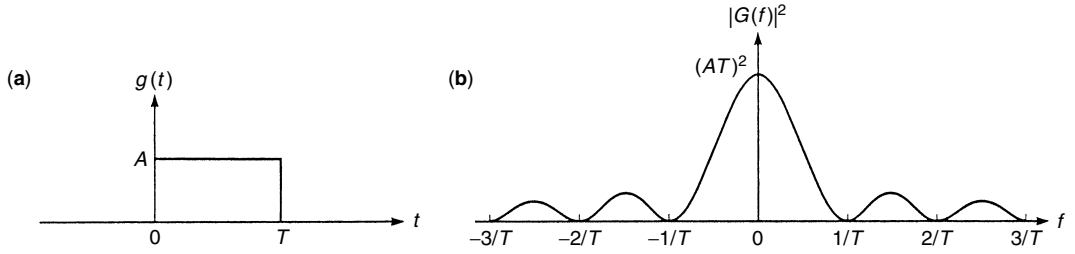

Figure 1. Rectangular pulse and its energy density spectrum.

the discrete spectral components in Eq. (20) vanish. Thus, on substitution for $|G(f)|^2$ from Eq. (21), Eq (20) reduces to

$$\Phi_{vv}(f) = \sigma_i^2 A^2 T \left(\frac{\sin \pi fT}{\pi fT}\right)^2 + A^2 \mu_i^2 \delta(f)$$

To illustrate that spectral shaping can also be accomplished by operations performed on the input information sequence, we consider a binary sequence $\{b_n\}$ from which we form the symbols

$$I_n = b_n + b_{n-1}$$

The $\{b_n\}$ are assumed to be uncorrelated random variables, each having zero mean and unit variance. Then the autocorrelation function of the sequence $\{I_n\}$ is

$$\begin{aligned}\phi_{ii}(m) &= E(I_n I_{n+m}) \\ &= \begin{cases} 2 & (m = 0) \\ 1 & (m = \pm 1) \\ 0 & (\text{otherwise}) \end{cases}\end{aligned}$$

Hence, the power density spectrum of the input sequence is

$$\begin{aligned}\Phi_{ii}(f) &= 2(1 + \cos 2\pi fT) \\ &= 4 \cos^2 \pi fT\end{aligned}$$

and the corresponding power density spectrum for the (lowpass) modulated signal is

$$\Phi_{vv}(f) = \frac{4}{T}|G(fg)|^2 \cos^2 \pi fT$$

Since $\cos^2 \pi fT$ has its first null at $f = 1/2T$, the effect of multiplying $|G(f)|^2$ by $\cos^2 \pi fT$ is to narrow the width of the mainlobe of the signal spectrum.

2. POWER SPECTRA OF CONTINUOUS-PHASE MODULATED SIGNALS

A CPM signal is described mathematically as

$$s(t) = A \cos[2\pi f_c t + \phi(t; \mathbf{I})] \tag{22}$$

where A is the signal amplitude, f_c is the carrier frequency, and $\phi(t; \mathbf{I})$ is the phase of the signal that carries the information. The phase function may be defined as

$$\phi(t; \mathbf{I}) = 2\pi h \sum_{k=-\infty}^{n} I_k q(t - kT), \quad nT \le t \le (n+1)T \tag{23}$$

where $\{I_k\}$ is the data sequence selected from the M-level amplitude alphabet $\{\pm 1, \pm 2, \ldots, \pm(M-1)\}$, h is the modulation index, and $q(t)$ is defined as the integral of a pulse $g(t)$:

$$q(t) = \int_0^t g(\tau)\, d\tau \tag{24}$$

The pulse $g(t) = 0$ for $t < 0$ and $t > LT$, where L is an integer and T is the symbol interval. When $L = 1$, the pulse $g(t)$ is nonzero over a single signal interval, and the CPM signal is called *full-response CPM*. When $L \ge 2$, the pulse $g(t)$ is nonzero over two or more signal intervals and the CPM signal is called partial response. Furthermore $g(t)$ is normalized in area so that

$$q(LT) = \int_0^{LT} g(\tau)\, d\tau = \frac{1}{2}$$

The phase continuous signal may be viewed as having been generated as an FM signal. Suppose that the lowpass data signal $d(t)$ is a PAM signal of the form

$$d(t) = \sum_k I_k g(t - kT) \tag{25}$$

where $\{I_m\}$ is the data sequence of symbols selected from the alphabet $\{\pm 1, \pm 3, \ldots, \pm(M-1)\}$ and $g(t)$ is a pulse with unit area that is nonzero over the interval $0 \le t \le LT$. If $d(t)$ is used to frequency modulate the carrier f_c, then, the phase of the carrier is

$$\begin{aligned}\phi(t; \mathbf{I}) &= 4\pi f_d T \int_{-\infty}^{t} d(\tau)\, d\tau \\ &= 2\pi h \sum_{k=-\infty}^{n} I_k q(t - nT), \quad nT \le t \le (n+1)T\end{aligned} \tag{26}$$

where f_d is the peak frequency deviation and the modulation index is defined as $h = 2f_d T$.

Some examples of the pulseshapes $g(t)$ and $q(t)$ are illustrated in Fig. 2. When $L = 1$ and $g(t)$ is a rectangular pulse, as shown in Fig. 2a, the CPM signal reduces to the special case called *continuous-phase frequency shift keying* (CPFSK). Furthermore, if the modulation index is selected as $h = \frac{1}{2}$, the CPFSK signal is called minimum-shift keying (MSK). The signal pulse $g(t)$ shown in Fig. 2b is called a *raised-cosine pulse*, and the resulting CPM is a full-response CPM signal. On the other hand, the signal pulses $g(t)$ shown in Fig. 2c,d extend over two signal intervals, and hence the CPM signals are partial response.

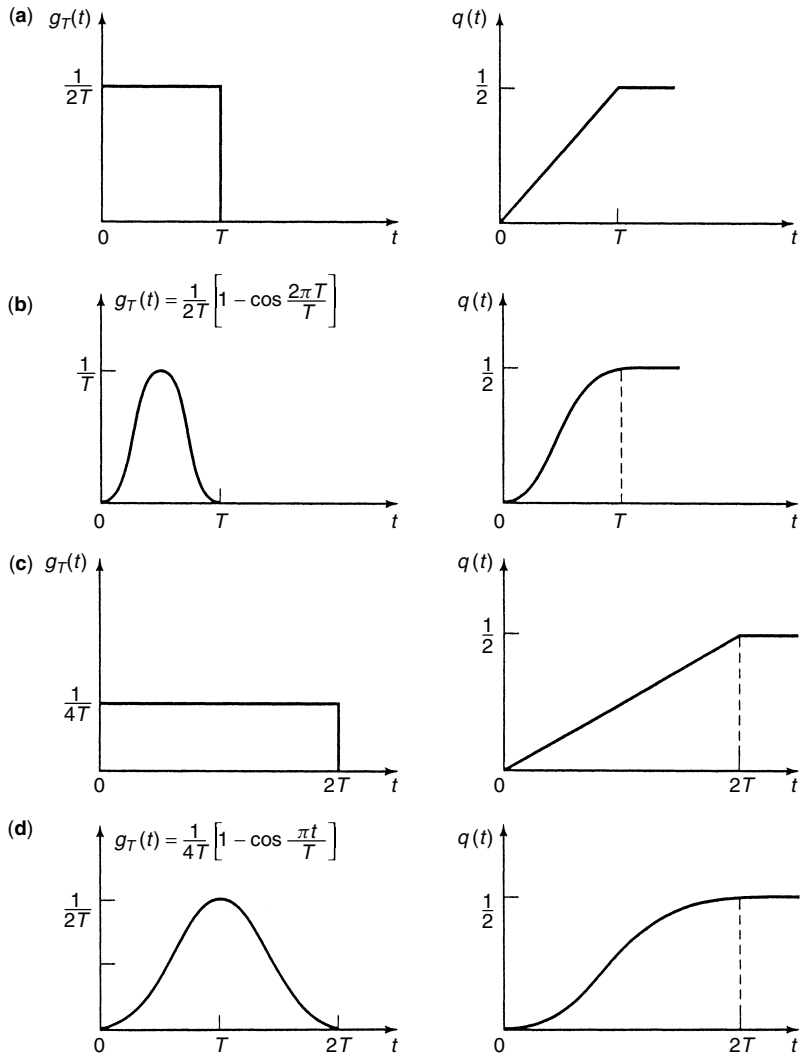

Figure 2. Pulseshapes for full-response (**a**,**b**) and partial-response (**c**,**d**) CPM.

To determine the power spectrum of the CPM signal, the general procedure described in the preceding section may be used. One begins with the equivalent lowpass signal

$$v(t) = e^{j\phi(t;\mathbf{I})} \tag{27}$$

where $\phi(t;\mathbf{I})$ is given by Eq. (26) with $n = \infty$. The autocorrelation function of $v(t)$ is easily shown to be

$$\phi_{vv}(t+t;t) = \frac{1}{2}E\left[\exp\left(j2\pi h \sum_{k=-\infty}^{\infty} I_k[q(t+\tau-kT) - q(t-kT)]\right)\right] \tag{28}$$

The sum of exponents may also be expressed as a product of exponents:

$$\phi_{vv}(t+\tau;t) = \frac{1}{2}E\left(\prod_{k=-\infty}^{\infty} \exp\{j2\pi h I_k[q(t+\tau-kT) - q(t-kT)]\}\right) \tag{29}$$

Although Eq. (29) implies that there are an infinite number of factors in the product, the pulse $g(t) = 0$ for $t < 0$ and $t > LT$, and $q(t) = 0$ for $t < 0$. Consequently only a finite number of terms in the product have nonzero exponents. The next step is to perform the expectation over the data symbols $\{I_k\}$ and then to average the periodic autocorrelation function over the period $(0, T)$:

$$\overline{\phi}_{vv}(\tau) = \frac{1}{T}\int_0^T \phi_{vv}(t+\tau;t)\,dt \tag{30}$$

The final step is to compute the Fourier transform of $\overline{\phi}_{vv}(t)$ to obtain the power spectrum.

Unfortunately, these computations do not yield a closed-form solution except in special cases. When the information symbols are equally likely, the average autocorrelation function is given as

$$\overline{\phi}_{vv}(\tau) = \frac{1}{2T}\int_0^T \prod_{k=1-L}^{[t/T]} \frac{1}{M} \times \frac{\sin 2\pi h M[q(t+\tau-kT) - q(t-kT)]}{\sin 2\pi h[q(t+\tau-kT) - q(t-kT)]}\,dt \tag{31}$$

and the corresponding expression for the power density spectrum is

$$\Phi_{vv}(f) = 2\left[\int_0^{LT} \overline{\phi}_{vv}(\tau)\cos 2p\pi f\tau\, d\tau + \frac{1-\psi(jh)\cos 2\pi fT}{1+\psi^2(jh)-2\psi(jh)\cos 2\pi fT} \times \int_{LT}^{(L+1)T} \overline{\phi}_{vv}(\tau)t\cos 2\pi f\tau\, d\tau - \frac{\psi(jh)\sin 2\pi fT}{1+\psi^2(jh)-2\psi(jh)\cos 2\pi fT} \times \int_{LT}^{(L+1)T} \overline{\phi}_{vv}(\tau)\sin 2\pi f\tau\, d\tau\right] \tag{32}$$

where $\psi(jh)$ is the characteristic function of the information symbols $\{I_k\}$, which is given as

$$\begin{aligned}\psi(jh) &= \sum_{\substack{n=-(M-1)\\ n \text{ odd}}}^{M-1} p_n e^{j\pi hn} \\ &= \frac{1}{M}\sum_{\substack{n=-(M-1)\\ n \text{ odd}}}^{M-1} e^{j\pi hn} \\ &= \frac{1}{M}\frac{\sin M\pi h}{\sin \pi h}\end{aligned} \tag{33}$$

where $p_n = 1/M$ is the probability of each of the M levels. The expression for the power density spectrum given in Eq. 32 must be evaluated numerically.

2.1. Power Density Spectrum of CPFSK

A closed-form expression for the power density spectrum can be obtained from Eq. (32) when the pulseshape $g(t)$ is rectangular and zero outside the interval $[0, T]$. In this case, $q(t)$ is linear for $0 \le 1 \le T$. The resulting power spectrum may be expressed as

$$\Phi_{vv}(f) = T\left[\frac{1}{M}\sum_{n=1}^{M} A_n^2(f) + \frac{2}{M^2}\sum_{n=1}^{M}\sum_{m=1}^{M} B_{nm}(f)A_n(f)A_m(f)\right] \tag{34}$$

where

$$\begin{aligned}A_n(f) &= \frac{\sin \pi[fT - \frac{1}{2}(2n-1-M)h]}{\pi[fT - \frac{1}{2}(2n-1-M)h]} \\ B_{nm}(f) &= \frac{\cos(2\pi fT - \alpha_{nm}) - \psi\cos\alpha_{nm}}{1+\psi^2-2\psi\cos 2\pi fT} \\ \alpha_{nm} &= \pi h(m+n-1-M) \\ \psi \equiv \psi(jh) &= \frac{\sin M\pi h}{M\sin \pi h}\end{aligned} \tag{35}$$

The power density spectrum of CPFSK for $M = 2, 4$ is plotted in Figs. 3 and 4 as a function of the normalized frequency fT, with the modulation index $h = 2f_dT$ as a parameter. Note that only one-half of the bandwidth occupancy is shown in these graphs. The origin corresponds to the carrier f_c. The graphs illustrate that the spectrum of CPFSK is relatively smooth and well confined for $h < 1$. As h approaches unity, the spectra become very peaked and, for $h = 1$ when $|\psi| = 1$, we find that impulses occur at M frequencies. When $h > 1$, the spectrum becomes much broader. In communication systems where CPFSK is used, the modulation index is designed to conserve bandwidth, so that h is selected to be less than unity.

The special case of binary CPFSK with $h = \frac{1}{2}$ (or $f_d = 1/4T$) and $\psi = 0$ corresponds to MSK. In this case, the spectrum of the signal is

$$\Phi_{vv}(f) = \frac{16T}{\pi^2}\left(\frac{\cos 2\pi fT}{1-16f^2T^2}\right)^2 \tag{36}$$

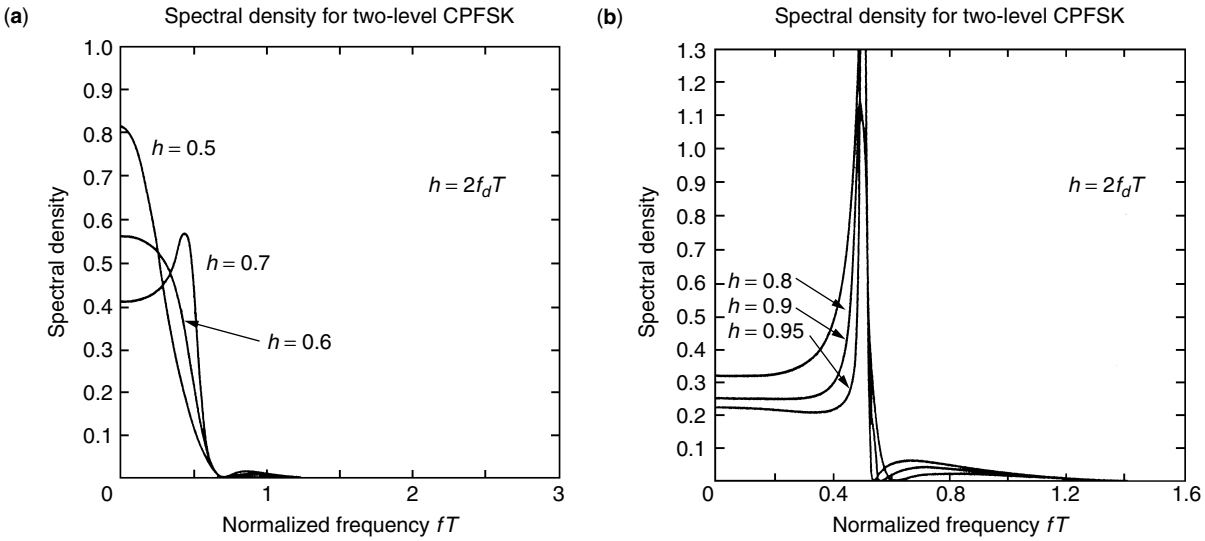

Figure 3. Power spectra for binary CPFSK.

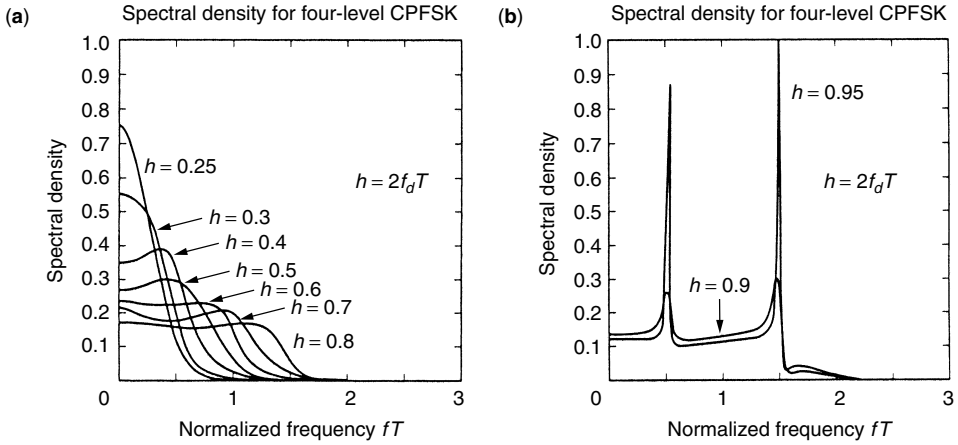

Figure 4. Power spectra for quaternary CPFSK.

2.2. Power Density Spectrum of CPM

The use of smooth pulses such as raised-cosine pulses of the form

$$g(t) = \begin{cases} \dfrac{1}{2LT}\left(1 - \cos\dfrac{2\pi t}{LT}\right) & (0 \le t \le LT) \\ 0 & \text{otherwise} \end{cases} \tag{37}$$

where $L = 1$ for full response and $L > 1$ for partial response, result in smaller bandwidth occupancy and, hence, greater bandwidth efficiency than the use of rectangular pulses. For example, Fig. 5 illustrates the power density spectrum for binary CPM with different partial-response raised-cosine (LRC) pulses when $h = \frac{1}{2}$. For comparison, the spectrum of (MSK) binary CPFSK is also shown. Note that as L increases the pulse, $g(t)$ becomes smoother and the corresponding spectral occupancy of the signal is reduced.

The effect of varying the modulation index in a CPM signal is illustrated in Fig. 6 for the case of $M = 4$ and a raised-cosine pulse of the form given in Eq. (37) with $L = 3$. Note that these spectral characteristics are similar to the ones illustrated previously for CPFSK, except that these spectra are narrower because of the use of a smoother pulseshape.

3. CONCLUDING REMARKS

PAM, PSK, QAM, and CPM signals are described in greater detail in other articles of this encyclopedia as well as in Ref. 1. Additional numerical results on the spectral characteristics of CPM signals can be found in Refs. 2 and 3.

BIOGRAPHY

Dr. John G. Proakis received the B.S.E.E. from the University of Cincinnati in 1959, the M.S.E.E. from MIT in 1961, and the Ph.D. from Harvard University in 1967. He is an Adjunct Professor at the University of California at San Diego and a Professor Emeritus at Northeastern University. He was a faculty member at Northeastern University from 1969 through 1998 and held the following academic positions: Associate Professor of Electrical Engineering, 1969–1976; Professor of Electrical Engineering, 1976–1998; Associate Dean of the College

of Engineering and Director of the Graduate School of Engineering, 1982–1984; Interim Dean of the College of Engineering, 1992–1993; Chairman of the Department of Electrical and Computer Engineering, 1984–1997. Prior to joining Northeastern University, he worked at GTE Laboratories and the MIT Lincoln Laboratory.

His professional experience and interests are in the general areas of digital communications and digital signal processing and more specifically, in adaptive filtering, adaptive communication systems and adaptive equalization techniques, communication through fading multipath channels, radar detection, signal parameter estimation, communication systems modeling and simulation, optimization techniques, and statistical analysis. He is active in research in the areas of digital communications and digital signal processing and has taught undergraduate and graduate courses in communications, circuit analysis, control systems, probability, stochastic processes, discrete systems, and digital signal processing. He is the author of the book *Digital Communications* (McGraw-Hill, New York: 1983, first edition; 1989, second edition; 1995, third edition; 2001, fourth edition), and co-author of the books *Introduction to Digital Signal Processing* (Macmillan, New York: 1988, first edition; 1992, second edition; 1996, third edition), *Digital Signal Processing Laboratory* (Prentice-Hall, Englewood Cliffs, NJ, 1991); *Advanced Digital Signal Processing* (Macmillan, New York, 1992), *Algorithms for Statistical Signal Processing* (Prentice-Hall, Englewood Cliffs, NJ, 2002), *Discrete-Time Processing of Speech Signals* (Macmillan, New York, 1992, IEEE Press, New York, 2000), *Communication Systems Engineering* (Prentice-Hall, Englewood Cliffs, NJ: 1994, first edition; 2002, second edition), *Digital Signal Processing Using MATLAB V.4* (Brooks/Cole-Thomson Learning, Boston, 1997, 2000), and *Contemporary Communication Systems Using MATLAB* (Brooks/Cole-Thomson Learning, Boston, 1998, 2000). Dr. Proakis is a Fellow of the IEEE. He holds five patents and has published over 150 papers.

1. INTRODUCTION

Powerline communications (PLC) uses the standard electrical power distribution network in parallel with the energy distribution for the transmission of digital data. This avoids the installation of a new telecommunications infrastructure, where a power grid already exists. PLC with low data rates of ~1 kbps (kilobit per second) has been in use since 1990 or 1991. This narrowband technology has been standardized in Europe by CENELEC EN 50065 [1]. It operates in the frequency band from 3 to 148.5 kHz and uses simple digital modulation schemes, such as frequency shift keying (FSK).

With the advent of high-speed digital signal processors, advanced digital modulation techniques can be implemented. As an example, OFDM not only allows a high data rate but is also able to cope with a time-varying transmission channel. This presently allows transmission data rates over the powerline of $\leq$4 Mbps. PLC is therefore able to compete with, For example, digital subscribers lines (DSLS) on the telephone two-wire copper line or with wireless LAN techniques in the home area.

PLC offers an advantage for developing countries, because the power distribution network is already in place and a second network need not be built. In developed countries PLC also opens an opportunity for prospective network operators, who plan to compete with the incumbent operator, the earlier monopolist. Here again, an existing infrastructure can be used, and therefore the often prohibitive costs of new cabling can be avoided.

Within the power grid, PLC technology may be used in the backbone links in the high-voltage area, in the medium-voltage plane in urban areas, in the low-voltage plane for the access to the customer's premises, and, finally, within a household to reach the subscriber's communications terminal. In modern backbone's underground cables, there is usually an integrated fiber offering a nearly unlimited capacity, much higher than current PLC technology. Also the traffic of a large number of subscribers cannot be transported by current PLC technology. The medium voltage feeder network may be a candidate for PLC, but the bandwidth needed for a large number of high-speed customers cannot be supported by state-of-the-art technology. Also many medium- to low-voltage transformers are now reached by a fiber.

PLC has a promising application area and business case in the low-voltage area of the power grid. Here the number of customers per distribution section is limited to approximately 10–50, such that today's gross bandwidth still allows sufficient bandwidth per subscriber. This access network is usually limited in its size, the so-called last mile. In the case of in-home PLC, the size is even further limited (<100 m) and also the number of terminals may correspond to the number of persons in a home.

PLC operates as a shared medium. This means that the total capacity is shared in a statistical manner by all users on the same distribution section. Therefore a MAC protocol is needed to coordinate the sharing of the bandwidth fairly (see Section 5.3).

A major challenge for PLC is electromagnetic compatibility (EMC) (see Section 4.4). This is a bidirectional problem. On one hand, PLC is disturbed by electric noise (spikes, etc.; see Section 4.4). PLC systems also generate

radiation that disturbs other wireless communications. For this reason, countries have issued radiation limits, which constitute the main reason for capacity limits in PLC. In Germany, for example, these limits are defined by the regulatory body RegTP in regulation NB30 [2]. Currently under discussion is the replacement of the actual "chimney" regulation of forbidden frequency bands by a limiting curve within the entire frequency range of 1–30 MHz.

2. APPLICATION OF PLC TECHNOLOGY

2.1. Overview

The application of electrical supply networks in telecommunications has been known since the beginning of the twentieth century. The first *carrier frequency systems* (CFSs) have been operated in high-voltage electrical networks that were able to span distances over 500 km using 10 W signal power [3]. Such systems have been used for internal communication of electrical utilities and realization of remote measurements and control tasks. Also, communication over medium- and low-voltage electrical networks has been implemented by ripple carrier signaling (RCS) systems for realization of load management in electrical supply systems. Internal electrical networks have been used mostly for realization of various automation services within buildings or private houses.

The electrical supply systems consist of three network levels that can be used as a transmission medium for the realization of PLC networks (Fig. 1):

- *High-voltage networks* (110–380 kV) usually connect the power stations with supply regions or very big customers. They span very long distances, allowing the power exchange within a continent. Electrical supply grids of high-voltage networks are realized mostly as overhead lines.
- *Medium-voltage networks* (10–30 kV) supply large regions, cities, and big industrial or commercial complexes. The spanned distances are significantly shorter than those with high-voltage networks. These networks are realized by overhead lines or by underground cables.
- *Low-voltage networks* (230/400 V; in the United States, 110 V) directly supply the end users that are connected either as individual customers or single users belonging to a big customer (e.g., within a business building). Low-voltage networks are usually realized by overhead lines in rural areas and by underground cables within cities. The cable length between the last transformer unit and the customers is varying, but normally not longer than a few hundred meters.

In-home electrical installations belong to the low-voltage network level (Fig. 1). However, internal installations are usually owned by the users. They are connected to the supply network over an electrical power meter unit (M) (see Fig. 2). On the other hand, the rest of the low-voltage network (outdoor) belongs to the electrical supply utilities.

2.2. Narrowband PLC

As a successor to the ANSI X-10 standard, CENELEC has standardized PLC in the frequency range 3–148.5 kHz. This allows mainly private home or business building automation applications with data rates up to 1200 bps. This is the PLC variant of the European installation bus, named Powernet EIB. It became a de facto industry standard with FSK modems and a simple MAC protocol.

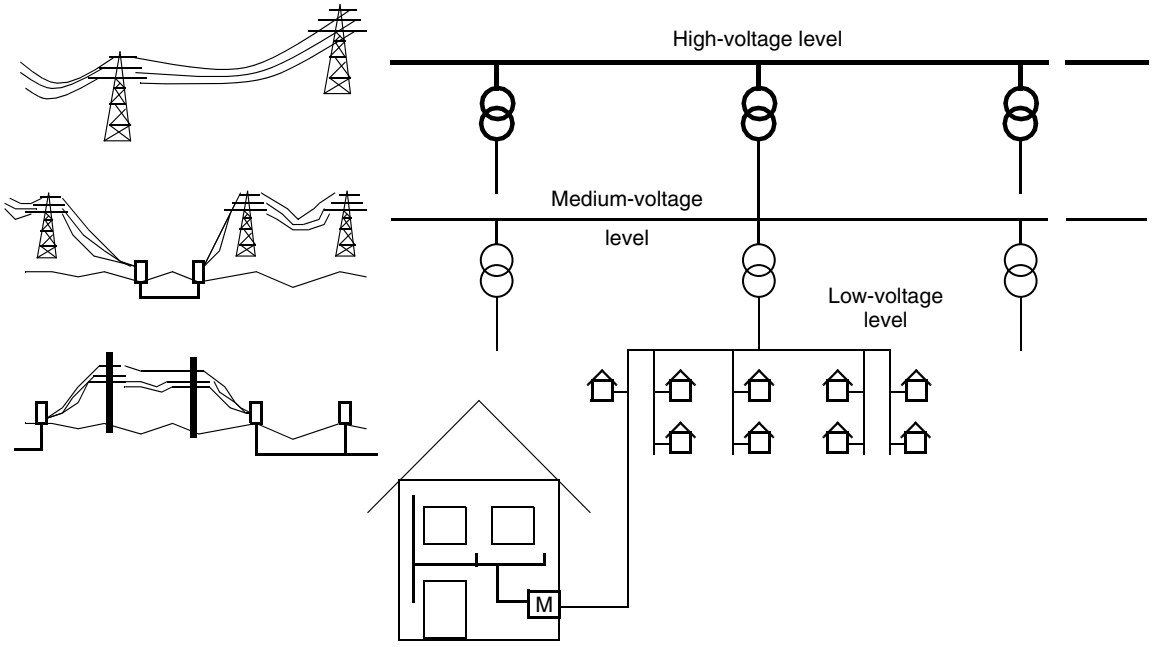

Figure 1. Structure of electrical supply networks.

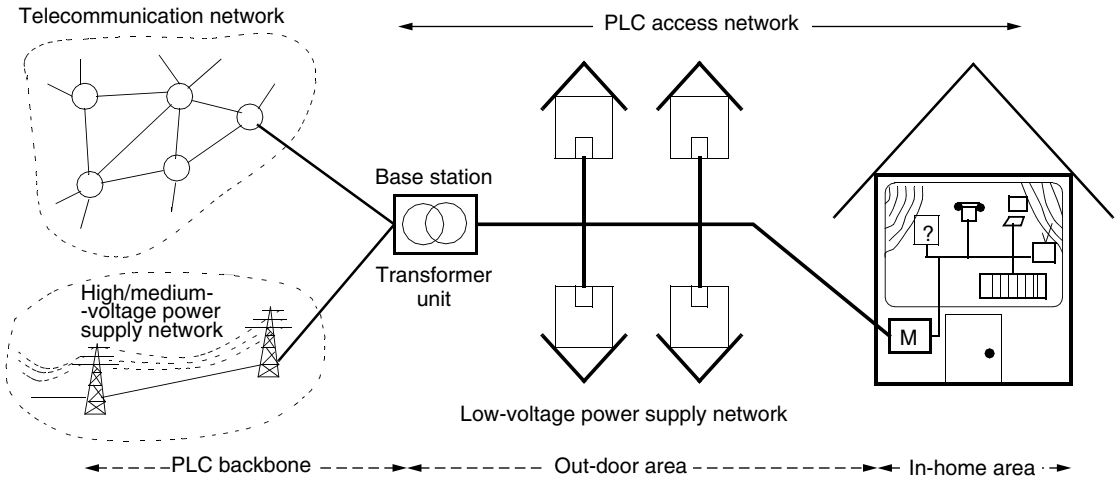

Figure 2. Structure of PLC access networks.

Loss of data may occur especially under high load. This is circumvented by ARQ mechanisms at the higher layers.

2.3. Broadband PLC

Broadband PLC systems provide significantly higher data rates (>2 Mbps) than do narrowband PLC systems. Where the narrowband networks can realize only a small number of voice channels and data transmission with very low bit rates, broadband PLC networks offer realization of more sophisticated telecommunication services: multiple voice connections, high-speed data transmission, transfer of video signals, and narrowband services as well. Therefore, PLC broadband systems are also considered as a capable telecommunication technology.

The realization of broadband communication services over powerline grids offers a great opportunity for cost-effective telecommunication networks without laying of new cables. However, electrical supply networks are not designed for information transfer, and there are some limiting factors in the application of broadband PLC technology. Therefore, the distances that can be covered are limited, as well as the data rates that can be realized by PLC systems. A further very important aspect for application of broadband PLC is its electromagnetic compatibility. For realization of broadband PLC, a significantly wider frequency spectrum is needed (≤30 MHz) than is provided within CENELEC bands. On the other hand, a PLC network acts as an antenna becoming a noise source for other communication systems working in the same frequency range (e.g., various radio services). For this reason, broadband PLC systems have to operate with a limited signal power, which decreases their performance (data rates, distances).

In contrast to narrowband PLC systems, no specified standards apply to broadband PLC networks. The standardization process is currently led by several international bodies. PLCforum [4] is an international association formed to unify and represent the interests of all players engaged in PLC (utility, providers, manufacturers, developers, researchers) and to expedite standardization and regulation on PLC technology worldwide as well as to support its commercialization. HomePlug Powerline Alliance [5] is a similar organization that is oriented to in-home PLC technology, providing both narrowband and broadband applications. Concrete work on technical standardization is done within ETSI (European Telecommunications Standards Institute) and CENELEC.

Current broadband PLC systems provide data rates beyond 2 Mbps in the outdoor arena, which includes middle- and low-voltage supply networks (Fig. 1), and up to 12 Mbps in the in-home area. Some manufacturers have already developed product prototypes providing much higher data rates (~40 Mbps). Middle-voltage PLC technology is usually used for realization of point-to-point connections bridging distances up to several hundred meters. Typical application areas of such systems is connection of LAN networks between buildings or campuses and connection of antennas and base stations of cellular communication systems to their backbone networks. Low-voltage PLC technology is used for realization of the so-called last mile of telecommunication access networks. Because of the importance of telecommunication access, current development of broadband PLC technology is directed mostly to applications in access networks, including the in-home area.

3. PLC ACCESS NETWORKS

3.1. PLC Alternative for Communication Over the "Last Mile"

The access networks are very important for network providers because of their high costs and the possibility for the realization of a direct access to the end users and subscribers. Typically, about 50% of all investments in the telecommunication infrastructure is needed for the realization of the access networks. Following the deregulation of the telecommunication market in a large number of countries, the access networks are still owned by the former monopolistic companies (incumbent providers). New network providers build up their wide-area networks (WANs), but they still have to use the access infrastructure owned by incumbent providers.

Consequently, the new network providers are trying to find a solution to realize their own access network.

Building new access networks (cable or fiberoptic networks, mobile and fixed wireless access systems, satellite networks) is the best way to implement the newest communication technology, which allows realization of attractive services and applications. On the other hand, the realization of new access networks is expensive and, in the case of laying new fiber or cable, takes a long time. The expensive buildup of new communication networks can be avoided by using existing infrastructure. In this case, already existing wireline networks are candidates for connection of subscribers to the telecommunication transport networks. This is possible by using the following infrastructure:

- Telephone networks
- TV cable networks (CATV)
- Power supply networks

Telephone networks usually belong to the former monopolistic companies, and this is a major disadvantage for new network providers to use them to offer services such as ADSL. That is very often the case with CATV networks, too. Additionally, CATV networks have to be made capable for bidirectional transmission, which results in extra costs. Therefore, the usage of power supply networks for communications seems to be reasonable.

3.2. Network Structure

A low-voltage supply network consists of a transformer unit and a number of power supply cables connecting the end users/subscribers (Fig. 2). The transformer unit connects the low-voltage supply network to the medium- and high-voltage levels. A PLC system applied to a low-voltage network uses the power grids as a communication medium and is connected to the backbone communication networks (WAN) via a base station that is usually placed within the transformer unit. The base station may also be located elsewhere on the powerline, such as at a subscriber's premises.

Many utilities supplying electrical power have their own telecommunication networks that can be used as backbone networks for PLC access systems. If this is not the case, a PLC access network can be connected to a conventional telecommunication network. In any case, the transmitted signal from the backbone has to be converted into a form that makes possible its transmission over a low-voltage power supply network. The conversion takes place at the base station of a PLC system.

PLC subscribers are connected to the network via a PLC modem, placed in the electrical power meter unit (Fig. 2, M). The modem converts the signal received from the PLC network in a standard form that can be processed by the conventional communication systems. On the user side, standard communication interfaces (Ethernet, ISDN S_0, etc.) are offered. Within a house, the transmission can be realized via a separate communication network or via an internal electric installation (in-home PLC solution). In this way, a number of communication devices within a house can be directly connected to a PLC access network.

3.3. In-Home PLC Networks

In-home PLC (indoor) systems use the internal electrical infrastructure as a transmission medium. This makes it possible to setup PLC local networks that connect the typical devices used in private homes, including telephones, computers, printers, and video devices. In the same way, small offices can be interconnected by LAN systems realized with PLC technology. Automation services have become more and more popular not only for their application in the industrial and business sector within large buildings but also for private households. The systems providing automation services such as security observation, heating control, and automatic light control, have to connect a big number of end devices, such as sensors, cameras, electromotors, and lights. Therefore, in-home PLC technology seems to be a reasonable solution for the realization of such networks with a large number of end devices, especially within older houses and buildings that do not have an appropriate internal communication infrastructure.

Basically, the structure of in-home PLC networks is not much different from PLC access systems using low-voltage supply networks. There is also a base/main station that controls the in-home PLC network and connects it to the outdoor area. The base station can be placed within the meter unit (Fig. 2), but also in any other suitable place in the in-home PLC network. All devices of an in-home network, are connected via PLC modems like subscribers of a PLC access network.

An in-home PLC network can exist as an independent network covering only a house or a building. However, it excludes usage and control of in-home PLC services from a distance and also access to WAN services from each electrical socket within a house. In-home PLC networks can be connected to a PLC access system and also to an access network realized by any other communication technology.

3.4. Network Elements

PLC systems consists of the following network elements:

- Basic PLC network elements, which exist in every PLC network
  - PLC modem
  - PLC base/master station
- Additional network elements
  - PLC repeater
  - PLC gateway

A PLC modem connects standard communication equipment, used by PLC subscribers, to a powerline transmission medium. The user-side interface can provide various standard interfaces for different communication devices (e.g., Ethernet and USB interfaces for realization of data transmission and S_0 and *a/b* interfaces for telephony). On the other side, the PLC modem is connected to the power grid using a specific coupling method [3] that allows the feeding of communication signals to the powerline medium and its reception. The coupling has to ensure a safe galvanic separation and to act as a highpass filter dividing the

communication signal (>9 kHz) from the electrical power (50 or 60 Hz). To reduce electromagnetic emission from the powerline (Section 4.4), the coupling is realized between two phases in the access area and between a phase and the neutral conductor in the indoor area. The PLC modem implements all functions of the physical layer including modulation and coding. The second communication layer (link layer) is also implemented within the modem, including its MAC (media access control) and LLC (logical link control) sublayers.

A PLC base station (master station) connects a PLC access system to its backbone network (Fig. 2). It realizes the connection between the backbone communication network and the powerline transmission medium. However, the base station does not connect individual subscriber devices, but it may provide multiple network communication interfaces. Usually, the base station controls the operation of a PLC access network. However, the realization of network control or its particular functions can be realized in a distributed manner.

Additional network elements are needed in some PLC systems to provide signal conversion between different network segments. Repeaters (R) make it possible to realize longer network distances, consisting of several network segments (Fig. 3). The segments are separated by using different frequency bands or by different time slots. In the second case, a time slot is used for the transmission within the first network segment, and another slot for the second segment. A repeater does not modify the contents of the transmitted information.

A gateway is used to interconnect a PLC access network and an in-home PLC network. Similar to a repeater, a gateway also converts the signal between the access and in-home frequencies or time slots. It is usually placed near the house meter unit (Fig. 2) providing the division of the access and in-home areas on the logical network level, too. In this case, an in-home network is fully controlled by the gateway and operates independently form the access network. Therefore, the gateway acts as a subscriber of the access network realizing the connection between the in-home and the access areas. Generally, a gateway can be also placed anywhere in a PLC access network to provide both network segmentation (repeater functionality) and network separation on the logical level.

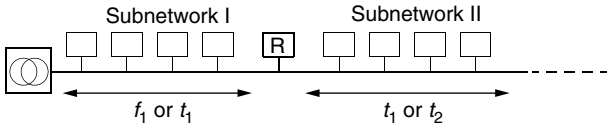

Figure 3. PLC network with repeaters.

4. PLC SYSTEM CHARACTERISTICS

4.1. Network Topology

Low-voltage supply networks are realized by various technologies (different types of cable, transformer units, etc.) according to the existing standards, which differ from country to country. The topologies of low-voltage power supply networks are also different and depend on several factors:

- *Network location* — a PLC network can be installed in a residential, industrial or business area. Furthermore, there is a difference between rural and urban residential areas.
- *Subscriber density* — the number of users/subscribers as well as the user concentration vary from network to network. The subscribers can be placed in family houses (low subscriber density), within houses with several individual customers, in buildings with a larger number of flats or offices, and within apartment or business towers (very high subscriber density).
- *Network span* — the longest distance between the transformer unit and a customer also varies.
- *Network structure* — low-voltage networks usually consist of several network sections/branches, and this number also varies.

Figure 4 shows a possible PLC network structure. There are generally several network sections and branches from the transformer station to the end users. Each branch can have a different topology and connects a variable number of users.

Some characteristic values describing a typical European PLC network, given in Refs. 6 and 7, are listed below — note that the number of users, the number of

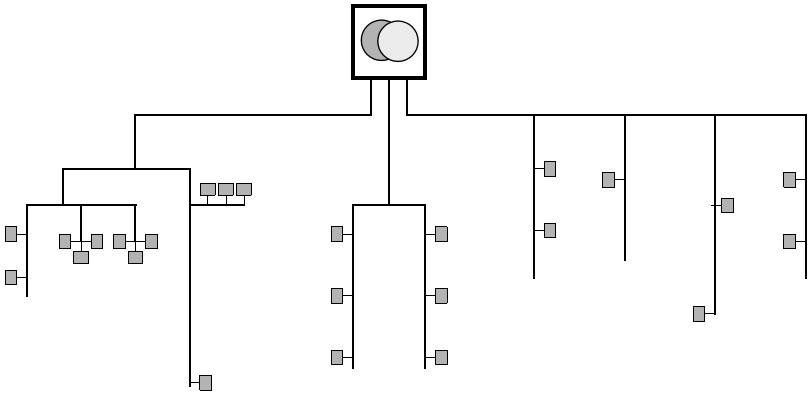

Figure 4. Possible topology of a low-voltage supply network.

potential PLC subscribers, in the United States is significantly lower:

- Number of users in the network: 250–400
- Number of network sections: ~5
- Number of users in a network section: 50–80
- Network span: ~500 m

The PLC base station is usually located within the transformer unit (Fig. 4). However, it could also be placed somewhere else within the network depending on the appropriate interconnection point to the backbone. Each network section/branch may form an individual PLC subnetwork, including a base station and a number of subscribers. Furthermore, a network can be segmented into multiple PLC subnetworks by using repeaters or gateways (Section 3.4). A large PLC network can also cover multiple low-voltage networks. In this case, a number of electrical networks are connected, but only for data transmission (passing only the high-frequency communication signal). Independently of the position of the base station and the kind of network segmentation or concentration, PLC access networks as well as PLC in-home systems physically maintain a tree network topology.

In any network configuration, the communication between PLC subscribers and the WAN is carried out over a base station. This is also the case for internal communication between PLC subscribers. A signal sent by any network station to the base station (uplink transmission direction) reaches all network stations. This is also the case for a signal transmitted in the downlink. Thus, a PLC access network has a star topology with a base station in its center, which leads to a logically bus network structure representing a shared transmission medium.

4.2. Characteristics of the PLC Transmission Channel

The electrical power grid has not been designed to support telecommunication services. To use these lines as an information transmission medium, we need to determine the transfer characteristics, including the attenuation and the impedance. From these parameters, we construct a mathematical channel model that is used in the design of the PLC systems.

The propagation of signals over powerlines introduces an attenuation, which increases with the length of the line and frequency. The attenuation is a function of the powerline characteristic impedance Z_L and the propagation constant γ [8]. These two parameters are defined by the primary resistance R' per unit length, the conductance G' per unit length, the inductance L' per unit length and the capacitance C' per unit length, which are generally frequency dependent, as

$$Z_L(f) = \sqrt{\frac{R'(f) + j2\pi f \cdot L'(f)}{G'(f) + j2\pi f \cdot C'(f)}} \tag{1}$$

and

$$\gamma(f) = \sqrt{(R'(f') + j2\pi f L'(f)) \cdot (G'(f') + j2\pi f C'(f))} \tag{2}$$

$$\gamma(f) = \alpha(f) + j\beta(f) \tag{3}$$

Considering a matched transmission line, which is equivalent to regarding only the wave propagation from source to destination, the transfer function of a line with length l can be expressed by

$$H(f) = e^{-\gamma(f)\cdot l} = e^{-\alpha(f)\cdot l} \cdot e^{-j\beta(f)\cdot l} \tag{4}$$

Investigations and measurements of the fundamental properties of power cables have revealed that $R'(f) \ll 2\pi f L'(f)$ and $G'(f) \ll 2\pi f C'(f)$ is valid in the frequency range from 1 to 30 MHz. Consequently, the dependence of L' and C' on frequency is neglected so that the characteristic impedance Z_L and the propagation constant γ in this frequency range can be expressed as [8]

$$Z_L = \sqrt{\frac{L'}{C'}} \tag{5}$$

and

$$\gamma(f) = \frac{1}{2} \cdot \frac{R'(f)}{Z_L} + \frac{1}{2} \cdot G'(f) \cdot Z_L + j2\pi f \cdot \sqrt{L'C'} \tag{6}$$

$$\gamma(f) = k_1 \cdot \sqrt{f} + k_2 \cdot f + jk_3 \cdot f \tag{7}$$

$$\gamma(f) = \alpha(f) + j\beta(f) \tag{8}$$

where k_1, k_2, and k_3 are constants.

The real part of the propagation constant, describing the cable losses, can be approximated by the equation

$$\alpha(f) = a_0 + a_1 \cdot f^k \tag{9}$$

and with a suitable selection of the attenuation parameters a_0, a_1, and k, the powerline attenuation, representing the amplitude of the channel transfer function, can be defined by the formula [9]

$$A(f, l) = e^{-\alpha(f)\cdot l} = e^{-(a_0 + a_1 \cdot f^k)} \cdot l \tag{10}$$

where l represents the length of the path for the signal wave propagation and k is the exponent of the attenuation factor.

4.3. PLC Channel Model

In addition to the frequency-dependent attenuation that characterizes the powerline channel, deep narrowband notches occur in the transfer function, which may be spread over the whole frequency range. These notches are caused by multiple reflections at impedance discontinuities. The length of the impulse response and the number of the occurred peaks can vary considerably depending on the environment. This behavior can be described by the "echo model" [10]. Transfer characteristics of powerline channels can be regarded as quasistationary, as their changes occur only as a result of changes in the topology and changes in the load situation. Load changes are caused mainly by the connecting or switching of electrical appliances.

Complying with the echo model, each transmitted signal reaches the receiver on N different paths (see Fig. 5). Each path i is defined by a certain delay τ_i and

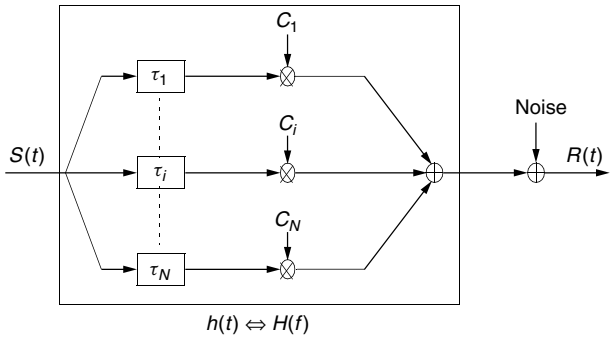

Figure 5. The echo model representing the PLC channel.

a certain attenuation factor C_i. The PLC channel can be described by means of a discrete-time impulse response:

$$h(t) = \sum_{i=1}^{N} C_i \cdot \delta(t - \tau_i) \Leftrightarrow H(f) = \sum_{i=1}^{N} C_i \cdot e^{-j2\pi f \tau_i} \qquad (11)$$

Factoring in the formula of the channel attenuation, the transfer function in the frequency domain can be written

$$H(f) = \sum_{i=1}^{N} g_i \cdot A(f, l_i) \cdot e^{-j2\pi f \tau_i} \qquad (12)$$

where g_i is a weighting factor representing the product of the reflection and transmission factors along the path. The variable τ_i, representing the delay introduced by the path i, is a function of the pathlength l_i.

By replacing the medium attenuation $A(f, l_i)$ by the expression given in Eq. (10), we obtain the final equation defining the PLC channel model, encompassing the parameters of its three main characteristics: attenuation, impedance fluctuations, and multipath effects. This equation is composed of a weighting term, an attenuation term, and a delay term:

$$H(f) = \sum_{i=1}^{N} g_i \cdot e^{-(a_0 + a_1 \cdot f^k) \cdot l_i} \cdot e^{-j2\pi f \tau_i} \qquad (13)$$

4.4. Electromagnetic Compatibility

Broadband PLC systems operate in the high-frequency range from 1.6 to 30 MHz, in order to achieve data rates above 1 Mbps and to avoid the high noise level in the low-frequency range. On the other hand, experiments have shown that PLC systems must overcome an attenuation of about 70 dB, in order to reach from the transformer unit to the subscribers premises [11]. Unlike other communications media, powerlines are electrically asymmetric, as they were not built to transmit information. As a consequence, electromagnetic fields emitted by these lines are high. A solution has to be found to guarantee the coexistence of PLC systems and the radio systems operating in the same spectrum. To solve the problems of electromagnetic compatibility, two solutions are proposed [3]:

1. According to the regulating administration for telecommunications and post (RegTP) in Germany, at present a total spectrum of approximately 7.5 MHz in the frequency range between 0 and 30 MHz may be used principally for PLC. This spectrum is not contiguous, as schematically represented in Fig. 6. It represents some gaps of different width and distributed arbitrarily in the frequency band depicted. This is to secure certain public frequency bands.

At a first glance, it appears feasible to assign the open gaps to PLC services, permitting an increased transmission power spectral density within these chimneys. From such a solution, multicarrier modulation schemes are attractive, particularly those that are able to use narrow gaps with high spectral efficiency, such as orthogonal frequency division multiplex (OFDM). Unfortunately this chimney approach (Fig. 6) encounters some serious problems that render this solution less practical: (a) these gaps are not really free, but they are already dedicated to certain primary users for wireless services, who reserved them for future use; and (b) if the chimneys are very narrow, their use will require the implementation of complex filters.

2. Another proposed solution to accomplish EMC without the chimney approach is a general limitation of radiated fields from powerlines. In March 1999, the RegTP in Germany issued a limitation for the "radiation of telecommunications services in and alongside of cables" (including CATV, xDSL, and PLC). These radiation limitations are part of a plan for the frequency allocation in Germany and are known as NB30.

In comparison with the FCC Part 15, which is the EMC American standard for wire communications, the disadvantages imposed by the German regulations become clearly obvious. At ~2 MHz, for example, the allowed American limits are ~30 dB above the NB30. This means a factor of 1000 in terms of transmitted power or a factor of ~10 in data rate.

4.5. Noise Behavior

Generally, noise in PLC networks can be defined as a superposition of five types, distinguished by their origin, time duration, and spectrum occupancy (see Fig. 7) [12]:

- *Colored background noise* — whose power spectral density (PSD) is relatively low and decreasing with

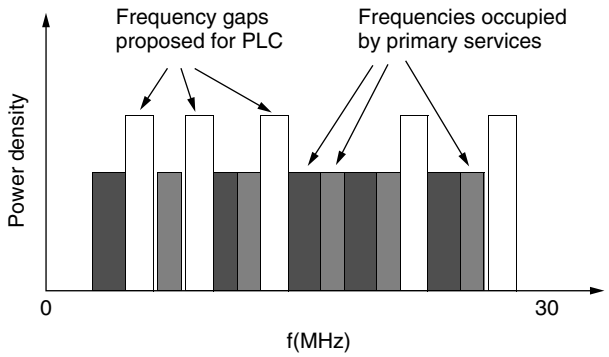

Figure 6. The "chimney approach" for PLC frequency allocation guaranteeing EMC.

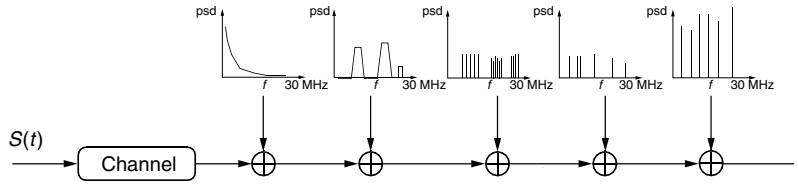

Figure 7. Noise types present in the PLC environment.

frequency. This type of noise is caused mainly by a superposition of numerous noise sources with lower power. Its parameters vary over time in terms of minutes and hours.

- *Narrowband noise* — mostly sinusoidal signals, with modulated amplitudes. This type of noise is caused mainly by ingress of broadcast stations in the medium- and short-wave broadcast bands. Their amplitude generally varies during the daytime.
- *Periodic impulsive noise*, *asynchronous to the main frequency* — impulses that usually have a repetition rate between 50 and 200 kHz, which results in a spectrum with discrete lines with a frequency spacing according to the repetition rate. This type of noise is caused mostly by switching power supplies.
- *Periodic impulsive noise*, *synchronous with the main frequency* — impulses that have a repetition rate of 50 or 100 Hz and are synchronous with the main powerline frequency. They are of short duration (some microseconds) and have a PSD that decreases with frequency. This type of noise is caused by power supplies operating synchronously with the main frequency.
- *Asynchronous impulsive noise* — a type of impulsive noise caused by switching transients in the networks. The impulses have durations of some microseconds up to a few milliseconds with arbitrary arrival times. The PSD of this type of noise can reach values of more than 50 dB above the background noise, which makes it the main cause of occurrence of error in digital transmission.

4.6. PLC Services

PLC access networks together with their backbone provide a bearer service ensuring realization of different teleservices that allow the use of various communication applications [7]. Accordingly, the specification of a PLC transmission system has to include the definition of specific bearer network layers: the physical layer, including modulation and coding methods as well as the data-link layer specifying MAC and LLC sublayers. PLC networks have to offer a large palette of telecommunications services with certain quality requirements to be able to compete with other communications technologies applied to the access area. Therefore, the following four groups of teleservices have to be provided by PLC access networks:

- Connectionless services without QoS guarantees
- Connection-oriented constant-bit-rate (CBR) services, such as telephony
- Connectionless services with QoS guarantees
- Specific PLC services

Present PLC systems provide the connectionless services offering high-speed Internet access to customers. However, PLC networks should also support the classical telephone service, because of its significant penetration in the communications world. Therefore, the manufacturers of PLC equipment have already released systems supporting telephony service, based mostly on VoIP solutions. A special emphasis has to be given to the specific PLC services (home automation, energy management, security, remote functions, etc.), which usually require low data rates and do not require very low transmission delays. So, most of these services can be realized by the connectionless services class without guarantees.

The support of teleservices mentioned above can ensure a competitive position of PLC networks toward other access technologies. However, further development of PLC access networks leads to realization of CBR services with higher data rates and connectionless data services achieving higher QoS requirements.

5. REALIZATION OF PLC NETWORKS

5.1. Specific Performance Problems

The regulatory bodies specify the limits for electromagnetic radiation, which is allowed to be produced by PLC systems operating out of the frequency range defined by the CENELEC standard. In Germany, NB30 directions define very low radiation limits for systems like PLC, which operate in the frequency range up to 30 MHz (see Section 4.4). Accordingly, PLC networks have to operate with a limited signal power to stay within the NB30 limits. Because of the limited signal power, PLC networks are more sensitive to disturbances and are not able to span longer distances.

Well-known error-handling mechanisms can also be applied to PLC systems to reduce the problem of transmission errors caused the disturbances [e.g., forward error correction (FEC) and ARQ]. However, the application of FEC consumes an additional part of the transmission capacity because of the overhead needed for the error detection and correction. ARQ retransmits defective data units, which also consumes a part of the transmission capacity. Additionally, the powerline is a transmission medium that has to be shared by all PLC subscribers.

PLC systems have to compete with other access technologies and to offer a satisfactory QoS and sufficient data rates, but at the same time, to be economically efficient. Therefore, broadband PLC systems have to be provided with the following features:

- Application of efficient modulation schemes ensuring a good utilization of used frequency spectrum and a certain robustness against disturbances

- Realization of suitable coupling methods to reduce electromagnetic radiation
- Implementation of efficient media access control (MAC) protocols to achieve near-maximal utilization of limited PLC network capacity and realization of needed QoS
- Application of optimal error-handling methods to deal with an unfavorable noise scenario consuming a minimum of network resources

5.2. Modulation and Transmission Schemes

Within the PLC systems, the communication is supposed to occur in a channel characterized by frequency-selective phenomena, presence of echoes, and impulsive and colored noise with the superposition of narrowband interferences. This requires that the modulation scheme adopted for PLC effectively face such a hostile environment.

Direct-sequence code-division multiple access (DSCDMA) and orthogonal frequency-division multiplexing (OFDM) are considered as candidates for future broadband PLC [13,14] (see Table 1). As DSCDMA and OFDM permit the separation of the overall transmitted data in many parallel independent substreams, flexible resource management strategies can be implemented. This characteristic is very important in order to cope with channel impairments and to provide fine granularity. This fine granularity is necessary for multimedia services and to achieve a high utilization.

The CDMA technique has the advantages of robustness to narrowband interference and multiple access with low power spectrum density, thus reducing EMC problems. On the other hand, the OFDM technique allows for significant reduction of channel equalizer complexity and increased resistance to narrowband and impulsive noise. Moreover, bit-loading techniques make it possible to achieve a capacity very near the theoretical limit, but at the cost of an increased system complexity, [14].

Overall OFDM seems to be advantageous compared to DSCDMA:

1. The main advantage is obtained by the fact that the channel (the spectrum) is divided into many narrow subchannels. Therefore, equalizing in OFDM is a simple procedure, compared with wideband equalizing.
2. OFDM inherently solves one essential problem associated with high-speed PLC: intersymbol interference (ISI) caused by the multipath delay spread. This is achieved by the introduction of the "guard interval," which is filled by a cyclic prefix.

For channel coding, two variants have been investigated: Reed–Solomon coding [15] and Hamming codes [3]. Several types of interleavers can be implemented with different variants of OFDM, such as OFDM with diversity or adaptive OFDM [15].

5.3. MAC Layer

The MAC layer specifies a multiple-access scheme and a resource-sharing strategy (MAC protocol). Particularly in PLC systems, the MAC layer has to be robust against disturbances and must allow for the use of various telecommunication services [16].

The most widely applied access scheme in PLC networks is TDMA. Because of the disturbances, data packets (e.g., IP packets) are usually segmented into smaller data units whose size is chosen according to the length of a time slot specified by the TDMA scheme. So, if a disturbance occurs, only erroneous data segments are retransmitted. This consumes a smaller network capacity than does retransmission of the entire data packets. The data segmentation ensures a fine network granularity and an easier provision of QoS guarantees.

An effective solution to avoid the influence of narrowband disturbances is to apply FDMA methods, where particular carrier frequencies can be switched off, if they are affected by narrowband disturbances. Therefore, a TDMA/FDMA combination seems to be a reasonable solution for PLC networks (realized by Ascom [17]). PLC networks using OFDM modulation can also provide transmission channels distributed in a frequency spectrum. Unlike FDMA, the transmission channels are realized by a number of subcarriers, which leads to an OFDM access scheme (OFDMA). A further division of the transmission channels in the time domain can also be done according to a slotted nature of OFDM transmission systems combining both multiple-access schemes (OFDMA/TDMA) [18].

MAC protocols for PLC systems have to achieve a maximum utilization of the limited network capacity and to realize time-critical telecommunication services. This can be ensured by reservation of bandwidth that allows particular QoS guarantees needed for various services [16]. In the case of reservation protocols, a part of the network resources is reserved for the reservation procedure: signaling, organized according to a random or dedicated access principle as well as by application of various hybrid solutions [18]. Figure 8 presents the signaling delay caused by the reservation protocols with a signaling procedure organized according to random and dedicated access methods. The protocols based on random access achieve significantly shorter signaling delay, if the transmission requests are relatively infrequent. However, in the case of frequent requests, protocols with dedicated

Table 1. Comparison of PLC Modulation Candidates

	Spectral Efficiency (bps/Hz)	Maximum Data Rate (Mbps)	Robustness against Channel Distortions	Flexibility and Adaptive Features	System Costs (Including Equalizers and Repeaters)	EMC
DSCDMA	<0.1	~ 0.5	Poor	Very poor	Very poor	Excellent
OFDM	$\gg 1$	>10	Excellent	Excellent	Poor	Good

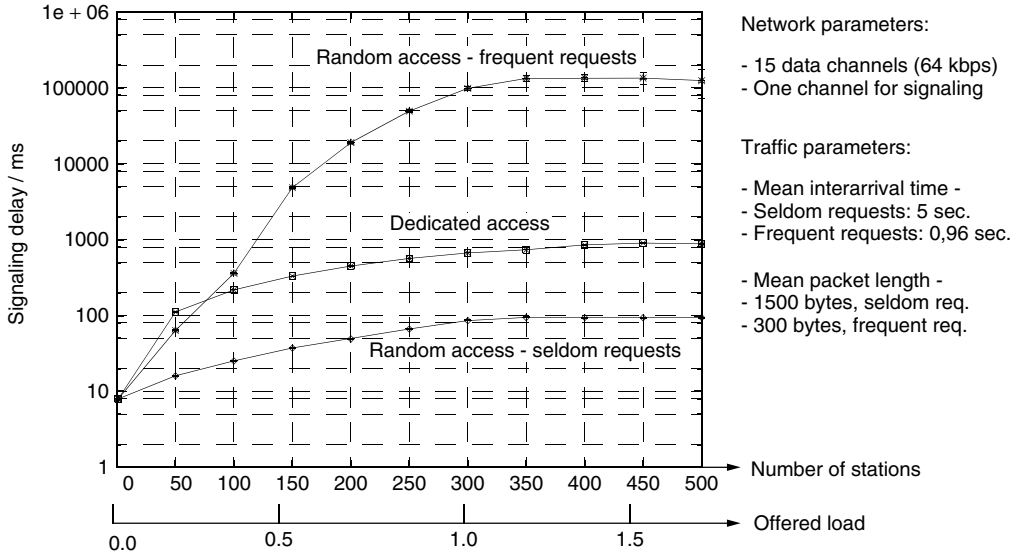

Figure 8. Average signaling delay of different reservation protocols.

access behave much better. So, an optimal solution for the organization for the reservation/signaling procedure can be achieved by a hybrid protocol changing dynamically from random to dedicated access depending on the current situation in the network (network load, number of active stations, etc.). However, the reservation procedure has to be particularly protected against disturbances [19]. Besides reservation MAC protocols, variations of the CSMA/CA protocol ensuring realization of multiple priorities for different services [20] are also widely applied to PLC systems (e.g., Itran technology [21]).

Because of the asymmetric and changing nature of data traffic in the access area, dynamic duplex schemes are used in PLC access networks. This allows the optimal utilization of the network resources, in both downlink and uplink transmission directions according to the current load situation. However, the relatively small PLC network capacity makes it difficult for the simultaneous provision of a required QoS for a high number of subscribers. Therefore, PLC systems have to implement traffic scheduling strategies, including connection admission control (CAC), to limit the number of active subscribers ensuring a satisfactory QoS for currently admitted connections. In the same way, a part of the network resources has to be reserved for capacity reallocation in case of disturbances.

5.4. Error Handling

Because of the special disturbance characteristic, error handling within different network layers warrants careful attention [19]. After a correct dimensioning, it is assumed that the signal-to-noise ratio (SNR) is sufficient to avoid any influence of the background noise. However, the impulsive noise makes it difficult to ensure error-free transmission (Section 4.5). Its influence is reduced by the following methods:

- Setting a sufficient duration of the transmitted symbol within the physical network layer (e.g., duration of an OFDM symbol) eliminates disturbances that are shorter than the symbol duration.
- Channel coding using FEC mechanisms and interleaving allow for the correction of a number of erroneous bits in the case of various kind of disturbances (e.g., single, periodic, and burst errors). However, FEC mechanisms provide overhead, and interleaving increases the transmission delay. Because of the limited network capacity and the demand for low delays, channel coding in PLC networks is organized in a dynamic manner, providing a changing level of protection according to the current noise conditions in the network.
- If the reduction of the BER by channel coding is not sufficient and delay requirements are not too hard (e.g., data traffic), even ARQ mechanisms (retransmission of erroneous data) can be used.

Application of ARQ can improve network performances significantly (Fig. 9). Network utilization in a network without ARQ (only a simple packet retransmission is provided) can achieve a maximum of 50%. Application of go-back-N ARQ retransmitting smaller portions of erroneous packets (disturbed data segments) improves the network utilization by 23%. If the ARQ is additionally adjusted to a per packet reservation method (e.g., ARQ + mechanism [19]), utilization achieves 81%.

In the case of long-term disturbances, a part of the network capacity is unavailable for a longer time. This cannot be improved by FEC and ARQ. Therefore, this part of the transmission capacity (a frequency spectrum) is temporarily not usable (is switched off).

6. SUMMARY

Present powerline communications systems, using electrical power grids as transmission media, provide relatively high data rates (>2 Mbps). PLC can be applied to high-,

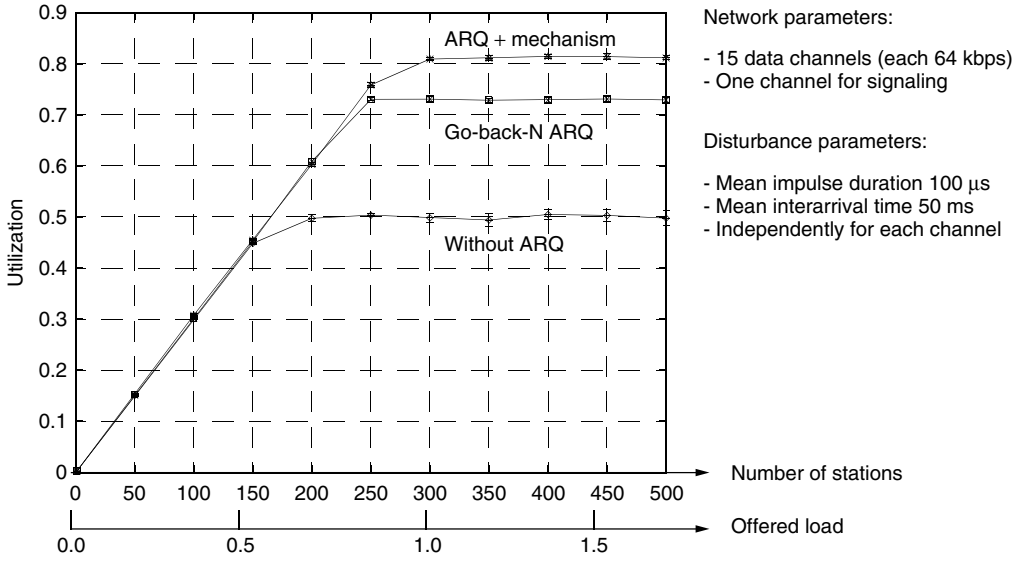

Figure 9. Performances of different ARQ mechanisms — average network utilization.

medium-, and low-voltage supply networks as well as within buildings. PLC technology is now used mainly for access networks and in-home communication networks. This is because of the high cost of the access networks (about 50% of the investments in network infrastructure are needed for the access area) and the liberalization of the telecommunication market in many countries.

Power supply networks are not designed for communications, and they do not present a favorable transmission medium. The PLC transmission channel is characterized by a large, frequency-dependent attenuation, changing impedance, and fading, as well as a strong influence of noise. On the other hand, broadband PLC networks have to operate in a frequency spectrum up to 30 MHz, which is used by various radio services, too. Therefore, the regulatory bodies specify very strong limits regarding the electromagnetic emission from PLC networks to the environment. As a consequence, PLC networks have to operate with a limited signal power, which reduces network distances and data rates, and also increases sensitivity to disturbances.

To reduce the negative impact of powerline transmission medium, PLC systems apply efficient modulation, such as OFDM, which is able to avoid restricted frequency bands. OFDM is also robust against narrowband and impulsive noise and can deal with fading. The problem of longer noise spikes can be solved by well-known error-handling mechanisms (e.g., FEC, ARQ). However, their application consumes a certain portion of the PLC network capacity due to overhead and retransmission. The PLC bandwidth is shared by the subscribers, and therefore any reduction of capacity due to protocol overhead should be minimized. At the same time, PLC systems have to compete with other access technologies and to offer a wide palette of telecommunication services with a satisfactory QoS. Both good network utilization and provision of QoS guarantees can be achieved by an efficient MAC layer. We have shown that reservation-based MAC protocols can achieve these goals efficiently.

ACRONYMS

ADSL	Asymmetric digital subscriber line
ARQ	Automatic repeat request
BER	Bit error rate
CAC	Connection admission control
CATV	Cable TV
CBR	Constant bit rate
CFS	Carrier frequency systems
CSMA/CA	Carrier sensing multiple access with collision avoidance
DS-CDMA	Direct sequence code division multiple access
DSL	Digital subscriber line
EMC	Electromagnetic compatibility
ETSI	European Telecommunications Standards Institute
FDD	Frequency-division duplex
FDMA	Frequency-division multiple access
FEC	Forward error correction
FSK	Frequency shift keying
IP	Internet Protocol
ISDN	Integrated Services Digital Network
LAN	Local-area network
LLC	Logical link control
MAC	Media access control
OFDM	Orthogonal frequency-division multiplexing
OFDMA	OFDM access
PLC	Powerline communications
psd	Power spectral density
QoS	Quality of service
RCS	Ripple carrier signaling
RegTP	Regulating Administration for Telecommunications and Post
TDD	Time-division duplex

TDMA	Time-division multiple access
VBR	Variable bit rate
VoIP	Voice over IP
WAN	Wide-area network

BIOGRAPHIES

Halid Hrasnica, graduated in 1993 at the Faculty for Electrical Engineering — Department for Telecommunications, at the University of Sarajevo — Bosnia and Herzegovina. From 1993 to 1995 he was working in Energoinvest Communications in Sarajevo as developing software engineer for the telephone exchange systems. In 1995 he joined the Chair for Telecommunications at Dresden University of Technology, Germany, as visitor scientist. Since 1996 he is research assistant at Dresden University of Technology and he is currently working toward his Ph.D. He has been involved in several research projects: development of least cost routing strategy, performance analysis and simulation of broadband communications networks. His current research interest is performance analysis of powerline communication networks and investigation on PLC MAC layer and protocols.

Abdelfatteh Haidine received the B.S. in electronics and telecommunications from the University Cadi Ayyad in Marrakech and the MSc in telecommunications from University Chouaib Doukkali El Jadida in 1999, in Morocco. Since 2000, he joined the University of Technology Dresden in Germany as research assistant. He worked in different European and German projects about power line communication networks. His actual research domain is planning and optimization of the access network based on optical fiber and Very high bit Digital Subscriber Line (VDSL) technology.

Ralf Lehnert received both his 1972 diploma degree and the 1979 Ph.D. degree in electrical engineering from Aachen University, Germany. Since 1980 he has been with the basic development department at Philips Communication Systems in Nuremberg, Germany, as the head of a group on applied research in performance evaluation of communication networks, traffic engineering and network planning. In July 1994 he took over the chair for telecommunications, as a full professor in the department of electrical engineering at Dresden University, Germany. His current research interests are in the field of performance evaluation of telecommunication systems, including modeling of B-ISDN networks, network planning and optimization. He has been involved in RACE (Parasol, Exploit, Tribune) and ACTS projects (Expert) all on the subject of ATM.

PRODUCT CODES

FRANK R. KSCHISCHANG
University of Toronto
Toronto, Ontario, Canada

1. INTRODUCTION

The *product construction*, introduced by Peter Elias in 1954 [1], is one of the simplest ways to combine simple error control codes to get more powerful ones, and any code that results from the product construction is called a *product code*. The codewords of a product code are defined as matrices that are constrained, like crossword puzzles, so that rows and columns form valid codewords in some constituent codes. Decoding typically also proceeds in crossword-puzzle fashion, alternating between the horizontal and vertical constraints in an attempt to find a valid codeword near the received word. Although more complicated codes may offer superior performance, product codes are often attractive for practical implementation — they can be designed to provide excellent performance with reasonably low decoding complexity, and their structure leads to hardware decoder implementations with natural parallelism that is easily exploited.

This article describes product codes, derives some of their basic properties, discusses methods to decode them, and provides a number of examples.

1.1. Linear Codes

We consider only *linear block codes* in this article, so, to establish notation and to be somewhat self-contained, we will start with a brief review of their properties. The basic theory of linear block codes is described in every textbook on coding theory; see, [e.g., 2,3]. While all of the constructions we describe will apply to codes defined over any finite field $\mathbb{F}$, for simplicity we will confine all of our examples to codes defined over the binary field $\mathbb{F}_2 = \{0, 1\}$, with all scalar arithmetic (addition and multiplication) computed modulo 2. For use throughout this article, it is convenient to denote the vector space of $m \times n$ matrices over $\mathbb{F}$ as $\mathbb{F}^{m\times n}$, where m and n are positive integers. The space of $1 \times n$ row vectors is denoted as $\mathbb{F}^n$. If $\mathbf{M}$ is a matrix in $\mathbb{F}^{m\times n}$, then $[\mathbf{M}]_{i,j}$ denotes the component of $\mathbf{M}$ in row i, column j, where $i \in \{1, \ldots, m\}$ and $j \in \{1, \ldots, n\}$.

A block code C of length n over $\mathbb{F}$ is any nonempty subset of $\mathbb{F}^n$. More specifically, C is *linear* if it forms a subspace of $\mathbb{F}^n$, that is, if C satisfies all the axioms that define a vector space, including the requirement that every $\mathbb{F}$-linear combination of codewords is itself a codeword. A code of length n and dimension k is referred to as an $[n, k]$ code.

The simplest example of a binary linear code is the $[k + 1, k]$ single-parity-check (SPC) code, which consists of all binary vectors of length $k + 1$, each having an even number of ones. For example, the $[3, 2]$ SPC code has four codewords: $\{000, 011, 101, 110\}$. It is easy to check that any linear combination of codewords is a codeword; for example, $011 + 101 = 110$.

An *encoder* for a linear code C maps a message of k (input) symbols to a codeword of $n \geq k$ (output) symbols. The ratio of input to output symbols, namely, k/n, is called the *rate* of the code. An encoder is called *systematic* if the message symbols appear directly as the first k symbols of each codeword. A systematic encoder for the binary SPC code would take in k message bits and append a single *check bit*, chosen to make the total number of ones in the codeword an even number.

1.2. Generator and Parity-Check Matrices

An $[n, k]$ code C is a k-dimensional vector space; accordingly, it is always possible to find k linearly independent vectors $g_1, \ldots, g_k$ in C. Any such set is a basis or *generating set* for C, since every codeword v of C may be expressed (uniquely) as an $\mathbb{F}$-linear combination of the generators

$$v = \sum_{i=1}^{k} u_i g_i, \tag{1}$$

where $u_i \in \mathbb{F}$ for all $i \in \{1, \ldots, k\}$. Writing $u = (u_1, \ldots, u_k)$ as a (row) vector with k components, and collecting $g_1, \ldots, g_k$ as the rows of a matrix $\mathbf{G} \in \mathbb{F}^{k\times n}$, we may express (1) in matrix form as $v = u\mathbf{G}$. The matrix $\mathbf{G}$ is referred to as a *generator matrix* for C, and C is equal to the *row space* of $\mathbf{G}$. Since C can have many different bases, it follows that C can have many different generator matrices (all of which, however, must have row space C).

Suppose that C has a generator matrix of the form $\mathbf{G} = [\mathbf{I}_k \mid \mathbf{P}]$, where $\mathbf{I}_k$ is the $k \times k$ identity matrix and $\mathbf{P} \in \mathbb{F}^{k\times(n-k)}$ is arbitrary. Then multiplication of an information vector u by $\mathbf{G}$ results in the systematic encoding $u\mathbf{G} = (u, u\mathbf{P})$ of u. In this case, $\mathbf{G}$ is said to be in *systematic form*. Although not every code has a generator matrix in systematic form, the $[3, 2]$ SPC code *does* have a generator matrix in systematic form given by

$$\mathbf{G} = \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix}$$

In general, since multiplication by $\mathbf{G}$ effects a one-to-one mapping from $\mathbb{F}^k$ to $\mathbb{F}^n$, it follows that $\mathbf{G}$ always has at least one (in general more than one) right-inverse $\mathbf{G}^{-1} \in \mathbb{F}^{n\times k}$, with the property that $\mathbf{G}\mathbf{G}^{-1} = \mathbf{I}_k$. In other words, from every codeword $c = u\mathbf{G}$, it is always possible to recover a unique message $u = c\mathbf{G}^{-1}$.

An alternative description of a code C arises as follows. Define the scalar ("inner" or "dot") product between two vectors $v = (v_1, \ldots, v_n)$ and $w = (w_1, \ldots, w_n)$ as $\langle v, w\rangle := \sum_{i=1}^{n} v_i w_i$. For every $[n, k]$ code C, one can always find a set of linearly independent n vectors $h_1, \ldots, h_{n-k}$ such that the scalar product $\langle h_i, v\rangle = 0$ for all $i \in \{1, \ldots, n - k\}$ if and only if v is a codeword of C. Collecting $h_1, \ldots, h_{n-k}$ as the rows of an matrix $\mathbf{H} \in \mathbb{F}^{(n-k)\times n}$, we see that a given vector v is a codeword of C if and only if v satisfies the *parity-check equation* $v\mathbf{H}^T = 0$. The matrix $\mathbf{H}$ is called a *parity-check matrix for* C. As is the case with generator matrices, a code C can have many different parity-check matrices. One possible parity-check matrix

for a code with systematic generator matrix $\mathbf{G} = [\mathbf{I}_k \mid \mathbf{P}]$ is $\mathbf{H} = [-\mathbf{P}^T \mid \mathbf{I}_{(n-k)}]$. For example, the $[3, 2]$ SPC code has parity-check matrix $\mathbf{H} = [111]$. In general, it is useful to allow *any* matrix $\mathbf{H}$ with n columns and rank $n - k$ satisfying $v\mathbf{H}^T = 0$ for all $v \in C$ to serve as a parity-check matrix for C, even if $\mathbf{H}$ contains some linearly dependent rows (redundant checks).

1.3. Minimum Hamming Distance

The *Hamming weight* $wt(v)$ of a vector v is defined as the number of positions in which v is nonzero. For example, $wt(110) = 2$. The *Hamming distance* $d(v, w)$ between two vectors v and w of the same length is defined as the Hamming weight of their difference: $d(v, w) := wt(v - w)$. For example, $d(011, 101) = wt(011 - 101) = wt(110) = 2$. It is easily seen that the Hamming distance between two vectors is the number of positions in which the two vectors differ. Thus, since 011 and 101 differ in their first two positions, but not in their last position, we have $d(011, 101) = 2$.

The minimum Hamming distance between pairs of *distinct* codewords in a code C is called the *minimum distance of* C, and is denoted $d_{\min}(C)$. The minimum distance of a code has traditionally been regarded as a parameter of fundamental importance, since this parameter determines the error correction radius $t = \lfloor (d_{\min} - 1)/2 \rfloor$ within which all error patterns are guaranteed correctable by any decoder that maps a received word to the nearest (in the sense of Hamming distance) codeword. In general, it is desirable to make the minimum distance d as large as possible for a given n and k.

For linear codes, since $d(v, w) = wt(v - w)$, the Hamming distance between two codewords v and w is always equal to the weight of some codeword, namely, $v - w$. In other words, every distance (between two codewords) is a weight (of some codeword). On the other hand, since $wt(v) = d(v, 0)$, every weight (of some codeword) is a distance (between two codewords). This equivalence between weight and distance implies that the minimum distance of a linear code C is given by the minimum weight of its nonzero codewords. The $[3, 2]$ SPC code, for example, has minimum distance 2. In general, an $[n, k]$ code with minimum distance d is often referred to as an $[n, k, d]$ code.

For many values of n and k, there are methods known to construct $[n, k]$ codes with large minimum distance, (e.g., see the articles BCH CODES, CYCLIC CODES, FINITE GEOMETRY CODES, HADAMARD CODES, REED–MULLER CODES, and REED–SOLOMON CODES in this encyclopedia).

2. THE PRODUCT CONSTRUCTION

2.1. Definition and Basic Properties

Let A and B be codes over $\mathbb{F}$ of length n_A and n_B, respectively. Whereas the codewords of A and B are vectors, we will now define a code of length $n_A n_B$, the *direct product* of A and B, whose codewords may be viewed as $n_A \times n_B$ matrices over $\mathbb{F}$, namely, as elements of $\mathbb{F}^{n_A \times n_B}$. Every such matrix is readily converted to a vector of length $n_A n_B$ simply by ordering the matrix elements in some way; see Section 2.3.

Definition 1. The direct product $A \otimes B$ is the code consisting of all $n_A \times n_B$ matrices with the property that each matrix column is a codeword of A and each matrix row is a codeword of B.

When A and B are general nonlinear codes, there is no guarantee that $A \otimes B$ is even nonempty. When A and B are linear codes, however, $A \otimes B$ is also linear, with parameters given in the following theorem.

Theorem 1. If A is an $[n_A, k_A, d_A]$ linear code over $\mathbb{F}$ and B is an $[n_B, k_B, d_B]$ linear code over $\mathbb{F}$, then $A \otimes B$ is an $[n_A n_B, k_A k_B, d_A d_B]$ linear code over $\mathbb{F}$.

Before proving this theorem, we give a small example. When A and B both are $[3, 2]$ SPC codes, $A \otimes B$ consists of all the 3×3 matrices in which each row and column contains an even number of ones. The codewords of $A \otimes B$ are listed as follows:

$$\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{bmatrix}, \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 1 \\ 1 & 0 & 1 \end{bmatrix},$$
$$\begin{bmatrix} 0 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 1 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 1 & 1 \\ 0 & 0 & 0 \\ 0 & 1 & 1 \end{bmatrix}, \begin{bmatrix} 0 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 0 \end{bmatrix},$$
$$\begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 1 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 1 \end{bmatrix},$$
$$\begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 0 \end{bmatrix}, \begin{bmatrix} 1 & 0 & 1 \\ 1 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} 1 & 0 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix},$$
$$\begin{bmatrix} 1 & 1 & 0 \\ 0 & 0 & 0 \\ 1 & 1 & 0 \end{bmatrix}, \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix},$$
$$\begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

There are $2^{2\times 2} = 16$ codewords of length $3 \times 3 = 9$ with minimum nonzero weight $2 \times 2 = 4$, exactly as predicted by Theorem 1. Even though the SPC codes themselves cannot correct errors, their direct product is single-error correcting, since a single error that occurs in row i, column j causes a parity-check violation in that row and column, a situation that is easily detected and corrected by the decoder.

Given any two codewords $a = (a_1, \ldots, a_{n_A}) \in A$ and $b = (b_1, \ldots, b_{n_B}) \in B$, define the $n_A \times n_B$ matrix $a \otimes b$ as the "outer product" $a^T b$ of a and b, specifically, where $[a \otimes b]_{i,j} = a_i b_j$. It is easy to see that each column of $a \otimes b$ is a scalar multiple of a and each row of $a \otimes b$ is a scalar multiple of b. Thus $a \otimes b$ is in fact a codeword of $A \otimes B$. A codeword in $A \otimes B$ of the form $a \otimes b$ is said to be *separable*. In general $A \otimes B$ contains $1 + (|\mathbb{F}|^{k_A} - 1)(|\mathbb{F}|^{k_B} - 1)$ separable codewords, where $|\mathbb{F}|$ denotes the number of elements in $\mathbb{F}$. When k_A and k_B are large, the separable codewords represent a tiny fraction of

all possible codewords, yet, as we will see, the separable codewords generate the entire product code.

Proof of Theorem 1 The code $C = A \otimes B$ contains the zero matrix, and so is clearly a nonempty code of length $n_A n_B$. The linearity of C follows directly from the linearity of codes A and B and the fact that every $\mathbb{F}$-linear combination of codewords gives rise to a corresponding $\mathbb{F}$-linear combination of rows (or columns).

To see that C has minimum distance $d_A d_B$, let v be a nonzero codeword of C. Then v has a nonzero column $a \in A$, whose weight must be at least d_A. Each nonzero component of a also participates in a nonzero row, and each such row is a nonzero codeword of B of weight at least d_B. Thus v has weight at least $d_A d_B$, and so (1) the minimum distance of C is at least $d_A d_B$; on the other hand, if $a \in A$ and $b \in B$ are nonzero codewords of weight d_A and d_B, respectively, then $a \otimes b$ is a codeword of C of weight $d_A d_B$, so (2) the minimum distance of C is at most $d_A d_B$. Statements (1) and (2) together imply that C has minimum distance exactly $d_A d_B$.

The fact that the dimension of $A \otimes B$ is given by $k_A k_B$ follows directly from Theorem 2 (below).

2.2. Encoding of Product Codes

Given generator matrices for A and B, a convenient encoder for $A \otimes B$ is obtained via the following theorem.

Theorem 2. Let code A have generator matrix $\mathbf{G}_A \in \mathbb{F}^{k_A \times n_A}$, let code B have generator matrix $\mathbf{G}_B \in \mathbb{F}^{k_B \times n_B}$, and let $\mathbf{M}$ be an arbitrary matrix in $\mathbb{F}^{n_A \times n_B}$. Then $\mathbf{M} \in A \otimes B$ if and only if $\mathbf{M} = \mathbf{G}_A^T \mathbf{U} \mathbf{G}_B$, for some $\mathbf{U} \in \mathbb{F}^{k_A \times k_B}$.

Before proving Theorem 2, we remind the reader of the following simple property of matrix multiplication.

Lemma 1. Let $\mathbf{X}$ and $\mathbf{Y}$ be matrices conformable for the product $\mathbf{XY}$. Then each column of $\mathbf{XY}$ is in the column space of $\mathbf{X}$ and each row of $\mathbf{XY}$ is in the row space of $\mathbf{Y}$.

Proof of Theorem 2 Let $\mathbf{U}$ be an arbitrary $k_A \times k_B$ matrix over $\mathbb{F}$, and consider the matrix product $\mathbf{M} = \mathbf{G}_A^T \mathbf{U} \mathbf{G}_B$. From Lemma 1 (setting $\mathbf{X} = \mathbf{G}_A^T \mathbf{U}$ and $\mathbf{Y} = \mathbf{G}_B$) we see that every row of $\mathbf{M}$ is in the row space of $\mathbf{G}_B$, and hence is a codeword of B. Likewise (setting $\mathbf{X} = \mathbf{G}_A^T$ and $\mathbf{Y} = \mathbf{U}\mathbf{G}_B$) we see from Lemma 1 that every column of $\mathbf{M}$ is in the column space of $\mathbf{G}_A^T$ or equivalently is in the row space of $\mathbf{G}_A$, and hence is a codeword of A. Thus $\mathbf{M}$ is a codeword of $A \otimes B$.

Conversely, let $\mathbf{M}$ be a codeword of $A \otimes B$. Then, since every row of $\mathbf{M}$ is a codeword of B, it follows that $\mathbf{M} = \mathbf{W}\mathbf{G}_B$ for some $n_A \times k_B$ matrix $\mathbf{W}$. Now, since $\mathbf{W} = \mathbf{M}\mathbf{G}_B^{-1}$, where $\mathbf{G}_B^{-1}$ is a right-inverse of $\mathbf{G}_B$, from Lemma 1 it follows that every column of $\mathbf{W}$ is in the column space of $\mathbf{M}$, and hence is a codeword of A. Thus $\mathbf{W} = \mathbf{G}_A^T \mathbf{U}$ for some $\mathbf{U} \in \mathbb{F}^{k_A \times k_B}$, and $\mathbf{M} = \mathbf{W}\mathbf{G}_B = \mathbf{G}_A^T \mathbf{U} \mathbf{G}_B$.

Observe that the encoder mapping $m: \mathbb{F}^{k_A \times k_B} \to \mathbb{F}^{n_A \times n_B}$ defined by $m(\mathbf{U}) = \mathbf{G}_A^T \mathbf{U} \mathbf{G}_B$ is linear. The kernel of this mapping [i.e., the set of matrices $\mathbf{U}$ such that $m(\mathbf{U}) = \mathbf{0}$] contains just the zero matrix $\mathbf{U} = \mathbf{0}$. Since the kernel of m is trivial, the mapping m is one-to-one, and C, the image of $\mathbb{F}^{k_A \times k_B}$ under the mapping m, has dimension equal to that of $\mathbb{F}^{k_A \times k_B}$, namely, $k_A k_B$, as claimed in Theorem 1.

When $\mathbf{G}_A = [\mathbf{I}_{k_A} \mid \mathbf{P}_A]$ and $\mathbf{G}_B = [\mathbf{I}_{k_B} \mid \mathbf{P}_B]$, so that A and B have systematic encoders, then the encoder mapping m takes the information matrix $\mathbf{U}$ to the codeword

$$m(\mathbf{U}) = \mathbf{G}_A^T \mathbf{U} \mathbf{G}_B = \begin{bmatrix} \mathbf{U} & \mathbf{U}\mathbf{P}_B \\ \mathbf{P}_A^T \mathbf{U} & \mathbf{P}_A^T \mathbf{U} \mathbf{P}_B \end{bmatrix}$$

as illustrated in Fig. 1. The matrix block $\mathbf{U}$ is the information matrix; the block $\mathbf{U}\mathbf{P}_B$ contains "checks on rows," namely, parity-check symbols corresponding to the rows of the message matrix $\mathbf{U}$; the block $\mathbf{P}_A^T \mathbf{U}$ contains "checks on columns," specifically, parity-check symbols corresponding to the columns of the message matrix $\mathbf{U}$; and the block $\mathbf{P}_A^T \mathbf{U} \mathbf{P}_B$ contains "checks on checks," namely, parity-check symbols corresponding to other parity-check symbols. Since $m(\mathbf{U}) = \mathbf{G}_A^T(\mathbf{U}\mathbf{G}_B) = (\mathbf{G}_A^T \mathbf{U})\mathbf{G}_B$, checks on rows and checks on columns may be computed in either order while yielding the identical codeword.

2.3. The Krönecker Product

Let $\mathbf{E}_{i,j}$ be the $k_A \times k_B$ matrix with a one in row i, column j, and zeros in all other positions. Since the set $\{\mathbf{E}_{i,j}: 1 \le i \le k_A, 1 \le j \le k_B\}$ is a basis for $\mathbb{F}^{k_A \times k_B}$, and the encoder mapping m is one-to-one, it follows that $\{m(\mathbf{E}_{i,j}): 1 \le i \le k_A, 1 \le j \le k_B\}$ is a basis for $A \otimes B$. Denote the ith row of $\mathbf{G}_A$ as g_i^A and the jth row of $\mathbf{G}_B$ as g_j^B. Then $m(\mathbf{E}_{i,j}) = \mathbf{G}_A^T \mathbf{E}_{i,j} \mathbf{G}_B = (g_i^A)^T (g_j^B) = g_i^A \otimes g_j^B$. Thus, given a basis $\{g_i^A: 1 \le i \le k_A\}$ for A and a basis $\{g_j^B: 1 \le j \le k_B\}$ for B, the set of outer products $\{g_i^A \otimes g_j^B: 1 \le i \le k_A, 1 \le j \le k_B\}$ is a basis for $A \otimes B$. This proves that separable codewords do indeed generate the entire product code.

It is often useful to "flatten" a product code by converting codewords that are $n_A \times n_B$ matrices into a vectors of length $n_A n_B$. This may be accomplished by establishing a one-to-one correspondence between matrix and vector components. For example, we may define the mapping $s: \mathbb{F}^{n_A \times n_B} \to \mathbb{F}^{n_A n_B}$ that maps a matrix $\mathbf{M}$ to a vector $s(\mathbf{M})$ be assigning $[\mathbf{M}]_{i,j}$ to the $[(i-1)n_B + j]$th component of $s(\mathbf{M})$. In effect, $s(\mathbf{M})$ is obtained by concatenating together the consecutive rows of $\mathbf{M}$; for example

$$s\left(\begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{bmatrix}\right) = (110011101)$$

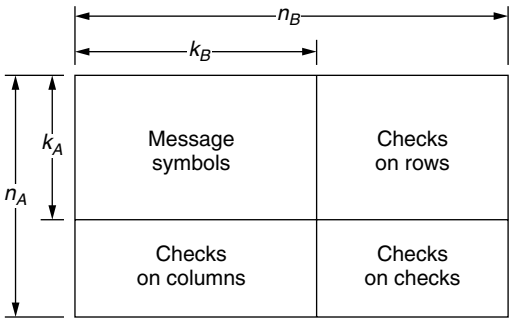

Figure 1. The array formed by the direct product of systematic $[n_A, k_A]$ and $[n_B, k_B]$ codes.

When a and b are vectors in codes A and B, respectively, it is interesting to flatten their outer product. We have

$$\begin{aligned} s(a \otimes b) &= (a_1 b, a_2 b, \ldots, a_{n_A} b) \\ &= a_1 b_1, \ldots, a_1 b_{n_B}, a_2 b_1, \ldots, a_2 b_{n_B}, \\ &\quad \ldots, a_{n_A} b_1, \ldots, a_{n_A} b_{n_B}) \end{aligned}$$

which, in fact, is the *Krönecker product* of the vectors a and b. Recall that the Krönecker product of an $m \times n$ matrix $\mathbf{X}$ with a $p \times q$ matrix $\mathbf{Y}$ is the $mp \times nq$ matrix $\mathbf{X} \otimes \mathbf{Y}$ given in block form as

$$\begin{bmatrix} [\mathbf{X}]_{1,1}\mathbf{Y} & [\mathbf{X}]_{1,2}\mathbf{Y} & \cdots & [\mathbf{X}]_{1,n}\mathbf{Y} \\ [\mathbf{X}]_{2,1}\mathbf{Y} & [\mathbf{X}]_{2,2}\mathbf{Y} & \cdots & [\mathbf{X}]_{2,n}\mathbf{Y} \\ \vdots & \vdots & \ddots & \vdots \\ [\mathbf{X}]_{m,1}\mathbf{Y} & [\mathbf{X}]_{m,2}\mathbf{Y} & \cdots & [\mathbf{X}]_{m,n}\mathbf{Y} \end{bmatrix}.$$

Note that the symbol $\otimes$ has been burdened to designate the direct product of codes, the outer product of vectors, and now the Krönecker product of matrices. When a and b are vectors, the interpretation of $a \otimes b$ either as an outer product or as a Krönecker product must be made clear.

Observe that the rows of the Krönecker product of $\mathbf{X}$ and $\mathbf{Y}$ are precisely the Krönecker products of all possible pairs of rows, one drawn from $\mathbf{X}$, the other from $\mathbf{Y}$. In light of our observation that the set of all possible outer products $\{g_i^A \otimes g_j^B : 1 \le i \le k_A, 1 \le j \le k_B\}$ of the rows of $\mathbf{G}_A$ and $\mathbf{G}_B$ is a basis for $A \otimes B$, it follows that "flattened code" $s(A \otimes B)$ is generated by the Krönecker product $\mathbf{G}_A \otimes \mathbf{G}_B$. For example, the "flattened" $[9, 4, 4]$ product code from Section 2.1 has generator matrix

$$\begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix} \otimes \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 & 1 \end{bmatrix}$$

3. ITERATED PRODUCT CODES AND THE ELIAS CONSTRUCTION

The product construction may be *iterated*, that is, applied to more than two codes. For example, given linear codes A, B, and C of length n_A, n_B, and n_C, respectively, and with generator matrices $\mathbf{G}_A$, $\mathbf{G}_B$, and $\mathbf{G}_C$, respectively, one can define a code $A \otimes B \otimes C$ of length $n_A n_B n_C$. Although one might visualize such codes in terms of structures of higher order than matrices, it is often easier to deal with the "flattened" versions of such codes, by defining $A \otimes B \otimes C$ as the code generated by the Krönecker product $\mathbf{G}_A \otimes \mathbf{G}_B \otimes \mathbf{G}_C$. The Krönecker product is associative:

$$(\mathbf{G}_A \otimes \mathbf{G}_B) \otimes \mathbf{G}_C = \mathbf{G}_A \otimes (\mathbf{G}_B \otimes \mathbf{G}_C)$$

Thus the order in which the Krönecker products are formed does not affect the final outcome. The Krönecker product is *not* commutative, however, so the code generated by $\mathbf{G}_A \otimes \mathbf{G}_B \otimes \mathbf{G}_C$ is not, in general, equal to that generated by $\mathbf{G}_B \otimes \mathbf{G}_A \otimes \mathbf{G}_C$, although they are equivalent.

If $A_1, \ldots, A_L$ is a sequence of codes, where A_i is a linear $[n_i, k_i, d_i]$ code over $\mathbb{F}$, then it follows directly from Theorem 1 that $A_1 \otimes \cdots \otimes A_L$ is a linear $[n_1 n_2 \ldots n_L, k_1\, k_2 \ldots k_L, d_1 d_2 \ldots d_L]$ code.

For example, in his 1954 paper [1], Elias constructed a family of binary codes, each member of which is the direct product of a sequence of extended Hamming codes. Recall that for $m \ge 2$, the extended binary Hamming code H_m of length 2^m is a $[2^m, 2^m - m - 1, 4]$ code. Let $C_{m,L} = H_m \otimes H_{m+1} \otimes \cdots \otimes H_{m+L-1}$. Then $C_{m,L}$ has rate

$$R(m, L) = \prod_{i=m}^{m+L-1} (1 - (i+1)2^{-i})$$

It can be shown that, even when L approaches infinity, the rate $R(m, \infty)$ approaches a nonzero limit. Table 1 tabulates the numerical value of $R(m, \infty)$ for some small values of m. The key point is that the Elias product codes all have finite nonzero rate.

Assuming transmission through a binary symmetric channel with crossover probability p, Elias considered a straightforward strategy for decoding $C_{m,L}$. In the first stage of decoding, decoders for H_m are employed, corresponding to the "rows" of the product code. In the second stage, decoders for H_{m+1} are employed, corresponding to the "columns" of the product code, and so on.

A decoder for the extended Hamming code will successfully correct any single error in a given block. If an even number of errors occur, the Hamming decoder makes no changes to the block. If an odd number of errors greater than 1 occurs, the Hamming decoder will map the received word to a codeword by flipping some bit. This may increase the number of errors (if the flipped bit was correct), or decrease the number of errors (if the flipped bit was in error). Although the exact relationship between the expected number of output errors per block, e_o, and the expected number of input errors per block, e_i, is complicated, it can be shown that if e_i is sufficiently small, then the Hamming decoder for H_m actually *reduces* errors: $e_o < e_i$. In particular, as shown in [2, Sect. 14.83], for large values of m, if $e_i < 2.1779$, then $e_o < e_i$, and if $e_i < 0.6246$, then $e_o < e_i/2$.

Although the ith-stage Hamming decoder introduces statistical dependency among the symbols *within* the decoded word, since each symbol supplied to the $(i+1)$th-stage Hamming decoder is drawn from the output of an independent decoder at stage i, decoders at all stages are supplied with words in which errors in the bits are statistically independent. Provided that at each stage of

Table 1. Limiting Rates for Elias Product Codes

m	2	3	4	5	6	7	8	9
$R(m, \infty)$	0.054	0.215	0.431	0.627	0.772	0.866	0.924	0.958

decoding $e_i < 0.6246$, the expected number of errors per block supplied to the next decoder stage will also satisfy $e_i < 0.6246$, and in fact the number of errors per block will approach zero as the number of stages approaches infinity. Berlekamp [2, Sect. 14.84], provides a table of "threshold values" for the channel crossover probability p that will result in a chain of decreasing error probability at successive decoding stages. When $m = 3$, for example, the threshold is 0.0828, indicating that if $p < 0.0828$, then the family of codes $C_{3,L}$ can be decoded at arbitrarily small error rates when L is large enough. For $m = 4$, the threshold is 0.0402, and for $m = 5$, the threshold is 0.0192.

According to Table 1, $R(3, \infty) = 0.215$. A code operating at the Shannon limit on a binary symmetric channel would be able to tolerate a crossover probability $p = \mathcal{H}^{-1}(1 - 0.215) = 0.234$, while still providing error-free transmission, a value considerably larger than the threshold value 0.0828. [Here $\mathcal{H}$ denotes the binary entropy function $\mathcal{H}(p) := -p \log_2 p - (1-p) \log_2(1-p)$.] Similar conclusions hold for other values of m. Thus, one concludes that the Elias product codes are not capacity-achieving. Nevertheless, they were the first explicitly known family of codes to achieve asymptotically zero error probability at positive code rates. While certain families of irregular low-density parity-check codes (see the article LOW-DENSITY PARITY-CHECK CODES in this encyclopedia) are now known to contain codes with better threshold performance under message-passing decoding than the Elias product codes, it is remarkable indeed that the underlying principles — the use of simple constituent codes with intercommunicating decoders — had already been discovered by Elias as early as 1954.

4. ITERATIVE DECODING OF PRODUCT CODES

The Elias scheme for decoding product codes is strictly sequential. Decoders from one stage pass decoding results on to the next stage, without feedback. In crossword-puzzle terms, this decoding strategy is analogous to looking at the "across" clues, filling in the letters as well as possible, and then looking at the "down" clues, filling in any remaining letters, and then stopping. This leads to a tractable analysis for the decoder; however, as every aficionado of crossword puzzles knows, a far more effective decoding strategy is to alternate or *iterate* between the "across" and "down" clues, since solutions to the "down" clues provide information that are helpful in solving the "across" clues, and vice versa. While the statistical dependence between these interacting decoders makes an exact analysis of the decoder very difficult, simulations of decoder performance show that such iterative decoding can be extremely effective. In fact, it is precisely this sort of iterative decoding that underlies many of the most powerful practical coding schemes known (see, for example, the articles TURBO CODES and LOW-DENSITY PARITY-CHECK CODES in this encyclopedia).

To explain the iterative decoding of product codes, it is helpful to describe these codes in graph-theoretic terms, an approach pioneered by R. M. Tanner [4]. Figure 2 shows a *Tanner graph* for the direct product of codes of length n_A and n_B. A Tanner graph is a bipartite graph containing

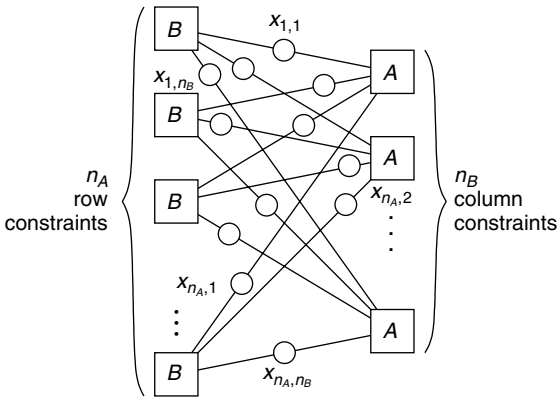

Figure 2. A Tanner graph for the direct product of $[n_A, k_A]$ and $[n_B, k_B]$ codes. The codeword symbol appearing in row i, column j is denoted $x_{i,j}$.

symbol nodes (shown as circles in Fig. 2) and check nodes (shown as squares in Fig. 2). Two nodes are *adjacent* if they are connected by an edge in the graph. In true bipartite fashion, symbol nodes can be adjacent only to check nodes (not to other symbol nodes), and similarly for check nodes.

The symbol nodes represent codeword symbols; in the binary case, each symbol node represents a bit. The purpose of the check nodes is to define the set of *valid configurations* or codewords of the code. They do this locally: each check node imposes a constraint only on the adjacent symbol nodes. While many global configurations may satisfy one or more local configurations, only those global configurations that satisfy *all* the local constraints are deemed to be globally valid configurations.

An example should make this clear. In the product code $A \otimes B$, the symbols in each column of a valid codeword must be a codeword of A and the symbols of each row of a valid codeword must be a codeword of B. Thus there are naturally n_B column constraints (constraining adjacent symbols to codewords of A) and n_A row constraints (constraining adjacent symbols to codewords of B), giving $n_A + n_B$ check nodes in the Tanner graph, as shown in Fig. 2. Each codeword symbol participates in exactly one row and one column, and hence each variable node is adjacent to exactly one column check node and one row check node.

Iterative decoding of this code may be interpreted as a process of *message passing* on the edges of the Tanner graph. We provide here only an intuitive description of the decoding procedure, and refer the reader to, for example, Ref. 5 for a more precise treatment.

The "messages" passed by the algorithm can be interpreted as probabilities or "beliefs" concerning the value of the corresponding symbol node. For example, the beliefs are often expressed as loglikelihood ratios (LLRs), defined as $\lambda(x) = \log(P[x = 0]/P[x = 1])$. When $\lambda(x)$ is large and positive, this indicates a strong belief that x has value 0; when $\lambda(x)$ is large and negative, this indicates a strong belief that x has value 1. A $\lambda(x)$ value that is close to zero indicates that $P[x = 0]$ and $P[x = 1]$ are nearly equal. The initial beliefs are determined by the received word.

Decoding proceeds iteratively. Each symbol node x transmits $\lambda(x)$ to, say, the adjacent-row check nodes.

Each row check node receives n_B incoming messages, and produces n_B outgoing messages that *update* the $\lambda(x)$ values, taking into account the constraints imposed by the structure of B. This updating procedure is sometimes referred to as "soft-in/soft-out" decoding, since the inputs and outputs of the decoder are beliefs, not hard decisions about the values of the bits.

For example, suppose that B is a $[3, 2]$ SPC code, and that a particular row check node receives three messages: two of which represent strong beliefs that the symbols x_1 and x_2 have value 1, and one representing a relatively weaker belief that symbol x_3 is a 1. Since 111 is not a valid local configuration, the most likely explanation is that x_3 is in fact 0. Thus the decoder would update the beliefs, reinforcing the belief that x_1 and x_2 are 1, and suggesting that x_3 is in fact zero.

These updated beliefs are then passed to the column decoders. Each column decoder receives n_A incoming messages, and produces n_A outgoing messages that update the belief values, taking into account the constraints imposed by the structure of A.

These newly updated beliefs could then be passed back to the row decoders, and the whole decoding process would repeat. The process would normally halt when the updated beliefs suggest a valid configuration, or when some predetermined upper limit on the number of iterations is reached.

It is important to note that different row decoders operate independently of one another. In a hardware decoder implementation, it would be possible to operate these decoders fully in parallel. The same is, of course, true for the column decoders. The local soft-in/soft-out decoders are typically implemented using the forward/backward algorithm [5] operating on a trellis representation of the local code. Any codes for which an efficient trellis representation exists would therefore be candidate constituent codes for such a product code. Since the different decoders are interconnected by a simple row/column structure, message passing can be implemented in hardware in straightforward fashion.

The performance of practically decodable product codes can be quite good, with performance on an additive white Gaussian noise channel with BPSK modulation that is within $\sim$2 dB of the Shannon limit at blocklengths on the order of 4000 bits [6]. While Turbo codes and low-density parity-check codes can approach somewhat closer to the Shannon limit, the simplicity of product codes and the prospect of high-speed decoder implementations in hardware make product codes very suitable for a wide variety of practical applications.

BIOGRAPHY

Frank R. Kschischang is a Professor in the Department of Electrical and Computer Engineering at the University of Toronto, where he has been a faculty member since 1991. He received the B.A.Sc. degree with honors from the University of British Columbia in 1985, and the M.A.Sc. and Ph.D. degrees from the University of Toronto in 1988 and 1991, respectively, all in electrical engineering. From October 1997 to October 2000, Dr. Kschischang served as *IEEE Transactions on Information Theory* Associate Editor for Coding Theory. In April 1999, he received the Ontario Premier's Research Excellence Award, and in December 2000, he was named a Canada Research Chair. His research interests lie in the general area of channel coding techniques, particularly in iterative decoding of codes defined on graphs.

PROPAGATION MODELS FOR INDOOR COMMUNICATIONS

1. INTRODUCTION

The performance of wireless communication systems depends in a fundamental way on the mobile radio channel. In contrast to wired channels that are stationary and easy to design, radio channels show a time-variant behavior which complicates their analysis. Inside buildings the transmission path between transmitter and receiver can vary from simple line-of-sight to one severely obstructed by walls and furniture. As a consequence, predicting the propagation characteristics between two antennas still belongs to the most important tasks for the design and installation of wireless indoor communication systems, ranging from low-bit-rate cordless telephone and cellular systems to high-bit-rate wireless local-area networks (WLANs).

This article reviews and discusses a variety of methods for modeling wave propagation in indoor scenarios. The basic requirements necessary for predicting path loss and other relevant parameters are discussed. Apart from well known and widely used propagation models, new

approaches with minimized computational complexity are also introduced.

1.1. The Mobile Indoor Radio Channel

The mobile radio channel concerning transmission within buildings is characterized by a multipath scenario as shown in Fig. 1. The signal from the transmitting antenna (usually only the downlink is considered as the principle of reciprocity applies) propagates along different paths to the antenna of the (mobile) receiver. In many cases there is no direct line of sight and the only paths connecting transmitter and the receiver penetrate several walls and are reflected, diffracted, and scattered at a number of different obstacles. Since the phases of the waves are randomly distributed, the superposition of these contributions causes constructive and destructive interference (i.e., small-scale fading), which leads to rapidly fluctuating signal levels over very short distances. Figure 2 illustrates this small-scale fading and the slower large-scale signal variation for an indoor radiocommunication system. While the small-scale fading is random, the large-scale variations occur as a result of fundamental changes of the propagation paths (e.g., larger distances, different obstacles). Typically, the local average of the received power is computed by averaging signal measurements over an interval of 10λ to 20λ, which corresponds to movements of the receiver of 1.5–3 m at a frequency of 2 GHz.

1.2. Radiowave Propagation within Buildings

With decreasing wavelength, that is, increasing frequency, wave propagation becomes more and more similar to the propagation of light. A radio ray is assumed to propagate essentially along a straight line and is influenced only by the given obstacles. For a criterion for this type of modeling to be successful, the wavelength should be much smaller than the extensions of the partitions of the building structure. At the frequencies used for wireless indoor communication networks, this criterion is sufficiently fulfilled.

The phenomena that influence radiowave propagation can generally be described by four basic mechanisms: penetration, reflection, diffraction, and scattering. For the practical usage of propagation models in real

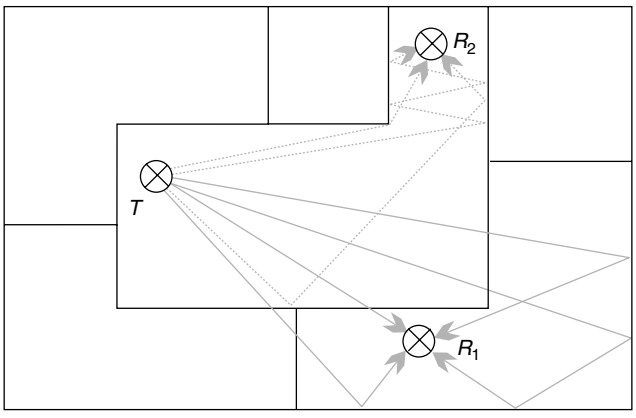

Figure 1. Multipath propagation within buildings.

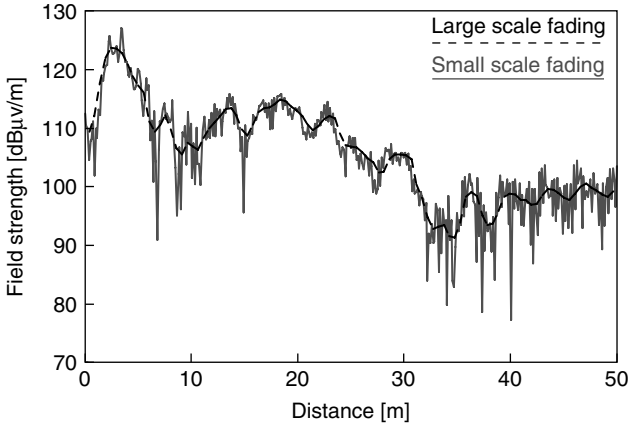

Figure 2. Large-scale and small-scale fading.

scenarios, these mechanisms must be introduced by approximations. This requires a multistage modeling process [1], introduced in the following paragraphs.

In the first step the propagation environment has to be digitized, leading to a database that describes the considered scenario in an adequate way. The second step includes the definition of mathematical approximations for the physical propagation phenomena. On the basis of the solutions for the basic problems, both empirical and deterministic approaches have been developed, forming the third modeling step.

The indoor radio channel differs considerably from that of an outdoor scenario [2,3]. The transmitter–receiver distance is shorter in order to compensate for the high attenuation along the path caused by internal walls and furniture and also because of the lower transmitter power. The short distance implies shorter delay of echoes and consequently a lower delay spread. The temporal variations of the channel are slower than those of mobile antennas moving with an automobile. Nevertheless, the conditions within buildings are time-variant even when transmitter and receiver are fixed; for instance, whether interior doors are open or closed can change the propagation scenario considerably. In general, the propagation within buildings is strongly influenced by the local environment, namely, the layout of the particular building under consideration and the construction materials used for walls, floors, and ceilings. According to the type of building and the corresponding layout, four different categories of indoor environments can be defined as listed in Table 1 [1,4].

As it is the case in outdoor scenarios, there are several important propagation parameters to be predicted. The path loss and the statistical characteristics of the received signal strength are most important for coverage planning applications. The wideband characteristics (delay spread, impulse response) and the time variation are essential for the evaluation of the system performance.

1.3. Properties of Materials

The buildings taken into account within a planning process have a wide variety of walls and obstacles that form the internal and external structure. Hard partitions and soft

Table 1. Different Categories of Indoor Environments [1]

Environment Category	Description	Typical Values for the Delay Spread (ns)
Corridor	Transmitter and receiver along the same corridor (LoS)	≤20
Dense	Small rooms; typically an office where each employee has his own room; mostly non-line-of-sight (NLoS) conditions	10–30
Open	Large rooms; typically an office where one room is shared by several employees; mostly line-of-sight (LoS) or obstructed-line-of-sight conditions (OLoS)	20–50
Large	Environments consisting of very large rooms; typically a factory hall, shopping center, or airport building; mostly LoS or OLoS conditions	50–80

partitions can be distinguished according to the magnitude of the penetration loss for electromagnetic waves [2]. While hard partitions are formed as bearing parts of the building structure (e.g., walls constructed from reinforced concrete or brick, thickness >10 cm), soft partitions may be moved and therefore show lower losses (e.g., plasterboard or plywood, thickness <10 cm). In order to get a more accurate modeling of wave propagation, a detailed description of the electrical properties for all building elements considered is necessary. However, in most cases the partitions are made out of several layers and are not homogenous. Nevertheless, a lot of researchers have collected databases for a great amount of different materials. While the physical behavior is described by the complex permittivity ε, the resulting partition losses as given in Table 2 are of more interest from a practical point of view.

The total loss experienced by electromagnetic waves when penetrating walls can be divided into two independent parts. The first part refers to the penetration of the wall surface and shows no explicit frequency dependence, whereas the second part belongs to the in depth penetration of the wall material. The magnitude of the latter depends on the wavelength and leads to higher losses with increasing frequency (see Table 2).

1.4. Databases for Buildings

The basis for any propagation model is a database that describes the propagation environment. For the purpose of propagation modeling, each building element should be categorized into classes (wall, floor, door, window, etc.) and specified by its coordinates and finally its material properties (thickness and electrical characteristics).

Modern planning tools [5,6] store the building data in a 3D-vector format including all walls, doors, and windows. Usually all elements inside the building are described in terms of plane elements; for example, every wall is represented by a plane and its extent and location is defined by its corners as indicated in Fig. 3. Through the use of

Table 2. Partition Losses of Different Construction Materials

Material Type	Frequency (MHz)	Loss (dB)	Ref.

Metal	815	26	2

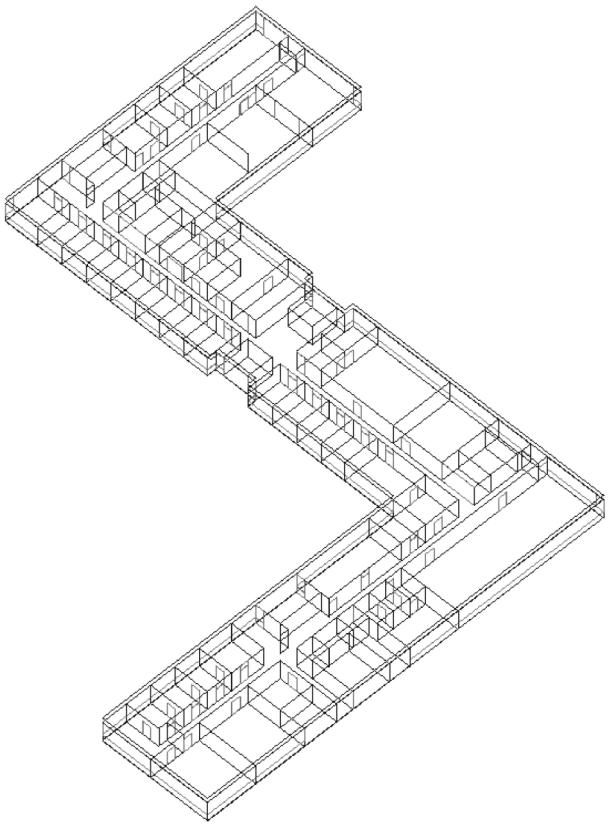

Figure 3. Example of an indoor database.

such building databases, which may be drawn or digitized utilizing standard graphical CAD (computer-aided design) software packages, wireless system designers are able to include accurate representations of building features. With respect to an efficient use it is often possible to import drawing interchange files (DXFs), a very common CAD data format in architecture. Figure 3 shows an example for a three dimensional building data base utilized within a commercial planning tool [6].

2. PROPAGATION MODELS

Propagation models focus on the prediction of the averaged received signal strength, as well as the variability of the signal strength in close vicinity of the particular location. This leads to the distinction between large-scale propagation models that predict the mean signal strength and small-scale propagation models that characterize the rapid fluctuations of the received signal strength over very short distances (a few wavelengths) or short time durations (in the order of seconds) [2].

Similar to this distinction, the propagation models presented here can be divided into three groups: empirical narrowband models, empirical wideband models, and deterministic ones. Empirical narrowband models are expressed in form of simple mathematical equations that give the path loss as an output result. The equations are obtained by fitting the model parameters to measurement results. The empirical wideband models allow the prediction of the wideband characteristics of the channel (e.g., impulse response, delay spread). Deterministic models simulate the propagation of radiowaves in a more physical way. These models predict both narrowband and wideband information of the mobile radio channel inside buildings. Additionally, directional channel properties such as angular spread are readily available, a fact that may be very important for the planning of future systems [7]. Propagation models for the prediction of field strength levels will generally provide only mean or median values, as the small-scale fading within indoor environments is adequately represented by Rayleigh distributions for NLoS (see Table 1) conditions and Rice distributions for clear LoS conditions with K factors up to 15 dB. The long-term fading, which describes the fluctuation of the mean value, can be approximated by a lognormal distribution with standard deviations between 2.7 and 5.3 dB [1].

2.1. Empirical Narrowband Models

Figure 4 shows the two basic approaches to the prediction of the field strength inside buildings. There are empirical models that analyze the direct path between the transmitter and the receiver. A calibration of these empirical models is mandatory, and their computation times are very small. All models of this type are based on the free-space propagation model.

2.1.1. Free-Space Propagation Model. This model is utilized to predict the received power if transmitter and receiver have a clear, unobstructed line-of-sight path. Generally this is not the case within indoor scenarios; nevertheless, this model gives a valuable insight into propagation modeling. The received power of an antenna at a distance d from the radiating transmitter antenna is calculated by the Friis equation:

$$P_r(d) = \frac{P_t G_t G_r \lambda^2}{(4\pi)^2 d^2} \tag{1}$$

where P_t is the transmitted and P_r is the received power, G_t and G_r are the antenna gains of the transmitter (Tx) and receiver (Rx), respectively, already mention before equation and λ is the free space wavelength. The free space path loss L_{FS}, which represents the signal attenuation as a positive quantity measured in decibels (dB), is defined as difference (in dB) between the transmitted and the received power level:

$$L_{FS} = 10 \log \frac{P_t}{P_r} = 10 \log \left(\frac{4\pi d}{\lambda} \right)^2 - 10 \log G_t - 10 \log G_r \tag{2}$$

Obviously the path loss increases both with distance and with frequency at a rate of 20 dB/decade. With the

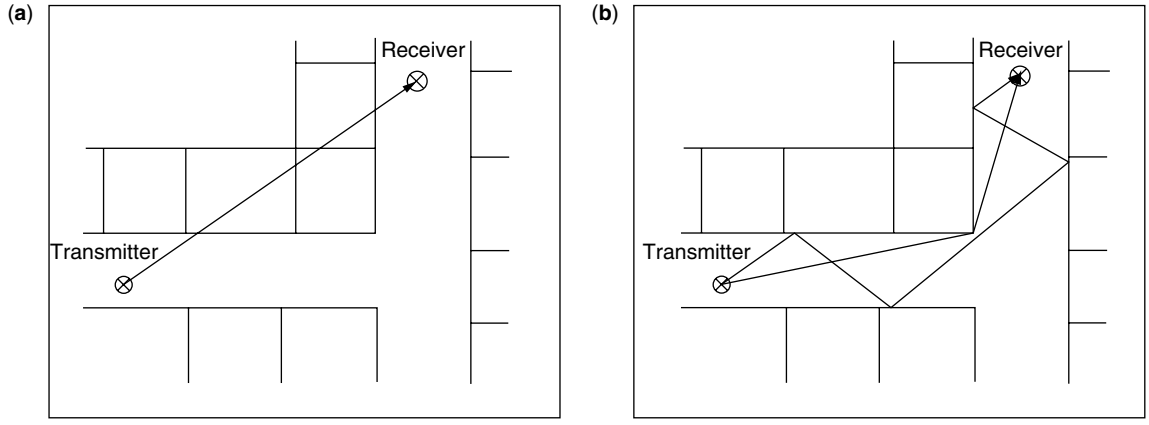

Figure 4. Basic approaches to the modeling of indoor propagation: (**a**) empirical models; (**b**) deterministic models.

introduction of the default loss L_0 (including the antenna gains) at distance d_0, Eq. (2) can be simplified to

$$L_{FS} = L_0 + 2 \cdot 10 \log\left(\frac{d}{d_0}\right) \tag{3}$$

2.1.2. One-Slope Model. The one-slope model analyses the building concerning distances between walls and penetration losses of the walls, but the individual positions of the walls and their material properties are not considered (see Fig. 5). Therefore this model computes the path loss L_{OS} (in dB) similar to the free space loss with adaptable power decay factor n and offset L_0.

$$L_{OS} = L_0 + n \cdot 10 \log\left(\frac{d}{d_0}\right) \tag{4}$$

The walls of the building are not taken into account by the one-slope model; thus no building database is required. With constant values for n and L_0 for every receiver location the prediction leads to path loss values increasing in concentric circles around the transmitter. Consequently, the prediction results are fairly inaccurate and suited only for a rough estimation. For line-of-sight the values of n are in the range between 1.4 and 1.8; in non-line-of-sight scenarios values up to 5.0 are possible [1,2].

2.1.3. Motley–Keenan Model. The model according to Motley and Keenan [8] computes the path loss L_{MK} based on the direct path between transmitter and receiver. In contrast to the one-slope model, in this model the exact locations of the walls, floors, and ceilings are considered. Additional factors for the attenuation of the direct path by partitions account for the shadowing effects.

$$L_{MK} = L_{FS} + k \cdot L_W \tag{5}$$

As shown in Fig. 6, parameter k describes the number of walls intersected by the direct path between transmitter and receiver. A uniform penetration loss L_W (in dB) of all partitions is taken for the computation (see Table 2); thus the individual material properties of the different walls are not considered. This uniform penetration loss as well

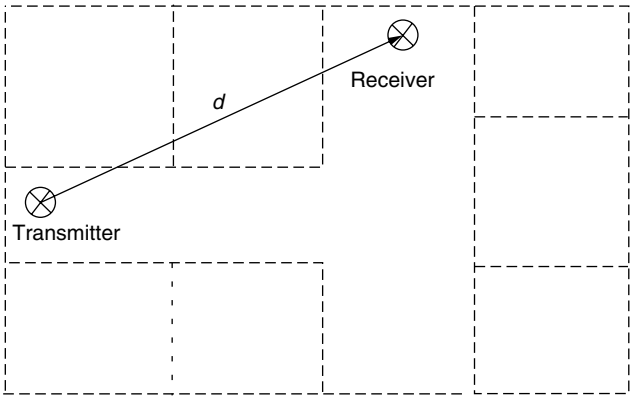

Figure 5. Principle of the one-slope model.

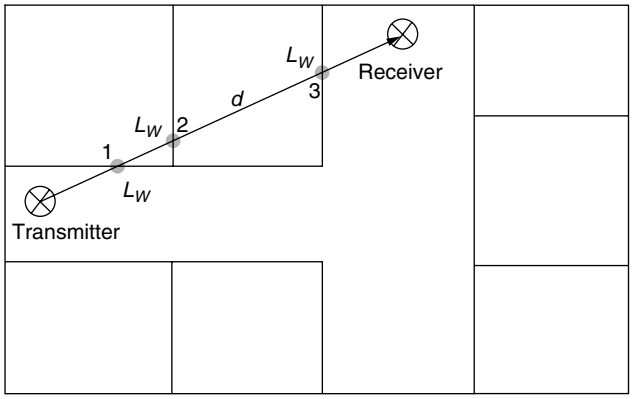

Figure 6. Principle of the Motley–Keenan model.

as the default loss L_0 which is part of the free-space path loss L_{FS} can be calibrated by measurements.

2.1.4. Multiwall Model. The multiwall model [1] gives the path loss L_{MW} as the free-space loss added to losses introduced by the walls and floors penetrated by the direct path between transmitter and receiver (see Fig. 6). In contrast to the Motley–Keenan model, for the multiwall model, individual penetration losses of the walls (depending on their electrical characteristics) are considered for the prediction of the path loss. It has been observed that the total floor loss is a nonlinear function of the number of floors penetrated. This effect is taken into account by introducing an empirical factor b. Hence the multiwall model can be expressed as follows:

$$L_{MW} = L_{FS} + \sum_{i=1}^{N} k_{Wi} \cdot L_{Wi} + k_f^{[(k_f+2)/(k_f+1)-b]} \cdot L_f \tag{6}$$

where k_{Wi} represents the number of penetrated walls of type i and k_f the number of penetrated floors. The parameter L_{Wi} describes the penetration loss of wall type i and L_f the loss between adjacent floors, and N denotes the number of different wall types.

The default loss L_0 as a part of the free-space path loss L_{FS} may be calibrated according to measurement results by evaluating a multiple linear regression technique. It is important to note that the loss factors in the Eq. (6) do not represent physical wall losses but model coefficients that are optimized by the measured path-loss data. Consequently, the loss factors implicitly include the effect of furniture. However, hard partitions such as concrete walls are overemphasized, which leads to pessimistic values of predicted field strength behind these elements as indicated in Fig. 7. Additionally, waveguiding effects are not taken into account within this model; thus its accuracy is only moderate. Nevertheless, this more refined empirical narrowband model has a low dependency on database accuracy and, because of the simple approach, a very short computation time (in the order of seconds).

Within the European cooperation of COST 231, measurements in different environments from several institutions have been evaluated [1] in order to optimize the coefficients of the empirical narrowband models (as given

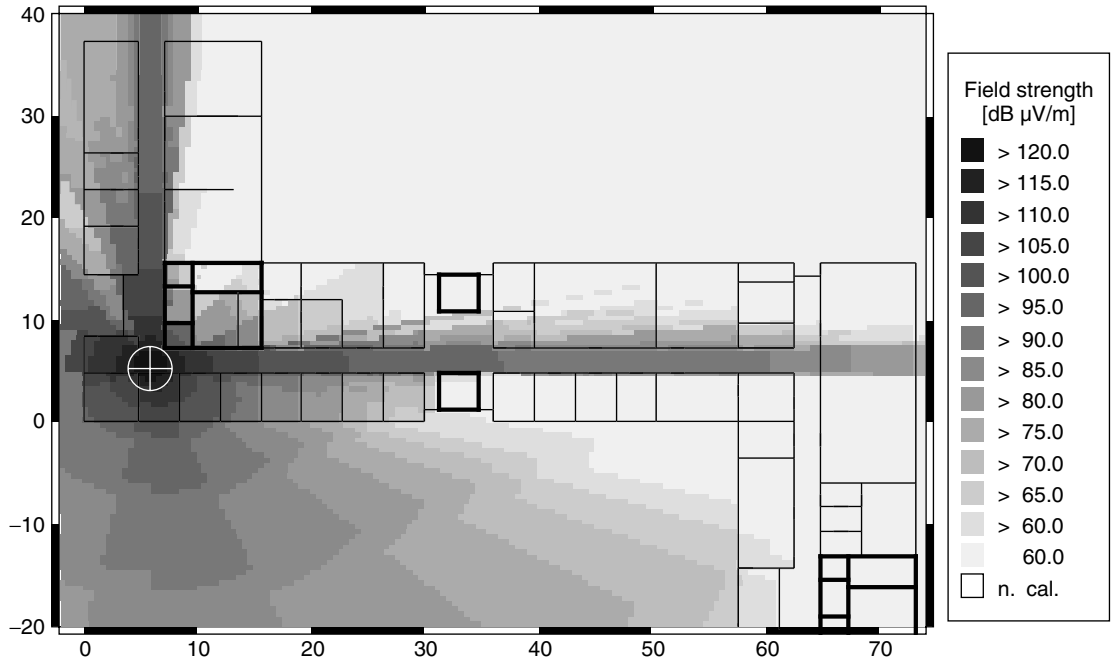

Figure 7. Prediction of the field strength by evaluating the multiwall model at 1800 MHz for a transmitter with 100 mW and omnidirectional Tx-antenna pattern.

Table 3. Investigated Coefficients at 1800 MHz for Empirical Narrowband Models [1]

	One-Slope Model		Multiwall Model			
Environment	L_0 (dB)	n	L_{W1} (dB)	L_{W2} (dB)	L_f (dB)	b
Corridor	39.2	1.4	3.4	6.9	18.3	0.46
Dense						
One floor	33.3	4.0	3.4	6.9	18.3	0.46
Two floors	21.9	5.2				
Multifloor	44.9	5.4				
Open	42.7	1.9	3.4	6.9	18.3	0.46
Large	37.5	2.0	3.4	6.9	18.3	0.46

in Table 3). For the multiwall model two different wall types have been taken into account corresponding to the previous distinction between hard and soft partitions. The coefficients of the multiwall model have been optimized for the category "dense." However, these values can also be utilized within other environments, leading to results close to the free-space model. According to measurements at 900 MHz, the values of the multiwall model should be reduced by 1.5 dB for the soft partition loss and by 3.5 dB for the floor loss. Concerning the one-slope model, the default loss L_0 should be reduced about 10 dB, while the values for the decay index remain constant.

2.2. Empirical Wideband Models

Beyond the planning and deployment of wireless communication networks, propagation models are also utilized for studying and evaluating new radio systems. The propagation models provide a valuable input for so-called channel models. These models reproduce the behavior of the radio channel in order to estimate the performance and the capacity of different system implementations concerning access, modulation, or coding schemes.

Empirical wideband models provide average impulse responses and power delay profiles (PDP) for this purpose. This kind of data can be derived from wideband measurements (e.g., channel sounder or network analyzer) as well as from deterministic propagation models. On the basis of wideband measurements, the delay spread values as given in Table 1 have been determined [1], indicating lowest values in dense environments and increasing values in open and large environments.

Impulse response models are usually defined as tapped delay lines, including a limited number of paths with individual amplitude and delay (both referred to the dominant path). The ITU channel models [9] as given in Table 4 contain six different paths and describe typical impulse responses for large office buildings with an open layout and a Tx-Rx separation less than 100 m. While the tap delay-line models represent typical impulse responses for unlimited bandwidth, the power delay

Table 4. Impulse Response Model for Indoor Office Environments [9]

	Channel A			Channel B		
	Delay Spread = 35 ns			Delay Spread = 100 ns		
Tap #	Delay (ns)	Loss (dB)	Doppler Spectrum	Delay (ns)	Loss (dB)	Doppler Spectrum
1	0	0.0	Flat	0	0.0	Flat
2	50	−3.0	Flat	100	−3.6	Flat
3	110	−10.0	Flat	200	−7.2	Flat
4	170	−18.0	Flat	300	−10.8	Flat
5	290	−26.0	Flat	500	−18.0	Flat
6	310	−32.0	Flat	700	−25.2	Flat

profiles characterize the radio channel with respect to the limited bandwidth of a specific radio system. Typical averaged power delay profiles within buildings show a logarithmic (for LoS and OLoS conditions) to linear (for NLoS conditions) decay on dB scale depending on the specific environment [1].

Because of the slow movements of indoor terminals (in most cases they are more portable than mobile) the Doppler spectrum has maximal values of about 10 Hz for frequencies utilized within personal communication systems (about 2 GHz). For simplicity a flat spectrum is often considered (see Table 4).

2.3. Deterministic Models

Deterministic models utilize physical phenomena in order to describe the propagation of radiowaves. Here, the effect of the actual environment is taken into account more accurately than within empirical models.

2.3.1. Basic Mechanisms. The mobile radio channel in indoor environments is characterized by multipath propagation (see Fig. 1). Dominant propagation phenomena in these scenarios are reflection, transmission, diffraction, and scattering. Because of the multiple reflections, waveguiding in corridors can be observed. Deterministic propagation models are generally based on ray optical techniques. With such an approach it is possible to consider the abovementioned effects as well as the multipath situation within the propagation model (as indicated in Fig. 4). The ray optical models determine all relevant rays between the transmitter and the receiver. Calibration of the deterministic models is not necessary because the predicted values are computed with the Fresnel equations for reflection and transmission and with the universal theory of diffraction (UTD) for diffracted rays [10]. Alternatively, there are empirical equations available for the calculation of the reflection, diffraction, and transmission loss [11].

2.3.1.1. Reflection and Transmission. When an electromagnetic wave propagating in one medium impinges on another medium with different electrical properties, the wave is partially reflected and partially penetrates the medium. Although this phenomenon is valid for the incidence on a perfect dielectric, all the incident energy is reflected back to the first medium if the second medium is a perfect conductor. If there is a smooth boundary between the two materials, the impinging wave is reflected specularly. Concerning the penetration of a dielectric plate, the direction of the penetrated radiowave corresponds to the incident direction if there is the same medium in front of and behind the dielectric plate. The electric field intensities of the reflected and transmitted waves are related to the incident wave through a reflection coefficient. The most common mathematical description of the reflection is the Fresnel reflection coefficient, which is valid for an infinite boundary between two media. The coefficients for reflection and transmission are a function of the material properties, and generally depend on the polarization and the angle of incidence of the propagating wave [10].

2.3.1.2. Diffraction. The diffraction process in ray modeling is the *propagation phenomenon*, which explains the transition from the lit region to the shadowed regions behind obstacles. Although the electrical field strength decreases as a receiver moves deeper into the shadowed region, the diffraction field still exists and often has enough strength to guarantee a sufficient signal. According to the principle of Huygens, the diffraction field is the vector sum of the electric field components of all secondary wavelets in the space around the obstacle. Diffraction by a single wedge can be solved in various ways: empirical formulas, perfectly absorbing wedge, geometric theory of diffraction (GTD) or universal theory of diffraction (UTD) [10]. The advantages and disadvantages of using either of these formulations is difficult to address since it may not be independent of the investigated environments. Indeed, reasonable results are possible with each formulation. The various expressions differ mainly in the approximations being made on the surface boundaries of the wedge considered. However, diffraction around a corner is commonly modeled using the heuristic UTD formulas since they behave well in the lit/shadow transition region and account for the polarization of the incident wave as well as the wedge material. Generally, the wedge diffraction coefficient is inversely proportional to the square root of the frequency, specifically, the coefficient decreases with increasing frequency. Therefore the effect of diffraction can be neglected for millimeter waves ($f > 30$ GHz).

2.3.1.3. Scattering. Rough surfaces and finite surfaces (i.e., surfaces with small extensions in comparison to the wavelength) scatter the incident energy in all directions according to a radiation pattern which depends on the roughness and size of the surface or volume. The dispersion of energy through scattering means a decrease of the energy reflected in specular direction, which can be

taken into account by reducing the reflection coefficient. The consideration of the true dispersion of radio energy in various directions is much more difficult and may be described by radar cross-sectional models. Surface roughness is often tested using the Rayleigh criterion, which defines a critical height of surface protuberances for a given angle of incidence [10].

2.3.2. Path Finding. For the determination of valid rays between transmitter and receiver, which is the most time-consuming part of the ray optical approach, two different principles can be utilized: ray launching and ray tracing.

2.3.2.1. Ray Launching. This approach launches rays in discrete angular increments from the transmitter and determines their path through the database (as indicated in Fig. 8). If there is an intersection between the ray and a wall, the ray is split into a penetrating and a reflecting part and both rays are further launched independently from each other. When the ray impinges on a wedge, new rays are launched on the diffraction cone, which leads to multiple rays. Every time when a ray intersects the prediction plane, the field strength of this ray is added to the already computed field strength at the specific receiver point. The consideration of the path ends if the number of interactions is higher than a given number or if the field strength at the end of the ray is smaller than a given threshold. In order to keep the resolution of the rays independent of the distance to the transmitter, a splitting algorithm may be introduced (ray splitting).

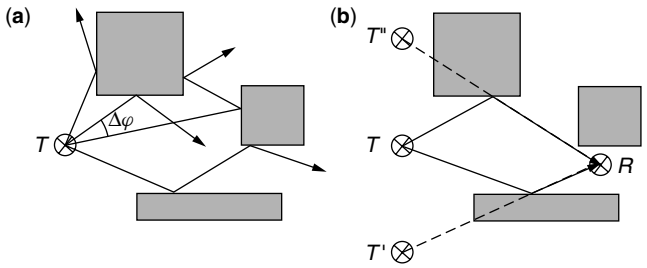

Figure 8. Algorithms for path finding: (**a**) ray launching; (**b**) ray tracing.

2.3.2.2. Ray Tracing (Ray Imaging). The ray tracing algorithm determines valid rays between the transmitter and a given receiver point (as indicated in Fig. 8). For coverage predictions the receiver has to be assigned subsequently to all pixels in the prediction area. Obviously the computation time increases linearly with the number of receiver points and shows an exponential dependence on the number of walls and the number of interactions, respectively. In comparison to the ray launching there is a higher computational effort, but on the other hand, ray tracing obtains a constant resolution and a high degree of accuracy.

Figure 9 shows a prediction with a rigorous 3D ray tracing for the situation already presented in Fig. 7. The differences between empirical and ray optical predictions are obvious especially the waveguiding in corridors due to multiple reflections, the coupling of the waves into the rooms and the diffraction around corners are responsible for the high accuracy of the ray optical models.

2.3.3. Advanced Ray Optical Model Based on Database Preprocessing. The main disadvantage of the deterministic prediction models is their excessive computation time (in the order of hours). Different authors presented ideas to accelerate the path finding, and some of the methods lead to considerable acceleration factors. A further disadvantage of the ray optical propagation models is the abovementioned dependence on the accuracy of the database, in which even small errors in the positions and

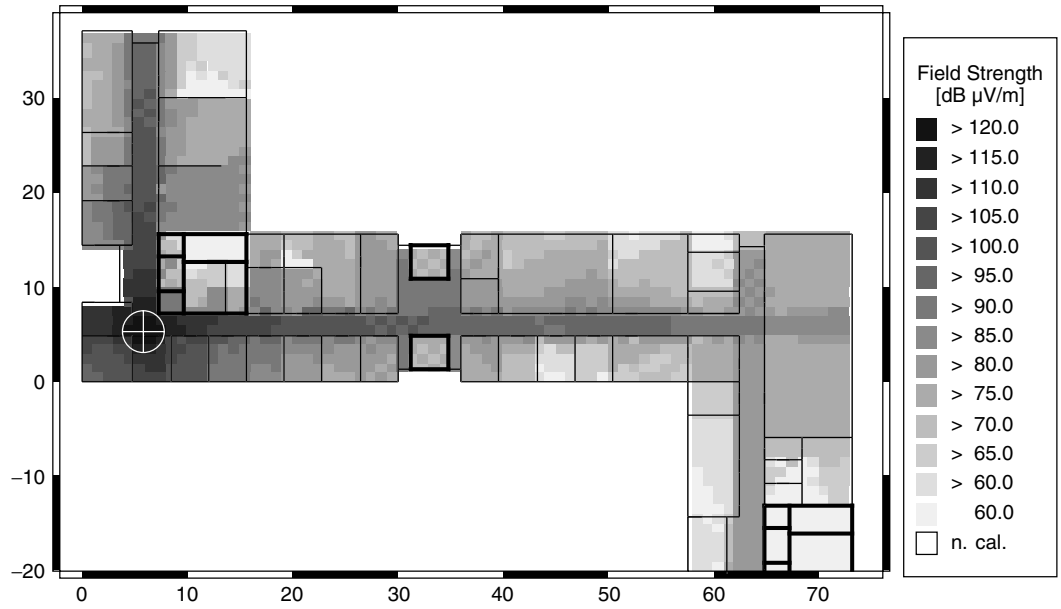

Figure 9. Prediction of the field strength by evaluating the 3D ray tracing at 1800 MHz for a transmitter with 100 mW and omnidirectional Tx-antenna pattern.

materials of the walls or missing parts (e.g., furniture) influence the predicted results. The advanced model [11] presented in this section neglects these disadvantages and is therefore well suited for the planning and deployment of indoor wireless communication networks.

One major application of propagation models is to evaluate the degree of coverage that can be achieved in a radio cell depending on the position of the base station. While the database of the building in question remains the same and only the position of the transmitter changes, the overwhelming part of the different rays remains unchanged; only the rays between the transmitting antenna and primary obstacles or receiving points in line of sight change.

This is the basis for "intelligent database preprocessing." In a first step the walls of the building (or other obstacles) are divided into tiles (reflections and penetrations) and the edges (diffractions) into horizontal and vertical segments. After this, the visibility conditions between these different elements (possible rays) are determined and stored in a file. Figure 10 shows the visibility relation between a central tile and a receiving point. The result of this preprocessing can be represented in the shape of a "visibility tree" as shown in Fig. 11. For a different transmitter location only the uppermost branches in this tree must be computed again. Consequently, all branches below the first interaction layer have to be computed only once, which can be done prior to optimizing the location of the transmitter. The remaining computation time after the preprocessing is many orders of magnitude lower than that needed for the conventional analysis without preprocessing. As a consequence, 3D deterministic models, with their supreme accuracy, can be utilized for all practical applications with computation times in the order of those found with empirical models.

When analyzing rays that contribute to the field strength at the receiving point of a typical indoor situation (as given in Fig. 1), it is obvious that a number of different rays reach the receiver after passing the same sequence of rooms and penetrating the same walls. These rays can be summarized into several dominant paths, each of them characterizing the propagation of a bundle of waves [12]. There is generally more than one dominant path between transmitter and receiver. Figure 12 shows dominant paths for the scenario depicted in Fig. 1. The dominant paths can be deduced using simple algorithms that consider the arrangement of the rooms within the building relative to the transmitter and the receiver [12].

3. PLANNING TOOLS

With the increasing computational and visualization capabilities of computers, new methods for predicting radio signal coverage have been established, which are based on site specific propagation models and building databases as described in Section 1.4. As planning tools become prevalent, wireless system designers will be able to design and deploy indoor wireless networks for covering the buildings adequately without performing extensive radio measurements. Generally, indoor planning tools support graphical user interfaces in order to generate and visualize building databases, including

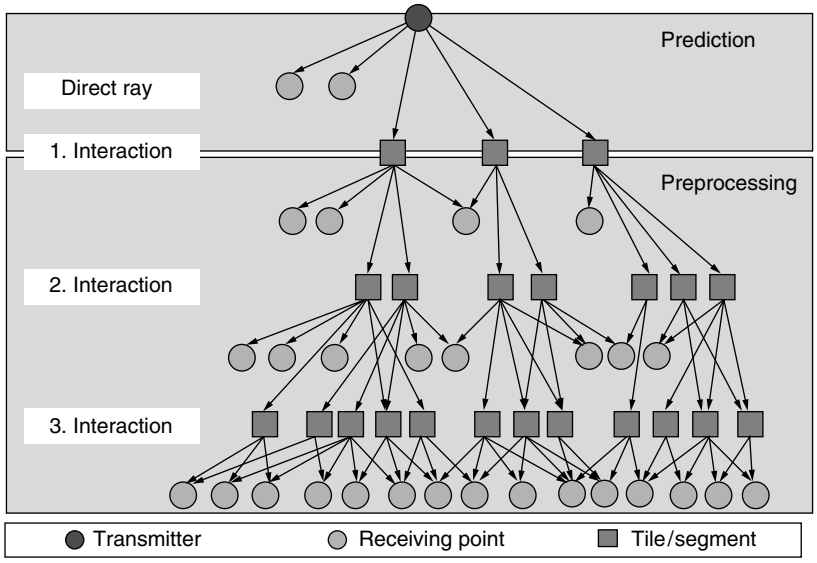

Figure 11. Tree structure of the visibility relations.

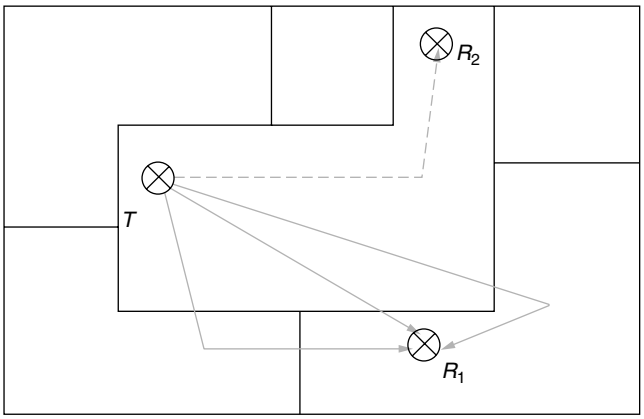

Figure 12. Dominant paths concept.

the material properties as well as to define the characteristics of transmitters and receivers (e.g., antenna patterns). Beyond this, most planning tools provide deterministic and empirical propagation models (as presented in Section 2) for predicting the large-scale path loss in a wide range of building structures and capabilities to visualize and analyze the corresponding results [5,6].

BIOGRAPHIES

Friedrich M. Landstorfer received a Dipl.-Ing. degree in 1964 and a Dr.-Ing. degree in 1967 in electrical engineering from the Technical University of Munich, Germany. In 1971 he became lecturer at the same institution and professor in 1976. In 1986, he moved to Stuttgart to become professor and head of the RF-Institute at the University of Stuttgart, Germany. His research interests include antennas, microwaves, electromagnetic theory, wave propagation in connection with mobile communications, navigation, and electromagnetic compatibility. He received the award of the NTG (Nachrichtentechnische Gesellschaft in VDE, now ITG) in 1977 for the optimization of wire antennas and was chairman of the 21st European Microwave Conference in Stuttgart in 1991. Professor Landstorfer is a member of URSI, was awarded honorary professor of Jiaotong University in Chengdu, China, in 1993, and became fellow of the IEEE in 1995.

Gerd Woelfle received his Dipl.-Ing. and Ph.D. degrees in electrical engineering from the University of Stuttgart, Germany, in 1994 and 1999, respectively. In his Ph.D. thesis he analyzed the indoor multipath propagation channel and developed adaptive models for indoor propagation. In 1999, he joined AWE Communications as a R&D Engineer, where he has been working on propagation models for wireless communication networks. Dr. Woelfle has received several best paper awards on wireless communication conferences. His areas of interest are empirical and deterministic propagation models, network planning tools, and channel modeling. Since 1999, he has been a lecturer for mobile communications at the University of Stuttgart.

Reiner A. Hoppe received his Dipl.-Ing. degree in electrical engineering in 1997 from the University of Stuttgart, Germany. Since this time, he has been a research scientist at the Institute of Radio Frequency Technology (University of Stuttgart), where he is working towards his Ph.D. degree. His research interests include wave propagation modeling and radio network planning especially within urban and indoor scenarios.

PULSE AMPLITUDE MODULATION

BJØRN A. BJERKE
Qualcomm, Inc.
Concord, Massachusetts

1. INTRODUCTION

Pulse amplitude modulation (PAM) is a modulation method used in digital communication systems to facilitate

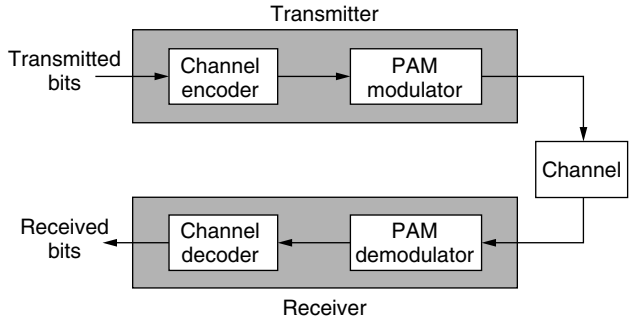

Figure 1. The basic elements of a digital communication system that uses pulse amplitude modulation.

transmission of digital information from a source (the transmitter) to a destination (the receiver). In such systems, the digital information is represented by a sequence of binary digits, or bits. Figure 1 shows the basic elements of a communication system that uses PAM. The transmitter consists of two blocks, namely, a channel encoder and a digital modulator. The channel encoder adds redundancy in a controlled manner to the transmitted bits in order to enable detection and possibly also correction of bit errors. Such errors may occur as a result of disturbances in the transmission system.

The output sequence from the encoder is passed to the PAM modulator, which transforms the discrete-time sequence into a signal that conforms to the limitations of the transmission channel. The channel is the physical medium through which transmissions occur. Most channels are analog in nature, so the modulator outputs analog waveforms that correspond to the particular coded sequence. The physical channel can, for example, be a cable, an optical fiber, or a wireless radio channel. In each of these channels, the signal is affected by disturbances such as thermal noise and interference from various sources. These disturbances corrupt the signal in a number of ways that ultimately may lead to bit errors at the receiver.

The role of the PAM demodulator is to recover the sequence of coded information bits from the corrupted received signal. In so doing, the demodulator often must compensate for the various channel disturbances. Finally, the coded sequence is passed to the channel decoder. Using knowledge of the channel code and the redundancy contained in the received sequence, the decoder attempts to reconstruct the original information bit sequence with as few bit errors as possible.

In this article, we shall concentrate on the modulator/demodulator pair, commonly referred to as the *modem*. The remainder of the article is organized into three sections, each dealing with different aspects of PAM. First, in Section 2, we introduce a convenient mathematical representation of PAM signals. This representation is used in the subsequent sections where we investigate the properties and characteristics of such signals. In Section 3, we discuss the spectral characteristics of PAM signals, and, finally, in Section 4, we discuss the various aspects of signal demodulation and detection, including carrier recovery and symbol synchronization.

2. PAM SIGNAL REPRESENTATION

Many digital communication systems are *bandpass* systems, where the digital information is transmitted over the communication channel by means of carrier modulation. At the transmitter, the information-bearing *lowpass* signal is impressed on the carrier signal by the modulator, thus translating the information signal from *baseband* frequencies to the carrier frequency. At the receiver, the demodulator performs the reverse process of recovering the digital lowpass signal from the modulated carrier, translating the signal from the frequency band of the carrier down to baseband. When representing bandpass signals mathematically, it is often convenient to reduce them to equivalent lowpass signals so that they may be characterized independently of the particular carrier frequency or frequency band in use.

A bandpass signal may be represented as

$$s(t) = \mathrm{Re}\{x(t)e^{j2\pi f_c t}\} \tag{1}$$

where $\mathrm{Re}\{\cdot\}$ denotes the real part of a complex-valued quantity and $x(t)$ is the equivalent lowpass signal that is impressed on the carrier signal with center frequency f_c. In general, $x(t)$ is a complex-valued signal and it is often referred to as the *complex envelope* of the real signal $s(t)$, but in PAM the lowpass signal is real-valued.

A PAM modulator maps digital information (bits) into analog, finite energy waveforms that differ only in amplitude. The mapping is usually performed by taking groups of k bits at a time and selecting one out of a total of $M = 2^k$ possible such waveforms for transmission over the channel. The signal waveforms may be represented as

$$s_m(t) = \mathrm{Re}\{A_m g(t)e^{j2\pi f_c t}\} = A_m g(t)\cos 2\pi f_c t,$$
$$m = 1, 2, \ldots, M, \quad 0 \le t \le T \tag{2}$$

where $\{A_m, m = 1, 2, \ldots, M\}$ denotes the set of M possible amplitudes, $g(t)$ is a real-valued signal pulse, and T is the duration of a symbol interval. The shape of $g(t)$ may be tailored to achieve a certain spectral shaping of the transmitted signal so that it matches the spectral characteristics of the channel.

The energy of the PAM signal is dependent on the energy in the signal pulse, and is given by

$$E_m = \int_0^T s_m^2(t)\,dt = \int_0^T \left[A_m g(t)\cos 2\pi f_c t\right]^2 dt$$
$$= A_m^2 \int_0^T g^2(t)\cos^2 2\pi f_c t\,dt = \frac{1}{2}A_m^2 E_g \tag{3}$$

where $E_g = \displaystyle\int_0^T g^2(t)\,dt$ denotes the signal pulse energy. When $g(t)$ has a rectangular shape, as shown in Fig. 2, the resulting modulation is also known as *amplitude shift keying* (ASK). In this case, the pulseshape is given as

$$g(t) = \begin{cases} a, & 0 \le t \le T \\ 0, & \text{otherwise} \end{cases} \tag{4}$$

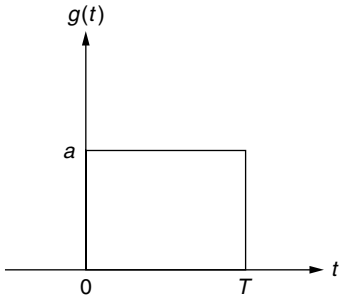

Figure 2. Rectangular signal pulse $g(t)$.

The reciprocal of the symbol interval, $R_s = 1/T$, is known as the symbol rate, namely, the rate at which the modulated carrier changes amplitude. The symbol rate is related to the bit rate $R_b = 1/T_b$ as

$$R_s = \frac{R_b}{k} \tag{5}$$

where k is the number of bits transmitted per symbol and T_b is the duration of a bit interval. The equivalent lowpass representation of the PAM waveform is real-valued and given by

$$x_m(t) = A_m g(t), \quad m = 1, 2, \ldots, M, \quad 0 \le t \le T \tag{6}$$

The signal amplitude can take on the discrete values

$$A_m = (2m - 1 - M)\, d, \quad m = 1, 2, \ldots, M \tag{7}$$

where $2d$ is the distance between adjacent signal amplitudes. Figure 3 illustrates the signal amplitude diagram for binary ($M = 2$) and quaternary ($M = 4$) PAM signals, respectively, as well as examples of possible bit mappings. In the examples shown in the figure, *Gray mapping* is used, where only a single bit differs in adjacent constellation points. Since the signal amplitudes are confined to the real line, we refer to these signals as *one-dimensional*.

Digital PAM may also be used in baseband transmission systems, that is, systems that do not require carrier modulation. In this case, the signals are represented by the equivalent lowpass formulation of Eq. (6). Figure 4 illustrates a four-level baseband PAM signal using rectangular signal pulses with amplitude $a = 1$.

3. SPECTRAL CHARACTERISTICS OF PAM

Now that we have introduced a mathematical representation of pulse-amplitude-modulated (PAM) signals, we are

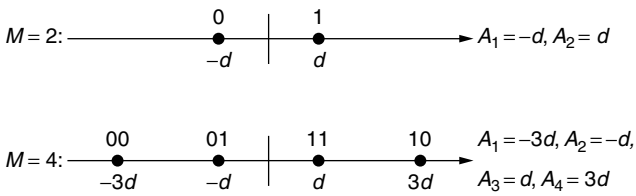

Figure 3. Signal amplitude diagram for binary and quaternary PAM signals.

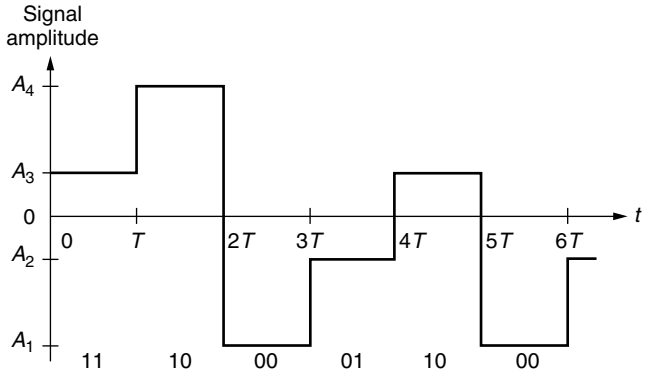

Figure 4. Four-level baseband PAM signal.

ready to discuss their spectral characteristics. Most transmission channels offer a limited bandwidth, due to either physical limitations or regulatory constraints. It is therefore important to determine the spectral content of PAM signals, or any modulated signals, for that matter, to make sure that the bandwidth of the signal does not exceed that of the channel. Also, since bandwidth is such a precious resource, it is important that it is utilized efficiently.

Let us again consider the bandpass signal $s(t)$ introduced in (1). The transmitted information sequence is a random sequence. Consequently, the corresponding PAM signal is a stochastic process whose spectral characteristics are described by its power density spectrum. The power density spectrum, denoted by $\Phi_{ss}(f)$, is obtained by Fourier transforming the autocorrelation function of $s(t)$, which is given by

$$\phi_{ss}(\tau) = \mathrm{Re}\{\phi_{xx}(\tau) e^{j2\pi f_c \tau}\} \tag{8}$$

The Fourier transformation results in

$$\Phi_{ss}(f) = \tfrac{1}{2}[\Phi_{xx}(f - f_c) + \Phi_{xx}(-f - f_c)] \tag{9}$$

where $\Phi_{xx}(f)$ is the power density spectrum of the lowpass equivalent signal $x(t)$. It is evident from (9) that in order to investigate the spectral characteristics of $s(t)$ it is sufficient to consider the power density spectrum of $x(t)$.

The lowpass signal has the general form

$$x(t) = \sum_{n=-\infty}^{\infty} A_n g(t - nT) \tag{10}$$

where the subscript n is a time index. The mean of $x(t)$ and its autocorrelation function are both periodic with period T. Hence, $x(t)$ is a *cyclostationary process*. The autocorrelation function averaged over a single period can be shown to be [1]

$$\overline{\phi}_{xx}(\tau) = \frac{1}{T} \sum_{m=-\infty}^{\infty} \phi_{AA}(m) \phi_{gg}(\tau - mT) \tag{11}$$

where $\phi_{AA}(m)$ is the autocorrelation of the information sequence represented by the amplitudes $\{A_n\}$, and $\phi_{gg}(\tau)$ is the autocorrelation function of the pulse $g(t)$, defined as

$$\phi_{gg}(\tau) = \int_{-\infty}^{\infty} g^*(t) g(t + \tau)\, dt \tag{12}$$

where $*$ denotes the complex conjugate. By taking the Fourier transform of (11), we obtain the power density spectrum

$$\Phi_{xx}(f) = \frac{1}{T}|G(f)|^2 \Phi_{AA}(f) \tag{13}$$

where $G(f)$ is the Fourier transform of $g(t)$ and $\Phi_{AA}(f)$ is the power density spectrum of the information sequence. From (13) we realize that the power density spectrum $\Phi_{xx}(f)$ depends directly on the spectral characteristics of both the information sequence $\{A_n\}$ and the pulse $g(t)$. Consequently, we may shape the spectral characteristics of the PAM signal by manipulating either the transmitter pulseshape or the correlation properties of the transmitted sequence. In the latter case, dependence between signals transmitted in different symbol intervals is introduced in a process known as *modulation coding*, resulting in a signal with memory. However, standard pulse amplitude modulation is a *memoryless* modulation since the mapping of bits into symbol waveforms is performed independently of any previously transmitted waveforms.

We shall assume here that the information symbols in the transmitted sequence are uncorrelated and have zero mean. In this case, the power density spectrum of the transmitted sequence is simply $\Phi_{AA}(f) = \sigma_A^2$. Thus, spectral shaping of the PAM signal is accomplished exclusively by selecting the pulseshape $g(t)$. Let us consider two examples that illustrate the spectral shaping that results from two different pulses. The first is the rectangular pulse introduced earlier in Fig. 2, which is used in amplitude shift keying. The energy density spectrum of the rectangular pulse, given as the square of the magnitude of the Fourier transform $G(f)$, is

$$|G(f)|^2 = (aT)^2 \left(\frac{\sin \pi f T}{\pi f T}\right)^2 \tag{14}$$

The energy spectrum is shown in Fig. 5. We note that the spectrum has a main lobe with a width of $2/T$ and zeros at $f = n/T$, $n = \pm 1, \pm 2, \ldots$. Its tail decays inversely as f^2. The resulting power density spectrum of the lowpass signal is given by
