$$\Phi_{xx}(f) = \sigma_A^2 a^2 T \left(\frac{\sin \pi f T}{\pi f T}\right)^2 \tag{15}$$

In the second example, the pulse is a *raised-cosine* pulse as shown in Fig. 6 and mathematically represented by

$$g(t) = \frac{a}{2}\left[1 + \cos \frac{2\pi}{T}\left(t - \frac{T}{2}\right)\right], \quad 0 \le t \le T. \tag{16}$$

The corresponding energy density spectrum is given by

$$|G(f)|^2 = \frac{(aT)^2}{4}\left(\frac{\sin \pi f T}{\pi f T(1 - f^2T^2)}\right)^2 \tag{17}$$

In this case, the main lobe has a width of $4/T$, which is twice the width of the main lobe of the rectangular pulse. Zeros occur at $f = n/T$, $n = \pm 2, \pm 3, \ldots$. However, the tails of the spectrum decay inversely as f^6, which means that the energy outside the main lobe is virtually zero. This is illustrated in Fig. 7, which shows a heavily magnified version of the energy density spectrum.

These two examples serve to illustrate how the spectral shape of the transmitted signal can be tailored to match the spectral characteristics of the channel. The raised-cosine pulse requires a greater bandwidth, but in return the out-of-band energy is much lower than with the rectangular pulse.

4. DEMODULATION AND DETECTION OF PAM SIGNALS

In this section, we describe the various elements of the optimal receiver for PAM signals transmitted over the additive white Gaussian noise (AWGN) channel. Furthermore, we evaluate the performance of this receiver in terms of the symbol error and bit error probabilities. The AWGN channel is the most benign of channels, and the performance that can be achieved on this channel is

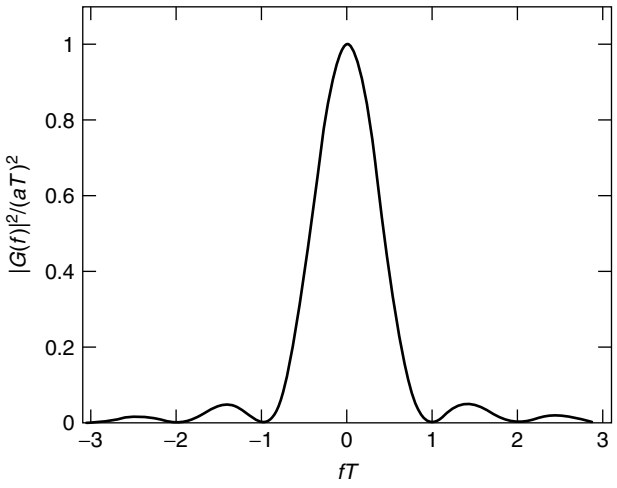

Figure 5. Energy density spectrum $|G(f)|^2$ for a rectangular pulse.

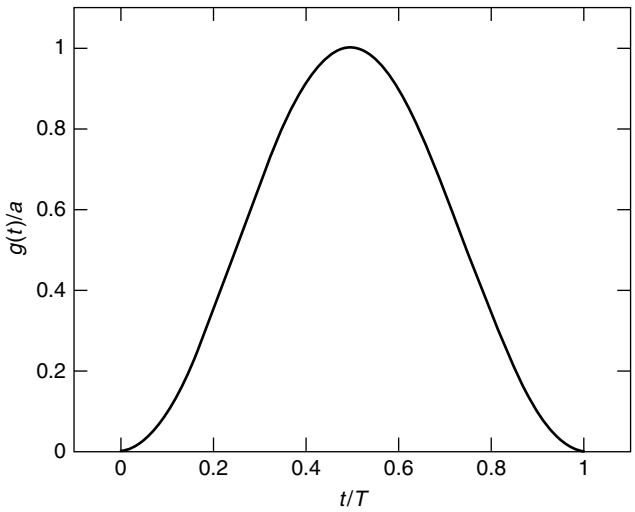

Figure 6. Raised-cosine pulse.

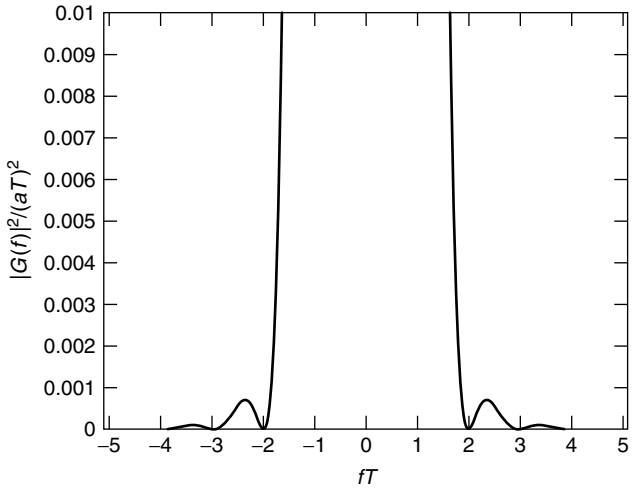

Figure 7. Energy density spectrum $|G(f)|^2$ for a raised-cosine pulse.

often used as a benchmark for evaluating a particular modulation scheme and receiver structure on other types of channels (e.g., fading channels, multipath channels, and channels with various kinds of interference). At the end of this section, we discuss carrier-phase recovery and symbol synchronization for PAM signals.

Let us first consider the input to the receiver, that is, the received signal, which consists of the original transmitted signal as well as white Gaussian noise. As described earlier, in each signaling interval the transmitted signal consists of one of M possible signal waveforms $\{s_m(t), m = 1, 2, \ldots, M\}$. The received signal can therefore be represented as

$$r(t) = s_m(t) + n(t), \quad 0 \le t \le T \tag{18}$$

where $n(t)$ is a sample function of the stochastic AWGN process with power spectral density $N_0/2$. At this point it is useful to introduce the concept of *signal space*. Signal waveforms can be given an equivalent vector representation, where, in general, the M finite energy waveforms are represented by weighted linear combinations of $N \le M$ orthonormal functions $f_n(t)$. Thus, any signal can be represented as a point in the N-dimensional signal space spanned by the basis functions $\{f_n(t), n = 1, 2, \ldots, N\}$. The *Euclidean distance* between these points is a measure of the similarity of the signal waveforms, and consequently dictates how well the receiver will be able to determine which waveform was transmitted. As noted earlier, PAM signals are one-dimensional ($N = 1$) and can therefore be represented simply by the general form

$$s_m(t) = s_m f(t) \tag{19}$$

where the basis function $f(t)$ is defined as the unit energy signal waveform

$$f(t) = \sqrt{\frac{2}{E_g}}\, g(t) \cos 2\pi f_c t \tag{20}$$

and s_m is a point on the real line given as

$$s_m = A_m \sqrt{\frac{E_g}{2}}, \quad m = 1, 2, \ldots, M \tag{21}$$

The Euclidean distance between any pair of signal points is

$$d_{lk} = \sqrt{(s_l - s_k)^2} = d\sqrt{2E_g}\,|l - k|, \quad l, k = 1, 2, \ldots, M, l \ne k \tag{22}$$

where $2d$ is the distance between adjacent signal amplitudes, as defined earlier. The distance between a pair of adjacent signal points is known as the minimum Euclidean distance, and is given by $d_{\min} = d\sqrt{2E_g}$.

A block diagram of an M-ary PAM receiver is shown in Fig. 8. The receiver consists of a demodulator and a detector as well as circuits for carrier recovery and symbol synchronization. The task of the demodulator is to compute the projection r of the received waveform $r(t)$ onto the basis function spanning the one-dimensional signal space. Based on r, the detector then decides which one of the M possible waveforms was transmitted. Since we assume a memoryless modulated signal, the detector can make its decisions separately for each signaling interval. In

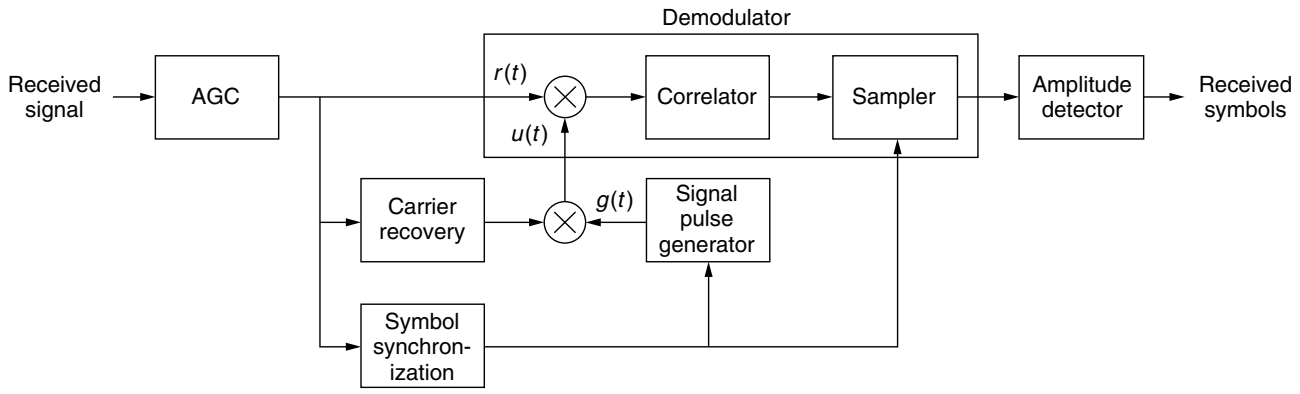

Figure 8. Block diagram of M-ary PAM receiver.

order to perform these tasks, the demodulator output must be sampled periodically, once per symbol interval. Symbol synchronization is therefore required and must be established before demodulation and detection can be performed. Because of the unknown propagation delay from the transmitter to the receiver, the symbol timing must be extracted from the received signal. Carrier-phase offset is another consequence of the unknown propagation delay. In the case of *phase-coherent detection*, this offset must be estimated, and this is the task of the carrier-phase recovery circuit. In the subsequent sections, we examine in more detail the functions of signal demodulation, signal detection, carrier recovery, and symbol synchronization.

4.1. Signal Demodulator

Let us first assume that the carrier phase has been accurately estimated and symbol synchronization has been properly established. The demodulator computes the projection of the received waveform onto the signal space by passing the received signal $r(t)$ through a *correlator*, as shown in Fig. 8. The result of this projection is

$$r = \int_0^T r(t)f(t)\,dt = s_m + n \tag{23}$$

where

$$s_m = \int_0^T s_m(t)f(t)\,dt \tag{24}$$

and n is the projection of the noise onto the signal space, given as the zero-mean random variable

$$n = \int_0^T n(t)f(t)\,dt \tag{25}$$

with variance $\sigma_n^2 = N_0/2$. The correlator output is a Gaussian random variable with mean $\mathrm{E}[r] = s_m$ and variance equal to the noise variance, i.e., $\sigma_r^2 = \sigma_n^2 = N_0/2$. Thus, the probability density function of r, conditional on the mth signal waveform being transmitted, is the Gaussian *likelihood function* given by

$$p(r|s_m) = \frac{1}{\sqrt{\pi N_0}} \exp\left[-\frac{(r-s_m)^2}{N_0}\right] \tag{26}$$

Instead of using a correlator for signal demodulation, a *matched filter* may be used in its place. In general, the matched filter is a bank of N filters whose impulse responses are matched to the N basis functions $\{f_n(t)\}$. In our case, where $N = 1$, the impulse response of the single filter is given by

$$h(t) = f(T-t), \quad 0 \le t \le T \tag{27}$$

The output of the matched filter is

$$\begin{aligned} y(t) &= \int_0^t r(\tau)h(t-\tau)\,d\tau \\ &= \int_0^t r(\tau)f(T-t+\tau)\,d\tau \end{aligned} \tag{28}$$

Sampling this output at $t = T$ yields

$$y(T) = \int_0^T r(\tau)f(\tau)\,d\tau = r \tag{29}$$

which is identical to the output of the correlator. An important property of the matched filter is that it maximizes the output signal-to-noise ratio (SNR) in an AWGN channel. The output SNR is given by

$$\mathrm{SNR}_{\mathrm{out}} = \frac{(\mathrm{E}[r])^2}{\sigma_n^2} \tag{30}$$

4.2. Signal Detector

The correlator (or matched-filter) output contains all the relevant information, namely, the *sufficient statistic*, about the transmitted signal that the detector needs in order to make a decision, assuming that the carrier phase is known at the receiver and symbol synchronization has been established. The detector applies a decision rule that seeks to maximize the probability of a correct decision. More specifically, it decides in favor of the signal which has the maximum a posteriori probability

$$\Pr\{s_m|r\}, \quad m = 1, 2, \ldots, M \tag{31}$$

of the M possible transmitted signals. This decision rule is known as the *maximum a posteriori probability* (MAP) criterion. The a posteriori probabilities can be expressed as

$$\Pr\{s_m|r\} = \frac{p(r|s_m)\Pr\{s_m\}}{p(r)} \tag{32}$$

where $p(r|s_m)$ was given in (26) and $\Pr\{s_m\}$ is the a priori probability that the mth signal will be transmitted. The denominator is independent of which signal is transmitted. When all the M transmitted signals are equally likely, the MAP criterion is reduced to maximizing the likelihood function (26) over the M possible signals, and this is called the *maximum-likelihood* (ML) criterion. For ease of computation, it is common to use the *loglikelihood function* given by

$$\ln p(r|s_m) = -\frac{1}{2}\ln(\pi N_0) - \frac{1}{N_0}(r-s_m)^2 \tag{33}$$

Maximizing (33) is equivalent to finding the signal that minimizes the Euclidean distance metric

$$d(r, s_m) = (r-s_m)^2 \tag{34}$$

In our case, the detector is an amplitude detector, as shown in Fig. 8. An *automatic gain control* (AGC) circuit [2] is added to the front end of the receiver to eliminate short-term channel gain variations that would otherwise affect the amplitude detector. The AGC maintains a fixed average SNR at its output.

4.3. Detector Performance

Armed with the knowledge gained in the previous two sections, we may evaluate the performance of the optimal

receiver for M-ary PAM signals in terms of the symbol error and bit error probabilities. As before, we assume equally probable transmitted signals. First we need to define some quantities that we will use in our calculations. The average energy of the transmitted signals, using the representations given in (3) and (7), is

$$E_{\text{av}} = \frac{1}{M}\sum_{m=1}^{M} E_m = \frac{d^2 E_g}{2M}\sum_{m=1}^{M}(2m-1-M)^2 = \frac{1}{6}(M^2-1)d^2 E_g \tag{35}$$

The average power is given as $P_{\text{av}} = E_{\text{av}}/T$, and the average energy per transmitted bit is $E_b = P_{\text{av}} T_b$.

Now let us consider the Euclidean distance metric given by (34). The detector compares the projection r with all the M signal candidates and decides in favor of the signal with the smallest metric. Equivalently, the detector compares r with a set of $M-1$ thresholds located at the midpoints between adjacent signal amplitude levels. A decision is made in favor of the level that is closer to r. An erroneous decision will occur if the magnitude of the noise is significant enough to make r extend into one of the two regions belonging to the neighboring amplitude levels. This is true for all but the two outermost levels $\pm(M-1)$, where an error can be made in only one direction. Hence, the average probability of a symbol error, P_M, is equal to the probability that the noise component $n = r - s_m$ exceeds one-half of the distance between two thresholds, $d_{\min}/2$:

$$P_M = \frac{M-1}{M}\Pr\left\{|n| > \frac{d_{\min}}{2}\right\} = \frac{2(M-1)}{M}\Pr\left\{n > \frac{d_{\min}}{2}\right\} \tag{36}$$

where

$$\Pr\left\{n > \frac{d_{\min}}{2}\right\} = \frac{1}{\sqrt{\pi N_0}}\int_{d_{\min}/2}^{\infty} e^{-x^2/N_0}\,dx \tag{37}$$

It is straightforward to show that the symbol error probability is equal to

$$P_M = \frac{2(M-1)}{M} Q\left(\sqrt{\frac{d_{\min}^2}{2N_0}}\right) \tag{38}$$

where $Q(\cdot)$ is the standard error function [1]. It is customary to express the error probability as a function of the average SNR per bit, $\gamma_b = E_b/N_0$, and using the definition of $d_{\min}$ and (35), we can easily show that the symbol error probability can be expressed as

$$P_M = \frac{2(M-1)}{M} Q\left(\sqrt{\frac{6k}{M^2-1}\gamma_b}\right) \tag{39}$$

where $k = \log_2 M$. Figure 9 shows the symbol error probability as a function of γ_b for $M = 2, 4, 8, 16$. When Gray coding is used in the mapping of bits into symbols, adjacent symbols differ in only a single bit and in most

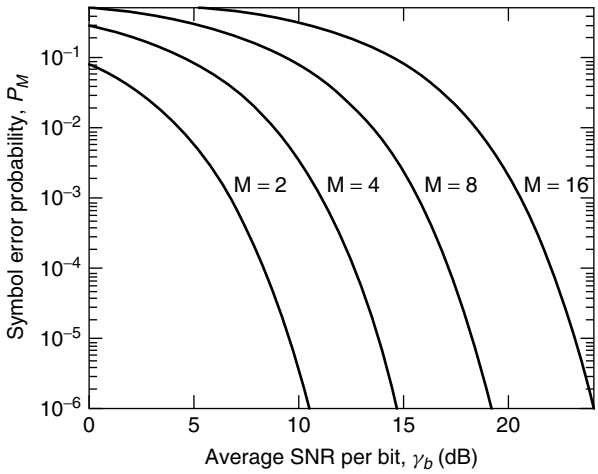

Figure 9. Symbol error probability for M-ary PAM.

cases a symbol error will result in only a single bit error. The bit error probability P_b is therefore approximated as

$$P_b \approx \frac{1}{k} P_M \tag{40}$$

4.4. Carrier-Phase Recovery

If phase-coherent detection is employed, the carrier phase needs to be known or accurately estimated. In most practical systems the phase is estimated directly from the modulated signal. Let us assume that the received signal has the form

$$r(t) = x(t)\cos(2\pi f_c t + \phi) + n(t) \tag{41}$$

where $x(t)$ is the information-bearing lowpass signal and ϕ is the carrier phase. For simplicity, we assume here that the propagation delay is known and we set it equal to zero. As shown in Fig. 8, the carrier recovery circuit computes a phase estimate $\hat{\phi}$, which is then used to generate the reference signal $u(t) = g(t)\sin(2\pi f_c t + \hat{\phi})$ for the correlator.

A *phase-locked loop* (PLL) [2] may be used to provide the maximum-likelihood estimate of the carrier phase. The PLL consists of a multiplier, a loop filter, and a *voltage-controlled oscillator* (VCO), as shown in Fig. 10. Let us for a moment assume that the input to the PLL is an unmodulated carrier signal represented by the sinusoid $\cos(2\pi f_c t + \phi)$. The output of the VCO is another sinusoid

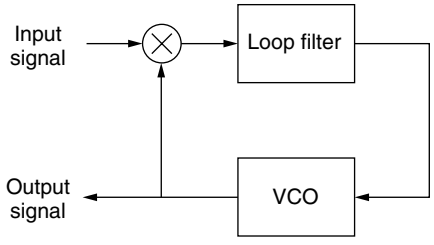

Figure 10. Phase-locked loop.

given by $\sin(2\pi f_c t + \hat{\phi})$. The output of the multiplier is the product of these two signals, given by

$$\cos(2\pi f_c t + \phi)\sin(2\pi f_c t + \hat{\phi}) = \tfrac{1}{2}\sin(\hat{\phi} - \phi) + \tfrac{1}{2}\sin(4\pi f_c t + \phi + \hat{\phi}) \quad (42)$$

The loop filter is a lowpass filter that effectively removes the double-frequency ($2f_c$) component. The output of this filter is a voltage signal that controls the VCO. The resulting PLL tracks the phase of the incoming carrier, seeking to minimize the phase error $\Delta\phi = \hat{\phi} - \phi$. In normal operation, the phase error is small and therefore $\sin(\hat{\phi} - \phi) \approx \hat{\phi} - \phi$.

We now consider two specific methods for estimating the carrier phase of a PAM signal. One widely used method involves employing a square-law device to square the received signal and generate a double-frequency signal that can then be used to drive a PLL tuned to $2f_c$ [1]. Figure 11 illustrates such a *squaring loop*, where, for the sake of clarity, we have ignored the noise term of the received signal. The output of the squarer is

$$r^2(t) = x^2(t)\cos^2(2\pi f_c t + \phi) = \tfrac{1}{2}x^2(t) + \tfrac{1}{2}x^2(t)\cos(4\pi f_c t + 2\phi) \quad (43)$$

This signal is passed through a bandpass filter tuned to $2f_c$, resulting in a periodic signal without the sign information contained in $x(t)$, namely, a phase-coherent signal at twice the carrier frequency. The filtered frequency component at $2f_c$ is used to drive the PLL. Finally, the output signal $u'(t) = \sin(4\pi f_c t + 2\hat{\phi})$ from the VCO is passed through a frequency divider to provide the output signal $u(t) = \sin(2\pi f_c t + \hat{\phi})$. This output has a phase ambiguity of 180° relative to the phase of the received signal, so binary data must be differentially encoded at the transmitter and, consequently, differentially decoded at the receiver. The squaring operation leads to some noise enhancement that results in an increase in the variance of the phase error $\Delta\phi$.

Another well-known carrier-phase estimation method is the *Costas loop* [1], which is illustrated by the block diagram shown in Fig. 12. As before, we ignore the noise term of the received signal for the sake of clarity. In this method, the received signal is multiplied by two versions of the VCO output, one phase-shifted 90° relative to the other. The multiplier outputs are

$$y_{\cos}(t) = r(t)\cos(2\pi f_c t + \hat{\phi}) = \tfrac{1}{2}x(t)\cos(\hat{\phi} - \phi) + \tfrac{1}{2}\cos(4\pi f_c t + \phi + \hat{\phi}) \quad (44)$$

and

$$y_{\sin}(t) = r(t)\sin(2\pi f_c t + \hat{\phi}) = \tfrac{1}{2}x(t)\sin(\hat{\phi} - \phi) + \tfrac{1}{2}\sin(4\pi f_c t + \phi + \hat{\phi}) \quad (45)$$

These signals are passed through lowpass filters that reject the double-frequency terms. An error signal is generated by multiplying the filtered outputs of the multipliers, yielding

$$e(t) = \tfrac{1}{8}x^2(t)\sin(2(\hat{\phi} - \phi)) \quad (46)$$

The error signal is then filtered by the loop filter, and the resulting signal is a voltage signal that controls the VCO.

As in the squaring loop, some noise enhancement occurs that causes the variance of the phase error to increase. Also, the VCO output has a 180° phase ambiguity which necessitates the use of differential encoding and decoding of the binary data.

4.5. Symbol Synchronization

As mentioned at the beginning of Section 4, the output of the correlator or matched filter must be sampled once per symbol interval. Because of the unknown propagation delay τ from the transmitter to the receiver, symbol synchronization must first be established in order to perform the sampling at the right time instants. This is usually accomplished by extracting a clock signal directly from the received signal itself and using it to control the sampling time instants $t_k = kT + \hat{\tau}$, where $\hat{\tau}$ denotes an estimate of the propagation delay.

The maximum-likelihood estimate of the propagation delay can be obtained by maximizing its likelihood

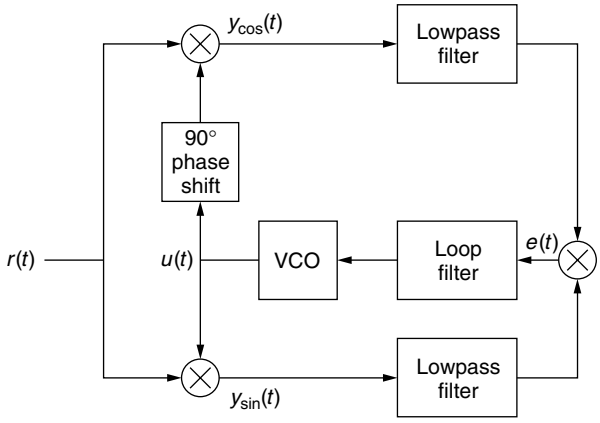

Figure 12. Carrier-phase recovery using a Costas loop.

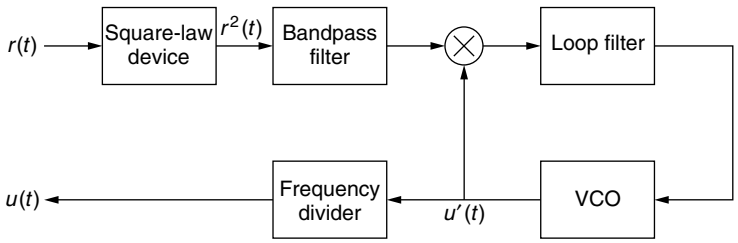

Figure 11. Carrier-phase recovery using a squaring loop.

function. Let us, for simplicity, consider baseband PAM since the procedure is easily extended to carrier-modulated PAM. The received signal is represented by

$$r(t) = s(t;\tau) + n(t) \tag{47}$$

where $s(t;\tau)$ is the (delayed) transmitted signal

$$s(t;\tau) = \sum_k x(t - kT - \tau) = \sum_k A_k g(t - kT - \tau) \tag{48}$$

and $\{A_k\}$ is the transmitted symbol sequence. The likelihood function has the form

$$\begin{aligned}\Lambda(\tau) &= C \int_{T_0} r(t)s(t)\,dt \\ &= C \sum_k A_k y_k(\tau)\end{aligned} \tag{49}$$

where $y_k(\tau)$ is the output of the correlator given by

$$y_k(\tau) = \int_{T_0} r(t)g(t - kT - \tau)\,dt \tag{50}$$

and T_0 is the integration interval. The maximum-likelihood estimate is obtained by averaging $\Lambda(\tau)$ over the probability density function (PDF) of the information symbols, $p(A_k)$, and differentiating the result. In the case of binary PAM, where $A_k = \pm 1$ with equal probability, the PDF is given as

$$p(A_k) = \tfrac{1}{2}\delta(A_k - 1) + \tfrac{1}{2}\delta(A_k + 1) \tag{51}$$

In the case of M-ary PAM, we may approximate the PDF by assuming that the symbols are continuous random variables with a zero-mean, unit-variance Gaussian distribution. In this case, the PDF is given by

$$p(A_k) = \frac{1}{\sqrt{2\pi}} e^{-A_k^2/2} \tag{52}$$

It can be shown that averaging the likelihood function over the Gaussian PDF and taking the natural logarithm yields a loglikelihood function of the form

$$\overline{\Lambda}_L(\tau) \approx \frac{1}{2} C^2 \sum_k y_k^2(\tau) \tag{53}$$

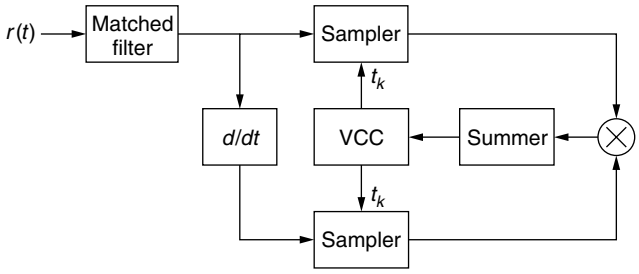

Figure 13. Non-decision-directed symbol synchronization for baseband PAM.

Next, we find the derivative of (53) and set it equal to zero:

$$\frac{d}{dt} \sum_k y_k^2(\tau) = 2 \sum_k y_k(\tau) \frac{dy_k(\tau)}{d\tau} = 0 \tag{54}$$

Figure 13 shows a symbol synchronization circuit that performs timing estimation by using a tracking loop based on Eq. (54). The circuit attempts to move the sampling instant until the derivative is zero, which occurs at the peak of the signal. The summation element serves as the loop filter that drives the voltage-controlled clock (VCC). We note that the structure of the circuit is quite similar to that of the Costas loop discussed earlier in the section on carrier-phase estimation.

A related technique, illustrated in Fig. 14, is known as the *early–late gate* synchronizer. In this technique, the output of the matched filter (or correlator) is sampled 2 times extra per symbol interval, once prior to the proper sampling instant (i.e., $T_- = T - \delta$) and once after the proper sampling instant (i.e., $T_+ = T + \delta$). As an example, let us consider the output of the filter matched to the rectangular symbol waveform introduced in Section 2. The matched-filter output attains its peak at the midpoint $t = T$, as shown in Fig. 15, and this time instant is naturally the optimal sampling time. Since the output is even with respect to the optimal sampling instant, the magnitudes of the samples taken at T_- and T_+ are equal. Hence, the proper sampling instant can be determined by adjusting the early and late sampling instants until the absolute values of the two samples are equal. An error signal is formed by taking the difference between the absolute values of the two samples, and the filtered error signal is used to drive the VCC. If the timing is off, the error signal will be nonzero and the timing signal is either advanced or retarded, depending on the sign of the error.

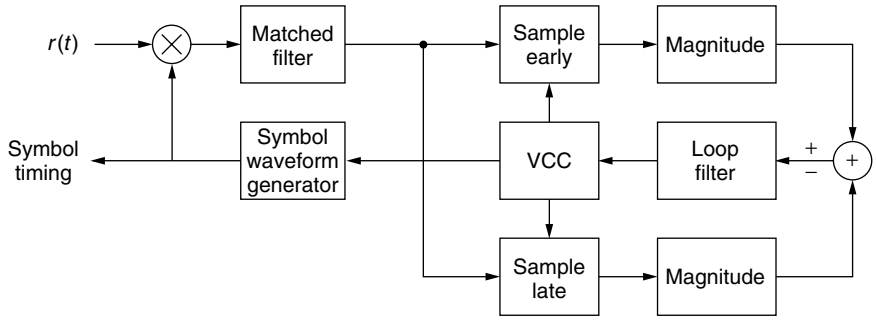

Figure 14. Symbol synchronization using an early–late gate synchronizer.

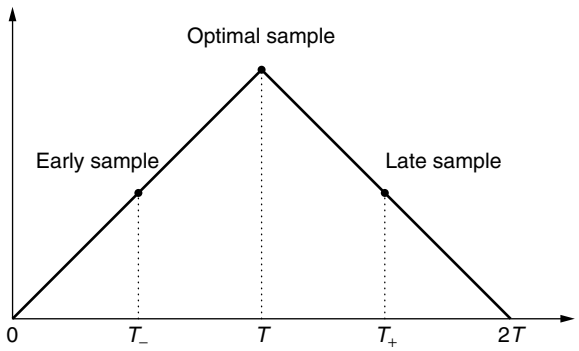

Figure 15. Matched-filter output for a rectangular signal pulse.

5. CONCLUSION

In this article, we have given an overview of the modulation method known as *pulse amplitude modulation*. We started out by introducing a mathematical representation of PAM signals and discussing their spectral characteristics. In particular, we noted that the spectrum of memoryless PAM signals can be manipulated to match the spectral characteristics of the transmission channel by selecting an appropriate signal pulse. Next, we discussed the various elements of PAM receivers for use in AWGN channels, including signal demodulation and detection, carrier-phase recovery, and symbol synchronization. We also discussed the performance of PAM detectors in terms of symbol and bit error probabilities. PAM is a well-established and mature modulation technique and has been treated in numerous articles and textbooks over the years. The interested reader will find comprehensive treatments of the topic in the works listed in the Bibliography.

BIOGRAPHY

Bjørn A. Bjerke received his Siv. Ing. degree in electrical engineering from the Norwegian Institute of Technology (NTH), Trondheim, Norway, in 1995, and his M.S. and Ph.D. degrees from Northeastern University, Boston, Massachusetts, in 1997 and 2001, respectively, both in electrical engineering. He joined Qualcomm, Inc. in 2001 and is currently a senior systems Engineer in their Concord, Massachusetts, R&D unit. His research focuses on physical layer algorithms and architectures for multi-antenna wireless communications, including channel coding/decoding, adaptive modulation, interference cancellation and channel equalization. Dr. Bjerke is a member of Eta Kappa Nu, IEEE, the Norwegian Signal Processing Society and the Norwegian Society of Chartered Engineers.

PULSE POSITION MODULATION

G. CARIOLARO
T. ERSEGHE
Università di Padova
Padova, Italy

1. INTRODUCTION

This article deals with *pulse position modulation* (PPM), which is now introduced in the more general context of *pulse modulations*. In any communication system we deal with some kind of information that we wish to send through a medium (or channel) separating the transmitter from the receiver. The information is rarely in a form that is suitable for direct transmission. In this context we call *modulation* the process of transforming the original signal in such a way that the resulting waveform can be efficiently transferred through the medium and that the original signal can be efficiently reconstructed at the receiver's end.

In *pulse modulation* systems the information is usually carried over a series of regularly recurrent pulses on which we intervene by varying parameters such as amplitude, duration, shape and, of course, temporal position. If the signal that we wish to transmit is a continuous-time function $s(t), t \in \mathbb{R}$, it will be sampled to be conformable to the discrete nature of pulses. In considering the feasibility of pulse modulations, it is important to recognize that the continuous transmission is unnecessary, provided that the continuous function $s(t)$ is band-limited and the pulses occur often enough [1]. That is, pulse modulations are inherently discrete modulations.

The necessary conditions for their feasibility are thus given by the sampling theorem stating, in its basic formulation, that any analog signal $s(t)$ with limited bandwidth range B can be uniquely expressed by samples $s_n = s(nT), n \in \mathbb{Z}$ taken at regular intervals T, where the sampling frequency $F = 1/T$ is at least twice the bandwidth range. The original signal can then be exactly reconstructed from its samples by an interpolating filter. Fortunately, in any physically realizable transmission system this condition is always satisfied and so pulse modulations constitute a feasible way to transfer information.

Nowadays, PPM is mainly used for digital transmission (which does not exclude that the original message may have an analog format converted to digital just on the basis of the sampling theorem), where the discrete sequence s_n takes the values from a finite set of amplitudes (alphabet) and where the size is typically a power of 2. So we have 2-PPM, 4-PPM, 8-PPM, and so on.

The article is organized as follows. In Section 2 we introduce PPM (both analog and digital) in the more general framework of pulse modulations, and in Section 3 we consider the problem of the generation of PPM signals. In these preliminary sections, the signals may be interpreted as deterministic or random functions as well. However, following the lines of modern communication theory, in the subsequent parts a probabilistic methodology becomes mandatory. Thus, in Section 4 we formulate the spectral analysis where the signal is modeled in terms of random processes. In the two final sections, Section 5 and Section 6, we evaluate performances of digital PPM systems in the presence of noise and also their achievable information rates. The article concludes with a brief record of modern applications, mainly in optical communication systems.

We have deliberately omitted the performance evaluation of analog PPM systems. To this regard we suggest to the interest reader the optimal lectures of [2], [3].

2. VARIETIES OF PULSE MODULATIONS

In pulse modulations the unmodulated carrier is usually a periodic repetition of a given pulse $q(t)$

$$v_0(t) = \sum_{n=-\infty}^{+\infty} q(t - nT) \tag{1}$$

and the message is always a discrete-time signal, $s_n = s(nT)$, with sampling spacing T equal to the period of the carrier. The fundamental parameters of the carrier are the *pulse shape* $q(t)$, usually rectangular with duration limited to a fraction of T and the period T that uniquely determines the sampling instants nT, $-\infty < n < +\infty$, which express the repetitiveness of pulses, that is the *synchronism*.

The message s_n can be a sampled version of an analog signal $s(t)$, $t \in \mathbb{R}$, as previously discussed, in which case we will talk of *analog* modulation. Conversely, the message can be digital, in which case the modulation becomes *digital*. The way to reconstruct the original signal is pretty different in these two cases.

Modulation of the carrier is obtained by varying the nth pulse in dependence of the value s_n, that is, the reference pulse $q(t - nT)$ is replaced by a pulse $q(t - nT, s_n)$ dependent on s_n. The modulated signal can thus be written as

$$v(t) = \sum_{n=-\infty}^{+\infty} q(t - nT, s_n) \tag{2}$$

The transmitter has a double role: to generate the modulated pulses $q(t, s_n)$ and to position them at the synchronism instant nT. In the digital case, if $\mathcal{A}$ is the finite set (alphabet) of values that s_n can assume, the set of modulated pulses

$$\{q(t, a) \mid a \in \mathcal{A}\} \tag{3}$$

must be in a one-to-one correspondence with $\mathcal{A}$ to guarantee demodulation. For example, if the alphabet $\mathcal{A}$ has 64 values, the modulator must be capable of generating 64 different pulses. In the analog case, s_n belongs to a continuous set, usually given by a finite interval to assure that pulses do not overlap.

The simplest pulse modulation, and maybe the most common approach, is pulse amplitude modulation (PAM), which varies the pulse amplitude proportionally to the value of s_n, that is, we have $q(t, s_n) = s_n q(t)$ (Fig. 1). Another classical modulation, the one of interest to us, is PPM which modifies the *position* of the pulses, that is, we have

$$q(t, s_n) = q(t - K\, s_n) \tag{4}$$

where K is a suitable constant with the constraint $-\frac{1}{2}T \le K\, s_n < \frac{1}{2}T$ or, alternatively, $0 \le K\, s_n < T$ to guarantee that modulated pulses do not overlap. In PPM the modulated signal has the expression

$$\boxed{v(t) = \sum_{n=-\infty}^{+\infty} q(t - nT - K\, s_n)} \tag{5}$$

A closely related alternative, called pulse duration modulation (PDM) or pulse width modulation (PWM), would instead consider to modify the duration of pulses, that is,

$$q(t, s_n) = q(t/(K\, s_n)) \tag{6}$$

In this case the constraint is in the duration of the modulated pulses, which must be positive and not bigger

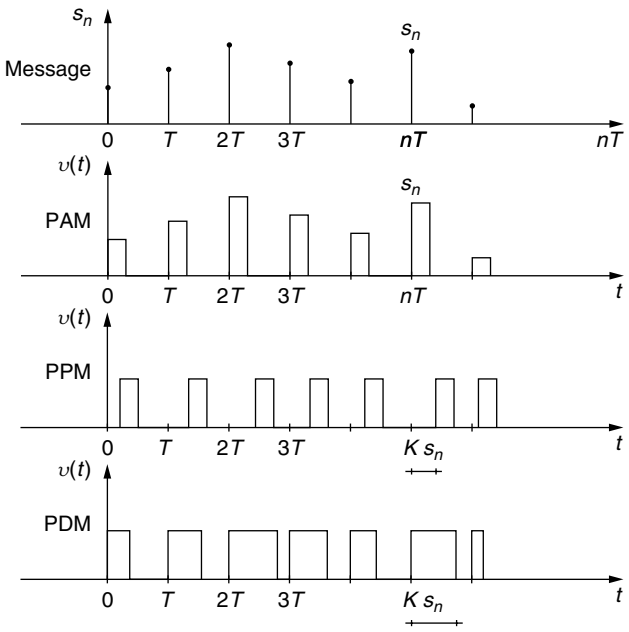

Figure 1. Classical pulse modulations.

than T, so that in (6) we have the further constraint $s_n > 0$; if s_n is not strictly positive, then the expression $K\,s_n$ must be substituted by something of the form of $T_0 + K\,s_n$.

Another worth mentioning modulation format related to PPM is pulse interval modulation (PIM), also known as differential PPM where the information is contained in the relative-distance between successive pulses. The relation to PPM can be seen in Fig. 2, where it is underlined that PIM discards the void portion of the frame after the PPM pulse, thus resulting more efficient in terms of transmission capacity and bandwidth requirements (but not in terms of transmitted-power).

3. GENERATION AND MODELS OF PPM SIGNALS

In a PPM signal the information is confined to the sequence of instants (positions) $nT + K\,s_n$ and the shape of the fundamental pulse $q(t)$ is, in some respects, irrelevant. In the ideal case the pulse may be a delta function, that is

$$v_\delta(t) = \sum_{n=-\infty}^{+\infty} \delta(t - nT - K\,s_n) \tag{7}$$

The transition from the ideal PPM signal $v_\delta(t)$ to a PPM with a given pulse shape $q(t)$ is simply obtained by a shaping filter, that is

$$v(t) = v_\delta * q(t) = \sum_{n=-\infty}^{+\infty} q(t - nT - K\,s_n)$$

where $*$ denotes convolution.

2.1. Generation of Analog PPM Signals (general approach)

The traditional generation of analog PPM signals is based on the preliminary generation of a PDM signal. In practice, the principal use of PDM is for the generation and detection of PPM because the latter is superior for message transmission.

A sequence of operations to produce a PPM signal starting from the sampling sequence $s_n = s(nT)$ is depicted in Fig. 3. It is assumed that s_n is unipolar and bounded, that is $0 \le s_n < S_0$. The first operation is a holding of the value s_n for the corresponding time-slot $\mathcal{I}_n = [nT, (n+1)T)$, thus producing a PAM signal $\tilde{s}(t)$ with

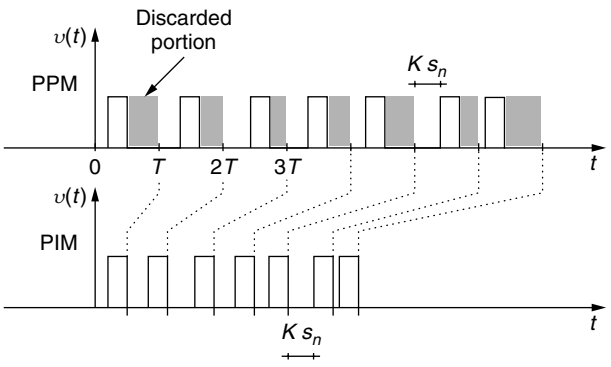

Figure 2. From PPM to PIM.

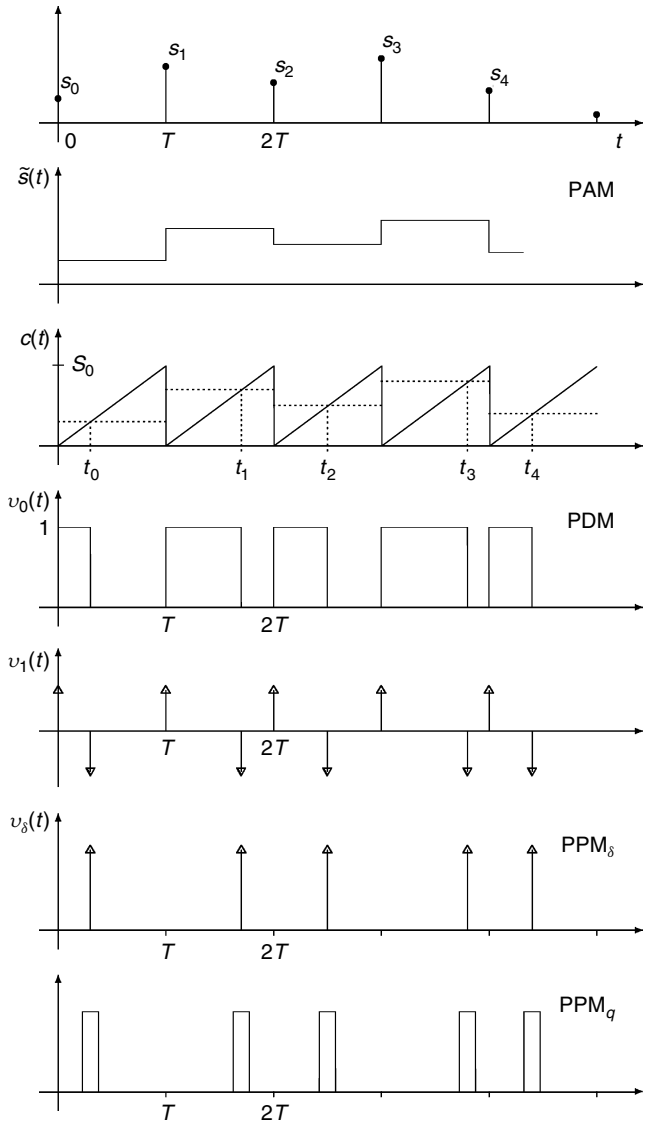

Figure 3. Generation of a PPM signal.

a full duty cycle. In the second step, a triangular carrier $c(t)$, running linearly from $c(nT) = 0$ to $c((n+1)T) = S_0$, is compared with $\tilde{s}(t)$ and a unitary output is produced as long as $\tilde{s}(t)$ is above $c(t)$. In this way, a sequence of rectangular pulses $v_0(t)$ is produced with the nth pulse starting at time nT with a duration proportional to the value of $\tilde{s}(t)$ in $\mathcal{I}_n$, that is $K\,s_n$. Hence, $v_0(t)$ is just a PDM signal. The derivative of $v_0(t)$ produces a sequence of paired delta functions $\delta(t - nT) - \delta(t - nT - K\,s_n)$. With an inverse half-wave rectification which removes the upward delta functions, the PPM signal

$$v_\delta(t) = \sum_{n=-\infty}^{+\infty} \delta(t - nT - K\,s_n) \tag{8}$$

is obtained. Finally, a reshaping of these *spikes* gives the standard PPM format.

It is clear that an ideal receiver can recover from the PPM wave the modulating sequence s_n. The natural way

is to first obtain a PDM signal from (8), which can be done in the presence of synchronization which marks the beginning nT of the time slot. Next, the PDM signal is integrated starting from nT and with a finite integration time ($< T$). Hence, a uniform sampling at time just before $(n+1)T$ gives a sequence proportional to s_n. If s_n was obtained by sampling an analog signal $s(t)$, an interpolation finally provides the full recovery of $s(t)$. For digital PPM other more efficient recovery systems are used (see Section 5).

2.2. Analog PPM Signals with Nonuniform Sampling

In the standard analog PPM the modulating sequence s_n is obtained from a continuous-time message $s(t)$ with a sampling at the equally-spaced instants nT (uniform sampling), as remarked by writing $s_n = s(nT)$. There is another format of PPM, which is obtained by a nonuniform sampling. Historically, this form came first for its implementation is easier, at least with analog circuitry.

As a matter of fact, if in the sequence of operations of Fig. 3 we avoid the sampling, that produces the sequence s_n, and the holding, which gives $\tilde{s}(t)$ from s_n, and we feed the comparator directly with the analog message $s(t)$, the subsequent operations work as well to produce a PPM format. But, the times t_n, in correspondence of which the signal values $s_n = s(t_n)$ are taken, are no more equally spaced (Fig. 4). In fact, in the nth time-slot the carrier ramp is given by $c(t) = (t - nT)S_0/T, t \in \mathcal{I}_n$ and it is compared directly with $s(t)$. Hence, the coincidence $s(t) = c(t)$ happens at the instant

$$t_n = nT + K\, s(t_n), \qquad K = S_0/T \tag{9}$$

and the final PPM signal becomes

$$v\delta(t) = \sum_{n=-\infty}^{+\infty} \delta(t - nT - K\, s(t_n)) \tag{10}$$

with nonuniform sampling instants determined by (9).

Although more easy to generate (with analog circuitry!), the analysis of this PPM format is very difficult because the instants t_n are determined by an implicit equation, as (9) is. Fortunately, Rowe [2], using some powerful properties of the delta function, was able to obtain a very interesting expression of (10), namely

$$\begin{aligned} v_\delta(t) &= F|1 - K\, s'(t)| \sum_{n=-\infty}^{+\infty} e^{j2\pi nF(t - K\ s(t))} \\ &= F|1 - K\, s'(t)| \left\{ 1 + 2 \sum_{n=1}^{+\infty} \cos 2\pi nF[t - K\, s(t)] \right\} \end{aligned} \tag{11}$$

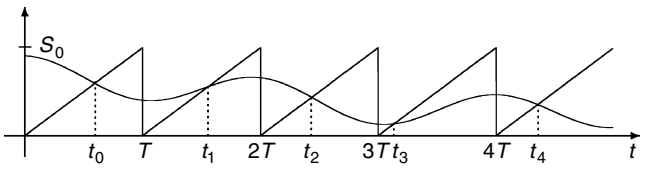

Figure 4. PPM with nonuniform sampling.

where $F = 1/T$. In Appendix A, we give an alternative and easier deduction of this expression. According to (11) the PPM signal $v\delta(t)$ consists of a baseband term $F|1 - K\ s'(t)| = A_0(t)$ and of bandpass terms around the frequencies nF,

$$2\, A_0(t) \cos 2\pi\, [nFt + \varphi_n(t)]$$

which exhibit both an amplitude modulation and a phase modulation with phase deviation $\varphi_n(t) = -nFT_0 s(t)$. Note that with a little signal processing it is possible to obtain a phase or a frequency modulated signal starting from a PPM signal with a nonuniform sampling. As a matter of fact, this possibility was concretely used in the past under the name of *serrasoid* technique.

We remark that (11), although suggestive, should be used with caution, especially in spectral analysis, because in the frequency domain the terms in (11) may have a strong overlapping.

2.3. Generation of Digital PPM Signals

For the generation of digital PPM signals, the general method can be used, but more specific methods, which rely upon the consideration that the permitted positions are finitely many, are possible. Here, we outline a general method, which is valid for all pulse modulations and gives the PPM as a special case.

Let $v(t)$ be the pulse modulated signal

$$v(t) = \sum_{n=-\infty}^{+\infty} q(t - nT, s_n)$$

where the data sequence $s_n = s(nT)$ belongs to an M-ary alphabet $\mathcal{A}_M = \{0, 1, \ldots, M-1\}$. The modulation format is specified by M distinct pulses $q(t, \alpha) = q_\alpha(t)$, which we store in a vector $\mathbf{q}(t) = [q_0(t), q_1(t), \ldots, q_{M-1}(t)]$. In particular, for PPM we have

$$q(t, \alpha) = q_\alpha(t) = q(t - \alpha T_0), \qquad T_0 = T/M$$

so that the vector $\mathbf{q}(t)$ collects M replicas of a same pulse uniformly distributed in the time slot $[0,\ T)$. The key of the method lies on a representation of the M-ary data s_n by a binary word of length M, $\mathbf{b}_n = [b_n(0), b_n(1), \ldots, b_n(M-1)]$, where

$$b_n(\alpha) = \delta_{s_n,\alpha} = \begin{cases} 1 & \text{for } s_n = \alpha \\ 0 & \text{for } s_n \neq \alpha \end{cases} \tag{12}$$

$\delta_{s_n,\alpha}$ being the Kronecker delta function. For instance, for $M = 4$, we find

$$\begin{aligned} \mathbf{b}_n &= [1\ 0\ 0\ 0] \quad \text{when } s_n = 0 \\ &= [0\ 1\ 0\ 0] \quad \text{when } s_n = 1 \\ &= [0\ 0\ 1\ 0] \quad \text{when } s_n = 2 \\ &= [0\ 0\ 0\ 1] \quad \text{when } s_n = 3 \end{aligned}$$

Clearly, the word sequence $\mathbf{b}_n = \mathbf{b}(nT)$ brings the same information of the original data sequence s_n without

ambiguity, and in fact one can uniquely determine s_n from $\mathbf{b}_n$ because

$$s_n = \alpha \quad \Longleftrightarrow \quad b_n(\alpha) = 1$$

that is, the value of s_n at the time nT is given by the position of the 1 in the vector $\mathbf{b}_n$.

Next, consider that the words $\mathbf{b}_n$ feed a bank of interpolating filters with impulse responses $q_\alpha(t)$ (Fig. 5). The input-output relationship of the αth filter is

$$v_\alpha(t) = \sum_{n=-\infty}^{+\infty} b_n(\alpha) q_\alpha(t - nT)$$

and in the nth time slot the output is $q_\alpha(t - nT) = q(t - nT, s_n)$ if $s_n = \alpha$ and 0 otherwise. Hence, the contribution of all filters

$$\sum_{\alpha \in \mathcal{A}_M} v_\alpha(t) = \sum_{n=-\infty}^{+\infty} \sum_{\alpha \in \mathcal{A}_M} b_n(\alpha) q_\alpha(t - nT) = v(t) \tag{13}$$

provides the desired modulated signal $v(t)$. In other words, the word sequence $\mathbf{b}_n$ gives the signaling to the filter-bank to turn on the right filter (one per time) in every time slot.

Note that the scheme of Fig. 5 provides a powerful representation of a pulse modulator because it explicitly separates the nonlinear part of the modulator, given by the word formatting operation, from the linear part, given by the filter bank $\mathbf{q}(t)$. Finally, we remark that (13) can be written in the elegant form

$$v(t) = \sum_{n=-\infty}^{+\infty} \mathbf{b}_n \mathbf{q}(t - nT)$$

provided that $\mathbf{b}_n$ is regarded as a row vector (matrix $1 \times M$) and $\mathbf{q}(t)$ is a column vector (matrix $M \times 1$).

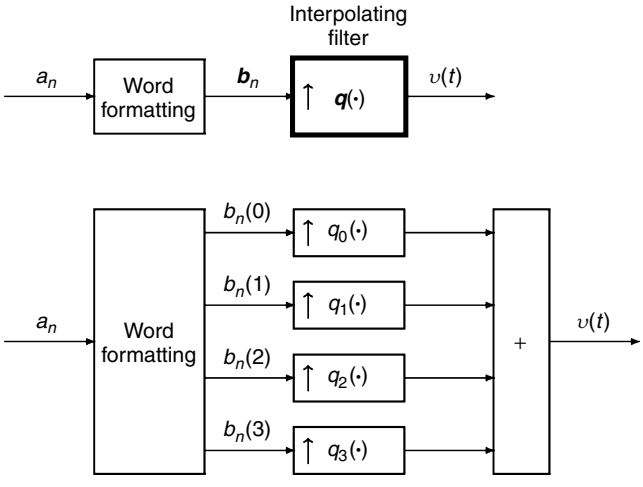

Figure 5. Generation of digital pulse modulated signals.

2.4. Digital PPM Signals Through PAM Signals

In the case of PPM, where the interpolating filters have impulse responses $q_\alpha(t) = q(t - \alpha T_0)$ that are uniformly distributed delayed versions of a reference pulse $q(t)$, the scheme of Fig. 5 can be further simplified to express PPM in terms of PAM modulations.

In particular, we obtain the scheme of Fig. 6, where the word sequence $\mathbf{b}_n$ is mapped by a parallel-to-serial conversion, called de-framing, to the binary sequence c_m (with rate $1/T_0$), where

$$c_{nM+\alpha} = b_n(\alpha)$$

The binary sequence c_m is then interpolated by a filter with impulsive response $q(t)$ to obtain the PPM signal

$$\sum_{m=-\infty}^{+\infty} c_m q(t - mT_0) = \sum_{n=-\infty}^{+\infty} \sum_{\alpha=0}^{M-1} c_{nM+\alpha} q(t - (nM + \alpha)T_0)$$
$$= \sum_{n=-\infty}^{+\infty} \sum_{\alpha=0}^{M-1} b_n(\alpha) q_\alpha(t - nT)$$

which, by use of (13), gives $v(t)$. Again, in Fig. 6 the nonlinear operations are contained in the word formatting, while the final PPM signal is obtained from the binary sequence c_m by a simple PAM modulation.

Simple modifications of the scheme of Fig. 6 let us easily define the discrete version of modulations related to PPM. For example, PDM with $M = 4$ is obtained by redefining the words

$$\begin{aligned} \mathbf{b}_n &= [1\ 0\ 0\ 0] \quad \text{when } s_n = 0 \\ &= [1\ 1\ 0\ 0] \quad \text{when } s_n = 1 \\ &= [1\ 1\ 1\ 0] \quad \text{when } s_n = 2 \\ &= [1\ 1\ 1\ 1] \quad \text{when } s_n = 3 \end{aligned}$$

Similarly we have for PIM, for which the word mapping becomes a variable-length operation,

$$\begin{aligned} \mathbf{b}_n &= [1] \quad \text{when } s_n = 0 \\ &= [0\ 1] \quad \text{when } s_n = 1 \\ &= [0\ 0\ 1] \quad \text{when } s_n = 2 \\ &= [0\ 0\ 0\ 1] \quad \text{when } s_n = 3 \end{aligned}$$

and de-framing must take into account for the variable length of words.

4. SPECTRAL ANALYSIS

As for every other modulation format, spectral analysis is a fundamental tool for understanding the band occupancy of the PPM modulation but also for several other reasons. Surely, PPM produces a *baseband* signal, that is with a

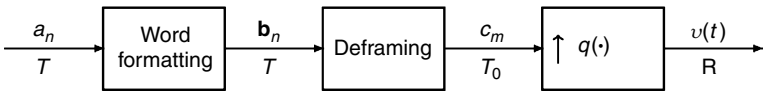

Figure 6. Digital PPM signals generated by a PAM filter.

spectrum displayed around the frequency origin, which is essentially determined by the fundamental pulse $q(t)$, and we also have to expect that the bandwidth is of the order of $1/T_0$, where T_0 is the duration of $q(t)$. However, the exact evaluation of the spectrum is not trivial for two main reasons: 1) PPM is a nonlinear modulation and 2) PPM contains a periodic component, given by the mean value, which determines the presence of spectral lines and that causes a nonstationary behavior.

4.1. Formulation of Spectral Analysis

In spectral analysis signals are modeled as random processes. In particular, we assume that the sample sequence $s_n = s(nT)$ is a discrete-time *stationary* random process. Then, it is easy to show that the PPM signal

$$v(t) = \sum_{n=-\infty}^{+\infty} q(t - nT - s_n) \tag{14}$$

is not stationary, rather it is *cyclostationary*, that is with a statistical description which is periodic with respect to a reference time, being the period given by the sampling period T. We start by showing this for the mean value $m_v(t) = \mathrm{E}[v(t)]$, where $\mathrm{E}[\cdot]$ is the expectation operator. Considering that s_n is stationary, we have

$$m_v(t) = \sum_{n=-\infty}^{+\infty} \mathrm{E}[q(t - nT - s_n)] = \sum_{n=-\infty}^{+\infty} \overline{q}(t - nT)$$

where $\overline{q}(t) = \mathrm{E}[q(t - s_n)]$ is the *average pulse*, which is independent of n because of stationarity. Hence, $m_v(t)$ is the periodic repetition of the average pulse and has period T.

The spectral analysis starts from the *correlation* function of $v(t)$, defined as $\tilde{r}_v(t, \tau) = \mathrm{E}[v(t)v(t + \tau)]$, which is periodic with respect to the reference time t. Then, taking the time average

$$r_v(\tau) = \frac{1}{T} \int_0^T \tilde{r}_v(t, \tau)\, dt \tag{15}$$

the dependence on t is removed. The (average) power spectral density (PSD), that is the quantity of interest in spectral analysis, is then obtained as the Fourier transform of the average correlation (15), namely

$$R_v(f) = \int_{-\infty}^{+\infty} r_v(\tau) e^{-j2\pi f\tau}\, d\tau \tag{16}$$

This is the most common approach to determine the PSD for cyclostationary processes.[1]

In general, the PSD $R_v(f)$ can be decomposed in a *continuous* part $R_v^{(c)}(f)$ and in a *discrete* part $R_v^{(d)}(f)$, which exhibits *spectral lines* (Lebesgue decomposition). Spectral lines are due to the periodic component of the PPM signal, that is by the mean value $m_v(t)$. In fact, it can be shown that $m_v(t)$ has PSD $R_v^{(d)}(f)$ and the deviation $v(t) - m_v(t)$ has PSD $R_v^{(c)}(f)$. For a correct spectral analysis it is important to evaluate the two components separately.

4.2. Evaluation of the PSD

Because PPM is a nonlinear modulation, the evaluation of the PSD requires to know the second-order statistics of the modulating sequence s_n. More specifically, let $\Psi_s(f)$ and $\Psi_s(f_1, f_2; \tau)$ be the characteristic functions of first and second order of s_n, written in terms of "frequency" in place of the usual z variables, namely

$$\begin{aligned} \Psi_s(f) &= \mathrm{E}[e^{j2\pi f s_n}] \\ \Psi_s(f_1, f_2; kT) &= \mathrm{E}[e^{j2\pi(f_1 s_n + f_2 s_{n+k})}] \end{aligned} \tag{17}$$

Let also $\Phi_s(f_1, f_2; f)$ be the (discrete) Fourier transform of $\Psi_s(\cdot; kT)$ with respect to kT, that is

$$\Phi_s(f_1, f_2; f) = \sum_{k=-\infty}^{+\infty} \Psi_s(f_1, f_2; kT) e^{-j2\pi fkT} \tag{18}$$

Then, as shown in Appendix B, the PSD of the PPM signal $v(t)$ is given by

$$\boxed{R_v(f) = F\Phi_s(-f, f; f)|Q(f)|^2} \tag{19}$$

where $F = 1/T$ and $Q(f)$ is the Fourier transform of the fundamental pulse $q(t)$, that is

$$Q(f) = \int_{-\infty}^{+\infty} q(t) e^{-j2\pi ft}\, dt$$

This result holds in general as soon as the modulating sequence s_n is a stationary process. For the spectral separation of the continuous and the discrete parts, further assumptions should be done concerning the behavior of the characteristic function $\Psi(f_1, f_2; kT)$ for $k \to \infty$. Here, we consider the simplest case in which s_n is statistically independent and refer to Ref. [2] for a more general situation.

If s_n and s_{n+k} are independent for $k \neq 0$, then the second part of (17) gives

$$\Psi_s(f_1, f_2; kT) = \begin{cases} \Psi_s(f_1 + f_2) & k = 0 \\ \Psi_s(f_1)\Psi_s(f_2) & k \neq 0 \end{cases} \tag{20}$$

Moreover, at the level of the characteristic function the separation between the discrete and continuous part is such that $\Psi_s(f_1)\Psi_s(f_2)$ determines the discrete part and the difference $\Psi_s(f_1 + f_2) - \Psi_s(f_1)\Psi_s(f_2)$ for $k = 0$ determines the continuous part. So, from (18) we obtain

$$\begin{aligned} \Phi_s^{(c)}(f_1, f_2; f) &= \Psi_s(f_1 + f_2) - \Psi_s(f_1)\Psi_s(f_2) \\ \Phi_s^{(d)}(f_1, f_2; f) &= \Psi_s(f_1)\Psi_s(f_2) \sum_{k=-\infty}^{+\infty} e^{-j2\pi fkT} \\ &= \Psi_s(f_1)\Psi_s(f_2) F \sum_{k=-\infty}^{+\infty} \delta(f - kF) \end{aligned} \tag{21}$$

[1] An equivalent way is the introduction of a *stationary version* of the cyclostationary signal, defined as $v_\vartheta(t) = v(t + \vartheta)$ where ϑ is a random variable uniformly distributed in $[0, T)$ and statistically independent on $v(t)$. It can be shown that $v_\vartheta(t)$ is stationary with correlation given by (15) and PSD given by (16).

where in the last row we used a widely known identity between sequences of exponentials and sequences of delta functions.

Finally, by substituting (21) in (19) we obtain

$$\begin{aligned} R_v^{(c)}(f) &= F|Q(f)|^2(1-|\Psi_s(f)|^2) \\ R_v^{(d)}(f) &= F^2|Q(f)|^2|\Psi_s(f)|^2 \sum_{k=-\infty}^{+\infty} \delta(f-kF) \\ &= F^2 \sum_{k=-\infty}^{+\infty} |Q(kF)|^2|\Psi_s(kF)|^2\delta(f-kF) \end{aligned} \tag{22}$$

where we see the presence of spectral lines at the frequencies that are multiples of the sampling rate $F = 1/T$, at least for those instances where $Q(kF) \neq 0$.

4.3. Spectrum of Digital PPM

In digital PPM the "positions" s_n are the discrete and equally spaced instants $0, T_0, \ldots, (M-1)T_0$ with $T_0 = T/M$ and each position is taken with a given probability $p_i = \mathrm{P}[s_n = iT_0]$. Then, the characteristic function of the first order becomes

$$\Psi_s(f) = \sum_{i=0}^{M-1} p_i e^{j2\pi fiT_0}$$

We now assume equally likely positions, that is $p_i = 1/M$ and a rectangular pulse $q(t) = 1$ for $0 < t < \alpha T_0$, where α is the duty cycle ($0 < \alpha < 1$). Then, the result will be expressed by the very well-known function $\mathrm{sinc}(x) = \sin(\pi x)/(\pi x)$ and by its (less known) periodic version

$$\mathrm{sinc}_M(x) = \frac{1}{M}\frac{\sin(\pi x)}{\sin(\frac{\pi}{M}x)} \tag{23}$$

which has period M for M odd and period $2M$ for M even. Note that $\mathrm{sinc}^2(k) = 0$ for k an integer that is not a multiple of M and that $\mathrm{sinc}^2(kM) = 1$. The periodic sinc allows us to express the characteristic function in the form

$$\Psi_s(f) = \frac{1}{M}\frac{1-e^{-j2\pi MfT_0}}{1-e^{-j2\pi fT_0}} = e^{-j2\pi(M-1)fT_0}\mathrm{sinc}_M(fMT_0)$$

Conversely, the Fourier transform of the pulse is given by

$$Q(f) = \alpha T_0 e^{-j\pi\alpha T_0 f}\mathrm{sinc}(\alpha T_0 f)$$

Hence, by substitution in (22) we have

$$\begin{aligned} R_v^{(c)}(f) &= F(\alpha T_0)^2\,\mathrm{sinc}^2(\alpha T_0 f)(1-\mathrm{sinc}_M^2(fT)) \\ R_v^{(d)}(f) &= F^2(\alpha T_0)^2 \sum_{k=-\infty}^{+\infty} \mathrm{sinc}^2(k\alpha/M)\,\mathrm{sinc}_M^2(k)\delta(f-kF) \end{aligned}$$

The plot of this PSD is given in Fig. 7 for $M = 8$ and for two values of α. Note that $R_v^{(c)}(f)$ is always zero at $f = 0$ and other zeros fall at frequencies multiple of $F_0 = MF$. An indication of the bandwidth may be given by the side lobe determined by the factor $\mathrm{sinc}^2(f\alpha T_0)$, that is $1/\alpha T_0 = F_0/\alpha$. The spectral lines may be present at frequencies multiples of F_0 whenever $\mathrm{sinc}^2(k\alpha) \neq 0$. Note, in particular, that for $\alpha = 1$ there is only a line at $f = 0$; this is in agreement with the fact that in this case the mean value $m_v(t)$ degenerates to a constant value.

4.4. Spectrum of Analog PPM

When the sampling sequence s_n is continuous the characteristic function is given by

$$\Psi_s(f) = \int_{-\infty}^{+\infty} e^{-j2\pi fa} f_s(a)\,da$$

where $f_s(a)$ is the probability density function of s_n. Assuming a rectangular pulse with duration T_0, we consider two cases: a) s_n is uniform in $[0, T-T_0)$, not extended to $[0, T)$ to avoid collisions, and b) s_n is Gaussian with mean $m_s = (T-T_0)/2$ and variance σ_s^2 with $\sigma_s << T$ so that the probability of collision is negligible.

With s_n uniform the characteristic function is

$$\Psi_s(f) = e^{-j\pi(T-T_0)f}\mathrm{sinc}(f(T-T_0))$$

and hence

$$\begin{aligned} R_v^{(c)}(f) &= FT_0^2\,\mathrm{sinc}^2(fT_0)[1-\mathrm{sinc}^2(f(T-T_0))] \\ R_v^{(d)}(f) &= (FT_0)^2 \sum_{k=-\infty}^{+\infty} \mathrm{sinc}^2(kFT_0) \\ &\quad \times \mathrm{sinc}^2(k(1-FT_0))\delta(f-kF) \end{aligned}$$

which are illustrated at the top of Fig. 8 for $T_0 = \frac{1}{8}T$.

With s_n Gaussian we find that

$$\Psi_s(f) = e^{-j2\pi fm_s}e^{-(2\pi f\sigma_s)^2/2}$$

and hence

$$\begin{aligned} R_v^{(c)}(f) &= FT_0^2\,\mathrm{sinc}^2(fT_0)[1-e^{-(2\pi f\sigma_s)^2}] \\ R_v^{(d)}(f) &= (FT_0)^2 \sum_{k=-\infty}^{+\infty} \mathrm{sinc}^2(kFT_0)e^{-(2\pi kF\sigma_s)^2}\delta(f-kF) \end{aligned}$$

which are illustrated below in Fig. 8 for $T_0 = \sigma_s = \frac{1}{8}T$. We recall that these results hold when the samples s_n are statistically independent.

5. DIGITAL PPM DEMODULATION AND ERROR PROBABILITY

Digital PPM is the common approach in practical applications, mainly because of the digital nature of the information available for transmission. So, in the following we will concentrate on this "digital" format, for which the PPM signal is

$$v(t) = \sum_{n=-\infty}^{+\infty} q(t-nT-s_n)$$

where s_n is an M-ary data sequence with alphabet $\mathcal{A}_M = \{0, T_0, \ldots, (M-1)T_0\}$ with $T_0 = T/M$. The receiver

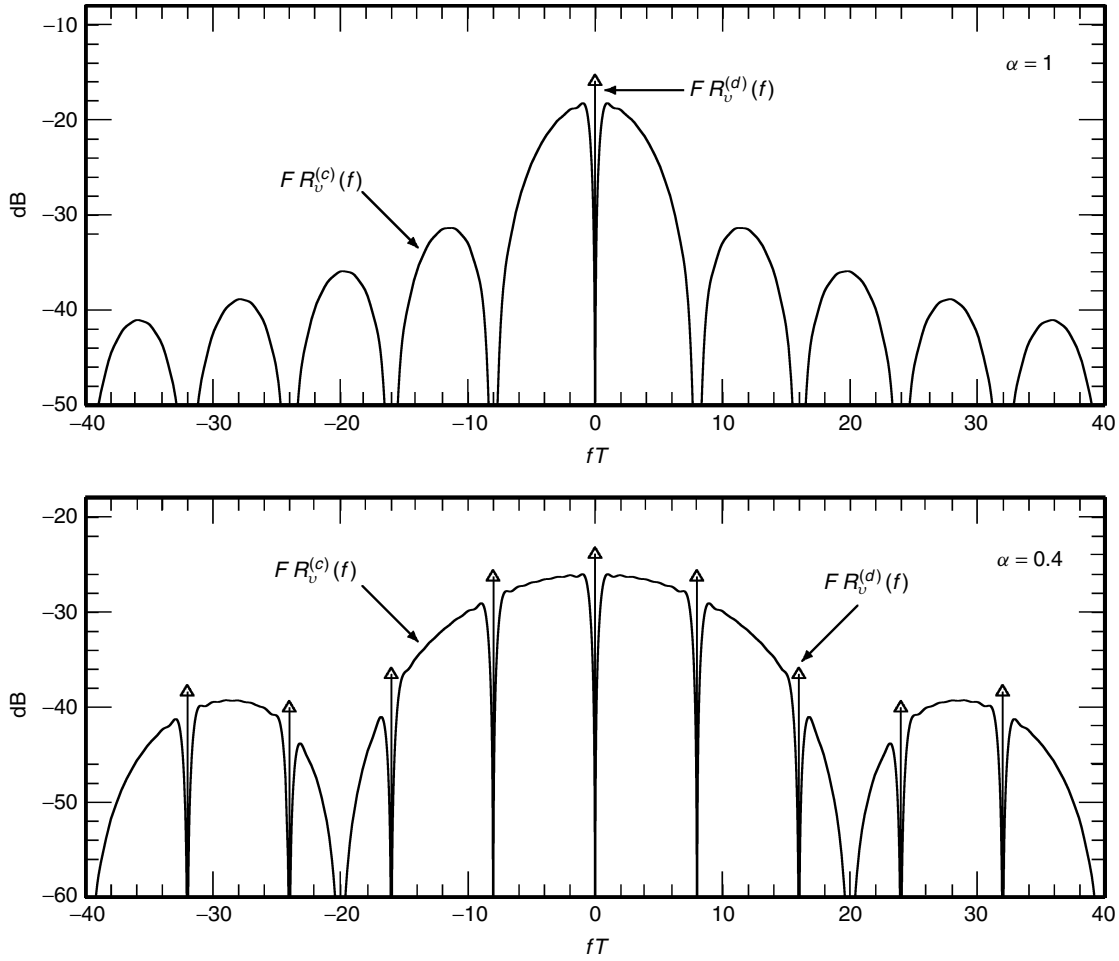

Figure 7. PSD examples for digital PPM and $M = 8$. Spectral lines are highlighted by vertical arrows.

structure is based upon optimal detection strategies and relies on banks of correlators. Fundamental performance measures of the system are given by the error probability evaluation, but also by more sophisticated capacity measures (see Section 6), which set a target for the maximum amount of information that can be sent through the PPM channel with an arbitrarily small probability of error.

5.1. Optimal Detection of Digital PPM Signals

Optimal strategies for detecting digital PPM signals rely on the assumption of ideal propagation and additive white Gaussian noise (AWGN), where the received signal can be modeled as

$$r(t) = Av(t) + \eta(t)$$

with A the attenuation and $\eta(t)$ a stationary Gaussian noise with zero mean and power spectral density $R_\eta(f) = N_0/2$. Optimal detection, that is the one that minimizes the symbol error probability (also known as maximum likelihood), is achieved by use of a matched-filter bank where the demodulator selects the value resulting in the largest cross-correlation between the received signal $r(t)$ and each of the pulses $q_\alpha(t - nT) = q(t - nT - \alpha), \alpha \in \mathcal{A}_M$.

The implementation is illustrated in Fig. 9, where the M-tuple $\varphi_n(\alpha), \alpha \in \mathcal{A}_M$ is generated by a bank of sampling filters that constitute the dual of the interpolating filter bank of Fig. 5. In particular, we have

$$\varphi_n(\alpha) = \int_{-\infty}^{+\infty} r(t) q_\alpha(t - nT)\, dt = \int_{-\infty}^{+\infty} r(t) q(t - nT - \alpha)\, dt$$

where the integration can be limited to a finite region by taking into account that, in practice, $q(t)$ always has limited extension. This extension is usually constrained to $[0, T_0)$ to overcome the superposition of adjacent pulses and, in the following, we consider this assumption (see [4] for more general cases). Finally, the demodulated sequence becomes

$$\hat{s}_n = \arg \max_\alpha \varphi_n(\alpha)$$

The statistical properties of the M-tuple $\varphi_n(\alpha), \alpha \in \mathcal{A}_M$ are usually given under the condition that the transmitted sample s_n is known. By setting $s_n = \beta$, with a little effort one easily derives that

$$\varphi_n(\alpha \mid \beta) = \varphi_n(\alpha \mid s_n = \beta) = \underbrace{AE_q \delta_{\alpha,\beta}}_{\text{expected signal}} + \underbrace{\eta_n(\alpha)}_{\text{Gaussian noise}} \qquad (24)$$

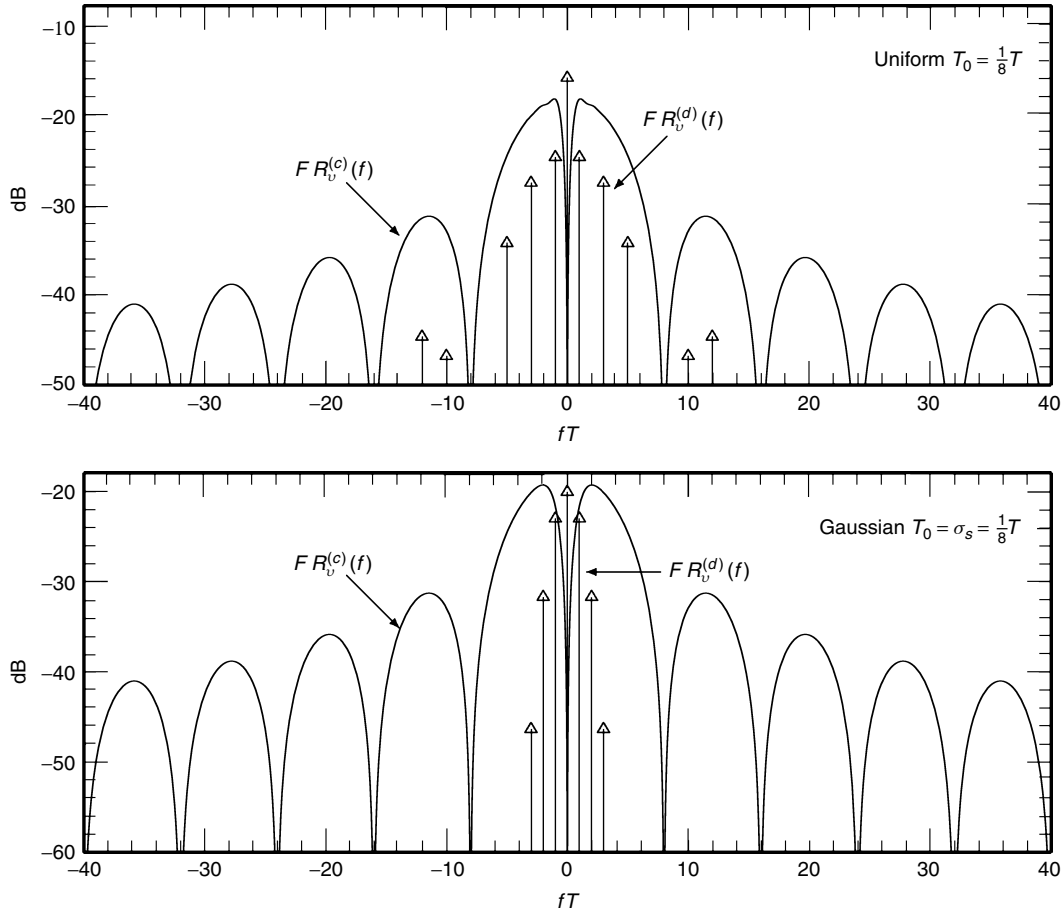

Figure 8. PSD examples for analog PPM: uniform (above) and Gaussian (below). Spectral lines are highlighted by vertical arrows.

where $E_q = \int |q(t)|^2\, dt$ is the energy of the pulse and $\delta_{\alpha,\beta}$ is the Kronecker delta function, giving 1 when $\alpha = \beta$ and 0 otherwise. Note that, the Gaussian noise is the only random term of (24) and, moreover, it is independent on the value of s_n. Because we are dealing with an AWGN channel, for any given instant nT, the random variables $\varphi_n(\alpha \mid \beta)$ are Gaussian and are thus completely specified by their means and covariances. In Appendix C we prove that these Gaussian random variables are independent with mean and variance

$$\begin{aligned} m_{\alpha|\beta} &= \mathrm{E}\,[\varphi_n(\alpha \mid \beta)] = AE_q\delta_{\alpha,\beta} \\ \sigma^2 &= \mathrm{E}\,[(\varphi_n(\alpha \mid \beta) - m_{\alpha|\beta})^2] = \tfrac{1}{2}N_0E_q \end{aligned} \tag{25}$$

where only the mean depends on the transmitted value.

5.2. Symbol Error Probability Evaluation

In the above context, the symbol error probability is given by

$$\begin{aligned} P_e = \mathrm{P}\,[\hat{s}_n \neq s_n] &= \sum_{\alpha\in\mathcal{A}_M} \mathrm{P}\,[\hat{s}_n \neq \alpha \mid s_n = \alpha]\,\mathrm{P}\,[s_n = \alpha] \\ &= \sum_{\alpha\in\mathcal{A}_M} (1 - \mathrm{P}\,[\hat{s}_n = \alpha \mid s_n = \alpha])\,\mathrm{P}\,[s_n = \alpha] \end{aligned}$$

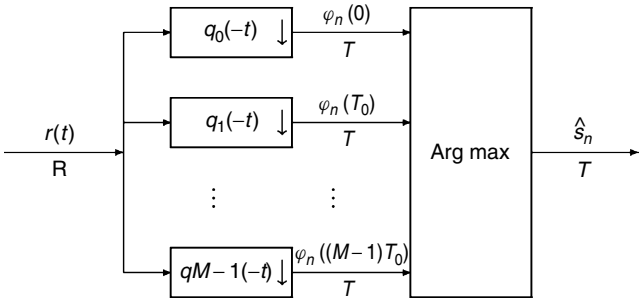

Figure 9. Optimal detection of digital PPM signals.

Because the diagonal transition probabilities

$$\mathrm{P}[\hat{s}_n = \alpha \mid s_n = \alpha] = \mathrm{P}[\alpha = \arg\max_{\gamma} \varphi_n(\gamma \mid \alpha)] = P_c$$

are independent of the value of α, as can be easily derived from the symmetric statistical properties of the M-tuple $\varphi_n(\gamma \mid \alpha)$, $\gamma \in \mathcal{A}_M$, the symbol error probability becomes

$$P_e = 1 - P_c = 1 - \mathrm{P}[\varphi_n(0 \mid 0) = \max_{\gamma} \varphi_n(\gamma \mid 0)] \tag{26}$$

where we deliberately set $\alpha = 0$.

The probability of a correct decision P_c in (26) may be further expressed in compact form as

$$\begin{aligned} P_c &= \int \mathrm{P}[\varphi_n(T_0 \mid 0) < x, \varphi_n(2T_0 \mid 0) < x, \ldots, \varphi_n \\ &\quad \times ((M-1)T_0 \mid 0) < x \mid \varphi_n(0 \mid 0) = x] f_0(x)\, dx \\ &= \int \mathrm{P}[\varphi_n(T_0 \mid 0) < x] \mathrm{P}[\varphi_n(2T_0 \mid 0) < x] \\ &\quad \times \ldots \mathrm{P}[\varphi_n((M-1)T_0 \mid 0) \times < x] f_0(x)\, dx \\ &= \int (\mathrm{P}[\varphi_n(T_0 \mid 0) < x])^{M-1} f_0(x)\, dx \end{aligned}$$

where $f_0(x)$ is the probability density of $\varphi_n(0 \mid 0)$ and where we have taken into account that all $\varphi_n(\alpha \mid 0), \alpha \neq 0$ are statistically independent and identically distributed. Then, by considering the Gaussian distribution of all $\varphi_n(\alpha \mid 0)$, we finally find

$$P_e = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} (1 - \Phi^{M-1}(x)) \exp\left[-\frac{1}{2} \left(x - \sqrt{\frac{2\mathcal{E}_s}{N_0}} \right)^2 \right] dx \tag{27}$$

where $\mathcal{E}_s = A^2 E_q$ is the received energy per symbol and $\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} \exp[-t^2/2]\, \mathrm{d}\, t$ is the normalized cumulative Gaussian distribution function.

Note that, in general, equation (27) must be evaluated numerically, except for the case $M = 2$ for which the exact expression is known to be $P_e = Q(\sqrt{2\mathcal{E}_s/N_0})$ with $Q(x) = 1 - \Phi(x)$ the complementary Gaussian cumulative distribution function.

5.3. Bit Error Probability

Sometimes, it is also desirable to convert the probability of a symbol error into the equivalent probability of a binary digit error. This is a welcome operation if we wish to compare performances of different PPM alphabets and is usually done by considering that M is a power of 2, say $M = 2^k$. So, provided that the M-ary symbol α is mapped into the k-bit word $\mathbf{d}_\alpha = (d_{\alpha,0}, \ldots, d_{\alpha,k-1})$, the bit error probability becomes

$$P_b = \sum_{\alpha \in \mathcal{A}_M} \mathrm{P}[s_n = \alpha] \sum_{\substack{\beta \in \mathcal{A}_M \\ \beta \neq \alpha}} \mathrm{P}[\hat{s}_n = \beta \mid s_n = \alpha] \frac{\mathrm{dist}(\mathbf{d}_\alpha, \mathbf{d}_\beta)}{\log_2 M}$$

where $\mathrm{dist}(\mathbf{d}_\alpha, \mathbf{d}_\beta)$ expresses the Hamming distance. Note that nondiagonal transition probabilities are independent on α and β, that is, $\mathrm{P}[\hat{s}_n = \beta \mid s_n = \alpha] = P_e/(M-1)$ for $\alpha \neq \beta$, because of the symmetric behavior of the channel. So, by further considering equally likely symbols, $\mathrm{P}[s_n = \alpha] = 1/M$, we obtain

$$P_b = \frac{2^{k-1}}{2^k - 1} P_e \tag{28}$$

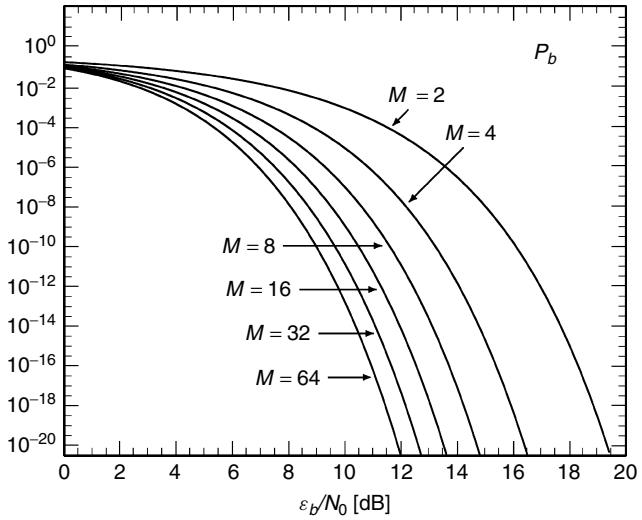

Figure 10. Bit error probability P_b versus SNR per bit $\mathcal{E}_b/N_0$ for different values of M.

that, for large values of M, reaches the limit $P_b \to P_e/2$.

In Fig. 10 we show bit error rate curves for various values of M as a function of the signal-to-noise ratio (SNR) per bit $\mathcal{E}_b/N_0$, where $\mathcal{E}_b = \mathcal{E}_s/\log_2 M$ is the energy-per-bit. Note that, for high values of the SNR, the bit error probability can be drastically reduced by increasing the cardinality M of the PPM alphabet. In particular, it can be demonstrated that as M approaches infinity, the probability of error approaches zero exponentially, provided that $\mathcal{E}_b/N_0 > \ln 2 (= -1.6\ \mathrm{dB})$.

6. INFORMATION RATES

Another fundamental measure in communications is given by the concept of *capacity* (or information rate) which expresses the maximum amount of information that can be sent through a channel with arbitrarily small error probability by use of appropriate coding techniques [5]. One of the main advantages of capacity is that it does not require us to specify the coding technique and represents a target to be (hopefully) met in the construction of error correcting codes. In the following section we investigate the capacity of digital PPM.

6.1. Formulation of Capacity

The basic concept in capacity evaluation is that of *entropy* $H(A)$ of a symbol source A, expressing the amount of information (in bits) carried by each of the symbols of the source. Entropy takes different expressions in dependence on the form of the source output (analog, digital, vectorial).

In digital PPM the source A outputs the digital symbol sequence s_n. We consider s_n to be stationary and with independent and identically distributed symbols with probabilities $p_A(\alpha) = \mathrm{P}[s_n = \alpha]$, in which case the entropy of the PPM source is

$$H(A) = \mathrm{E}[-\log_2 p_A(s_n)] = -\sum_{\alpha \in \mathcal{A}_M} p_A(\alpha) \log_2 p_A(\alpha) \quad [\text{bit/symbol}] \tag{29}$$

with the property $0 \le H(A) \le \log_2 M$, where $H(A) = \log_2 M$ if and only if the symbols are equally likely, that is $p_A(\alpha) = 1/M$.

The symbols s_n are then transmitted through the PPM channel, which includes modulation and demodulation. The output of the PPM channel is thus represented by an output source B that, in the case of optimal detection of each PPM pulse (as in the previous section), produces the symbol sequence $\hat{s}_n$. This approach is called *hard-detection*. Alternatively, one could use the correlation-measures $\varphi_n(\alpha)$ as weights in a Viterbi trellis, in which case we will talk of soft-detection and consider the real-valued vector sequence $\boldsymbol{\varphi}_n = (\varphi_n(0), \varphi_n(1), \ldots, \varphi_n(M-1))$ as the output of the source B. For ease of mathematical treatment, in the following we consider the hard-detection case.

The second quantity of interest is not represented by the entropy of B, rather on the conditional entropy $H(A \mid B)$ expressing the uncertainty on the output value of A once the output value of B is known (e.g., on the value of s_n once $\hat{s}_n$ is known). In hard-detection, the conditional entropy is expressed as

$$H(A \mid B) = \mathrm{E}[-\log_2 p_{A|B}(s_n \mid \hat{s}_n)] = -\sum_{\alpha,\beta \in \mathcal{A}_M} p_{AB}(\alpha, \beta) \log_2 p_{A|B}(\alpha \mid \beta) \qquad (30)$$

where we used the conditional probabilities $p_{A|B}(\alpha \mid \beta) = \mathrm{P}[s_n = \alpha \mid \hat{s}_n = \beta]$ and the joint probabilities $p_{AB}(\alpha, \beta) = \mathrm{P}[s_n = \alpha, \hat{s}_n = \beta]$.

From the source entropy $H(A)$ and the conditional entropy $H(A \mid B)$ it is customary to define the *average information flow* $I(A;B) = H(A) - H(A \mid B)$ expressing the difference between the information $H(A)$ carried by the source and the information $H(A \mid B)$ lost during transmission. In this context, capacity is defined as

$$C = \max_{p_A(\alpha)} I(A;B) = \max_{p_A(\alpha)} H(A) - H(A \mid B) \qquad \text{[bit/symbol]} \qquad (31)$$

that is the maximum value, taken with respect to the source symbol probabilities $p_A(\alpha), \alpha \in \mathcal{A}_M$, of the information flow. Note that, because we always have $H(A \mid B) \le H(A)$, capacity is a positive quantity.

When further taking into account that the symbol rate is $F = 1/T$, we can introduce the related concept of *information rate*

$$R = CF \qquad \text{[bit/s]} \qquad (32)$$

expressing the maximum amount of bit per second that can be sent through the channel with arbitrarily small error probability.

6.2. Information Rates for Digital PPM

In order to derive a compact expression for digital PPM capacity, it is appropriate to use the well-known identity for conditional probabilities $p_{A|B}(\alpha \mid \beta)p_B(\beta) = p_{AB}(\alpha, \beta) = p_{B|A}(\beta \mid \alpha)p_A(\alpha)$, where the meaning of the two new measures $p_{B|A}(\beta \mid \alpha)$ and $p_B(\beta)$ is obvious. With a little effort, this property lets us express the information flow as a function of the transition probabilities $p_{B|A}(\beta \mid \alpha)$ and of the source probabilities $p_A(\alpha)$, and we have

$$I(A;B) = \sum_{\alpha,\beta \in \mathcal{A}_M} p_{B|A}(\beta \mid \alpha)p_A(\alpha) \log_2 \frac{p_{B|A}(\beta \mid \alpha)}{p_B(\beta)} \qquad (33)$$

where

$$p_B(\beta) = \sum_{\gamma \in \mathcal{A}_M} p_{B|A}(\beta \mid \gamma)p_A(\gamma)$$

Moreover, from the results of the previous section we know that the transition probabilities satisfy

$$p_{B|A}(\beta \mid \alpha) = \begin{cases} 1 - P_e & \alpha = \beta \\ P_e/(M-1) & \alpha \ne \beta \end{cases}$$

where P_e is given by (27).

In the present situation, it can be proved that the maximization of (33) occurs when equally likely symbols are used, that is $p_A(\alpha) = 1/M$ in which case we also have $p_B(\beta) = 1/M$, and the capacity thus becomes

$$C = \log_2 M + P_e \log_2 \frac{P_e}{M-1} + (1 - P_e)\log_2(1 - P_e) \qquad (34)$$

while the information rate is expressed by $R = C/T$.

For a fair comparison between modulations employing different alphabet cardinalities M, it is convenient to assume that the source bit rate is fixed to $R_s = \log_2(M)/T$, and in Fig. 11 we show the normalized information rate R/R_s (efficiency) as a function of the bit-to-noise ratio $\mathcal{E}_b/N_0$. We note that for higher values of M the curves display higher efficiency and saturate faster. However, it is perhaps worth recalling that increased values of M correspond to a decrease of the pulse width T_0, and in fact $T_0 = \log_2(M)/(MR_s)$, in which case the available pulse technology could be a limiting factor for the choice of M.

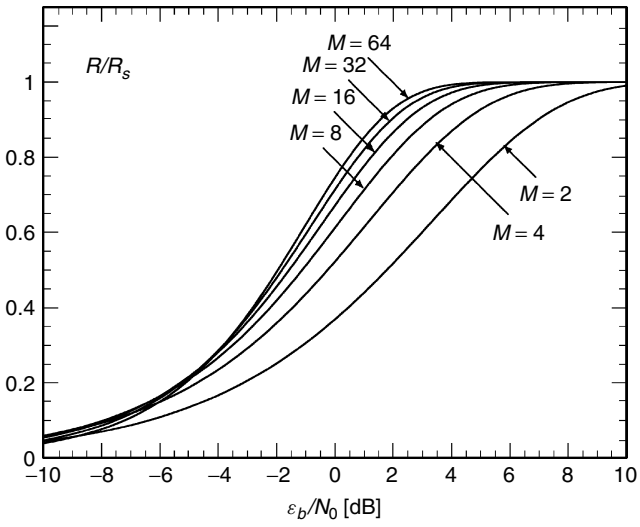

Figure 11. Efficiency R/R_s for hard-detected PPM versus SNR per bit $\mathcal{E}_b/N_0$ for different values of M.

7. APPLICATIONS (MAINLY IN WIRELESS OPTICAL COMMUNICATIONS)

PPM is perhaps the most widely used form of pulse modulation for its efficiency. We have to make a clear distinction between the analog era (the past) and the digital era (the present and the future).

In the past, analog PPM was normally used in the form of nonuniform sampling, also in connection with other modulations, since this approach resulted a simplified circuitry. To this regard the interested reader can refer to [2,3].

More recently, the digital PPM format found remarkable applications mainly in the field of optical communications, where the technology of generating very short pulses perfectly matches with the unipolar nature of PPM. It is worth recalling that PPM found some applications in fiber optics during the transition from copper-cable, where transmission required line encoding strategies with multilevel formats; in place of using multilevel PAM, in fiber optics it was more convenient to use multilevel PPM.

Nowadays, the interest on PPM is mainly restricted to wireless optical communications using infrared links, which require high average-power efficiency to minimize ocular hazards and power consumption. PPM is a technique that achieves very good power efficiency and it is largely used in these applications. For example, the Infrared Data Association (IrDA) has designated 4-PPM as the standard modulation technique for 4-Mb/s optical wireless links working over very short distances (1 m or less) [6]. These are envisioned to connect laptop computers, PDAs, palmtops, printers calculators, and mobile phones. NASA has proposed use of PPM in various free-space applications.

PPM also enters the IEEE 802.11 standard for infrared communications over local area networks (LANs), using 16-PPM schemes for 1 Mb/s links and 4-PPM for 2 Mb/s links. These are diffuse systems for which PPM is the technique that offers the best characteristics for transmission. We may thus emphasize the definitive success of PPM because of its use in many important standards in the digital format.

APPENDIX

Appendix A. Expression of PPM with Nonuniform Sampling

To prove (11) we can follow the sequence of operations of Fig. 3 with $\tilde{s}(t)$ replaced by $s(t)$, as requested in the case of nonuniform sampling.

The PDM signal can be written in the form

$$v_0(t) = u[s(t) - c(t)] \tag{35}$$

where $u(x)$ is the step function: $u(x) = 1$ for $x > 0$ and $u(x) = 0$ for $x < 0$. In fact, (35) gives 1 whenever $s(t) > c(t)$ and 0 otherwise. Considering that the derivative of the step function is the delta function, $du(x)/dx = \delta(x)$, the derivative of $v_0(t)$ is given by

$$v_1(t) = [s'(t) - c'(t)]\delta(s(t) - c(t))$$

Considering that $c(t) = (t - nT)S_0/T, t \in \mathcal{I}_n$ and recalling the property $\delta(\pm Ax) = (1/|A|)\delta(x)$, in the nth time slot we find

$$v_1(t) = [-1 + K\,s'(t)]\delta(t - nT - K\,s(t)), \quad t \in \mathcal{I}_n$$

The inverse half-wave rectification inverts the sign and we find

$$v_\delta(t) = |1 - K\,s'(t)|\delta(t - nT - K\,s(t)), \quad t \in \mathcal{I}_n$$

Hence, the expression of $v_\delta(t)$ for all t is

$$v_\delta(t) = |1 - K\,s'(t)| \sum_{n=-\infty}^{+\infty} \delta(t - nT - K\,s(t))$$

and (11) follows after use of the well-known identity

$$\sum_{n=-\infty}^{+\infty} \delta(t - nT) = F \sum_{n=-\infty}^{+\infty} e^{j2\pi nFt}.$$

Appendix B. Proof of the PSD Expression (19)

We first introduce the PPM expression in Eq. (14) in the correlation definition

$$\begin{aligned}\tilde{r}_v(t,\tau) &= \mathrm{E}[v(t)v^*(t+\tau)] \\ &= \sum_{m,k=-\infty}^{+\infty} \mathrm{E}[q(t - mT - s_m) \\ &\quad \times q^*(t + \tau - (m+k)T - s_{m+k})]\end{aligned}$$

where the conjugate is irrelevant (because the pulse function $q(t)$ is real valued) but useful in the following. By next expressing $q(t)$ as an inverse Fourier transform, $q(t) = \int Q(f)e^{j2\pi ft}df$, and by introducing the characteristic functions (17) and the function defined by (18), we obtain

$$\begin{aligned}\tilde{r}_v(t,\tau) &= \sum_{m,k=-\infty}^{+\infty} \mathrm{E}\left[\int df_1 \int df\; Q(f_1)Q^*(f)\right. \\ &\quad \left. \times e^{j2\pi[f_1(t-mT-s_m)-f(t+\tau-(m+k)T-s_{m+k})]}\right] \\ &= \sum_{m,k=-\infty}^{+\infty} \int df_1 \int df\; Q(f_1)Q^*(f)\Phi_s(-f_1, f; kT) \\ &\quad \times e^{j2\pi[f_1(t-mT)-f(t+\tau-(m+k)T)]} \\ &= \sum_{m=-\infty}^{+\infty} \int df_1 \int df\; Q(f_1)Q^*(f)\Psi_s(-f_1, f; f) \\ &\quad \times e^{j2\pi[f_1(t-mT)-f(t+\tau-mT)]}\end{aligned}$$

which clearly shows that $\tilde{r}_v(t,\tau)$ has period T in t. At this point we evaluate (15)

$$r_v(\tau) = \frac{1}{T}\int df_1 \int df\; Q(f_1)Q^*(f)\Psi_s(-f_1, f; f)A(f_1, f)e^{-j2\pi f\tau}$$

where

$$A(f_1,f)=\sum_{m=-\infty}^{+\infty}\int_0^T e^{j2\pi(f_1-f)(t-mT)}\,dt$$
$$=\int_{-\infty}^{+\infty}e^{j2\pi(f_1-f)u}\,du=\delta(f_1-f)$$

The presence of this delta function allows us to remove the integral with respect to f_1 setting $f_1=f$ elsewhere. Hence,

$$r_v(\tau)=\frac{1}{T}\int df\; Q(f)Q^*(f)\Psi_s(-f,f;f)e^{-j2\pi f\tau}$$

which expresses $r_v(\tau)$ as the inverse Fourier transform of the quantity defined in Eq. (19). Because the inverse Fourier transform is unique, the proof is complete.

Appendix C. Mean and Covariances of $\varphi_a(nT)$

We derive mean and cross-correlation for the Gaussian random variables $\eta_n(\alpha), \alpha\in\mathcal{A}_M$ of (24). The mean value gives

$$\mathrm{E}[\eta_n(\alpha)]=\mathrm{E}\left[\int \eta(t)p(t-nT-\alpha)\,dt\right]$$
$$=\int \mathrm{E}[\eta(t)]p(t-nT-\alpha)\,dt=0$$

because $\eta(t)$ is a zero-mean Gaussian process. This proves the first of Eq. (25) since the expected signal term in Eq. (24) is a deterministic quantity. Covariance of (24) is instead completely determined by the noise terms $\eta_n(\alpha)$ and we have

$$\mathrm{E}[\eta_n(\alpha)\eta_n(\beta)]=\mathrm{E}\left[\int \eta(t)p(t-nT-\alpha)\right.$$
$$\left.\times dt\int \eta(x)p(x-nT-\beta)\,dx\right]$$
$$=\int\int \mathrm{E}[\eta(t)\eta(x)]p(t-nT-\alpha)$$
$$\times p(x-nT-\beta)\,dt\,dx$$
$$=\frac{N_0}{2}\int\int \delta(t-x)p(t-nT-\alpha)$$
$$\times p(x-nT-\beta)\,dt\,dx$$
$$=\frac{N_0}{2}\int p(t-nT-\alpha)p(t-nT-\beta)\,dt \tag{36}$$

where we used the property $\mathrm{E}[\eta(t)\eta(x)]=\frac{1}{2}N_0\delta(t-x)$. By further considering that pulses in the last of (36) are non-colliding for $\alpha\neq\beta$, the Gaussian random variables $\eta_n(\alpha)$ become statistically uncorrelated (hence independent) and the second of (25) follows straightforwardly.

BIOGRAPHIES

Gianfranco Cariolaro (M'66) was born in 1936. He received the degree in Electrical Engineering from the University of Padova, Italy, in 1960, and the Libera Docenza degree in Electrical Communications in 1968 from the same university. He was appointed full professor in 1975 and is currently Professor of Electrical Communications and Signal Theory at the University of Padova. His main research is in the fields of data transmission, images, digital television, multicarrier modulation systems (OFDM), cellular radios, deep space communications, and the fractional Fourier transform. He is author of several books including "Unified Signal Theory" (Torino, Italy: UTET, 2nd Edition, 1996).

Tomaso Erseghe was born in Valdagno, Italy, in 1972. He received the laurea degree in Telecommunication Engineering from the University of Padova, Italy, in 1996, with a thesis on the fractional Fourier transform, and the Ph.D. in Telecommunication Engineering from that same university, in 2002, with a thesis on ultra-wide-band communications. From 1997 to 1999 he worked as an R&D Engineer at Snell & Wilcox a British broadcast equipment manufacturer, in the areas of image restoration and motion compensation. He is now a Post Doc at the University of Padova. His research interests include fractional Fourier transforms, the theory of symmetries with application to the DFT, ultra-wide-band impulse radio, time-hopping constructions. He has also been involved in some research projects sponsored by the European Community.

1. INTRODUCTION

Quadrature amplitude modulation (QAM), or quadrature amplitude shift keying (QASK), is a linear method of digital modulation in which M-ary symbols are transmitted by varying the amplitude of two carriers in quadrature. QAM requires coherent detection and linear amplifiers. QAM has an excellent bandwidth efficiency (i.e., the ratio of bit rate to occupied bandwidth is high), a moderate energy efficiency (i.e., moderate values of energy-to-noise ratio per bit for a given bit error probability), and a high degree of complexity at the receiver because there is a need to track the amplitude, phase, and frequency of the carrier as well as the clock of the symbols. QAM is used mainly in modems over telephone lines but its application is growing in satellite communications, coaxial cables and line-of-sight microwave systems. Numerous papers have been published about various aspects of QAM. Reference 1 is a book totally devoted to QAM. Most books (both undergraduate and graduate level) on digital communications contain chapters of various degree of depth on QAM. A partial list of these books is presented in Refs. 2–7. The first paper about QAM was published in September 1960 and at the time of writing this article (January 2002), papers on this topic still appear in the professional literature.

2. QAM SYSTEM

A model of a typical QAM system is shown in Fig. 1.

A sequence of M-ary independent and equiprobable symbols ($M = 2^\mu$, $\mu =$ integer) $\boldsymbol{a} = (a_0 a_1 \ldots)$ is generated by a source at the rate R bauds (symbols/s) so that symbol a_i is produced at time $t = iT$, where $T = 1/R$. Symbol a_i takes values from the set

$$\Omega = \{a(m): m = 1, 2, \ldots, M\} \tag{1}$$

In QAM the symbols are two-dimensional or complex

$$a(m) = a_I(m) + j a_Q(m) \tag{2}$$

where subscripts I and Q denote the in-phase (real) and quadrature-phase (imaginary) components. The symbol set forms a symbol constellation. Several typical but simple symbol constellations are shown in Fig. 2 for $M = 8, 12, 16$. These are examples of (a) square, (b) rectangular, (c) cross, and (d) star constellations.

For rectangular constellations with $M = M_I M_Q$, $a_x(m) = \pm 1, \pm 3, \pm(M_x - 1)$, $x = I, Q$, and for square constellations $M_I = M_Q = \sqrt{M}$. At the destination, we receive the sequence $\hat{\mathbf{a}} = (\hat{a}_0 \hat{a}_1 \ldots)$ where $\hat{a}_i \in \Omega$ and $\hat{a}_i$ may differ from a_i. Hence, the symbol error probability (SEP) is

$$P(e) = P(\hat{a}_i \neq a_i) \tag{3}$$

Each symbol represents μ bits. For example, if $\mu = 4$, the 4 bits represented by a_i are $(b_{\mu i+1}, b_{\mu i+2}, b_{\mu i+3}, b_{\mu i+4})$, $b_j \in \{0, 1\}$. The bit error probability (BEP) is

$$P_b(e) = P(\hat{b}_j \neq b_j) \tag{4}$$

and the bit rate is

$$R_b = \frac{R}{\mu} \tag{5}$$

The BEP and SEP are related by the particular representation or mapping between the symbols and bit sequences. For example, in Gray coding two neighboring symbols in the symbol constellation differ by only 1 bit. In Fig. 3 we illustrate for the case of $M = 4$ two mappings of which (a) is a Gray code and (b) is not. The aim in designing a communication system is to minimize $P(e)$ and $P_b(e)$ when all other factors remain equal.

More complicated and optimal symbol constellation can be found in Refs. 8 and 9. By *optimal* we mean the one producing the minimum SEP or BEP for a given average energy-to-noise ratio. In the process of transmitting the symbols through a physical channel, we impose the sequence of symbols $\boldsymbol{a}$ on a signal that can pass through the channel. For a bandpass channel with transfer function $\tilde{H}_C(f)$ and bandwidth $\tilde{B}_c$ around the frequency f_c (illustrated in Fig. 4 for an ideal channel with rectangular frequency response) the impulse response is

$$\tilde{h}_C(t) = \mathrm{Re}\{2h_C(t)e^{jw_c t}\} = 2h_{CI}(t)\cos(w_c t) - 2h_{CQ}(t)\sin(w_c t) \tag{6}$$

where Re { } denotes the real part of the term in the braces, $\omega_c = 2\pi f_c$ and

$$h_C(t) = h_{CI}(t) + j h_{CQ}(t) \tag{7}$$

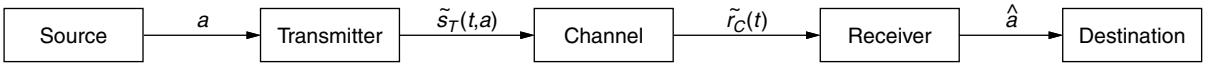

Figure 1. Typical QAM system.

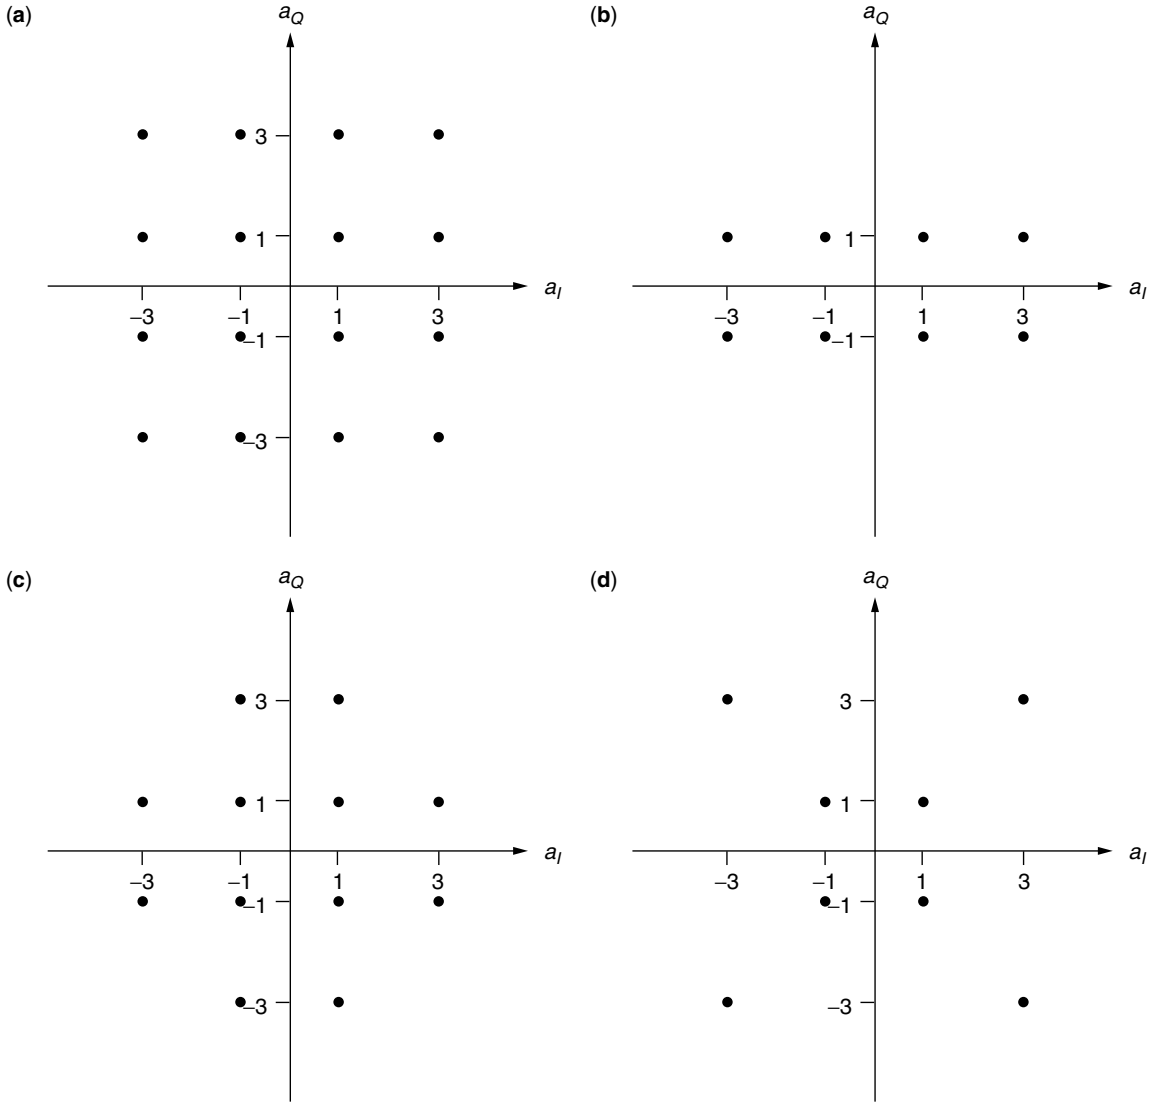

Figure 2. QAM symbol constellations: (**a**) square; (**b**) rectangular; (**c**) cross; (**d**) star.

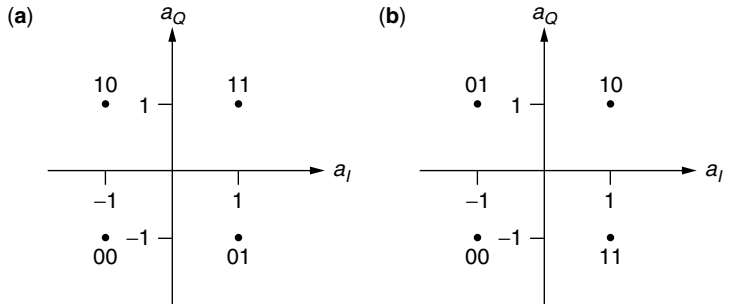

Figure 3. (**a**) Gray code; (**b**) arbitrary code.

is called the *baseband equivalent* or *complex envelope* of $\tilde{h}_C(t)$ with transfer function

$$H_C(f) = \tilde{H}_C(f+f_c)u(f+f_c), \quad u(f) = \begin{cases} 1 & f \geq 0 \\ 0 & f < 0 \end{cases} \tag{8}$$

and bandwidth $B_C = \tilde{B}_C/2$.

The terms $H_c(f)$ and $h_c(t)$ form a Fourier transform pair. Similar notation will be used for other bandpass filters, signals, and noise. Since the channel is bandpass the transmitted signal has to be also bandpass, and is generated in three stages as shown in Fig. 5.

At the first stage, we produce a bandpass signal with a certain desirable baseband shaping pulse, $h_S(t)$ and

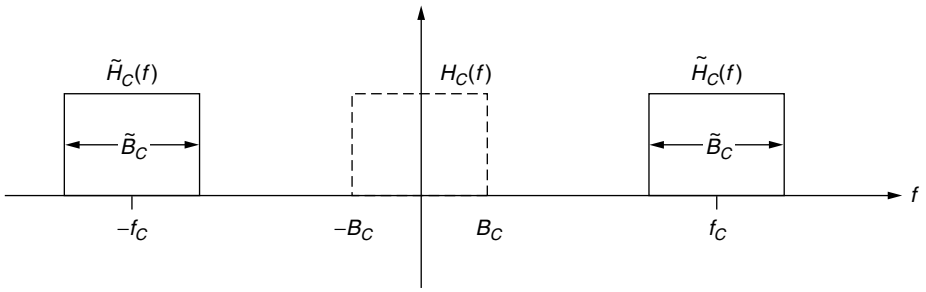

Figure 4. Transfer function of bandpass and baseband equivalent channel.

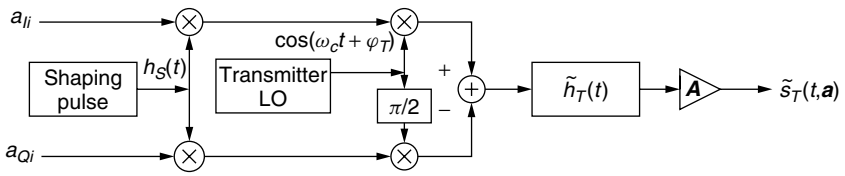

Figure 5. Transmitter of QAM.

two carriers in quadrature $\cos(w_c t + \varphi_T)$, $\sin(w_c t + \varphi_T)$ with carrier frequency f_c and phase φ_T generated by the transmitter local oscillator. This signal is

$$\begin{aligned}\tilde{s}_S(t,\boldsymbol{a}) &= \sum_i [a_{Ii} h_S(t - iT)\cos(w_c t + \varphi_T) \\ &\quad - a_{Qi} h_S(t - iT)\sin(w_c t + \varphi_T)] \\ &= \mathrm{Re}\left\{\sum_i a_i h_S(t - iT) e^{j(w_c t + \varphi_T)}\right\} \end{aligned} \tag{9}$$

with complex envelope

$$s_S(t,\boldsymbol{a}) = \sum_i a_i h_S(t - iT) e^{j\varphi_T} \tag{10}$$

The frequency upconversion from baseband to bandpass is called *modulation*. At the second stage the signal in (9) is filtered by the transmitter bandpass filter with impulse response $\tilde{h}_T(t)$. At the third stage the signal is amplified by a linear amplifier to the required power level. The total amplification of the transmitter is combined into one amplitude A. The transmitted signal is similar to those in (9) and (10) with $H_S(f)$ replaced by the transmitter transfer function $G_T(f) = H_S(f)H_T(f)$ and subscript S replaced by T.

The selection of the pulse shape is of paramount importance in the design of the communication system because it determines the power spectral density (PSD) and hence the bandwidth of transmitted signal. It can be shown [1,2] that the PSD of the signal in (10) is

$$\begin{aligned} S_S(f) &= 0.5A^2\sigma_a^2 |H_S(f)|^2, \\ \sigma_a^2 &= \frac{1}{M}\sum_{m=1}^{M} |a(m)|^2 = \frac{2}{3}(M-1) \end{aligned} \tag{11}$$

where the last equality represents a square constellation. Similarly, the PSD of the signal in (9) is a shifted version of (11) centered at $\pm f_c$.

We shall see later that in order to eliminate intersymbol interference (ISI), which increases the SEP and BEP, only certain pulses (called *Nyquist pulses*) are desirable. Many Nyquist pulses differ in duration and bandwidth. For example a rectangular pulse of duration T

$$h_s(t) = u_T(t) = u(t) - u(t - T) \tag{12}$$

is simple to generate however the resulting bandwidth is very large and more severe filtering is required by $h_T(t)$. In fact the 99% bandwidth, B_{99} of this pulse defined by

$$\int_0^{B_{99}} |H_S(f)|^2\, df = 0.99 \int_0^{\infty} |H_S(f)|^2\, df \tag{13}$$

and that contains 99% of the energy or power of the signal is $B_{99} = 8.65R$. On the other hand the infinite duration pulse $h_S(t)$ (called the raised cosine in frequency) with

$$H_S(f) = \begin{cases} 1 & 0 \le |f| \le (1-\alpha)R/2 \\ \cos\left(\dfrac{\pi}{4\alpha}\left(\left|\dfrac{2f}{R}\right| - 1 + \alpha\right)\right) & (1-\alpha)R/2 \le |f| \\ & \quad \le (1+\alpha)R/2 \\ 0 & (1+\alpha)R/2 \le |f| \le \infty \end{cases} \tag{14}$$

has a 100% bandwidth

$$B = B_{100} = \frac{(1+\alpha)R}{2} \tag{15}$$

where the parameter $0 \le \alpha \le 1$ determines the excess bandwidth beyond the minimum bandwidth of $R/2$. These two pulses are shown in Fig. 6.

For the raised-cosine pulse, no additional filtering is required as long as $B \le B_c$. In designing the system we usually select $B = B_c$ unless guard bands [to reject adjacent-channel interference (ACI) signals with carrier frequencies $f_c \pm \Delta f_c$] are required.

The bandwidth efficiency is defined by the ratio of bit rate and bandpass bandwidth:

$$\eta = \frac{R_b}{\tilde{B}} = \frac{\mu R}{2B} = \frac{\mu}{1+\alpha} \tag{16}$$

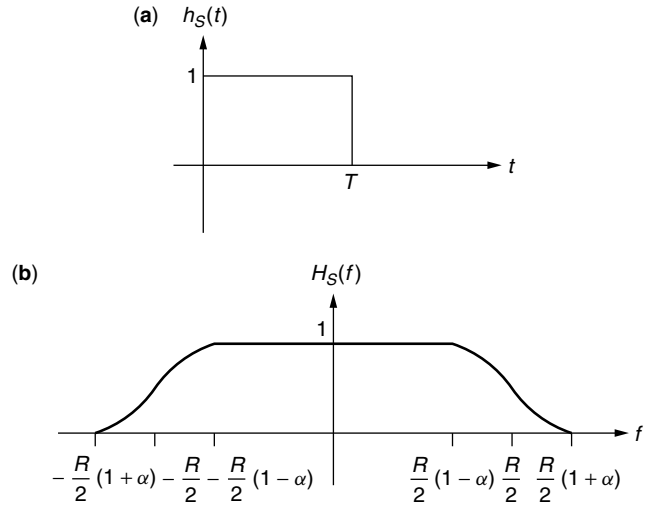

Figure 6. Nyquist pulses: (**a**) rectangular pulse; (**b**) raised cosine pulse in frequency domain with bandwidth $(1+\alpha)R/2$.

Thus we increase the bandwidth efficiency by decreasing α. In practice values of $\alpha \geq 0.15$ are achievable. The bandwidth efficiency as a function of α for $\mu = 2, 4, 6, 8, 10$ (corresponding to $M = 4, 16, 64, 256, 1024$, respectively) is shown in Fig. 7.

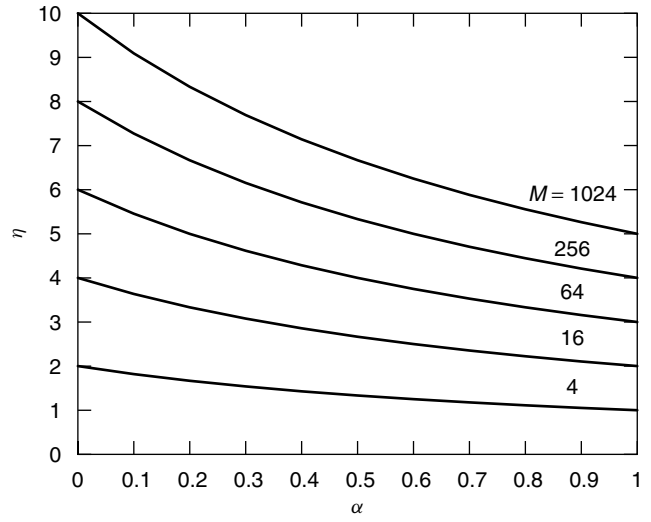

Figure 7. The bandwidth efficiency of QAM as a function of excess bandwidth.

There is a version of QASK called OQASK (offset QASK) or SQASK (staggered QASK) in which the quadrature term in (9) is delayed by $T/2$ [instead of $h_S(t-iT)$, we have $h_S(t-iT-T/2)$]. There is a whole range of shaping pulses, $h_S(t)$ for which we obtain in OQASK with $M=4$ a constant envelope signal for all time: $|\tilde{s}_T(t,\boldsymbol{a})| = c$. This enables the usage of nonlinear amplifiers, which are more efficient than linear amplifiers. In QASK there is only one shaping pulse, namely, a rectangular pulse that gives a constant envelope; however, the resulting bandwidth is large. In OQASK there are many pulses available with a reduced bandwidth. The application of nonlinear amplifiers to QAM with $M > 4$ has been presented in many papers and a comprehensive review can be found in Chap. 7 of Ref. 3.

The channel, a model of which is shown in Fig. 8, is composed of the channel filter, $\tilde{h}_C(t)$ and additive white Gaussian noise (AWGN), $\tilde{n}_C(t)$ with PSD $N_0/2$ for all frequencies. Such a channel is called a AWGN channel.

The channel filter takes into account the channel attenuation and phase shift. The channel output is thus

$$\tilde{r}_C(t) = \tilde{s}_C(t,\boldsymbol{a}) + \tilde{n}_C(t) = \mathrm{Re}\left\{A\sum_i a_i g_C(t-iT)e^{j(w_c t+\varphi_T)}\right\} + \tilde{n}_C(t), \quad G_C(f) = G_T(f)H_C(f) \tag{17}$$

The receiver, a model of which is shown in Fig. 9, is also composed of several stages.

First there is a receiver bandpass filter, $\tilde{h}_R(t)$, whose main task is to eliminate the noise beyond the signal bandwidth and to reduce ACI or spurious interference. The output of this filter is

$$\begin{aligned}\tilde{r}_R(t) &= [\tilde{s}_C(t,\boldsymbol{a}) + \tilde{n}_C(t)] * \tilde{h}_R(t) = \tilde{s}_R(t,\boldsymbol{a}) + \tilde{n}_R(t)\\ &= \mathrm{Re}\left\{\left[A\sum_i a_i g_{CR}(t-iT) + n_R(t)\right]e^{j(w_c t+\varphi_T)}\right\}\\ &= [s_{RI}(t,\boldsymbol{a}) + n_{RI}(t)]\cos(w_c t+\varphi_T)\\ &\quad - [s_{RQ}(t,\boldsymbol{a}) + n_{RQ}(t)]\sin(w_c t+\varphi_T),\\ G_{CR}(f) &= G_C(f)H_R(f)\end{aligned} \tag{18}$$

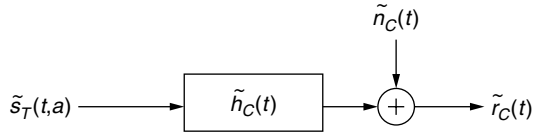

Figure 8. Model of AWGN with filter.

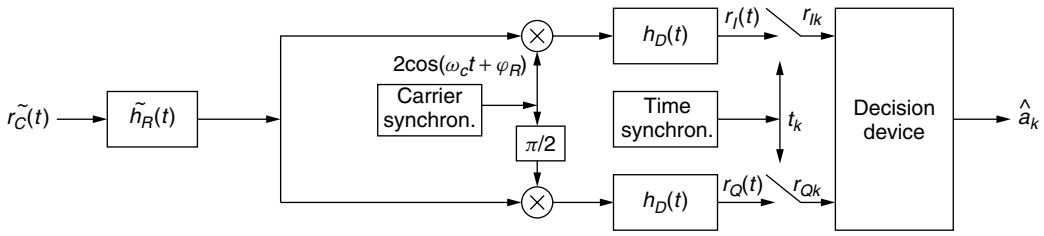

Figure 9. Receiver of QAM.

where $n_R(t)$ is the complex envelope of $\tilde{n}_R(t)$ and is a zero mean complex baseband Gaussian noise process with PSD

$$S_{n_R}(f) = N_0|H_R(f)|^2 \tag{19}$$

In the second stage the output of the receiver filter is multiplied by two carriers in quadrature, $2\cos(w_c t + \varphi_R)$, $2\sin(w_c t + \varphi_R)$ generated by the receiver local oscillator where φ_R tracks φ_T. There is a random phase error

$$\Delta\varphi = \varphi_T - \varphi_R \tag{20}$$

which also takes into account a carrier frequency error. This receiver is called a coherent receiver because it tracks the phase and frequency of the transmitter. Since

$$\begin{aligned} &2\cos(w_c t + \varphi_T)\cos(w_c t + \varphi_R) \\ &\quad = \cos\Delta\varphi + \cos\ (2w_c t + \varphi_T + \varphi_R) \\ &2\sin(w_c t + \varphi_T)\sin(w_c t + \varphi_R) \\ &\quad = \cos\Delta\varphi - \cos\ (2w_c t + \varphi_T + \varphi_R) \\ &2\sin(w_c t + \varphi_T)\cos(w_c t + \varphi_R) \\ &\quad = \sin\Delta\varphi + \sin\ (2w_c t + \varphi_T + \varphi_R) \end{aligned} \tag{21}$$

the multiplier output is the sum of a baseband signal and a bandpass signal with a carrier frequency of $2f_c$, which is easily eliminated by the baseband demodulator filter, $h_D(t)$. The frequency downconversion from bandpass to baseband is called *demodulation* or *detection* and is the inverse of the modulation. The outputs of the detector filters are

$$\begin{aligned} r_I(t) &= s_I(t,\boldsymbol{a}) + n_I(t) = \mathrm{Re}\left\{A\sum_i a_i g(t - iT)e^{j\Delta\varphi}\right\} + n_I(t) \\ r_Q(t) &= s_Q(t,\boldsymbol{a}) + n_Q(t) = \mathrm{Im}\left\{A\sum_i a_i g(t - iT)e^{j\Delta\varphi}\right\} + n_Q(t) \end{aligned} \tag{22}$$

where the transfer function of $g(t)$

$$G(f) = G_R(f)H_D(f) = H_S(f)H_T(t)H_C(f)H_R(f)H_D(f) \tag{23}$$

is the combined effect of all filters in the system on the shaping pulse and $n_I(t)$, $n_Q(t)$ are zero mean, real, baseband, independent, Gaussian noises with identical PSDs

$$S_n = N_0|G_R(f)|^2, \quad G_R(f) = H_R(f)H_D(f) \tag{24}$$

and power or variance

$$P_n = \sigma_n^2 = N_0\int_{-\infty}^{\infty}|G_R(f)|^2\,df \tag{25}$$

In (22) we left the noise unchanged by $\Delta\varphi$ because $n(t)$ and $n(t)e^{j\Delta\varphi}$ are identical, Gaussian processes. The signal in (22)

$$r(t) = r_I(t) + jr_Q(t) = A\sum_i a_i g(t - iT)e^{j\Delta\varphi} + n(t) \tag{26}$$

is sampled at times $t_k = t_0 + kT$. The timing is generated by a time synchronizer from the incoming signal therefore random variations in sampling time are expected. From $r(t_k)$ the decision circuit produces an estimate of symbol a_k, $\hat{a}_k$. We can obtain the result of (26) from the baseband equivalent block diagram shown in Fig. 10, which is composed only of baseband filters and in which the carrier frequency is irrelevant. It can be shown that the receiver presented in Fig. 9 is an optimal receiver provided $g(t)$ is a Nyquist pulse and $g_R(t)$ is a filter matched to $g_C(t)$, namely, $g_R(t) = g_C^*(t_0 - t)$, where x^* denotes the complex conjugate of x.

3. COMPUTATION OF ERROR PROBABILITY

3.1. Computation of SEP

Using the notation

$$r = r(t_k), \quad s = s(t_k,\boldsymbol{a}), \quad n = n(t_k), \quad g_k = g(t_k) \tag{27}$$

we obtain from (26)

$$r = s + n, \quad s = Ag_o e^{j\Delta\varphi}a_k + \mathrm{ISI}, \quad \mathrm{ISI} = A\sum_{i\neq 0} a_{k-i}g_i e^{j\Delta\varphi} \tag{28}$$

Under ideal conditions both $\Delta\varphi = 0$ and $\mathrm{ISI} = 0$. We may also assume that g_0 is real and nonnegative and there is a matched filter; hence

$$r = s + n, \quad s = A_0 a_k, \quad A_0 = Ag_0, \quad s(m) = A_0 a(m) \tag{29}$$

In deciding which symbol is transmitted, we divide the plane of $r = r_I + jr_Q$ into M nonoverlapping regions $\{R_m\}$

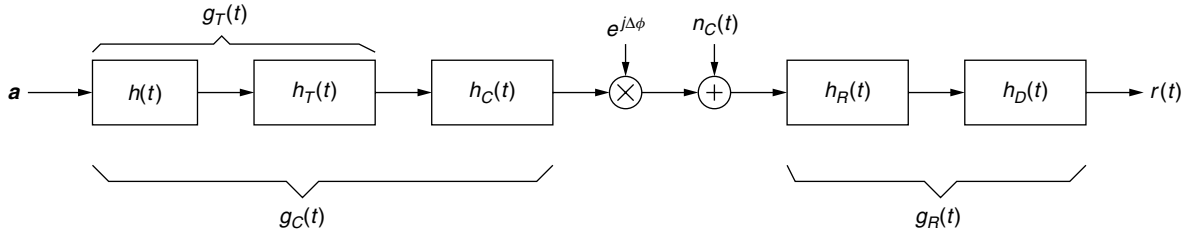

Figure 10. Baseband equivalent of QAM system.

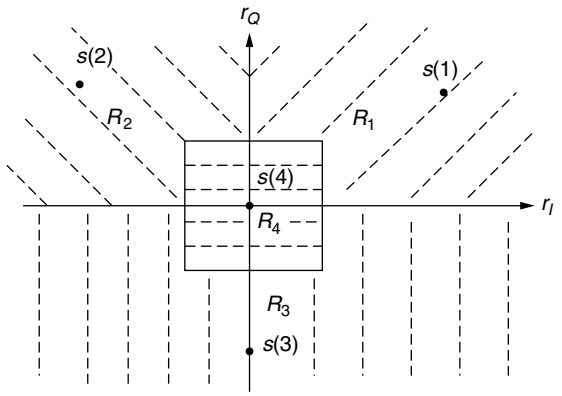

Figure 11. Arbitrary regions of the r plane.

such that if $r \in R_m$ the decision is $\hat{a}_k = a(m)$. This is illustrated in Fig. 11.

The conditional error probability that $\hat{a}_k = a(\hat{m})$ given that $a_k = a(m)$ is computed from

$$P(\hat{a}_k = a(\hat{m}) \mid a_k = a(m)) = P(r \in R_{\hat{m}} \mid a_k = a(m)) = P(\{s(m) + n\} \in R_{\hat{m}}) \tag{30}$$

For equiprobable symbols the SEP is

$$P(e) = P(\hat{a}_k \neq a_k) = \frac{1}{M} \sum_m \sum_{\hat{m} \neq m} P(\hat{a}_k = a(\hat{m}) \mid a_k = a(m)) \tag{31}$$

It can be shown that for optimum decisions we select $r \in R_m$ only if $|r - A_0 a(m)|$ is minimum. These optimum regions are illustrated for two constellations in Fig. 12.

For the square constellations the decision regions are

$$R_m = \{r : s_I(m) - C \leq r_I \leq s_I(m) + C, s_Q(m) - C \leq r_Q \leq s_Q(m) + C\} \tag{32}$$

where C is either A_0 or ∞ depending on whether the regions are finite in both dimensions, finite in one direction or infinite in both dimensions. This is illustrated in Fig. 12a. For square QAM the SEP is [2,5–7]

$$P(e) = 4\left(1 - \frac{1}{\sqrt{M}}\right) Q\left(\sqrt{\frac{3}{M-1}\gamma}\right) - 4\left(1 - \frac{1}{\sqrt{M}}\right)^2 Q^2\left(\sqrt{\frac{3}{M-1}\gamma}\right) \tag{33}$$

where

$$\gamma = \frac{E}{N_0}, \quad E = \frac{A^2 \sigma_a^2 g_0^2}{2} \tag{34}$$

is the energy-to-noise ratio per symbol and

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-0.5y^2}\, dy = \frac{1}{\pi} \int_0^{\pi/2} e^{-0.5x^2/\sin^2\phi}\, d\phi \tag{35}$$

is the standard Q function illustrated in Fig. 13 with lower and upper bounds. $Q^2(x)$ in (33) can be computed from (35) with $\pi/2$ replaced by $\pi/4$ in the limit of the second integral.

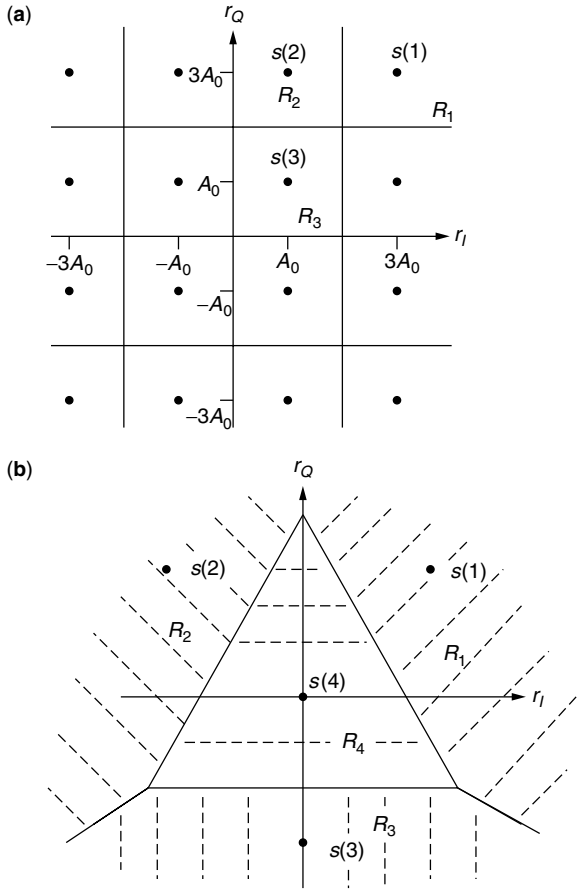

Figure 12. Optimal decision regions: (**a**) square constellation for $M = 16$; (**b**) signal constellation as in Fig. 11.

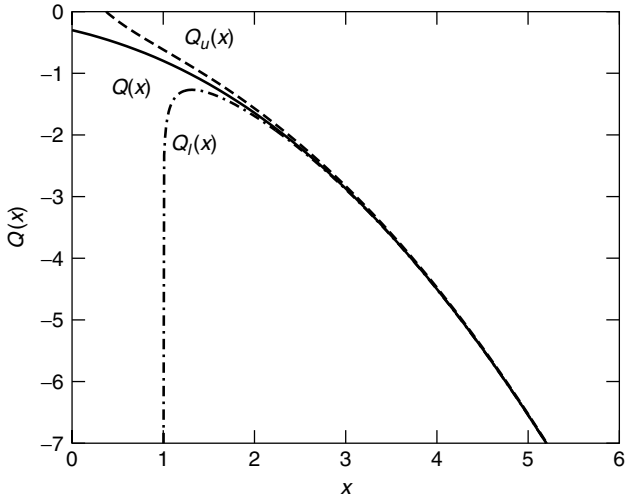

Figure 13. The variations of $Q(x)$, $Q_u(x) = \frac{1}{\sqrt{2\pi x^2}} e^{-(x^2/x)}$ and $Q_1(x) = \frac{1}{\sqrt{2\pi x^2}} \left(1 - \frac{1}{x^2}\right) e^{-(x^2/2)}$.

The SEP as a function of γ is shown in Fig. 14.

The square constellation is optimal for $M = 4$ and very close to optimal [8,9] for other M. For example, to achieve

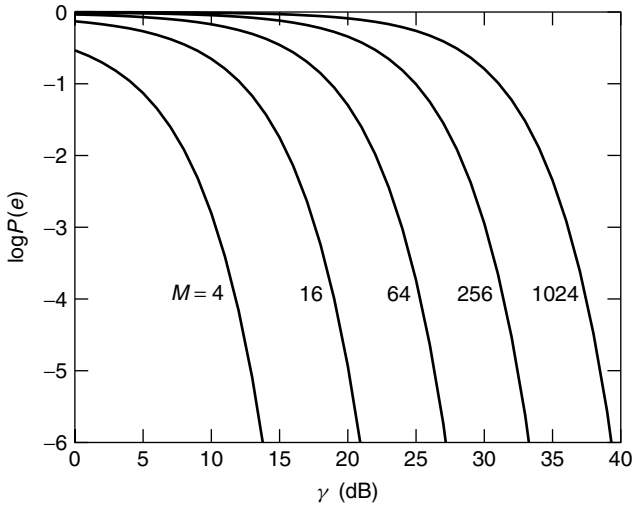

Figure 14. The SEP as a function of energy-to-noise ratio per symbol.

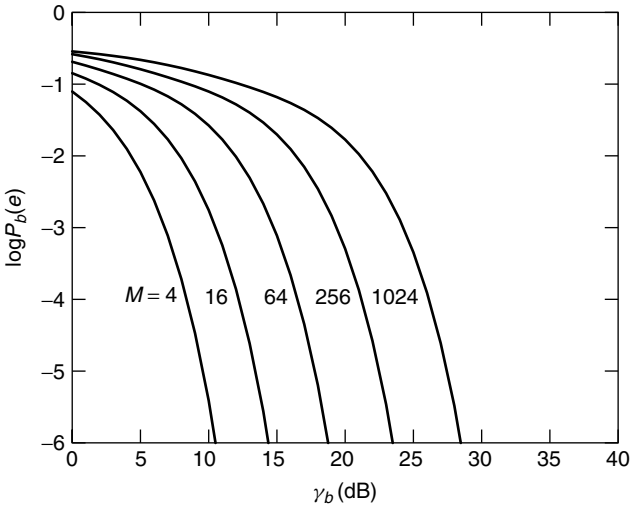

Figure 15. The BEP as a function of energy-to-noise ratio bit.

a SEP of 10^{-5}, γ increases by only 0.1 dB for $M = 16$ and by 0.4 dB for $M = 64$ relative to optimum constellation [2].

3.2. Computation of BEP

When computing the BEP, we have to take into account the mapping between symbols and bits. Let $w_{m\hat{m}}$ be the number of bits by which symbols $a(m)$ and $a(\hat{m})$ differ. Thus, even if the symbols are in error only $w_{m\hat{m}}$ out of the μ bits are in error. The BEP is

$$P_b(e) = \frac{1}{M}\sum_m \sum_{\hat{m}\neq m} \frac{w_{m\hat{m}}}{\mu} P(\hat{a}_k = a(\hat{m}) \mid a_k = a(m)) \geq \frac{P(e)}{\mu} \tag{36}$$

and the lower bound is obtained by substituting $w_{m\hat{m}} = 1$. For square constellations and Gray coding, we can compute $P_b(e)$ precisely:

$$P_b(e) = \sum_{i=1}^{I_M} c_i Q(\sqrt{d_i \gamma_b}), \quad \gamma_b = \frac{E_b}{N_0} \tag{37}$$

For example, for $M = 4$, $I_M = c_1 = 1$, $d_1 = 2$ and for $M = 16$, $I_M = 3$, $c_1 = 0.75$, $c_2 = 0.5$, $c_3 = -0.25$, $d_1 = 0.8$, $d_2 = 7.2$, $d_3 = 20$. An excellent approximation is given by [16]

$$P_b(e) \cong 4\left(1 - \frac{1}{\sqrt{M}}\right) \frac{Q\left(\sqrt{\frac{3\mu\gamma_b}{M-1}}\right) + Q\left(\sqrt{\frac{27\mu\gamma_b}{M-1}}\right)}{\mu} \tag{38}$$

In Fig. 15 we show the BEP as a function of γ_b.

3.3. Optimal Receiver and Transmitter Filters

It follows from (29) that there is no ISI if

$$g_i = \begin{cases} g_0 \neq 0 & i = 0 \\ 0 & i \neq 0 \end{cases} \tag{39}$$

where using the Inverse Fourier transform and assuming $t_0 = 0$ (there is no loss in generality in that because the delay t_0 can be introduced in the final stage so that the matched filter is physically realizable)

$$\begin{aligned} g_i = g(iT) &= \int_{-\infty}^{\infty} G(f) e^{j2\pi fiT}\, df = \sum_{k=-\infty}^{\infty} \int_{-f_N+kR}^{f_N+kR} G(f) e^{j2\pi fiT}\, df \\ &= \sum_{k=-\infty}^{\infty} \int_{-f_N}^{f_N} G(f' + kR) e^{j2\pi(f'+kR)iT}\, df' \\ &= \int_{-f_N}^{f_N} G_{\sum}(f) e^{j2\pi fiT}\, df \end{aligned} \tag{40}$$

where $f_N = R/2$, $R = 1/T$, and

$$G_{\sum}(f) = \sum_k G(f + kR) = T \sum_{i=-\infty}^{\infty} g_i e^{-j2\pi fiT} \tag{41}$$

is a periodic function of f with period R. Thus, if there is no ISI, then

$$G_{\sum}(f) = g_0 T \tag{42}$$

A function $G(f)$ which satisfies this (Nyquist) condition is called a *Nyquist function* $G_N(f)$. No function $G(f)$ with bandwidth less than $R/2$ can satisfy (42). The raised-cosine family with bandwidth $f_N(1+\alpha)$ satisfies this condition [2]. The square root of $G_N(f)$ is denoted by

$$H_N(f) = \sqrt{G_N(f)} \tag{43}$$

The pulse in (14) is $H_N(f)$ for the raised cosine with $g_0 T = 1$.

For a matched filter we can select

$$\begin{aligned} G_C(f) &= H_C(f) G_T(f) = H_N(f), \\ G_R(f) &= H_R(f) H_D(f) = H_N(f) \end{aligned} \tag{44}$$

Knowing one of the filters in the receiver or transmitter, we can find the other filters, which are now the optimal filters. In deriving (44) (although not stated explicitly), we

optimized the filters under the condition of fixed energy, E, at receiver input. If we optimize the filters with the condition of fixed energy at the transmitter the results are different [7] if $H_C(f) \neq 1$ in the range $|f| \leq R_N(1+\alpha)$.

4. QAM IN FADING CHANNELS

There are many fading channels, particularly in mobile communications. The simplest fading channel is a flat and slow fading channel [6]. In such a channel the random channel filter does not distort the signal and the variations in the channel are slow relative to the symbol rate. In such a channel only the amplitude A and phase φ_T are random. Since A is random, the energy-to-noise ratios and their square roots

$$\gamma = \frac{E}{N_0}, \quad \gamma_b = \frac{E_b}{N_0}, \quad \alpha = \sqrt{\gamma}, \quad \alpha_b = \sqrt{\gamma_b} \tag{45}$$

are random variables with probability density function (PDF) $p_x(x)$, where $x = \gamma, \gamma_b, \alpha, \alpha_b$. The SEP and BEP computed in Section 3 are based on the assumption that the receiver tracks the amplitude and phase and knows their values. Without knowledge of A, for example, the decision regions $\{R_m\}$ are useless. Thus the formulas for the SEP and BEP in Section 3 are conditional on the value of γ and γ_b, $P_S(e \mid \gamma)$, and $P_b(e \mid \gamma_b)$. In fading channels these formulas have to be averaged over γ and γ_b.

4.1. The Error Probability without Diversity

The SEP follows from (32) and (33)

$$\begin{aligned} P(e) &= \int_0^\infty P(e \mid \gamma) p_\gamma(\gamma)\, d\gamma = 4C_1 \int_0^\infty Q(\sqrt{C_2\gamma}) p_\gamma(\gamma)\, d\gamma \\ &\quad - 4C_1^2 \int_0^\infty Q^2(\sqrt{C_2\gamma}) p_\gamma(\gamma)\, d\gamma \\ &= \frac{4C_1}{\pi} \int_0^\infty \int_0^{\pi/2} e^{-0.5C_2\gamma/\sin^2\phi} p_\gamma(\gamma)\, d\gamma\, d\phi \\ &\quad - \frac{4C_1^2}{\pi} \int_0^\infty \int_0^{\pi/4} e^{-0.5C_2\gamma/\sin^2\phi} p_\gamma(\gamma)\, d\gamma\, d\phi \end{aligned} \tag{46}$$

where $C_1 = 1 - 1/\sqrt{M}$, $C_2 = 3/(M-1)$.

Applying the Laplace transform (LT)

$$\hat{p}_\gamma(s) = \int_0^\infty e^{-s\gamma} p_\gamma(\gamma)\, d\gamma \tag{47}$$

and combining with (46), we obtain

$$\begin{aligned} P(e) &= \frac{4C_1}{\pi} \int_0^{\pi/2} \hat{p}_\gamma\left(\frac{0.5C_2}{\sin^2\phi}\right) d\phi \\ &\quad - \frac{4C_1^2}{\pi} \int_0^{\pi/4} \hat{p}_\gamma\left(\frac{0.5C_2}{\sin^2\phi}\right) d\phi \end{aligned} \tag{48}$$

Instead of the LT, we can use the moment generating function $M_\gamma(s) = \hat{p}_\gamma(-s)$.

There are many models for the fading channel [6]. A popular and versatile model is the Nakagami $-m$ channel (the m here is a parameter of fading and is unrelated to the m used previously in symbol counting) for which

$$\begin{aligned} p_\gamma(\gamma) &= \frac{m^m \gamma^{m-1}}{(\overline{\gamma})^m \Gamma(m)} e^{-m\gamma/\overline{\gamma}} u(\gamma), \; p_\alpha(\alpha) = \frac{2m^m \alpha^{m-1}}{(\overline{\gamma})^m \Gamma(m)} \\ &\quad \times e^{-m\alpha^2/\overline{\gamma}} u(\alpha), \quad 0.5 \leq m \leq \infty \end{aligned} \tag{49}$$

$$\hat{p}_\gamma(s) = \left(\frac{1+s\overline{\gamma}}{m}\right)^{-m} \tag{50}$$

where

$$\Gamma(m) = \int_0^\infty t^{m-1} e^{-t}\, dt \tag{51}$$

is the gamma function, which for integer m is

$$\Gamma(m) = (m-1)! \tag{52}$$

and $\overline{\gamma}$ is the average value of γ. Note that for $m = 1$, $p_\alpha(\alpha)$ is a Rayleigh PDF, for $m = 0.5$ $p_\alpha(\alpha)$ is a half-Gaussian PDF (because $\Gamma(0.5) = \sqrt{\pi}$), and for $m = \infty$ there is no fading, $p_\alpha(\alpha) = \delta(\alpha - \sqrt{\overline{\gamma}})$ where $\delta(x)$ is impulse function. The fading becomes less severe when m increases. Thus the SEP follows from (48) and (50) as

$$\begin{aligned} P(e) &= \frac{4C_1}{\pi} \int_0^{\pi/2} \left(1 + \frac{0.5C_2\overline{\gamma}}{m \sin^2\phi}\right)^{-m} d\phi \\ &\quad - \frac{4C_1^2}{\pi} \int_0^{\pi/4} \left(1 + \frac{0.5C_2\overline{\gamma}}{m \sin^2\phi}\right)^{-m} d\phi \end{aligned} \tag{53}$$

There is a closed-form formula for integer m that can be found in Eq. (8.108) of Ref. 6. In Fig. 16 we present the SEP as a function of $\overline{\gamma}$ of 16-QAM for several values of m. We can see from this figure that to obtain a SEP of 10^{-2} for a Rayleigh channel, we need an average energy-to-noise ratio per symbol of ~28 dB instead of about ~15 dB with no fading.

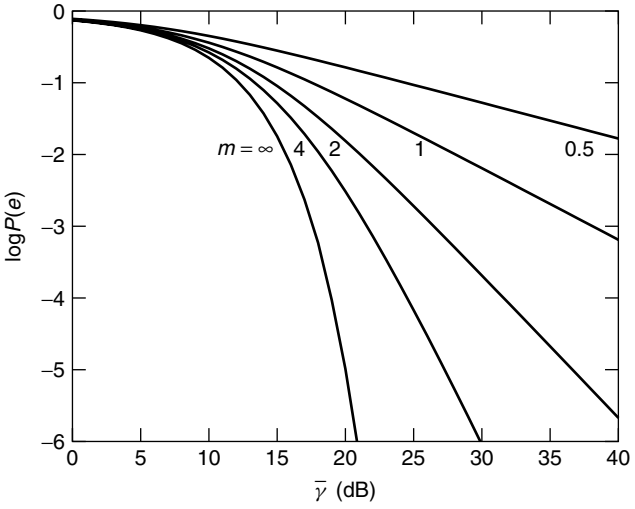

Figure 16. The SEP of 16-QAM as a function of average energy-to-noise ratio per symbol in Nakagami $-m$ fading channel.

The BEP is computed similarly. We cannot use the approximation of (38) unless $\overline{\gamma}_b$ is large. To be precise, we have to now use the conditional BEP (37):

$$P_b(e \mid \gamma_b) = \sum_{i=1}^{I_M} c_i Q(\sqrt{d_i \gamma_b}) \tag{54}$$

After averaging with respect to $p_{\gamma_b}(\gamma_b)$, we obtain

$$P_b(e) = \sum_{i=1}^{I_M} \frac{c_i}{\pi} \int_0^{\pi/2} \hat{p}_{\gamma_b}\left(\frac{0.5 d_i}{\sin^2 \phi}\right) d\phi \tag{55}$$

For $M = 16$ and Nakagami $-m$ fading, the result is

$$\begin{aligned} P_b(e) = {} & \frac{3}{4\pi} \int_0^{\pi/2} \left(1 + \frac{0.4\overline{\gamma}_b}{m \sin^2 \phi}\right)^{-m} d\phi \\ & + \frac{1}{2\pi} \int_0^{\pi/2} \left(1 + \frac{3.6\overline{\gamma}_b}{m \sin^2 \phi}\right)^{-m} d\phi \\ & - \frac{1}{4\pi} \int_0^{\pi/2} \left(1 + \frac{10\overline{\gamma}_b}{m \sin^2 \phi}\right)^{-m} d\phi \end{aligned} \tag{56}$$

There is a closed-form for integer m [see Eq. (5.17a) of Ref. 6]. In Fig. 17 we show the BEP as a function of $\overline{\gamma}_b$ for QAM with $M = 16$ for several values of m.

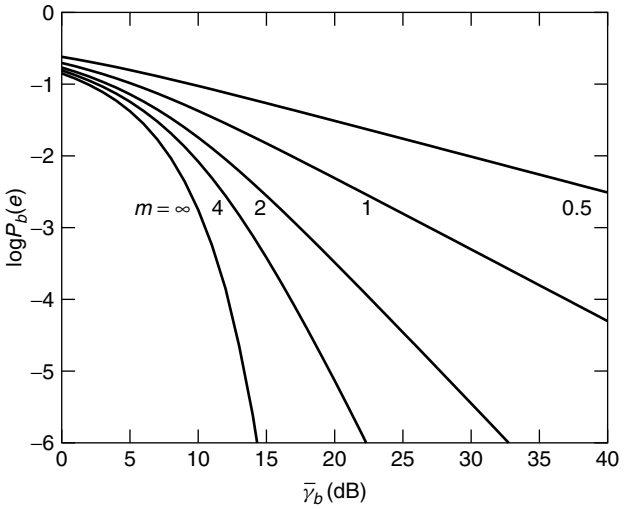

Figure 17. The BEP of 16-QAM as a function of average energy-to-noise ratio per bit for Nakagami $-m$ fading channel.

4.2. The Error Probability with Diversity

In order to reduce the error probability in fading channels, we use *diversity*, where the signal is received simultaneously via K fading channels (by using, e.g., L antenna), which hopefully fade independently so that at least one of the signals has sufficient energy. The received signals are (using complex envelope notation)

$$r_{Cl}(t) = A_l e^{j\varphi_l} \sum_l a_l \cdot g_T(t - \tau_l) + n_{Cl}(t), \quad l = 1, 2, \ldots, L \tag{57}$$

where the amplitudes $\{A_l\}$, phases $\{\varphi_l\}$, and delays $\{\tau_l\}$ are independent random variables that can be tracked by the receiver and $n_{Cl}(t)$ are independent, zero mean, Gaussian, white noises. These signals are combined in an optimal way, called *maximal ratio combining* (MRC) [6] by first aligning the signals in time, using delays $\tau_L - \tau_l$ (τ_L has the maximal delay), then multiplying by $A_l e^{-j\varphi_l}$ and finally processing by $g_R(t)$, which should be a matched filter matched to $g_T(t)$. We have not included the channel filter $h_C(t)$ because we assume flat fading. The block diagram of MRC receiver is shown in Fig. 18.

The decision is based on

$$r(t) = \sum_{l=1}^{L} A_l e^{-j\varphi_l} r_{Ck}(t - \tau_L + \tau_l) \tag{58}$$

For MRC the energy-to-noise ratio per symbol is the sum of the energy-to-noise ratios in each channel [6]

$$\gamma_{\text{MRC}} = \sum_{l=1}^{L} \gamma_l, \quad \gamma_l = \frac{E_l}{N_0} \tag{59}$$

and $\{\gamma_l\}$ are independent random variables. The SEP is

$$\begin{aligned} P(e) = \overline{P(e \mid \gamma_{\text{MRC}})} = {} & \frac{4C_1}{\pi} \int_0^{\pi/2} \overline{e^{-0.5C_2 \gamma_{\text{MRC}}/\sin^2 \phi}}\, d\phi \\ & - \frac{4C_1^2}{\pi} \int_0^{\pi/4} \overline{e^{-0.5C_2 \gamma_{\text{MRC}}/\sin^2 \phi}}\, d\phi \end{aligned} \tag{60}$$

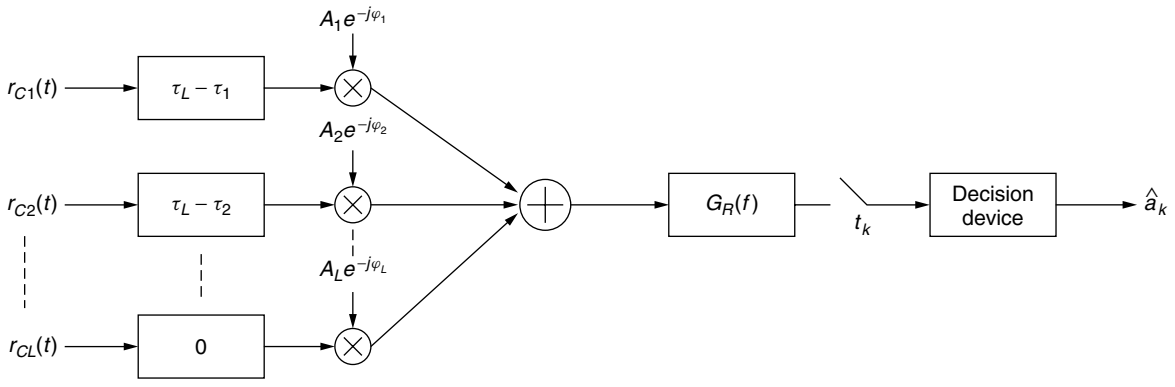

Figure 18. Maximal ratio combining of L fading signals.

where the overbar (vinculum) denotes the average operation. For independent random variables

$$\overline{e^{-C\gamma_{\mathrm{MRC}}}} = \overline{e^{-C\sum_{l=1}^{L}\gamma_l}} = \prod_{l=1}^{L}\overline{e^{-C\gamma_l}} = \prod_{l=1}^{L}\hat{p}_{\gamma_l}(C) = \hat{p}_{\gamma}^{L}(C) \quad (61)$$

where $C = 0.5\,C_2/\sin^2\phi$, $\hat{p}_{\gamma_l}(s)$ is the LT of $p_{\gamma_l}(\gamma_l)$, and the last equality is for identical PDFs for all γ_l,. We thus have

$$P(e) = \frac{4C_1}{\pi}\int_0^{\pi/2}\prod_{l=1}^{L}\hat{p}_{\gamma_l}\left(\frac{0.5C_2}{\sin^2\phi}\right)d\phi - \frac{4C_1^2}{\pi}\int_0^{\pi/4}\prod_{l=1}^{L}\hat{p}_{\gamma_l}\left(\frac{0.5C_2}{\sin^2\phi}\right)d\phi \quad (62)$$

which is a generalization of (48). For Nakagami $-m$ fading with m_l in channel l (62) turns into

$$P(e) = \frac{4C_1}{\pi}\int_0^{\pi/2}\prod_{l=1}^{L}\left(1+\frac{0.5C_2\overline{\gamma}_l}{m_l\sin^2\phi}\right)^{-m_k}d\phi - \frac{4C_1^2}{\pi}\int_0^{\pi/4}\prod_{l=1}^{L}\left(1+\frac{0.5C_2\overline{\gamma}_l}{m_l\sin^2\phi}\right)^{-m_k}d\phi \quad (63)$$

If all $m_l = m$ and $\overline{\gamma}_l = \overline{\gamma}$, we obtain

$$P(e) = \frac{4C_1}{\pi}\int_0^{\pi/2}\left(1+\frac{0.5C_2\overline{\gamma}}{m\sin^2\phi}\right)^{-mL}d\phi - \frac{4C_1^2}{\pi}\int_0^{\pi/4}\left(1+\frac{0.5C_2\overline{\gamma}}{m\sin^2\phi}\right)^{-mL}d\phi \quad (64)$$

which is identical to (53) for $L = 1$ (no diversity). For integer m, the SEP in (64) can be written in a closed form (without integrals). In Fig. 19 we show the SEP of 16-QAM as a function of $\overline{\gamma}$ (energy-to-noise ratio per symbol in one channel) for $m = 1$ (Rayleigh fading) and several values of L. We see from this figure that diversity significantly reduces the SEP.

The corresponding BEP can be calculated in terms of the respective bit quantities

$$\gamma_{b\mathrm{MRC}} = \sum_{l=1}^{L}\gamma_{bl}, \quad \gamma_{bl} = \frac{E_{bl}}{N_0} \quad (65)$$

and replacing (55) by

$$P_b(e) = \sum_{i=1}^{I_M}\frac{c_i}{\pi}\int_0^{\pi/2}\prod_{l=1}^{L}\hat{p}_{\gamma_{bl}}\left(\frac{0.5d_i}{\sin^2\phi}\right)d\phi = \sum_{i=1}^{I_M}\frac{c_i}{\pi}\int_0^{\pi/2}\hat{p}_{\gamma_b}^{L}\left(\frac{0.5d_i}{\sin^2\phi}\right)d\phi \quad (66)$$

where the last equality is for identical PDFs for all γ_{bl}.

For Nakagami $-m$ fading with identical $m_l = m$ and $\overline{\gamma}_{bl} = \overline{\gamma}_b$, we obtain

$$P_b(e) = \sum_{i=1}^{I_M}\frac{c_i}{\pi}\int_0^{\pi/2}\left(1+\frac{0.5d_i}{m\sin^2\phi}\right)^{-mL}d\phi \quad (67)$$

which can be written in a closed form for integer m.

For 16-QAM, we obtain an equation similar to (56) with the exponential $-m$ replaced by $-mL$. In Fig. 20 we show the BEP of 16-QAM as a function of $\overline{\gamma}_b$ (energy-to-noise ratio per bit in one channel) for $m = 1$ and several values of L.

We conclude that the BEP is also reduced by diversity.

5. CARRIER AND SYMBOL SYNCHRONIZATION

At the receiver of QAM we have to estimate the incoming carrier frequency and phase (this is called *carrier synchronization* or *carrier recovery*) as well as the symbol rate and time delay (this is called *time* or *symbol synchronization* or *clock recovery*). Several books and many papers [11–15] as well as a special (August 1980) issue of

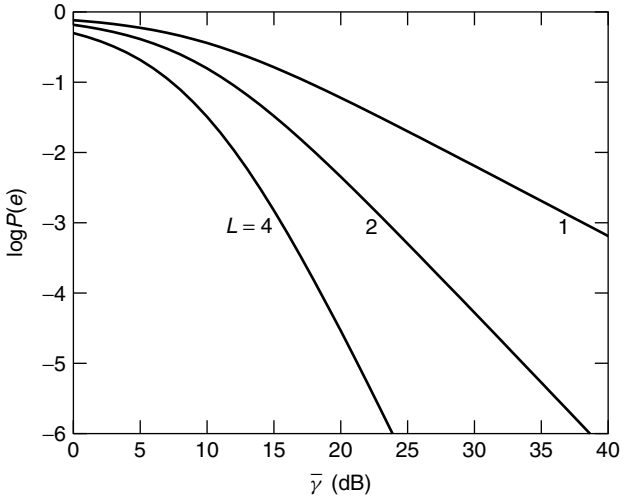

Figure 19. The SEP of 16-QAM with MRC diversity in Rayleigh fading channel.

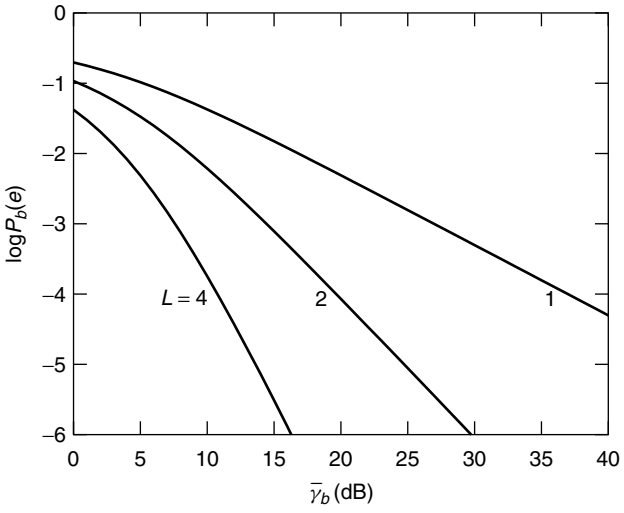

Figure 20. The BEP of 16-QAM with MRC diversity in Rayleigh fading channel.

the *IEEE Transactions on Communications* are dedicated to this problem.

The estimation is performed in two stages: an acquisition stage and a tracking stage. At the acquisition stage we can either use a known sequence of symbols (called *pilot symbols*), which form a preamble to the random data sequence, or we use the unknown data symbols, in which case the acquisition is called blind. At the tracking stage (when the SEP and BEP are already low), we can use the detected symbols $\{\hat{a}_k\}$ instead of the pilot symbols in which case the tracking is called decision directed. The basic device of every synchronizer is a phase-locked loop (PLL) [16].

5.1. Carrier Recovery with Pilot Tone

A block diagram of a PLL is shown in Fig. 21.

We shall assume that the input is a pilot signal corrupted by bandpass noise with PSD $N_0/2$ in the vicinity of the carrier frequency:

$$\tilde{r}_R(t) = A\cos(w_c t + \varphi(t)) + \tilde{n}_R(t) \tag{68}$$

The voltage controlled oscillator (VCO) produces a carrier whose phase is controlled by the input voltage

$$\tilde{s}_v(t) = A_v\cos(w_c t + \hat{\varphi}(t)), \quad \hat{\varphi}(t) = K_v\int_0^t v(t')\,dt' \tag{69}$$

The multiplier output is

$$e(t) = K_m\tilde{s}_v(t)\tilde{r}_R(t) = A_L[\sin(\varphi(t) - \hat{\varphi}(t)) + n(t)] + \text{HFT},$$
$$A_L = \frac{AA_vK_m}{2} \tag{70}$$

where $n(t)$ is zero mean, Gaussian noise with PSD, N_0/A^2, and HFT is a high-frequency term that is eliminated by the loop filter, which is a lowpass filter with transfer function $H_L(f)$. In terms of the phases we obtain the nonlinear circuit in Fig. 22.

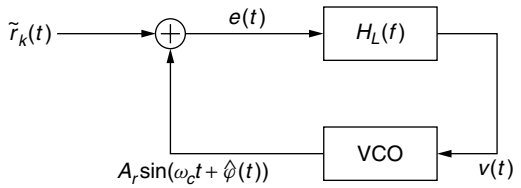

Figure 21. A phase-locked loop.

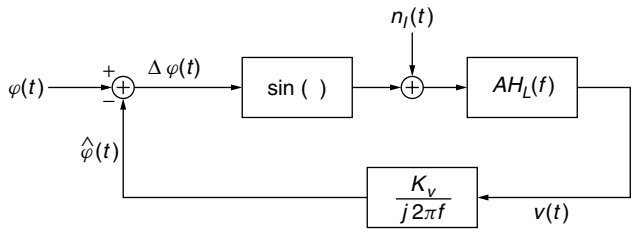

Figure 22. Equivalent circuit of PLL.

The nonlinearity is caused by the term $\sin(\Delta\varphi)$ where

$$\Delta\varphi(t) = \varphi(t) - \hat{\varphi}(t) \tag{71}$$

Note that as long as $|\Delta\varphi(t)| \le \pi/2$, when $\varphi(t)$ increases so does $\Delta\varphi(t)$ and the control signal $v(t)$, hence also $\hat{\varphi}(t)$ which thus tracks $\varphi(t)$. When $\Delta\varphi(t) = 0$, the PLL is locked and $\hat{\varphi}(t) = \varphi(t)$. For small values of $\Delta\varphi(t)$, $\sin(\Delta\varphi) \approx \Delta\varphi$; hence we obtain the linear PLL shown in Fig. 23.

If the input signal has a carrier frequency offset Δf_c, the input phase

$$\varphi(t) = 2\pi f_c t + \varphi(0) \tag{72}$$

may become very large and the PLL may not be able to lock. Therefore during the acquisition stage the frequency of the VCO is swept over a large range until it is locked to $f_c + \Delta f_c$. After locking, the PLL tracks the slow variations in the input phase. There are several methods of sweeping or equivalent operations to obtain frequency locking. These include (1) two switched loop filters, a wideband for acquisition and a narrowband for tracking; (2) nonlinear loop filter with greater sensitivity near lock; and (3) a frequency detector in parallel with a phase detector that is switched off after locking. An example of (3) can be found in Ref. 13.

For the linear PLL in Fig. 24 we can write the equation

$$\hat{\varphi}(t) = [\varphi(t) - \hat{\varphi}(t) + n(t)] * h(t) \tag{73}$$

where

$$H(f) = \frac{KH_L(f)}{j2\pi f} \quad K = A_LK_L \tag{74}$$

is the open-loop transfer function of the PLL. The closed loop transfer function of the PLL is [setting $n(t) = 0$]

$$G_L(f) = \frac{\hat{\Phi}(f)}{\Phi(f)} = \frac{H(f)}{1 + H(f)} = \frac{KH_L(f)}{j2\pi f + KH_L(f)} \tag{75}$$

The noise term that affects $\hat{\varphi}(t)$ has a PSD of $(N_0/A^2)|G_L(f)|^2$ and a variance of

$$\sigma_{\hat{\varphi}}^2 = \frac{2N_0}{A^2}B_L, \quad B_L = \int_0^\infty |G_L(f)|^2\,df \tag{76}$$

where $2B_L$ is the noise bandwidth of the PLL. The signal to noise ratio of the input signal of (68) when taken within the bandwidth $2\tilde{B}_L = 4B_L$ is

$$\text{SNR} = \frac{0.5A^2}{0.5N_0 2\tilde{B}_L} = \frac{0.5A^2}{2N_0B_L} \tag{77}$$

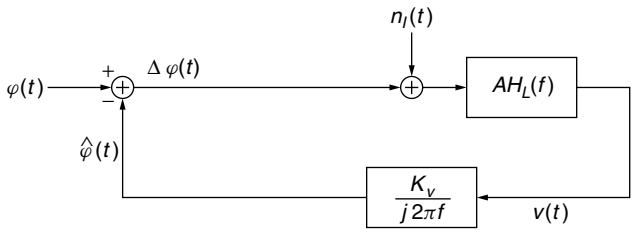

Figure 23. Linear approximation of PLL.

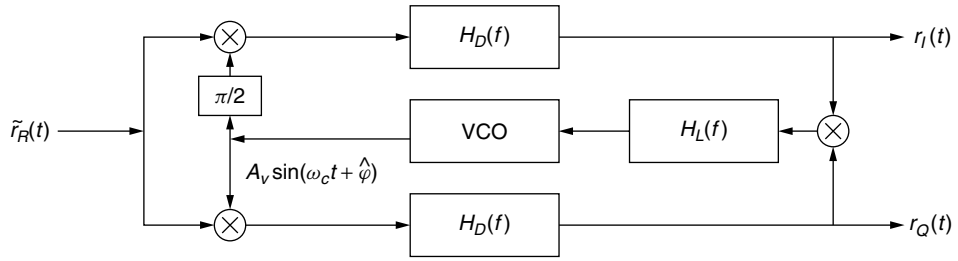

Figure 24. Costas loop.

therefore

$$\sigma_{\hat{\varphi}}^2 = \frac{1}{2\text{SNR}} \tag{78}$$

The variance in (78) is also the variance of the phase $\Delta\varphi$. The nonlinear PLL has been analyzed for the case $H_L(f) = 1$ in Ref. 16, and it has been found that the resulting variance is greater than that of the linear PLL. An alternative to the PLL is the Costas loop, shown in Fig. 24.

For the input in (68), the output of the multipliers are

$$e_I(t) = A_L[\cos(\Delta\varphi) + n_I(t)], \quad e_Q(t) = A_L[\sin(\Delta\varphi) + n_Q(t)] \tag{79}$$

with additional high-frequency terms that are eliminated by the filters. Thus the control voltage (assuming the filters do not change) follows from (79) as

$$v(t) = 0.5K_v A_L^2 \sin\ (2\Delta\varphi) + \text{noise terms} \tag{80}$$

and again $\hat{\varphi}(t)$ will track $\varphi(t)$.

5.2. ML Carrier Recovery with Pilot Symbols or Decision Directed

Here we assume that K symbols $\{a_i\}$ are known. The received signal after the detector filters is

$$r(t) = A\sum_i a_i g(t - iT)e^{j\varphi} + n(t) \tag{81}$$

Taking samples and assuming no ISI, we have

$$r_k = A_0 a_k e^{j\varphi} + n_k, \quad k = 1, 2, \ldots, K, \quad A_0 = Ag_0 \tag{82}$$

The ML estimate of the phase is the minimum of

$$\Lambda_L(\varphi) = \sum_{k=1}^{K} |r_k - A_0 a_k e^{j\varphi}|^2 \tag{83}$$

or equivalently the maximum of

$$\Lambda_L(\varphi) = \text{Re}\left\{\sum_{k=1}^{K} r_k^* a_k e^{j\varphi}\right\}$$

$$= z_I \cos\varphi - z_Q \sin\varphi, \quad z = \sum_{k=1}^{K} r_k^* a_k \tag{84}$$

The maximum is achieved when the derivative is zero, and the solution is

$$\hat{\varphi} = -\tan^{-1}\frac{z_Q}{z_I} \tag{85}$$

It can be shown that $\overline{\hat{\varphi}} = \varphi$; hence the estimate is unbiased. Since z is Gaussian, we can also compute the PDF and variance of $\hat{\varphi}$, which is also $(2KE/N_0)^{-1}$. The block diagram of the QAM system with pilot symbols is shown in Fig. 25, which is very similar to the Costas loop. In the tracking stage we replace the pilot symbol with the estimated symbols $\{\hat{a}_k\}$ which is also shown in the figure.

5.3. Blind Carrier Recovery of QAM Using PLL

We have to create a pilot tone from the QAM signal

$$\tilde{r}_R(t) = A_I(t)\cos(w_c t + \varphi) - A_Q(t)\sin(w_c t + \varphi) + \tilde{n}_R(t) \tag{86}$$

where [assuming for simplicity that $g_{CR}(t)$ is real]

$$A_x(t) = A\sum_i a_{xi} g_{CR}(t - iT), \quad x = I, Q \tag{87}$$

For a symmetric constellation we have

$$\overline{a_{Ii}^p} = \overline{a_{Qi}^p}, \quad \overline{a_{Ii}a_{Qi}} = \overline{a_{Ii}a_{Qi}}, \quad \overline{a_{Ii}} = \overline{a_{Qi}} = 0 \tag{88}$$

therefore

$$\overline{A_I^p(t)} = \overline{A_Q^p(t)}, \quad \overline{A_I(t)A_Q(t)} = \overline{A_I(t)A_Q(t)} = 0 \tag{89}$$

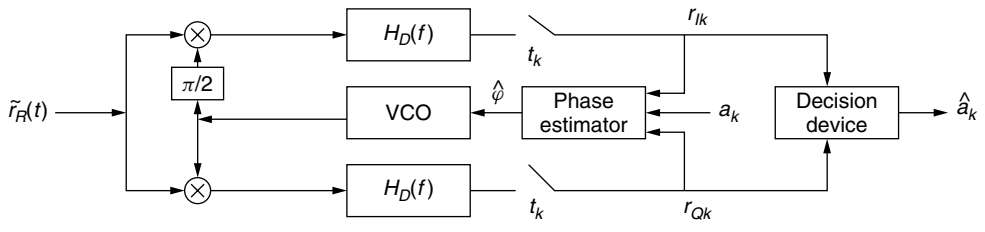

Figure 25. QAM with pilot symbols or decision directed.

The minimum value of p for which we have a pilot tone is 4, namely, $\tilde{s}_R^4(t)$. The pilot tone component is

$$A(t)\cos(4w_c t + 4\varphi(t)), \quad A(t) = 0.25[\overline{A_I^4(t)} - 3(\overline{A_I^2(t)})^2] \tag{90}$$

This component is tracked by the PLL, however to obtain the original carrier we need a frequency divider by 4. The corresponding PLL for QAM is shown in Fig. 26.

Because only a small part of $\tilde{s}_R^4(t)$ contains energy at frequency $4f_c$ and the additional noise terms in the vicinity of this frequency, the variance of the estimated phase is

$$\sigma_{\hat{\varphi}}^2 = \frac{S_L}{2\text{SNR}}, \quad S_L \le 1 + \frac{9}{\text{SNR}} + \frac{6}{\text{SNR}^2} + \frac{1.5}{\text{SNR}^3} \tag{91}$$

where S_L is called a *power loss*. The estimate of the phase can also be computed [14] from discrete samples as in Fig. 25:

$$\hat{\varphi} = 0.25 \arg\left[\overline{a_k^4} \sum_{k=1}^{K} r_k^4\right] \tag{92}$$

with a variance which can be approximated by

$$\sigma_{\hat{\varphi}}^2 = \left(\frac{c_1}{2\gamma} + c_2\right)\frac{1}{K}, \quad \gamma = \frac{E}{N_0} \tag{93}$$

The values of c_1 and c_2 can be computed and are shown in Table 1 for various QAM square and cross-constellations. Note that there is a self-noise represented by c_2 and that both c_1 and c_2 are large for cross-constellations. A reduced constellation power law algorithm [14] in which only r_k with amplitudes that exceeds a certain threshold gives a better estimate.

Note that if $2n\pi$ is added to $4\hat{\varphi}(t)$, the VCO output is unchanged however after the frequency divider $\hat{\varphi}(t)$ has an uncertainty of $n\pi/2$. To resolve this uncertainty, we need again pilot symbols or we have to use differential phase modulation, in which the phase of the symbols in each quarter of the constellation is transmitted as a phase difference instead of an absolute phase. The first 2 bits of each symbol can be represented by this phase.

5.4. Blind ML Carrier Recovery for QAM

The blind ML estimate of the phase maximizes

$$\Lambda_L(\varphi) = \exp -\overline{\frac{1}{2\sigma_n^2}\sum_{k=1}^{K}\left|r_k - A_0 a_k e^{j\varphi}\right|^2}$$

$$= \prod_{k=1}^{K} \exp -\overline{\frac{1}{2\sigma_n^2}\left|r_k - A_0 a_k e^{j\varphi}\right|^2} \tag{94}$$

where the average is over the symbols. For the square constellations, this is equivalent to maximizing

$$\Lambda_L(\varphi) = \sum_{k=1}^{K} \ln\left\{\sum_{i=1}^{\sqrt{M}-1} \exp -\left(\frac{A_0^2(2i-1)^2}{2\sigma_n^2}\right) \times \cosh\frac{r_{Ik}\cos\varphi(2i-1)A_0}{\sigma_n^2}\right\}$$

$$+ \sum_{k=1}^{K} \ln\left\{\sum_{i=1}^{\sqrt{M}-1} \exp -\left(\frac{A_0^2(2i-1)^2}{2\sigma_n^2}\right) \times \cosh\frac{r_{Qk}\sin\varphi(2i-1)A_0}{\sigma_n^2}\right\} \tag{95}$$

The Cramer–Rao lower bound (CELB) [15] to any estimate is

$$\sigma_{\hat{\varphi}}^2 \ge \text{CRLB}(\hat{\varphi}) = -\left(\frac{d^2\Lambda_L(\varphi)}{d\varphi^2}\right)^{-1} \tag{96}$$

The CRLB of phase and also of frequency has been derived for QAM [15]. The results are

$$\text{CRLB}(\hat{\varphi}) = \left[2K\gamma F\left(\frac{1}{2\gamma}\right)\right],$$

$$\text{CRLB}(\hat{f}_c) = \left[2K\gamma\frac{K^2-1}{12}F\left(\frac{1}{2\gamma}\right)\right]^{-1} \tag{97}$$

where $F(x)$ is an integral that is evaluated numerically. The values of CRLB $(\hat{\varphi})$ and of $\sigma_{\hat{\varphi}}^2$ for several

practical systems [histogram algorithm (HA), two-stage conjugate algorithm (2SC), MDE-minimum-distance algorithm (MDA), and power-law estimate (PLE) ($P = 4$)] are shown in Fig. 27 (which is Fig. 8 of Ref. 15) as a function of γ for 64-QAM and $K = 200$. The CWCRLB is $(2K\gamma)^{-1}$. CRLB $(\hat{f}_c)$ is presented in Fig. 28 (which is Fig. 3 of Ref. 15) for several QAM constellations. More figures on this matter can be found in Refs. 14 and 15.

5.5. Time Recovery with Pilot Symbols or Decision Directed

The ML estimator of τ maximizes

$$\Lambda_L(\tau) = \mathrm{Re}\left\{\sum_{k=1}^{K} a_{ki}^{*} r_k(\tau)\right\} = \sum_{k=1}^{K} r_{Ik}(\tau)a_{Ik} + r_{Qk}(\tau)a_{Qk}, r_k(\tau) = r(kT+\tau) \tag{98}$$

Taking the derivative, we have

$$v(\tau) = \frac{d\Lambda_L(\tau)}{d\tau} = \sum_{k=1}^{K} r'_{Ik}(\tau)a_{Ik} + r'_{Qk}(\tau)a_{Qk}, r'_{Xk}(\tau) = \left.\frac{dr(t)}{dt}\right|_{t=kT+\tau} \tag{99}$$

The maximum is achieved when $v(\hat{\tau}) = 0$. The implementation of this equation is shown in Fig. 29. The VCC (voltage controlled clock) is a VCO that produces rectangular pulses instead of a sinusoid. The summer is the digital equivalent of an integrator and forms the loop filter.

In the tracking stage estimated symbols are reliable and can be used instead of the pilot symbols. This is the decision directed mode of the clock recovery.

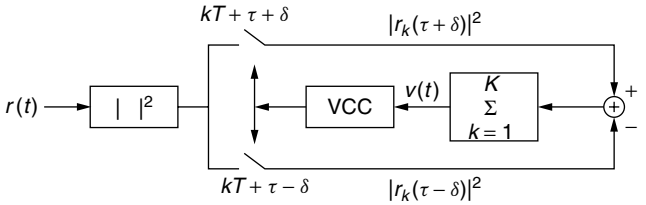

Figure 28. Standard deviation of frequency, $\sigma_{\hat{f}_c}$, for $K = 200$ symbols. (*Source*: F. Riou, B. Cowley, B. Morgan, and M. Rice, Cramer–Rao lower bounds for QAM phase and frequency estimation, *IEEE Trans. Commun.* **COM-49**: 1582–1591, © 2001 IEEE.)

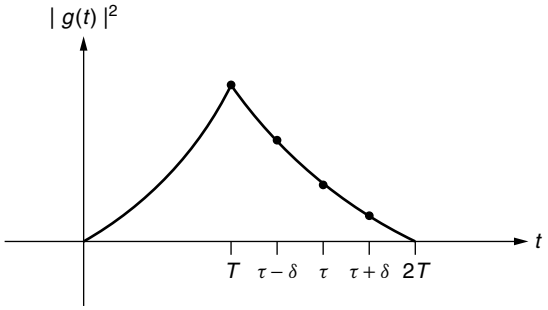

Figure 29. ML clock recovery with pilot symbols or decision directed.

5.6. Blind ML Clock Recovery

Here we maximize an equation similar to (94)

$$\Lambda(\tau) = \exp -\overline{\frac{1}{2\sigma_n^2}\sum_{k=1}^{K}|r_k(\tau) - A_0 a_k|^2} = \prod_{k=1}^{K}\exp -\overline{\frac{1}{2\sigma_n^2}|r_k(\tau) - A_0 a_k|^2} \tag{100}$$

where the average is over the symbols. For QAM with square constellation, this is equivalent to maximizing

$$\Lambda_L(\tau) = \sum_{lk=1}^{K}\ln\left\{\exp -\frac{|r_k(\tau)|^2}{2\sigma_n^2}\sum_{i=1}^{\sqrt{M}-1} \times \exp -\left(\frac{A_0^2(2i-1)^2}{2\sigma_n^2}\right)\cosh\frac{r_{Ik}(\tau)(2i-1)A_0}{\sigma_n^2}\right\} + \sum_{k=1}^{K}\ln\left\{\exp\left(-\frac{|r_k(\tau)|^2}{2\sigma_n^2}\right)\sum_{i=1}^{\sqrt{M}-1} \times \exp -\left(\frac{A_0^2(2i-1)^2}{2\sigma_n^2}\right)\cosh\frac{r_{Qk}(\tau)(2i-1)A_0}{\sigma_n^2}\right\} \tag{101}$$

The optimal $\tau$is the solution of

$$\frac{d\Lambda_L(\tau)}{d\tau} = 0\ |_{\tau=\hat{\tau}} \tag{102}$$

An approximation to the ML synchronizer is the E-L (early–late) gate synchronizer, which computes

$$\Delta\Lambda(\tau) = \frac{\Lambda_L(\tau+\delta) - \Lambda_L(\tau-\delta)}{2\delta}, \quad \Lambda_L(\tau) \approx \sum_{k=1}^{K} |r_k(\tau)|^2 \tag{103}$$

A block diagram of this scheme is shown in Fig. 30.

The E-L algorithm is based on the idea that the pulse at the receiver has a peak at the correct sampling time and is symmetric around this point as shown in Fig. 31. Note that the correct sampling time is T and $\Delta\Lambda(T) = 0$ while $\Delta\Lambda(\tau) > 0$ if $\tau < T$ and $\Delta\Lambda(\tau) < 0$ if $\tau > T$. The E-L has to be modified for QAM because certain sequences of symbols will result in false values of $\Delta\Lambda(\tau)$ (see Ref. 1 for elaborations).

A simple blind recovery of the symbol rate is based on the autocorrelation of the signal

$$\begin{aligned} R_s(\tau) &= 0.5\overline{s(t)s^*(t-\tau)} \\ &= 0.5A^2\sigma_a^2 \sum_i g(t-iT)g(t-iT-\tau) \end{aligned} \tag{104}$$

which is a periodic function of t with period T. Therefore a bandpass filter with center frequency $R = 1/T$ or nR can produce a clock frequency directly or after frequency division by n. This circuit is implemented in Fig. 32. The best results are obtained for $\tau = T/2$.

6. SUMMARY

We have described a QAM system and computed the error probability in both Gaussian and fading channels with and without diversity. We presented various methods of carrier and clock recovery. Many topics such as equalization, effect of errors in carrier and clock recovery on the error probability, the error probability of differential phase detection, combined differential phase and differential amplitude for mobile communication, joint phase, frequency and time synchronization, and QAM in spread-spectrum systems have been omitted for lack of space.

R

RADIO PROPAGATION AT LF, MF, AND HF

JOHN C. H. WANG
Federal Communications Commission
Washington, District of Columbia

1. INTRODUCTION

Electromagnetic (or radio) waves can be transmitted from a transmitting site to a receiving site by a number of different mechanisms. At the frequencies under study (between about 30 kHz and 30 MHz), the most important ones are ground wave and sky wave. At higher frequencies, the space (or tropospheric) wave becomes more important. The ground (or surface) wave exists when the transmitting and receiving antenna are on or near the surface of the earth. Standard broadcast signals received in daytime are all ground waves.

The sky wave represents energy that travels from the transmitting antenna to the receiving antenna as a result of a "bending" by the earth's upper atmosphere called the *ionosphere*. The ionosphere, which consists of several different layers, begins about 50 km above the earth's surface. Shortwave signals and nighttime medium-wave signals are examples of sky waves. Under certain conditions, the ground-wave and sky-wave components from the same source may be comparable in amplitude but arrive at slightly different times, resulting in interference.

The space (or tropospheric) wave represents energy that travels from the transmitting antenna to the receiving antenna in the earth's troposphere. The troposphere is the lower portion of the earth's atmosphere in which the temperature decreases with increasing altitude. This part of the atmosphere extends to an altitude of about 9 km at the earth's poles and 17 km at the equator. TV and FM signals are examples of space waves. Space wave propagation is beyond the scope of this article.

In the subsequent sections factors affecting propagation will be described. Methods of predicting field strength will also be analyzed and compared. Definitions of the most frequently used terms are given in Section 6.

2. GROUND-WAVE PROPAGATION

2.1. Early Pioneering Studies

At frequencies between about 10 kHz and 30 MHz, ground-wave propagation is possible because the surface of the earth is a conductor. The ground wave is vertically polarized. Any horizontal component of an electric field on the surface of the earth is shorted-circuited by the earth. The earliest work on ground-wave propagation was carried out by Summerfield [1]. His flat-earth theory states that ground-wave field strength, E_g, can be expressed in the form

$$E_g = A\frac{E_0}{d} \tag{1}$$

where E_0 = field strength of wave at the surface of the earth at unit distance from the transmitting antenna, neglecting earth's losses
d = distance to transmitting antenna
A = factor taking into account the ground losses

The field strength E_0 at unit distance in Eq. (1) depends on the power radiated by the transmitting antenna and the directivity of the antenna in the vertical and horizontal planes. If the radiated power is 1 kW and the short vertical antenna is omni-directional in the horizontal plane, then, $E_0 = 300$ mV/m when the distance is 1 km. The reduction factor A is a complicated function of electrical constants of the earth, frequency, and the distance to the transmitter in wavelengths. The reduction is highly frequency-dependent; it increases with increasing frequency. Thus, at LF and MF ground-wave signals can be sufficiently strong for broadcasting service. On the other hand, at HF, ground-wave signals are usually too weak for broadcasting purposes. The Summerfield flat-earth approach, the subsequent Watson transformation [2], and the Bremmer residue series [3] were the important milestones and theoretical advances on which the modern ground-wave theory is still based.

2.2. The Development of Ground-Wave Curves

Intensive efforts to convert the theoretical advances to simple and practical field strength curves took place between 1930 and 1940 [4]. Extensive measurement programs were conducted by many organizations including the Federal Communications Commission. In 1939, the FCC released a complete set of ground-wave curves as an appendix to the Standards for Good Engineering Practice Concerning Standard Broadcasting Stations [5]. These curves and a comprehensive discussion were included in a paper by Norton [6]. Similar but not identical ground-wave curves can also be found in ITU-R Recommendation PN.368-7 [7]. The current FCC curves cover the frequency range of 535–1705 kHz. The ITU-R curves cover a much wider range of frequency, from 10 kHz to 30 MHz. [*Note*: ITU-R, which appears frequently in this article, is the abbreviated name of the *Radiocommunication Study Groups of the International Telecommunication Union*, formerly known as the CCIR (see Section 6). PN denotes propagation in nonionized media. PI, which will appear in the subsequent sections, denotes propagation in ionized media. Numeral 7 after a dash means it is the 7th revised edition. In 2000, ITU-R decided to use the prefix P to replace both PN and PI.]

2.3. Available Software

Currently, there are three computer programs available for calculating ground-wave field strengths. The first

program is called *ITSGW* [8]. The second program, GRWAVE [9], is in ITU-R Recommendation PN.368-7. This program, which takes into account the effects of refraction in an exponential atmosphere, is available from ITU Sales Service, Place des Nations, 1211 Geneva, Switzerland. The third program is called *FCCGW* [10]. FCCGW has been used to generate the metric version of the FCC curves. The FCC curves take into account the effect of refraction by using an effective radius that is $\frac{4}{3}$ times the actual radius of the earth. Refraction is insignificant at distances less than about 100 km. At greater distances, it becomes progressively more significant. It should also be mentioned that GRWAVE is designed for personal computers while FCCGW is designed for mainframe computers. A comparison of these programs has been done [10,11]. It is reported that the three methods give ground-wave field strength predictions sufficiently close in value that they could be considered identical for frequency management purposes.

2.4. Ground-Wave Propagation over Inhomogeneous Terrain

For predicting ground-wave field strengths over paths composed of successive sections of terrain of different conductivities (e.g., land and sea), there are two basic methods available. These are the equivalent-distance (or Kirke) method [12] and the equivalent-field (or Millington) method [13]. The Kirke method has the advantage of simplicity, but in cases where the successive sections show considerable differences in conductivities, it can lead to large error. On the other hand, the Millington method does not suffer from this problem. Furthermore, the Millington method is now no longer as difficult to apply as before, because a simplified graphical solution has been developed by Stokke [14]. The Millington method and the Stokke approximation are presented in ITU-R Recommendation PN.368-7.

2.5. Ground Conductivity

Ground-wave propagation can be considered a reasonably well understood topic. In one area, however, more work is needed. Ground conductivity is a very important factor in calculating ground-wave field strengths. Accurately measured data should be used. Although several maps are available, they present estimates and are not very accurate. A map showing the estimated ground conductivities of the continental United States has been published by the FCC [15]. An atlas of ground conductivities in different parts of the world can be found in ITU-R Recommendation PN.832-2 [16].

Conductivity of seawater is typically 5 siemens per meter (5 S/m) while that of freshwater is about 10 mS/m. Conductivities of rocky land, hills, and mountains vary between 1 and 2 mS/m. Conductivity of rich agricultural land is typically 10 mS/m. Cities and residential areas have a conductivity of about 2 mS/m. In industrial areas, it is even less.

3. THE SKY-WAVE PROPAGATION MECHANISM

3.1. The Solar–Terrestrial System

In 1901, Guglielmo Marconi (1874–1937), a young Italian engineer, succeeded in sending a Morse code message from Cornwall, England, across the Atlantic Ocean to Newfoundland. It is generally believed that the frequency Marconi used was about 1.6 MHz. This revolutionary wireless experiment not only brought him a Nobel Prize later in 1909 but also created a new frontier in the scientific world. Perhaps Oliver Heaviside, an English physicist, gave the earliest satisfactory explanation of his experiment. He theorized that in the earth's upper atmosphere, there is a sufficiently conducting layer [17]. This conducting layer is known as the *ionosphere*, so called because it consists of heavily ionized molecules. To understand sky-wave propagation, it is essential to study the entire solar–terrestrial system, not just the ionosphere alone. In this article, we shall discuss this subject only briefly. For more details, see books by Davies [18] and by Goodman [19]. It should be mentioned that the discussion in this section applies to LF, MF, and HF (low, medium, and high frequency).

3.2. The Ionosphere

The ionosphere consists of three regions (or layers). They are the D, E, and F regions, respectively, in increasing order of altitude.

The D region spans the approximate altitude range of 50–90 km. It exists only in daytime and disappears shortly after sunset. The D region can be considered as an absorber, causing significant signal attenuation. The absorption is frequency-dependent; it decreases with increasing frequency.

The E region spans the approximate altitude range of 90–130 kilometers. This region is important for nighttime low- and medium-frequency propagation at distances greater than about 200 km. The E region exhibits a solar cycle dependence with maximum electron density occurring at solar maximum.

Sporadic E (Es), which has very little relationship with solar radiation, is an anomalous form of ionization embedded within the E region. It can have significant effects on propagation at HF and VHF.

The F region extends upward from about 130 kilometers to about 600 kilometers. The lower and upper portions of the F region display different behaviors at daytime, resulting in a further subdivision into F1 and F2 layers. The F1 layer is the region between 130 and 200 km above the surface of the earth. The F2 layer, which is the highest and the most prominent one, is the principal reflecting region for long-distance high-frequency communications. At night, the F1 layer merges with the F2 layer and the average height of the combined layer (still called the "F2 layer") is about 350 km.

3.3. Solar Activity

The existence of the ionosphere is a direct result of the radiation from the sun, both electromagnetic and corpuscular. The electromagnetic radiation travels toward

the earth at the speed of light, and the entire journey takes about 8.3 min. The ionization process is linked with the intensity of the solar radiation, which in turn varies with factors such as time of day, latitude, and season. Solar activity changes drastically from time to time. Sunspot number is a reasonably good index of the state of solar activity, although several other indices are also available. Sunspots are dark areas on the surface of the sun. Sunspots were, perhaps, first observed by the Chinese in March of 20 A.D. [20] during the Han Dynasty (206 B.C.–220 A.D.). Sunspots appear dark because the temperature is low, only about 3000 K, while the average temperature of the sun is about 6000 K. Sunspots tend to group together and display an 11-year cyclic nature. The astronomic records of the Jin Dynasty (265–418 A.D.) of China [21] indicate that for quite a while in the fourth century, sunspots were observed every 11 years (e.g., 359, 370, 381, and 393 A.D.). Sunspot numbers vary from day to day and year to year. Routine observations have been made since 1749. The cycle beginning in 1755, a year of minimum sunspot number, is considered cycle 1. The ascending portion of a cycle (on average, 4.5 years) is usually much shorter than the descending one (6.5 years). The Zurich (or Wolf) number R is given by

$$R = k(10\,g + s) \tag{2}$$

where g is the number of sunspot groups, s is the number of observed small spots, and k is a correction factor, approximately unity, used to equalize the results from different observations and equipment. The sunspot number is subject to wide variations from month to month and is of little usefulness. Furthermore, it is known that the characteristics of the ionosphere do not follow the short-term variations. In order to achieve a better correlation, some kind of "smoothing" technique is desirable. Consequently, the 12-month smoothed sunspot number (R_{12}) has been adopted and is the most widely used index in ionospheric work today:

$$R_{12} = \frac{1}{12}\left[(0.5)(R_{n+6} + R_{n-6} + \sum_{n-5}^{n+5}(R_n)\right] \tag{3}$$

Thus, by definition, the value of R_{12} is known only 7 months after the recorded observation. R_{12} varies from a minimum of about 10 to a maximum generally of 100–150, although in December 1957 it reached a record high of 239.4.

3.4. Atmospheric Radio Noise

In order to estimate the performance to be expected in a communication system, it is insufficient to consider field strength alone. Equally important is radio noise. There are many different sources of noise: the atmosphere, the receiving system, human activity, the sun, and galaxies. In this article, we emphasize atmospheric noise. For an excellent discussion on all types of noise, see ITU-R Recommendation PI.372-6 [22].

Atmospheric noise is produced mainly by lightning discharges in thunderstorms. Discharges take place between 2 and 4 km above ground. The power released is very great, typically greater than 10 GW [23]. Atmospheric radio noise obeys the same propagation laws as do sky-wave signals. Thus, it travels to distances several thousands of kilometers away. The noise level thus depends on the time of day, season of the year, weather, geographic location, and frequency. In general, atmospheric noise is the highest (1) when the receiver is located near a thunderstorm center, (2) during local summer, (3) during the night, or (4) when the frequency is low. There are three major thunderstorm (hence, noise) centers in the world: the Caribbean, Equatorial Africa, and Southeast Asia. Maps showing the atmospheric noise levels for different parts of the world corresponding to different seasons of the year and different hours of the day have been developed by the CCIR since 1964. The most recent maps can be found in ITU-R Recommendation PI.372-6 [22].

3.5. Magnetic Coordinates

There are several definitions of latitude connected with the geomagnetic field. The centered dipole latitude, or simply the dipole latitude, is an approximation and has been used for ionospheric work for decades. Corrected geomagnetic latitude more accurately represents the real geomagnetic field and should be used when accuracy is desired. Conversion tables from geographical coordinates to corrected latitude are readily available [24].

4. SKY-WAVE PROPAGATION AT LF AND MF

4.1. Results of Six Decades of Worldwide Efforts

This section presents a brief summary of the historical background behind the development of the four currently used LF and MF sky-wave propagation models. For a more detailed presentation, see a paper by Wang [25].

4.1.1. The Cairo Curves. The earliest worldwide efforts to study LF/MF sky-wave propagation began in 1932. At its meeting held in Madrid, the CCIR established a committee, chaired by Balthasar van der Pol of Holland, to study propagation at frequencies between 150 and 2000 kHz. Measurements were made on 23 propagation paths between 1934 and 1937. Consequently, two sky-wave propagation curves were developed. One of the curves is for paths far away from the earth's magnetic poles; this is better known as the *north–south curve*. The other curve is for paths approaching the earth's magnetic poles and is better known as the *east–west curve*. Actually, the former should have been called the *low-latitude curve*; the latter, the *high-latitude curve*. The two curves were formally adopted by the CCIR at the 1938 International Radio Conference, Cairo. Therefore, these curves are known as the *Cairo curves*. In1974 the LF/MF Conference adopted the north–south curve for use in the Asian part of Region 3 [26].

4.1.2. The Region 2 Method (the FCC Clear-Channel Curve). Recognizing the needs for a set of sound engineering standards, the FCC, under the leadership of the late Ken Norton, carried out a sky-wave field

strength measurement program in the spring of 1935, a year of moderate sunspot number. Nighttime signals of all eight clear-channel stations were monitored at 11 widely scattered receiving sites. From these measurements, the FCC clear-channel curve was derived. The 1980 Broadcasting Conference for Region 2 adopted this method for applications in Region 2 [27]. Hence, this method is also known as the Region 2 method. The staff of the FCC has since developed a newer and more accurate method. The newer method, which is being used by the FCC for domestic applications, will be discussed in the subsequent sections.

4.1.3. Comparison of the Two Graphical Methods. Both the Cairo and the FCC curves present field strength as a function of distance only. They do not take into account effects of latitude, sunspot number, and so on. When converted to the same conditions, the two Cairo curves and the FCC clear-channel curve are similar for distances up to about 1400 km. At 3000 km, the north–south curve is about 8 dB greater than the east–west curve; at 5000 km, the difference is about 18 dB. The FCC clear-channel curve falls between the two Cairo curves. The Cairo north–south curve offers good results when applied to low latitudes. When applied to higher latitudes, it tends to overpredict field strength levels [25]. The FCC curve offers reasonable results when applied to temperate latitudes. Neither of these methods is a true worldwide method. The Cairo east–west curve, because it often underestimates field strength levels, has virtually been disregarded.

4.1.4. The Development of Recommendation 435 (the Udaltsov–Shlyuger Method). Recognizing the need for a simple but accurate field strength prediction method for worldwide applications, and in anticipation of a broadcasting conference, the CCIR at its Xth Plenary Assembly (Geneva, 1963) established International Working Party (IWP) 6/4 to undertake such a task. This IWP was first chaired by J. Dixon (Australia), succeeded by G. Millington, P. Knight (UK), and J. Wang (USA). In the late 1960s and early 1970s a number of administrations and scientific organization were very active and collected valuable data. For example, the European Broadcasting Union (EBU), which started its sky-wave studies soon after World War II, reactivated its efforts. Its counterpart in Eastern Europe, the International Organization of Radio and Television (OIRT) was also active. The administration of the former USSR also collected a significant amount of measurements. Results of their analysis together with a new propagation model were published in 1972 [28], although their data have not been made available to the public.

Three international organizations jointly planned and carried out a measurement campaign in Africa between 1963 and 1964. They are the EBU, the OIRT, and the Union of National Radio afd Television Organizations (URTNA). Later, the British Broadcasting Corporation set up seven receiving stations in Africa and signals from two transmitters on the British Ascension Islands were monitored. The BBC project was intended to study polarization coupling loss and sea gain. The Max Planck Institute also conducted measurements at Tsumeb, southwest Africa.

Administrations in ITU Region 3 (parts of Asia, Australia, and New Zealand), in cooperation with the Asian-Pacific Broadcasting Union (ABU), were equally active and productive. Furthermore, the Japanese administration carried out a number of mobile experiments in different parts of the Pacific [29].

While the administrations in the Eastern Hemisphere were busy preparing for the 1974/75 Regional LF/MF Conference for ITU Regions 1 and 3, IWP 6/4 was actively developing a propagation model to be used as part of the technical bases for such a conference. After extensive studies and lengthy deliberations, the IWP was able to agree on the following: the method developed by Udaltsov and Shlyuger [28] was recommended together with the Knight sea gain formula [30] and the Phillips and Knight polarization coupling loss term [31]. Later in 1974, this method was adopted by the CCIR as Recommendation 435 [32]. In the subsequent sections, this method will be called the *Udaltsov–Shlyuger method*. This method, which includes a sound treatment of latitude, appeared to be very promising at that time. When applied to one-hop intra-European paths, good results were obtained [33]. After years of extensive testing against measured data from other parts of the world, however, some major limitations have surfaced. For example, when applied to paths longer than, say, 4000 km, the method has a strong tendency to underestimate field strengths, in many cases by more than 20 dB [25]. Furthermore, Region 2 data do not seem to corroborate the frequency term of this method [34]. Although this method is a great step forward from the two previous methods, it is something short of a true worldwide method.

4.1.5. The Development of Recommendation 1147-1 (the Wang Method). Knowing the clear-channel curve has some limitations and the need for more field-strength data, the FCC initiated a long-term and large-scale measurement program in 1939. Data from more than 40 propagation paths were collected. The measurement lasted for one sunspot cycle. Unfortunately, the midpoint geomagnetic latitude of the majority of the paths range from 45 °N to 56° North, a narrow window of 11°. Recognizing the need for additional data from the low- and the high-latitude areas, the FCC later initiated two separate projects. In 1980, the FCC and the Institute for Telecommunication Sciences of the Department of Commerce jointly began collecting low-latitude data at Kingsville, Texas, and at Cobo Rojo, Puerto Rico. In 1981, the FCC awarded a contract to the Geophysical Institute, University of Alaska. This project called for the acquisition of sky-wave data from the high-latitude areas. The Alaskan project lasted for about 7 years; data representing different levels of solar activity have been successfully collected. On the basis of the enlarged data bank, a new field strength prediction method was developed by Wang [34]. In 1990 the FCC adopted this method for domestic applications. In 1999 the ITU-R adopted this method as Recommendation P.1147-1 [35], replacing the Udaltsov–Shlyuger method. Like the Udaltsov–Shlyuger method, the Wang method

also contains a similar latitude term. This method has essentially linked the Cairo and the FCC clear-channel curves together mathematically. The special case corresponding to geomagnetic latitude of 35° in the Wang method is extremely close to the Cairo curve. The special case corresponding to 45° is very similar to the FCC curve. It works well for long paths and short paths alike.

4.2. Data Bank

The work of IWP 6/4 is now being handled by Working Party 3L (Ionospheric Propagation) of Study Group 3 (Propagation). The most recent version of the data bank consists of field strengths from 417 propagation paths. Great-circle lengths range from 290 to 11,890 km. Signals of the few very short paths have been verified to be sky waves. Frequencies range from 164 to 1610 kHz. Control-point geomagnetic latitudes range from 46.2° south to 63.8° north. This data bank is available to the general public from the ITU Website (*www.itu.int/brsg/sg3/databanks*).

4.3. Characteristics of LF/MF Sky-Wave Propagation

4.3.1. Amplitude Distribution. Nighttime sky-wave field strengths vary greatly from minute to minute and night to night. The within-the-hour short-term variation usually takes the form of Rayleigh distribution. Night-to-night median values of field strengths for a given reference hour are lognormally distributed. For frequency management purposes, the yearly median value of field strength at six hours after sunset is usually used to determine sky-wave (or secondary) service area of a station while the yearly upper-decile value is used to determine interference level. The difference between the annual upper-decile and the median value varies with latitude, from 6 dB in tropical areas [18] to 12 dB or more at high latitudes [36].

4.3.2. Diurnal Variation. At LF, the transition from daytime condition to nighttime condition in winter is very gradual, and field strength does not reach its maximum value until about 2 h before sunrise. The change at sunrise is more rapid. In summer, field strength increases more rapidly at sunset.

At MF, field strength changes very rapidly at sunset as well as sunrise. Field strength reaches its maximum value shortly after midnight or 6 h after sunset. U.S. data suggest that field strength is highly frequency-dependent during transition hours. For example, the signal of a 1530-kHz station is about 15 dB stronger than that of a 700-kHz station at sunrise. At 6 h after sunset, the difference is only about 3 dB in favor of the higher frequency [35].

4.3.3. Seasonal Variation. At LF and in daytime, sky waves propagating in winter are at least 20 dB stronger than in summer. At night, LF signals are strongest in summer and winter and are weakest in spring and autumn. The summer maximum is more pronounced.

At MF and in daytime, sky waves are strongest in winter months. The seasonal variation may exceed 30 dB. At night, MF sky waves propagating at temperate latitudes are strongest in spring and autumn and are weakest in summer and winter. The summer minimum is more pronounced. The overall variation may be as much as 15 dB at the lowest frequencies in the MF band, decreasing to about 3 dB at the upper end of the band. The variation is much smaller in tropical latitudes.

Nighttime high-latitude field strength data collected in Alaska show a pronounced summer minimum and a consistent maximum in April [36]. In a year of minimum sunspot number, the nighttime monthly median field strength of April is typically 10–15 dB greater than the annual median value.

4.3.4. Effect of Sunspots. At LF, the effect of sunspots is virtually nonexistent. At MF, sunspots greatly reduce sky-wave field strength levels. The reduction (L_r) is a function of sunspot number, latitude, distance, and, to a lesser degree, frequency [37].

The effect of sunspots is clearly latitude-dependent. In low-latitude areas (e.g., Central America, Mexico), annual median values of field strengths vary slightly (less than 3 dB) within a sunspot cycle and there is no detectable pattern. A pattern of correlation begins to surface at higher latitudes (e.g., central USA). For example, measured field strengths from a path in the southern parts of the United States (San Antonio, TX to Grand Island, NE; 1200 kHz, 1279 km, 45.1°N) decreased by about 3 dB when the sunspot number reached from minimum to maximum in cycle 18. The correlation becomes more pronounced at still higher latitudes. For example, measured field strengths of a path in the northern United States (Chicago, IL to Portland, OR, 890 kHz, 2891 km, 54°N) decreased by 15 dB in the same cycle. In Alaska, in a year of maximum solar activity, there are virtually no sky waves from northern-tier U.S. stations, although signals can be very strong in a year of low or moderate solar activity [36].

The effect of sunspots has a diurnal variation of its own. In other words, L_r is different at different hours of the night. At 6 h after sunset, L_r is considerably smaller than that at two hours after sunset. For example, consider a path from Cincinnati, OH to Portland, OR (700 kHz, 3192 km, 53.2°N). From 1944 (a year of minimum sunspot number) to 1947 (a year of maximum sunspot number), field strength for the sixth hour after sunset decreased by 7.3 dB; that for the fourth hour after sunset decreased by 13.3 dB, and that for the second hour after sunset decreased by 16.9 dB [37].

4.3.5. Effect of the Magnetic Field. When a radiowave enters the ionosphere in the presence of a magnetic field, it is split into two components: the ordinary and the extraordinary waves. Both are elliptically polarized. The extraordinary wave is then absorbed. Further loss occurs when the wave leaves the ionosphere. Because of the nature of elliptical polarization, only its vertical component normally couples with the receiving antenna. This process is known as polarization coupling loss (L_p). At LF, L_p is negligible. At MF, L_p is negligible in high and temperate latitudes. In tropical areas, however, it can be very large and depends on the direction of propagation relative to that of the earth's magnetic field. In some

extreme cases (e.g., east–west paths in equatorial Africa), polarization coupling losses of more than 20 dB have been observed. This phenomenon is not yet fully understood, and more data are needed. An interim formula, however, has been developed by Phillips and Knight [31].

4.3.6. Influence of Seawater. When at least one terminal of a path is situated near the sea and a significant portion of the path is over seawater, the received signal is significantly stronger than otherwise. This is commonly called sea gain (G_s). Sea gain is a complicated function of several factors, including pathlength (i.e., elevation angle), distance from antenna to the sea, and frequency. Under ideal conditions (elevation angle = 0, antenna is on the coast), sea gain is about 4 dB at LF and about 10 dB at MF. For a more detailed discussion, see a paper by Knight [30].

4.3.7. Propagation at Daytime. Daytime measurements from more than 30 paths are believed to be sky waves and have been studied by Wang [38]. Some trends are briefly stated as follows:

LF Cases. LF sky-wave field strengths at noon can be surprisingly strong, particularly in winter months. Daytime annual median field strength is typically 20 dB lower than its counterpart at night. Daytime upper-decile value is about 13 dB stronger than the median value.

MF Cases. MF sky-wave field strengths at noon display a consistent seasonal variation pattern with maximum occurring in winter months. The average winter-month field strength is about 10 dB stronger than the annual median value. The winter : summer ratio can exceed 30 dB. The annual median value of field strength at noon is about 43 dB lower than its counterpart at 6 h after sunset. Field strength exceeded for 10% of the days of the year is about 13 dB stronger than the median value.

4.4. Comparison of Predicted and Measured Field Strengths

An extensive comparative study using the most recent data bank has been carried out [25]. For each and every propagation path in the data bank, field strengths have been calculated by using the four most popular methods discussed in this article. Polarization coupling loss and sea gain, if applicable, have been included. In a very small number of cases where measurements were taken in a year of maximum sunspot number, the Wang formula [37] for sunspot losses has also been used. Calculated results are compared with measured data, and prediction errors are thus obtained and analyzed. Prediction errors are analyzed from four different viewpoints (path length, latitude, frequency, and geographic regions) and tabulated in detail [25]. In this article, only pathlength and latitude are considered.

4.4.1. Pathlength and Path Accuracy. We arbitrarily define a short path as one whose length is shorter than 2500 km, a medium path between 2500 and 4999 km, and a long path greater than 5000 km. Then there are 267 short paths, 85 medium paths, and 65 long paths. On the RMS (root-mean-square) basis, the prediction errors of the Cairo curve are 6.6 dB for short paths, 7.5 dB for medium paths, and 10.1 dB for long paths. The corresponding errors of the Region 2 method are 6.6, 7.5, and 12.0 dB, respectively. Those of the Udaltsov–Shlyuger method are 5.7, 7.8, and 16.4 dB, respectively. The errors of the Wang method are 5.5, 6.5, and 6.7 dB, respectively. The Wang method is the only method that offers good to excellent results in all distance ranges.

4.4.2. Latitude and Accuracy. In this section we arbitrarily define low latitudes as those between 0° and 35° (geomagnetic), temperate latitudes as those between 35.1° and 50°, and high latitudes as those greater than 50°. Then there are 203 paths in the low-latitude areas, 152 paths in the temperate-latitude areas, and 62 paths in the high latitudes. On the RMS basis, the prediction errors of the Udaltsov–Shlyuger method are 7.9 dB in low-latitude areas, 6.5 dB in temperate-latitude areas, and 14.0 dB in high-latitude areas, respectively. On the other hand, the corresponding errors of the Wang method are 5.7, 5.6, and 4.4 dB, respectively.

In summary, the Wang method is the only method that offers good to excellent results for short and long paths alike, at all frequencies in the LF/MF bands, at all latitudes, and in all regions.

4.5. The Recommended Propagation Model

In this section we recommend and present the Wang method. For a complete step-by-step procedure, see ITU-R Recommendation P.1147-1 [35]. This section is not meant to be self-contained. Only the most important equations are given here.

4.5.1. Annual Median Field Strength. According to the Wang method, the annual median sky-wave field strength at 6 h after sunset, E (in decibels above 1 μV/m), is given by

$$E = P + G + (A - 20\log p) - k\left(\frac{p}{1000}\right)^{0.5} - L_p + G_s - L_r \quad (4)$$

$$k = 2\pi + 4.95\tan^2(\Phi) \quad (5)$$

where P = radiated power in dB above 1 kW
G = transmitting antenna gain (dB)
A = a constant (at LF, $A = 110.2$; at MF, $A = 110$ in Australia and New Zealand; and $A = 107$ in all other places)
p = actual slant distance of the path under study, in kilometers, assuming that average height of E layer is 100 km
Φ = geomagnetic latitude of the midpoint of the path under study in degrees
L_p = polarization coupling loss (dB) [31]
G_s = sea gain (dB) [30]
L_r = loss of field strength due to solar activity (dB) [37]

4.5.2. Upper Decile Field Strength. Field strength exceeded for 10% of the nights of a year $E(10)$, is greater than the annual median value by Δ dB. Then

$$\Delta = 0.2|\Phi| - 2 \tag{6}$$

where Δ is limited between 6.0 and 10 dB.

5. SKY-WAVE PROPAGATION AT HF

5.1. General Description of HF Propagation

HF sky-wave propagation may be represented by rays between the ground and the ionosphere. In the ionosphere, the radiowaves experience dispersion and changes in polarization. The propagation is affected by, among other factors, ionization, operating frequency, ground conductivity and elevation angle. HF waves in the ionosphere undergo continuous refraction (i.e., bending of the ray path). At any given point, refraction is less at lower electron densities, for higher frequencies, and for higher elevation angle. For a given elevation angle, there exists a certain frequency below which the rays will be reflected back to earth. At a higher frequency, the refraction is too low for the rays to be returned to earth. Waves launched vertically may be reflected, if their frequency is below the "critical frequency" (see Section 6).

The apparent height of reflection varies between about 100 and 300 km. Radiowaves that are launched more obliquely travel to greater range. The maximum range attained after one hop arises for rays launched at grazing incidence. For typical E, F1, and F2 layers, it is about, 2000, 3400, and 4000 km, respectively. In HF communication, several propagation paths are often possible between a given transmitter and a given receiver, such as a single reflection from the E region (1E mode), a single reflection from the F region (1F mode), and double reflection from the F region (2F mode). Mode 2F is said to have higher "order" than mode 1F in propagation terms. This feature is known as *multipath*.

At frequencies above the critical frequency, there is an area surrounding the transmitter defined by "skip distance" in which sky wave cannot be received because the elevation angle is too high. The maximum usable frequency (MUF), a very important concept in HF propagation, may be defined as the frequency that makes the distance from the transmitter to a given reception point equal to the skip distance (see also Section 6). The MUF increases with pathlength and decreases with the height of the ionospheric layer. The MUF also undergoes diurnal, seasonal, solar cycle, and geographic variations. The MUF tends to be high during the day and low during the night. Also, the MUF is higher in summer than in winter during the night. Furthermore, the MUF tends to increase with increasing sunspot number. The F2-layer MUF may increase as much as 100% from sunspot minimum and sunspot maximum. The MUF has a very complex geographic variation. The most authoritative presentation of MUF is undoubtedly the CCIR Report 340, *Atlas of Ionospheric Characteristics* [39], which presents world maps of MUF for the F2 layer corresponding to different month of the year, solar activity levels, and distance ranges.

5.2. Fading

5.2.1. Interference Fading. Interference fading results from interference between two or more waves, which travel by different paths to arrive at the receiving point. This type may be caused by interference between multiple reflected sky waves, sky wave, and ground wave. This type of fading may last for a period of a fraction of a second to a few seconds, during which time the resultant field intensity may vary over wide limits.

5.2.2. Polarization Fading. Polarization fading occurs as a result of changes in the direction of polarization of the downcoming wave, relative to the orientation of the receiving antenna, due to random fluctuations in the electron density along the path of propagation. This type of fading also lasts for a fraction of a second to a few seconds.

5.2.3. Absorption Fading. Absorption fading is caused by variation in the absorption due to changes in the densities of ionization, and it may sometimes last longer than one hour.

5.2.4. Skip Fading. Skip fading may be observed at receiving locations near the skip distance at about sunrise and sunset, when the basic MUF for the path may oscillate around the operating frequency. The signal may decrease abruptly when the skip distance increases past the receiving point (or increase with a decrease in the skip distance).

5.3. Regional Anomalies

5.3.1. Tropical Anomalies. In the tropical zone, sky-wave propagation is characterized by the presence of equatorial sporadic E and the spread F. Equatorial sporadic E (Es-q), which appears regularly during daytime in a narrow zone near the magnetic equator, is the principal cause for fading at daytime. In the equatorial zone after local sunset, some irregularities develop in the F-region ionization and are called *spread F*. Under these conditions, the F region increases markedly in height and seems to break up into patchy irregular regions. As a result, a peculiar type of rapid fading, called flutter fading, usually occurs after sunset. Flutter fading is one of the most important factors in the degradation of HF broadcast service in tropical areas. Flutter fading is most pronounced following the equinoxes. Flutter fading correlates negatively with magnetic activity. On magnetically quiet days, it is usually evident, whereas on magnetically disturbed days, it is absent. The fading rate is proportional to the wave frequency and may range between 10 and 300 per minute [19].

5.3.2. High-Latitude Anomalies. At high latitudes, the ionosphere is exposed to the influence of disturbances in interplanetary space and in the magnetosphere, since the magnetic field lines extend far from the earth. Electrically charged particles can move easily along the field lines and perturb the high-latitude ionosphere. The

absorption is inversely proportional to frequency squared. The absorption may be preceded by a sudden ionospheric disturbance (SID) on the sunlit side of the earth, at all latitudes, caused by X rays from solar flares. At HF, absorption can be greater than 100 dB [40,41]. The magnetic storm-related absorption in the sunlit part of the polar cap is much stronger than in the dark side. The average duration of the event is about 2 days, but may be as long as 4 days. It may spread to lower latitudes too.

5.4. Predicting HF Sky-Wave Field Strength

The calculation of HF field strengths is a very complicated process. It requires a computer. In the succeeding section, a survey of existing programs will be presented. In this section, only a brief outline of the calculation procedure is given. The purpose is to illustrate the general procedures and terms involved. For a more detailed presentation, see, for example, ITU-R Recommendation PI.533-4 [42].

The median value of sky-wave field strength for a given mode of propagation, in dB (μV/m), is given by

$$E_{ts} = 136.6 + P_t + G_t + 20\log f - L_{bf} - L_i - L_m - L_g - L_h - 12.2 \quad (7)$$

where P_t = transmitter power in dB relative to 1 kW
G_t = transmitting antenna gain (dB)
f = transmitting frequency (MHz)
L_{bf} = basic free space transmission loss = $32.45 + 20\log f + 20\log p$ (8)
p = slant distance (km)
L_i = absorption loss (dB)
L_m = above MUF loss (dB)
L_g = ground reflection loss (dB)
L_h = auroral and other signal losses

5.5. Performance Prediction Software

A large number of computer programs have been developed for predicting HF circuit performance. The following is a brief list of the programs that are widely used today. For an excellent discussion on this topic, see a paper by Rush [43].

5.5.1. IONCAP. Ionospheric Communications Analysis and Prediction Program (IONCAP) was developed by staff of the Institute for Telecommunication Sciences (ITS) of the National Telecommunications and Information Administration (NTIA), Department of Commerce [44]. The propagation features include refraction bending, scattering on frequencies above the MUF, and sporadic E propagation. The predicted field strength and noise levels can help the designer to determine optimum frequencies, correct antennas, required transmitter powers. IONCAP is available from NTIA/ITS, Department of Commerce, Boulder, CO (USA).

5.5.2. VOACAP. At the request of the Voice of America, IONCAP has been modified and improved [45]. The resultant program, VOACAP, is available from ITS Website *http://elbert.its.bldrdoc.gov/hf.html*.

5.5.3. ITU-R Recommendation 533-4 (REC533). In preparation for the 1984 HF World Administrative Radio Conference (WARC HFBC-84), the CCIR established Interim Working Party 6/12. After extensive deliberations, it adopted the following. For paths shorter than 7000 km, IWP 6/12 adopted a simplified version of the method described in CCIR Report 252-2, similar to IONCAP. For paths longer than 9000 km, the FTZ method [46] was adopted. For in-between paths, a linear interpolation scheme is used. The FTZ method has been known for its simplicity and accuracy when applied to very long paths. Results of the work of IWP 6/12 are documented in Recommendation PI.533-4 [42]. This software is known as REC533, available from the ITU, Geneva, Switzerland; also available from the abovementioned ITS Website.

5.5.4. Input Data and Results of Calculations. In order to use any of the aforementioned programs, the following required input information is usually needed for each given circuit: (1) time of day, month, and year; (2) expected sunspot number; (3) antenna type; (4) geographic locations of the transmitter and receiver; (5) human-made noise level; (6) required reliability; and (7) required signal-to-noise ratio. The results of calculations usually include the following: (1) great-circle and slant distances, (2) angles of departure and arrival, (3) number of hops, (4) time delay of the most reliable propagation mode, (5) the virtual height, (6) MUF and the probability that the frequency exceeds the predicted MUF, (7) median system loss in dB, (8) median field strength in dB above 1 μV/m, (9) median signal power in dBW, (10) median noise power in dBW, (11) median signal/noise ratio in dB, and (12) LUF (the lowest usable frequency).

6. GLOSSARY

CCIR. French acronym for International Radio Consultative Committee (now ITU-R).

Critical frequency fo. The highest frequencies at which a radio wave is reflected by a layer of the ionosphere at vertical incidence. There is usually one such frequency for each ionospheric component (e.g., foE, foF2). The critical frequency is determined by the maximum electron density in that layer. Waves with their frequency below fo will be reflected. As the frequency is increased beyond this, the ray will penetrate the layer.

Fading. The temporary and significant decrease of the magnitude of the electromagnetic field or of the power of the signal due to time variation or the propagation conditions.

Free-space propagation. Propagation of an electromagnetic wave in a homogeneous ideal dielectric medium, which may be considered of infinite extent in all directions.

Frequency band. Continuous set of frequencies in the frequency spectrum lying between two specific limiting frequencies; generally includes many channels.

Low-frequency (LF) band. The part of the spectrum between 30 and 300 kHz. This band is also known as band 5 because the center frequency is 1×10^5 Hz. The corresponding waves are sometimes called the *kilometric* or *long waves*.

Medium-frequency (MF) band. The part of the spectrum between 300 and 3000 kHz. This band is also known as band 6. The corresponding waves are sometimes called the *hectometric* or *medium waves*.

High-frequency (HF) band. The part of the spectrum between 3 and 30 MHz. This band is also known as band 7. The corresponding waves are sometimes called *decametric* or *short waves*.

ITU. International Telecommunication Union.

ITU-R. Radiocommunication Study Groups of the ITU.

ITU Region 1. Africa, Europe, the entire territory of the former USSR, Outer Mongolia, and Turkey.

ITU REGION 2. The Americas and Greenland.

ITU REGION 3. Australia, New Zealand, and all other Asian countries.

Ionosphere. The ionized region of the earth's upper atmosphere.

MUF. Maximum usable frequency.

Basic MUF. The highest frequency by which a radiowave can propagate between given terminals, on a specific occasion, by ionospheric refraction alone. Where the basic MUF is restricted to a particular propagation mode, the values may be quoted together with an indication of that mode (e.g., 2F2 MUF, 1E MUF). Furthermore, it is sometimes useful to quote the ground range for which the basic MUF applies. This is indicated in kilometers following the indication of the mode type [e.g., 1F2(4000) MUF].

Operational MUF (or simply MUF). The highest frequency that would permit acceptable performance of a radio circuit by signal propagation via the ionosphere between giving terminals at a given time under specific working conditions.

Median values of field strengths—yearly median. The median of daily values for the year, usually for a given reference hour.

Multipath propagation. Propagation of the same radio signal between a transmission point and a reception point over a number of separate propagation paths.

Noise

- **Atmospheric noise**. Radio noise produced by natural electric discharges below the ionosphere and reaching the receiving point along the normal propagation paths between the earth and the lower limit of the ionosphere.
- **Human-made noise**. Radio noise having its source in synthetic (human-made) devices.
- **Galactic noise**. Radio noise arising from natural phenomena outside the earth's atmosphere.

Propagation. Energy transfer between two points without displacement of matter.

Reliability. Probability that a specific performance is achieved.

- **Basic reliability**. The reliability of communications in the presence of background noise alone.
- **Overall reliability**. The reliability of communications in the presence of background noise and of known interference.

Skip distance. The minimum distance from the transmitter at which a sky wave of a given frequency will be returned to earth by the ionosphere.

Solar activity. The emission of electromagnetic radiation and particles from the sun, including slowly varying components and transient components caused by phenomena such as solar flares.

Sudden ionospheric disturbance (SID). A sudden marked increase in electron density of the lower ionosphere during daylight hours. This is caused by X-ray emission from the sun.

Transmission loss. The ratio, usually expressed in decibels, for a radio link between the power radiated by the transmitting antenna and the power that would be available at the receiving antenna output.

Basic free-space transmission loss (L_{bf}). The transmission loss that would occur if the antennas were replaced by isotropic antennas located in a perfectly dielectric, homogeneous, isotropic, and unlimited environment [see also Eq. (8)].

Zenith angle. The angle between the sun and the zenith (i.e., directly overhead) at a given geographic location.

BIOGRAPHY

John C. H. Wang received his B.S. degree in electrical engineering in 1959 from the University of Maryland, and his M.S. degree in electrical engineering in 1968 from the University of Pittsburgh, Pennsylvania. He has been with the technical research staff of the Federal Communications Commission in Washington D.C. since 1969. His main area of research is ionospheric propagation and has published more than 30 technical papers. He is also active in the Radiocommunication Study Groups of the Telecommunication Union (ITU-R) and chairs its Working Party on Ionospheric Propagation. His other interests include astronomy and Chinese history. With that unique combination, he has written papers on the sighting of sunspots in ancient China and on the subject of unearthing the star of Bethlehem from Chinese history. He is a fellow of the IEEE.

RATE-DISTORTION THEORY

TOBY BERGER
Cornell University
Ithaca, New York

Coding, in the sense of C. E. Shannon's information theory [1], divides naturally into channel coding and source coding. Source coding exhibits a further dichotomy into lossless source coding and lossy source coding. Lossless source coding is treated in a separate article in this encyclopedia. Here, we discuss the theory of lossy source coding, also widely known as *rate-distortion theory*.[1]

Shannon's principal motivation for including "Section V: The Rate for a Continuous Source" in his celebrated paper was that it provided a means for extending information theory to analog sources. Since all analog sources have infinite entropy, they cannot be preserved losslessly when stored in or transmitted over physical, finite-capacity media.

Shannon's famous formula for the capacity of an ideal band-limited channel with an average input power constraint and an impairment of additive, zero-mean, white Gaussian noise reads

$$C = W \log_2(1 + P/N) \quad \text{bits/s} \tag{1}$$

In this formula — the most widely known and the most widely abused of Shannon's results — P is the prescribed limitation on the average input power, W is the channel bandwidth in positive frequencies measured in Hz, and N is the power of the additive noise. Since the noise is white with one-sided power spectral density N_0 or two-sided power spectral density $N_0/2$, we have $N = N_0 W$. Common abuses consist of applying (1) when

1. The noise is non-Gaussian.
2. The noise is not independent of the signal and/or is not additive.
3. Average power is not the (only) quantity that is constrained at the channel input.
4. The noise is not white across the passband and/or the channel transfer function is not ideally bandlimited.

Abuse (1) is conservative in that it underestimates capacity because Gaussian noise is the hardest additive noise to combat. Abuse (2) may lead to grossly underestimating or grossly overestimating capacity. A common instance of abuse (3) consists of failing to appreciate that it actually may be peak input power, or perhaps both peak and average input power, that are constrained. Abuse (4) leads to an avoidable error in that the so-called "water pouring" result [8], generalizing (1), yields the exact answer when the noise is not white, the channel is not bandlimited, and/or the channel's transfer function is not flat across the band. (See also [3,4].) There is a pervasive analogy between source coding theory and channel coding theory. The source coding result that corresponds to (1) is

$$R = W \log_2(S/N) \quad \text{bits/s} \tag{2}$$

It applies to situations in which the data source of interest is a white Gaussian signal bandlimited to $|f| \leq W$ that has power $S = S_0 W$, where S_0 denotes the signal's one-sided constant power spectral density for frequencies less than W. The symbol, N, although often referred to as a "noise," is actually an estimation error. It represents a specified level of mean squared error (MSE) between the signal $\{X(t)\}$ and an estimate $\{\hat{X}(t)\}$ of the signal constructed on the basis of data about $\{X(t)\}$ provided at a rate of R bits/s. That is,

$$N = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} dt\, E[\hat{X}(t) - X(t)]^2$$

It was, and remains, popular to express MSE estimation accuracy as a "signal-to-noise ratio," S/N, as Shannon did in Eq. (2). It must be appreciated, however, that $\{\hat{X}(t) - X(t)\}$ is not noise in the sense of being an error process that is independent of $\{X(t)\}$ that nature adds to the signal of interest. Rather, it is a carefully contrived error signal, usually dependent on $\{X(t)\}$, that the information/communication theorist endeavors to create in order to conform to a requirement that no more than R bits/s of information may be supplied about $\{X(t)\}$. In modern treatises on information theory, the symbol "D," a mnemonic for average distortion, usually is used in place of N. This results in an alternative form of (2), namely

$$R(D) = W \log_2(S/D) \quad \text{bits/s} \tag{3}$$

which is referred to as the MSE rate-distortion function of the source.

Equation (3) also suffers widespread abuse which takes the form of applying it to situations in which

1. The signal is non-Gaussian.
2. Distortion does not depend simply on the difference of $\hat{X}(t)$ and $X(t)$
3. Distortion is measured by a function of $\hat{X}(t) - X(t)$ other than its square.
4. The signal's spectral density is not flat across the band.

Again, abuse (1) is conservative in that it results in an overestimate of the minimum rate R needed to achieve a specified MSE estimation accuracy because white Gaussian sources are the most difficult to handle in the sense of bit rate versus MSE. Abuses (2) and (3),

[1] This article is drawn in considerable measure from the first half of a survey paper on lossy source coding by T. Berger and J. Gibson [2] that appeared in the 50th Anniversary Issue of the *IEEE Transactions on Information Theory* in October 1998. There have been some additions, some corrections, some enhancements, and many deletions.

which often stem in practice from lack of knowledge of a perceptually appropriate distortion measure, can result in gross underestimates or overestimates of R. Abuse (4) can be avoided by using a water-pouring generalization of (3) which we shall soon discuss. Toward that end we recast (3) in the form

$$R(D) = \max[0, W \log(S_0 W/D)] \tag{4}$$

This explicitly reflects the facts that (2) the signal spectrum has been assumed to be constant at level S_0 across the band of width W in which it in nonzero, and (2) $R(D) = 0$ for $D \geq S_0 W$, because one can achieve a MSE of $S = S_0 W$ without sending any information simply by guessing that $X(t) = m(t)$, the signal's possibly time-varying deterministic mean value function. The base of the logarithm in Eq. (4) determines the information unit — bits for $\log_2$ and nats for $\log_e$. When we deal with continuously distributed quantities, it is more "natural" to employ natural logs. When no log base appears, assume henceforth that base e is intended.

A basic inequality of information theory is

$$D \geq R^{-1}(C) \tag{5}$$

which we shall refer to as the *information transmission inequality*. It says that if you are trying to transmit data from a source with rate-distortion function $R(D)$ over a channel of capacity C, you can achieve only those average distortions that exceed the distortion-rate function evaluated at C. (The distortion-rate function is the inverse of the rate-distortion function; denoted $D(R)$, it always exists because $R(D)$ always is convex.)

Suppose, for example, that we wish to send data about the aforementioned band-limited white-Gaussian process $\{X(t)\}$ over an average-input-power-limited, ideally band-limited AWGN channel and then construct on the basis of the channel output an approximation $\{\hat{X}(t)\}$ that has the least possible MSE. The source and the channel have the same frequency band $|f| \leq W$. Since $R(D) = W \log_2(S/D)$, the distortion-rate function is

$$D(R) = S 2^{-R/W}$$

so Eqs. (1) and (4) together tell us that

$$D \geq D(C) = S \exp\left[-\frac{W \log(1 + P/N)}{W}\right]$$

or

$$D/S \geq (1 + P/N)^{-1} \tag{6}$$

This tells us that the achievable error power per unit of source power (i.e., the achievable normalized MSE) is bounded from below by the reciprocal of one plus the channel SNR. There happens to be a trivial scheme for achieving equality in Eq. (5) when faced with the communication task in question. It consists of the following steps:

Step 1. Transmit $X(t)$ scaled to have average power P; that is, put $\sqrt{P/S}X(t)$ into the channel.

Step 2. Set $\hat{X}(t)$ equal to the MMSE estimate of $X(t)$ based solely on the instantaneous channel output $\sqrt{P/S}X(t) + N(t)$ at time t.

Since the signal and the channel noise are jointly Gaussian and zero mean, the optimum estimate in Step 2 is simply a linear scaling of the received signal, namely

$$\hat{X}(t) = \alpha[\sqrt{P/S}X(t) + N(t)]$$

The optimum α, found from the requirement that the error of the optimum estimator must be orthogonal to the data, is $\alpha = \sqrt{PS}/(P + N)$. The resulting minimized normalized MSE is easily computed to be

$$D/S = (1 + P/N)^{-1} \tag{7}$$

which means we have achieved equality in Eq. (5).

Thus, the simple two-step scheme of instantaneously scaling appropriately at the channel input and output results in an end-to-end communication system that is optimum. No amount of source and/or channel coding could improve upon this in the MSE sense for the problem at hand. This fortuitous circumstance is attributable to a double coincidence. The first coincidence is that the source happens to be the random process that drives the channel at capacity. That is, the given source, scaled by $\sqrt{P/S}$, is that process of average power not exceeding P which maximizes the mutual information between the input and output of the channel. The second coincidence is that the channel just happens to provide precisely the transition probabilities that solve the MSE rate-distortion problem for the given source. That is, when the channel is driven by the scaled source, its output minimizes mutual information rate with the source over all processes from which one can calculate an approximation to the source that achieves a normalized MSE not in excess of $(1 + P/N)^{-1}$.

We are operating at a saddle point at which the *mutual information* rate is simultaneously maximized subject to the average power constraint and minimized subject to the average distortion constraint. The slightest perturbation in any aspect of the problem throws us out this saddle — unequal source and channel bandwidths, non-Gaussianness of the source or channel, an error criterion other than MSE, and so on. The result of any such perturbation is that, in order to recover optimality, it is in general necessary to code both for the source and for the channel. From 1949 to 1958 no research was reported on rate-distortion theory in the United States or Europe. However, there was a stream of activity during the 1950s at Moscow University by members of Academician *A. N. Kolmogorov's* probability seminar. Kolmogorov saw in Shannon's entropy rate an ideal candidate for the long-sought "invariant" in the challenging isomorphism problem of ergodic theory. Kolmogorov and Sinai [5,7] succeeded in showing that equal entropy rates were a necessary condition for isomorphism of ergodic flows. Years later, Ornstein [9] proved sufficiency within an appropriately defined broad class of random stationary processes comprising all finite-order Markov sources and

their closure in a certain metric space that will not concern us here. With the Moscow probability seminar's attention thus turned to information theory, it is not surprising that some of its members also studied Shannon's Section V, The Rate for a Continuous Source. Pinsker, Dobrushin, Iaglom, Tikhomirov, Oseeyevich, Erokhin, and others made contributions to a subject that has come to be called ε-entropy, a branch of mathematics that is intimately intertwined with what information theorists today call rate-distortion theory. Thus, when invited to address an early information theory symposium, Kolmogorov [8] reported without attribution the exact answer for the ε-entropy of a stationary Gaussian process with respect to the squared L_2-norm. That result, and its counterpart for the capacity of a power-constrained channel with additive colored Gaussian noise, have come to be known as the "water pouring" formulas of information theory. In this generality the channel formula is attributable to [12] and the source formula to Pinsker [13,14].

Accordingly, we shall call them the Shannon–Pinsker water pouring formulas. They generalize the formulas given by Shannon in 1948 for the important case in which the spectrum of the source or of the channel noise is flat across a band and zero elsewhere.

The Shannon–Pinsker water pouring formula for the MSE information rate of a Gaussian source can be derived by using the fact that processes formed by bandlimiting a second-order stationary random processes to nonoverlapping frequency bands are uncorrelated with one another. In the case of a Gaussian process, this uncorrelatedness implies independence. Thus, we can decompose a Gaussian process $\{X(t)\}$ with one-sided spectral density $S(f)$ into independent Gaussian processes $\{X_i(t)\}, i = 0, 1, \ldots$ with respective spectral densities $S_i(f)$ given by

$$S_i(f) = \begin{cases} S(f), & \text{if } i\Delta \le f < (i+1)\Delta; \\ 0, & \text{otherwise} \end{cases}$$

Let us now make Δ sufficiently small that $S_i(f)$ becomes effectively constant over the frequency interval in which it is nonzero, $S_i(f) \approx S_i, i\Delta \le f < (i+1)\Delta$. It is easy to see that the best rate-distortion tradeoff we can achieve for subprocess $\{X_i(t)\}$ is

$$R_i(D_i) = \max[0, \Delta \log(S_i\Delta/D_i)]$$

By additively combining said approximations over all the subprocesses, we get an approximation to $\{X(t)\}$ that achieves an average distortion of

$$D = \sum_i D_i$$

and requires a total coding rate of

$$R = \sum_i R_i(D_i) = \sum_i \max[0,\ \Delta \log(S_i\Delta/D_i)]$$

In order to determine the MSE rate-distortion function of $\{X(t)\}$, it remains only to select those D_i's summing to D which minimize this R. Toward that end we set

$$d(R + \lambda D)/dD_i = 0, i = 0, 1, 2, \ldots,$$

where λ is a Lagrange multiplier subsequently selected to achieve a desired value of D or of R. It follows that the D and R values associated with parameter value λ are

$$\begin{aligned} D_\lambda &= \sum_{\{i:S_i\Delta > (\lambda\Delta)^{-1}\}} (\lambda\Delta)^{-1} + \sum_{\{i:S_i\Delta \le (\lambda\Delta)^{-1}\}} S_i\Delta \\ &= \sum_i \min[(\lambda\Delta)^{-1}, S_i\Delta] \end{aligned}$$

and

$$R_\lambda = \sum_i \max[0, \Delta \log(S_i\Delta/(\lambda\Delta)^{-1})]$$

If we use

$$\gamma = (\lambda\Delta^2)^{-1}$$

as our parameter instead of λ and then let $\Delta \to 0$, a parametric expression for the rate-distortion function emerges. Casting the result in terms of the two-sided spectral density $\Phi(f)$, an even function of frequency satisfying $\Phi(f) = S(f)/2, f \ge 0$ and replacing the parameter γ by $\theta = \gamma/2$, we obtain

$$D_\theta = \int_{-\infty}^{\infty} \min[\theta, \Phi(f)]df \tag{8}$$

$$R_\theta = \int_{-\infty}^{\infty} \max\left[0, \frac{1}{2}\log(\Phi(f)/\theta)\right]df \tag{9}$$

[Some practitioners prefer to use angular frequency $\omega = 2\pi f$ as the argument of $\Phi(\cdot)$; of course, df then gets replaced in Eqs. (8) and (9) by $d\omega/(2\pi)$.]

The parametric representation (8) of the MSE rate-distortion function of a stationary Gaussian source is the source coding analog of the Shannon-Pinsker "water pouring" result for the capacity of an input-power-limited channel with additive stationary Gaussian noise. In a rate-distortion function of a time-discrete Gaussian sequence provided we limit the range of integration to $|f| \le 1/2$ or to $|\omega| \le \pi$. In such cases $\Phi(\omega)$ is the discrete-time power spectral density, a periodic function defined by

$$\Phi(\omega) = \sum_{k=-\infty}^{\infty} \phi(k)\exp(j\omega k)$$

where $\phi(k) = EX_jX_{j\pm k}$ is the correlation function of the source data. Note that when the parameter θ assumes a value less than the minimum[2] of $\Phi(\cdot)$, which minimum we shall denote by D^*, (8a) reduces to $D_\theta = \theta$, which eliminates the parameter and yields the explicit expression

$$R(D) = \frac{1}{4\pi}\int_{-\pi}^{\pi} \log[\Phi(\omega)/D]d\omega,\ D \le D^*$$

This may be recast in the form

$$R(D) = \tfrac{1}{2}\log(Q_0/D),\ D \le D^*$$

[2] More precisely, less than the essential infimum.

where

$$Q_0 = \exp\left[\frac{1}{2\pi}\int_{-\pi}^{\pi} \log \Phi(\omega) d\omega\right]$$

is known both as the entropy rate power of $\{X_k\}$ and as its optimum one-step prediction error. In 1959 Shannon delivered a paper at the IRE Convention in New York City entitled "Coding Theorems for a Discrete Source with a Fidelity Criterion" [15]. This paper not only introduced the term "rate-distortion function" but also put lossy source coding on a firmer mathematical footing. Major contributions of the paper are:

- Definition and properties of the rate-distortion function.
- Calculating and bounding of R(D).
- Coding theorems.
- Insights into source-channel duality.

A discrete information source is a random sequence $\{X_k\}$. Each X_k assumes values in a discrete set $\mathcal{A}$ called the source alphabet. The elements of $\mathcal{A}$ are called the letters of the alphabet. We shall assume until further notice that there are finitely many distinct letters, say M of them, and shall write $\mathcal{A} = \{a(0), a(1), \ldots, a(M-1)\}$. Often we let $a(j) = j$ and hence $\mathcal{A} = \{0, 1, \ldots, M-1\}$; the binary case $\mathcal{A} = \{0, 1\}$ is particularly important.

The simplest case, to which we shall restrict attention for now, is that in which:

1. The X_k are independent and identically distributed (i.i.d.) with distribution $\{p(a), a \in \mathcal{A}\}$.
2. The distortion that results when the source produces the n-vector of letters $a = (a_1, \ldots, a_n) \in \mathcal{A}^n$ and the communication system delivers the n-vector of letters $b = (b_1, \ldots, b_n) \in \mathcal{B}^n$ to the destination as its representation of a is

$$d_n(a, b) = n^{-1} \sum_{k=1}^{n} d(a_k, b_k) \tag{10}$$

Here, $d(\cdot, \cdot) : \mathcal{A} \times \mathcal{B} \to [0, \infty)$ is called a single-letter distortion measure. The alphabet $\mathcal{B}$—variously called the reproduction alphabet, the user alphabet, and the destination alphabet—may be but need not be the same as $\mathcal{A}$. We shall write $\mathcal{B} = \{b(0), b(1), \ldots, b(N-1)\}$, where $N < M, N = M$ and $N > M$ all are cases of interest. When Eq. (9) applies, we say we have a *single-letter fidelity criterion* derived from $d(\cdot, \cdot)$.

Shannon defined the rate-distortion function $R(\cdot)$ as follows. First, let $Q = \{Q(b \mid a), a \in \mathcal{A}, b \in \mathcal{B}\}$ be a conditional probability distribution over the letters of the reproduction alphabet given a letter in the source alphabet.[3] Given a source distribution $\{p(j)\}$, we associate with any such Q two nonnegative quantities $d(Q)$ and $I(Q)$ defined by

$$d(Q) = \sum_{a \in \mathcal{A}} \sum_{b \in \mathcal{B}} p(a) Q(b|a) d(a, b)$$

and

$$I(Q) = \sum_{a \in \mathcal{A}} \sum_{b \in \mathcal{B}} p(a) Q(b|a) \log\left(\frac{Q(b|a)}{q(b)}\right)$$

where

$$q(b) = \sum_{a \in \mathcal{A}} p(a) Q(b|a)$$

The quantities $d(Q)$ and $I(Q)$ are, respectively, the average distortion and the average Shannon mutual information associated with Q.

The rate-distortion function of the i.i.d. source $\{X_k\}$ with letter distribution $\{p(a) = P[X_k = a]\}$ with respect to the single-letter fidelity criterion generated by $d(\cdot, \cdot)$ is defined by the following minimization problem:

$$R(D) = \min_{Q: d(Q) \le D} I(Q) \tag{11}$$

Since the generally accepted object of communication is to maximize mutual information, not to minimize it, many people find the definition of the rate-distortion function counterintuitive. In this regard it often helps to interchange the independent and dependent variables, thus ending up with a distortion-rate function defined by

$$D(R) = \min_{Q: I(Q) \le R} d(Q) \tag{12}$$

Everyone considers that minimizing average distortion is desirable, so no one objects to this definition. Precisely the same curve results in the (D, R)-plane, except that now R is the independent variable instead of D. Distortion-rate functions are more convenient for certain purposes, and rate-distortion functions are more convenient for others. One should become comfortable with both.

Properties of the rate-distortion function include:

(a) $R(D)$ is well defined for all $D \ge D_{\min}$, where

$$D_{\min} = \sum_{a \in \mathcal{A}} p(a) \min_{b \in \mathcal{B}} d(a, b)$$

The distortion measure can be modified to assure that $D_{\min} = 0$. This is done via the replacement $d(a, b) \leftarrow d(a, b) - \min_b d(a, b)$, whereupon the whole rate-distortion curve simply translates leftward on the D-axis by $D_{\min}$.)

(b) $R(D) = 0$ for $D \ge D_{\max}$, where

$$D_{\max} = \min_b \sum_a p(a) d(a, b)$$

$D_{\max}$ is the maximum value of D that is of interest, since $R(D) = 0$ for all larger D. It is the value of D associated with the best guess at $\{X_k\}$ in the absence of any information about it other

[3] Such a Q often is referred to as a test channel. However, it is preferable to call it a test system because it functions to describe a probabilistic transformation from the source all the way to the user—not just across the channel. Indeed, the rate-distortion function has nothing to do with any channel per se. It is a descriptor of the combination of an information source and a user's way of measuring the distortion of approximations to that source.

than *a priori* statistical knowledge. For example, $D_{\max} = 1 - \max_a p(a)$ when $\mathcal{A} = \mathcal{B}$ and $d(a, b) = 1$ if $b \neq a$ and 0 if $b = a$.

(c) $R(D)$ is nonincreasing in D and is strictly decreasing at every $D \in (D_{\min}, D_{\max})$.

(d) $R(D)$ is convex downward. It is strictly convex in the range $(D_{\min}, D_{\max})$ provided $N \leq M$, where $N = |\mathcal{B}|$ and $M = |\mathcal{A}|$. In addition to the ever-present straight-line segment $R(D) = 0, D \geq D_{\max}$, if $N > M$ then $R(D)$ can possess one or more straight line segments in the range $D_{\min} < D < D_{\max}$.

(e) The slope of $R(D)$ is continuous in $(D_{\min}, D_{\max})$ and tends to $-\infty$ as $D \downarrow D_{\min}$. If there are straight-line segments in $(D_{\min}, D_{\max})$ (see (d) above), no two of them share a common endpoint.

(f) $R(D_{\min}) \leq H$, where

$$H = -\sum_{a \in \mathcal{A}} p(a) \log p(a)$$

is the source entropy. If for each $a \in \mathcal{A}$ there is a unique $b \in \mathcal{B}$ that minimizes $d(a, b)$, and each $b \in \mathcal{B}$ minimizes $d(a, b)$ for at most one $a \in \mathcal{A}$, then $R(D_{\min}) = H$.

Some of these properties were established by Shannon [15], including the essential convexity property (d). For proofs of the others see Gallager [3], Jelinek [16], and Berger [17].

In the special case of a binary equiprobable source and an error-frequency (or Hamming) distortion measure, calculations reveal that

$$R(D) = 1 - h(D) = 1 + D \log_2 D + (1 - D) \log_2 (1 - D), \ 0 \leq D \leq 1/2 = D_{\max}$$

where $h(\cdot)$ is Shannon's binary entropy function,

$$h(x) = -x \log_2 x - (1 - x) \log_2 (1 - x)$$

The desired end-to-end system behavior then becomes that of a binary symmetric channel (BSC) with crossover probability D. It follows that, if one seeks to send a Bernoulli(1/2) source over a BSC that is available once per source letter, then optimum performance with respect to the single-letter fidelity criterion generated by $d(a, b) = 1 - \delta_{a,b}$ can be obtained simply by connecting the source directly to the BSC and using the raw BSC output as the system output. There is need to do any source and/or channel coding. The average distortion will be $D = \varepsilon$, where ε is the crossover probability of the BSC.

This is another instance of a double "coincidence." This time the first coincidence is that a Bernoulli(1/2) source drives every BSC at capacity, and the second coincidence is that BSC(ε) provides precisely the end-to-end system transition probabilities that solve the rate-distortion problem for the Bernoulli(1/2) source at $D = \varepsilon$. Again, their combination represents a precarious saddle point. If the channel were not available precisely once per source symbol, if the Bernoulli source were to have a bias $p \neq 1/2$ if the channel were not perfectly symmetric, or if the distortion measure were not perfectly symmetric (i.e., if $d(0, 1) \neq d(1, 0)$), it would become necessary to employ source and channel codes of long memory and high complexity in order to closely approach performance that is ideal in the sense of achieving equality in the information transmission inequality (5). To enhance appreciation for the fragility of the double-coincidence saddle point, let us replace the Bernoulli(1/2) source with a Bernoulli(p) source, $p \neq \frac{1}{2}$. Calculations (see [17], p. 46–47) reveal that the rate-distortion function then becomes

$$R(D) = h(p) - h(D), \ 0 \leq D \leq \min(p, 1 - p) = D_{\max}$$

Although the optimum backward system transition probabilities $P(a|b)$ remain those of BSC(D), the optimum forward transition probabilities become those of a binary asymmetric channel. Hence, it is no longer possible to obtain an optimum system simply by connecting the source directly to the BSC and using the raw channel output as the system's reconstruction of the source. Not only does the asymmetric source fail to drive the BSC at capacity, but the BSC fails to provide the asymmetric system transition probabilities required in the $R(D)$ problem for $p \neq 1/2$. For example, suppose $p = 0.25$ so that $R(D) = 0.811 - h(D)$ bits/letter, $0 \leq D \leq 0.25 = D_{\max}$. Further suppose that $\varepsilon = 0.15$ so that the channel capacity is $C = 1 - h(0.15) = 0.390$ bits/channel use. Direct connection of the source to the channel yields an error frequency of $D = \varepsilon = 0.15$. However, evaluating the distortion-rate function at C in accordance with Eq. (5) shows that a substantially smaller error frequency of $R^{-1}(0.390) = 0.0855$ can be achieved using optimum source and channel coding. It is noteworthy that, even when treating continuous-amplitude sources and reconstructions, Shannon always employed discrete output random variables. "Consider a finite selection of points $z_i (i = 1, 2, \ldots, l)$ from the B space, and a measurable assignment of transition probabilities $q(z_i|m)$"[15]. One reason for why he did this is the he appreciated that the representation of the source would always have to be stored digitally; indeed, his major motivation for Section V in 1948 had been to overcome the challenge posed by the fact that continuous-amplitude data has infinite entropy. But, an even better explanation is that it turns out that the output random variable $\hat{X}$ that results from solving the rate-distortion problem for a continuous-amplitude source usually is discrete! In retrospect, it seems likely that Shannon knew this all along. (For more about this discreteness, see the excellent article by Rose [18] and also work of Fix [19] dealing with cases in which X has finite support.) Shannon did not state or prove any lossy source coding theorems in his classic 1948 paper. He did, however, state and sketch the proof of an end-to-end information transmission theorem for a communication system, namely his Theorem 21. Since the notation $R(D)$ did not exist in 1948, Shannon's theorem statement has v_1 in place of D and R_1 in place of $R(D)$. It reads:

Theorem 21. If a source has a rate R_1 for a valuation v_1 it is possible to encode the output of the source and

transmit it over a channel of capacity C with fidelity as near v_1 as desired provided $R_1 \leq C$. This is not possible if $R_1 > C$.

In 1959, however, Shannon proved many lossy source coding theorems, information transmission theorems, and their converses in the quite general case of stationary and ergodic sources. These theorems have since been considerably generalized by various authors; see, for example, the work of Gray and Davisson [20], Bucklew [21], and Kieffer [22]. It is not our purpose here to enter into the details of proofs of source coding theorems and information transmission theorems. Suffice it to say that at the heart of most proofs of positive theorems lies a random code selection argument, Shannon's hallmark. In the case of sources with memory, the achievability of average distortion D at coding rate $R_n(D)$ is established by choosing long-code words constructed of concatenations of "super-letters" from $\mathcal{B}^n$. Each super-letter is chosen independently of all the others in its own code word and in the other code words according to the output marginal $q(b)$ of the joint distribution $p(a)Q(b|a)$ associated with the solution of the variational problem that defines $R_n(D)$. Shannon concluded his 1959 paper on rate-distortion theory with some memorable, provocative remarks on the duality of source theory and channel theory. He mentions that, if costs are assigned to the use of its input letters of a channel, then determining its capacity subject to a bound on expected transmission cost amounts to maximizing a mutual information subject to a linear inequality constraint and results in a capacity-cost function for the channel that is concave downward. He says, "Solving this problem corresponds, in a sense, to finding a source that is just right for the channel and the desired cost." He then recapitulates that finding a source's rate-distortion function is tantamount to minimizing a mutual information subject to a linear inequality constraint and results in a function that is convex downward. "Solving this problem," Shannon says, "corresponds to finding a channel that is just right for the source and allowed distortion level." He concludes this landmark paper with the following two provocative sentences:

> This duality can be pursued further and is related to a duality between past and future and the notions of control and knowledge. Thus we may have knowledge of the past but cannot control it; we may control the future but have no knowledge of it.

Gallager [3] introduced the following dual to the convex mathematical programming problem that defines $R(D)$: Let λ denote a vector with components $\lambda(a)$ indexed by the letters of the source alphabet, $\mathcal{A}$. Given any real s and any $\lambda 0$ let c denote the vector with components $c(b)$, $b \in \mathcal{B}$ defined by

$$c(b) = \sum_{a \in \mathcal{A}} \lambda(a) p(a) \exp[sd(a,b)]$$

Let

$$\Lambda_s = \{\lambda \geq 0 : c \leq 1\}$$

Gallager proved that

$$R(D) = \max_{s \leq 0, \lambda \in \Lambda_s} \left[sD + \sum_{a \in \mathcal{A}} p(a) \log \lambda(a) \right]$$

Expressing $R(D)$ as a maximum rather than a minimum allows one to generate lower bounds to $R(D)$ readily. Just pick any $s \leq 0$ and any $\lambda \geq 0$. Then evaluate c. If the largest component of c exceeds 1, form a new λ by dividing the original λ by this largest $c(b)$. The new λ then belongs to Λ_s. It follows that the straight line $sD + \Sigma_a p(a) \log \lambda(a)$ in the (D, R)-plane underbounds $R(D)$. Not only are lower bounds to $R(D)$ produced aplenty this way, but we are assured that the upper envelope of all these lines actually *is* $R(D)$. This dual formulation is inspired by and capitalizes on the fact that a convex downward curve always equals the upper envelope of the family of all its tangent lines. It turns out that all known interesting families of lower bounds to $R(D)$ are special cases of this result. In particular, choosing the components of λ such that $\lambda(a)p(a)$ is constant yields Shannon's lower bound [15] for cases in which the distortion measure is balanced (i.e., every row of the distortion matrix is a permutation of the first row and every column is a permutation of the first column) and yields a generalization of the Shannon lower bound when the distortion measure is not balanced. The families of lower bounds introduced by Wyner and Ziv also can be shown to be obtainable via dual problem investigations.

Although it may have appeared in the early 1970s that the then 25-year-old subject of rate-distortion theory was reaching maturity, this has not turned out to be the case. Rate-distortion theory thrived at Stanford under Gray, at Cornell under Berger, who wrote a text devoted entirely to the subject [17], at JPL under Posner, at UCLA under Omura and Yao, and at Bell Labs under Wyner.[4]

Attending a seminar on the mathematics of population genetics and epidemiology somehow inspired Blahut to work on finding a fast numerical algorithm for the computation of rate-distortion functions. He soon thereafter found that the point on an $R(D)$ curve parameterized by s could be determined by the following iterative procedure [23]:[5]

Step 0. Set $r = 0$. Choose any probability distribution $q_0(\cdot)$ over the destination alphabet that has only positive components, for example, the uniform distribution $q_0(b) = 1/|\mathcal{B}|$.

Step 1. Compute $\lambda_r(a) = (\Sigma_b q_r(b) \exp[sd(a,b)])^{-1}$, $a \in \mathcal{A}$.

[4] Centers of excellence in rate-distortion emerged in Budapest under Csiszar, in Tokyo under Amari, in Osaka under Arimoto, in Israel under Ziv and his "descendants," in Illinois under Pursley and at Princeton under Verdu.

[5] Blahut and, independently, Arimoto [24] found an analogous algorithm for computing the capacity of channels. Related algorithms have since been developed for computing other quantities of information-theoretic interest. For a treatment of the general theory of such max-max and min-min alternating optimization algorithms, see Csiszar and Tusnady [25].

Step 2. Compute $c_r(b) = \Sigma_a \lambda_r(a) p(a) \exp[sd(a,b)]$, $b \in \mathcal{B}$. If $\max_b c_r(b) < 1 + \varepsilon$, halt.

Step 3. Compute $q_{r+1}(b) = c_r(b) q_r(b)$. $r \leftarrow r+1$. Return to Step 1.

Blahut proved the following facts.

1. The algorithm terminates for any rate-distortion problem for any $\varepsilon > 0$.
2. At termination, the distance from the point (D_r, I_r) defined by

$$D_r = \sum_{a,b} p(a)\lambda_r(a) q_r(b) \exp[sd(a,b)] d(a,b)$$

and

$$I_r = sD_r + \sum_a p(a) \log \lambda_r(a)$$

to the point D, $R(D)$ parameterized by s (i.e., the point on the $R(D)$-curve at which $R'(D) = s$) goes to zero as $\varepsilon \to 0$. Moreover, Blahut provided upper and lower bounds on the terminal value of $I_r - R(D_r)$ that vanish with ε.

Perhaps the most astonishing thing about Blahut's algorithm is that it does not explicitly compute the gradient of $R + sD$ during the iterations, nor does it compute the average distortion and average mutual information until after termination. In practice, the iterations proceed rapidly even for large alphabets. Convergence is quick initially but slows for large r; Newton-Raphson methods could be used to close the final gap faster, but practitioners usually have not found this to be necessary. The Blahut algorithm can be used to find points on rate-distortion functions of continuous-amplitude sources, too; one needs to use fine-grained discrete approximations to the source and user alphabets. See, however, the so-called "mapping method" recently introduced by Rose [18], which offers certain advantages especially in cases involving continuous alphabets; Rose uses reasoning from statistical mechanics to capitalize on the fact, alluded to earlier, that the support of the optimum distribution over the reproduction alphabet usually is finite even when $\mathcal{B}$ is continuous. Following his seminal work on autoregressive sources and certain generalizations thereof, Gray joined the Stanford faculty. Since rate-distortion is a generalization of the concept of entropy and conditional entropy plays many important roles, Gray sensed the likely fundamentality of a theory of conditional rate-distortion functions and proceeded to develop it [26] in conjunction with his student, Leiner [27,28]. He defined

$$R_{X|Y}(D) = \min I(X; \hat{X}|Y)$$

where the minimum is over all r.v., $\hat{X}$ jointly distributed with (X, Y) in such a manner that $E_{X,Y,\hat{X}} d(X, \hat{X}) \le D$. This not only proved of use per se but also led to new bounding results for classical rate-distortion functions. However, it did not treat what later turned out to be the more challenging problem of how to handle side-information $\{Y_k\}$ that was available to the decoder only and not to the encoder. That had to await groundbreaking research by Wyner and Ziv [29].

Gray also began interactions with the mathematicians Ornstein and Shields during this period. The fruits of those collaborations matured some years later, culminating in a theory of sliding block codes for sources and channels that finally tied information theory and ergodic theory together in mutually beneficial and enlightening ways. Other collaborators of Gray in those efforts included Neuhoff, Omura, and Dobrushin [30–32]. The so-called process definition of the rate-distortion function was introduced and related to the performance achievable with sliding block codes with infinite window width (codes in the sense of ergodic theory). It was shown that the process definition agreed with Shannon's 1959 definition of the rate-distortion function $\liminf_{n\to\infty} R_n(D)$ for sources and/or distortion measures with memory. More importantly, it was proved that one could "back off" the window width from infinity to a large, finite value with only a negligible degradation in the tradeoff of coding rate versus distortion, thereby making the theory of sliding block codes practically significant.

Seeing that Slepian and Wolf [33] had conducted seminal research on lossless multiterminal source coding problems analogous to the multiple access channel models of Ahlswede [34] and Liao [35], Berger and Wyner agreed that research should be done on a lossy source coding analog of the novel Cover-Bergmans [36,37] theory of broadcast channels. Gray and Wyner were the first to collaborate successfully on such an endeavor, authoring what proved to the first of many papers in the burgeoning subject of multiterminal lossy source coding [38]. The seminal piece of research in multiterminal lossy source coding was the paper by Wyner and Ziv [29], who considered lossy source coding with side information at the decoder. Suppose that in addition to the source $\{X_k\}$ that we seek to convey to the user, there is a statistically related source $\{Y_k\}$. If $\{Y_k\}$ can be observed both by the encoder and the decoder, then we get conditional rate-distortion theory a la Gray. The case in which neither the encoder nor the decoder sees $\{Y_k\}$, which perhaps is under the control of an adversary, corresponds to Berger's source coding game [39]. The case in which the encoder sees $\{Y_k\}$ but the decoder does was long known [40] to be no different from the case in which there is no $\{Y_k\}$. But the case in which the decoder is privy to $\{Y_k\}$ but the encoder is not proves to be both challenging and fascinating. For the case of a single-letter fidelity criterion and (X_k, Y_k)-pairs that are i.i.d. over the index k, Wyner and Ziv showed that the rate-distortion function, now widely denoted by $_{WZ}(D)$ in their honor, is given by

$$R_{WZ}(D) = \min_{Z \in cal Z_D} I(X; Z \mid Y) \tag{13}$$

where $\mathcal{Z}_D$ is the set of auxiliary r.v. $Z \in \mathcal{Z}$ jointly distributed with a generic (X, Y) such that:

1. $Y - X - Z$ is a Markov chain; i.e., $p_{Y,X,Z}(y,x,z) = p_Y(y) p_{X|Y}(x|y) p_{Z|X}(z|x)$.
2. There exists $g : \mathcal{Z} \times \mathcal{Y} \to \mathcal{X}$ such that $Ed(X, g(Z, Y)) \le D$.

3. The cardinality of the alphabet $\mathcal{Z}$ may be constrained to satisfy $|\mathcal{Z}| \leq |\chi| + 1$.

In the special case in which $\{X_k\}$ and $\{Y_k\}$ are Bernoulli(1/2) and statistically related as if connected by a BSC of crossover probability $p \leq 1/2$ and $d(a, b) = 1 - \delta_{a,b}$,

$$R_{WZ}(D) = \begin{cases} h(p) - h(p * D), & \text{if } 0 \leq D \leq D_{ci} \\ \text{straight line from } (D_c, h(p) - h(p * D_c) \text{ to } (p, 0) & \text{if } D_c \leq D \leq p \end{cases} \tag{14}$$

where $p * d = p(1 - D) + (1 - p)D$ and D_c is such that the straight-line segment for $D \geq D_c$ is tangent to the curved segment for $D \leq D_c$. Berger had used Bergmans [37] theory of "satellites and clouds" to show that Eq. (17) was a upper bound to $R(D)$ for this binary symmetric case. The major contribution of Wyner and Ziv's paper resided in proving a converse to the unlikely effect that this performance cannot be improved upon, and then generalizing to Eq. (17) for arbitrary (X, Y) and $d(\cdot, \cdot)$.

The advent of Wyner-Ziv theory gave rise to a spate of papers on multiterminal lossy source coding, codified, and summarized by Berger in 1977 [41]. Contributions described therein include works by Korner and Marton, [42–44], Berger and Tung [45,46], Chang [47], Shohara [48], Omura and Housewright [49], Wolfowitz [50], and Sgarro [51]. In succeeding decades further strides have been made on various side-information lossy coding problems [52–58]. Furthermore, challenging new multiterminal rate-distortion problems have been tackled with considerable success, including the multiple descriptions problem [59–68], the successive refinements problem [69], and the *CEO problem* [70–72]. Applications of multiple descriptions to image, voice, audio and video coding are currently in development, and practical schemes based on successive refinement theory are emerging that promise application to progressive transmission of images and other media. In order for rate-distortion theory to be applied to images, video, and other multidimensional media, it is necessary to extend it from random processes to random fields (i.e., collections of random variables indexed by multidimensional parameters or, more generally, by the nodes of a graph). The work of Hayes, Habibi, and Wintz [73] extending the water-table result for Gaussian sources to Gaussian random fields already has been mentioned. A general theory of the information theory of random fields has been propounded [74], but we are more interested in results specific to rate-distortion. Most of these have been concerned with extending the existence of critical distortion to the random field case and then bounding the critical distortion for specific models. The paper of Hajek and Berger [75] founded this subfield. Work inspired thereby included Bassalygo and Dobrushin [76], Newman [77], Newman and Baker[78] in which the critical distortion of the classic Ising model is computed exactly, and several papers by Berger and Ye [79,80]. For a summary and expansion of all work in this arena, see the monograph by Ye and Berger [81].

Work by Fitingof, Lynch, Davisson, and Ziv in the early 1970s showed that lossless coding could be done efficiently without prior knowledge of the statistics of the source being compressed, so-called universal lossless coding. This was followed by development of Lempel-Ziv coding [82,83], arithmetic coding [84–86] and context-tree weighted encoding [87,88], which have made universal lossless coding practical and, indeed, of great commercial value.

Universal lossy coding has proven more elusive as regards both theory and practice. General theories of universal lossy coding based on ensembles of block codes and tree codes were developed [89–95], but these lack sufficient structure and hence require encoder complexity too demanding to be considered as solving the problem in any practical sense. Recent developments are more attractive algorithmically [96–103]. The paper by Yang and Kieffer [100] is particularly intriguing; they show that a lossy source code exists that is universal not only with respect to the source statistics but also with respect to the distortion measure. Though Yang–Kieffer codes can be selected a priori in the absence of any knowledge about the fidelity criterion, the way one actually does the encoding does, of course, depend on which fidelity criterion is appropriate to the situation at hand. All universal lossy coding schemes found to date lack the relative simplicity that imbues Lempel–Ziv coders and arithmetic coders with economic viability. Perhaps as a consequence of the fact that approximate matches abound whereas exact matches are unique, it is inherently much faster to look for an exact match than it is to search a plethora of approximate matches looking for the best, or even nearly the best, among them. The right way to tradeoff search effort in a poorly understood environment against the degree to which the product of the search possesses desired criteria has long been a human enigma. This suggests it is unlikely that the "holy grail" of implementable universal lossy source coding will be discovered soon.

We have several times noted how sources can be matched to given channels and channels can be matched to given sources. Indeed, we even quoted Shannon's 1959 comments about this. Doubly matched situations that require no coding in order to for optimum performance to be achieved have been stressed. Whereas these situations are rarely encountered in the context of man-made communication systems, there is growing evidence that *doubly matched* configurations are more the norm that the exception in sensory information processing by living organisms. A growing community of biologists and information theorists are engaged in active collaboration on mathematical and experiments treatments of information handling within living systems. These bioinformation theorists are finding that chemical pathways and neural networks within organisms not only exhibit double matching but do so robustly over a range of data rates and energy consumption levels. The evolutionist's explanation for how this comes to pass is that, over eons, natural selection evolves channels within successful organisms that are matched to the information sources that constitute the environment. These channels extract just enough information to provide a representation of each facet of the environment that is sufficiently accurate for the organism's purposes. That is, lossy coding that is nearly optimal in the sense of rate-distortion theory is routinely performed by living

organisms. Moreover, these channels evolve so as to reside at saddle points which correspond not only to minimizing information flow subject to fidelity constraints but also simultaneously to maximizing the mutual information between their inputs and outputs subject to constraints on rates at which they consume bodily resources, especially metabolic energy. Further information about lossy coding in living systems can be found in the works of Levy and Baxter [104,105] and especially in the Shannon Lecture recently delivered by Berger [106].

BIOGRAPHY

Toby Berger received the B.E. degree in electrical engineering from Yale in 1962 and the M.S. and Ph.D. degrees in applied mathematics from Harvard in 1964 and 1966. From 1962 to 1968, he was a senior scientist at Raytheon Company. In 1968, he joined the faculty of Cornell University where he is presently the Irwin and Joan Jacobs professor of engineering. His research interests include information theory, random fields, communication networks, wireless communications, video compression, voice and signature compression and verification, biological information theory, quantum information theory, and coherent signal processing. Berger has been a Guggenheim Fellow, a Fulbright Fellow, a Fellow of the Japan Association for Advancement of Science, and a Fellow of the Ministry of Education of the PRC. An IEEE Fellow, he has served as editor-in-chief of the IEEE Transactions on Information Theory and as president of the IEEE Information Theory Society. Berger received the 1982 Frederick E. Terman Award from the American Society for Engineering Education and the 2002 Shannon Award from the IEEE Information Theory Society.

1. APERTURE ANTENNA FUNDAMENTALS

1.1. Introduction

A critical component in a high-performance wireless telecommunications system is the antenna, which couples the signals carried by wires into and from waves propagating through space. For point-to-point communications links, specific antennas are used to constrain radiated power in a prescribed manner. In satellite and terrestrial applications, the antenna concentrates waves in an angular region of high intensity in desired directions and minimizes the power that would be wasted elsewhere. This key measure of antenna performance, the gain, depends directly on the effective antenna aperture area. Common high-gain antennas with large effective apertures include lenses, reflectors, and phased arrays.

The first two devices increase the effective aperture area by a purely geometric transformation, whereas the phased array electrically transforms the aperture. The lens antenna is a heavy and often complex structure, which, like the phased array, is (in most cases) frequency-dependent. The reflector antenna is the simplest, cheapest, and lightest alternative and has been the primary means of providing high-gain microwave beams for over half a century. With each type of antenna, the input signal flowing on cables is distributed in a prescribed way across the outer radiating surface. The particular phase and amplitude distribution of field (or equivalently, current density) at this aperture governs the radiation pattern shape of the antenna.

1.2. Far-Field Radiation Concepts

Most telecommunications applications involve links with distant stations. When the distance r to these stations is great compared with the antenna size D, $r \gg 2D^2/\lambda$, the stations are in the far-field of the antenna. The wavelength is given by $\lambda = c/f$, for frequency f and speed of light c. In the farfield, or Fraunhofer region, the spatial field distribution pattern is independent of the radial distance from the source. Indeed the electromagnetic field falls off as $\exp(-jkr)/kr$, with wavenumber $k = 2\pi f/c$, while the radiation pattern is a function of polar angle from boresight (direction the antenna is aimed) θ, and circumferential angle φ. The radiation pattern is proportional to the two-dimensional spatial Fourier transform of the aperture current phase and amplitude distribution [1–9]. Thus, the spatial current distribution across a finite aperture $A(x, y)$ is mapped to the angular radiation pattern $P(k_x, k_y)$, with angular wavenumbers, $k_x = k\cos\theta\cos\varphi$, and $k_y = k\cos\theta\sin\varphi$. Clearly, a larger aperture (bigger antenna) produces a higher-intensity beam, with a narrower beamwidth. A rectangular aperture of dimension $2a$ by $2b$ — illuminated by a wave with uniform amplitude and constant phase — produces a beam proportional to $\sin(k_x a)/(k_x a) \bullet \sin(k_y b)/(k_y b)$, while a circular aperture of radius R produces a radiation pattern proportional to $J_1(u)/u$, where $u = k_\rho R$, $k_\rho = \sqrt{(k_x^2 + k_y^2)}$ and J_1 is the first-order Bessel function of first kind. This radiation pattern of radiated power as a function of angle is shown in Fig. 1 for a 20-wavelength-diameter aperture. Figure 2 displays the same pattern in 3D polar format. The antenna pattern is very sensitive to the current distribution at the aperture. Beam direction, maximum gain, power outside the mainlobe, and associated sidelobe levels depend strongly on the aperture phase function [10,11].

The gain of an antenna is the measure of field intensity in a particular direction relative the average intensity over all directions. The peak gain, or directivity, specifies the ratio of the power density at boresight in the middle of the antenna's main beam at a distance r to the average power density (total radiated power divided by $4\pi r^2$). An aperture antenna with area A has maximum peak gain when the current amplitude and phase are uniform across the aperture. Such an aperture is referred to as having 100% illumination efficiency. In this case the peak gain is

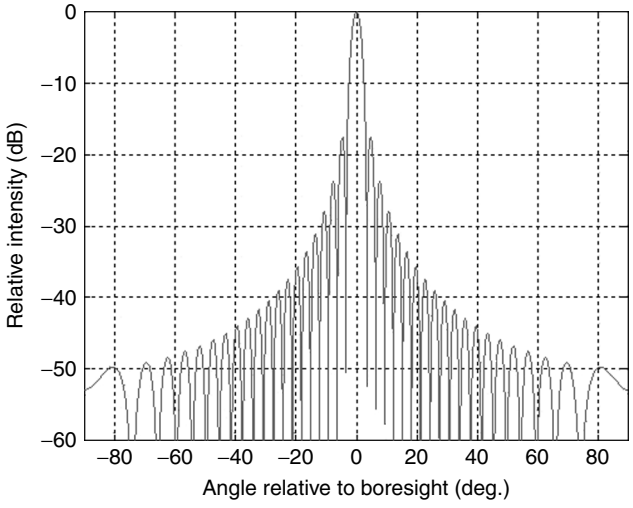

Figure 1. Far-field radiation pattern of an ideal, uniformly illuminated 20-wavelength-diameter circular aperture.

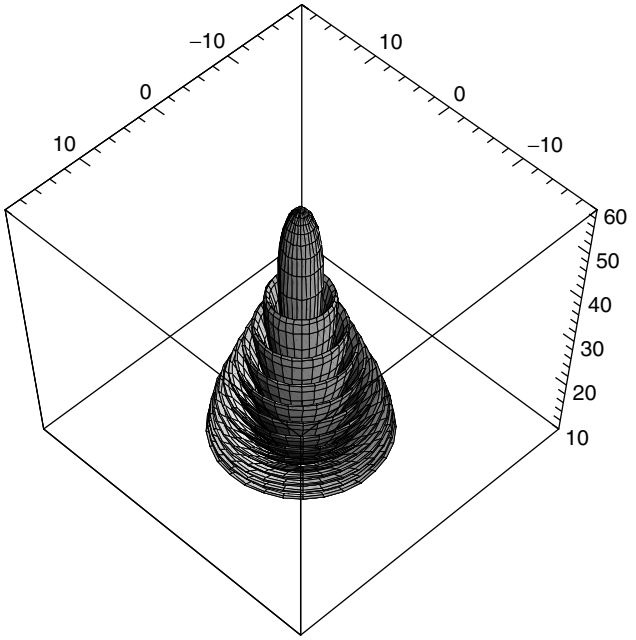

Figure 2. Three-dimensional polar plot of the far-field antenna pattern of field intensity (in dB) produced by a uniformly illuminated 20-wavelength-diameter circular aperture.

given by [2]

$$G = \frac{4\pi A}{\lambda^2}$$

and for circular apertures of diameter D

$$G = \left(\frac{\pi D}{\lambda}\right)^2$$

or in decibels

$$G(dB) = 20 \log \frac{\pi D}{\lambda}$$

Doubling the antenna diameter — or doubling its frequency of operation — leads to a 6-dB increase in antenna gain (as long as no aberrations are introduced in the electrically larger aperture).

The 3-dB, or half-power, antenna beamwidth can be approximated for large apertures as [1]

$$BW = \lambda / D$$

and the beamwidth between first nulls is double this.

The first sidelobe level is another important antenna specification, as it gives a measure of crosstalk intensity outside the main beam. For circular apertures it is −17.3 dB, and for rectangular apertures it is −13.5 dB [9]. By altering the amplitude distribution, it is possible to reduce these first sidelobe levels; but in doing so, the peak gain decreases as well. For example, a same-size rectangular aperture with a triangular amplitude distribution in the x direction could be thought of as the spatial convolution of two half-size uniform amplitude distributions, which would produce a radiation pattern with dependence $\sin^2(k_x a/2)/(k_x a/2)^2 \bullet \sin(k_y b)/(k_y b)$. The first sidelobe level in the x direction is lowered by 6 dB to −19.5 dB, but since the effective area is halved, the gain is also reduced by 3 dB.

Variations in the current phase across the aperture have an even greater effect on the radiation pattern than amplitude variations. A linear phase variation steers or "scans" the beam in the direction perpendicular to a plane of constant phase, without changing the beam pattern shape. Any quadratic or higher-order phase variations across the aperture are aberrations and lead to beam pattern degradation. It is essential to understand the effects of phase aberrations when designing antenna systems [12].

The simplest aperture antennas provide a single high-gain beam in the boresight direction. More sophisticated antennas produce specifically tailored beam shapes, or multiple simultaneous or independently excited beams. To maintain good beam quality, each radiated beam must have only linear phase variation. Although maintaining a flexible linear phase function while minimizing higher-order optical aberration terms is generally difficult, a phased-array antenna can accomplish these goals fairly simply by applying the required phase shifts to successive elements. With enough elements, a linear variation can be approached as closely as desired.

For single fixed-beam antennas, the aperture conditions depend only on the reflector surface placement and geometry. There is only one source input, the antenna feed, with fixed position and orientation. However, a scanning antenna must be able to produce a variable linear phase distribution that depends on varying source conditions.

One important issue with reflector antennas is blockage of the aperture with the feed or subreflector structure. There is no blockage with the transmission-based lens antennas, because the feed structure is on the other side of the antenna from the radiating aperture. However, surface impedance-matching requirements and dissipative transmission losses, as well as weight and bandwidth limitations, render lenses inferior to reflectors in most satellite applications.

2. REFLECTOR DESIGN FUNDAMENTALS

2.1. Geometric Optics Analysis

While the radiation pattern of a reflector antenna is determined by diffraction analysis of the fields across its radiating aperture, the conventional method for reflector shape synthesis and optimization makes use of geometric optics. Geometric optics follows from the eikonal equation [13,6] $|\nabla L(\boldsymbol{r})|^2 = n^2$, which is the lowest order (infinite frequency) approximation of wave equation, in which all field variation is assumed to be contained in the phase $\Phi = \omega/c\ L(r)$. This approximation assumes that all waves in uniform media propagate along straight rays, where each wavefront is perpendicular to these rays, occurring at the same distance from a given source. The rays are reflected by metal reflector surfaces as if they encountered piecewise perfectly conducting planes with the same surface normal at the reflection point [14–17]. Geometric optics cannot be used to find the

far-field radiation pattern of a well-formed beam, because this pattern is entirely determined by diffraction [18,19]. However, since a focused reflector antenna must receive plane waves from distant sources, it can be thought of as a single surface — or collection of multiple surfaces — that converts parallel incoming rays into rays that converge on a feed element. Conversely, when transmitting, reflectors *collimate* rays by ideally converting spherically diverging rays from a point-source feed to a set of parallel rays. Furthermore, the pathlength from the source point (or any starting wavefront) to any given wavefront along each ray must be the same regardless of one or more redirections of the rays by reflector surfaces.

The behavior of rays incident on metal surfaces is governed by Snell's law of reflection, which ensures that incident and reflected rays and the surface normal at the point of intersection are coplanar, and that the angle of incidence equals the angle of reflection. Snell's law and the constant-pathlength condition are sufficient to synthesize a focused reflector system. In general, two additional constraints are applied to the reflector surface synthesis formulation: surface continuity and field amplitude concentration.

Although phased arrays and some lens antennas divide the aperture into separate physical regions [20–22], reflectors tend to be continuous surfaces, with few steps or cusps. Discontinuities in the surface or the surface normal lead to diffraction effects that are unpredictable with geometric optics. Thus, the surface reflection point and its normal are coupled, and specifying the pathlengths of the set of reflected rays along with their directions greatly restricts the family of focusing surfaces. For a single reflector, only the circular paraboloid satisfies the Snell's law, constant-pathlength, and continuous-surface constraints. For multireflector systems, Snell's law must be specified on each reflector, and the pathlength condition applies to the full path from source to aperture plane. In designing reflector antenna systems, usually a two-dimensional profile is generated first; then this cross section is rotated about the central system axis line of symmetry.

The other useful addition to geometric optics analysis is the assumption that each ray represents a constant differential power flow [9]. The power within a bundle of rays must remain constant throughout the optical system. Power density on any two wavefronts is inversely proportional to the ratio of areas on those wavefronts bounded by a given set of rays. This property of conservation of energy is useful in many synthesis applications.

Additional parameters must be specified if the energy-conservation constraint is imposed. This constraint merely describes how the feed phase and amplitude distribution are transformed to an aperture distribution. Thus it is necessary to specify the input and output distributions. In many cases discussed in the literature, the input is assumed to be a tapered feed pattern with amplitude of the form $\cos^n \theta$, and with a spherical phase distribution [4]. In many cases, attempts are made to ensure that the aperture has high illumination efficiency, with the output field as close as possible to a uniformly amplitude plane wave. Occasionally the exact pathlength constraints are relaxed in favor of a particular aperture amplitude distribution.

Many attempts have been made to alter the geometry of dual reflectors to improve their performance [23–32]. Unlike with the single reflector, there are an infinite number of pairs of surfaces that produce a plane-wave output for spherical wave input at the focus. Although it is possible to generate a symmetric dual reflector with various arbitrary phase and amplitude distributions at the aperture [33,34], most efforts have been directed toward simply improving the main reflector illumination efficiency.

2.2. Single Reflectors

The simplest reflector antenna systems are single reflectors with parabolic cross section, as shown in Fig. 3. Often referred to as *prime focus reflectors*, these paraboloidal reflectors are specified entirely by their focal length F, aperture diameter D, and vertex position z_0. The paraboloid shape is given by [35]

$$z = \frac{x^2 + y^2}{4F} + z_0$$

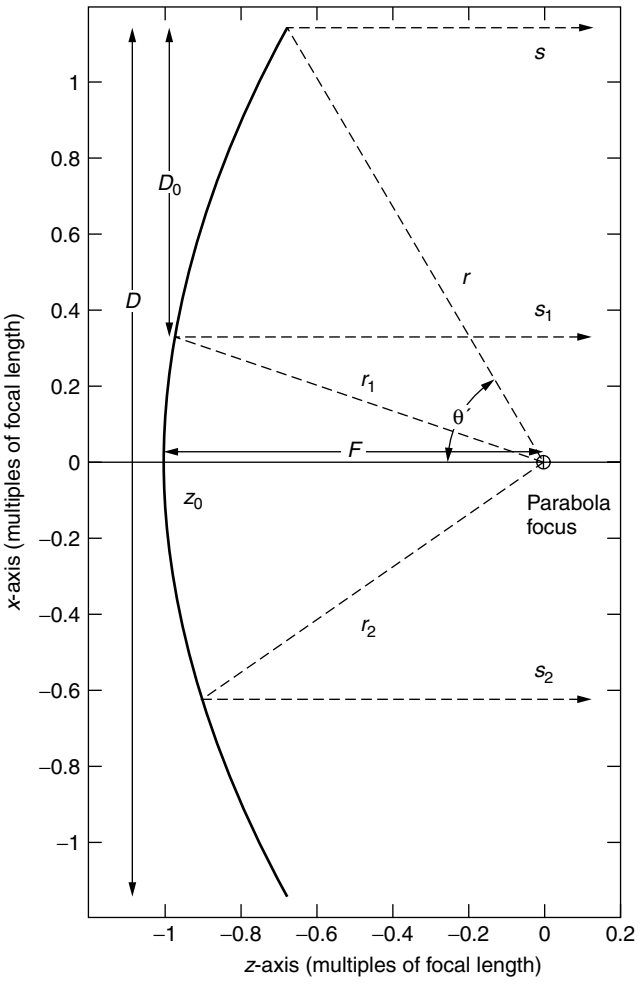

Figure 3. Parabolic single-reflector geometry, with offset section shown.

or equivalently, in terms of distance from the focus to the reflector surface r and angle from the negative axis of symmetry θ' [7,8]:

$$r = \frac{2F}{1+\cos\theta'} = F\sec^2\frac{\theta'}{2}$$

The feed is positioned at the parabola focus, facing the paraboloid at a distance F from its vertex. The pathlength condition demands that for any combination of rays, the total distance to the planar wavefront $r+s$, or r_1+s_1, or r_2+s_2 be the same. Since the feed structure lies in the path of outwardly reflected rays, it tends to block the central portion of the aperture.

An important characteristic of this single-reflector antenna is the ratio of focal length to diameter F/D [also known as the *f number* (or *f stop*; aperture) of camera lenses]. Reflectors with smaller F/D have greater surface curvature, and are more physically compact, with closer feed structures than those with larger F/D ratios, but are more sensitive to the precise feed position and beam pattern.

Offset single reflectors avoid the blockage problem by using only a portion of a larger symmetric paraboloid that reflects unblocked rays [36,37]. In Fig. 3, a possible offset parabolic section would be bounded by rays s and s_1, and have diameter D_0. While offset designs enhance both radiated power and prevent some beam distortion, the lack of perfect symmetry introduces differential effects for waves polarized parallel and perpendicular to the offset direction.

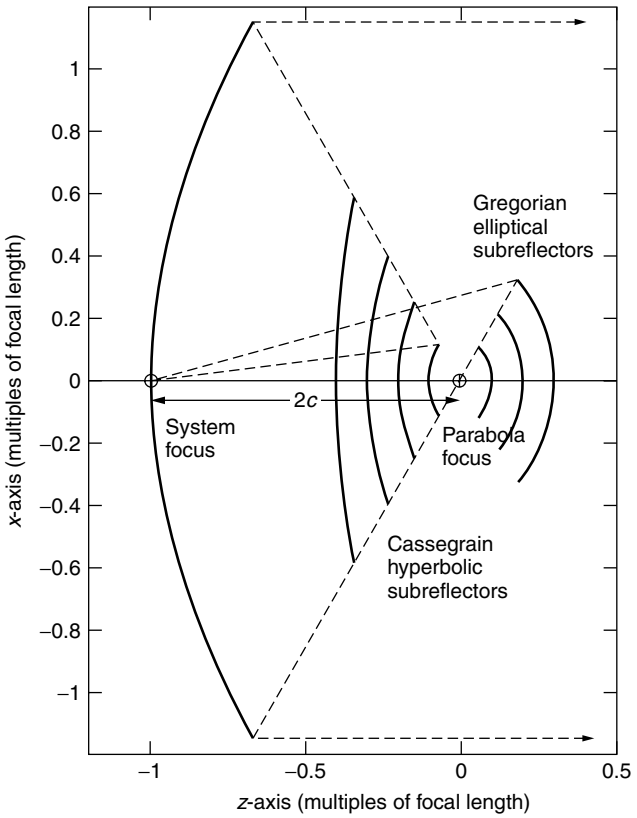

Figure 4. Cassegrain and Gregorian dual-reflector profiles with sample ray paths.

2.3. Multiple Reflectors

Conventional dual reflectors are of two major types: the Cassegrain and the Gregorian. Based on the optical telescope designs first introduced in 1672, they consist of a paraboloidal main reflector and, respectively, either a hyperboloidal or ellipsoidal secondary or subreflector [38]. As long as the paraboloid focus coincides with one hyperboloid (ellipsoid) focus, and the feed is positioned at the other hyperboloid (ellipsoid) focus, the dual reflector will collimate outgoing rays. For a given paraboloidal main reflector, there are infinitely many possible subreflectors with differing size and position relative to the main reflector. A family of possible Cassegrain and Gregorian subreflector profiles for a parabola with unit focal length and system focus at the parabola vertex is shown in Fig. 4. All rays originating at the system focus reflect from a subreflector as if they had originated at the common focal point. Since the difference of segments from each hyperbola focus to a point on the hyperbola is constant and equal to the major hyperbola axis length $2a$, the pathlength from feed to an aperture plane is again constant, $2a$ greater than for the main reflector if it were used as a prime focus single reflector. The same argument applies for the ellipse, with constant sum of segments from each focus equal to $2a$.

The equation for the subreflector profile is given by

$$\frac{(z-z_c)^2}{a^2} + \frac{x^2+y^2}{c^2-a^2} = 1$$

where the central point is found by associating the common foci $z_c = z_0 + F - c$. The equivalent polar form of the subreflector equation is [5]

$$r_s = \frac{c^2-a^2}{a+c\cos\theta'}$$

where the distance between subreflector foci $2c = F$ for the profiles of Fig. 4, with positive values of r_s corresponding to hyperbolas and negative values corresponding to ellipses.

It should be noted that the system focus need not be positioned at the parabola vertex. The subreflector size to chosen so that the extreme ray from feed to the edge of the paraboloid reflects from its edge. Generally, subreflectors are kept as small as possible to minimize blockage without requiring too narrow a taper of the feed radiation pattern.

Dual-reflector systems offer an improvement over paraboloidal single reflectors in both packaging efficiency and design flexibility. Because the subreflector redirects rays to the main reflector, the actual length involved in the system is much less than its equivalent focal length. Also, when a subreflector is used, the feed can be positioned near or behind the main reflector, so that feedlines are shortened, and the placement of the associated electronics is simplified. Servicing and maintenance of the feed is simplified as well. Another mechanical advantage is the ease of supporting a relatively lightweight subreflector.

There are several disadvantages to symmetric (nonoffset) dual reflectors. The subreflector blocks the center

of the aperture, thereby reducing efficiency and increasing the sidelobe levels. The fact that two surfaces must intercept the rays also introduces the requirement for minimizing power missing the surfaces (spillover) while keeping the illumination efficiency high. Alignment is crucial in dual reflectors. Unlike single reflectors, where the feed concentrates power over the wide angle subtended by the main reflector, the dual-reflector feed must illuminate a much smaller subreflector. Thus larger feedhorns are required, and their placement must be precise. Also, the subreflector placement relative to the main reflector is critical [39–42]. Larger feedhorns are less preferable for multibeam antennas, since their size may prevent their phase centers from being close enough to generate adjacent component beams.

With symmetric dual reflectors, subreflector blockage can be regarded as the removal of a circle of uniform, constant-amplitude power from the center of the aperture. Thus one subtracts a lower intensity, much wider $J_1(u')/u'$ pattern from the original far-field amplitude pattern. This effect lowers the mainlobe power level, lowering gain and increasing sidelobe magnitude. Power spilling past the subreflector is sufficiently large and sufficiently close to the axis to also become apparent on the combined pattern. With single reflectors, the spillover is almost always at least 150° away from the boresight axis, so its effect is negligible for communications antennas.

Methods of making the subreflector less obstructive have been proposed [43–47], such as serrating or perforating the surface; or fabricating it from a linearly polarized material, illuminating it with radiation of the orthogonal polarization, and using a twist reflection material for the main reflector. A much more feasible concept is the offset configuration, which consists of a (usually circular) section of the main reflector and the corresponding section of the subreflector of a symmetric dual reflector. Blockage is eliminated, and the VSWR (reflection back into the feed) is reduced, but the focal length : diameter ratio (F/D) increases by the ratio of the parent main reflector diameter to the offset section diameter. The lack of symmetry also tends to increase cross-polarization and make analysis much more difficult.

Offset designs often make use of the Gregorian configuration. In the symmetric case, having a concave subreflector increases the reflector separation without much improvement in performance. For an offset geometry, however, the Gregorian subreflector can be placed entirely below the antenna axis, where it can still illuminate the entire main reflector above the axis. Blockage is avoided while still using a large offset section of the main reflector. By properly tilting the axis of the ellipsoidal subreflector with respect to the main reflector focal axis, cross-polarization can be significantly reduced [48,49].

Several methods are used for analyzing Cassegrain antennas. One very powerful approximate technique is that of defining the equivalent parabola (Fig. 5), which has the same aperture and feed illumination angle as the Cassegrain [50,51]. The equivalent focal length can be found using the maximum subreflector angle θ_m to be

$$F_e = F\frac{c+a}{c-a}$$

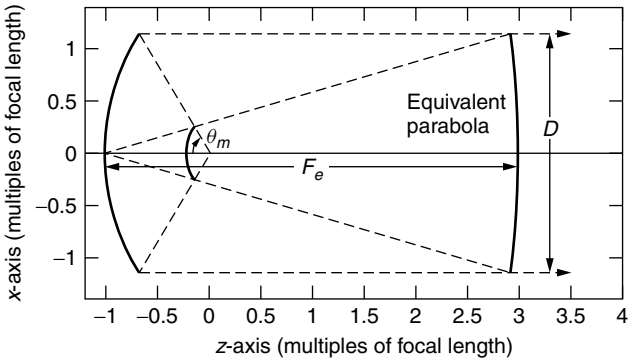

Figure 5. Equivalent parabola for Cassegrain dual reflector.

The factor $m = (c + a)/(c - a)$ is called the *magnification factor*. The F/D ratio of the equivalent parabola is m times larger than the physical Cassegrain system. The equivalent parabola concept can be used to determine the amplitude distribution across the aperture by replacing the real dual-reflector system with a single reflector.

Scattering theory and geometric theory of diffraction have been used for a more detailed analysis of dual reflectors [40–42,52–54]. The mathematics is complicated, and numerical methods are often required. Dual reflectors have less frequency dependence because of their relatively long effective focal length for their given packaging volume. Also, illumination efficiency is directly dependent on the system's geometry, and this tends to have the dominant effect in scanning.

2.4. Dual-Reflector Shaping

Much effort has been spent on dual-reflector designs that keep one of the standard Cassegrain surfaces fixed (usually the main reflector) and shape the other. Green first showed that by shaping the subreflector and then by making small alterations to the main reflector to preserve the planar phase front, uniform illumination could be attained [28]. The resulting beam is not exactly focused, but the improvement in performance is appreciable. Other systems consider subreflectors that correct for main reflector deformations or errors, or generate particular aperture distributions and polarizations [29,32,55,57].

Simultaneous shaping of both surfaces of dual-offset reflectors has been explored [26,27,34,35,43–47]. The problem involves solving a pair of partial nonlinear differential equations. These simplify to ordinary differential equations for symmetric systems. Approximate methods of solving the equations show reasonable numerical results [46], but the processes involve considerable trial and error and significant amounts of numerical computation. However, Westcott et al. [47], claim to have arrived at an exact solution.

3. BEAM SCANNING WITH REFLECTOR ANTENNAS

3.1. Analysis of Reflector Beam Scanning

For reflectors and lenses, beam steering, or "scanning" is accomplished by transversely displacing the feed from

the antenna focus, or unscanned, aberration-free source position [58,59]. For systems with a single perfect focal point, this displacement always produces higher-order phase terms. The absence of higher-order terms at any other position would imply the existence of a second perfect focal point there.

Scanning is of great concern for antennas used in satellite applications. When high resolution is important, as is the case with point-to-point networking and direct broadcast communications, the antenna must provide a large number of high-gain, well-formed spot beams over its entire field of view [60–67]. Well-formed beams are also required in multibeam antennas. High-efficiency shaped coverage contours are useful for illuminating specific geographic regions. Because they are produced by coherently combining component beams, each beam must have low-intensity sidelobes and well-defined nulls to prevent undesirable interference.

The optical aberrations, caused by lateral feed displacement, cause an asymmetric effect in the plane of scan [13–15,68]. The beam broadens, the first null in the scanned direction fills, and the first sidelobe on the axial side, the coma lobe, rises. Several authors have addressed the problem of finding the best focal locus of a paraboloidal antenna [58,59,61,69]. The most general solution appears to be given in Balling [62].

For small scan angles, the equivalent parabola concept is very useful [51] for predicting the performance degradation in dual reflectors. The scanning tradeoff analysis of dual reflectors is much more complex than it is for paraboloids. The effective focal length increases as subreflector curvature increases; however, the subreflector is smaller and spillover is of greater concern. For larger feed displacements and scan angles, spillover and distorted imaging prevents acceptable modeling of the dual reflector as an equivalent paraboloid [70,71]. Choosing the optimum focal point for a particular scan angle is strongly dependent on the particular Cassegrain geometry. Changing the surface curvature of either reflector surface will greatly change the position of the focal surface.

Scanning with an offset antenna system is slightly different from that in the symmetric case. The optimum focal locus is no longer symmetrically disposed about the antenna axis. Instead, the best focal positions for scanned beams, to the first approximation, are on the plane perpendicular to the offset axis [36,37,64,72]. The precise feed position depends on spillover and illumination efficiency as well as pathlength and phase error considerations.

3.2. Reflectors Designed for Scanning

Several antennas have been developed specifically for efficient scanning applications. The spherical cap [73] is the simplest scanning antenna. With a source positioned approximately halfway between the sphere and its center, the surface resembles a paraboloid over a limited angular region. In fact, if the parabola's curvature value at its vertex is inverted and used as the radius of the osculating circle at that vertex, this circle corresponds to the profile of the spherical cap. Several feeds can be positioned on the spherical focal surface (with radius $F/2$), each generating a beam in a different scanned direction.

Because it is not a perfect paraboloid, the spherical cap introduces phase errors in the reflected wave in the form of spherical aberration. This optical aberration increases with larger angular illumination from the feed or with higher frequencies. Since the symmetry of the sphere produces identical patterns for all scan directions, the entire reflector is underilluminated for wide-field-of-view ($>5^\circ$) applications; that is, only a fraction of the reflector is illuminated by each feed for any given beam. A compromise is made frequently between scanning perfection and reflector inefficiency.

Subreflector correctors have been designed to eliminate the spherical aberration in the cap [74]. The Gregorian type corrector makes use of caustics formed by rays reflected by the spherical surface to collimate incoming rays. The corrector applies only for a single scan direction; therefore, it must be moved mechanically if the beam is to be redirected. This characteristic makes scanning arrays impractical and shaped beams impossible for corrected spherical caps.

One improvement to the basic spherical cap is the torus [3,75]. The torus is a double-curved surface with a circular profile in the plane of scan and a parabolic profile in the orthogonal plane. Reflected waves suffer from spherical aberration in the scan plane, but are focused without aberration in the orthogonal plane. The torus can scan in only one plane, so it is well suited for communication with multiple stations situated on a single arc, such as a group of satellites in geostationary orbit. Like the spherical cap, the torus has poor illumination efficiency in the scan direction.

An alternative to the torus is a specifically shaped single-reflector surface that balances the aperture phase errors with illumination efficiency [76,77]. This surface is described by a polynomial whose coefficients minimize the variations across a symmetric pair of specified subapertures of the pathlengths from a symmetric pair of specified focal points to a pair of scanned aperture planes. In addition to minimizing the optical aberrations for these extreme scan angles, a third beam direction — that of boresight — is considered as well. The feed is positioned along the axis of symmetry, at the point that minimizes phase errors across a central subaperture, and the surface polynomial coefficients are adjusted to reduce the errors for the boresight beam without greatly worsening the errors for the scanned beams. It has been shown that for equivalent beam quality across a 60° wide field of view, this type of reflector can be made about 40% smaller than the torus.

Dual offset reflectors have been designed specifically for scanning and multiple beam applications [60,63–67,78–85]. Acceptable multibeam systems are achievable for large F/D conventional Cassegrain systems with oversized main and subreflectors. Unconventional designs include the confocal paraboloid [64,79], which has a feed array in the near field of a small offset parabolic subreflector with focal point coinciding with that of a parabolic main reflector. This type of antenna has been shown to scan effectively up to 3°.

The bifocal dual reflector [82] is a totally redesigned antenna system, with two perfect focal points, one for each extreme scanned beam. Since it consists of two reflectors, each tracing of rays through the system has 2 degrees of freedom. The two Snell's law conditions allow for two independent collimating pathlength conditions. The design principle for the bifocal is based on this idea by insisting that each point on each reflector will lie on the path from one focal point to its corresponding aperture plane, as well as on the path from the second point to its aperture plane. First, the focal points are selected, an initial subreflector point and it normal are chosen, and the total pathlength to the first scanned aperture plane is specified. Ray tracing uniquely determines the corresponding main reflector point and its normal. Next, this main reflector point is used with ray tracing from the second focal point to the second scanned aperture to determine the subsequent subreflector point. This process continues until a full set of reflector profile points are generated. These points are joined by spline fitting, and then the profiles are rotated about the axis of symmetry to generate a pair of reflector surfaces. The focal points are also smeared out into a focal ring, which unfortunately introduces aberrations.

The need for an oversized subreflector to simultaneously redirect both positively and negatively scanned rays to the main reflector causes severe blockage in the symmetric bifocal. The offset bifocal reflector antenna system [83] overcomes this deficiency by choosing asymmetric focal points, limiting the illuminated sections of the main reflector to only an unblocked aperture, and synthesizing each entire reflector surfaces from the ray-tracing procedure rather than by rotating the profiles about the axis of symmetry. The offset bifocal surfaces only approximate the continuous surface condition, but the resulting dual-reflector system produces insignificant phase errors. Performance results indicate that it is possible to design a compact dual-reflector system that can radiate well-formed 1° beams across the 17° field of view subtended by the earth as seen from geostationary orbit.

One last type of scanning dual-reflector antenna system incorporates the ideas of the shaped single reflector [76,77] with a mechanically tilting subreflector [84–86]. This configuration is driven by the need to minimize antenna cost, by using only a single feed along with a single front end (amplifier, filter, polarizer), yet providing the capability to scan a single beam across a wide field of view. Having the smaller subreflector rotate instead of the entire antenna structure provides mechanical and cost advantages for mass-market communication systems such as direct broadcast television. The subreflector can be planar or specially shaped [86] for additional packaging benefits.

BIOGRAPHY

Carey M. Rappaport (M., S.M. 1996) received five degrees from the Massachusetts Institute of Technology: the S.B. in Mathematics, the S.B., S.M., and E.E. in Electrical Engineering in June 1982, and the Ph.D. in Electrical Engineering in June 1987. He is married to Ann W. Morgenthaler and has two children, Sarah and Brian.

Professor Rappaport has worked as a teaching and research assistant at MIT from 1981 until 1987, and during the summers at COMSAT Labs in Clarksburg, Maryland, and The Aerospace Corp. in El Segundo, California. He joined the faculty at Northeastern University in Boston, in 1987. He has been Professor of Electrical and Computer Engineering since July 2000. During fall 1995, he was Visiting Professor of Electrical Engineering at the Electromagnetics Institute of the Technical University of Denmark, Lyngby, as part of the W. Fulbright International Scholar Program. He has consulted for Geo-Centers, Inc., PPG, Inc., and several municipalities on wave propagation and modeling, and microwave heating and safety. He is Principal Investigator of an ARO-sponsored Multidisciplinary University Research Initiative on Demining and Co-Principal Investigator of the NSF-sponsored Center for Subsurface Sensing and Imaging Systems (CenSSIS) Engineering Research Center.

Professor Rappaport has authored over 190 technical journal and conference papers in the areas of microwave antenna design, electromagnetic wave propagation and scattering computation, and bioelectromagnetics, and has received two reflector antenna patents, two biomedical device patents, and three subsurface sensing device patents. He was awarded the IEEE Antenna and Propagation Society's H.A. Wheeler Award for best applications paper, as a student in, 1986. He is a member of Sigma Xi and Eta Kappa Nu professional honorary societies.

RADIO RESOURCE MANAGEMENT IN FUTURE WIRELESS NETWORKS

JENS ZANDER
Royal Institute of Technology
Stockholm, Sweden

1. INTRODUCTION

The rapid increase of the size of the wireless mobile community and their demands for high speed, multimedia communications stands in clear contrast to the rather limited spectrum resource that has been allocated in international agreements. Efficient spectrum or Radio Resource Management (RRM) is of paramount importance due to these increasing demands. Figure 1 illustrates the principles of wireless network design. The network consists of a fixed network part and a wireless access system. The fixed network provides connections between base stations or Radio Access Ports (RAP), which in turn provide the wireless "connections" to the mobiles. The RAPs are distributed over the geographical area where we wish to provide the mobile users with communication services. We will refer to this area simply as the service area. The area around a RAP where the transmission conditions are favorable enough to maintain a connection of the required quality between a mobile and the RAP, is denoted the coverage area of the RAP. The transmission quality and thus

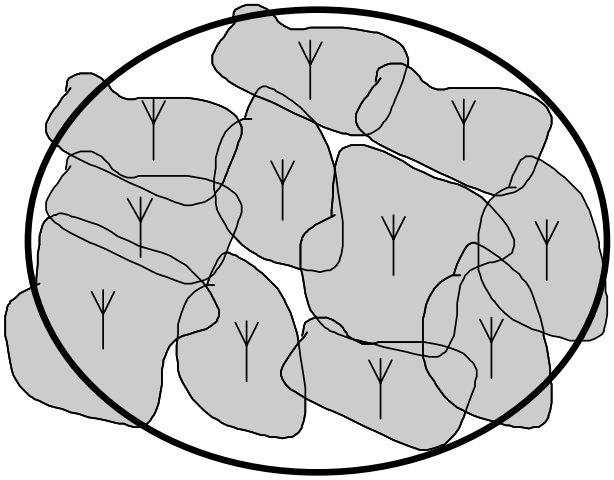

Figure 1. Wireless area communication system.

the shape of these regions will, as we may expect, depend heavily on the propagation conditions and the current interference from other users in the system. The coverage areas are therefore usually of highly irregular shape.

The fraction of the service area where communication with some required quality of service (QoS) is possible is called the coverage or the area availability of the system. In two-way communication systems (such as mobile telephone systems), links have to be established both from the RAP to the mobile (down- or forward link) and between the mobile terminal and the RAP (up- or reverse link). At first glance these two links seem to have very similar properties, but there are some definite differences from a radio communication perspective. The propagation situation is quite different, in particular in wide area cellular phone systems, where the RAP (base station) usually has its antennas at some elevated location free of obstacles. The terminals, however, are usually located amidst buildings and other obstacles creating shadowing and multipath reflections. Also, the interference situation in the up- and downlink will be different since there are many terminals and varying locations and quite few RAPs at fixed locations.

For obvious economical reasons, we would like our wireless network to provide ample coverage with as few RAPs as possible. Clearly this would not only minimize the cost of the RAP hardware and installation, but also limit the extent of the fixed wired part of the infrastructure. Coverage problems due to various propagation effects

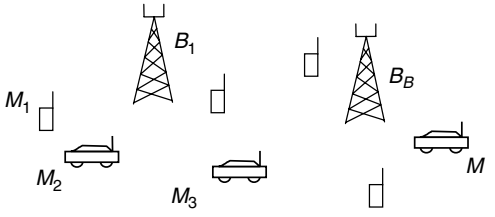

Figure 2. Resource management problem formulation.

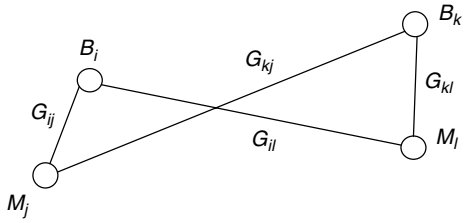

Figure 3. Link gains.

puts a lower limit to the number of RAP that are required. However not quite correct, one could say that the range of the RAPs is too small, compared to the inter-RAP distance. Such a system where this type of problem is dominant is called a range limited system. As the number of transmitters in the system becomes large within some fixed chunk of available RF-spectrum, the number of simultaneous connections (links) will become larger than the number of orthogonal signals that the available bandwidth may provide. In order to provide service for such a large population of users, it is obvious that the bandwidth used by the RAPs and terminals has to be reused in some clever way at the cost of mutual interference. The system is said to be bandwidth or interference-limited. Absolutely vital to the study of any resource management problem is a thorough understanding of the user requirements, that is, the required QoS and the traffic characteristics. All resource management schemes are designed (or optimized) using some model for the traffic. The resulting performance will clearly be a function of not only how well our design has been adapted to the traffic model, but also how accurate the traffic model is. Most wireless systems of today use circuit switched speech as the main design model (e.g., GSM). This does not prevent such systems to carry other types of traffic, but they always do this at a performance penalty. Future wireless access systems are expected to carry both large bandwidths as well as a mixture of services with very different and often conflicting service requirements. Particularly in these scenarios, accurate modeling is imperative for efficient resource utilization. Unfortunately, however, future user applications are little known and most work to derive realistic traffic models for these kinds of applications lies still ahead of the telecommunication community.

In the remainder of the article we present a more rigorous formulation of the radio resource management and review some of the ideas and results from the literature. Finally, we give an outlook on how these results can be applied to future wideband systems and which are the key problems that should be addressed in further studies.

2. RADIO RESOURCE MANAGEMENT — A GENERAL PROBLEM FORMULATION

Assume that M mobiles $(M_1, M_2, \ldots, M_M)$ are served by access ports (base stations), numbered from the set

$$\mathbf{B} = \{1, 2, 3, \ldots, B\}.$$

Now, let us assume that there are C (pairs of) waveforms (in conventional schemes these can be seen as orthogonal channels (channel pairs)) numbered from the set

$$\mathbf{C} = \{1, 2, 3, \ldots, C\}$$

available for establishing links between access ports and mobile terminals. To establish radio links, to each mobile the system has to assign

(a) an access port from the set **B**,
(b) a waveform (channel) from the set **C**,
(c) a transmitter power for the access port and the terminal.

This assignment (of access port, channel, and power) is performed according to the resource allocation algorithm (RAA) of the wireless communication system. The assignment is restricted by the interference caused by the access ports and mobiles as soon as they are assigned a "channel" and when they start using it. Another common restriction is that access ports are in many cases restricted to use only a certain subset of the available channels. Good allocation schemes will aim at assigning links with adequate SIR to as many (possibly all) mobiles as possible. Note that the RAA may well (should) opt for not assigning a channel to an active mobile if this assignment would cause excessive interference to other mobiles.

Let us now study the interference constraints on resource allocations in somewhat more detail. We now may compute the signal and interference power levels in all access ports and mobiles, given the link (power) gains, G_{ij}, between access port i and mobile terminal j. For the sake of simplicity, we will here consider only rather wideband modulation schemes that will make the link gains virtually independent of the frequency. Collecting all link gains in matrix form, we get a BxM rectangular matrix — the link gain matrix $\boldsymbol{G}$. The link gain matrix describes the (instantaneous) propagation conditions in the system. Note that in a mobile system, both the individual elements of the matrix (due to mobile motion) and the dimension of the matrix (due to the traffic pattern) may vary over time.

The task of the resource allocation scheme is to find assignments for the QoS that is sufficient in as many links as possible (preferably all). Providing a stringent definition to the QoS for a practical communication service is a complex and multifaceted problem. In this treatment we will confine ourselves to a simple measure the signal-to-interference ratio (SIR), or actually, to be precise, the signal-to-interference+noise ratio. This measure is strongly connected with performance measures as the bit or message error probability in the communication link. We require the SIR in link i to exceed a given threshold γ_i which is determined by both the QoS requirements for that particular link as well as by the modulation and coding formats of the system. This means that the following inequality must hold for both the up-(mobile-to-access port) and down-(access port-to-mobile) link of the connection:

$$\Gamma_i = \frac{P_j G_{ij}}{\sum_m P_m G_{im}\theta_{jm} + N} \geq \gamma_i \tag{1}$$

where Γ_j denotes the SIR at the receiver and N denotes the receiver (thermal) noise power at the access port. P_j denotes the transmitter power used by terminal j. The quantity θ_{jm} is the normalized crosscorrelation between the signals from mobiles j and m at the access port receiver, that is, the effective fraction of the received signal power from transmitter m contributes to the interference when receiving the signal from access port j. If the waveforms are chosen to be orthogonal (as in FDMA and TDMA) these correlations are either zero or one depending on if the station has been assigned the same frequency (time slot) or not. In nonorthogonal access schemes (e.g., DS-CDMA) the θ_{jm} take real values between zero and one. Note that we may not be certain that it is possible to comply with all the constraints (2) for all the M mobiles, in particular if M happens to be a large number. As system designers, we may have to settle for finding resource allocation schemes that assign channels with adequate quality to as many mobiles as possible.

In the classical single service (e.g., mobile telephony) case, the service requirements are identical in all links, that is, $\gamma_i = \gamma_0$ for all i. In this case the *system capacity* can be measured by the largest number of users that may be successfully handled by the system. Since the number of mobiles is a random quantity and the constraints (2) depend on the link matrix, that is, on the relative position of the mobiles, such a capacity measure is not a well-defined quantity. The classical approach for telephone type of traffic is to use as capacity measure the maximal relative arrival rate of calls ρ for which the blocking probability (the probability that a newly arrived session request is denied) can be kept below some predetermined level. Due to the mobility of the mobiles this is not an entirely satisfying measure. A call or session may be lost due to adverse propagation conditions. To include such phenomena into our capacity would require detailed specification of call-handling procedures (e.g., handling of new vs. old calls, hand-off procedures as a mobile moves from one access port to another, etc.). It may therefore be practical to choose a simpler and more fundamental capacity measure that will reflect the performance of the resource allocation scheme as such. For this purpose, the assignment failure probability ν (or assignment failure rate [14,15]) has been proposed. The instantaneous capacity $\omega * (\nu_o)$ of a wireless

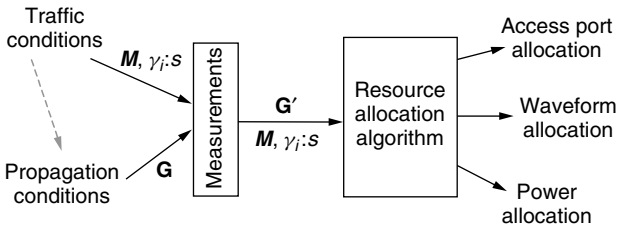

Figure 4. A resource allocation algorithm.

system is the maximum allowed traffic load in order to keep the assignment failure rate below some threshold level ν_o, that is,

$$\omega * (\nu_o) = \{\max \omega: \nu \leq \nu_o\} \quad (2)$$

As we have seen above, finding the optimum resource allocation for each mobile determining

(i) a waveform assignment (determining the θ_{jm})
(ii) an access port assignment (of one or more (!) ports)
(iii) a transmitter power assignment

that maximizes Y for a given link gain matrix, is a formidable problem. No efficient general algorithm that is capable of doing such an optimal assignment for arbitrary link gain matrices and mobile sets is known. Instead, partial solution and a number of more less complex heuristic schemes have been proposed (and are used in the wireless systems of today). These schemes are usually characterized by low complexity and by using simple heuristic design rules. The capacity $\omega*$ achieved by these schemes is, as expected, often considerably lower that can be expected to be achieved by optimum channel assignment.

3. CURRENT APPROACHES TO RESOURCE ALLOCATION STRATEGIES

The subproblem that has attracted most of the interest in the literature so far, is the choice and allocation of waveforms. Orthogonal waveforms such as frequency division multiplexing (FDMA) and time division (TDMA), which provide a "channelization" of the spectrum, have no doubt been the most popular ones, although considerable interest has recently been devoted to nonorthogonal waveforms, such as the IS-95 DS-CDMA waveforms [25]. Given the set of signaling waveforms **C**, the next problem is the allocation of waveforms to the different terminal-access port links. This allocation can be done numerous ways depending on the amount and quality of the information available regarding the matrix **G** and the traffic situation (activity of different terminals). Another important issue is the time scale on which resource (re-)allocation is feasible.

Channel allocation in early FDMA cellular radio systems operates on a long-term basis. Based on average type statistical information regarding **G** (i.e., large scale propagation predictions), frequencies are on a more or less permanent basis assigned to different access ports. Such a "cell plan" provides a sufficient reuse distance between RAPs providing a reasonably low probability of outage (to low SIR) [1]. Inhomogenuities in the traffic load can also be taken care of by adapting the number of channels in each RAP to the expected traffic carried by that access port. To minimize the planning effort, adaptive cell planning strategies (e.g., "channel segregation" [2]) have been devised using long-term average measurements of the interference and traffic to automatically allocate channels to the access port. These "static" (or "quasi-static") channel allocation schemes work quite well when employed in macrocellular systems with high-traffic loads. In short range (microcellular) systems propagation conditions tend to change more abruptly. Since each of the RAPs tend to carry less total traffic in small microcells, the relative traffic variations are also large, particularly in multimedia traffic scenarios. Employing "static" channel allocation schemes in the situations require considerable design margins. Large path loss variations are countered with large reuse distances, unfortunately at a substantial capacity penalty. In the same way microcellular traffic variations are handled by assigning excess capacity to handle traffic peaks. In recent years two principally different methods to approach this problem have been devised: Dynamic channel allocation (DCA) and Random Channel Allocation (RCA).

In dynamic (real-time) channel allocation(DCA), real-time measurements of propagation and/or traffic conditions are used to (re-)allocate spectrum resources. Early graph theoretic schemes, adapted only to traffic variations [4,5] yielding only moderate capacity gains (<50%) compared to static systems in microcellular environments. Other schemes adapt their channel allocation to the received wanted signal strength. One example of the latter type of schemes is the class of reuse-partitioning schemes [6,8]. Here, several overlaid cell plans with different reuse distances are used. Terminals with a high received signal level are tolerant to interference and can be allocated a channel from a dense reuse cell plan, whereas the "weaker" terminals get channels with a large reuse distance and lower interference levels. Capacity gains in the order of up to 100% have been reported for these schemes [7]. Also, schemes directly estimating the C/I and thereby in a distributed way finding channels with adequate quality have been proposed [2,9]. Similar gains as in the reuse partitioning schemes are found in the literature. A comprehensive survey of different DCA-schemes is provided in Ref. 46.

The performance of the DCA schemes is critically dependent on the rate at which allocation or reallocation occurs. Purely traffic adaptive schemes act on incoming user requests and users releasing capacity. Channel reallocation has to occur at these rates to fully utilize the potential of such a DCA scheme. For speech traffic this means that reallocations typically occur at second rates.

Path loss and interference adaptive schemes that "track" (at least slow fading) signal level variations and reallocation rates in the 10's of millisecond range may be required. An alternative class of allocation schemes are the random channel allocation schemes. The principle is most easily explained using Fig. 5. Figure 5a shows a typical set of C/I-trajectories of five terminals in a cellular system. As we can see, 4 of the 5 terminals achieve an adequate C/I, corresponding to an (ensemble) outage rate of 20%. Compare this situation to the one in Fig. 5b exhibiting the same outage rate. In contrast to the situation in Fig. 5a where 20% of the terminals are experiencing too low C/I, here each terminal will experience insufficient quality 20% of the time. In Fig. 5a channel coding is a waste of capacity since four terminals have sufficient quality and the last unlucky terminal is probably "beyond salvage." In Fig. 5b however, there

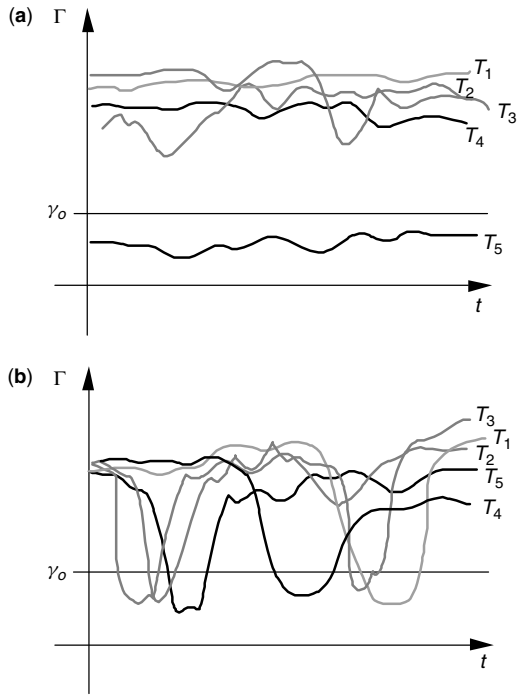

Figure 5. Typical realizations of terminal SIR:s in cellular systems with slowly moving terminals (**a**), and with rapidly moving terminals (**b**).

are probably a sufficient number of reliable channel symbols in all terminals to make reception possible, provided suitable constraint lengths and interleaving are used. The obvious way to achieve the latter situation, regardless of the mobile speed, is to permute channel allocations in a random fashion. The simplest way is to use (orthogonal) frequency hopping which can be seen as a static channel allocation where terminals allocated to a certain access port swap channels with each other [28,33]. Frequency hopping occurs typically 100–1000 times/second. Also nonorthogonal waveforms can be used as in the DS-CDMA based IS-95 scheme [25]. Effectively, a new random waveform is used for every transmitted bit. DS-CDMA schemes require only a very low level of synchronization and no cell planning, which has made them attractive. Regarding capacity the comparison between DS and FH schemes is not obvious although orthogonal schemes seem to have advantages in mixed cell environments [26]. Comparing the performance of (deterministic) DCA to the performance of the random allocation schemes is even more complex and stands out as one of the more fundamental research topics of the near future. Another quite different situation where similar interference conditions as in frequency hopping prevail are certain packet communication systems. Here the "randomness" is mainly induced by the random arrivals of packets triggering transmission events.

The selection of the proper transmitter power in terminals and access ports is another topic that has attracted considerable interest in recent years. There can be several objectives for this: to suppress adjacent channel (cross correlation) interference in nonorthogonal schemes, to minimize power consumption in order to extend terminal battery life, and to control cochannel interference (in schemes with orthogonal waveforms). In the resource allocation problem context, it can be shown that the maximum number of terminals is supported under a power control (PC) regime that balances the C/I of all terminals that can be supported and shuts off the rest [10].

Figure 6, showing the cumulative distribution function (CDF) of the received C/I in an (orthogonal signaling) cellular system under three power control regimes, illustrates why this is so. As we can see, the uncontrolled system exhibits a rather flat CDF with a high outage probability (at the threshold C/I). A received signal strength based algorithm, such as the constant received power scheme, reduces some of the variations in the C/I by limiting the variations in the "C" component. The variations in the interference part ("I") are however now larger than before and the figure shows a typical net result CDF. The outage probability is now slightly lower. In the C/I balancing scheme all stations have the same C/I, here slightly over the threshold, leaving only a small fraction of terminals without support. Finding this optimum set of nonsupported terminals is a problem closely related to the design of DCA schemes. Distributed implementations and different implementational constraints [11,12] have been studied. Results show that very robust near-optimum power control schemes can be devised at very low complexity. Performance results indicate that in static channel allocations substantial (>100%) capacity gains can be achieved using optimum power control. These gains are, of course, not additive with the gains obtained by DCA schemes. However, preliminary results regarding combined DCA/PC schemes show substantial capacity gains [13,15].

For packet communication with short messages or in frequency hopping environments, power control as described above may not work properly due to the fact that the feedback delay in the power control loop may in fact be longer than the time required to transmit the message (or in FH the chip/burst duration). The bursty interference caused by other users compounds to the problem of accurately measuring and predicting the C/I. Several approaches to this problem have been proposed. In systems utilizing mainly forward error correction, C/I-balancing power control strategies involving estimating statistical parameters of the C/I, such as the average C/I (measured over many packet/chip durations), and as

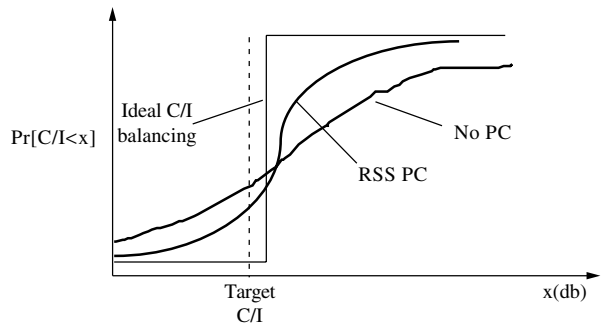

Figure 6. Outage probability minimization-CDF of received C/I.

well as fast C/I estimation/tracking schemes have been proposed [34–37].

In random access systems utilizing retransmissions (ARQ), however, the picture is quite different. Two important differences between these systems and the continuous ("circuit switched") systems can be noted. Providing equal transmission quality to all packet transmission (e.g., letting all packets be received with equal powers), turns out to be a disastrous strategy, since it guarantees that no packet can be received properly when several packets happen to be transmitted simultaneously (a "collision"). It has clearly been demonstrated that a received power spread, such as the one caused by near-far effects or Rayleigh/Shadow fading actually improves the capacity (throughput) of such systems [39]. Results show that power control, which creates an even larger power spread, can produce even better results [40–42].

4. MANAGING CHANGE — THE DYNAMICS OF RESOURCE ALLOCATION

As terminals move about in the service area, the propagation and interference situation may turn such that the terminal cannot be supported by the same access port on any waveform. New terminals may enter the service area requiring services, while others are terminating their communication sessions. As most of the basic resource allocation strategies described above deal mainly with static or quasi-static situations that are encountered on a microscopic, short term, time scale, we have to devise resource management schemes capable of handling these variations.

In the first case, where we have signal quality variations as a result of the terminal moving during a communication session some kind of resource reallocation may become necessary. This may be a waveform reallocation, or an "intra-port" handoff, which in principle involves a reexecution of the basic channel allocation scheme, or an inter-port ("inter-cell") handoff. In early cellular systems which are mainly noise-limited systems these handoffs were basically triggered by too low received signal levels. The handoff mechanism has, for these cases, often been modeled as a selection (macro-) diversity scheme where the terminals are assigned to the access port with the highest received signal level. This situation where hand-offs occur at more or less well-defined "cell-borders" has been extensively studied.

Maximizing the instantaneous received signal level may, however, not be neither very practical nor produce the best results. In high density wireless systems, the coverage areas of the access port overlap to a large extent. Low signal levels is rarely a problem since normally several access ports provide sufficient signal levels. In these cases the variations in the interference and not cell boundary crossings is the most probable cause of a handoff. When several access ports may provide sufficient C/I, the system is also able to handle traffic variations by means of *load sharing*, that is, by letting less loaded access ports support terminals even though they are providing less C/I than the best (often the closest) port [20]. Combinations of power control and access port selection also show promising results [21,22]. Instead of conventional handoff schemes ("switching diversity"), continuous combining schemes ("soft handoff") have been studied quite extensively [19].

Keeping track of the mobile terminals in a large (possibly global) wireless system, the mobility management, is a formidable task. Although this is handled mainly on the fixed network end, there are important implications to the resource management. The tradeoff between the capacity required for the air signaling to monitor the whereabouts of the terminals (the "locating" procedures) and the capacity required for finding, or paging, a terminal when a communication request comes from the network end, has received quite some attention [23,24] in CDMA schemes.

Handling arriving and departing terminals poses a slightly different problem. Whenever a new terminal arrives (a new request for service or an inter-port handoff) the RRM system has to decide if this particular terminal may be allowed into the system. An algorithm making these decisions is called an admission control algorithm. Since the exact terminal population and gain matrix may not be tracked exactly at all times and due to the complexity of the RRM-algorithms, determining the success of an admission decision may not be possible beforehand without physically executing the admission itself. The admission procedure may fail in two ways:

1. ("False admission") A terminal is admitted giving rise to a situation where one or more terminals cannot be supported (not necessarily including the admitted terminal).
2. ("False rejection") A terminal is rejected when successful resource allocation actually was possible.

Traditional approaches involving static channel allocation normally use simple thresholding strategies on the available channels in each cell. Access ports have been assigned a fixed set of channels that "guarantee" to provide a certain low-outage probability. Such a system is what we call "blocking limited," whenever a call arrives, we may check if there are channels available or not. Since we may choose to give priority to an ongoing session experiencing an inter-port handoff, new arriving calls are admitted only up to the point where there is only some small fraction of the resource remaining. This spare capacity is "reserved" for calls entering a cell due to an inter-cell handoff.

In systems using dynamic channel allocation or random allocation there is no clear limit on the number of channels/waveform that can be used. In such "interference-limited" systems, the feasibility of admitting new users will depend on the current interference situation. In particular in systems utilizing C/I-balancing power control this is complicated by the fact that already active terminals will react to the admission of a new terminal by adjusting (raising) their transmitter powers. It is therefore quite possible that the admission of yet another user may cause several of the original users (possibly all!) to no longer be supported at the required C/I-level. Admission control schemes can be grouped into noninteractive schemes and interactive schemes [43]. The noninteractive schemes proposed are mainly using

different types of interference or transmitter power thresholds [43], that is, when the measured interference (or the currently used power) on some channel (cell) is too high, admission is denied. The interactive schemes involve the gradual increase of the power of new terminals until they are finally admitted. Such a procedure to protect the already established procedure connection is referred to as "Soft-and Safe (SAS)" admission [44] or channel probing/active link protection [45].

5. MULTIPLE QUALITY-OF-SERVICE RESOURCE MANAGEMENT

Looking at the more general problem definition, most of the capacity definitions provided above fail if the users have different service requirements. In our problem definition this is reflected in the SIR requirements γ_i. Most of the techniques discussed above, properly generalized, lend themselves readily also for the nonspeech and multiservice cases. It has, however, to be understood that (for nonspeech services) the mapping of user perceived performance on technical parameters, such as the SIRs, in the wireless system is certainly a very complex task. With the proliferation of "best-effort"-type backbone networks, the user experience of the service provided is influenced not only by the shortcomings of the wireless system but also by other factors. As indicated by Fig. 7, such factors include the performance of the wireline backbone and switching, the service providers application software and hardware, and even the user interface provided by the service provider and the terminal manufacturer. In order to allow rational design of telecommunication systems, these overall (end-to-end) requirements are broken down to specific (sub-)service requirements for the individual building blocks. Here the interest is focused on studying the behavior of the radio network part of the "transport system." The "services" provided at this level have been coined bearer services in the UMTS/3G standardization process. These services have been divided into four classes as outlined in Table 1 [47] and are mainly distinguished by their delay requirements ranging from very strict delay requirements in "conversational class" (e.g., voice services) to the very relaxed requirements in the "background-best effort" class. In more technical terms, the services in the different classes are characterized by means of sets of service parameters, forming a QoS profile. Some of the QoS parameters (service attributes) in the 3G systems are found in Table 2.

In principle, an infinite set of QoS-profiles and thus different bearer services could be defined by varying these parameters — possibly one combination for each user. In practice, limitations on the number of modulation waveforms, codes, and so on, restrict the number of service

Table 1. 3G (UMTS) Bearer Service Classes [47]

Service Class	Typical Applications	Service Functional Characteristics
Conversational		
Real Time(RT) Streaming RT	Voice Video/Audio streams	• Preserve time relations between entities • Stringent preservation of conversational patterns (low delay)
Interactive		Preserve time relations between entities
Best effort (BE) Background BE	Web-browsing File transfer, E-mail	• Request-response pattern • Preserve payload (low error rate) • Not time critical • Preserve payload (low error rate)

offerings. Most systems will therefore offer a finite set of bearer services, where each parameter will be allowed to take one out of a few discrete values. Table 2 provides an indication of what ranges these service parameters can take in a 3G wireless system. In addition to these service parameters, the *availability* of the services has to be considered since it may vary over time and over the user services. Clearly, users with QoS-profiles with large "resource consumption" (e.g., high bit rate, poor location) or with low-relative priority will more often experience that the system is not capable of accommodating their service request.

Looking at a popular example to illustrate the problems we face, we take a web browsing session. Such a session consists of an irregular sequence of file transfers (using the TCP/IP protocol stack). Typical very short messages are transmitted in the uplink from the terminals (corresponding to a mouse-click) a random instants to request rather large files (web-pages, pictures, etc.) to be downloaded into the terminal. This can be seen as a service of the "interactive" class. The critical QoS characteristic to the user is the response-time (i.e., delay between request and the complete reception of the requested page). For large requested files the delay is dominated by the transfer delay of the files, that is, the average data rate is in fact the critical QoS parameter that will determine the user delay. The undetected error rate at the user level has to be below 10^{-8} corresponding to 1 error in about 10 MB. The radio bearer may however have a larger undetected error probability since the TCP/IP protocol provides end-to-end error control of its own. Classical models for data traffic of this type are based on Poisson distributions — both for

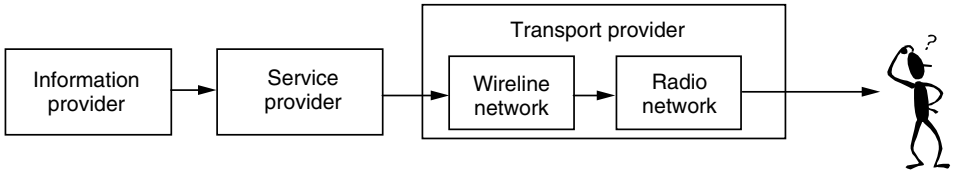

Figure 7. Service provisioning in modern information and communication systems.

Table 2. Some 3G (UMTS) Service Attribute/Parameter Ranges [47]

Traffic Class	Conversational	Streaming	Interactive	Background
Max bit rate(kbps)	<2000	<2000	<2000-overhead	<2000-overhead
Max SDU size(byte)	<1500	<1500	<1500	<1500
Guaranteed bit rate	<2000	<2000		
Transfer delay(ms)	80-max value	500-max value		
Priority	1,2,3	1,2,3	1,2,3	1,2,3
Residual BER	$5*10^{-2}$, 10^{-2}, 10^{-3}, 10^{-6}	$5*10^{-2}$, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}	$4*10^{-3}$,10^{-5}, $6*10^{-8}$	$4*10^{-3}$,10^{-5}, $6*10^{-8}$

the interarrival time of packets as well as the size of the requested files. Recent studies of Internet traffic have however shown that these models tend to underestimate the time between packets and the packet sizes. As an alternative, the Pareto distributions, that is, stochastic variables with density function

$$f(x) = \frac{\beta a^{\beta}}{x^{\beta+1}} a, \beta \geq 0, x \geq a$$

have been proposed [49]. These distributions are "heavy-tailed," they assign higher probability to large values of x compared to the exponential distributions found in Poisson point processes. Another approach for simulation purposes, is to use a more detailed model of the actual TCP/IP protocol [48].

After having discussed the user performance perspective, let us now briefly return to the discussion of the network performance. Defining a capacity performance measure for such a single service system is not obvious. Examples of popular measures (for non–real-time service systems as in the example above) found in the literature are the total throughput, that is, the sum data rate of all connections in the systems (possibly per area unit) and the user Circuit switched equivalent Bit Rate (CBR, i.e., the constant data rate would provide the same user perceived performance). In non–real-time, "best-effort," systems efficient resource management makes use of the extra degree of freedom provided by not fixing the delay. Efficient scheduling and adapting the transmission rate to the current propagation and SIR conditions may be used to maximize throughput. In a fading channel (as illustrated by Fig. 5b), the channel conditions may be bad for a certain user during one time frame. That particular user could thus postpone its transmission, allowing some other users with favorable data rates to transmit — potentially at a much higher data rate. Typically, such schemes maximize the total throughput by favoring terminals with good propagation conditions as they generally have more time slots at their disposal and can use higher data rates [52,53].

When mixing services, the situation becomes even more complex. In order for any capacity definition to be precise in the general (multiservice) case requires a model, not only for the number of users, but also for their behavior. What will be the QoS-profile requested for a certain user (which is then mapped to the individual γ_i), and what is the required service availability? Typically, random models will be used for this purpose. A user will, with some given probability, belong to a certain class of users with an identical QoS-profile. The probability distribution of class membership is usually referred to as the service mix.

Determining which service mix should be used for the capacity definition is indeed difficult. One approach has been to look at the pricing strategy and maximizing the revenue of the operator. This leads to both an optimal service mix and maximal revenue derived from the network. A difficulty is that this type of model disregards the fact that if the demand for the service provided is finite, operators are prone to competition from either other similar operators or alternative technical solutions. In these situations the pricing strategy clearly affects the demand for the services.

Given a certain service mix, several capacity definitions have been tried in the literature, but a generally acceptable single definition has still to be found. Looking at the total throughput or the total operator revenue is one approach. The main difficulty with this is to set the price parameters to reasonable values due to the interdependence of the pricing and the service mix. More promising is to use the (total) number of users satisfied with their respective service, this is one approach that leads to a capacity definition very close to the one discussed above [50,51]. In this approach, the capacity regions, that is, the permissible combinations of numbers of users in the different service classes play an important role in the cases where no price structure can be determined [50].

Another problem caused by mixing traffic, in particular circuit-switched and bursty best-effort traffic, is that it makes link-quality assessment more difficult. The main result from traffic theory tells us to dynamically share all the available spectrum for all types of traffic. A sideeffect of this is, however, that also the interference experienced by different users will exhibit the same wide span in character [38]. In particular if we would like to estimate the link quality for a high quality circuit switched service, the link will be subject to both quasi-constant as well as intermittent interference (from packet service users). Reliably estimating, for instance, using the C/I as a basis for RRM decisions, will be considerably more difficult.

6. DISCUSSION

We have previously presented a formulation of the radio resource problem based on the three basic allocation decisions: waveform, access port, and transmitter power. As the reader may have realized, these are closely related. Most of the recent work indicates that good results are achieved when these decisions are coordinated. Combinations of power control and DCA [13,15], base station assignment and power control [21,22], as well as power control assisted admission schemes, have provided

interesting results. Another area where research is just in its preliminary stages is the combination of detailed modulation waveforms/channel coding and its interaction with DCA and power control. Although the current mobile telephony systems are rather easily modeled in the terms described above, it seems clear that also most of the RRM problems expected in the future can be mapped onto the framework presented here. A key problem in bursty and mixed traffic is the tradeoff between maximizing instantaneous resource utilization (transmit only when data is available) and obtaining reliable quality measurements to facilitate the efficient adaptation of the radio resources to the needs of the users.

Traditionally, we consider the frequency spectrum to be the resource to be shared. Since there, in fact, does not exist any upper limit on the capacity that can be provided (with a dense enough infrastructure), it is important that we widen the resource management perspective. Parameters such as infrastructure density costs and terminal power consumption play important roles. One could easily identify tradeoffs such as where the signal processing load should be put in a wireless system — in the terminal where power is scarce or in the fixed infrastructure. The key question here is: Should the access port infrastructure be very dense (and costly) allowing for dumb, cheap, low-power terminals, or should terminals be more complex allowing for the rapid deployment of a cheap infrastructure at the expense of battery life and terminal cost ?

BIOGRAPHY

Jens Zander (S'82–M'85) received the M.S degree in electrical engineering (Y) and the Ph.D degree (in datatransmission) from Linköping University, Sweden, in 1979 and 1985, respectively.

From 1985 to 1989 he was a partner of SECTRA, a high-tech company in telecommunications systems and applications. In 1989 he was appointed professor and head of the Radio Communication Systems Laboratory at the Royal Institute of Technology, Stockholm, Sweden. Since 1992 he also serves as Senior Scientific Advisor to the Swedish National Defence Research Institute (FOI). He currently is the Scientific Director of the Center for Wireless Systems (Wireless@KTH) at the Royal Institute of Technology, Stockholm.

Dr. Zander has published numerous papers in the field of radio communication, in particular on resource management aspects of personal communication systems. He has also coauthored four textbooks on radio communication systems, including the English textbooks *Principles of Wireless Communications* and *Radio Resource Management for Wireless Networks*. He was the recipient of the IEEE Veh. Tech. Soc. Jack Neubauer Award for best systems paper in 1992.

Dr. Zander is a member of the Royal Academy of Engineering Sciences. He is the chairman of the IEEE VT/COM Swedish chapter. He is associate editor of the ACM *Wireless Networks* Journal and area editor of *Wireless Personal Communications*.

His current research interests include future wireless infrastructures, in particular related resource allocation and economic issues.

ROUTING AND WAVELENGTH ASSIGNMENT IN OPTICAL WDM NETWORKS

GEORGE N. ROUSKAS
North Carolina State University
Raleigh, North Carolina

1. INTRODUCTION TO OPTICAL WDM NETWORKS

A basic property of a single-mode optical fiber is its enormous low-loss bandwidth of several tens of terahertz. However, because of dispersive effects and limitations in optical device technology, single-channel transmission is limited to only a small fraction of the fiber capacity. To take full advantage of the potential of fiber, the use of wavelength-division multiplexing (WDM) technology

has become the option of choice. With WDM, a number of distinct wavelengths are used to implement separate channels [1]. An optical fiber can carry several channels in parallel, each on a particular wavelength. The number of wavelengths that each fiber can carry simultaneously is limited by the physical characteristics of the fiber and the state of the optical technology used to combine these wavelengths onto the fiber and isolate them off the fiber. With currently available commercial technology, a few tens of wavelengths can be supported within the low-loss window at 1550 nm, but this number is expected to grow rapidly in the near future. Therefore, optical fiber links employing WDM technology have the potential of delivering an aggregate throughput in the order of terabits per second, enough to satisfy the ever-growing demand for more bandwidth per user on a sustained, long-term basis.

Unfortunately, because of the mismatch between aggregate fiber capacity and peak electronic processing speeds, simply upgrading existing point-to-point fiber links to WDM creates the well-known *electrooptic bottleneck* [2]: rather than achieving the multiterabit-per-second throughput of the fiber, one has to settle for the multigigabit-per-second throughput that can be expected of the electronic devices where the optical signals terminate. Overcoming the electrooptic bottleneck, therefore, involves the design of properly structured architectures to interconnect the fiber links. An optical WDM network is a network with optical fiber transmission links and with an architecture that is designed to exploit the unique features of fibers and WDM. Such networks offer the promise of an all-optical information highway capable of supporting a wide range of applications that involve the transport of massive amounts of data and/or require very fast response times. Such applications include video on demand and teleconferencing, telemedicine applications, multimedia document distribution, remote supercomputer visualization, and many more to come. Consequently, optical WDM networks have been a subject of extensive research both theoretically and experimentally [3,4].

The architecture for wide-area WDM networks that is widely expected to form the basis for a future all-optical infrastructure is built on the concept of *wavelength routing*. A wavelength routing network, shown in Fig. 1, consists of two types of nodes: *optical cross-connects* (OXCs), which connect the fibers in the network, and *edge nodes*, which provide the interface between non-optical end systems (such as IP routers, ATM switches, or supercomputers) and the optical core. Access nodes provide the terminating points (sources and destinations) for the optical signal paths; the communication paths may continue outside the optical part of the network in electrical form.

The services that a wavelength routed network offers to end systems attached to edge nodes are in the form of *logical* connections implemented using *lightpaths*. Lightpaths (also referred to as λ-*channels*), are clear optical paths between two edge nodes, and are shown in Fig. 1 as red and green directed lines. Information transmitted on a lightpath does not undergo any conversion to and from electrical form within the optical network, and thus, the architecture of the optical network nodes can be very simple because they do not need to do any signal processing. Furthermore, since a lightpath behaves as a literally transparent "clear channel" between the source and destination edge node, there is nothing in the signal path to limit the throughput of the fibers.

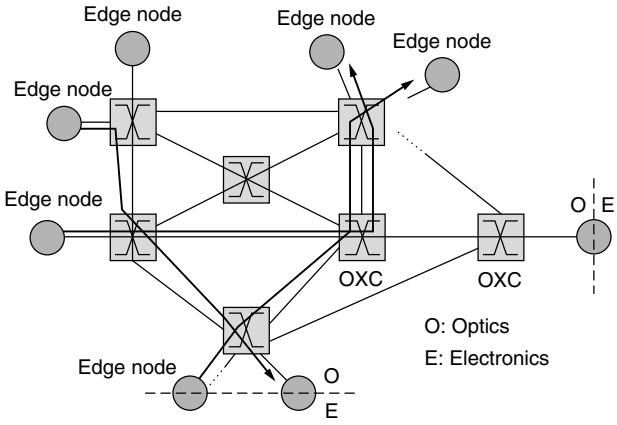

Figure 1. A wavelength-routed WDM network.

The OXCs provide the switching and routing functions for supporting the logical connections between edge nodes. An OXC takes in an optical signal at each wavelength at an input port, and can switch it to a particular output port, independent of the other wavelengths. An OXC with N input and N output ports capable of handling W wavelengths per port can be thought of as W independent $N \times N$ switches. These switches have to be preceded by a wavelength demultiplexer and followed by a wavelength multiplexer to implement an OXC, as shown in Fig. 2. Thus, an OXC can cross-connect the different wavelengths from the input to the output, where the connection pattern of each wavelength is independent of the others. By appropriately configuring the OXCs along the physical path, a logical connection (lightpath) may be established between any pair of edge nodes.

A unique feature of optical WDM networks is the tight coupling between routing and wavelength selection. As can be seen in Fig. 1, a lightpath is implemented by selecting a path of physical links between the source and destination edge nodes, and reserving a particular wavelength on each of these links for the lightpath. Thus, in establishing an optical connection we must deal with both routing (selecting a suitable path) and wavelength assignment (allocating an available wavelength for the connection). The resulting problem is referred to as the *routing and wavelength assignment* (RWA) problem [5], and is significantly more difficult than the routing problem in electronic networks. The additional complexity arises from the fact that routing and wavelength assignment are subject to the following two constraints:

1. *Wavelength continuity constraint* — a lightpath must use the same wavelength on all the links along its path from source to destination edge node. This constraint is illustrated in Fig. 1 by representing

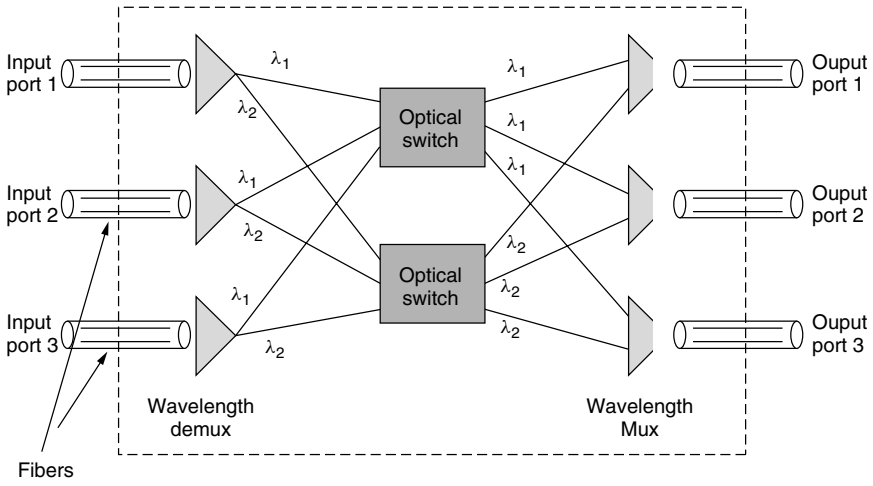

Figure 2. A 3×3 optical cross-connect (OXC) with two wavelengths per fiber.

each lightpath with a single color (wavelength) along all the links in its path.

2. *Distinct wavelength constraint* — all lightpaths using the same link (fiber) must be allocated distinct wavelengths. In Fig. 1 this constraint is satisfied since the two lightpaths sharing a link are shown in different colors (wavelengths).

The RWA problem in optical networks is illustrated in Fig. 3, where it is assumed that each fiber supports two wavelengths. The effect of the wavelength continuity constraint is represented by replicating the network into as many copies as the number of wavelengths (in this case, two). If wavelength i is selected for a lightpath, the source and destination edge node communicate over the ith copy of the network. Thus, finding a path for a connection may potentially involve solving W routing problems for a network with W wavelengths, one for each copy of the network.

The wavelength continuity constraint may be relaxed if the OXCs are equipped with *wavelength converters* [6]. A wavelength converter is a single input/output device that converts the wavelength of an optical signal arriving at its input port to a different wavelength as the signal departs from its output port, but otherwise leaves the optical signal unchanged. In OXCs without a wavelength conversion capability, an incoming signal at port p_i on wavelength λ can be optically switched to any port p_j, but must leave the OXC on the same wavelength λ. With wavelength converters, this signal could be optically switched to any port p_j on some other wavelength λ'. Thus, wavelength conversion allows a lightpath to use different wavelengths along different physical links.

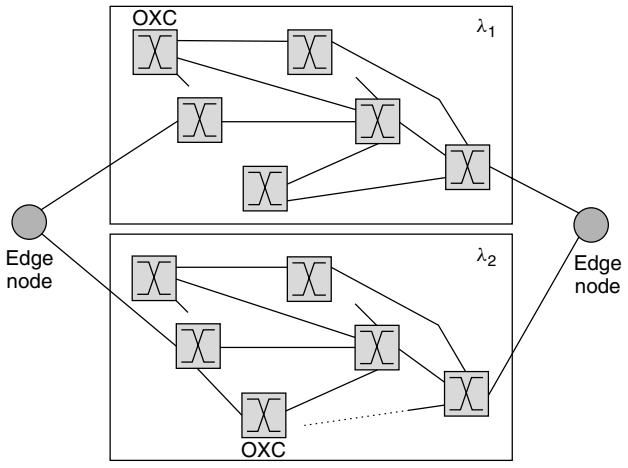

Figure 3. The RWA problem with two wavelengths per fiber.

Different levels of wavelength conversion capability are possible. Figure 4 illustrates the differences for single-input and single-output port situations; the case for multiple ports is more complicated but similar. *Full wavelength conversion* capability implies that any input wavelength may be converted to any other wavelength. *Limited wavelength conversion* [7] denotes that each input wavelength may be converted to any of a specific set of wavelengths, which is not the set of all wavelengths for at least one input wavelength. A special case of this is *fixed wavelength conversion*, where each input wavelength can be converted to exactly one other wavelength. If each wavelength is "converted" only to itself, then we have no conversion.

The advantage of full wavelength conversion is that it removes the wavelength continuity constraint, making it possible to establish a lightpath as long as each link along the path from source to destination has a free wavelength (which could be different for different links). As a result, the RWA problem reduces to the classical routing problem, that is, finding a suitable path for each connection in the

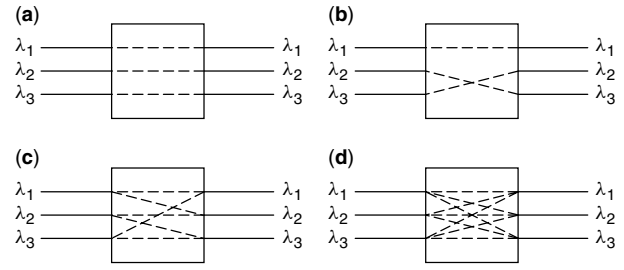

Figure 4. Wavelength conversion: (**a**) no conversion; (**b**) fixed conversion; (**c**) limited conversion; (**d**) full conversion.

network. Referring to Fig. 3, full wavelength conversion collapses the W copies of the network into a single copy on which the routing problem is solved. On the other hand, with limited conversion, the RWA problem becomes more complex than with no conversion. To see why, note that employing limited conversion at the OXCs introduces links between *some* of the network copies of Fig. 3. For example, if wavelength λ_1 can be converted to wavelength λ_2 but not to wavelength λ_3, then links must be introduced from each OXC in copy 1 of the network to the corresponding OXC in copy 2, but not to the corresponding OXC in copy 3. When selecting a path for the connection, at each OXC there is the option of remaining at the same network copy or moving to another one, depending on the conversion capability of the OXC. Since the number of alternatives increases exponentially with the number of OXCs that need to be traversed, the complexity of the RWA problem increases accordingly.

Wavelength conversion (full or limited) increases the routing choices for a given lightpath (i.e., makes more efficient use of wavelengths), resulting in better performance. Since converter devices increase network cost, a possible middle ground is to use *sparse conversion*, that is, to employ converters in some, but not all, OXCs in the network. In this case, a lightpath must use the same wavelength along each link in a segment of its path between OXCs equipped with converters, but it may use a different wavelength along the links of another such segment. It has been shown that implementing full conversion at a relatively small fraction of the OXCs in the network is sufficient to achieve almost all the benefits of conversion [8,9].

Routing and wavelength assignment is the fundamental control problem in optical WDM networks. Since the performance of a network depends not only on its physical resources (OXCs, converters, fibers links, number of wavelengths per fiber, etc.) but also on how it is controlled, the objective of an RWA algorithm is to achieve the best possible performance within the limits of physical constraints. The RWA problem can be cast in numerous forms. The different variants of the problem, however, can be classified under one of two broad versions: a static RWA, whereby the traffic requirements are known in advance, and a dynamic RWA, in which a sequence of lightpath requests arrive in some random fashion. Sections 2 and 3 discuss the static and dynamic versions, respectively, of the RWA problem, and present some algorithms to solve them. Finally, Section 4 presents the multicast RWA problem and algorithms to build *light trees* that connect a source edge node to multiple destinations.

2. STATIC ROUTING AND WAVELENGTH ASSIGNMENT

If the traffic patterns in the network are reasonably well known in advance and any traffic variations take place over long timescales, the most effective technique for establishing optical connections (lightpaths) between edge nodes is by formulating and solving a static RWA problem. For example, static RWA is appropriate for provisioning a set of semipermanent connections. Since these connections are assumed to remain in place for relatively long periods of time, it is worthwhile to attempt to optimize the way in which network resources (e.g., physical links and wavelengths) are assigned to each connection, even though optimization may require a considerable computational effort.

A solution to the static RWA problem consists of a set of long-lived lightpaths that create a *logical* (or *virtual*) topology among the edge nodes. This virtual topology is embedded onto the physical topology of optical fiber links and OXCs. Accordingly, the static RWA problem is often referred to as the *virtual topology design* problem [10]. In the virtual topology, there is a directed link from edge node s to edge node d if a lightpath originating at s and terminating at d is set up (refer also to Fig. 1), and edge node s is said to be "one hop away" from edge node d in the virtual topology, although the two nodes may be separated by a number of physical links. The type of virtual topology that can be created is usually constrained by the underlying physical topology. In particular, it is generally not possible to implement fully connected virtual topologies: for N edge nodes this would require each edge node to maintain $N-1$ lightpaths and the optical network to support a total of $N(N-1)$ lightpaths. Even for modest values of N, this degree of connectivity is beyond the reach of current optical technology, in terms of both the number of wavelengths that can be supported and in the optical hardware (transmitters and receivers) required at each edge node.

In its most general form, the RWA problem is specified by providing the physical topology of the network and the traffic requirements. The physical topology corresponds to the deployment of cables in some existing fiber infrastructure, and is given as a graph $G_p(V, E_p)$, where V is the set of OXCs and E_p is the set of fibers that interconnect them. The traffic requirements are specified in a traffic matrix $\mathbf{T} = [\rho p_{sd}]$, where ρp_{sd} is a measure of the long-term traffic flowing from source edge node s to destination edge node d [11]. Quantity ρ represents the (deterministic) total offered load to the network, while the p_{sd} parameters define the distribution of the offered traffic.

Routing and wavelength assignment are considered together as an optimization problem using mixed-integer programming (MIP) formulations. Usually, the objective of the formulation is to minimize the maximum congestion level in the network subject to network resource constraints [10,12]. While other objective functions are possible, such as minimizing the average weighted number of hops or minimizing the average packet delay, minimizing network congestion is preferable since it can lead to mixed-integer linear programming (MILP) formulations. While we do not present the RWA problem formulation here, the interested reader may refer to the literature [11–12]. These formulations turn out to have extremely large numbers of variables, and are intractable for large networks. This fact has motivated the development of heuristic approaches for finding good solutions efficiently.

Before we describe the various heuristic approaches, we note that the static RWA problem can be logically decomposed into four subproblems. The decomposition is approximate or inexact, in the sense that solving the subproblems in sequence and combining the solutions may

not result in the optimal solution for the fully integrated problem, or some later subproblem may have no solution given the solution obtained for an earlier subproblem, so no solution to the original problem may be obtained. However, the decomposition provides insight into the structure of the RWA problem and is a first step towards the design of effective heuristics. Assuming no wavelength conversion, the subproblems are as follows:

1. *Topology subproblem* — determine the logical topology to be imposed on the physical topology; that is, determine the lightpaths in terms of their source and destination edge nodes.
2. *Lightpath routing subproblem* — determine the physical links which each lightpath consists of; that is, route the lightpaths over the physical topology.
3. *Wavelength assignment subproblem* — determine the wavelength each lightpath uses; that is, assign a wavelength to each lightpath in the logical topology so that wavelength restrictions are obeyed for each physical link.
4. *Traffic routing subproblem* — route packet traffic between source and destination edge nodes over the logical topology obtained.

A large number of heuristic algorithms have been developed in the literature to solve the general static RWA problem discussed here or its many variants. Overall, however, the different heuristics can be classified into three broad categories: (1) algorithms that solve the overall MILP problem suboptimally, (2) algorithms that tackle only a subset of the four subproblems, and (3) algorithms that address the problem of embedding regular logical topologies onto the physical topology.

Suboptimal solutions can be obtained by applying conventional tools developed for complex optimization problems directly to the MILP problem. One technique is to use LP relaxation followed by rounding [13]. In this case, the integer constraints are relaxed creating a nonintegral problem which can be solved by some linear programming method, and then a rounding algorithm is applied to obtain a new solution that obeys the integer constraints. Alternatively, genetic algorithms or simulated annealing [14] can be applied to obtain locally optimal solutions. The main drawback of these approaches is that it is difficult to control the quality of the final solution for large networks: simulated annealing is computationally expensive and thus, it may not be possible to adequately explore the state space, while LP relaxation may lead to solutions from which it is difficult to apply rounding algorithms.

Another class of algorithms tackles the RWA problem by initially solving the first three subproblems listed above; traffic routing is then performed by employing well-known routing algorithms on the logical topology. One approach for solving the three subproblems is to maximize the amount of traffic that is carried on one-hop lightpaths, where traffic that is routed from source to destination edge node directly on a lightpath. A greedy approach taken is to create lightpaths between edge nodes in order of decreasing traffic demands as long as the wavelength continuity and distinct wavelength constraints are satisfied [15]. This algorithm starts with a logical topology with no links (lightpaths) and sequentially adds lightpaths as long as doing so does not violate any of the problem constraints. The reverse approach is also possible [16]; starting with a fully connected logical topology, an algorithm sequentially removes the lightpath carrying the smallest traffic flows until no constraint is violated. At each step (i.e., after removing a lightpath), the traffic routing subproblem is solved in order to find the lightpath with the smallest flow.

The third approach to RWA is to start with a given logical topology, thus avoiding the need to directly solve the first of the four subproblems listed above. Regular topologies are good candidates as logical topologies since they are well understood and results regarding bounds and averages (e.g., for hop lengths) are easier to derive. Algorithms for routing traffic on a regular topology are usually simple, so the traffic routing subproblem can be trivially solved. Also, regular topologies possess inherent load balancing characteristics which are important when the objective is to minimize the maximum congestion.

Once a regular topology is decided on as the one to implement the logical topology, it remains to decide which physical node will realize each given node in the regular topology (this is usually referred to as the *node mapping* subproblem), and which sequence of physical links will be used to realize each given edge (lightpath) in the regular topology (this *path mapping* subproblem is equivalent to the lightpath routing and wavelength assignment subproblems discussed earlier). This procedure is usually referred to as *embedding* a regular topology in the physical topology. Both the node and path mapping subproblems are intractable, and heuristics have been proposed in the literature [16,17]. For instance, a heuristic for mapping the nodes of shuffle topologies based on the gradient algorithm has been developed [17].

Given that all the algorithms for the RWA problem are based on heuristics, it is important to be able to characterize the quality of the solutions obtained. To this end, one must resort to comparing the solutions to known bounds on the optimal solution. A comprehensive discussion of bounds for the RWA problem and the theoretical considerations involved in deriving them can be found in [10]. A simulation-based comparison of the relative performance of the three classes of heuristic for the RWA problem has been presented [12]. The results indicate that the second class of algorithms discussed earlier achieve the best performance.

3. DYNAMIC ROUTING AND WAVELENGTH ASSIGNMENT

Under a dynamic traffic scenario, edge nodes submit to the network requests for lightpaths to be set up as needed. Thus, connection requests are initiated in some random fashion. Depending on the state of the network at the time of a request, the available resources may or may not be sufficient to establish a lightpath between the corresponding source–destination edge node pair. The network state consists of the physical path (route) and

wavelength assignment for all active lightpaths. The state evolves randomly in time as new lightpaths are admitted and existing lightpaths are released. Thus, each time a request is made, an algorithm must be executed in real time to determine whether it is feasible to accommodate the request, and, if so, to perform routing and wavelength assignment. If a request for a lightpath cannot be accepted because of lack of resources, it is blocked.

Because of the real-time nature of the problem, RWA algorithms in a dynamic traffic environment must be very simple. Since combined routing and wavelength assignment is a hard problem, a typical approach to designing efficient algorithms is to decouple the problem into two separate subproblems: the routing problem and the wavelength assignment problem. Consequently, most dynamic RWA algorithms for wavelength routed networks consist of the following general steps:

1. Compute a number of candidate physical paths for each source–destination edge node pair and arrange them in a path list.
2. Order all wavelengths in a wavelength list.
3. Starting with the path and wavelength at the top of the corresponding list, search for a feasible path and wavelength for the requested lightpath.

The specific nature of a dynamic RWA algorithm is determined by the number of candidate paths and how they are computed, the order in which paths and wavelengths are listed, and the order in which the path and wavelength lists are accessed.

Let us first discuss the routing subproblem. If a *static* algorithm is used, the paths are computed and ordered independently of the network state. With an *adaptive* algorithm, on the other hand, the paths computed and their order may vary according to the current state of the network. A static algorithm is executed offline and the computed paths are stored for later use, resulting in low latency during lightpath establishment. Adaptive algorithms are executed at the time when a lightpath request arrives and require network nodes to exchange information regarding the network state. Lightpath setup delay may also increase, but in general adaptive algorithms improve network performance.

The number of path choices for establishing an optical connection is another important parameter. A *fixed* routing algorithm is a static algorithm in which every source–destination edge node pair is assigned a single path. With this scheme, a connection is blocked if there is no wavelength available on the designated path at the time of the request. In *fixed–alternate* routing, a number k, $k > 1$, of paths are computed and ordered off-line for each source–destination edge node pair. When a request arrives, these paths are examined in the specified order, and the first one with a free wavelength is used to establish the lightpath. The request is blocked if no wavelength is available in any of the k paths. Similarly, an adaptive routing algorithm may compute a single path, or a number of alternate paths at the time of the request. A hybrid approach is to compute k paths offline, however, the order in which the paths are considered is determined according to the network state at the time the connection request is made (e.g., least to most congested).

In most practical cases, the candidate paths for a request are considered in increasing order of pathlength. *Pathlength* is typically defined as the sum of the weights assigned to each physical link along the path, and the weights are chosen according to some desirable routing criterion. Since weights can be assigned arbitrarily, they offer a wide range of possibilities for selecting path priorities. For example, in a static (fixed–alternate) routing algorithm, the weight of each link could be set to 1, or to the physical distance of the link. In the former case, the path list consists of the k minimum-hop paths, while in the latter the candidate paths are the k minimum-distance paths (where *distance* is defined as the geographic length). In an adaptive routing algorithm, link weights may reflect the load or "interference" on a link (i.e., the number of active lightpaths sharing the link). By assigning small weights to least loaded links, paths with larger number of free channels on their links rise to the head of the path list, resulting in a *least-loaded* routing algorithm. Paths that are congested become "longer" and are moved further down the list; this tends to avoid heavily loaded bottleneck links. Many other weighting functions are possible.

When pathlengths are sums of link weights, the k shortest path algorithm [18] can be used to compute candidate paths. Each path is checked in order of increasing length, and the first that is feasible is assigned the first free wavelength in the wavelength list. However, the k shortest paths constructed by this algorithm usually share links. Therefore, if one path in the list is not feasible, it is likely that other paths in the list with which it shares a link will also be infeasible. To reduce the risk of blocking, the k shortest paths can be computed so as to be pairwise link-disjoint. This can be accomplished as follows. When computing the ith shortest path, $i = 1, \ldots, k$, the links used by the first $i - 1$ paths are removed from the original network topology and Dijkstra's shortest path algorithm [19] is applied to the resulting topology. This approach increases the chances of finding a feasible path for a connection request.

Let us now discuss the wavelength assignment subproblem, which is concerned with the manner in which the wavelength list is ordered. For a given candidate path, wavelengths are considered in the order in which they appear in the list to find a free wavelength for the connection request. Again, we distinguish between the static and adaptive cases. In the *static* case, the wavelength ordering is fixed (e.g., the list is ordered by wavelength number). The idea behind this scheme, also referred to as *first-fit*, is to pack all the in-use wavelengths toward the top of the list so that wavelengths toward the end of the list will have higher probability of being available over long continuous paths. In the *adaptive* case, the ordering of wavelengths is typically based on usage. Usage can be defined either as the number of links in the network in which a wavelength is currently used, or as the number of active connections using a wavelength. Under the *maximum-reuse* method, the most used wavelengths are considered first (i.e., wavelength are considered in order of decreasing usage). The rationale

behind this method is to reuse active wavelengths as much as possible before trying others, packing connections into fewer wavelengths and conserving the spare capacity of less used wavelengths. This is turn makes it more likely to find wavelengths that satisfy the continuity requirement over long paths. Under the *minimum-reuse* method, wavelengths are tried in the order of increasing usage. This scheme attempts to balance the load as equally as possible among all the available wavelengths. However, minimum-reuse assignment tends to "fragment" the availability of wavelengths, making it less likely that the same wavelength is available throughout the network for connections that traverse longer paths.

Both reuse schemes introduce communication overhead because they require global network information in order to compute the usage of each wavelength. The first-fit scheme, on the other hand, requires no global information, and since it does not need to order wavelengths in real time, it has significantly lower computational requirements than either maximum reuse or minimum reuse. Another adaptive scheme that avoids the communication and computational overhead of maximum reuse and minimum reuse is *random* wavelength assignment. With this scheme, the set of wavelengths that are free on a particular path is first determined. Among the available wavelengths, one is chosen randomly (usually with uniform probability) and assigned to the requested lightpath.

We note that in networks in which all OXCs are capable of wavelength conversion, the wavelength assignment problem is trivial; since a lightpath can be established as long as at least one wavelength is free at each link and different wavelengths can be used in different links, the order in which wavelengths are assigned is not important. On the other hand, when only a fraction of the OXCs employ converters (i.e., a sparse conversion scenario), a wavelength assignment scheme is again required to select a wavelength for each segment of a connection's path that originates and terminates at an OXC with converters. In this case, the same assignment policies discussed above for selecting a wavelength for the end-to-end path can also be used to select a wavelength for each path segment between OXCs with converters.

The performance of a dynamic RWA algorithm is generally measured in terms of the *call blocking probability*, that is, the probability that a lightpath cannot be established in the network because of lack of resources (e.g., link capacity or free wavelengths). Even in the case of simple network topologies (such as rings) or simple routing rules (such as fixed routing), the calculation of blocking probabilities in WDM networks is extremely difficult. In networks with arbitrary mesh topologies, and/or when using alternate or adaptive routing algorithms, the problem is even more complex. These complications arise from both the link load dependencies (due to interfering lightpaths) and the dependencies among the sets of active wavelengths in adjacent links (due to the wavelength continuity constraint). Nevertheless, the problem of computing blocking probabilities in wavelength-routed networks has been extensively studied in the literature, and approximate analytical techniques that capture the effects of link load and wavelength dependencies have been developed in [8,9,20]. A detailed comparison of the performance of various wavelength assignment schemes in terms of call blocking probability can be found in Zhu et al. [21].

Although important, average blocking probability (computed over all connection requests) does not always capture the full effect of a particular dynamic RWA algorithm on other aspects of network behavior, in particular, fairness. In this context, *fairness* refers to the variability in blocking probability experienced by lightpath requests between the various edge node pairs, such that lower variability is associated with a higher degree of fairness. In general, any network has the property that longer paths are likely to experience higher blocking than shorter ones. Consequently, the degree of fairness can be quantified by defining the *unfairness factor* as the ratio of the blocking probability on the longest path to that on the shortest path for a given RWA algorithm. Depending on the network topology and the RWA algorithm, this property may have a cascading effect that can result in an unfair treatment of the connections between more distant edge node pairs — blocking of long lightpaths leaves more resources available for short lightpaths, so that the connections established in the network tend to be short ones. These shorter connections "fragment" the availability of wavelengths, and thus the problem of unfairness is more pronounced in networks without converters since finding long paths that satisfy the wavelength continuity constraint is more difficult than without this constraint.

Several studies [8,9,20] have examined the influence of various parameters on blocking probability and fairness, and some of the general conclusions include the following:

- Wavelength conversion significantly affects fairness. Networks employing converters at all OXCs sometimes exhibit orders of magnitude improvement in fairness (as reflected by the unfairness factor) compared to networks with no conversion capability, despite the fact that the improvement in overall blocking probability is significantly less pronounced. It has also been shown that equipping a relatively small fraction (typically, 20–30%) of all OXCs with converters is sufficient to achieve most of the fairness benefits due to wavelength conversion.
- Alternate routing can significantly improve the network performance in terms of both overall blocking probability and fairness. In fact, having as few as three alternate paths for each connection may in some cases (depending on the network topology) achieve almost all the benefits (in terms of blocking and fairness) of having full wavelength conversion at each OXC with fixed routing.
- Wavelength assignment policies also play an important role, especially in terms of fairness. The random and minimum-reuse schemes tend to "fragment" the wavelength availability, resulting in large unfairness factors (with minimum-reuse having the worst performance). On the other hand, the maximum-reuse assignment policy achieves the best performance in terms of fairness. The first-fit scheme exhibits a

behavior very similar to maximum-reuse in terms of both fairness and overall blocking probability, and has the additional advantage of being easier and less expensive to implement.

4. MULTICAST ROUTING AND WAVELENGTH ASSIGNMENT

In Sections 2 and 3, we considered static and dynamic RWA algorithms, respectively, for establishing lightpaths in optical networks. In Ref. 22, the concept of a lightpath was generalized into that of a *light tree*, which, like a lightpath, is a clear channel originating at given source node and implemented with a single wavelength. But unlike a lightpath, a light tree has multiple destination nodes, hence it is a point-to-multipoint channel. The physical links implementing a light tree form a tree, rooted at the source node, rather than a path in the physical topology, hence the name. That study [22] focused on virtual topology design (i.e., static RWA) for point-to-point traffic and observed that, since a light tree is a more general representation of a lightpath, the set of virtual topologies that can be implemented using light trees is a superset of the virtual topologies that can be implemented only using lightpaths. Thus, for any given virtual topology problem, an optimal solution using light trees is guaranteed to be at least as good and possibly an improvement over the optimal solution obtained using only lightpaths. Furthermore, it was demonstrated that by extending the lightpath concept to a light tree, the network performance (in terms of average packet hops) can be improved while the network cost (in terms of the number of optical transmitters and receivers required) decreases.

Light trees are implemented by employing optical devices known as *power splitters* [2] at the OXCs. A power splitter has the ability to split an incoming signal, arriving at some wavelength λ, into up to m outgoing signals, $m \geq 2$; m is referred to as the *fanout* of the power splitter. Each of these m signals is then independently switched to a different output port of the OXC. Note that, because of the splitting operation and associated losses, the optical signals resulting from the splitting of the original incoming signal must be amplified before leaving the OXC. Also, to ensure the quality of each outgoing signal, the fanout m of the power splitter may have to be limited to a small number. If the OXC is also capable of wavelength conversion, each of the m outgoing signal may be shifted, independently of the others, to a wavelength different than the incoming wavelength λ. Otherwise, all m outgoing signals must be on the same wavelength λ.

While the authors of Ref. 22 considered mainly point-to-point traffic, another attractive feature of light trees is the inherent capability for performing multicasting in the optical domain (as opposed to performing multicasting at a higher layer, e.g., the network layer, which requires electrooptic conversion). Such wavelength-routed light trees are useful for transporting high-bandwidth, real-time applications such as high-definition TV (HDTV). Therefore, OXCs equipped with power splitters will be referred to as *multicast-capable* OXCs (MC-OXCs). Note that, just like with converter devices, incorporating power splitters within an OXC is expected to increase the network cost because of the large amount of power amplification and the difficulty of fabrication.

With the availability of MC-OXCs and the existence of multicast traffic demands, the problem of establishing light trees to satisfy these demands arises. We will call this problem the *multicast routing and wavelength assignment* (MC-RWA) problem. MC-RWA bears many similarities to the RWA problem discussed in Sections 2 and 3. Specifically, the tight coupling between routing and wavelength assignment remains, and even becomes stronger; in the absence of wavelength conversion the same wavelength must be used by the multicast connection not only along the links of a single path but also along the links of the whole light tree. Since the construction of optimal trees for routing multicast connections is by itself a hard problem [23], the combined MC-RWA problem becomes even harder. Depending on the nature of traffic demands, we also distinguish between static and dynamic MC-RWA problems. As we already know, optimal solutions for the point-to-point RWA problems are not practically obtainable, and with a more general construct (the light tree) and hence a much larger search space, this will be even more true for the MC-RWA problems. In general, the approaches to tackling the static and dynamic MC-RWA problems are similar to the ones we described for the static and dynamic RWA problems, respectively. The challenge in this case is to design heuristics that can cope with the increased complexity of the problem and yet produce good solutions. In the following we summarize the most recent work on multicasting in optical networks, but the reader should keep in mind that this is an area of current research.

The benefits of multicasting in wavelength routed optical networks were first demonstrated by Malli et al. [24]. Specifically, it was shown that using light trees (spanning the source and destination nodes) rather than individual parallel lightpaths (each connecting the source to an individual destination) requires fewer wavelengths and consumes a significantly lower amount of bandwidth. In another paper [25] both the static and the dynamic MC-RWA problems were studied. A MILP formulation that maximizes the total number of multicast connections was presented for the static MC-RWA problem. Rather than providing heuristic algorithms for solving the MILP, bounds on the objective function were presented by relaxing the integer constraints. The dynamic MC-RWA problem, on the other hand, was solved by decoupling the routing and wavelength assignment problems. A number of *alternate* trees were constructed for each multicast connection using existing routing algorithms. When a request for a connection arrives, the associated trees are considered in a fixed order. For each tree, wavelengths are also considered in a fixed order (i.e., the first-fit strategy). The connection is blocked if no free wavelength is found in any of the trees associated with the multicast connection.

Finally, the problem of constructing trees for routing multicast connections was studied [26] independently of wavelength assignment, under the assumption that not all OXCs are multicast capable, that is, that there is a limited number of MC-OXCs in the network. Four new algorithms were developed for routing multicast

connections under this *sparse light splitting* scenario. While the algorithms differ slightly from each other, the main idea to accommodate sparse splitting is to start with the assumption that all OXCs in the network are multicast capable and use an existing algorithm to build an initial tree. Such a tree is infeasible if a non-multicast-capable OXC is a branching point. In this case, all but one branches out of this OXC are removed, and destination nodes in the removed branches have to join the tree at a MC-OXC.

BIOGRAPHY

George N. Rouskas received his degree in electrical engineering from the National Technical University of Athens (NTUA), Athens, Greece, in 1989, and M.S. and Ph.D. degrees in computer science from the College of Computing, Georgia Institute of Technology, Atlanta, Georgia, in 1991 and 1994, respectively. He joined the Department of Computer Science, North Carolina State University, Raleigh, North Carolina, in August 1994, where he is currently an associate professor. During the 2000–2001 academic year he spent a sabbatical term at Vitesse Semiconductor, Morrisville, North Carolina, and in May and June 2000 he was an invited professor at the University of Evry, Evry, France. He is a recipient of a 1997 NSF Faculty Early Career Development (CAREER) Award, and a coauthor of a paper that received the Best Paper Award at the 1998 SPIE conference on all-optical networking. He also received the 1995 Outstanding New Teacher Award from the Department of Computer Science, North Carolina State University, and the 1994 Graduate Research Assistant Award from the College of Computing, Georgia Tech. He was a coguest editor for the *IEEE Journal on Selected Areas in Communications*, Special Issue on Protocols and Architectures for Next Generation Optical WDM Networks, October, 2000, and is on the editorial boards of the *IEEE/ACM Transactions on Networking, Computer Networks, and Optical Networks*. Dr. Rouskas' interests include network architectures and protocols, optical networks, multicast communication, and performance evaluation.

S

SAMPLING OF ANALOG SIGNALS

JOHN G. PROAKIS
Northeastern University
Boston, Massachusetts

1. INTRODUCTION

Many communication signals that are transmitted from a source to a destination are analog signals. Examples of such signals are speech, images, and video. Since the middle of the twentieth century, the trend has been to convert such analog signals to digital form and to transmit the digital signal using a digital modulation technique. At the receiver, the digital signal can be converted back to an analog signal for the user.

An analog signal is converted to a digital signal through the process of sampling the analog signal periodically and quantizing the samples to obtain a digital signal (a sequence of binary digits), which is then transmitted by a digital communication system. The sampling and quantization processes are generally performed by an analog-to-digital (A/D) converter, whose basic functions are illustrated in Fig. 1. Thus, conceptually, we may view A/D conversion of an analog signal as a three-step process:

1. *Sampling*. This is the conversion of a continuous-time signal $x_a(t)$ into a discrete-time signal $x_a(nT) = x(n)$, where $\{x_a(nT)\}$ are samples of $x_a(t)$ taken at times $t = nT$, and where T is the *sampling interval* and n takes integer values.
2. *Quantization*. This is the conversion of the continuous-valued signal samples $\{x(n)\}$ into discrete-valued signal samples $\{x_q(n)\}$, where the values $\{x_q(n)\}$ are selected from a finite set of possible values. The difference $x(n) - x_q(n)$ is called the *quantization error*.
3. *Coding*. This is the process of representing each quantized value $x_q(n)$ by a b-bit binary sequence.

Although we model the A/D conversion process as shown in Fig. 1, in practice the A/D conversion is performed by a single device whose input is the analog signal $x_a(t)$ and whose output is a sequence of b-bit values representing the quantized samples $x_q(n)$.

2. SAMPLING OF ANALOG SIGNALS

As indicated above, an analog signal $x_a(t)$ that is sampled periodically at $t = nT$ results in the sampled sequence

$$x(n) \equiv x_a(nT), \quad -\infty \le n \le \infty \tag{1}$$

The sampling process is illustrated in Fig. 2. The time interval T between successive samples is called the *sampling interval*, and its reciprocal $1/T$ is called the *sampling frequency*, denoted as

$$F_s = \frac{1}{T} \tag{2}$$

The choice of the sampling frequency is governed by the frequency content of the analog signal $x_a(t)$. To establish this basic relationship, let us consider the sampling of the sinusoidal signal

$$x_a(t) = A \cos 2\pi F t \tag{3}$$

Its sampled values are

$$\begin{aligned} x(n) \equiv x_a(nT) &= A \cos 2\pi F n T \\ &= A \cos 2\pi n \frac{F}{F_s} \end{aligned} \tag{4}$$

We note that $x(n)$ is a discrete-time sinusoidal signal having a normalized frequency $f = F/F_s$. We also observe that discrete-time sinusoids whose normalized frequencies are separated by an integer multiple of unity (or 2π radians) are identical. That is

$$x(n) = A \cos 2\pi n(f + k) = A \cos 2\pi n f \tag{5}$$

where k is any integer. We further observe that the highest rate of oscillation in a discrete-time sinusoid is attained

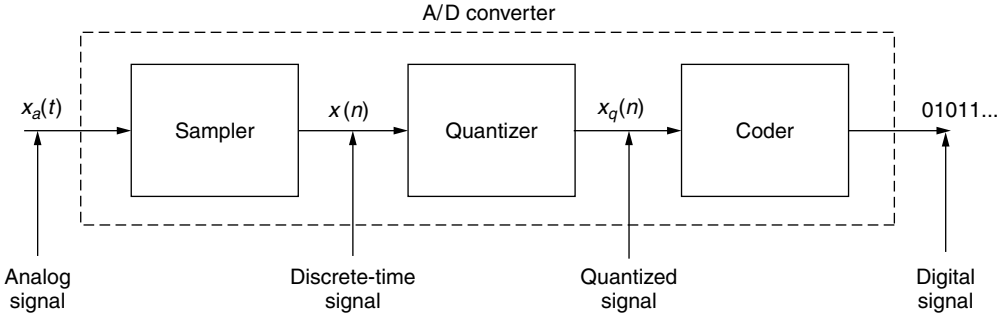

Figure 1. Elements of an analog-to-digital (A/D) converter.

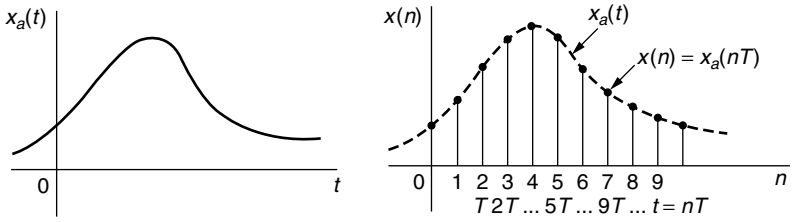

Figure 2. Periodic sampling of an analog signal.

when the normalized frequency $f = \pm\frac{1}{2}$. Any discrete-time sinusoid with frequency $f > \frac{1}{2}$ takes values that are identical to a discrete-time sinusoid whose frequency is contained in the *fundamental range* $-\frac{1}{2} \le f \le \frac{1}{2}$.

The implications of these observations can be fully appreciated by considering the sampling of the two analog sinusoidal signals

$$\begin{aligned} x_1(t) &= \cos 2\pi(10)t \\ x_2(t) &= \cos 2\pi(50)t \end{aligned} \tag{6}$$

at a rate $F_s = 40$ Hz (samples per second). The corresponding discrete-time signals are

$$\begin{aligned} x_1(n) &= \cos 2\pi \left(\frac{10}{40}\right) n = \cos \frac{\pi}{2} n \\ x_2(n) &= \cos 2\pi \left(\frac{50}{40}\right) n = \cos \frac{5\pi}{2} n = \cos \frac{\pi}{2} n \end{aligned} \tag{7}$$

Hence, $x_1(n) = x_2(n)$, so the two sampled signals are identical and, consequently, indistinguishable.

If we are given the sampled values obtained from $\cos \pi n/2$, there is ambiguity as to whether these sampled values correspond to $x_1(t)$ or $x_2(t)$. Since $x_2(t)$ yields exactly the same values as $x_1(t)$ when sampled at $F_s = 40$ samples per second, we say that the frequency $F_2 = 50$ Hz is an alias of the frequency $F_1 = 10$ Hz at the sampling rate of $F_s = 40$ Hz. We also note that F_2 is not the only alias of F_1. At the sampling rate of $F_s = 40$ Hz, the frequencies $F_3 = 90$ Hz, $F_4 = 130$ Hz, and so on, are all aliases of $F_1 = 10$ Hz; that is, the sinusoids $\cos\ 2\pi(F_1 + 40k)t$, $k = 1, 2, \ldots$ sampled at $F_s = 40$ Hz yield identical values.

The preceding observations lead to the conclusion that the highest frequency that can be represented uniquely by sampling an analog signal $x_a(t)$ at a rate F_s is $F_{\max} = F_s/2$. Hence, to avoid aliasing, an analog signal that is to be sampled must be band-limited. This is usually accomplished in practice by prefiltering the analog signal prior to sampling. Thus, the frequency content of the analog signal will be confined to a well-defined frequency band with highest frequency $F_{\max}$. Such a band-limited signal is then sampled at a rate $F_s \ge 2F_{\max}$, so as to avoid aliasing. The critical rate $2F_{\max} = F_N$ is called the *Nyquist sampling rate*.

For example, speech signals that are transmitted over telephone channels are limited to approximately 3200 Hz: $F_{\max} = 3200$ Hz. In this case, the Nyquist sampling rate is $F_N = 6400$ Hz. Such signals are typically sampled at a nominal rate of $F_s = 8000$ Hz. If the speech signal is to be transmitted by pulse code modulation (PCM), for example, each sample is typically (quantized) represented as a 7-bit binary word.

3. FREQUENCY-DOMAIN RELATIONSHIPS

If $x_a(t)$ is an aperiodic signal with finite energy, its (voltage) spectrum $X_a(f)$ is related to $x_a(t)$ by the inverse Fourier transform:

$$x_a(t) = \int_{-\infty}^{\infty} X_a(F) e^{j2\pi Ft} dF \tag{8}$$

The sampled signal sequence is

$$\begin{aligned} x(n) \equiv x_a(nT) &= \int_{-\infty}^{\infty} X_a(F) e^{j2\pi FnT} dF \\ &= \int_{-\infty}^{\infty} X_a(F) e^{j2\pi fF/F_s} dF \end{aligned} \tag{9}$$

The integration range of this integral can be subdivided into an infinite number of intervals of width F_s. Thus, we obtain

$$\begin{aligned} x(n) &= \sum_{k=-\infty}^{\infty} \int_{(k-1/2)F_s}^{(k+1/2)F_s} X_a(F) e^{j2\pi nF/F_s} dF \\ &= \sum_{k=-\infty}^{\infty} \int_{-F_s/2}^{F_s/2} X_a(F - kF_s) e^{j2\pi nF/F_s} dF \\ &= \int_{-F_s/2}^{F_s/2} \left[\sum_{k=-\infty}^{\infty} X_a(F - kF_s) \right] e^{j2\pi nF/F_s} dF \end{aligned} \tag{10}$$

Changing variables in Eq. (10) from F to the normalized frequency $f = F/F_s$ yields

$$x(n) = \left[\int_{-1/2}^{1/2} F_s \sum_{k=-\infty}^{\infty} X_a[(f - k)F_s] \right] e^{j2\pi nf}\, df \tag{11}$$

This equation is simply the inverse Fourier transform that relates the discrete-time signal $x(n)$ to its spectrum $X(f)$. Hence, the spectrum $X(f)$ of the discrete-time signal $x(n)$ is related to the spectrum $X_a(F)$ of the analog signal $x_a(t)$ by the expression

$$X(f) = F_s \sum_{k=-\infty}^{\infty} X_a[f - k)F_s] \tag{12}$$

or, equivalently

$$X\left(\frac{F}{F_s}\right) = F_s \sum_{k=-\infty}^{\infty} X_a(F - kF_s) \tag{13}$$

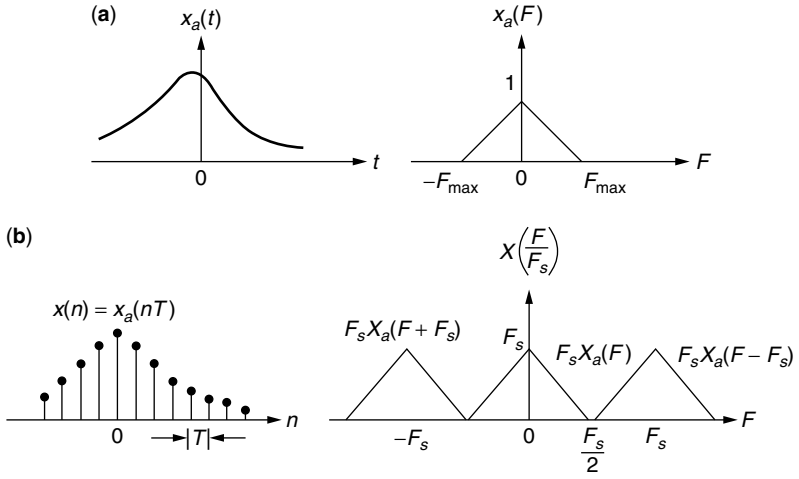

Figure 3. Time-domain and frequency-domain relationships between $x_a(t)$ and $x(n)$.

Figure 3 illustrates the time-domain and frequency-domain relationships between the analog signal $x_a(t)$ and its discrete-time sampled version. We observe that the spectrum of the discrete-time signal $x(n)$ is periodic with period F_s. With $F_s \geq 2F_{\max}$, the spectrum of the discrete-time signal within the fundamental range $|F| \leq F_s/2$ is simply

$$X\left(\frac{F}{F_s}\right) = F_s X_a(F) \tag{14}$$

Hence, the spectrum of the sampled signal is identical (within the scale factor F_s) to the spectrum of the analog signal. This implies that we can reconstruct the analog signal $x_a(t)$ from its samples $x(n)$.

If the sampling frequency F_s is selected such that $F_s < 2F_{\max}$, the periodic continuation of $X_a(f)$, given by Eq. (13) results in spectral overlap. Hence, the spectrum of the sampled signal $x(n)$ contains aliased frequency components of the analog signal spectrum $X_a(F)$. As a consequence, the spectrum of the discrete-time signal $x(n)$ is no longer equal to $F_s X_a(F)$ in the fundamental frequency range $|F| \leq F_s/2$. Therefore, we are unable to reconstruct the analog signal $x_a(t)$ from its samples $x(n)$.

4. THE SAMPLING THEOREM

Given the discrete-time signal sequence $x(n)$ with its spectrum $X(F/F_s)$, as illustrated in Fig. 3, with no aliasing, it is possible to reconstruct the original analog signal $x_a(t)$. This can be accomplished by passing the discrete-time sequence $x(n)$ through an ideal lowpass filter with frequency response

$$G(F) = \begin{cases} T, & |F| \leq \dfrac{F_s}{2} \\ 0, & |F| > \dfrac{F_s}{2} \end{cases} \tag{15}$$

The input to this filter may be expressed as

$$v(t) = \sum_{n=-\infty}^{\infty} x_a(nT)\delta(t - nT) \tag{16}$$

where $T = 1/F_s$ and $\delta(t)$ represents a unit impulse. With $F_s = F_N = 2F_{\max}$, the output of the ideal lowpass filter is

$$x_a(t) = \sum_{n=-\infty}^{\infty} x_a(nT)\frac{\sin(\pi/T)(t - nT)}{(\pi/T)(t - nT)} \tag{17}$$

This equation provides the formula for the ideal reconstruction of the analog signal $x_a(t)$ from its samples $x_a(nT)$. We observe that the ideal reconstruction involves the interpolation function

$$g(t) = \frac{\sin(\pi t/T)}{\pi t/T} \tag{18}$$

and its time-shifted versions (time shifts of nT, $n = \pm 1, \pm 2, \ldots$) which are multiplied by the corresponding samples $x_a(nT)$. We also observe that the interpolation function $g(t - nT)$ is zero at $t = kT$, except at $k = n$. Consequently, $x_a(t)$ evaluated at $t = kT$ is simply the sample $x_a(kT)$. At all other time instants, the weighted sum of the time-shifted versions of the interpolation function combine to yield $x_a(t)$.

The reconstruction formula given by Eq. (17) forms the basis for the *sampling theorem*, which can be stated as follows.

Sampling Theorem. A band-limited continuous-time signal $x_a(t)$ with highest-frequency (bandwidth) $F_{\max}$ can be uniquely recovered from the samples $x_a(nT)$, provided the sampling rate $F_s \geq 2F_{\max}$ samples per second.

5. SAMPLING OF BANDPASS SIGNALS

Suppose that a real-valued analog signal $x(t)$ has a frequency content concentrated in a narrow band of frequencies in the vicinity of a frequency F_c, as shown in Fig. 4. The bandwidth of the signal is defined as $B = B_2 - B_1$ and, usually, $F_c \gg B$. Such a signal is usually called a (narrowband) bandpass signal. Clearly, the highest frequency contained in this signal is $F_{\max} = B_2$. If we blindly apply the sampling principle described in the previous sections, we would sample such a signal at a rate

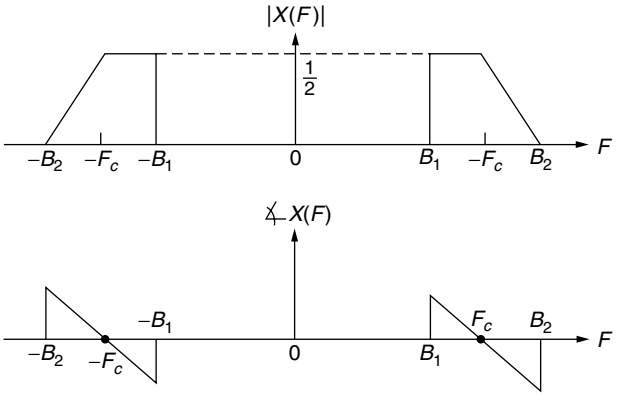

Figure 4. Spectrum of a bandpass signal.

$F_s \geq 2B_2$. However, it is not necessary to sample $x(t)$ at such a high rate.

It is easily shown that any (narrowband) bandpass signal (see, e.g., Ref. 1) can be represented by an equivalent lowpass signal. This representation may be expressed as

$$\begin{aligned} x(t) &= u_c(t)\cos 2\pi f_c t - u_s(t)\sin 2\pi F_c t \\ &= \mathrm{Re}\{[u_c(t) + ju_s(t)]e^{j2\pi F_c t}\} \end{aligned} \tag{19}$$

where $u_c(t)$ and $u_s(t)$ are called the *quadrature components* of the bandpass signal. The complex-valued signal

$$x_l(t) = u_c(t) + ju_s(t) \tag{20}$$

is called the *equivalent lowpass signal*. Its spectrum $X_l(F)$ is illustrated in Fig. 5, and it corresponds to the spectrum obtained by a frequency translation of F_c of the bandpass signal spectrum $X(F)$, shown in Fig. 4. We observe that the spectrum of the bandpass signal is related to the spectrum of the equivalent lowpass signal by the formula

$$X(f) = \tfrac{1}{2}[X_l(f - F_c) + X_l^*(-F - F_c)] \tag{21}$$

Hence, the spectrum of the bandpass signal $x(t)$ can be obtained from the spectrum of the equivalent lowpass signal $x_l(t)$ by a frequency translation.

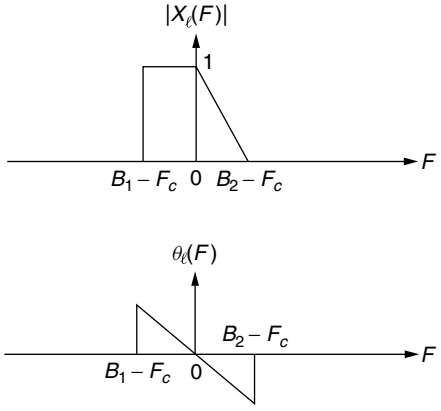

Figure 5. Spectrum of equivalent lowpass signal.

Given the equivalence between the bandpass signal $x(t)$ and the lowpass signal $x_l(t)$, it is advantageous to perform a frequency translation of the bandpass signal by an amount

$$F_c = \frac{B_1 + B_2}{2} \tag{22}$$

and sampling the equivalent lowpass signal. Such a frequency shift can be achieved by multiplying the bandpass signal as given in Eq. (19) by the quadrature carriers $\cos 2\pi F_c t$ and $\sin 2\pi F_c t$ and lowpass-filtering the products to eliminate the signal components at $2F_c$. Clearly, the multiplication and the subsequent filtering are first performed in the analog domain, and then the outputs of the filters are sampled. The resulting equivalent lowpass signal has a bandwidth $B/2$, where $B = B_2 - B_1$. Therefore, it can be represented uniquely by samples taken at the rate of B samples per second for each quadrature component. Thus the sampling can be performed on each lowpass filter output at the rate of B samples per second, as indicated in Fig. 6. Therefore, the resulting rate is $2B$ samples per second.

In view of the fact that frequency conversion to lowpass allows us to reduce the sampling rate to $2B$ samples per second, it should be possible to sample the bandpass signal at a comparable rate. In fact, it is.

Suppose that the upper frequency $F_c + B/2$ is a multiple of the bandwidth B (i.e., $F_c + B/2 = kB$), where k is a positive integer. If we sample $x(t)$ at the rate $2B = 1/T$ samples per second, we have

$$\begin{aligned} x(nT) &= u_c(nT)\cos 2\pi F_c nT - u_s(nT)\sin 2\pi F_c nT \\ &= u_c(nT)\cos\frac{\pi n(2k-1)}{2} - u_s(nT)\sin\frac{\pi n(2k-1)}{2} \end{aligned} \tag{23}$$

where the last step is obtained by substituting $F_c = kB - B/2$ and $T = 1/2B$.

For n even, say, $n = 2m$, Eq. (23) reduces to

$$x(2mT) \equiv x(mT_1)\cos\pi m(2k-1) = (-1)^m u_c(mT_1) \tag{24}$$

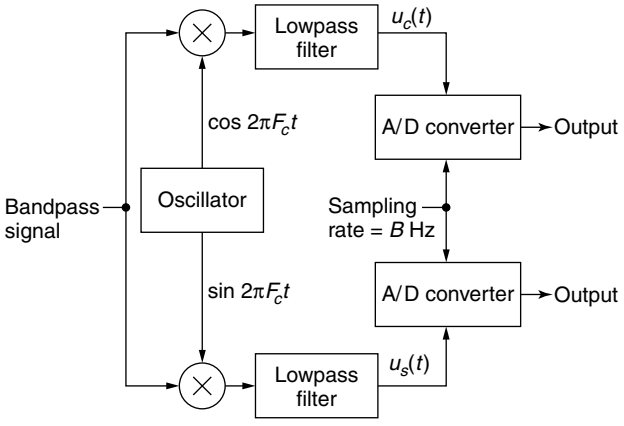

Figure 6. Sampling of a bandpass signal after converting it to a lowpass signal.

where $T_1 = 2T = 1/B$. For n odd, say, $n = 2m - 1$, Eq. (23) reduces to

$$x(2mT - T) \equiv x\left(mT_1 - \frac{T_1}{2}\right) = u_s\left(mT_1 - \frac{T_1}{2}\right)(-1)^{m+k+1} \tag{25}$$

Therefore, the even-numbered samples of $x(t)$, which occur at the rate of B samples per second, produce samples of the lowpass signal component $u_c(t)$. The odd-numbered samples of $x(t)$, which also occur at the rate of B samples per second, produce samples of the lowpass signal component $u_s(t)$.

Now, the samples $\{u_c(mT_1)\}$ and the samples $\{u_s(mT_1 - T_1/2)\}$ can be used to reconstruct the equivalent lowpass signals. Thus, according to the sampling theorem for lowpass signals with $T_1 = 1/B$, we obtain

$$u_c(t) = \sum_{m=-\infty}^{\infty} u_c(mT_1)\frac{\sin(\pi/T_1)(t - mT_1)}{(\pi/T_1)(t - mT_1)} \tag{26}$$

$$u_s(t) = \sum_{m=-\infty}^{\infty} u_s\left(mT_1 - \frac{T_1}{2}\right) \times \frac{\sin(\pi/T_1)(t - mT_1 + T_1/2)}{(\pi T_1)(t - mT_1 + T_1/2)} \tag{27}$$

Furthermore, the relations in Eqs. (24) and (25) allow us to express $u_c(t)$ and $u_s(t)$ directly in terms of samples of $x(t)$. Now, since $x(t)$ is expressed as

$$x(t) = u_c(t)\cos 2\pi F_c t - u_s(t)\sin 2\pi F_c t \tag{28}$$

substitution from Eqs. (27), (26), (25), and (24) into Eq. (28) yields

$$x(t) = \sum_{m=-\infty}^{\infty}\left\{(-1)^m x(2mT)\frac{\sin(\pi/2T)(t - 2mT)}{(\pi/2T)(t - 2mT)} \times \cos 2\pi F_c t + (-1)^{m+k}x((2m-1)T) \times \frac{\sin(\pi/2T)(t - 2mT + T)}{(\pi/2T)(t - 2mT + T)}\sin 2\pi F_c t\right\} \tag{29}$$

But

$$(-1)^m \cos 2\pi F_c t = \cos 2\pi F_c(t - 2mT)$$

and

$$(-1)^{m+k}\sin 2\pi F_c t = \cos 2\pi F_c(t - 2mT + T)$$

With these substitutions, Eq. (29) reduces to

$$x(t) = \sum_{m=-\infty}^{\infty} x(mT)\frac{\sin(\pi/2T)(t - mT)}{(\pi/2T)(t - mT)}\cos 2\pi F_c(t - mT) \tag{30}$$

where $T = 1/2B$. This is the desired reconstruction formula for the bandpass signal $x(t)$, with samples taken at the rate of $2B$ samples per second, for the special case in which the upper-band frequency $F_c + B/2$ is a multiple of the signal bandwidth B.

In the general case, where only the condition $F_c \geq B/2$ is assumed to hold, let us define the integer part of the ratio $F_c + B/2$ to B as

$$r = \left\lfloor \frac{F_c + B/2}{B} \right\rfloor \tag{31}$$

While holding the upper cutoff frequency $F_c + B/2$ constant, we increase the bandwidth from B to B' such that

$$\frac{F_c + B/2}{B'} = r \tag{32}$$

Furthermore, it is convenient to define a new center frequency for the increased bandwidth signal as

$$F_c' = F_c + \frac{B}{2} - \frac{B'}{2} \tag{33}$$

Clearly, the increased signal bandwidth B' includes the original signal spectrum of bandwidth B.

Now the upper cutoff frequency $F_c + B/2$ is a multiple of B'. Consequently, the signal reconstruction formula in Eq. (30) holds with F_c replaced by F_c' and T replaced by T', where $T' = 1/2B'$:

$$x(t) = \sum_{n=-\infty}^{\infty} x(nT')\frac{\sin(\pi/2T')(t - mT')}{(\pi/2T')(t - mT')}\cos 2\pi F_c'(t - mT') \tag{34}$$

This proves that $x(t)$ can be represented by samples taken at the uniform rate $1/T' = 2Br'/r$, where r' is the ratio

$$r' = \frac{F_c + B/2}{B} = \frac{F_c}{B} + \frac{1}{2} \tag{35}$$

and $r = \lfloor r' \rfloor$.

We observe that when the upper cutoff frequency $F_c + B/2$ is not an integer multiple of the bandwidth B, the sampling rate for the bandpass signal must be increased by the factor r'/r. However, note that as F_c/B increases, the ratio r'/r tends toward unity. Consequently, the percent increase in sampling rate tends to zero.

The derivation given above also illustrates the fact that the lowpass signal components $u_c(t)$ and $u_s(t)$ can be expressed in terms of samples of the bandpass signal. Indeed, from Eqs. (24)–(27), we obtain the result

$$u_c(t) = \sum_{n=-\infty}^{\infty}(-1)^n x(2nT')\frac{\sin(\pi/2T')(t - 2nT')}{(\pi/2T')(t - 2nT')} \tag{36}$$

and

$$u_s(t) = \sum_{n=-\infty}^{\infty}(-1)^{n+r+1}x(2nT' - T)\frac{\sin(\pi/2T')(t - 2nT' + T)}{(\pi/2T')(t - 2nT' + T)} \tag{37}$$

where $r = \lfloor r' \rfloor$.

In conclusion, we have demonstrated that a bandpass signal can be represented uniquely by samples taken at a rate

$$2B \leq F_s < 4B$$

where B is the bandwidth of the signal. The lower limit applies when the upper frequency $F_c + B/2$ is a multiple

of B. The upper limit of F_s is obtained under worst-case conditions when $r = 1$ and $r' \approx 2$.

BIOGRAPHY

Dr. John G. Proakis received the B.S.E.E. from the University of Cincinnati in 1959, the M.S.E.E. from MIT in 1961, and the Ph.D. from Harvard University in 1967. He is an Adjunct Professor at the University of California at San Diego and a Professor Emeritus at Northeastern University. He was a faculty member at Northeastern University from 1969 through 1998 and held the following academic positions: Associate Professor of Electrical Engineering, 1969–1976; Professor of Electrical Engineering, 1976–1998; Associate Dean of the College of Engineering and Director of the Graduate School of Engineering, 1982–1984; Interim Dean of the College of Engineering, 1992–1993; Chairman of the Department of Electrical and Computer Engineering, 1984–1997. Prior to joining Northeastern University, he worked at GTE Laboratories and the MIT Lincoln Laboratory.

His professional experience and interests are in the general areas of digital communications and digital signal processing and more specifically, in adaptive filtering, adaptive communication systems and adaptive equalization techniques, communication through fading multipath channels, radar detection, signal parameter estimation, communication systems modeling and simulation, optimization techniques, and statistical analysis. He is active in research in the areas of digital communications and digital signal processing and has taught undergraduate and graduate courses in communications, circuit analysis, control systems, probability, stochastic processes, discrete systems, and digital signal processing. He is the author of the book *Digital Communications* (McGraw-Hill, New York: 1983, first edition; 1989, second edition; 1995, third edition; 2001, fourth edition), and co-author of the books *Introduction to Digital Signal Processing* (Macmillan, New York: 1988, first edition; 1992, second edition; 1996, third edition), *Digital Signal Processing Laboratory* (Prentice-Hall, Englewood Cliffs, NJ, 1991); *Advanced Digital Signal Processing* (Macmillan, New York, 1992), *Algorithms for Statistical Signal Processing* (Prentice-Hall, Englewood Cliffs, NJ, 2002), *Discrete-Time Processing of Speech Signals* (Macmillan, New York, 1992, IEEE Press, New York, 2000), *Communication Systems Engineering* (Prentice-Hall, Englewood Cliffs, NJ: 1994, first edition; 2002, second edition), *Digital Signal Processing Using MATLAB V.4* (Brooks/Cole-Thomson Learning, Boston, 1997, 2000), and *Contemporary Communication Systems Using MATLAB* (Brooks/Cole-Thomson Learning, Boston, 1998, 2000). Dr. Proakis is a Fellow of the IEEE. He holds five patents and has published over 150 papers.

SATELLITES IN IP NETWORKS

ABBAS JAMALIPOUR
University of Sydney
Sydney, Australia

Satellites have been an important element of telecommunications networks for many years in providing long-distance telephony and television broadcasting. The involvement of satellites in IP networks is a direct result of new trends in global telecommunications where the Internet traffic will have a dominant share of the total network traffic and special features of high-capacity satellite channels to be discussed in this article. The large geographical coverage of the satellite footprint and its unique broadcasting capabilities as well as its high-capacity channel keep the satellite as an irreplaceable part of communications systems, despite the high cost and long development and launching cycle of a satellite system.

In this article, we will review the satellite communications systems and introduce a new era for satellite communications toward broadband satellite systems and satellite-for-the Internet systems. This means that the satellite is changing its traditional role as being simply a relay in space into becoming an active element similar to a switch or a router in terrestrial networks. We will start the article with a short historical overview of satellite communications and then provide up-to-date information on new broadband and Internet satellite systems. We will briefly review third-generation wireless cellular systems, where Internet access is considered, in order to show the role and contribution of satellites in these systems and thus in the mobile Internet. Satellite applications within the third-generation wireless terrestrial systems as well as in the global Internet will be discussed. Several implementation topics, including mobility and location management that are common in satellite and terrestrial mobile networks, will also be discussed. We will then open the topics in satellite transport of Internet traffic and challenging issues that need to be resolved. Finally we will conclude the article with a concise but complete discussion on satellite future perspectives to the global Internet connectivity problem.

1. AN OVERVIEW OF SATELLITE COMMUNICATIONS

A satellite is one of the oldest components in telecommunications systems. For almost half a century, satellite networks have provided long-distance communications services to the public switching telephone network (PSTN) as well as television broadcasting. These services are particularly best justified by the large footprint coverage of the satellite, and to this date, there is no substitute for satellites in this field. In these types of service, a satellite acts as a communications repeater or relay (according to whether the transmitted signal is digital or analog) that communicates with ground stations and solves the problem of transmission of electromagnetic waves between different parts of the world that are not in line of sight of each other. A noteworthy achievement in satellite communications is

the formation of INTELSAT (International Telecommunications Satellite Organization), which in 1964 established a means of fixed-satellite service among nations [1].

In the 1980s, satellites were being deployed for the first time in mobile telecommunications by providing direct communications to maritime vessels and aircrafts. The first major development in this area was the INMARSAT satellite system. INMARSAT started a new era of satellite communications, called *mobile satellite services* (MSSs) in 1982. The INternational MARitime telecommunication SATellite organization used a geostationary satellite system using L-band (1.5–1.6 GHz) to provide telecommunication services mainly to ships. In the first generation of MSS, INMARSAT defined five standards: Standard A (1982), Standard B (1993), Standard C (1991), Standard M (1992/93), and the Aeronautical Standard (1992). Different worldwide telecommunication services, including voice, facsimile, and data were considered in these standards. While INMARSAT A and B are mostly considered the service to ships, INMARASAT C is planned to provide service to small craft, fishing boats, and land mobiles. INMARSAT continues its worldwide services as one of the most reliable satellite communication systems.

Although INMARSAT remains as the most distinguishable satellite system of its kind, there were other MSSs developed during the *first-generation mobile satellite systems*, such as QUALCOMM in North America (1989), ALCATEL QUALCOMM for Europe (1991), and the Japanese NASDA system (1987).

Reduction in size and cost of user terminals was the motive for second-generation MSSs started around 1985. In this generation, interconnection of satellite systems with terrestrial wireless systems has also been considered. INMARSAT defined its mini-M standard in 1995 with worldwide voice, data, facsimile, and telex service at 2.4 kbps (kilobits per second). American Mobile Satellite Corporation (AMSC), NSTAR of Japan, European mobile satellite (EMS), and several others are included in the second-generation MSSs.

Satellite systems have always being faced with unavoidable long propagation delay and large transmission power requirements. Consideration of small-size user terminals and direct radiocommunications between users and satellites (i.e., without using a ground station) led to the idea of using satellites in orbits lower in altitude than the geostationary orbit. Among possible orbit selections, low-earth-orbit (LEO) satellites with altitudes of 500–1500 km and medium-earth-orbit (MEO) satellites of altitude 5000–13000 km were considered [1]. The altitude selection given above assures that the satellites reside outside the two Van Allen belts to avoid the radiation damage to electronic components installed in satellites. The use of these nongeostationary satellite systems for commercial purposes started a new era in mobile satellite communications. Use of spot-beam antennas in these satellites produces a cellular-type structure within coverage areas, and hence a frequency reuse scheme can be applied, making the system a high-capacity cellular-like network on the ground with satellites as the base stations in space.

LEO and MEO satellite systems, because of their shorter distance to the earth, solve the problem of long propagation delay and high power consumption, but they introduced new challenges to the communications industry. Since the satellite is closer to the earth, compared to a geostationary satellite, it is not possible to employ just three satellites to cover all parts of the world as in case of geostationary satellite systems. Therefore, for LEO and MEO, a constellation of satellites in order of tens of satellites is required. This means more complexity and, of course, higher cost to the satellite system, which eventually must be passed to the users. Many LEO and MEO satellite systems were proposed in the early 1990s in North America and around the world and obtained frequency spectrum licenses. Only a few of these systems were completed and became operational, including IRIDIUM (1998) with 66 satellites and GLOBALSTAR (2000) with 48 satellites. However, financial problems associated with the high-cost of LEO systems forced IRIDIUM to cease its operation in 2000. Besides higher network complexity and more expensive control management requirements of nongeostationary satellite systems, a LEO or MEO satellite itself has a shorter lifetime than in geostationary systems. This means more frequent satellite launch requirements and higher maintenance cost to the satellite system.

The operational failure of the advanced but complex IRIDIUM satellite system revealed that although the technology for implementing a mobile satellite phone system is available, it is not possible to compete in the cost and services of such a system with the rapidly growing terrestrial cellular systems and new Internet services using LEO satellites. The roaming capability between different second-generation (2G) cellular networks in different countries and those considered in the third-generation (3G) wireless systems are quite adequate to provide telecommunications services to the majority of world population at lower cost and better quality (e.g., delay) than are those that can be achieved through satellite systems. The new trends in the telecommunications industry in transmitting data traffic and Internet traffic at high speed over wireless channels could not be matched by satellite systems. The IRIDIUM system, for example, could provide short data services at the very low data rate of only 2.4 kbps.

Satellite systems, however, maintain their unique feature of broadcasting. *Satellite broadcasting* has been a success for a long time and continues its dominance for long-distance coverage and service to highly populated telephony networks. If this unique feature of satellite systems can be incorporated into the new trends in telecommunications industry toward high-speed Internet access, then a new era of satellite communications technology will have begun. Broadband satellites are being developed for this market.

Broadband satellites [2–5] are recognized as systems that can provide high data rate transmission in the order of $\geq$1 Mbps. Digital video broadcasting (DVB) systems such as Eutelsat, SES, and INTELSAT; proprietary systems such as Spaceway, Astrolink, and iPSTAR; and proposed systems such as Teledesic, SkyBridge, WEST, and Celestri are among such broadband satellite systems. Standardizations of these satellite systems are

ongoing [6] in order to reduce the cost and increase applicability, similar to the way in which terrestrial cellular systems have developed and become successful. In this standardization, multicasting is also considered as a strong feature. Geostationary satellite systems are becoming of main interest for these services. Some of the applications of broadband satellite systems are shown in Fig. 1, which illustrates how satellites can interconnect geographically distant networks through land gateways. The system shown in this figure is designed to provide access to the Internet contents in one place by users of many other networks. Each network usually includes a caching system for fast local multicast to its Internet users.

Broadband satellite systems can be categorized according to their specifications and capabilities. This could be based on the frequency bands of operation (C band 4–8 GHz, Ku band 10–18 GHz, Ka band 18–31 GHz, and higher bands V and Q); the orbit altitude and hence the satellite lifetime; power requirements and antenna size; usage of bent-pipe or onboard processing (OBP) technologies; global or regional coverage of the system; satellite total capacity and user capacity; use of intersatellite links (ISL); number of supported terminals and required gateways; protocol used in the satellite system such as TCP/IP, DVB, and ATM; use of open or proprietary standards; total number of satellites in the system; and the total cost. Most new designs of satellite systems include onboard processing (OBP) and on-board switching (OBS) facilities so that the satellite node changes its simple role of relaying into being an active element in the network. An example of a functional satellite system that includes onboard switching and an ATM-switch-like satellite is shown in Fig. 2.

There are many regulatory and standard bodies currently involved in development of issues related to the satellite communications industry. Regulatory bodies include WRC, FCC, ITU, ERO, and many national and regional regulatory organizations. Standards are developed mainly in IETF, ETSI, TIA, and ITU.

To conclude this section, we must say that satellite systems have long development cycles compared to terrestrial systems, and usually less funding and fewer engineers are involved in their development. Moreover, they compete over a more limited market than cellular systems. Most satellite systems are still proprietary, and interfaces are not public, which, in turn, prevents competition. The standards for satellites will ensure interoperability and real competition and will be required for a broader consumer market. Therefore, in order to see further development in satellite systems, a widely acceptable standardization is vital.

2. SATELLITES FOR THE GLOBAL INTERNET

New multimedia and Internet services demand more cost-effective high-quality and high-speed telecommunication technologies and architectures. The primary issue is how the current global Internet infrastructure can be expanded so that the quality of service can be improved from current best-effort service and that high-speed access can be achieved. In this context, satellites can play an important role in expanding the Internet infrastructure using the large coverage area feature and in providing high-speed data transmission through a high-bandwidth-capacity channel. Satellites, however, would not perform this task as an isolated network but rather use an efficient integration with current terrestrial networks. So instead of having an IP network in the sky, as suggested in earlier proposals on some satellite IP networks, a combination of terrestrial and satellite networks would be a solution to the future high-speed Internet.

In a global Internet infrastructure, satellites can be used for many purposes. They can be used to connect geographically distant segments of the network or interconnect heterogeneous networks. Satellites can provide direct telecommunication service to aircraft, ships, and isolated local networks on the ground and even to individual users. Flexible and quick deployment of bandwidth by satellite systems, make them easily approachable by densely wired networks when required, as a good backup and supporting network.

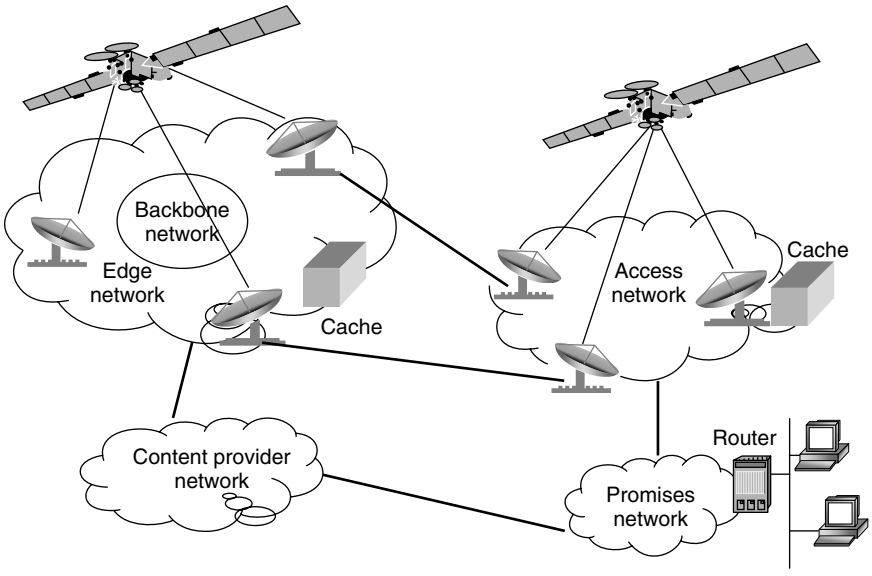

Figure 1. Applications of broadband satellites in interconnecting different networks.

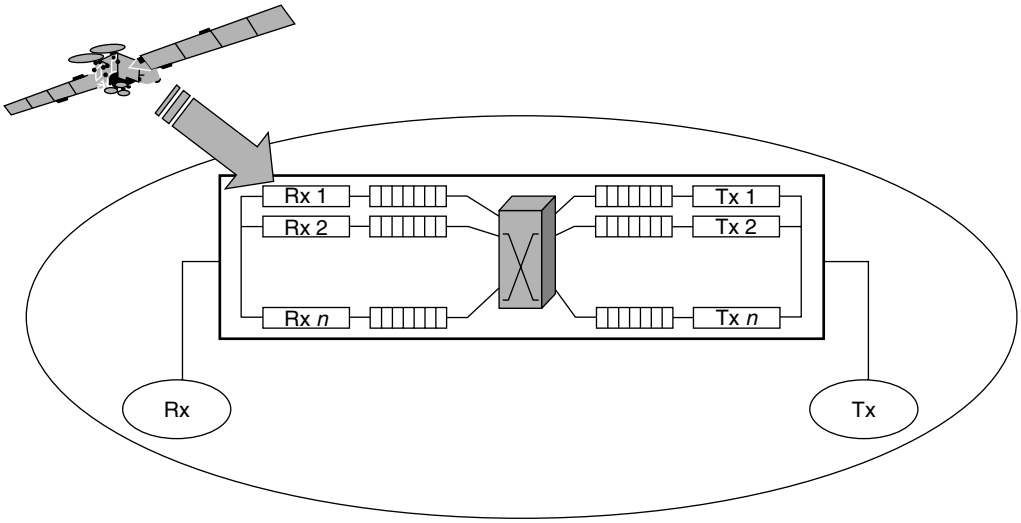

Figure 2. An example of satellite with onboard processing and switching facilities.

Figure 3 shows two different options for the satellite payload that can be used in satellite-based Internet architectures. In Fig. 3a the satellite is used as a reflector in space connecting separate network segments through ground gateways. In Fig. 3b, however, the satellite acts as an active component of the network that can utilize routing and switching processing. The satellites used in Fig. 3 can be on any of the altitudes explained in Section 1; that is, geostationary or nongeostationary (LEO or MEO) or a combination of different altitudes. The satellites shown in Fig. 3b, in addition to having connection to the ground gateways, are also employed in intersatellite links so that network connectivity can be created in the sky independently. This method should be considered as an important option in a future satellite-based Internet architecture. The method requires higher cost for the

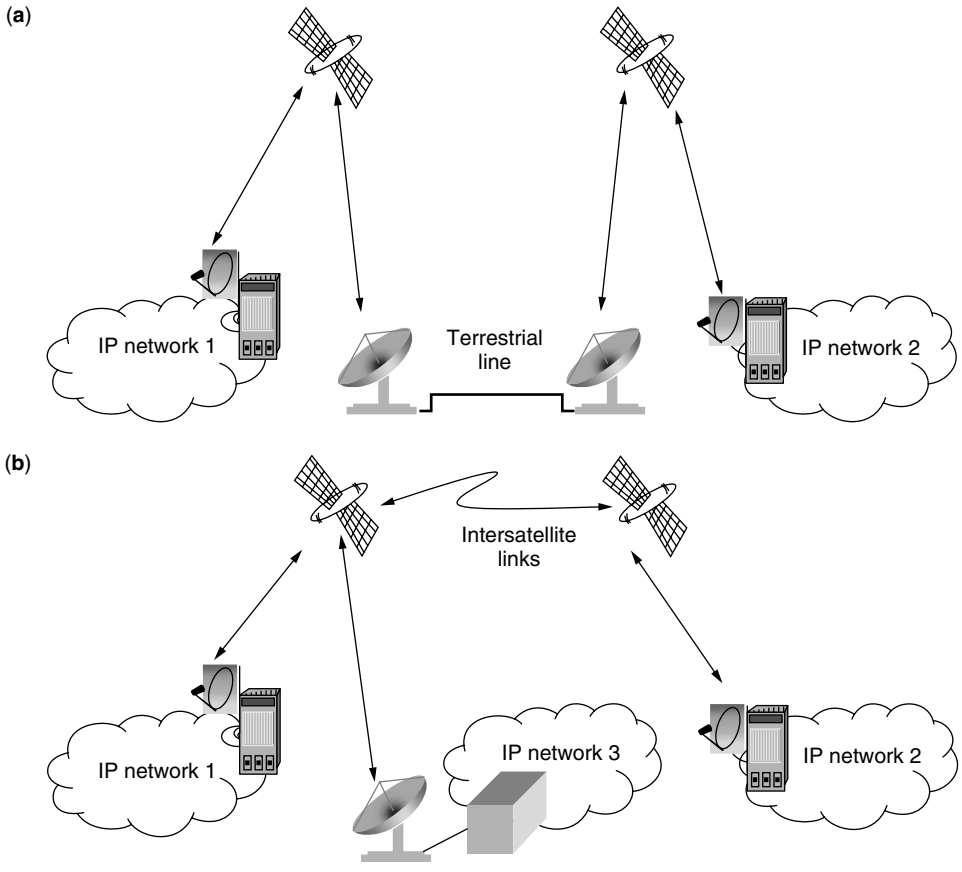

Figure 3. Two different payload options for satellite-based IP architectures: (**a**) bent-pipe architecture; (**b**) onboard processing satellites.

system and more complicated routing management. If special facilities are included in the mobile stations on the earth, both methods can provide direct Internet connectivity to remote users without any other alternative terrestrial telecommunications infrastructure. Hu and Li have summarized the satellite-based Internet architecture described above and current proposals of this kind [7].

A satellite node can also be used as a high-speed downlink for home Internet access. In this method, a home or office user with a satellite receiver, usually used for satellite television, can download the Internet contents at a very high data rate through the satellite downlink channel. A simple architecture of such a satellite–ground high-speed Internet is shown in Fig. 4. In the architecture shown in this figure, the user first connects to its Internet service provider (ISP) using a normal dialup connection. The dialup connection forms a low-speed data communication (e.g., a typical 56-kbps connection) mainly in order to send requests to the Internet servers at the local ISP site. All Internet contents can then be forwarded to the customer through the high-speed satellite downlink on receiving the request. The downlink can send the data to the user at speeds of 1 to a few Mbps using digital videobroadcasting satellites or other types of satellites. This method is especially appropriate for video-on-demand and other type of real-time Internet applications where many users located in the same region want to retrieve the same contents over the Internet. The asymmetry in the Internet traffic that usually results in up to 10 times more data traffic on a typical Internet downlink connection compared to the uplink makes this method of special interest and application. Currently this method is competing with other high-speed Internet access for home users, including cable modems and ADSL technologies. Some prototypes of these satellite Internet systems for home users have already been developed and demonstrated in Europe and other parts of the world [8,9]. With some modifications it is possible to extend the coverage of this type of Internet access to mobile users on the ground and also during long-distance flights and to ships.

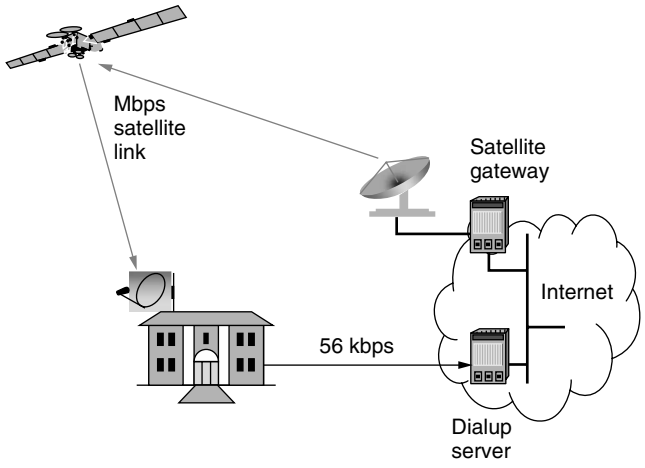

Figure 4. An architecture for satellite high-speed Internet access.

3. SATELLITES IN THIRD-GENERATION WIRELESS NETWORKS

With the increasing popularity of portable computers and the expanding Internet capabilities of mobile phone handsets, a large demand for mobile computing has been generated. Thus, instead of restricting data connections to be maintained always at a fixed position in the network, mobile users will be provided with equivalent multimedia and IP services. There is no doubt that the trend is toward a global mobile networking environment. In such a network, broadband satellites can be considered as an integral part of the network interconnecting the fast-growing terrestrial cellular and wired networks.

Broadband satellite networks for Internet access are the new generation of satellite networks in which Internet-based applications and services will be provided to users regardless of their degree of geographic mobility [2,3]. The main distinction from conventional satellite networks will be that the new satellite networks will support high-data-rate transmission and broadband services and in particular the Internet. The Internet is the most rapidly growing technology, and many new applications such as electronic commerce find their way through the Internet. Therefore, it is not surprising that broadband satellite networks focus on the Internet-based applications for their primary services, although voice and low-bit-rate applications still remain in the list of network services. Asynchronous transfer mode (ATM) will be the envisaged switching mode for future broadband satellites because of its support of a variety of traffic such as constant and variable bit rate and quality of service (QoS) support [2]. Nevertheless, IP routing is considered as another alternative for these satellites due to lower cost and "friendliness" toward the Internet traffic.

In the sphere of terrestrial networks, there are at present two possible approaches for establishing the task of mobile computing: cellular-based and IP-based solutions [3]. Intuitively, while a cellular-based solution enhances the current mobile communications by extending capacity for data and multimedia transmissions, an IP-based solution allows for user mobility by maintaining all ongoing Internet connections even in the presence of frequent handoffs or changes in the network point of attachments. In the forefront of these technologies, third-generation wireless systems are being considered.

Third-generation (3G) wireless communications systems evolve by orienting the integration of three essential domains: broadband, mobile, and Internet (IP). In such a milieu, the increasing feasibility of virtual connections allows mobile users not only to roam freely between heterogeneous networks but also to remain engaged in various forms of multimedia communications. Whether it is geographic coverage, bandwidth, or delay, it would then be up to the users to decide when and how to switch from one access network to another depending on the availability and appropriate cost/performance considerations and, thus, advancing toward an era of all-IP-based communications. Consequently, it will be necessary to implement the 3G system as a universal solution that prompts transparent user roaming (among different wireless networks)

while delivering the widest possible range of cost-effective services [10].

IMT-2000 (International mobile Telecommunications) is a unified 3G mobile system that supports both packet-switched and circuit-switched data transmissions with high spectrum efficiency, making the vision of anywhere, anytime communications a reality. Basically, it is a collection of standards that provides direct mobile access to a range of fixed and wireless networks. Among all, the three most significant developments are UMTS, cdma2000, and UWC-136, which are the 3G successors to the main 2G technologies of GSM, IS95, and AMPS, respectively [11]. The general idea was to make the development of 3G wireless technologies a gradual process from circuit-switched to packet-switched. Take GSM (Global System for Mobile communications) for example. In order to have the system enhanced with improved services (by means of increased capacity, coverage, quality, and data rates), the evolution to 3G was made possible through the incorporation of an intermediate stage called GPRS, the general packet radio services.

Based on the enhanced core network of GPRS, UMTS (Universal Mobile Telecommunications System) is designed to be the backward-compatible 3G standard for GSM. UMTS is the European proposal for a 3G mobile system aiming to support multimedia services with extended intelligent network features and functions. As a first step of the integration, UTRAN (the UMTS terrestrial access radio network) will coexist with GSM access networks. The idea was to develop the UMTS core network by gradually incorporating the desired UMTS features to the GSM/GPRS core network. At this stage, UTRA supports time-division duplex (WCDMA-DSTDD) and frequency-division duplex (WCDMA-DSFDD) modes with the combined operation offering an optimized solution to coverage areas of all sizes. A further multicarrier (MCFDD) mode is to be established at a later date intended mainly for the use in cdmaOne/cdma2000 evolutions [12].

For satellite systems, the situation is somehow different. The most apparent is that the market for satellite systems is much more limited than their cellular counterparts. Therefore, it would be difficult to assume the same approaches for satellite systems. Instead satellite systems can incorporate their global coverage feature for enhancement of the 3G terrestrial networks. Satellites can establish a high-speed backbone network to support the terrestrial networks and also to use their broadcast nature to deliver Internet content at high speed directly to a group a users.

Satellite UMTS (S-UMTS), for example, is considered as a component of 3G networks [13]. The satellite segment of the network connects through appropriate interworking units (IWUs) to the ground segments. An illustration of this incorporation of satellites in providing mobile Internet connectivity is shown in Fig. 5. IWU for the satellite has similar functionality as the gateways used to interconnect 2G and 3G networks for interoperation of these networks during the transition period from 2G to 3G as well as the gateways used for interconnection of different operator networks of the same kind (e.g., GSM). Such a concept is depicted in Fig. 6.

4. TECHNICAL ISSUES FOR SATELLITE-BASED INTERNET IMPLEMENTATION

After the overviews on satellite communications and third-generation wireless networks and introducing the role of satellites within the 3G network architecture in previous sections, in this and the following section we look at some specific but important issues for mobile satellite networks that also apply to terrestrial and cellular networks.

4.1. Mobility Management

It is widely agreed that to allow seamless user mobility, several considerations are necessary to ensure smooth

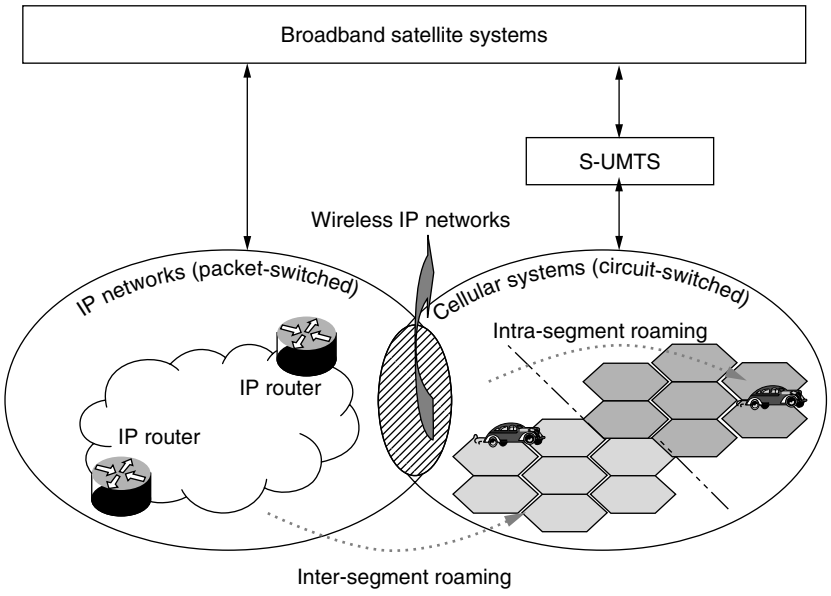

Figure 5. Satellite applications in global communications networks.

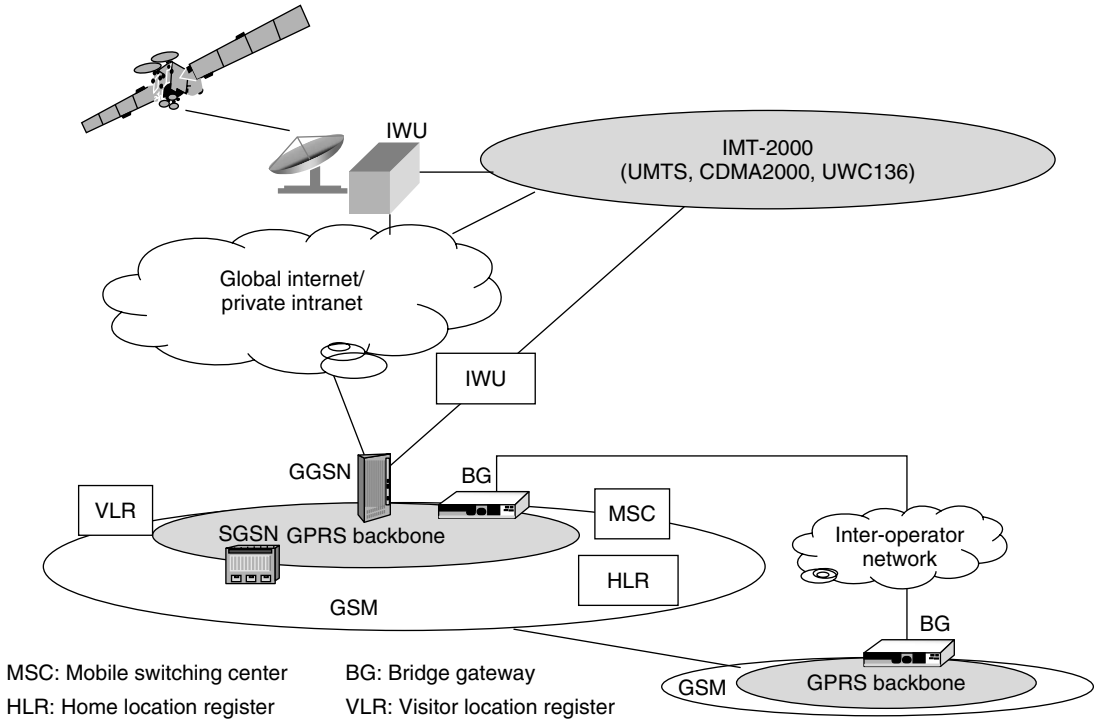

Figure 6. Interconnection of different terrestrial and satellite networks through interworking units.

transitions between different wireless technologies. Ultimately, mobility management is the key in enabling successful convergence between wireless communications and computing. Often, mobility management is interpreted as a process that simply routes packets from one point (the source) to the other (the intended destination). However, such an assumption becomes inadequate as more and more unsolvable issues gradually become apparent. Given its complexity, there seems to be an inevitable need to redefine the previously overlooked issue—*the mobility problem*.

Very briefly, mobility implies adaptability: the capability of maintaining any established network connections by accommodating different system characteristics when a mobile user roams within and/or between networks. More specifically, mobility refers to the initiation of a handoff process, not only when moving between cells (as in a cellular wireless environment) but also when roaming from one wireless network (e.g., satellite) to another (e.g., GPRS). Depending on the level of the network stack from which a movement is considered, mobility can be classified into three categories: air-interface mobility, link-level mobility, and network-level mobility.

Air-interface mobility is perhaps the most common case where a handoff takes place between two adjacent base stations (BSs) or access point (APs) within a radio access network. One can envisage this scenario as a pedestrian walking across microcell boundaries while being engaged in a conversation whether through voice or data transmissions. Link-level mobility goes one level up in the network hierarchy, and is concerned with maintaining a point-to-point protocol (PPP) context across multiple radio access networks. The transitions, however, would still be within the same domain and technology. On the highest network level (among the three categories), network (or IP) mobility provides network level mobility between different access networks (including wireless). Basically, this involves a change in the mobile's domain- (or location-) related IP address due to either (1) a change in radio access technologies or (2) a transition from one network operator to another. Note that in the latter case, the two networks involved might be implemented by the same access technology. Figure 7 attempts to illustrate the differences by listing the hierarchy of concern in the three cases. Note that the overall structure of a subnet can be considered to consist of three distinct stacks, with each stack developed depending on the specific technology (or network architecture) under consideration.

Most issues related to mobility are associated either directly or indirectly with service delivery. By and large, it involves, but is not limited to, the process of routing management, handoff management (including resource management), and also QoS management. Having said that, each operation has its own set of predefined actions. Given that it might be possible to incorporate some of the specific techniques used in satellite systems to enhance the complete operations in a 3G network, the purpose of the brief discussion in the next few paragraphs is to frame this part of the mobility problem.

4.2. Location Management

Obviously, mobility is managed largely through the process of location management. This action involves not only storing and/or retrieving information from the location database but also sending paging signals whenever necessary to locate a roaming user. Although

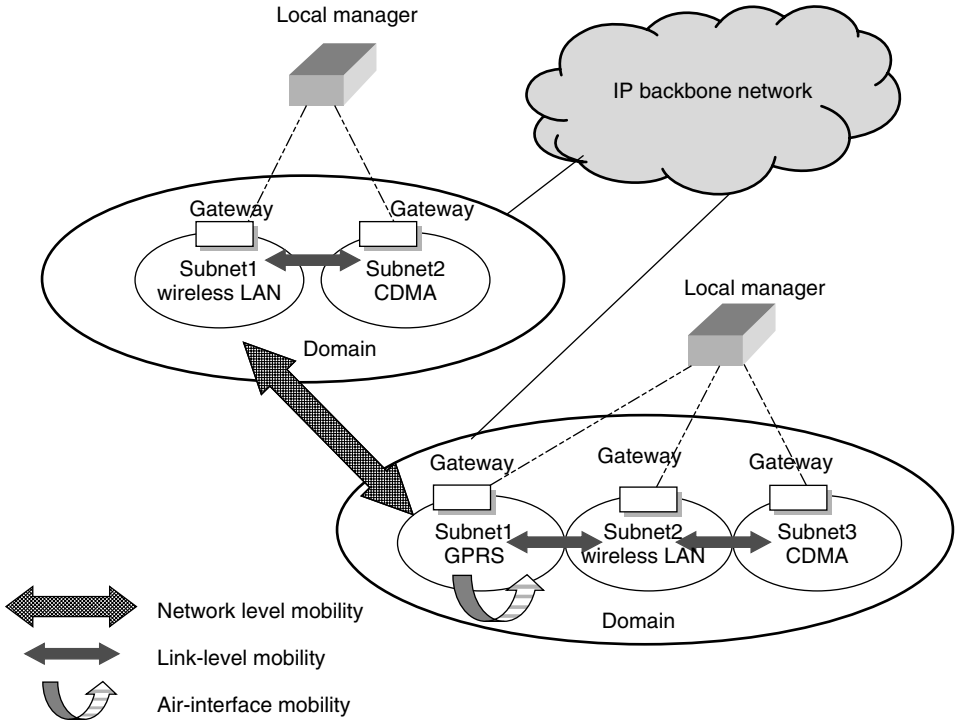

Figure 7. Different levels of mobility.

the need to notify the home network of mobile users' current locations is always present, it is questionable whether accurate location information is essential for mobile nodes (MNs) that are not committed to any data transmissions. Somehow, it seems logical to have separate mobility management techniques for idle and active mobile nodes and thus to allow variations in adjusting the updating frequency at which MNs' movement notifications are sent [14].

4.3. Routing Management

One issue that relates closely to the provision of global roaming is the establishment (or management) of roaming agreements between various networks. As a mobile user roams across various geographic and/or network boundaries, appropriate global roaming agreements between networks (or among ISPs) will also have to be established [15]. In fact, the incorporation of satellites is a particularly significant example of such operations. In scenarios where the limited users population (or terrain conditions) has made it infeasible to implement wireless terrestrial technologies, the availability of satellite systems would instantly form an alternative access medium for a dual-mode handheld terminal.

4.4. Handoff Management

A quality handoff management is particularly important for any real-time transmissions. As continuity plays a crucial part in grading the service quality for such a communicating purpose, it is worth exploring the factors that would have impact on handoff performance.

Mobility implies the necessity of MN handoffs. It is the process of reassociating the roaming mobile with a designated entity (in the new network) to maintain the much needed service continuity. Handoffs are performed at two layers; in the link layer (OSI layer 2, which maintains link connectivity) and also in the IP layer (OSI layer 3, which maintains network access). Physical connection to a base station can often be assumed to be seamless and almost instantaneous. The term network access denotes a MN's capability to exchange traffic in its current subnet without compromising its permanently allocated identity (IP address). A MN is said to have network access when its current subnet location corresponds with its registered network access point [16].

Successful handoffs are also crucial to ensure continuity of ongoing data connections (hence the provision of seamless roaming). However, to appreciate various coexisting network standards, decisions on the necessity of a handoff should be based on underlying network characteristics and specific application scenarios. This is particularly the case for intertechnology roaming (e.g., overlaying networks of Wireless LAN and GPRS), where the system characteristics might be significantly different. Essentially, a tradeoff analysis among the resultant throughput, data rate, latency, and disruption measures would be beneficial in such instances, to determine the actual essentiality of a handoff action. In this respect, the availability of resources has a direct influence on the number of successful handoffs. Thus, specific issues with regard to resource management, such as channel allocation schemes and call admission controls, should all be carefully considered.

4.5. Quality of Service Management

Quality of service management is another significant area that has gained tremendous research interest at both

academic and commercial levels. In particular, with the gradual replacement of voice traffic by data traffic (and multimedia transmissions), a proper implementation of suitable bandwidth allocation mechanisms is crucial to allow successful provision of satisfying customer services. Even apart from this, the possibility of having a network capable of maintaining multiple, concurrent QoS flows (for various applications running simultaneously) would also be advantageous. In addition, the users should be given the opportunity to alter or renegotiate (when desired) the predefined service-level specifications (SLS) with the corresponding providers through a continuous monitoring process of customer requirements [17].

Finally, there is a need to set up necessary SLS between networks. This is important as it allows user mobility to be managed independently of the access and backbone networks (e.g., B-ISDN or GSM), while maintaining a certain quality level that has been specified by any one particular mobile user.

5. MOBILITY MANAGEMENT IN MOBILE SATELLITE NETWORKS

In the previous section we discussed some important aspects of mobility management. Mobile satellite systems using nongeostationary orbits such as LEO and MEO have characteristics very similar to those of cellular networks, and thus those issues are common between both networks. The main similarity is that most of these systems use the cellular concept of increasing the total system capacity through a cellular-like coverage area arrangement introducing similar handoff issues as those involved in cellular systems. There is, however, a major difference between the proposed scheme in satellite systems and what exists in the sphere of cellular networks. The key operational concept that differentiates the specific operations of mobility management in the two systems is the "entity" being considered as the moving object. While the former encounters *mobile* movements within a fixed network architecture, the latter incurs *satellite* movements in reference to fixed mobile nodes. Essentially, this suggests that the mobility management technique will be different.

Furthermore, while the prediction of mobile's deterministic location is relatively easy to obtain (given the traveling characteristics, particularly speed of the LEO satellites), such certainty is not guaranteed in cellular systems. In other words, the difficulties encountered in cellular networks do not seem applicable to its satellite–mobile network counterparts. As a result, appropriate modification of the existing ground based solutions will be necessary before similar operations are suitable for applications on satellite-incorporated third-generation systems. Generally, it would be conceptually a lot easier to anticipate satellite movements than mobile movements. Besides, the rate of call arrival would not be essential in the latter case (i.e., paging seems to be less of a problem for satellite applications).

The use of LEO satellites is most favorable for its high traffic capacity and reduced user power requirements in both satellites and the ground terminal. However, as individual LEO satellites rotate relatively fast along the earth's surface, handoff becomes a particular concern in coping with the nonstationary nature of the coverage area. Depending on the relations of the two satellites involved in the handoff operations, three types of handoff are classified. Basically, *intrasatellite handoffs* are used to describe changes between spot beams under the management of the same satellite. With the increasing involvement of network management, *intersatellite handoffs* indicate handoffs between satellites and link handoffs incur due to changes in the connection pattern of satellite footprints (or satellite network topology). As an example of the latter scenario, such handoffs occur when links to adjacent orbits are turned off when the concerned satellite moves near to the polar region. Thus, the task is not only to utilize the available frequency spectrum efficiently but also to minimize unnecessary forced termination of connections due to handoff failures. In other words, it would be essential to at least attempt to anticipate user motions and to reserve the resources accordingly for the predicted residual time. A brief literature survey indicates that two major prioritization techniques were designed specifically for such purposes: (1) use of guard channels and (2) queuing of handoff requests when the resources were not currently available. Consequently, the operation of call admission control also becomes important as it decides whether sufficient resources would be available to accommodate the newly arrived transmission requests [18].

Cellular networks, on the other hand, focused more on the efficient operations of location management specifically for idle mobile users. Thus, although the basic problem of managing mobility is the same, the actual emphasis on the system developments is different for satellite and cellular systems. In fact, because of the movement of the LEO satellites, definitions of location area (LA) cannot be fixed even for the duration of a connection. Consequently, it is difficult to reapply some of the existing solutions from one system to the other (i.e., from cellular to satellite and vice versa). However, there are certain aspects where the "approaches" might be useful to seek alternative solutions for the open issues identified. For example, in terms of routing [19], a protocol has been developed in an attempt to reduce the frequency rerouting attempts during a link handoff.

Basically, *target probability* is defined to quantify the estimated duration of residency of a mobile terminal on one particular intersatellite link (ISL). During the route establishment of a new call, only links that can demonstrate a lifetime of greater than the target probability will be considered to form segments of the route. Although it might not seem obvious, this idea is similar to the predicting method used in location management operations in cellular networks, specifically, in the sphere of sequential paging where the optimal sequence is selected according to the probability of residence in individual subsections (or subareas). Thus, while acknowledging the fact that the prediction method would have been easier in the satellite systems (because its motion is deterministic and predictable), the goal

of determining efficient operations in both systems is the same.

Consequently, it becomes necessary to more closely identify the differences (or relations) between the operations of handoff and location management. Clearly, handoff management is significant only when the mobile unit is active; specifically, it is about the appropriate reservation of resources (such as bandwidth) along the roaming path of a mobile user while engaging in a call connection. Its efficient operation is important to ensure that the various aspects of the QoS requirements (e.g., throughput versus forced call termination) are satisfactorily complied. Location management, on the other hand, is intended mainly for users who are currently idle but are expected to receive calls (or become active) while they frequently change their point of attachment to the network. In essence, only sufficient location information (about the mobile) is maintained so that the network could loosely track the mobile's movement and subsequently incur a minimal paging (or searching) load when the precise residency is required. Consequently, it would be correct to conclude that the predicted information for handoff needs to be more reliable than that desired for efficient location management. On the basis of this observation, it seems potentially viable to combine (at least to some extent) the operations of the two management processes of handoff and location.

6. SATELLITE TRANSPORT OF INTERNET TRAFFIC

Broadband satellite networks are being developed to transport high-speed multimedia and in particular Internet traffic through high-capacity satellite channels to network segments as well as to individual users. As in the case of any other wireless network designed to deliver Internet traffic, broadband satellite networks need to connect to the backbone wired Internet on the ground. TCP (Transmission Control Protocol) is the most commonly used protocol at the transport layer of the network stack in the Internet, originally developed in wired networks with low bit error rate (BER) in the order of less than 10^{-8}. In this context, any wireless network with Internet service needs to be compatible with the protocol used in the wired network: mainly the TCP/IP protocol. There are, however, some design issues in the TCP/IP protocol, which make it difficult to use it efficiently over the wireless and satellite links. There have been many research activities comparing the performance of TCP in high-BER and high-latency channels and modification proposals to improve its performance in terrestrial and satellite wireless networks [20–24].

TCP has been designed and tuned for networks in which segment losses and corruption of performance are due mainly to network congestion. This assumption might be invalid in many of the emerging networks such as wireless networks. The flow control mechanism used in TCP is based on timeout and window-size adjustment, which can work with high utilization in wired networks with low BER, in the order of 10^{-8}. However, when the wireless channel is used (partially or totally) as the physical layer with a BER as high as 10^{-3}, it may perform inefficiently. The reason is that in the wireless channels the main cause for packet loss is the high BER and not congestion as it is in wired networks. The low efficiency of the TCP in a wireless channel is a result of the fact that the TCP misinterpreted the packet loss because of high error rate and congestion. On the other hand, in high-latency networks (such as satellite networks) adjustment of the window size could take a long time and reduce the system throughput.

TCP has the ability to probe the unused network bandwidth by a mechanism called *slow start* and also to back off the transmission rate on detection of congestion through the *congestion avoidance* mechanism. At the connection startup, TCP initializes a variable called *congestion window* to a value of one segment. This variable determines the transmission rate of TCP. The window size is doubled at every round-trip period until a packet loss is experienced. At this time, the congestion avoidance phase commences, the window size is halved, and the lost packet is retransmitted. During this phase of TCP, the window size is increased only linearly by one segment at each round-trip period and might be halved again on detection of another packet loss. If the retransmitted packet is lost, the timeout mechanism employed in TCP reduces the window size to one. Since all these procedures are performed at the periods equal to round-trip delay of the channel, the system throughput could be degraded significantly where high-latency channels such as geostationary satellites are involved. Therefore, the high-latency satellite channel, combined with the slow increase of the TCP congestion window size, results in underutilization of the satellite high-capacity channel.

Some modifications to the basic TCP can be made to ensure more efficient performance in high-latency satellite networks with Internet services (e.g., see Refs. 21–23 and their reference lists). *Selective acknowledgment* (SACK) TCP (RFC 2018), for example, is a method in which multiple losses in a transmission window can be recovered in one round-trip period instead of two in the basic TCP. *TCP for transactions* (T/TCP) also reduces the user perceived latency to one round-trip delay for short transmissions (RFC 1644). In *TCP spoofing* (cited by partridge and shepard [21]), a router close to the satellite link is considered that sends back acknowledgments for the TCP data. The responsibility of any segment loss in this method belongs to the router. In another method, called *split TCP*, a TCP connection is divided into multiple TCP connections and a special *satellite TCP* connection is employed for the satellite link part.

Another alternative for delivering Internet traffic through broadband satellite networks and simultaneously providing quality of service is to use IP-over-ATM or ATM protocols. In this regard, the IP protocol will provide the availability of various Internet applications, whereas the ATM protocol supports connection between two end-user terminals with a guaranteed end-to-end quality of service. An example of such protocol combination has been proposed for the Astra Return Channel System (ARCS), a geostationary multimedia satellite system using the Ka band on the return channels and the Ku bands on the forward channels [25].

In conclusion, we can say that the use of basic TCP in future broadband satellite networks will impose significant problems, especially in the case of short transmissions (compared with the channel delay–bandwidth product). For the geostationary satellite links the major problem with TCP is the long round-trip time, whereas in the case of non-geostationary satellite networks, the round-trip delay variation or jitter becomes more dominant. In both situations, the burst error nature of the satellite channel and the high BER require more sophisticated flow and congestion control mechanisms that can separate the segment loss because of network congestion or because of high channel error rate.

7. SUMMARY AND CONCLUSIONS

In this article, we summarized the satellite communications from a networking point of view in order to see the role of satellites in future mobile and fixed IP networks. The historical summary provided in the first section of this article revealed that despite the high initial investment and maintenance cost of satellite systems, satellites will remain as an irreplaceable component for long-distance communications and multimedia broadcasting. With the progress in optical communications and increasing number of transoceanic cables, it may be mistakenly thought that cable will replace the satellite for long-distance communications. However, the satellite's easy and quick deployment of additional capacity in any part of the world provides a distinct advantage over the deployment of cable systems. Improvement in cable television also could not replace satellite's broadcasting feature, especially due to the satellite's large footprint and simpler deployment.

When it comes to high-speed Internet access to the home, office, ships, aircraft, and mobile users, again satellite systems show its unique features. The global Internet needs expansion in both the geographic domain and data transport capacity. Satellites would be the main telecommunications component, if not the only one, as in many terrain circumstances, that can promise such expansion. The satellite huge onboard channel capacity and large coverage area are sufficient to provide future deployment of new systems. A very handy example would be the efforts toward realization of in-flight Internet access to passengers using satellite networks by major aircraft companies and airlines [26]. Satellites will soon bring inexpensive Internet access to long-distance flights and using voice-over-IP techniques make a huge reduction in the cost of phonecalls from and to airplanes.

For high-speed Internet access to the home and small-office users, currently ADSL and cable modem are the two leading technologies. With new digital videobroadcasting satellite systems in North America and Europe, however, these technologies found a need to compete with the satellites. The number of subscribers to satellite high-speed Internet access is increasing and close to the other two technologies, and this number is expected to increase even more rapidly by introduction of inexpensive satellite receivers in the near Future.

Satellites have an even larger contribution in IP networks than to the individual access discussed above. A satellite node can be an intelligent ATM switch or IP router in the sky interconnecting segments of the backbone networks on the earth. Similar to the conventional usage of satellites in public switching telephony networks, satellites can play an important role in future packet-switched networks, including the public Internet. The third-generation wireless networks and beyond consider Internet and multimedia traffic to have the dominant share of the network traffic load, and satellites have already shown their role in completion of any terrestrial mobile network. An example of satellite UMTS was given in this article to outline the role of satellites in future mobile communication systems. Satellite ground stations acting as an interworking unit can solve the roaming issue between heterogeneous wired and wireless terrestrial networks, expanding the telecommunications to its ultimate universal stage.

Some important technical implementation issues concerned with a global IP network have been discussed in this article. Mobility management has been revisited and redefined and location, handoff, routing, and quality of service managements have been discussed. All these issues are current research topics in mobile and satellite communications. For the high-latency satellite channel, as well as the error-prone wireless channel (including both satellite and terrestrial), the need for improvement in transport protocols currently employed in the Internet has been discussed and state-of-the art research activities toward improvement of TCP protocols has been reviewed. Note that other researchers are also currently working to improve the error probability of the wireless channel using forward error correction (FEC) schemes and sophisticated coding algorithms. Although these works are of great importance in the establishment of a better-quality wireless channel, we should not forget there are always situations in which the wireless signal-to-noise ratio is too low and no coding scheme can improve it. Therefore, a better solution would lie in the higher layers of the network, including the transport and network layers, where enhanced flow control algorithms speed up the data rate and the throughput of the wireless channel.

BIOGRAPHY

Abbas Jamalipour has been with the School of Electrical and Information Engineering at the University of Sydney, Australia, where he is responsible for teaching and research in wireless data communication networks and satellite systems, since 1998. He holds a Ph.D. degree in Electrical Engineering from Nagoya University, Japan. His current areas of research include wireless broadband data communications and wireless IP networks, mobile and satellite communications, traffic modeling, and congestion control. He is a recipient of a number of technology and paper awards and has authored two technical books and coauthored two others. He has authored numerous publications in these areas, and given short courses and tutorials in major international conferences. He has served on several major conferences technical committees, and organized and chaired many

technical sessions and panels in international conferences, including a symposium on satellite IP in IEEE Globecom 2001. He is the Vice Chair to the Satellite and Space Communications Committee of the IEEE ComSoc and has served as a guest editor to two special issues on 4G networks in IEEE magazines. He is a technical editor to the *IEEE Wireless Communications Magazine* (formerly, *Personal Communications Magazine*) and a Senior Member of IEEE.

SCALAR AND VECTOR QUANTIZATION

TIMO KAUKORANTA
Turku Centre for Computer Science (TUCS)
University of Turku
Turku, Finland

1. INTRODUCTION

Although the term *quantization* is not commonly used in our everyday life, the phenomenon itself is familiar to everyone. There the word *quantization* is known as *rounding*. We round the ages of the people to exact numbers of years even if the accurate age is a real number, which can have infinite decimal places. We apply rounding to several measurements in our life such as weights, distances, and periods of time. The purpose of rounding, or quantization, is to make these measurements easier to understand and handle. The measurements in these everyday examples are *scalars*, namely, single numbers, which present the amount of some quantity. This technique of rounding scalars is in fact known as *scalar quantization* (SQ).

Quantization can be considered as a technique for analog-to-digital conversion and data compression. By *quantization*, an originally analog signal, for example audio or video, is transformed into a digital form. This is very important operation because of the well-known benefits that digitization offers for signal processing. As

to the compression, speech and image data demand huge amounts of storage space so that many applications, such as in the fields of medicine or data communication, suffer from the lack of efficiency in coding of data.

Analog-to-digital conversion can be performed by SQ. There the original signal is sampled at some frequency f producing a sequence of samples x_i. These samples are then quantized so that they attain values from a set of predetermined *reproduction values* or *points* c_j. While the set of sample values may be unlimited, the size of the reproduction values is small and fixed. A unique binary word (code) w_j, which can simply be the index j of the reproduction value, is assigned to each reproduction value. This codeword is stored or transmitted instead of the original sample x_i.

In many applications we must store and transmit structured collections of data instead of scalars. If these data can be treated as vectors of fixed dimensionality, we can, instead of using the exact values of the vectors, handle their approximations. This is much like in the rounding process for individual scalars, but now we speak about *vector quantization* (VQ). Our hope is again to get advantage in transmission times and the storage space.

Generally, on the basis on the ability to preserve the information, compression techniques can be classified to *lossy* and *lossless*. A lossless compression technique reconstructs information exactly as it was before compression. Instead, a lossy compression technique can produce distortion to information, but the idea is that original information can be reproduced at sufficient accuracy, that is, that no necessary information is missing. The benefit of lossy compression is that it is possible to reach better compression ratios than by using lossless techniques.

Both scalar and vector quantization use fixed number of reproduction levels. Because the number M of these levels is normally much smaller than the number of all different inputs, the quantizer can be interpreted as a compression technique. The number of bits used to represent the binary word w_j may be a fraction of the number of bits needed to represent the corresponding sample of the original signal. On the other hand, quantization clearly loses some information; all possible input values cannot be reproduced. Therefore, quantization is a lossy compression technique.

It is typical that the input signal of a vector quantizer has already been scalar quantized. Single sample values (from the point of view of the vector quantizer) are organized as a sequence, and a fixed number of successive samples are grouped together to form vectors. The order of the samples in the sequence depends on the original source signal; in the case of one-dimensional signals such as audio, it is convenient to use time order. From images, which are two-dimensional inherently, $k \times k$-pixel blocks are often extracted and their pixels are assigned to vector elements in row-major order. In the case of color images, the RGB (red-green-blue) pixels can be interpreted as three-dimensional vectors.

VQ applies the same principles as SQ. In the encoding phase, the *vector quantizer* groups the values of the source signal into K-dimensional input vectors x_i. An appropriate transformation can be applied to the vectors. Then, for a given input vector x_i, the nearest *representative vector* c_j is searched from the *codebook* C of M K-dimensional *codevectors*. We suppose that the codebook, which is known by both the encoder and decoder, has been constructed before quantization as a separate process. The index, or binary word w_j, of the selected codevector c_j is stored or transmitted to the receiver. Compression rate can be improved by applying entropy coding to the indices. In the decoding phase, the receiver selects the representative vector from the codebook C using the transmitted and decoded index. A new reproduced signal is then constructed from the representative vectors. Compression is achieved because the cardinality of the set of the representative vectors is much smaller than the cardinality of the whole vector set. The encoding/decoding process is described as a sequence of successive steps in Fig. 1.

It is impossible to cover all the rich topics in scalar and vector quantization in a single article. We therefore restrict ourselves to topics, which we feel are important to a practitioner or a student in algorithmics who is interested in understanding the basic ideas in quantization methods. Our focus is more biased to the implementation issues whereas the theoretical consideration is largely omitted. This does not mean that the value of theory, including, for example, Shannon's source coding theory or Bennett's approximation on the quantization distortion, could be bypassed when evaluating different quantizers. These are dealt in depth, for example, in textbook of Gersho and Gray [1].

2. SCALAR QUANTIZATION

In scalar quantization we are given a set of numbers X drawn from a known distribution $f(x)$, and our task is to encode the numbers with a lower number of bits in such a way that the average distortion caused by this action is as small as possible. By the *distortion* we mean the difference of the original data x and the corresponding reproduction values $Q(x)$ obtained by the encoding and decoding sequence. When the original numbers are from $\Re$ (the set of real numbers), a natural choice of the distortion is the squared one-dimensional Euclidean distance $d(x, Q(x)) = (x - Q(x))^2$. Now it is clear that the distribution $f(x)$ has a profound influence on the proper choice of the quantization scheme. We should make more accurate quantization at the regions of high density than at the low-density regions.

The simplest way of thinking is to use a fixed number of bits for expressing the indices of the reproduction values $Q(X)$. If this number is M, we need $\log M$ bits for expressing each of them. This kind of method is called *fixed-rate coding*. Now one can fix M and ask for the best way (in distortion sense) to quantize the source data. This corresponds to minimization of the *distortion-rate function*. Another way of looking at the situation is to minimize M when the maximal distortion of the scalar quantizer has been fixed. Nothing restricts the coding to fixed-length codes. We can as well code the indices of the reproduction points by a *variable-length code*, in which case we may spend fewer bits to indices occurring more

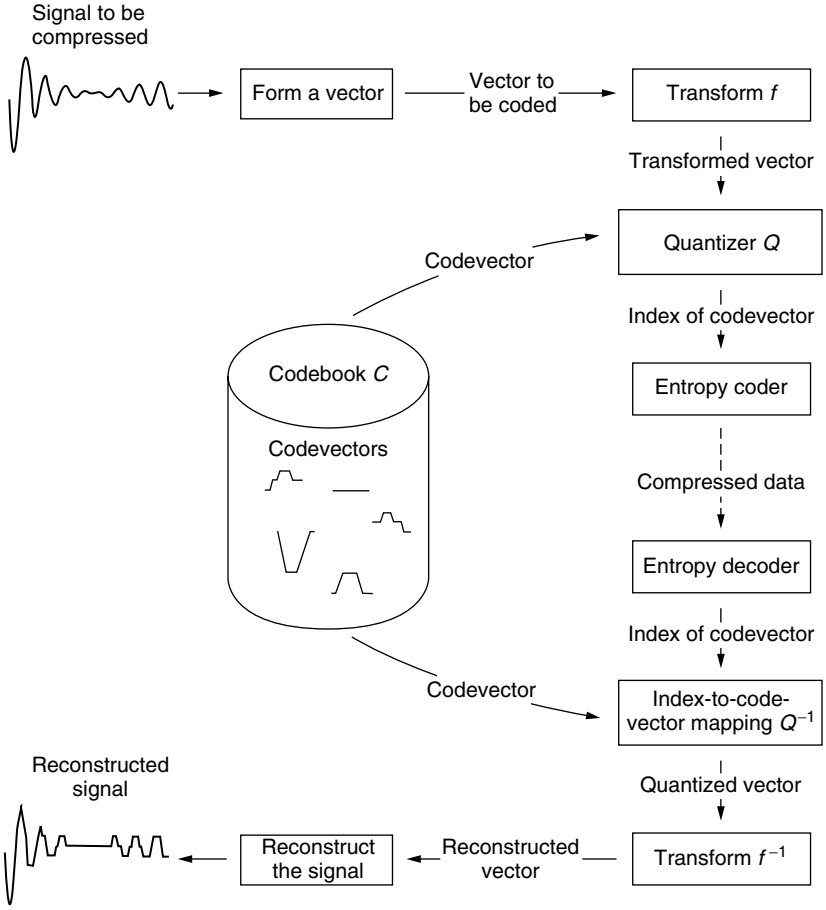

Figure 1. An example of a compression system based on (vector) quantization.

frequently. Note that here the coding must naturally be lossless (like Huffman code); compare with the encoding phase of the scalar quantizer, which is a lossy process. While the basic idea in SQ is the independent quantization of individual scalar data, there is no reason why we could not use entropy coding with some suitable context for the lossless compressor of the indices. By this way, we utilize the knowledge of the dependencies of individual samples on the history of the data when predicting the current quantization index. Then we code (e.g., by arithmetic coding) the difference between the actual and predicted index values.

2.1. Uniform Versus Nonuniform Quantizer

Quantizers can be divided into *uniform* and *nonuniform* depending on whether the reproduction values are at equal distances from their neighbors. A uniform scalar quantizer has an equal space $\Delta \in \Re$ between successive reproduction levels $c_i (i = 1, 2, \ldots, M)$, namely, $c_{i+1} = c_i + \Delta$. Correspondingly, the cell boundaries have the same space between them: $t_{i+1} = t_i + \Delta$. An example of a uniform quantizer is presented in Fig. 2. For this kind of quantizers one can show that the Euclidean squared distortion is of the size [2]

$$D_{un} \cong \frac{\Delta^2}{12} \tag{1}$$

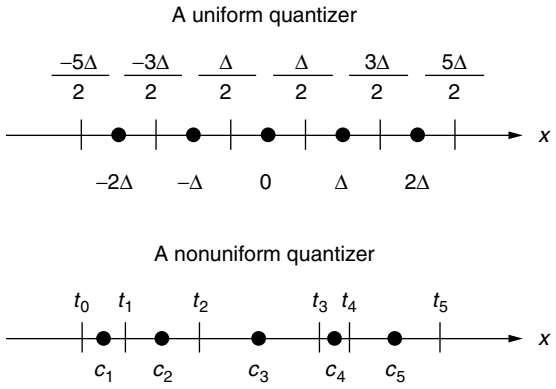

Figure 2. Illustration of a uniform and nonuniform quantizer.

The intervals of a nonuniform quantizer are of different lengths (see Fig. 2). This reflects the varying density of the samples in different regions of $\Re$, giving the overall distortion for samples at the range $[t_0, t_n]$

$$D_n = \sum_{i=1}^{n} \int_{t_{i-1}}^{t_i} d(x, c_i) f(x)\, dx \tag{2}$$

Several options for SQ are provided in the JPEG 2000 standard [3].

2.2. Lloyd's Conditions and Algorithm

Lloyd [4] showed two necessary optimality conditions for a scalar quantizer with fixed-length codewords to be optimal: (1) for a fixed setting of reproduction levels the cell boundaries must be selected optimally and (2) for a fixed setting of cell boundaries the reproduction levels should be selected optimally. This important observation can be turned to an algorithm (*Lloyd's algorithm*):

1. Initialize M cells and reproduction levels.
2. Repeat until the distortion converges:
   a. For each sample define the nearest centroid and place the sample to the set of samples mapping to this interval.
   b. Calculate new centroids for each interval by using the sets defined above.

In certain cases (e.g., for Gaussian and Laplacian densities of the samples), Lloyd's algorithm gives a globally optimal quantizer whereas there are applications where a local optimum will be found. Lloyd's algorithm is generalized and considered more closely in Section 4.1.

3. VECTOR QUANTIZATION

The goal and principle of vector quantization (VQ) are the same as in scalar quantization (SQ). The difference is in the nature of the samples. These are for VQ structured collections of scalars organized as vectors. One can separate four main tasks in the design of a vector quantizer: (1) *selection of a training set*, (2) *codebook generation* on the basis of the training set, (3) *encoding* of the source vectors with the aid of the codebook, and (4) *decoding* of the compressed vectors. The decoding commonly is the easiest of these tasks because it can often be performed extremely rapidly and simply by using a lookup table. The two main problems in the design of a vector quantizer are the construction of the codebook and efficient search from the codebook at the encoding phase. These problems are related because fast and accurate search methods are needed in codebook generation also.

A vector quantizer can be defined as a mapping Q of K-dimensional (Euclidean) space $\Re^K$ into a finite subset C of $\Re^K$:

$$Q: \Re^K \rightarrow C \tag{3}$$

where $C = (c_i; i = 1, 2, \ldots, M)$ is the set of *reproduction vectors* (i.e., the *codebook*) and M is the number of codevectors in C (see Fig. 3). Thus, a vector quantizer can be seen as a combination of two functions. The *encoder* produces an index i for input vector x. The *decoder* transforms the index i back to the reproduction vector c_i. As in the case of SQ, we may still have a lossless compressor of the indices. This may again produce a variable-length code, in which case we have a variable-rate VQ. One can also integrate the compression technique to the vector quantizer itself. Entropy-constrained VQ is one example of this kind (see Section 3.4), but other approaches exist also.

VQ has several benefits as a compression technique. The most important of these is the high decoding speed. By changing the number of codevectors in the codebook, the bit rate can be controlled quite easily. A drawback of VQ is that the vector quantizer has to be trained over a representative set of samples of the signal. Thus, a vector quantizer does not perform well for input vectors emitted by a source, which has characteristics very different from those of the original training set. The method suffers also from relatively high computational complexity both in the codebook generation and in the encoding of a signal.

3.1. Transforms

A suitable transform can be applied to vectors before the use of a vector quantizer. The purpose of the transform is to organize data in a vector in such way that important information is concentrated on some elements of the vector. This transformed representation is probably more suitable for quantization and the search for the nearest vector. For example, it may be reasonable to normalize the vectors by subtracting from each element their average. Another way to normalize a vector is to divide its elements by the norm of the vector. Also other transformations, such as the *discrete*

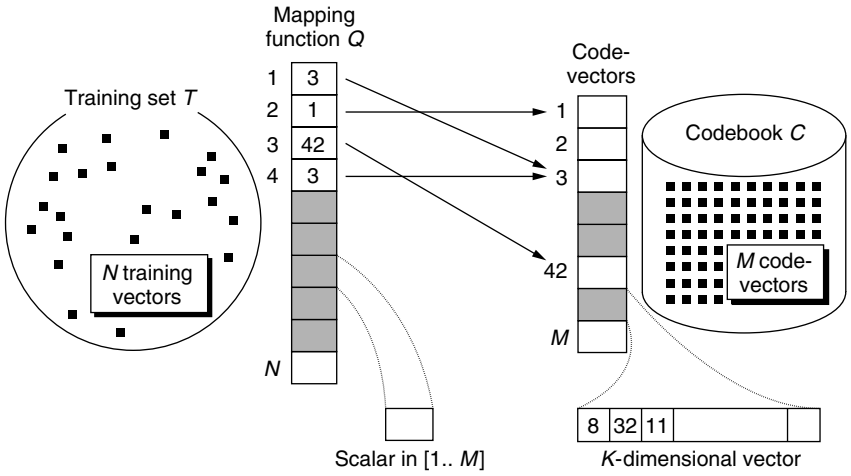

Figure 3. Roles of a training set and a codebook in vector quantization.

cosine transform and the *Walsh–Hadamard transform*, are used in applications. Transforms are often used in *product codevector quantization* (see Section 3.4). For general properties of transform based vector quantizers, see Ding's paper [5].

In some cases, the vectors to be quantized are sequences of the coefficients produced by a signal transformation technique, while in other cases, they may be simply blocks of individual pixels of a digitized image. (Note that this latter case clearly demonstrates the structural dependence of the elements in a vector.) Because of its fast decoding phase, VQ is suitable for compression situations demanding fast reproduction and therefore it has been popular in video codecs.

3.2. Quality and Resolution

The quality of a vector quantizer Q can be measured by the distortion between the original input vector x_i and the reproduction vector $y_j = Q(x_i)$. The smaller the distance, the better the quality. The most widely used distortion measure is the squared error or squared Euclidean distance defined by

$$d(x_i, y_j) = \|x_i - y_j\|^2 = \sum_{k=1}^{K} (x_{i,k} - y_{j,k})^2 \tag{4}$$

where $x_{i,k}$ and $y_{j,k}$ denote the kth element of the vectors x_i and y_j, respectively. Some other distortion measures have been proposed [1,6,7]. The quality of the quantizer is the average distance between the sample vectors and the corresponding reproduction vectors. This average can also be weighted for different components.

The distortion (quality) D of a codebook C can be measured in relation to the training set X for which the codebook has been constructed:

$$D(C, X) = \sum_{i=1}^{N} d(x_i - Q_C(x_i)) \tag{5}$$

Here N is the number of training vectors in the training set X and $Q_C(x_i)$ gives the nearest codevector in the codebook C. In other words, $Q_C(x_i)$ is an optimal mapping that minimizes the distance $\mathrm{d}(x_i, y_j)$, where $y_j \in C$.

There is one question largely omitted in VQ literature, namely, the representativeness of the training set. The VQ codebook is constructed on the basis of a training set of N samples, which are supposed to have the same statistical properties, the density, as the data to which VQ is later applied. A normal way to assert this is to evaluate the operation efficiency of the VQ codebook by an independent test set. Even here caution should be taken to the later changes of the source distribution.

The *resolution* (*code rate* or simply *rate*) of a fixed-rate vector quantizer is

$$r = \frac{\log_2 M}{K} \tag{6}$$

which measures the number of bits per vector element used to represent the K-dimensional input vector. The resolution gives an approximation of the quality of the reproduction of the vector quantizer. One problem of VQ is the *complexity barrier*, which is described as follows. If we limit the resolution r to a fixed value, we can increase the performance of the vector quantizer only by increasing the vector dimensionality K. The reason for this improvement of the performance is that long vectors express the statistical dependencies of the signal more extensively than short vectors. On the other hand, the amount of memory needed to store the codebook and the search complexity (operations per vector element in exhaustive search) are both relative to KM. Thus the space complexity, which is given by

$$KM = K2^{rK} \tag{7}$$

grows exponentially with dimension K. If we suppose that the encoding phase includes an exhaustive search of the codebook, the time complexity of the encoding is exponential on K, too.

3.3. Encoding and Decoding in Unstructured Vector Quantization

In *unstructured vector quantization*, the codebook is just a set of codevectors (reproduction vectors). In *structured vector quantization*, a fast encoding process is pursued by utilizing a special structure of the quantizer. Several structured vector quantizers are discussed in the next section. Here we concentrate on unstructured vector quantizers.

The decoding in unstructured VQ is performed by a table lookup and therefore is very fast and simple. Unfortunately, the encoding is not an easy task. In the encoding, the representative vector for the K-dimensional input vector is searched from the codebook of M codevectors. This *nearest-neighbor problem* is known in other applications, too. Search techniques can be classified into two groups: *exact methods* and *approximate methods*. The former ones always find the nearest codevector, whereas the approximate methods select a vector that is reasonably close and can be found quickly.

Several fast exact search techniques have been introduced to replace the exhaustive search. These techniques typically rely on the properties of the Euclidean vector space. Because the exhaustive search takes $O(MK)$ operations, it is therefore natural to try to reduce the effect of either M or K, or even both. *Partial distortion search* [8], *mean-distance-ordered partial search* [9,10], and *triangular inequality elimination* [11] are widely known methods for the exact search. The importance of efficient search techniques is emphasized by the fact that these techniques are also needed in the codebook generation algorithms, which are discussed later.

In an exact search, the approximate nearest-neighbor search is its own research field also. These techniques often guarantee some property, for example, that the selected codevector is at most at the distance ε from the input vector. One example of approximate techniques is the *tree-structured search*, in which the codebook is organized as a (binary) search tree.

3.4. Vector Quantization Structures

In the case of unstructured VQ, the codebook is just an array of codevectors. In addition, it is typical that the training vectors have been formed from the raw signal data without any special transformations. However, one should keep in mind that there are several alternatives for this basic organization of VQ [1,12,13]. We briefly discuss some of those structures in the following paragraphs.

In several compression methods, *prediction techniques* are utilized. The value of the next sample is predicted by the sample values, which have been coded thus far. The prediction is subtracted from the original pixel value giving a *prediction error* or *residual*, and then the residual is coded by a suitable technique. The same idea is exploited in *predictive vector quantization* (PVQ) [1] by predicting the next vector. The prediction is based on the previously coded vectors so that the decoder is capable of forming the same prediction. The prediction vector is then subtracted from the input vector to form a difference vector, which is finally quantized. Thus, the difference to basic schema of VQ is that here VQ is applied to residual vectors instead of pure vectors in the source domain. The design of a predictive vector quantizer [14–16] includes the design of the predictor in addition to the design of the codebook. These two are dependent on each other, which makes the whole process difficult. Basic approaches are *open-loop*, *closed-loop*, and *semi-closed-loop* designs, [1].

Finite-state vector quantization [1] uses several separate codebooks. The method is based on the assumption that the value of the next input vector depends on the values of the previous vectors. Therefore, a finite-state automaton is constructed to model the dependencies of the vectors. The encoding starts from an initial state of the automaton. In each state, a separate codebook is used for the quantization of the current input vector. The next state is selected on the basis of the reproduction vector. This approach allows us to construct a suitable quantizer for each particular vector context.

In *classified vector quantization* [17], an L-level classifier is used to select a subcodebook for the quantization of the input vectors. First, the encoder transmits the index of the proper subcodebook to the decoder and then the actual index of the selected codevector. The subcodebooks are designed separately and they can be of different sizes. There are several alternatives for the design of the classifier. One possibility is that the classifier is a common vector quantizer, which performs L-level clustering of the vector space. Statistical properties of the input vector can be utilized also. For image compression, the classifier can recognize the pixel blocks as *shade*, *midrange*, *edge*, or *mixed* blocks [17]. This approach has been inspired by the observation that there are too few edge vectors in a single codebook, which has been optimized according to the Euclidean distance. Therefore, the classified vector quantizer tries to guarantee a sufficient number of vectors for those image areas where errors are most annoying (cf. edge areas of the image). Other classified vector quantizers have been discussed [6,14,18].

Operating with high-dimensional vectors slows down both the encoding and the construction of the codebook. *Product code techniques* [1,13] are one way to relieve this problem. The idea is to divide the input vector into a collection of *subvectors*. Each of these describes a certain property of the vector, and therefore one can design a separate codebook for each property. The assumption is that the subvectors are easier to quantize because they take values from a smaller range of the K-dimensional space or have lower dimensionality. In particular, the dimension of a subvector can be one, in which case the property is a scalar. The encoder divides an input vector into a set of subvectors, which are quantized separately, and the corresponding indices are sent to the decoder. The decoder reproduces the subvectors from the indices and constructs a joint reproduction vector from these subvectors. This technique is called *product code vector quantization* because the whole (effective) reproduction codebook is a Cartesian product of all codebooks of the subvectors. Thus, when we have V subcodebooks with M_i codevectors in each, the number of possibilities to construct a reproduction vector is as large as

$$M = \prod_{i=1}^{V} M_i \tag{8}$$

but the storage space and encoding complexities are only of the magnitude

$$\tilde{M} = \sum_{i=1}^{V} M_i \tag{9}$$

The mean-removed vector quantizer [1] is one example of product codevector quantizers. It divides the input vector into two subvectors: a scalar that contains the average of the elements of the *input vector*, and a *difference vector*, where the average has been subtracted from each element of the input vector. *A shape–gain vector quantizer* [1,19] divides the input vector into the *gain* and *shape vectors* similarly. The gain is a scalar, whose value is the Euclidean norm (i.e., length) of the input vector. The shape vector consists of the elements of the input vector divided by the gain.

In *residual* or *multistage vector quantization* [16,20,21], the encoding process is divided into successive applications of separate vector quantizers. In the beginning, the input vector is coded by the first-stage quantizer. A residual vector is formed from the difference between the input vector and its reproduction vector. The second-stage quantizer is then applied to the residual vector. Again, a new residual vector is formed and the same procedure is iterated. By repeating this operation L times, we have an *L-stage vector quantizer*. A separate codebook is generated for each stage. The decoder constructs the whole reproduction vector by summing up the codevector of each quantizer. An upper bound for the number of separate reproduction vectors is the same as for the product codes [see Eq. (8)]. The complexity of the storage and encoding are also the same [see Eq. (9)].

A *lattice vector quantizer* [1,13] is simply a vector quantizer whose codebook is constructed from a lattice. Here the codevectors have a regular arrangement in the K-dimensional vector space. In fact, the lattice vector quantizer can be interpreted as a generalization of a

uniform scalar quantizer. An essential parameter in the design of a lattice vector quantizer is the density of the lattice, which defines how many lattice points per unit volume of the space are contained in the codebook. The higher the density, the higher the bit rate and the smaller the average distortion. The benefit of the lattice vector quantization is that special search methods can be applied because of the regular structure of the codevectors. In addition, the codebook can be expressed by its parameters instead of listing all the codevectors separately.

The output of the vector quantizer can be compressed further by applying entropy coding. Since the entropy codes can reduce the average length of the final code to the entropy of the vector, the vector quantizer should be designed to minimize its output entropy. In the design of an *entropy-constrained vector quantizer* [20,22–24], the task is to generate a codebook, which minimizes the average distortion between the source vectors and reproduction vectors subject to a constraint on the index entropy. Thus the distance between a training vector x_i and a codevector c_j is defined as

$$d(x_i, c_j) = \|x_i - c_j\|^2 + \lambda r_j \tag{10}$$

where r_j is the entropy of the index of codevector c_j, and λ is a weighting parameter for the entropy.

A vector quantizer is typically designed for a particular distribution of source vectors. However, it is possible that the input vectors given to the encoder are from a different distribution of vectors, and therefore the vector quantizer is unable to code these vectors well. In *adaptive vector quantization*, this problem is relieved by modifying the vector quantizer during the coding process. The predictive and finite-state vector quantizers could be considered as adaptive vector quantizers, because they change their encoding rule in time. However, usually, methods that change the codebook in order to match the local properties of input vectors are called *adaptive vector quantizers*.

4. CODEBOOK GENERATION

In the codebook generation problem, the task is to construct a codebook C that minimizes distortion D of Eq. (5) for a given training set X. If the VQ system transfers the codebook to a receiver as a part of compressed data, it is natural to form the training set from the source signal to be compressed. Instead, when the system uses a *static codebook*, which is known by both the encoder and the decoder, the training set is formed from a large set of similar signal samples as the signal source to be compressed. When generating a static codebook, its quality has to be determined against input vectors outside the training set. This process and the construction of training sets have been studied [25,26]. To exclude trivial problem instances, we suppose that the size M of the codebook is smaller than the size N of the training set (in practice we assume that $M \ll N$).

In addition to the distortion D of the produced codebook, the quality of a codebook generation algorithm can be characterized by other attributes. *Robustness* of the algorithm describes how independent the output of the algorithm is from the initial conditions and parameter setups. Another important property of the algorithm is small *running time*; especially in online applications. A *scalable* algorithm is able to improve the quality of the codebook with additional computing resources. *Memory requirements* should be reasonable, so that the algorithm would also work for large problem instances.

The codebook generation problem resembles the *clustering problem* [27], in which the task is to classify N input vectors into M clusters. However, the quality of the clustering is measured both by evaluating the *similarity* of objects (vectors) in the same cluster and *dissimilarity* of the objects in different clusters. Instead, in codebook generation, the task is to find a good set of *representatives* for the input vectors. In addition, the number of codevectors M is usually given in the setup of the codebook construction, whereas in clustering the search for the right number of clusters may be a vital part of the problem. The codebook generation problem also resembles the *P-median problem*, which differs from VQ in that the solution vectors of the P-median problem are limited to be vectors of the training set. A similar approach has been also applied to codebook generation in VQ by modifying the generalized Lloyd algorithm (GLA). Codebook generation for RGB-tuples is known as a *palette generation problem* in color image quantization [28,29].

Construction of an optimal codebook is a combinatorial optimization problem and it is NP-hard [30]. In other words, there is no known polynomial time algorithm for finding the globally optimal solution. However, reasonable suboptimal solutions are typically obtained by *heuristic algorithms* [31,32]. Methods to solve the codebook generation problem can be divided into *problem specific methods* and *general optimization methods*. Problem-specific methods have been developed particularly to solve the codebook generation problem (and the clustering problem). General optimization methods, however, are suitable for all optimization problems on the condition that the problem has been formulated properly for a particular optimization method.

In the following, we concentrate on codebook construction methods for unstructured vector quantizers. However, after minor modifications, these general methods are suitable for design of other vector quantizers also. By *iterative method*, we mean a method that attempts to improve the quality of an existing solution (codebook). Therefore, these methods need an initial codebook, which is feasible for the given problem. Examples of iterative methods are GLA and genetic algorithms, which are discussed later. *Hierarchical methods* are problem-specific and are widely used in clustering problems. Hierarchical methods can be classified as *divisive* and *agglomerative* types, and they repeatedly split or merge clusters until a clustering of the desired size has been reached. The splitting method and the pairwise nearest-neighbor (PNN) algorithm are two examples of hierarchical methods, which are discussed later. In the following three sections we briefly describe problem-specific methods. After that, we also briefly discuss general optimization methods.

4.1. Generalized Lloyd Algorithm

The *generalized Lloyd algorithm* (GLA) [33] is perhaps the most widely known and used method for codebook generation. The algorithm is based on the iterative use of the codebook modification operation generalized from the Lloyd's algorithm for SQ. The GLA is popular also in the context of clustering and pattern recognition, where it is known as a *C-means algorithm* [34]. C refers here to the number of clusters (codevectors).

The codebook modification operation is based on two optimality conditions: *nearest-neighbor condition* and *centroid condition*. These conditions describe how to generate an optimal clustering for a given codebook, and vice versa, how to generate the optimal codebook for a given clustering.

- *Nearest-Neighbor Condition*. For a given codebook, the optimal clustering of the training set is obtained by mapping each training vector to its nearest codevector in the codebook with respect to the distortion function.
- *Centroid Condition*. For a given cluster, the optimal codevector is the *centroid* (average vector) of the vectors within the cluster.

The GLA applies the two optimality conditions in turn. In the *clustering step*, the training set is grouped into clusters according to the existing codebook. The optimal clustering is obtained by mapping each training vector to the nearest codevector. In the *codebook step* a new codebook is constructed by calculating the centroids of the clusters defined in the clustering step. The two optimality conditions guarantee that the new solution is always equal to or better than the previous one. However, it should be noted that although these two steps are locally optimal, the whole process does not necessary produce an optimal codebook. Most of the computational burden of the GLA originates from the clustering step, which can be expedited by several techniques [35].

After the clustering step, it may happen that the codebook contains some codevectors to which no training vectors have been mapped, that is, that do not represent any of the training vectors. This so *empty-cluster problem* is usually solved by replacing the codevectors of empty clusters by some existing training vectors [1].

The GLA can be iterated until the quality of the codebook does not improve anymore. Another *stopping condition* is to require the relative improvement to be higher than a given threshold. The relative improvement can be measured by

$$\Delta D = \frac{D(C^{(t)}, X) - D(C^{(t+1)}, X)}{D(C^{(t)}, X)} \tag{11}$$

where $C^{(t)}$ refers to the codebook on the tth iteration round and $D(C, X)$ is the distortion of coding training set X with C. The process can also be limited to a certain number of iterations.

The GLA is a *descent* algorithm, which means that each iteration decreases (or at least never increases) the distortion. Because of the deterministic nature of the GLA, the process leads to a *local optimum*, which depends on the *initial codebook*. Because of this, the GLA is unable to locate a *globally optimal codebook*. The GLA can be seen as a *fine-tuner* of a codebook, and it has been integrated in many other algorithms.

The GLA tries to improve the quality of an existing codebook, and therefore it needs an initial codebook to start with. Techniques for generating an initial codebook are typically fast and simple; at least faster than the GLA itself. One such technique, which is often satisfactory, is to use M random training vectors as the codevectors. Several other techniques have been proposed in the literature [1,33].

4.2. Splitting Method

The splitting method [36] starts from a *singular codebook* containing a single codevector, which is the centroid of the whole training set. The codebook is then enlarged hierarchically by splitting a cluster (represented by a codevector) into two new clusters. This procedure is repeated until the codebook reaches the desired size. The selection of a codevector to be split is based on the properties of its cluster. For example, this property may be the *variance* of training vectors in the cluster. The problem of selecting the cluster is avoided in *binary splitting* [33], where all current clusters are split. However, this approach may allocate too many codevectors to sparse areas of the vector space.

Splitting of a given cluster is a special codebook generation problem ($M = 2$), where the task is to find two new representative codevectors for a given subcluster. We have two approaches to this problem. The *partition-based* approach divides the training vectors of the cluster into two subclusters and uses the two centroids of the subclusters as new codevectors. In the *codevector-based* approach, two codevectors are selected by some heuristic and the training vectors are mapped to them.

The overall structure of the splitting method is easy to understand. However, internal components of the method can be rather complicated. The selection of these components gives us a versatile way to generate codebooks of varying quality with controllable running time. The top–down process of the splitting method has the benefit that it can be used also for the construction of a *tree-structured vector quantizer* [37].

4.3. Pairwise Nearest Neighbor

The pairwise nearest-neighbor (PNN) algorithm [38] belongs to the class of *agglomerative clustering methods*. In the field of clustering research the PNN is often called *Ward's method* [39]. Because the cluster centroids can be easily used as codevectors of the codebook, the PNN is suitable for codebook construction. The algorithm starts by constructing an initial codebook in which each training vector is considered as its own codevector. Two nearest codevectors, whose merging increases the total distortion least, are merged at each step, and the process is repeated until the desired size of the codebook has been reached.

The algorithm is straightforward to implement in its basic form, and in comparison to the GLA, it gives good-quality results (i.e., codebooks with small distortion). The PNN has also the advantage that the hierarchical approach produces codebooks of differing sizes as a side product. Thus, the PNN can be easily applied to joint minimization of distortion and entropy of codevector indices [23,24,40]. The algorithm can also be used as a part of hybrid methods such as a genetic algorithm [41], or an iterative split-and-merge method [42].

A drawback of the PNN is the relatively high running time in its exact form [43]. There is a large number of steps to be performed by the algorithm, because typically we have $M \ll N$, and at each step, all pairwise distances are calculated for finding the pair of vectors to be merged. This makes the algorithm very slow for large training sets. It should also be noted that although a single merge operation is always performed optimally (i.e., two nearest clusters are merged), the whole process does not guarantee an optimal codebook of the size M.

Approximate PNN variants [44,46] reduce the number of distance calculations by relieving the condition of merging two nearest clusters. In the *K-d tree* variant [38], the nearest cluster is searched from a (small) subset of clusters only, and several cluster pairs are merged at the same iteration round. This approach is clearly faster than the original one, but the quality of the codebooks is worse. Fast *exact PNN variants* have been proposed [45].

4.4. General Optimization Methods

Although the codebook generation problem is NP-hard [30], good solutions can be produced by general heuristic optimization methods [1,47]. In this section, we describe briefly some methods, which have been observed to work well for several other difficult combinatorial problems and have been successful for codebook optimization also. Their application to the generation of unstructured codebooks is straightforward.

Genetic algorithms (GAs) are optimization techniques derived from the model of the natural selection in real-life evolution. The idea is that a *population* of possible solutions (codebooks) called *individuals* is first (randomly) generated. The next generation consists of the survivors and of new individuals generated from the individuals of the former population by genetic operations such as *crossover* and *mutation*. As in the real life, the genes of the best-fitted individuals survive.

A problem of several optimization methods is that the methods may stick in a local minimum. *Tabu search* [48,49] tries to avoid this problem by keeping the previous solutions in a *tabu list*. The method starts from an initial solution by generating a set of candidate solutions. Solutions, that appear in the tabu list are discarded. The best of the remaining candidates is selected as a new solution, and it is inserted in the tabu list. The procedure is repeated until a stopping condition is fulfilled. The purpose of the tabu list is to prevent the search from returning to solutions that have been evaluated recently. This forces the search to proceed into new directions instead of sticking in a local minimum and in its neighborhood.

Stochastic relaxation (SR) is a family of optimization techniques, which add perturbation to the current solution at each iteration. The amount of perturbation decreases with time, making convergence possible. Because the method allows an increase of the distortion, it can continue the search after reaching a local minimum. A popular variant of SR algorithms is known as *simulated annealing* (SA) [50,51]. The solutions, which decrease the distortion, are always accepted in the SA. However, the acceptation of a solution, which increases the distortion, is determined probabilistically. This probability depends on the change of the distortion value and the parameter called *temperature*, whose decrease rate is given by a *cooling schedule*.

Neural network algorithms used in learning applications are proposed for the codebook generation problem in Refs. 52 and 53. The idea is that the neural network learns the properties of the training set and the codebook is the result of this learning process. A popular method is the *self-organization feature maps* (SOM). The method starts from an initial codebook. One training vector is used to modify the codebook at the time. This is done by moving the training vector's nearest codevector and its neighboring codevectors toward the training vector. The size of the neighborhood reduces during the process and finally only the nearest codevector is moved. Because the method is based on the update of the existing codebook, it is also suitable for adaptive vector quantization.

5. SUMMARY

Scalar quantization is a basic technique for analog-to-digital signal transformation. It has an extensive theoretical background in addition to practical usefulness. One can augment the method with variable-rate compression techniques in order to decrease the storage space.

In theory, vector quantization offers very good possibilities for lossy signal compression. The method has the great advantage that its decoding runs extremely fast. Unfortunately, it includes other complexity problems. To obtain good compression results, one has to use codebooks with high dimensionality with respect to both the vector dimension and the number of reproduction vectors. This makes the encoding process slow and the memory consumption of the compression system unpractical.

1. INTRODUCTION

Pulseshapers of femtosecond laser pulses [1–6] are attractive in wide research fields such as optical communication, information processing, and spectroscopy. In an ultrafast data communication system, spatial data can be sent to remote users at an ultrafast rate, faster than terabit/s, via optical fiber communications. Because there is no device to handle temporal data directly at such an ultrafast rate, the pulseshaper is one of the most promising methods to send or process data. To send a large amount of data, it is also required to use optical storage systems that can readout data in parallel and at an ultrafast rate.

In this article, we present a secure ultrafast data communication system that can link remote users to an encrypted optical database with ultrafast transfer rate [7]. It is well known that holographic memories potentially have a large storage capacity with a fast data transfer rate [8,9]. Security communication is achieved by use of encrypted holographic memory. In the encrypted holographic memory, each data frame to be stored is encoded by optical encryption techniques, such as double-random-phase encryption [10,11] or by an exclusive-OR method. Spatial-temporal converters enable us to send the stored data in the encrypted holographic memory to the receiver at an ultrafast rate. At the remote users, the correct key is required to reconstruct the original data. Without the key information, it is very difficult to decrypt the data because optics can provide a high level of security. In the optical security system more than the one-dimensional nature of light and many physical parameters of the lightwave can be used to encode the data. We show the operation of the secure ultrafast data communication system and present some numerical results of encryption and decryption.

Section 2 describes a secure ultrafast data communication system. Section 3 numerically evaluates the performance of the secure data communication system.

2. SECURE ULTRAFAST DATA COMMUNICATIONS

Figure 1 shows a block diagram and a schematic of a secure data communication system. An encrypted holographic memory is linked to remote users via optical fibers. The secure holographic memory works as an encrypted database. All the data frames to be sent to the remote users were already encrypted by optical encryption techniques and then were recorded in the encrypted holographic memory. The data frame readout from the database is sent to the remote user via an optical fiber by spatio-temporal converters. After the transmission, an original data frame is decrypted at the remote users by using the correct key. The present system consists of four subsystems: the secure holographic memory system, a transmitter based on a space-to-time converter, a receiver based on a time-to-space converter, and a decrypting system to recover the original data. The following subsections describe the operation of each subsystem.

2.1. Secure Holographic Memory

Optical encryption opens new research fields in optical information processing [12–15]. An optical encryption technique, called *double random-phase encryption*, described by Rèfrègier and Javidi in 1995 [10], has been proposed and extensively investigated. The double-random-phase encryption technique can convert an original data frame into a white-noise distribution by using two random phase functions at the input and the Fourier planes. The double random phase encryption technique is easy to introduce into a holographic memory [16–19]. We

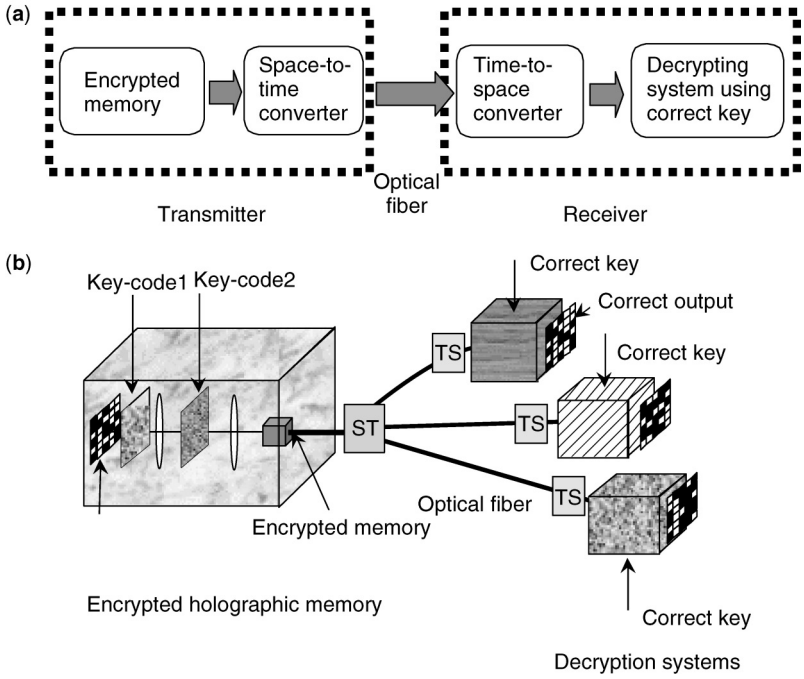

Figure 1. (**a**) Block diagram and (**b**) schematic of secure data communication system. ST and TS denote the space-to-time and time-to-space converters, respectively.

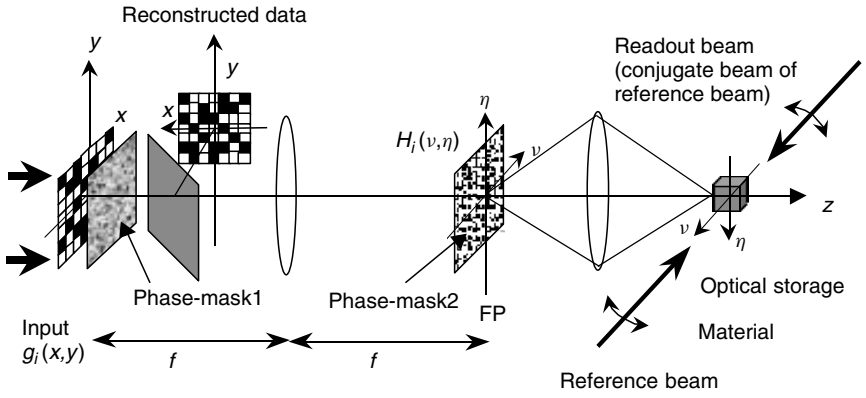

Figure 2. Encrypted holographic memory system.

briefly describe the encrypted holographic storage system, as shown in Fig. 2, using double-random-phase encryption.

Let $g_i(x)$ denote the ith positive and real data to be encrypted. We consider one-dimensional description because the following spatio-temporal converter uses one-dimension signals in the temporal domain. In the encryption process, the ith original data, $g_i(x)$, is multiplied by a random-phase mask (RPM1), $\exp\{-jn_i(x)\}$. This modulated input is Fourier-transformed and then is multiplied by a second random-phase mask (RPM2), $\tilde{H}_i(\nu) = \exp\{-h_i(\nu)\}$. Here x and ν denote the spatial domain and the Fourier domain coordinates, respectively. Two independent white sequences, as $n_i(x)$ and $h_i(\nu)$, are uniformly distributed on the interval $[0, 2\pi]$. After taking another Fourier transform, we obtain the encrypted data, $e_i(x)$:

$$e_i(x) = g_i(x) \exp\{-jn_i(x)\} \otimes F[\exp\{-jh_i(\nu)\}] \qquad (1)$$

where $\otimes$ denotes convolution and $F[\cdot]$ denotes the Fourier transformation. Equation (1) shows that encrypted data are white-noise-like data because of the convolution of two independent white noises.

In a holographic memory, as shown in Fig. 2, the Fourier transformed pattern of the encrypted data described by Eq. (1) is stored holographically together with a reference beam as a *plane wave*. Photorefractive materials are used to record volume holograms. In photorefractive materials, the intensity distribution is recorded as a refractive-index distribution. In order to record many data frames, angular multiplexing is employed. The total intensity distribution, $\phi(\nu)$, stored in the photorefractive material is given by

$$\phi(\nu) = \sum_{i=1}^{M} |\tilde{E}_i(\nu) + \tilde{R}_i(\nu)|^2 \qquad (2)$$

where M is the total number of stored images, $\tilde{E}_i(\nu)$ is the Fourier transform of ith input encrypted data described in Eq. (1), and $\tilde{R}_i(\nu)$ is a reference beam with a specific angle used to record the ith encrypted data.

A sufficient separation angle prevents crosstalk between adjacent stored data in the reconstruction.

Before we present the security of data communication, we show some experimental results in holographic encrypted memory systems as shown in Fig. 2. In the encrypted holographic memory, all stored images are encrypted. In the decryption process, we have to eliminate the phase modulation caused by the two random-phase modulations. Therefore we use the phase conjugate reconstruction in the decryption process. A readout beam is the conjugate beam of the reference beam used in the recording. The conjugate readout can eliminate the phase distortions of the optical field due to the random phase masks and the aberrations of optical elements. The data of the ith stored image can be reconstructed only when the readout beam is incident at a correct angle. The reconstructed data at the photorefractive material is written as $\tilde{E}_i^*(\nu)$, where the asterisk denotes complex conjugate. When we use a phase key, $\tilde{K}_i(\nu) = \exp\{-j2\pi k_i(\nu)\}$ in the Fourier plane, the reconstructed data in the Fourier plane is written as

$$\tilde{S}_i'(\nu) = F[g_i * (x)\exp\{jn_i(x)\}]\tilde{H}_i * (\nu)\tilde{K}_i(\nu) \tag{3}$$

The ith reconstructed image can be obtained by taking another Fourier transform of Eq. (3):

$$s_i'(x) = [g_i * (x)\exp\{jn_i(x)\}] \otimes C_i(x) \tag{4}$$

where

$$C_i(x) = F[\exp\{-jh_i(\nu)\}] \oplus F[\exp\{-jk_i(\nu)\}] \tag{5}$$

In Eq. (5), $\oplus$ denotes correlation. When a correct phase key, $k_i(\nu) = h_i(\nu)$, is used in the Fourier plane, the original data are successfully recovered because Eq. (5) becomes a delta function. The random phase function in the input plane is removed by detecting with an intensity-sensitive device such as a CCD (charge-coupled device) camera. When an incorrect phase key, $k_i(\nu) \neq h_i(\nu)$, is used, the reconstructed data frame is still a white-noise-like image.

Figure 3 shows the experimental setup. An Ar^+ laser at a wavelength of 514.5 nm is used as recording and readout beams. A light beam emitted from the Ar^+ laser was divided into an object beam and a reference beam by a beamsplitter, BS1. The reference beam was again divided into two reference beams by a beamsplitter BS2: one for recording holograms and one for the conjugate readout. All the beams were ordinarily polarized due to the creation of an interference pattern. We use a $10 \times 10 \times 10$ mm^3 $LiNbO_3$ crystal doped with 0.03 mol% Fe as a photorefractive material. The crystal was placed at the Fourier plane and was mounted on a rotary stage for angular multiplexing. The c axis is on the paper and is at 45° with respect to the crystal faces.

An input binary image is displayed on a liquid crystal display controlled by a computer. The input image is illuminated by a collimated beam and is then Fourier-transformed by lens L1. Two random phase-masks, RPM1 and RPM2, are located at the input and the Fourier planes, respectively. A reduced size of the Fourier-transformed image is imaged into the $LiNbO_3$ crystal by lens L2. This Fourier-transformed image and a reference beam interfere with an angle of 90° in the $LiNbO_3$ crystal. In holographic recording, shutters SH1 and SH2 are opened, and SH3 is closed. The encrypted image is observed by a CCD camera (CCD1) after the Fourier transform was taken by lens L3. The focal lengths of L1, L2, and L3 were 400, 58, and 50 mm, respectively.

In the decryption process, the readout beam is the conjugate beam of the reference beam used in the recording. In the experiments, a pair of counterpropagating plane waves is used as the reference and readout beams. Shutters SH1 and SH2 are closed, and SH3 is opened. If the same mask used in the recording is located at the same place, the original image is reconstructed successfully. The intensity information of the reconstructed image is obtained at the CCD camera (CCD2).

We present an example of the experimental results as shown in Fig. 4. In the experiments, angularly multiplexed recording of four binary images was demonstrated. One of the four original binary images is shown in Fig. 4a.

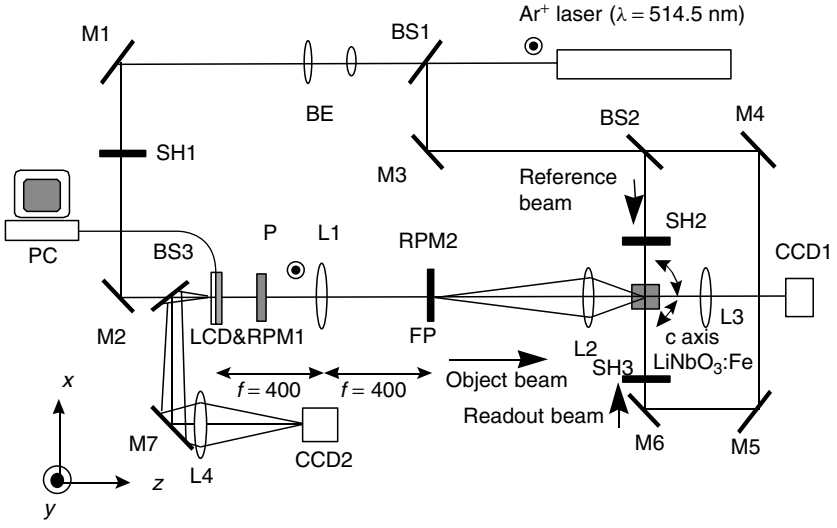

Figure 3. Experimental setup: LCD — liquid crystal display; RPM — random phase masks; BS — beamsplitters; L — lenses; M — mirrors; BE — beam expander; SH — shutters; CCD — CCD cameras; FP — Fourier plane; P — Polarizer; PC — personal computer.

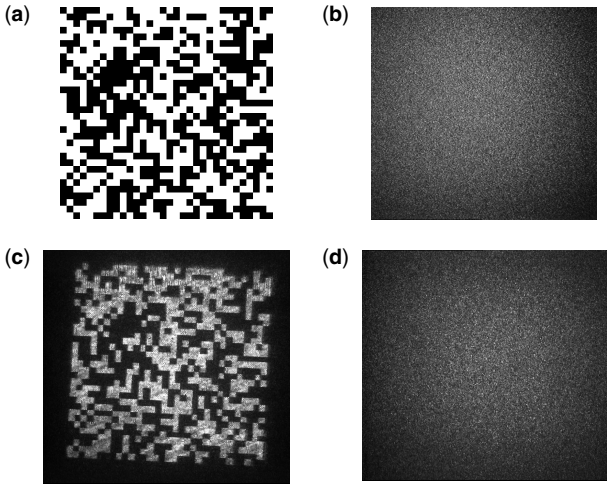

Figure 4. An example of encrypted holographic memory: (**a**) original binary image to be encrypted; (**b**) encrypted image; (**c**) reconstructed image by using correct key; (**d**) reconstructed image by using incorrect key.

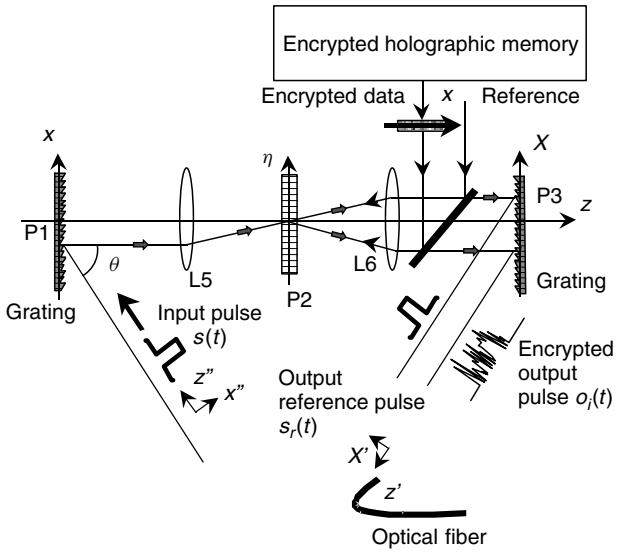

Figure 5. Transmitter based on space-to-time converter.

The image consists of 32×32 pixels and is randomly generated by a personal computer. Two diffusers are used as the random phase-masks, RPM1 and RPM2. Figure 4b shows the intensity distributions of the encrypted images. We can see that random-noise-like image was observed. In the recording process, the optical powers of the object and the reference beams were 78 and 1.4 W/cm^2, respectively. The exposure time was 60 s. Angular multiplexing was achieved by rotating the $LiNbO_3$ crystal in the plane of Fig. 3. The angular separation between adjacent stored images was 0.2°. Figure 4c shows the reconstructed images obtained by using the correct phase keys. These keys are the same as the random-phase masks in the Fourier plane used in the recording. Figure 4c shows that the stored image was reconstructed successfully. After the binarization, we confirmed that there is an error-free reconstruction in the four reconstructed images. Figure 4d shows the reconstructed image when an incorrect key was used. Here the incorrect key was generated by shifting the correct key. The reconstructed image was still a random-noise-like image. The average bit error rate for the reconstructed images with the incorrect keys was 0.502.

In the ultrafast secure communication system as described in Fig. 1, the encrypted data are transmitted to remote users by spatio-temporal converters via optical fibers and then the decryption is implemented at the remote users. To readout the encrypted data from the memory, we use the reference beam as the readout beam. In this case, the reconstructed data are given by Eq. (1) and then are converted into temporal data using the space-to-time converter.

2.2. Transmitter

Figure 5 shows an optical transmitter based on a space-to-time converter with ultrashort pulses. The space-to-time converter converts spatial data to temporal data by controlling the amplitude and phase of the spectra of the input pulse at the Fourier plane, P2 in Fig. 5. Sun and Fainman have extensively investigated the space-to-time converter [5,6]. Using their analysis, we briefly derive an output temporal signal to be sent to the receivers. Because the encrypted data readouts from the secure holographic memory are complex-valued, we introduce here a complex value notation to describe the operation of the space-to-time converter.

An input ultrashort pulse, $s(t)$, is described as

$$s(t) = p(t - t_0)\exp(j\omega_0 t) \tag{6}$$

where $p(t)$ is the envelope of the pulse, t_0 is the time of peak intensity, and ω_0 is the central temporal frequency of the pulse. The temporal frequency distribution of the input pulse, $\tilde{S}(\omega)$, is obtained, by taking the temporal Fourier transform of Eq. (6):

$$\tilde{S}(\omega) = \tilde{P}(\omega - \omega_0)\exp\{-j(\omega - \omega_0)t_0\} \tag{7}$$

where $\tilde{P}(\omega)$ is the temporal Fourier transform of $p(t)$. In the same pulseshaper as described in Fig. 5, each temporal frequency distribution is converted into the spatial distribution at the Fourier plane by using a grating and Fourier-transform lens, L5.

We consider the temporal frequency response of the space-to-time converter in Fig. 5 and then obtain an output temporal pulse. The space-to-time converter consists of two pairs of grating and Fourier transform lens. Suppose that the grating diffracts the light pulse with a temporal frequency of ω_0 into the direction parallel to the optical axis (z axis). When a monochromatic plane wave with a temporal frequency of ω is incident on the grating at an angle of θ, the diffracted optical field at plane P1 is given by

$$\psi_1(x;\omega) = \exp\left\{-j\frac{\omega - \omega_0}{c}\alpha x\right\} w(x) \tag{8}$$

where $\alpha = sin\theta$, w(x) is a pupil function of the grating, and c is the speed of light in vacuum. After taking the Fourier

transform of Eq. (8) by lens L5, the optical field at P2 is given by

$$\tilde{\psi}_2(\eta;\omega) = \tilde{W}\left\{\frac{\omega\eta}{2\pi cf} + \frac{\omega-\omega_0}{2\pi c}\alpha\right\} \tag{9}$$

where $\tilde{W}(\eta)$ is the spatial Fourier transform of $w(x)$, η is the Cartesian coordinate in the plane P2, and f is the focal length of lens L5. Equation (9) shows that the spectral distribution of the temporal delta function is projected into the spatial distribution as a function of the temporal frequency of light. When the pupil function $w(x)$ is infinite [i.e., $\tilde{W}(\eta) = \delta(\eta)$], the relation between η and $(\omega - \omega_0)$ is given by

$$\eta = -f\alpha\frac{\omega-\omega_0}{\omega} \tag{10}$$

The spatially spread spectra described in Eq. (9) are modulated by a hologram that is the interference pattern between the Fourier-transform of the encrypted signal described in Eq. (1) and a reference plane wave.

We suppose that the encrypted signal $e_i(x)$ is spatially sampled at an interval of Δ as follows:

$$\begin{aligned} r_i(x) &= \sum_n e_i(x)\delta(x-n\Delta) \\ &= \sum_n A_i(x)\exp\{j\phi_i(x)\}\delta(x-n\Delta) \\ &= \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\} \end{aligned} \tag{11}$$

where $A_i(x) = |e_i(x)|$, $\exp\{j\phi_i(x)\} = e_i(x)/|e_i(x)|$, and Δ is the sampling period. This data sampling is required to avoid the overlap between adjacent data in the reconstructed spatial data at the receiver. In Section 2.3, we show that the spatial data become wide at the receiver after the transmission of spatio-temporal converters. The encrypted data are Fourier-transformed by lens L6. The spatial Fourier transform of the encrypted data at P2 is given by

$$\tilde{R}_i(\eta) = \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\}\exp\left(-j\frac{n\Delta\omega'}{cf}\eta\right) \tag{12}$$

where $\omega' = 2\pi c/\lambda'$, f is the focal length of lens L6, and λ' is the wavelength of the light beam used to write the hologram. This signal is recorded as a real-time hologram together with a reference plane wave in an intensity-sensitive medium, such as a multiple-quantum-well photorefractive device with sufficient spectral response. Here we assume that the hologram works as a grating with the transmittance of

$$t_i(\eta) = \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\}\exp\left(-j\frac{n\Delta\omega'}{cf}\eta\right) \tag{13}$$

where we neglect the coefficient for normalization of transmittance and the effect of the carrier frequency of the hologram caused by the angle between the encrypted data and the reference beam. This hologram modulates the temporal signal described in Eq. (9). The optical field after the diffraction through the hologram is expressed by

$$\begin{aligned} \tilde{\psi}_3(\eta;\omega) &= \tilde{\psi}_2(\eta;\omega)t_i(\eta) \\ &= \tilde{W}\left\{\frac{\omega\eta}{2\pi cf} + \frac{\omega-\omega_0}{2\pi c}\alpha\right\} \times \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\} \\ &\quad \times \exp\left(-j\frac{n\Delta\omega'}{cf}\eta\right) \end{aligned} \tag{14}$$

This modulated field is then Fourier-transformed by lens L6:

$$\begin{aligned} \tilde{\psi}_4(X;\omega) &= \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\} \\ &\quad \times \exp\left\{j\frac{\omega-\omega_0}{c}\alpha\left(X + n\Delta\frac{\omega'}{\omega}\right)\right\} w\left(-X - n\Delta\frac{\omega'}{\omega}\right) \end{aligned} \tag{15}$$

This optical field is diffracted again by a grating and is given by

$$\begin{aligned} \tilde{\psi}_5(X';\omega) &= \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\} \\ &\quad \times \exp\left\{j\frac{\alpha n\Delta}{c}\frac{(\omega-\omega_0)\omega'}{\omega}\right\} w'\left(-X' - n\Delta\frac{\omega'}{\omega}\right) \end{aligned} \tag{16}$$

where X' is the coordinate as shown in Fig. 5, $w'(X')$ is the pupil function of the grating projected onto the X' coordinate. Equation (16) denotes the temporal frequency response of the system. Using Eqs. (7) and (16), we can obtain the output temporal signal by taking an inverse temporal Fourier transform of $\tilde{\psi}_5(X',\omega)\tilde{S}(\omega)$:

$$\begin{aligned} o_i(X',t) &= \int_{-\infty}^{\infty}\tilde{\psi}_5(X';\omega)\tilde{S}(\omega)\exp(-j\omega t)d\omega \\ &= \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\}w'\left(-X' - n\Delta\frac{\omega'}{\omega_0}\right) \\ &\quad \times p(t - t_0 + n\delta t)\exp(j\omega_0 t) \end{aligned} \tag{17}$$

where $\delta t = (\alpha\Delta/c) \times (\omega'/\omega_0)$. To derive Eq. (17) we used the approximation, $1/\omega \approx 1/\omega_0$. This is valid in case of $\Delta\omega = (\omega - \omega_0) \ll \omega_0$ in a few hundreds femtosecond pulse.

Another light pulse, which is passing through P2 without diffraction due to the hologram, is also sent to remote users. This pulse has the same envelope as the input pulse; thus it can be written as

$$s_r(t) = p(t - t_0)\exp(j\omega_0 t) \tag{18}$$

This pulse is used as a reference pulse at the remote users to eliminate the phase distortion in the optical fiber. Both the temporally encrypted signal described in Eq. (17) and the reference pulse in Eq. (18) are sent to the receiver through a single mode fiber. Both pulses travel along the same line with a sufficient temporal interval by using a delay line before the fiber.

2.3. Receiver

At the receiver as shown in Fig. 6, the temporally encrypted data are converted again into spatially

encrypted data using a time-to-space converter. Because a single-mode fiber is used to send the temporally encrypted pulse and the reference pulse, the spatial information of both pulses should be dropped. The time-to-space converter consists of a pair of grating and Fourier transform lens. As shown in Fig. 6, the two light pluses are incident on the grating at an angle of θ and then are diffracted by the grating. These two pulses create the interference pattern after taking the spatial Fourier transform by lens L7. Here the temporal frequency response is considered. Using Eqs. (9), (17), and (18), the intensity distribution of the interference pattern at the Fourier plane P5 is described by

$$\begin{aligned}\tilde{I}_i(\eta,\omega) &= \left|\tilde{O}_i(\omega)\tilde{W}\left[\frac{\omega\eta}{2\pi cf}+\frac{\omega-\omega_0}{2\pi c}\alpha\right]\right. \\ &\quad \left.+\,\tilde{S}_r(\omega)\tilde{W}\left[\frac{\omega\eta}{2\pi cf}+\frac{\omega-\omega_0}{2\pi c}\alpha\right]\right|^2 \\ &= |\tilde{O}_i(\omega)|^2\times\left|\tilde{W}\left[\frac{\omega\eta}{2\pi cf}+\frac{\omega-\omega_0}{2\pi c}\alpha\right]\right|^2 \\ &\quad +|\tilde{S}_r(\omega)|^2\times\left|\tilde{W}\left[\frac{\omega\eta}{2\pi cf}+\frac{\omega-\omega_0}{2\pi c}\alpha\right]\right|^2 \\ &\quad +\tilde{O}_i*(\omega)\tilde{S}_r(\omega)\left|\tilde{W}\left[\frac{\omega\eta}{2\pi cf}+\frac{\omega-\omega_0}{2\pi c}\alpha\right]\right|^2 \\ &\quad +\tilde{O}_i(\omega)\tilde{S}_r*(\omega)\left|\tilde{W}\left[\frac{\omega\eta}{2\pi cf}+\frac{\omega-\omega_0}{2\pi c}\alpha\right]\right|^2 \quad (19)\end{aligned}$$

where $W(\eta)$ is the spatial Fourier transform of $w(x)$ and $w(x)$ is a pupil function of the grating at P4. In Eq. (19)

$$\begin{aligned}\tilde{O}_i(\omega) &= \sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\}P(\omega-\omega_0) \\ &\quad\times\exp\{-j(\omega-\omega_0)(t_0-n\delta t)\} \quad (20)\end{aligned}$$

and

$$\tilde{S}_r(\omega)=\tilde{P}(\omega-\omega_0)\exp\{-j(\omega-\omega_0)t_0\} \quad (21)$$

Equations (20) and (21) denote the Fourier transforms of Eqs. (17) and (18), respectively.

We use the third term in Eq. (19) to reconstruct the spatially encrypted signal. A continuous-wave (CW) laser beam is incident on the hologram to read out the stored information. The reconstructed optical field is then spatially Fourier transformed by lens L7. When the pupil function of the grating and the beam width are large enough [$\tilde{W}(\eta)=\delta(\eta)$], the reconstructed signal at plane P6 is expressed by

$$\begin{aligned}\xi_i(x') &= F\left[\sum_n A_i(n\Delta)\exp\{-j\phi_i(n\Delta)\}|P(\omega-\omega_0)|^2\right. \\ &\quad\left.\times\ \exp\{-j(\omega-\omega_0)n\delta t\}\right] \quad (22)\end{aligned}$$

Note that F[·] denotes the spatial Fourier transform. Equation (22) is calculated as follows:

$$\begin{aligned}\xi_i(x') &= \int_{-\infty}^{\infty}\sum_n A_i(n\Delta)\exp\{-j\phi_i(n\Delta)\}\left|P\left(\frac{-\omega_0\eta}{f\alpha}\right)\right|^2 \\ &\quad\times\exp\left\{\frac{j\omega_0\eta n\delta t}{f\alpha}\right\}\exp\left\{\frac{-j2\pi x'\eta}{\lambda'' f}\right\}d\eta \\ &= \sum_n A_i(n\Delta)\exp\{-j\phi_i(n\Delta)\} \\ &\quad\times\exp\left\{-\frac{\alpha^2\left(\frac{1}{\lambda''}x'+n\frac{\Delta}{\lambda'}\right)^2}{4\omega_0^2\tau^2}\right\} \quad (23)\end{aligned}$$

To derive Eq. (23), we use a Gaussian-shaped input pulse envelope written as $p(t)=\exp(-t^2/2\tau^2)$, τ is a pulse width, and λ'' is the wavelength of the CW laser beam. Equation (23) shows that each pixel becomes wide by convolving a Gaussian function with a $1/e^2$ width of $w_d=4\sqrt{2}\omega_0\tau\lambda''/\alpha$. This reconstructed signal is used in the following decryption system as shown in Fig. 7 to reconstruct the original data.

2.4. Decryption System

When the sampling interval, Δ, is larger than w_d in Eq. (23) and $\lambda''=\lambda'$, the reconstructed data do not overlap each other. We sample again Eq. (23) at $x=n\Delta$. The sampled data are given by

$$\begin{aligned}\xi_i'(x) &= \sum_n \xi_i(x)\delta(x-n\Delta) \\ &= \sum_n A_i(n\Delta)\exp\{-j\phi_i(n\Delta)\} \\ &= \left[\sum_n A_i(n\Delta)\exp\{j\phi_i(n\Delta)\}\right]^* \quad (24)\end{aligned}$$

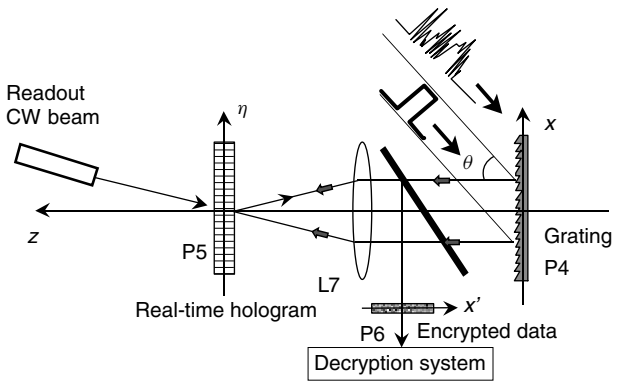

Figure 6. Receiver using time-to-space converter.

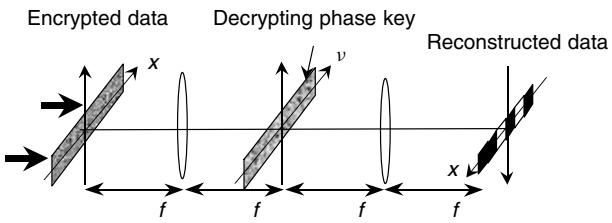

Figure 7. Decrypting system.

where the asterisk denotes complex conjugation. This equation shows that the complex conjugate of the encrypted signal in Eq. (11) is reconstructed. To decrypt the data, the spatial Fourier transform of Eq. (24) is multiplied by the phase key $\tilde{H}_i(\nu) = \exp\{-jh_i(\nu)\}$ as shown in Fig. 7. This phase key is the same random phase mask as that used in the encryption system. In the Fourier plane, the reconstructed data are written by

$$\tilde{\Psi}_i(\nu) = \left\{ \tilde{G}_i^*(\nu) \otimes F[\exp\{-jn_i(x)\}] * \tilde{H}_i^*(\nu) \otimes \exp\left(j\frac{2\pi}{\lambda f} n\Delta\nu\right) \right\} \tilde{H}_i(\nu) \tag{25}$$

where ν denotes the coordinate in the Fourier plane, and $\otimes$ denotes convolution. Finally the reconstructed data are obtained by taking another Fourier transform of Eq. (25):

$$I_{\text{out}}(x) = \sum_n g_i(x) \exp\{-jn_i(x)\} \otimes F * [\exp\{-jh_i(\nu)\}] \cdot \delta(x - n\Delta) \otimes F[\exp\{-jh_i(\nu)\}] \tag{26}$$

This equation shows that the reconstructed data are not exactly the same as the original data, $g_i(x)$ due to the spatial sampling of the encrypted data. In the following section, we numerically evaluate the reconstructed data.

3. NUMERICAL EVALUATIONS

We numerically evaluate the error between the original data and the reconstructed data by use of Eq. (26). When $\omega_0 = 6\pi \times 10^{14}$, $\lambda'' = 1\ \mu\text{m}$, $\alpha = 1/\sqrt{2}$, and $\tau = 50$ fs, the sampling interval, sufficient to avoid the overlap, is 754 μm. If the sampling interval, Δ is smaller than the width of the Gaussian distribution, w_d, the reconstructed spatial data overlap each other. Thus, the original data cannot be reconstructed when the overlap is large, even if we use the correct phase key in the decryption process. To avoid the overlap at the receiver, we have to use a large sampling interval at the transmitter. The sampling results in some loss of the encrypted data and leads to the error in the reconstructed data. In the following calculations, we evaluate the bit error rate in a binary data transmission using undersampled data.

When the encrypted data are undersampled by a factor of 2, half of the encrypted data are lost. This loss of information causes the error in the decrypted data. Using binary data, however, it is possible to reduce the noise in the decrypted data by thresholding. A mean squared error is used as the performance criterion

$$e = E\{|g(x) - m \times g'_\Delta(x)|^2\} \tag{27}$$

where $E\{\cdot\}$ denotes statistical average, $g(x)$ is the original data, m denotes the coefficient to compensate for the loss of total power due to undersampling the encrypted data, and $g'_\Delta(x)$ is the reconstructed data using Eq. (26) when the encrypted data are sampled at the interval of Δ.

The original binary data are 32-bit data, where each bit consists of 64 pixels. Thus the input data have 2048 pixels. This redundancy of the original data is introduced to recover the original binary data. Two random phase masks in the input and Fourier planes consist of 2048 pixels. The original binary data and the two random-phase masks are randomly generated in a computer. The average mean squared error was calculated over 1000 different trials. An example of the original data, encrypted data, and decrypted data is shown in Fig. 8. Here the decrypted data are lowpass-filtered. The lowpass filtering was performed by locally averaging the data with an 11-pixel window. We can see that the encrypted data are random, but the decrypted data have the same structure of the original data. This means that it is possible to recover the original binary data without bit error.

We calculated the bit error rate as a function of the sampling interval, Δ. The bit error rate is defined as a ratio of the number of error bits to the total number of bits. By using the reconstructed analog data as shown in Fig. 8, we calculated the energy of each cell of the reconstructed data. After the calculation of energy, each datum is binarized. To determine the threshold value, all energies are rank ordered. The threshold value is the Nth largest energy of the cells, where N is the number of bright pixels(ones) in the original binary data. Figure 9 shows the bit error rate as a function of the sampling interval Δ. For the binary data used here, the original binary data were reconstructed without error in the case of $\Delta = 1$ and 2. When the sampling interval becomes large, the loss of encrypted data causes a large number of bit errors.

4. CONCLUSION

We have presented a secure data communication system that links remote users to a secure holographic memory system at ultrafast transfer rate. In the encrypted holographic memory each data frame is recorded as a hologram after encrypting the original data by using double-random-phase encryption. The recorded data can be readout in parallel at a fast rate. The spatio-temporal converters based on ultrashort pulse shaper enable us to send the encrypted data at ultrahigh speed via optical fibers. At the remote users, only an authorized user can reconstruct the original data by using the correct keys. We expect that the system can provide a high level of security and ultrafast data communication.

BIOGRAPHIES

Bahram Javidi, distinguished Professor of Electrical and Computer Engineering at University of Connecticut, received the B.S. degree (1980) in electrical engineering from George Washington University, Washington, D.C., and the M.S. (1982) and Ph.D. (1986) degrees in electrical engineering from the Pennsylvania State University, University Park. He is fellow of Institute Of Electrical and Electronics Engineers, fellow of the Optical Society of America, and fellow of the International Society for Optical Engineering (SPIE). In 1990, he was named a Presidential Young Investigator by the National Science Foundation. He has been awarded the University of

1. INTRODUCTION

The convolutional coding technique is designed to reduce the probability of erroneous transmission over noisy communication channels. The most popular decoding algorithm for convolutional codes is perhaps the Viterbi algorithm. Although widely adopted in practice, the Viterbi algorithm suffers from a high decoding complexity for convolutional codes with long constraint lengths. While the attainable decoding failure probability of convolutional codes generally decays exponentially with the code constraint length, the high complexity of the Viterbi decoder for codes with a long constraint length to some extent limits the achievable system performance. Nowadays, the Viterbi algorithm is usually applied to codes with a constraint length no greater than nine.

In contrast to the limitation of the Viterbi algorithm, sequential decoding is renowned for its computational complexity being independent of the code constraint length [1]. Although simply suboptimal in its performance, sequential decoding can achieve a desired bit error probability when a sufficiently large constraint length is taken for the convolutional code. Unlike the Viterbi algorithm that locates the best codeword by exhausting all possibilities, sequential decoding concentrates only on a certain number of likely codewords. As the sequential selection of these likely codewords is affected by the channel noise, the decoding complexity of a sequential decoder becomes dependent on the noise level [1]. These specific characteristics make sequential decoding useful in particular applications.

Sequential decoding was first introduced by Wozencraft for the decoding of convolutional codes [2,3]. Thereafter, Fano developed the sequential decoding algorithm with a milestone improvement in decoding efficiency [4]. Fano's work subsequently inspired further research on sequential decoding. Later, Zigangirov [5], and independently, Jelinek [6], proposed the *stack algorithm*.

In this article, the sequential decoding will not be introduced chronologically. Rather, Algorithm A [7] — the general sequential search algorithm — will be introduced first because it is conceptually more straightforward. The rest of the article is organized as follows. Sections 2 and 3 provide the necessary background for convolutional codes and typical channel models for performance evaluation. Section 4 introduces Algorithm A, and then defines the general features of sequential decoding. Section 5 explores the Fano metric and its generalization for use to guide the search of sequential decoding. Section 6 presents the stack algorithm and its variants. Section 7 elucidates the well-known Fano algorithm. Section 8 is devoted to the trellis variants of sequential decoding, especially on the proposed maximum-likelihood sequential decoding algorithm (MLSDA). Section 9 examines the decoding performance. Section 10 discusses various practical implementation issues regarding sequential decoding, such as buffer overflow. For completeness, a section on the code construction (Section 11) is included at the end of the article. Section 12 concludes the article.

For clarity, only binary convolutional codes are considered throughout discussions on sequential decoding. Extension to nonbinary convolutional codes can be carried out similarly.

2. CONVOLUTIONAL CODE AND ITS GRAPHICAL REPRESENTATION

Denote a binary convolutional code by a 3-tuple (n, k, m), which corresponds to an encoder for which n output bits are generated whenever k input bits are received, and for which the current n outputs are linear combinations of the present k input bits and the previous $m \times k$ input

bits. Because m designates the number of previous k-bit input blocks that must be memorized in the encoder, m is called the *memory order* of the convolutional code. A binary convolutional encoder is conveniently structured as a mechanism of shift registers and modulo-2 adders, where the output bits are modulo-2 additions of selective shift register contents and present input bits. Then n in the 3-tuple notation is exactly the number of output sequences in the encoder, k is the number of input sequences (and hence, the encoder consists of k shift registers), and m is the maximum length of the k shift registers (i.e., if the number of stages of the jth shift register is K_j, then $m = \max_{1 \le j \le k} K_j$). Figures 1 and 2 exemplify the encoders of binary $(2, 1, 2)$ and $(3, 2, 2)$ convolutional codes, respectively.

During the encoding process, the contents of shift registers in the encoder are initially set to zero. The k input bits from the k input sequences are then fed into the encoder in parallel, generating n output bits according to the shift register framework. To reset the shift register contents at the end of input sequences so that the encoder can be ready for use for another set of input sequences, m zeros are usually padded at the end of each input sequence. Consequently, each k input sequence of length L bits is padded with m zeros, and these k input sequences jointly induce $n(L + m)$ output bits. As illustrated in Fig. 1, the encoder of the $(2, 1, 2)$ convolutional code extracts two output sequences, $\mathbf{v}_1 = (v_{1,0}, v_{1,1}, v_{1,2}, \ldots, v_{1,6}) = (1010011)$ and $\mathbf{v}_2 = (v_{2,0}, v_{2,1}, v_{2,2}, \ldots, v_{2,6}) = (1101001)$, due to the single input sequence $\mathbf{u} = (u_0, u_1, u_2, u_3, u_4) = (11101)$, where u_0 is fed in the encoder first. The encoder then interleaves $\mathbf{v}_1$ and $\mathbf{v}_2$ to yield

$$\begin{aligned}\mathbf{v} &= (v_{1,0}, v_{2,0}, v_{1,1}, v_{2,1}, \ldots, v_{1,6}, v_{2,6}) \\ &= (11\ 01\ 10\ 01\ 00\ 10\ 11)\end{aligned}$$

of which the length is $2(5 + 2) = 14$. Also, the encoder of the $(3, 2, 2)$ convolutional code in Fig. 2 generates the output sequences of $\mathbf{v}_1 = (v_{1,0}, v_{1,1}, v_{1,2}, v_{1,3}) = (1000)$, $\mathbf{v}_2 = (v_{2,0}, v_{2,1}, v_{2,2}, v_{2,3}) = (1100)$, and $\mathbf{v}_3 = (v_{3,0}, v_{3,1}, v_{3,2}, v_{3,3}) = (0001)$, due to the two input sequences $\mathbf{u}_1 = (u_{1,0}, u_{1,1}) = (10)$ and $\mathbf{u}_2 = (u_{2,0}, u_{2,1}) = (11)$, which in turn generate the interleaved output sequence

$$\begin{aligned}\mathbf{v} &= (v_{1,0}, v_{2,0}, v_{3,0}, v_{1,1}, v_{2,1}, v_{3,1}, v_{1,2}, v_{2,2}, v_{3,2}, v_{1,3}, v_{2,3}, v_{3,3}) \\ &= (110\ 010\ 000\ 001)\end{aligned}$$

of length $3(2 + 2) = 12$. Terminologically, the interleaved output $\mathbf{v}$ is called the *convolutional codeword* corresponding to the combined input sequence $\mathbf{u}$.

An important subclass of convolutional codes is the *systematic codes*, in which k out of n output sequences retain the values of the k input sequences. In other words, these outputs are directly connected to the k inputs in the encoder.

A convolutional code encoder can also be viewed as a linear system, in which the relation between its inputs and outputs is characterized by generator polynomials. For example, $g_1(x) = 1 + x + x^2$ and $g_2(x) = 1 + x^2$ can be used to identify $\mathbf{v}_1$ and $\mathbf{v}_2$ induced by $\mathbf{u}$ in Fig. 1, where the appearance of x^i indicates that a physical connection is applied to the $(i + 1)$th dot position, counted from the left. Specifically, putting $\mathbf{u}$ and $\mathbf{v}_i$ in polynomial form as $\mathbf{u}(x) = u_0 + u_1 x + u_2 x^2 + \cdots$ and $\mathbf{v}_i(x) = v_{i,0} + v_{i,1} x + v_{i,2} x^2 + \cdots$ yields that $\mathbf{v}_i(x) = \mathbf{u}(x) g_i(x)$ for $i = 1, 2$, where addition of coefficients is based on modulo-2 operation. With reference to the encoder depicted in Fig. 2, the relation between the input sequences and the output sequences can be formulated through matrix operation as

$$[\mathbf{v}_1(x)\ \mathbf{v}_2(x)\ \mathbf{v}_3(x)] = [\mathbf{u}_1(x)\ \mathbf{u}_2(x)] \times \begin{bmatrix} g_1^{(1)}(x) & g_2^{(1)}(x) & g_3^{(1)}(x) \\ g_1^{(2)}(x) & g_2^{(2)}(x) & g_3^{(2)}(x) \end{bmatrix}$$

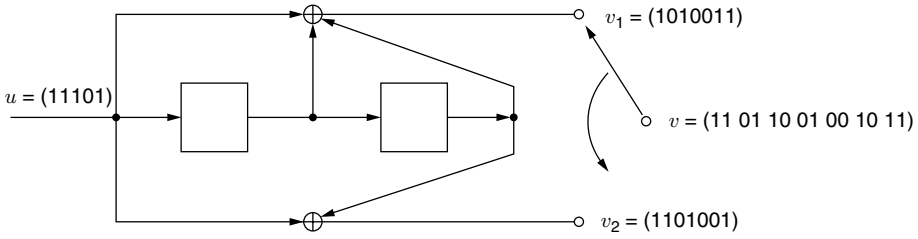

Figure 1. Encoder for the binary $(2, 1, 2)$ convolutional code with generators $g_1 = 7$ (octal) and $g_2 = 5$ (octal), where g_i is the generator polynomial characterizing the ith output.

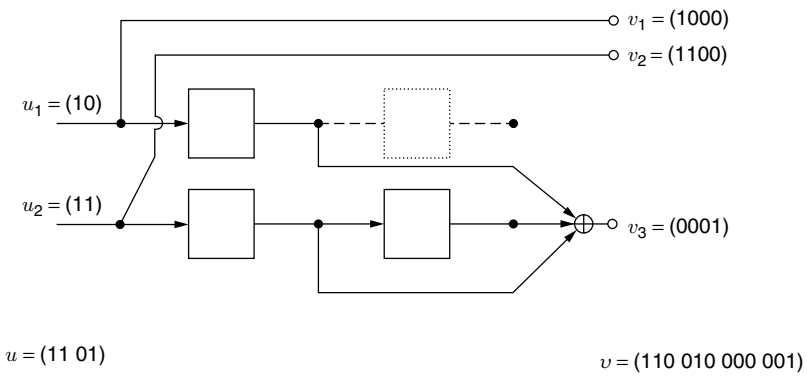

Figure 2. Encoder for the binary $(3, 2, 2)$ systematic convolutional code with generators $g_1^{(1)} = 4$ (octal), $g_1^{(2)} = 0$ (octal), $g_2^{(1)} = 0$ (octal), $g_2^{(2)} = 4$ (octal), $g_3^{(1)} = 2$ (octal), and $g_3^{(2)} = 3$ (octal), where $g_i^{(j)}$ is the generator polynomial characterizing the ith output according to the jth input. The dashed box is redundant and can actually be removed from this encoder; its presence here is only to help demonstrating the derivation of generator polynomials. Thus, as far as the number of stages of the jth shift register is concerned, $K_1 = 1$ and $K_2 = 2$.

where $\mathbf{u}_j(x) = u_{j,0} + u_{j,1}x + u_{j,2}x^2 + \cdots$ and $\mathbf{v}_i(x) = v_{i,0} + v_{i,1}x + v_{i,2}x^2 + \cdots$ define the jth input sequence and the ith output sequence, respectively, and the generator polynomial $g_i^{(j)}(x)$ characterizes the relation between the jth input and the ith output sequences. For simplicity, generator polynomials are sometimes abbreviated by their coefficients in octal number format, led by the least significant one. Continuing the example in Fig. 1 gives $g_1 = 111$ (binary) $= 7$ (octal) and $g_2 = 101$ (binary) $= 5$ (octal). A similar abbreviation can be used for each $g_i^{(j)}$ in Fig. 2.

An (n, k, m) convolutional code can be transformed to an equivalent linear block code with *effective code rate*[1] $R_{\text{effective}} = kL/[n(L+m)]$, where L is the length of the information input sequences. By taking L to infinity, the effective code rate converges to $R = k/n$, which is referred to as the *code rate* of the (n, k, m) convolutional code.

The *constraint length* of an (n, k, m) convolutional code has two different definitions in the literature: $n_A = m + 1$ [8] and $n_A = n(m + 1)$ [1]. In this article, the former definition is adopted, because it is more extensively used in military and industrial publications.

Let $\mathbf{v}_{(a,b)} = (v_a, v_{a+1}, \ldots, v_b)$ denote a portion of codeword $\mathbf{v}$, and abbreviate $\mathbf{v}_{(0,b)}$ by $\mathbf{v}_{(b)}$. The Hamming distance between the first rn bits of codewords $\mathbf{v}$ and $\mathbf{z}$ is given by

$$d_H(\mathbf{v}_{(rn-1)}, \mathbf{z}_{(rn-1)}) = \sum_{i=0}^{rn-1} v_i \oplus z_i$$

where "$\oplus$" denotes modulo-2 addition. The Hamming weight of the first rn bits of codeword $\mathbf{v}$ thus equals $d_H(\mathbf{v}_{(rn-1)}, \mathbf{0}_{(rn-1)})$, where $\mathbf{0}$ represents the all-zero codeword. The *column distance function* (CDF) $d_c(r)$ of a binary (n, k, m) convolutional code is defined as the minimum Hamming distance between the first rn bits of any two codewords whose first n bits are distinct

$$d_c(r) = \min\{d_H(\mathbf{v}_{(rn-1)}, \mathbf{z}_{(rn-1)}) : \mathbf{v}_{(n-1)} \neq \mathbf{z}_{(n-1)} \text{ for } \mathbf{v}, \mathbf{z} \in \mathcal{C}\}$$

where $\mathcal{C}$ is the set of all codewords. Function $d_c(r)$ is clearly nondecreasing in r. Two cases of CDFs are of specific interest: $r = m + 1$ and $r = \infty$. In the latter case, the input sequences are considered infinite in length.[2] Terminologically, $d_c(m + 1)$ and $d_c(\infty)$ (or d_{free} in general) are called the *minimum distance* and the *free distance* of the convolutional code, respectively.

The operational meanings of the minimum distance, the free distance and the CDF of a convolutional code are as follows. When a sufficiently large codeword length is taken, and an optimal (i.e., maximum-likelihood) decoder is employed, the error-correcting capability of a convolutional code [9] is generally characterized by d_{free}. In case a decoder figures the transmitted bits only on the basis of the first $n(m + 1)$ received bits (as in, e.g., the majority-logic decoding [10]), $d_c(m + 1)$ can be used instead to characterize the code error-correcting capability. As for sequential decoding algorithm that requires a rapid initial growth of column distance functions (to be discussed in Section 9), the decoding computational complexity, defined as the number of metric computations performed, is determined by the CDF of the code being applied.

Next, two graphical representations of convolutional codewords are introduced. They are derived from the graphs of *code tree* and *trellis*, respectively. A *code tree* of a binary (n, k, m) convolutional code presents every codeword as a path on a tree. For input sequences of length L bits, the code tree consists of $(L + m + 1)$ levels. The single leftmost node at level 0 is called the *origin node*. At the first L levels, there are exactly 2^k branches leaving each node. For those nodes located at levels L through $(L + m)$, only one branch remains. The 2^{kL} rightmost nodes at level $(L + m)$ are called the *terminal nodes*. As expected, a path from the single origin node to a terminal node represents a codeword; therefore, it is named the *code path* corresponding to the codeword. Figure 3 illustrates the code tree for the encoder in Fig. 1 with a single input sequence of length 5.

In contrast to a code tree, a code *trellis* as described by Forney [11] is a structure obtained from a code tree by merging those nodes in the same *state*. The *state* associated with a node is determined by the associated shift register contents. For a binary (n, k, m) convolutional code, the number of states at levels m through L is 2^K, where $K = \sum_{j=1}^{k} K_j$ and K_j is the length of the jth shift register in the encoder; hence, there are 2^K nodes on these levels. Due to node merging, only one terminal node remains in a trellis. Analogous to a code tree, a path from the single origin node to the single terminal node in a trellis also mirrors a codeword. Figure 4 exemplifies the trellis of the convolutional code presented in Fig. 1.

3. TYPICAL CHANNEL MODELS FOR CODING SYSTEMS

When the $n(L + m)$ convolutional code bits encoded from kL input bits are modulated into respective waveforms (or signals) for transmission over a medium that introduces attenuation, distortion, interference, noise, and other parameters, the received waveforms become "uncertain" in their shapes. A "guess" of the original information sequences therefore has to be made at the receiver end. The "guess" mechanism can be conceptually divided into two parts: demodulator and decoder.

The demodulator transforms the received waveforms into discrete signals for use by the decoder to determine the original information sequences. If the discrete demodulated signal is of two values (i.e., binary), then the demodulator is termed a *hard-decision demodulator*. If the demodulator passes analog (i.e., discrete-in-time but continuous-in-value) or quantized outputs to the decoder, then it is classified as a *soft-decision demodulator*.

[1] The effective code rate is defined as the average number of input bits carried by an output bit [1].

[2] Usually, $d_c(r)$ for an (n, k, m) convolutional code reaches its largest value $d_c(\infty)$ when r is a little beyond $5 \times m$; this property facilitates the determination of $d_c(\infty)$.

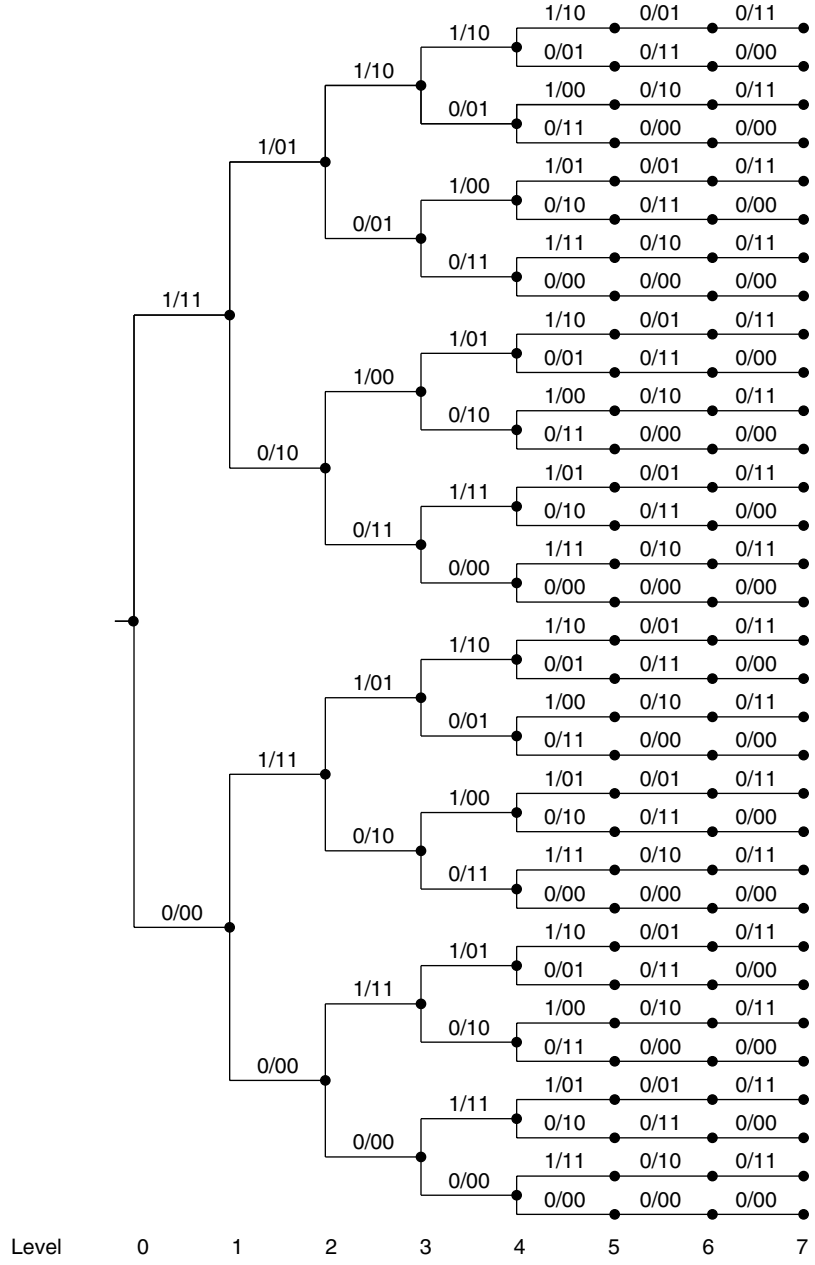

Figure 3. Code tree for the binary $(2, 1, 2)$ convolutional code in Fig. 1 with a single input sequence of length 5. Each branch is labeled by its respective "input bit/output code bits." The code path indicated by the thick line is labeled in sequence by code bits 11, 01, 10, 01, 00, 10 and 11, and its corresponding codeword is $\mathbf{v} = (11\ 01\ 10\ 01\ 00\ 10\ 11)$.

The decoder, on the other hand, estimates the original information sequences on the basis of the $n(L + m)$ demodulator outputs, or equivalently a received vector of $n(L + m)$ dimensions, according to some criterion. One frequently applied criterion is the *maximum-likelihood decoding* (MLD) rule, under which the probability of codeword estimate error is minimized subject to an equiprobable prior on the transmitted codewords. Terminologically, if a soft-decision demodulator is employed, then the subsequent decoder is classified as a *soft-decision decoder*. In a situation in which the decoder receives inputs from a hard-decision demodulator, the decoder is called a *hard-decision decoder* instead.

Perhaps, because of their analytic feasibility, two types of statistics concerning demodulator outputs are of general interest. They are respectively induced from the *binary symmetric channel* (BSC) and the *additive white Gaussian noise* (AWGN) *channel*. The former is a typical channel model for the performance evaluation of hard-decision decoders, while the latter is widely used in examining the error rate of soft-decision decoders. They are introduced after the concept of a channel is elucidated.

For a coding system, a *channel* is a signal passage that mixes all the intermediate effects onto the signal, including modulation, upconversion, medium, downconversion, and demodulation. The demodulator incorporates these aggregated channel effects into a widely adopted additive channel model as $r = s + n$, in which r is the demodulator output, s is the transmitted signal that is a function of encoder outputs, and n represents the aggregated signal distortion, simply termed *noise*. Its extension to multiple

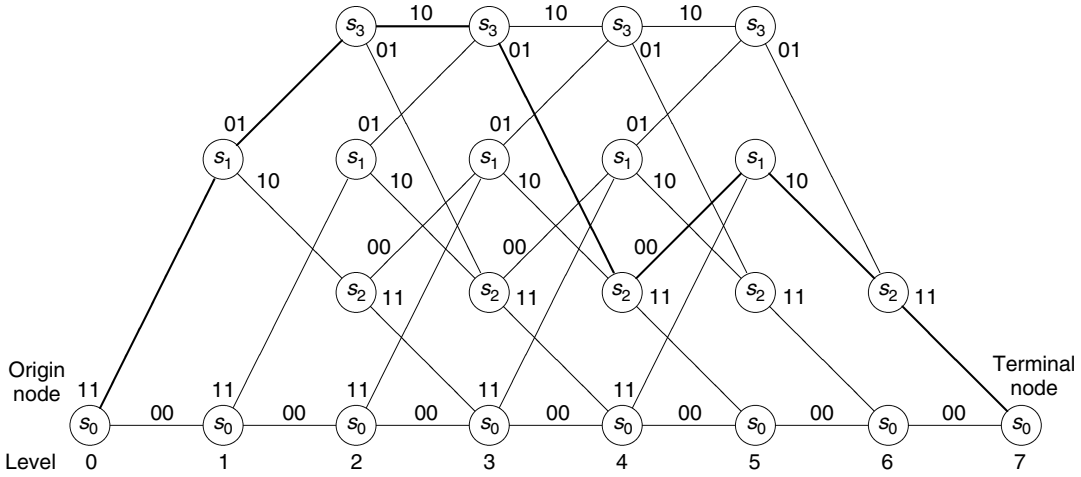

Figure 4. Trellis for the binary $(2, 1, 2)$ convolutional code in Fig. 1 with a single input sequence of length 5. States S_0, S_1, S_2, and S_3 correspond to the states of shift register contents that are 00, 01, 10, and 11 (from right to left in Fig. 1), respectively. The code path indicated by the thick line is labeled in sequence by code bits 11, 01, 10, 01, 00, 10 and 11, and its corresponding codeword is $\mathbf{v} = (11\ 01\ 10\ 01\ 00\ 10\ 11)$.

independent channel usages is given by

$$r_j = s_j + n_j \text{ for } 0 \le j \le N-1$$

which is often referred to as the *time-discrete channel*, since the *time* index j ranges over a *discrete* integer set. For simplicity, independence with common marginal distribution among noise samples $n_0, n_1, \ldots, n_{N-1}$ is often assumed, which is specifically termed *memoryless*. In situation where the power spectrum (i.e., the Fourier transform of the noise autocorrelation function) of the noise samples is a constant, which can be interpreted as the noise contributing equal power at all frequencies and thereby imitating the composition of a white light, the noise is dubbed *white*.

Hence, for a time-discrete coding system, the AWGN channel specifically indicates a memoryless noise sequence with a Gaussian distributed marginal, in which case the demodulator outputs $r_0, r_1, \ldots, r_{N-1}$ are independent and Gaussian distributed with equal variances and means $s_0, s_1, \ldots, s_{N-1}$, respectively. The noise variance exactly equals the constant spectrum value $N_0/2$ of the white noise, where N_0 is *the single-sided noise power per hertz* or $N_0/2$ is *the doubled-sided noise power per hertz*. The means that $s_0, s_1, \ldots, s_{N-1}$ are apparently decided by the choice of mappings from the encoder outputs to the channel inputs. For example, assuming an *antipodal* mapping gives $s_j(c_j) = (-1)^{c_j}\sqrt{E}$, where $c_j \in \{0, 1\}$ is the jth code bit. Under an implicit premise of equal possibilities for $c_j = 0$ and $c_j = 1$, the second moment of s_j is given by

$$E[s_j^2] = \tfrac{1}{2}(\sqrt{E})^2 + \tfrac{1}{2}(-\sqrt{E})^2 = E$$

which is commonly taken to be the average signal energy required for its transmission.

A conventional measure of the noisiness of AWGN channels is the *signal-to-noise ratio* (SNR). For the time-discrete system considered, it is defined as the average signal energy E (the second moment of the transmitted signal) divided by N_0 (the single-sided noise power per hertz). Notably, the SNR ratio is invariable with respect to scaling of the demodulator output; hence, this noisiness index is consistent with the observation that the optimal error rate of guessing c_j based on the knowledge of $(\lambda \cdot r_j)$ through equation

$$\lambda \cdot r_j = \lambda \cdot (-1)^{c_j}\sqrt{E} + \lambda \cdot n_j$$

is indeed independent of the scaling factor λ whenever $\lambda > 0$. Accordingly, the performance of the soft-decision decoding algorithms under AWGN channels is typically given by plotting its error rate against the SNR.[3]

The channel model can be further simplified to that for which the noise sample n and the transmitted signal s (usually the code bit itself in this case) are both elements of $\{0, 1\}$, and their modulo-2 addition yields the hard-decision demodulation output r. Then a binary input/binary output channel between convolutional encoder and decoder is observed. The channel statistics can be defined using the two crossover probabilities: $\Pr(r = 1 \mid s = 0)$ and $\Pr(r = 0 \mid s = 1)$. If the two crossover probabilities are equal, then the binary channel is *symmetric*, and is therefore called the *binary symmetric channel*.[4]

[3] The SNR per information bit, denoted as E_b/N_0, is often used instead of E/N_0 in picturing the code performance in order to account for the code redundancy for different code rates. Their relation can be characterized as $E_b/N_0 = (E/N_0)/R_{\text{effective}} = (E/N_0) \times n(L+m)/(kL)$ because the overall energy of kL uncoded input bits equals that of $n(L+m)$ code bits in principle.

[4] The BSC can be treated as a quantized simplification of the AWGN channel. Hence, the crossover probability p can be derived from $r_j = (-1)^{c_j}\sqrt{E} + n_j$ as $p = (1/2)\text{erfc}(\sqrt{E/N_0})$, where $\text{erfc}(x) = (2/\sqrt{\pi})\int_x^\infty \exp\{-x^2\}\,dx$ is the complementary error function. This convention is adopted here in presenting the performance figures for BSCs.

The correspondence between the transmitted signal s_j and the code bit c_j is often isomorphic. If this is the case, $\Pr(r_j \mid c_j)$ and $\Pr(r_j \mid s_j)$ can be used interchangeably to represent the channel statistics of receiving r_j given that c_j or $s_j = s_j(c_j)$ is transmitted. For convenience, $\Pr(r_j \mid v_j)$ will be used at the decoder end to denote the same probability as $\Pr(r_j \mid c_j)$, where $c_j = v_j$, throughout the article.

4. GENERAL DESCRIPTION OF SEQUENTIAL DECODING ALGORITHM

Following the background introduction to the time-discrete coding system, the optimal criterion that motivates the decoding approaches can now be examined. As a consequence of minimizing the codeword estimate error subject to an equiprobable codeword prior, the MLD rule, on receipt of a received vector $\mathbf{r} = (r_0, r_1, \ldots, r_{N-1})$, outputs the codeword $\mathbf{c}^* = (c_0^*, c_1^*, \ldots, c_{N-1}^*)$ satisfying

$$\Pr(\mathbf{r} \mid \mathbf{c}^*) \geq \Pr(\mathbf{r} \mid \mathbf{c}) \text{ for all } \mathbf{c} = (c_0, c_1, \ldots, c_{N-1}) \in \mathcal{C}$$

where $\mathcal{C}$ is the set of all possible codewords, and $N = n(L + m)$. When the channel is memoryless, the MLD rule can be reduced to

$$\prod_{j=0}^{N-1} \Pr(r_j \mid c_j^*) \geq \prod_{j=0}^{N-1} \Pr(r_j \mid c_j) \quad \text{for all} \quad \mathbf{c} \in \mathcal{C}$$

which in turn is equivalent to

$$\sum_{j=0}^{N-1} \log_2 \Pr(r_j \mid c_j^*) \geq \sum_{j=0}^{N-1} \log_2 \Pr(r_j \mid c_j) \quad \text{for all} \quad \mathbf{c} \in \mathcal{C} \quad (1)$$

A natural implication of (1) is that by simply letting $\sum_{j=n(\ell-1)}^{n\ell-1} \log_2 \Pr(r_j \mid c_j)$ be the metric associated with a branch labeled by $(c_{n(\ell-1)}, \ldots, c_{n\ell-1})$, the MLD rule becomes a search of the code path with the maximum metric, where the metric of a path is defined as the sum of the individual metrics of the branches of which the path consists. Any suitable graph search algorithm can then be used to perform the search process.

Of the graph search algorithms in artificial intelligence, Algorithm A is one that performs priority-first (or metric-first) searching over a graph [7,12]. In applying the algorithm to the decoding of convolutional codes, the graph G undertaken becomes either a code tree or a trellis. For a graph over which Algorithm A searches, a link between the origin node and any node, either directly connected or indirectly connected through some intermediate nodes, is called a *path*. Suppose that a real-valued function $f(\cdot)$, often referred to as the *evaluation function*, is defined for every path in the graph G. Then Algorithm A can be described as follows:

Algorithm A

Step 1. Compute the associated f-function value of the single-node path that contains only the origin node. Insert the single-node path with its associated f-function value into the stack.

Step 2. Generate all immediate successor paths of the top path in the stack, and compute their f-function values. Delete the top path from the stack.

Step 3. If the graph G is a trellis, check whether these successor paths end at a node that belongs to a path that is already in the stack. Restated, check whether these successor paths merge with a path that is already in the stack. If it does, and the f-function value of the successor path exceeds the f-function value of the subpath that traverses the same nodes as the merged path in the stack but ends at the merged node, redirect the merged path by replacing its subpath with the successor path, and update the f-function value associated with the newly redirected path.[5] Remove those successor paths that merge with some paths in the stack. (Note that if the graph G is a code tree, there is a unique path connecting the origin node to each node on the graph; hence, it is unnecessary to examine the path merging.)

Step 4. Insert the remaining successor paths into the stack, and reorder the stack in descending f-function values.

Step 5. If the top path in the stack ends at a terminal node in the graph G, the algorithm stops; otherwise go to step 2.

In principle, the *evaluation function* $f(\cdot)$ that guides the search of Algorithm A is the sum of two parts, $g(\cdot)$ and $h(\cdot)$; both range over all possible paths in the graph. The first part, $g(\cdot)$, is simply a function of all the branches traversed by the path, while the second part, $h(\cdot)$, called the *heuristic function*, help to predict a future route from the end node of the current path to a terminal node. Conventionally, the heuristic function $h(\cdot)$ equals zero for all paths that end at a terminal node. Additionally, $g(\cdot)$ is usually taken to be zero for the single-node path that contains only the origin node.

A question that follows is how to define $g(\cdot)$ and $h(\cdot)$ so that Algorithm A performs the MLD rule. Here, this question is examined by considering a more general problem of how to define $g(\cdot)$ and $h(\cdot)$ so that Algorithm A locates the code path with maximum metric over a code tree or a trellis. Suppose that a metric $c(n_i, n_j)$ is associated with the branch between nodes n_i and n_j. Define the metric of a path as the sum of the metrics of those branches contained by the path. The g-function value for a path can then be assigned as the sum of all the branch metrics experienced by the path. Let the h-function value of the same path be an estimate of the maximum cumulative metric from the end node of the path to a terminal node. Under such a system setting, if the heuristic function satisfies certain optimality criteria, such as whether it always upper-bounds the maximum cumulative metric

[5] The redirect procedure is sometimes time-consuming, especially when the f-function value of a path is computed based on the branches the path traverses. Section 8 introduces two approaches to reduce the burden of path redirection.

from the end node of the path of interest to any terminal node, then Algorithm A guarantees the finding of the maximum-metric code path.[6]

Following the discussion in the previous paragraph and the observation from Eq. (1), a straightforward definition for function $g(\cdot)$ is

$$g(\mathbf{v}_{(\ell n-1)}) = \sum_{j=0}^{\ell n-1} \log_2 \Pr(r_j \mid v_j) \tag{2}$$

where $\mathbf{v}_{(\ell n-1)}$ is the label sequence of the concerned path and the branch metric between the end nodes of path $\mathbf{v}_{(\ell(n-1)-1)}$ and path $\mathbf{v}_{(\ell n-1)}$ is given by $\sum_{j=\ell(n-1)}^{\ell n-1} \log_2 \Pr(r_j \mid v_j)$. Various heuristic functions with respect to the g function defined above can then be developed. For example, if the branch metric defined above is nonpositive, which apparently holds when the received demodulator output r_j is discrete for $0 \le j \le N-1$, a heuristic function that equals zero for all paths sufficiently upper-bounds the maximum cumulative metric from the end node of the concerned path to a terminal node, and thereby guarantees the finding of the code path with maximum metric. Another example is the well-known Fano path metric [4], which, by its formula, can be equivalently interpreted as the sum of the g-function defined in (2) and a specific h function. The details regarding the Fano metric will be given in the next section.

Notably, the branch metric used to define (2) depends not only on the labels of the concerned branch (i.e., $v_{\ell(n-1)}, \ldots, v_{\ell n-1}$) but also on the respective demodulator outputs (i.e., $r_{\ell(n-1)}, \ldots, r_{\ell n-1}$). Some researchers also view the received vector $\mathbf{r} = (r_0, r_1, \ldots, r_{N-1})$ as labels for another (possibly nonbinary) code tree or trellis; hence the term "received branch," which reflects a branch labeled by the respective portion of the received vector $\mathbf{r}$ was introduced. With such a naming convention, this section concludes by quoting the essential attributes of sequential decoding defined in Ref. 15. According to the authors, the very first attribute of sequential decoding is that "the branches are examined sequentially, so that at any node of the tree the decoder's choice among a set of previously unexplored branches does not depend on received branches deeper in the tree." The second attribute is that "the decoder performs at least one computation for each node of every examined path." The authors then remark at the end that "Algorithms which do not have these two properties are not considered to be sequential decoding algorithms." Thus, an easy way to visualize the defined features of sequential decoding is that the received scalars $r_0, r_1, \ldots, r_{N-1}$ are received *sequentially* in time in order of the subindices during the decoding process. The next path to be examined therefore cannot be in any sense related to the received scalars whose subindices are beyond the deepest level of the paths that are momentarily in the stack, because random usage, rather than sequential usage, of the received scalars (such as the usage of r_j, followed by the usage of r_{j+2} instead of r_{j+1}) implicitly indicates that all the received scalars should be ready in a buffer before the decoding process begins.

Based on the two attributes, the sequential decoding is simply Algorithm A with an evaluation function $f(\cdot)$ equal to the sum of the branch metrics of those branches contained by the examined path (i.e., the path metric), where the branch metric is a function of the branch labels and the respective portion of the received vector. Variants of sequential decoding therefore mostly reside on different path metrics adopted. The subsequent sections show that taking a general view of Algorithm A, rather than a restricted view of sequential decoding, promotes the understanding of various later generalizations of sequential decoding.

The next section introduces the most well-known path metric for sequential decoding, which is named after its discover, R. M. Fano.

5. FANO METRIC AND ITS GENERALIZATION

Since its discovery in 1963 [4], the Fano metric has become a typical path metric in sequential decoding. Originally, the Fano metric was discovered through mass simulations, and was first used by Fano in his sequential decoding algorithm on a code tree [4]. For any path $\mathbf{v}_{(\ell n-1)}$ that ends at level ℓ on a code tree, the *Fano metric* is defined as

$$M(\mathbf{v}_{(\ell n-1)} \mid \mathbf{r}_{(\ell n-1)}) = \sum_{j=0}^{\ell n-1} M(v_j \mid r_j)$$

where $\mathbf{r} = (r_0, r_1, \ldots, r_{N-1})$ is the received vector and

$$M(v_j \mid r_j) = \log_2 \frac{\Pr(r_j \mid v_j)}{\Pr(r_j)} - R$$

is the *bit metric*, and the calculation of $\Pr(r_j)$ follows the convention that the code bits — 0 and 1 — are transmitted with equal probability

$$\begin{aligned} \Pr(r_j) &= \sum_{v_j \in \{0,1\}} \Pr(v_j) \Pr(r_j \mid v_j) \\ &= \tfrac{1}{2} \Pr(r_j \mid v_j = 0) + \tfrac{1}{2} \Pr(r_j \mid v_j = 1) \end{aligned}$$

and $R = k/n$ is the code rate. For example, a hard-decision decoder with $\Pr\{r_j = 0 \mid v_j = 1\} = \Pr\{r_j = 1 \mid v_j = 0\} = p$ for $0 \le j \le N-1$ (i.e., a memoryless BSC channel with crossover probability p), where $0 < p < \frac{1}{2}$, will interpret the Fano metric for path $\mathbf{v}_{(\ell n-1)}$ as

$$M(\mathbf{v}_{(\ell n-1)} \mid \mathbf{r}_{(\ell n-1)}) = \sum_{j=0}^{\ell n-1} \log_2 \Pr(r_j \mid v_j) + \ell n(1-R) \tag{3}$$

where

$$\log_2 \Pr(r_j \mid v_j) = \begin{cases} \log_2(1-p), & \text{for} \quad r_j = v_j \\ \log_2(p), & \text{for} \quad r_j \ne v_j \end{cases}$$

[6] Criteria that guarantee optimal decoding by the Algorithm A are extensively discussed in Refs. 13 and 14.

In terms of the Hamming distance, (3) can be rewritten as

$$M(\mathbf{v}_{(\ell n-1)} \mid \mathbf{r}_{(\ell n-1)}) = -\alpha \cdot d_H(\mathbf{r}_{(\ell n-1)}, \mathbf{v}_{(\ell n-1)}) + \beta \cdot \ell \qquad (4)$$

where $\alpha = -\log_2[p/(1-p)] > 0$, and $\beta = n[1 - R + \log_2(1-p)]$. An immediate observation from (4) is that a larger Hamming distance between the path labels and the respective portion of the received vector corresponds to a smaller path metric. This property guarantees that if no error exists in the received vector (i.e., the bits demodulated are exactly the bits transmitted), and $\beta > 0$ (or equivalently, $R < 1 + \log_2(1-p)$),[7] then the path metric increases along the correct code path, and the path metric along any incorrect path is smaller than that of the equally long correct path. Such a property is essential for a metric to work properly with sequential decoding.

Later, Massey [17] proved that at any decoding stage, extending the path with the largest Fano metric in the stack minimizes the probability that the extending path does not belong to the optimal code path, and the usage of the Fano metric for sequential decoding is thus analytically justified. However, making such a *locally* optimal decision at every decoding stage does not always guarantee the ultimate finding of the *globally* optimal code path in the sense of the MLD rule in (1). Hence, the error performance of sequential decoding with the Fano metric is in general slightly inferior to that of the MLD-rule-based decoding algorithm.

A striking feature of the Fano metric is its dependence on the code rate R. Introducing the code rate into the Fano metric somehow reduces the complexity of the sequential decoding algorithm. Observe from (3) that the first term, $\sum_{j=0}^{\ell n-1} \log_2 \Pr(r_j \mid v_j)$, is the part that reflects the maximum-likelihood decision in (1), and the second term, $\ell n(1-R)$, is introduced as a bias to favor a longer path or specifically a path with larger ℓ, since a longer path is closer to the leaves of a code tree and thus is more likely to be part of the optimal code path. When the code rate increases, the number of incorrect paths for a given output length increases.[8] Hence, the confidence on the currently examined path being part of the correct code path should be weaker. Therefore, the claim that longer paths are part of the optimal code path is weaker at higher code rates. The Fano metric indeed mirrors the above intuitive observation by using a linear bias with respect to the code rate.

[7] The code rate bound below which the Fano-metric-based sequential decoding performs well is the *channel capacity*, which is $1 + p\log_2(p) + (1-p)\log_2(1-p)$ in this case. The alternative larger bound $1 + \log_2(1-p)$, derived from $\beta > 0$, can only justify the subsequent argument, and by no means ensure a good performance for sequential decoding under $1 + p\log_2(p) + (1-p)\log_2(1-p) < R < 1 + \log_2(1-p)$. Channel capacity is beyond the scope of this article. Interested readers can refer to the treatise by Cover and Thomas [16].

[8] Imagine that the number of branches that leave each node is 2^k, and increasing the code rate can be conceptually interpreted as increasing k subject to a fixed n for a (n, k, m) convolutional code.

The effect of taking other bias values has been examined in Refs. 18 and 19. The authors defined a new bit metric for sequential decoding as

$$M_B(r_j \mid v_j) = \log_2 \frac{\Pr(r_j \mid v_j)}{\Pr(r_j)} - B \qquad (5)$$

and found that a tradeoff between computational complexity and error performance of sequential decoding can be observed by varying the bias B.

Researchers began to investigate the effect of a joint bias on $\Pr(r_j)$ and R, providing new generalization of sequential decoding. Han et al. [20] observed that universally adding a constant to the Fano metric of all paths does not change the sorting result at each stage of the sequential decoding algorithm (see step 4 of Algorithm A). They then chose the additive constant $\sum_{j=0}^{N-1} \log_2 \Pr(r_j)$, and found that

$$M(\mathbf{v}_{(\ell n-1)} \mid \mathbf{r}_{(\ell n-1)}) + \sum_{j=0}^{N-1} \log_2 \Pr(r_j) = \sum_{j=0}^{\ell n-1} [\log_2 \Pr(r_j \mid v_j) - R] + \sum_{j=\ell n}^{N-1} \log_2 \Pr(r_j) \qquad (6)$$

for which the two terms on the right-hand side of (6) can be immediately reinterpreted as the g function and the h function from the perspective of Algorithm A.[9] As the g function is now defined based on the branch metric $\sum_{j=\ell(n-1)}^{\ell n-1} [\log_2 \Pr(r_j \mid v_j) - R]$, Algorithm A, according to the discussion in the previous section, becomes a search to find the code path $\mathbf{v}^*$ that satisfies

$$\sum_{j=0}^{N-1} [\log_2 \Pr(r_j \mid v_j^*) - R] \geq \sum_{j=0}^{N-1} [\log_2 \Pr(r_j \mid v_j) - R] \quad \text{for all code path } \mathbf{v}$$

This criterion is equivalent to the MLD rule in (1). Consequently, the Fano path metric indeed implicitly uses $\sum_{j=\ell n}^{N-1} \log_2 \Pr(r_j)$ as a heuristic estimate of the upcoming metric from the end node of the current path to a terminal node. A question that naturally follows regards the trustworthiness of this estimate. The question can be directly answered by studying the effect of varying weights

[9] Notably, defining a path metric as $\sum_{j=0}^{\ell n-1} [\log_2 \Pr(r_j \mid v_j) - R] + \sum_{j=\ell n}^{N-1} \log_2 \Pr(r_j)$ does not yield a sequential decoding algorithm according to the definition of sequential decoding in Ref. 15, for such a path metric depends on information of "the received branches" beyond level ℓ, i.e., $r_{\ell n}, \ldots, r_{N-1}$. However, a similarly defined evaluation function surely gives Algorithm A.

on the g function (i.e., the cumulative metric sum that is already known) and h function (i.e., the estimate) using

$$f_\omega(\mathbf{v}_{(\ell n-1)}) = \omega \sum_{j=0}^{\ell n-1} [\log_2 \Pr(r_j \mid v_j) - R] + (1-\omega) \sum_{j=\ell n}^{N-1} \log_2 \Pr(r_j) \tag{7}$$

where $0 \le \omega \le 1$. Subtracting a universal constant $(1-\omega)\sum_{j=0}^{N-1} \Pr(r_j)$ from (7) gives the *generalized Fano metric* for sequential decoding as

$$M_\omega(\mathbf{v}_{(\ell n-1)} \mid \mathbf{r}_{(\ell n-1)}) = \sum_{j=0}^{\ell n-1} (\log_2 \frac{\Pr(r_j \mid v_j)^\omega}{\Pr(r_j)^{1-\omega}} - \omega R) \tag{8}$$

When $\omega = \frac{1}{2}$, the generalized Fano metric reduces to the Fano metric with a multiplicative constant, $\frac{1}{2}$. As ω is slightly below $\frac{1}{2}$, which can be interpreted from (7) as the sequential search is guided more by the estimate on the upcoming metrics than by the known cumulative metric sum, the number of metric computations reduces but the decoding failure probability grows. When ω is closer to one, the decoding failure probability of sequential decoding tends to be lower; however, the computational complexity increases. In the extreme case, taking $\omega = 1$ makes the generalized Fano metric completely mirror the MLD metric in (1), and the sequential decoding becomes a maximum-likelihood (hence, optimal in decoding failure probability) decoding algorithm. The work in Ref. 20 thereby led to the conclusion that an (implicit) heuristic estimate can be elaborately defined to reduce fairly the complexity of sequential decoding with a slight degradation in error performance. Notably, for discrete symmetric channels, the generalized Fano metric is equivalent to the metric defined in Eq. (5) [21]. However, the generalized Fano metric and the metric of (5) are by no means equal for other types of channels such as the AWGN channel.

6. STACK ALGORITHM AND ITS VARIANTS

The stack algorithm or the ZJ algorithm was discovered by Zigangirov [5] and later independently by Jelinek [6] to search a code tree for the optimal codeword. It is exactly the Algorithm A with g-function equal to the Fano metric and zero h function. Because a stack is involved in searching for the optimal codeword, the algorithm is called the *stack algorithm*. An example is provided blow to clarify the flow of the stack algorithm.

Example 1. For a BSC with crossover probability $p = .045$, the Fano bit metric for a convolutional code with code rate $R = \frac{1}{2}$ can be obtained from (3) as

$$M(v_j \mid r_j) = \begin{cases} \log_2(1-p) + (1-R) = 0.434, & \text{for } r_j = v_j \\ \log_2(p) + (1-R) = -3.974, & \text{for } r_j \ne v_j \end{cases}$$

Consequently, only two Fano bit metric values are possible, 0.434 and −3.974. These two Fano bit metric values can be "scaled" to equivalent "integers" to facilitate the simulation and implementation of the system. Taking the multiplicative scaling factor of 2.30415 yields

$$M_{\text{scaled}}(v_j \mid r_j) = \begin{cases} 0.434 \times 2.30415 \approx 1, & \text{for } r_j = v_j \\ -3.974 \times 2.30415 \approx -9, & \text{for } r_j \ne v_j \end{cases}$$

Now, the convolutional code in Fig. 1 is decoded over its code tree (cf. Fig. 3) using the stack algorithm with the scaled Fano metric. Assume that the received vector is **r**=(11 01 00 01 10 10 11). Figure 5 presents the contents

Figure 5. Stack contents after each path metric reordering in Example 1. Here, different from that used in the Fano metric computation, the input bit labels rather than the code bit labels are used for each recorded path. The associated Fano metric follows each path label sequence (inside parentheses).

of the stack after each path metric reordering. Each path in the stack is marked by its corresponding input bit labels rather than by the code bit labels. Notably, while both types of labels can uniquely determine a path, the input bit labels are more frequently recorded in the stack in practical implementation since the input bit labels are the desired estimates of the transmitted information sequences. Code bit labels are used more often in metric computation and in characterizing the code, because the code characteristic, such as error-correcting capability, can only be determined from the code bit labels (codewords).[10] The path metric associated with each path is also stored. The algorithm is terminated at the ninth loop, yielding an ultimate decoding result of $\mathbf{u} = (11101)$.

Maintaining the stack is a significant implementation issue of the stack algorithm. In a straightforward implementation of the stack algorithm, the paths are stored in the stack in order of descending f-function values; hence, a sorting mechanism is required. Without a proper design, the sorting of the paths within the stack may be time-consuming, limiting the speed of the stack algorithm.

Another implementation issue of the stack algorithm is that the stack size in practice is often insufficient to accommodate the potentially large number of paths examined during the search process. The stack can therefore overflow. A common way of compensating for a stack overflow is to simply discard the path with the smallest f-function value [1], since it is least likely to be the optimal code path. However, when the discarded path happens to be an early predecessor of the optimal code path, performance is degraded.

Jelinek proposed the so-called *stack-bucket technique* to reduce the sorting burden of the stack algorithm [6]. In his proposal, the range of possible path metric values is divided into a number of intervals with prespecified, fixed spacing. For each interval, a separate storage space, a *bucket*, is allocated. The buckets are then placed in order of descending interval endpoint values. During decoding, the next path to be extended is always the top path of the first nonempty bucket, and every newly generated path is directly placed on top of the bucket in which interval the respective path metric lies. Some data structure can be used to reduce the maintenance burden and storage demand of stacked buckets, since some buckets corresponding to a certain metric range may occasionally (or even always) be empty during decoding. The sorting burden is therefore removed by introducing the stacked buckets. The time taken to locate the next path no longer depends on the size of the stack, rather on the number of buckets, considerably reducing the time required by decoding. Consequently, the stacked bucket technique was used extensively in the software implementation of the stack algorithm for applications in which the decoding time is precisely restricted [1,22,23]

The drawback of the stacked bucket technique is that the path with the best path metric may not be selected, resulting in degradation in performance. A *metric-first stacked bucket* implementation overcomes the drawback by sorting the top bucket when it is being accessed. However, Anderson and Mohan [24] indicated that the access time of the metric-first stacked buckets will increase at least to the order of $S^{1/3}$, where S is the total number of the paths ever generated.

Another software implementation technique for establishing a sorted stack was discussed by Mohan and Anderson [25], who suggested the adoption of a *balanced binary tree* data structure, such as an AVL tree [26], to implement the stack, offering the benefit that the access time of the stack becomes of order $\log_2(S)$, where S represents the momentary stack size. Briefly, a balanced binary tree is a sorted structure with node insertion and deletion schemes such that its depth is maintained equal to the logarithm of the total number of nodes in the tree, whenever possible. As a result, inserting or deleting a path (which is now a node in the data structure of a balanced binary tree) in a stack of size S requires at most $\log_2(S)$ comparisons (i.e., the number of times the memory is accessed). The balanced binary tree technique is indeed superior to the metric-first stacked bucket implementation, when the stack grows beyond certain size. Detailed comparisons of time and space consumption of various implementation techniques of sequential decoding, including the Fano algorithm to be introduced in the next section, can be found in another article [24].

In 1994, a novel systolic priority queue, called the *parallel entry systolic priority queue* (PESPQ), was proposed to replace the stacked buckets [27]. Although it does not arrange the paths in the queue in strict order, the systolic priority queue technique can identify the path with the largest path metric within a constant time. This constant time was shown to be comparable to the time required to compute the metric of a new path. Experiments revealed that the PESPQ stack algorithm is several times faster than its stacked bucket counterpart. Most importantly, the invention of the PESPQ technique has given a seemingly promising future to hardware implementation of the stack algorithm.

As stated at the end of Section 4, one of the two essential features of sequential decoding is that the next visited path cannot be selected based on the basis of the information deeper in the tree [15]. The above feature is subsequently interpreted as the information that is deeper in the tree is supposed to be received in some future time and hence is perhaps not available at the current decoding stage. This conservative interpretation apparently arises from the aspect of an online decoder. A more general reinterpretation, simply following the wording, is that any codeword search algorithm that decides the next visited path in sequence without using the information deeper in its own search tree is considered to be a sequential decoding algorithm. This new interpretation precisely suits the bidirectional sequential decoding algorithm

[10] For a code tree, a path can be also uniquely determined by its end node in addition to the two types of path labels, so putting the "end node" rather than the path labels of a path in the stack suffices to fulfill the need for the tree-based stack algorithm. Nevertheless, such an approach, while easing the stack maintenance load, introduces an extra conversion load from the path end node to its respective input bit labels (as the latter is the desired estimates of the transmitted information sequence).

proposed by Forney [11], in which each of the two decoders still performs the defined sequential search in its own search tree. Specifically, Forney suggested that the sequential decoding could also start its decoding from the end of the received vector, and proposed a bidirectional stack algorithm in which two decoders simultaneously search the optimal code path from both ends of the code tree. The bidirectional decoding algorithm stops whenever either decoder reaches the end of its search tree. This idea has been greatly improved by Kallel and Li by stopping the algorithm whenever two stack algorithms with two separate stacks meet at a common node in their respective search trees [28]. Forney also claimed that the same idea can be applied to the Fano algorithm introduced in the next section.

7. FANO ALGORITHM

The Fano algorithm is a sequential decoding algorithm that does not require a stack [4]. The Fano algorithm can only operate over a code tree because it cannot examine path merging.

At each decoding stage, the Fano algorithm retains the information regarding three paths: the current path, its immediate predecessor path, and one of its successor paths. On the basis of this information, the Fano algorithm can move from the current path to either its immediate predecessor path or the selected successor path; hence, no stack is required for queuing all examined paths.

The movement of the Fano algorithm is guided by a dynamic threshold T that is an integer multiple of a fixed step size Δ. Only the path whose path metric is no less than T can be next visited. According to the algorithm, the process of codeword search continues to move forward along a code path, as long as the Fano metric along the code path remains nondecreasing. Once all the successor path metrics are smaller than T, the algorithm moves backward to the predecessor path if the predecessor path metric beats T; thereafter, threshold examination will be subsequently performed on another successor path of this revisited predecessor. In case the predecessor path metric is also less than T, the threshold T is one step lowered so that the algorithm is not trapped on the current path. For the Fano algorithm, if a path is revisited, the presently examined dynamic threshold is always lower than the momentary dynamic threshold at the previous visit, guaranteeing that looping in the algorithm does not occur, and that the algorithm can ultimately reach a terminal node of the code tree, and stop.

Figure 6 displays a flowchart of the Fano algorithm, in which $\mathbf{v}_p$, $\mathbf{v}_c$, and $\mathbf{v}_s$ represent the path label sequences of the predecessor path, the current path and the successor path, respectively. Their Fano path metrics are denoted by M_p, M_c, and M_s, respectively. The algorithm begins with the path that contains only the origin node. The label sequence of its predecessor path is initially set to "dummy," and the path metric of such a dummy path is assumed to be negative infinity. The initialization value of the dynamic threshold is zero.

The algorithm then proceeds to find, among the 2^k candidates, the successor path $\mathbf{v}_s$ with the largest path metric M_s. Thereafter, it examines whether $M_s \geq T$. If so, the algorithm moves forward to the successor path and updates the necessary information. Then, whether the new current path is a code path is determined, and a positive result immediately terminates the algorithm. A delicate part of the Fano algorithm is "threshold tightening." Whenever a path is first visited, the dynamic threshold T must be "tightened" such that it is adjusted to the largest possible value below the current path metric, namely, $T \leq M_c < T + \Delta$. Notably, the algorithm can determine whether a path is first visited by simply examining $\min\{M_p, M_c\} < T + \Delta$. If $\min\{M_p, M_c\} < T + \Delta$ holds because of the validity of $M_c < T + \Delta$, the threshold is automatically tightened; hence, only the condition $M_p < T + \Delta$ is required in the tightening test. The above mentioned procedures are repeated until a code path is finally reached.

Along the other route of the flowchart, following a negative answer to the examination of $M_s \geq T$ (which implicitly implies that the path metrics of all the successor paths of the current path are less than T), the algorithm must lower the threshold if M_p is also less than T; otherwise, a deadlock on the current path arises. Using the lowered threshold, the algorithm repeats the finding of the best successor path whose path metric exceeds the new threshold, and proceeds the followup steps.

The rightmost loop of the flowchart considers the case for $M_s < T$ and $M_p \geq T$. In this case, the algorithm can only move backward, since the predecessor path is the only one whose path metric is no smaller than the dynamic threshold. The information regarding the current path and the successor path should be subsequently updated. Yet, the predecessor path, as well as its associated path metric, should be recalculated from the current $\mathbf{v}_p$, because information about the predecessor's predecessor is not recorded. Afterward, the Fano algorithm checks for the existence of a new successor path $\mathbf{v}_t$ that is not the current successor path from which the algorithm has just moved, and whose associated path metric exceeds the current M_s. Restated, this step finds the best successor path other than those that have already been examined. If such a new successor path does not exist, then the algorithm seeks either to reduce the dynamic threshold or to move backward again, depending on whether $M_p \geq T$. In case such a new successor path $\mathbf{v}_t$ with metric M_t is located, the algorithm refocuses on the new successor path by updating $\mathbf{v}_s = \mathbf{v}_t$ and $M_s = M_t$, and repeats the entire process.

A specific example is provided below to help in understanding of the Fano algorithm.

Example 2. Assume the same convolutional code and received vector as in Example 1. Let the step size Δ be four. Figure 7 presents the traces of the Fano algorithm during its decoding.

In this figure, each path is again represented by its input bit labels. S and D denote the paths that contains only the origin node and the dummy path, respectively. According to the Fano algorithm, the possible actions taken include MFTT = "move forward and tighten the threshold," MF = "move forward only," MBS = "move

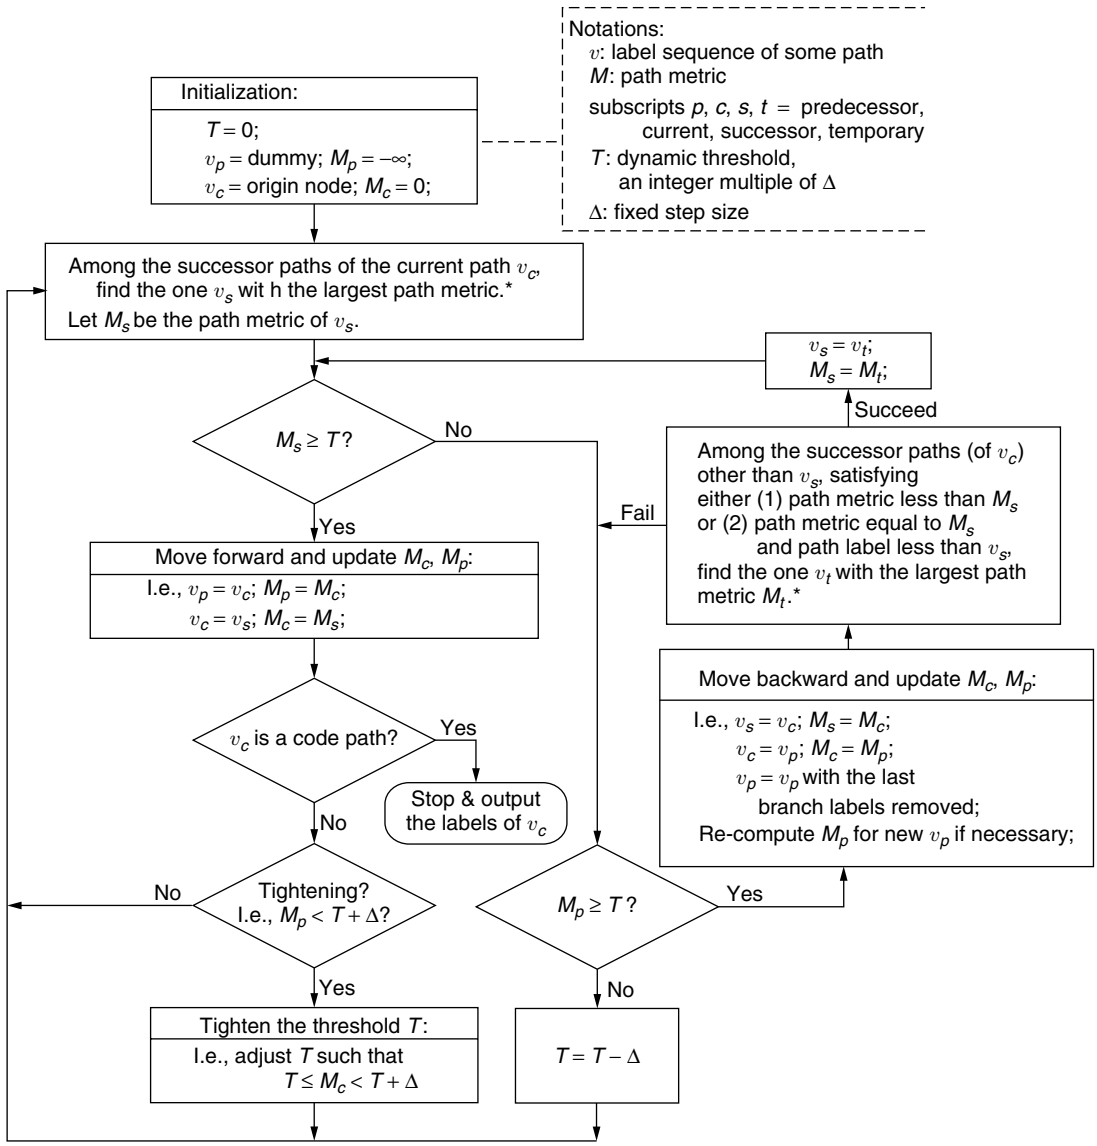

Figure 6. Flowchart of the Fano algorithm.

backward and successfully find the second best successor," MBF = "move backward but fail to find the second best successor," and LT = "lower threshold by one step." The algorithm stops after 36 iterations, and decodes the received vector to the same code path as that obtained in Example 1. This example clearly shows that the Fano algorithm revisits several paths more than once, such as path 11 (eight visits) and path 111 (five visits), and returns to path S three times.

As described in the previous example, the Fano algorithm may move backward to the path that contains only the origin node, and discover all its successors with path metrics less than T. In this case, the only action the algorithm can take is to keep decreasing the dynamic threshold until the algorithm can move forward again because the path metric of the predecessor path of the single-node path is set to $-\infty$. The impact of varying Δ should also be clarified. As stated by Lin and Costello [1], the load of branch metric computations executed during the finding of a qualified successor path becomes heavy when Δ is too small; however, when Δ is too large, the dynamic threshold T might be lowered too much in a single adjustment, forcing an increase in both the decoding error and the computational effort. Experiments suggest [1] that a better performance can be obtained by taking Δ within 2 and 8 for the unscaled Fano metric (Δ should be analogously scaled if a scaled Fano metric is used).

The Fano algorithm, perhaps surprisingly, while quite different in its design from the stack algorithm, exhibits broadly the same searching behavior as the stack algorithm. In fact, with a slight modification to the update procedure of the dynamic threshold (e.g., setting $\Delta = 0$, and substituting the "tightening test" and subsequent "tightening procedure" by "$M_c \neq T$?" and "$T = M_c$," respectively), both algorithms have been proved to visit almost the same set of paths during the decoding process [29]. Their only dissimilarity is that unlike the

Figure 7. Decoding traces of the Fano algorithm for Example 2.

stack algorithm which visits each path only once, the Fano algorithm may revisit a path several times, and thus has a higher computational complexity. From the simulations over the binary symmetric channel as illustrated in Fig. 8, the stack algorithm with stacked bucket modification is apparently faster than the Fano algorithm at crossover probability $p = .057$, when their software implementations are concerned. The stack algorithm's superiority in computing time gradually disappears as p becomes smaller (or as the channel becomes less noisy) [22].

In practice, the time taken to decode an input sequence often has an upper limit. If the decoding process is not completed before the time limit, the undecoded part of the input sequence must be aborted or erased; hence, the probability of input erasure is another system requirement for sequential decoding. Figure 9 confirms that the stack algorithm with stacked bucket modification remains faster than the Fano algorithm except when either admitting a high erasure probability (e.g., erasure probability > 0.5 for $p = .045$, and erasure probability > 0.9 for $p = .057$) or experiencing a less noisier channel (e.g., $p = .033$) [22].

An evident drawback of the stack algorithm in comparison with the Fano algorithm is its demand for an extra stack space. However, with recent advances in computer technology, a large memory requirement is no longer a restriction for software implementation.

Hardware implementation is now considered. In hardware implementation, stack maintenance normally

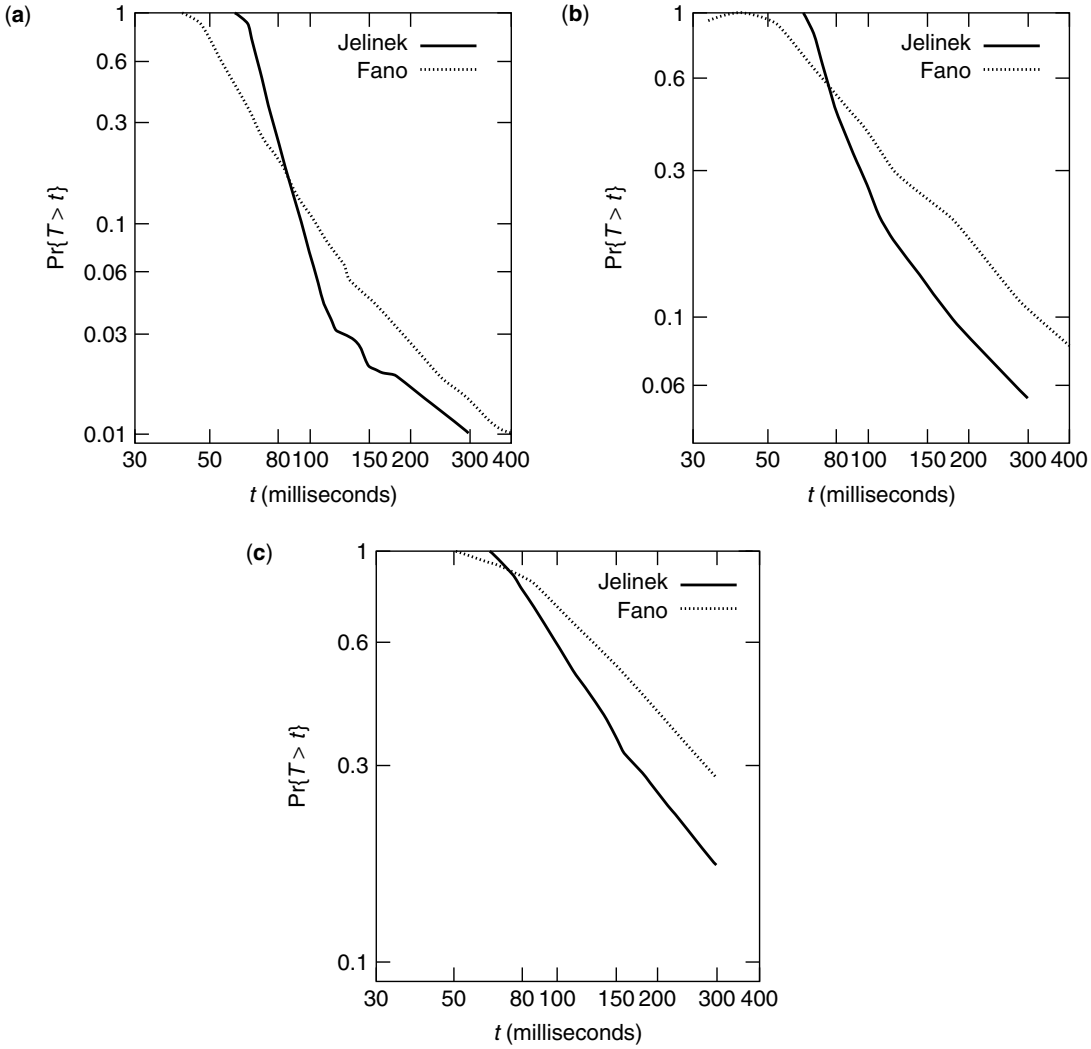

Figure 8. Comparisons of computational complexities of the Fano algorithm and the stack algorithm (with stacked bucket modification) based on the $(2, 1, 35)$ convolutional code with generator polynomials $g_1 = 53, 533, 676, 737$ and $g_2 = 733, 533, 676, 737$ and a single input sequence of length 256; simulations are performed over the binary symmetric channel with crossover probability p: (**a**) $p = .033$; (**b**) $p = .045$; (**c**) $p = .057$. $\Pr\{T \geq t\}$ is the empirical complement cumulative distribution function for the software computation time T. In simulations, $(\log_2[2(1-p)] - \frac{1}{2},\ \log_2(2p) - \frac{1}{2})$, which is derived from the Fano metric formula, is scaled to $(2, -18)$, $(2, -16)$ and $(4, -35)$ for $p = 0.033$, $p = 0.045$ and $p = 0.057$, respectively. In subfigures (a), (b) and (c), the parameters for the Fano algorithm are $\Delta = 16$, $\Delta = 16$ and $\Delta = 32$, and the bucket spacings taken for the stack algorithm are 4, 4, and 8, respectively. (Reproduced from Figs. 1–3 in Ref. 22).

requires accessing external memory a certain number of times, which usually bottlenecks the system performance. Furthermore, the hardware is renowned for its efficient adaptation to a big number of computations. These hardware implementation features apparently favor the no-stack Fano algorithm, even when the number of its computations required is larger than the stack algorithm. In fact, a hard-decision version of the Fano algorithm has been hardware-implemented, and can operate at a data rate of 5 Mbps (megabits per second) [30]. The prototype employs a systematic convolutional code to compensate for the input erasures so that whenever the prespecified decoding time expires, the remaining undecoded binary demodulator outputs that directly correspond to the input sequences are immediately outputted. Other features of this prototype include the following:

- The Fano metric is fixedly scaled to either $(1, -11)$ or $(1, -9)$, rather than adaptable to the channel noise level for convenient hardware implementation.
- The length (or depth) of the backward movement of the Fano algorithm is limited by a technique called *backsearch limiting*, in which the decoder is not allowed to move backward more than some maximum number J levels back from its furthest penetration into the tree. Whenever the backward

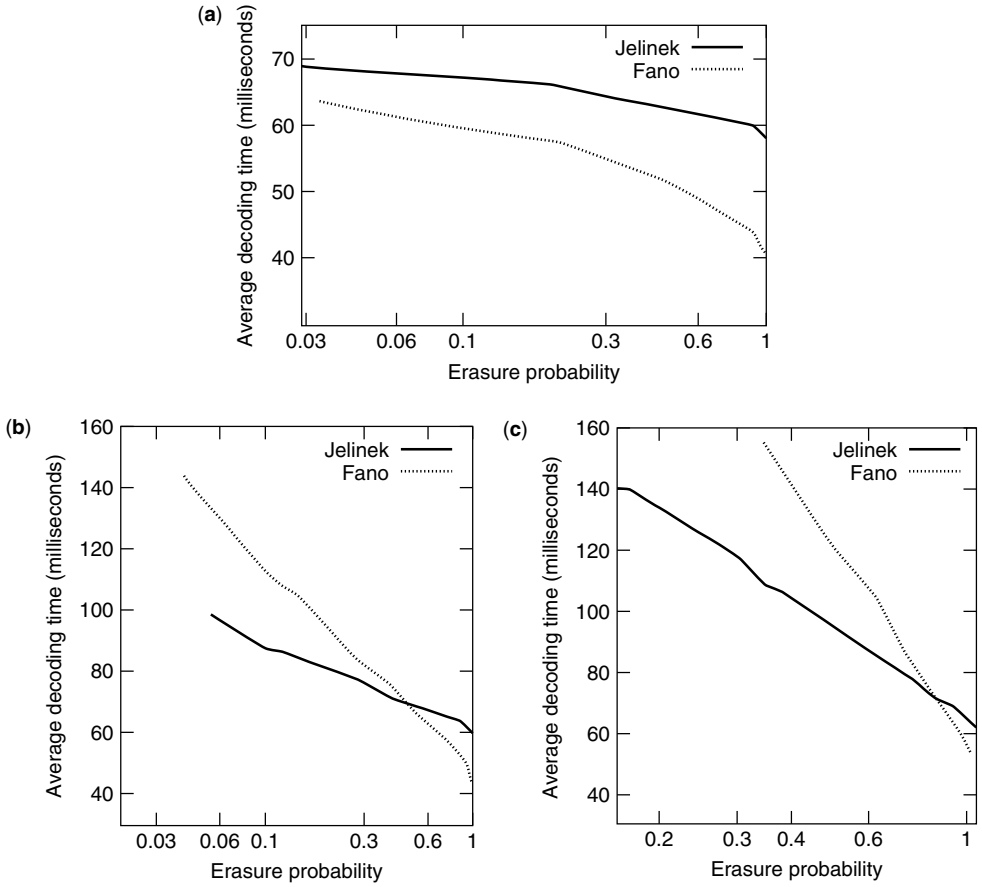

Figure 9. Comparisons of erasure probabilities of the Fano algorithm and the stack algorithm with stacked-bucket modification; all simulation parameters are taken to be the same as those in Fig. 8: (**a**) $p = .033$; (**b**) $p = .045$; (**c**) $p = .057$. (Reproduced from Figs. 5–7 in Ref. 22).

limit is reached, the decoder is forced forward by lowering the threshold until it falls below the metric of the best successor path.

- When the hardware decoder maintains the received bits that correspond to the backsearch J branches for use of forward and backward moves, a separate input buffer must, at the same time, actively receive the upcoming received bits. Once an input buffer overflow is encountered, the decoder must be resynchronized by directly jumping to the most recently received branches in the input buffer, and those information bits corresponding to J levels back are forcefully decoded. The forcefully decoded outputs are exactly the undecoded binary demodulator outputs that directly correspond to the respective input sequences. Again, this design explains why the prototype must use a systematic code.

Figure 10 shows the resultant bit error performances for this hardware decoder for BSCs [30]. An anticipated observation from Fig. 10 is that a larger input buffer, which can be interpreted as a larger decoding time limit, gives a better performance.

A soft-decision version of the hardware Fano algorithm was used for space and military applications in the late 1960s [31,32]. The decoder built by the Jet Propulsion Laboratory [32] operated at a data rate of 1 Mbps, and successfully decoded the telemetry data from the Pioneer Nine spacecraft. Another soft-decision variable-rate hardware implementation of the Fano algorithm was reported in Ref. 33, wherein decoding was accelerated to 1.2 Mbps.

A modified Fano algorithm, named *creeper algorithm*, was proposed in 1999 [34]. This algorithm is indeed a compromise between the stack algorithm and the Fano algorithm. Instead of placing all visited paths in the stack, it selectively stores a fixed number of the paths that are more likely to be part of the optimal code path. As anticipated, the next path to be visited is no longer restricted to the immediate predecessor path and the successor paths but is extended to these selected likely paths. The number of likely paths is usually set less than 2^k times the code tree depth. The simulations given in Ref. 34 indicated that in computational complexity, the creeper algorithm considerably improves the Fano algorithm, and can be made only slightly inferior to the stack algorithm.

8. TRELLIS-BASED SEQUENTIAL DECODING ALGORITHM

Sequential decoding was mostly operated over a code tree in early publications, although some early published

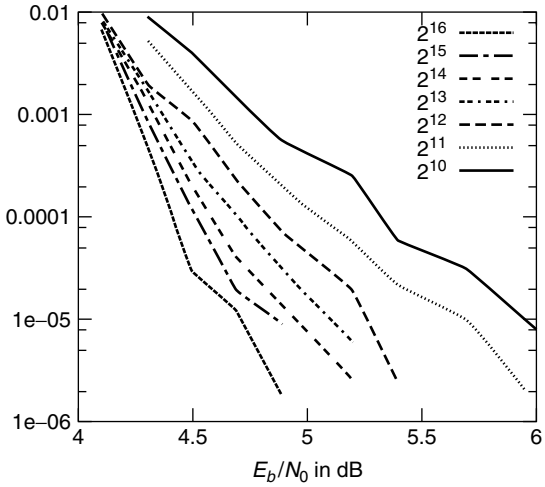

Figure 10. Bit error rate of the hardware Fano algorithm based on systematic $(2, 1, 46)$ convolutional code with generator polynomials $g_1 = 4,000,000,000,000,000$ and $g_2 = 7,154,737,013,174,652$. The legend indicates that the input buffer size tested ranges from $2^{10} = 1024$ to $2^{16} = 65,536$ branches. Experiments are conducted with 1 Mbps data rate over the binary symmetric channel with crossover probability $p = \frac{1}{2}\text{erfc}(\sqrt{E_b/N_0})$, where $\text{erfc}(x) = (2/\sqrt{\pi}) \int_x^\infty \exp\{-x^2\}\, dx$ is the complementary error function. The step size, the backsearch limit, and the Fano metric are set to $\Delta = 6$, $J = 240$, and $(1, -11)$, respectively. (Reproduced from Fig. 18 in Ref. 30).

work already hinted at the possibility of conducting sequential decoding over a trellis [35,36]. The first feasible algorithm that sequentially searches a trellis for the optimal codeword is the *generalized stack algorithm* [23]. The generalized stack algorithm simultaneously extends the top M paths in the stack. It then determines, according to the trellis structure, whether any of the extended paths merge with a path that is already in the stack. If so, the algorithm deletes the newly generated path after ensuring that its path metric is smaller than the cumulative path metric of the merged path up to the merged node. No redirection on the merged path is performed, even if the path metric of the newly generated path exceeds the path metric of the subpath that traverses along the merged path, and ends at the merged node. Thus, the newly generated path and the merged path may coexist in the stack. The generalized stack algorithm, although it generally yields a larger average computational complexity than the stack algorithm, has lower variability in computational complexity and a smaller probability of decoding error [23].

The main obstacle in implementing the generalized stack algorithm by hardware is the maintenance of the stack for the simultaneously extended M paths. One feasible solution is to employ M independent stacks, each of which is separately maintained by a processor [37]. In such a multiprocessor architecture, only one path extraction and two path insertions are sufficient for each stack in a decoding cycle of a $(2, 1, m)$ convolutional code [37]. Simulations have shown that this multiprocessor counterpart not only retained the low variability in computational complexity as the original generalized stack algorithm but also had a smaller average decoding time.

When the trellis-based generalized stack algorithm simultaneously extends 2^K most likely paths in the stack (i.e., $M = 2^K$), where $K = \sum_{j=1}^{k} K_j$ and K_j is the length of the jth shift register in the convolutional code encoder, the algorithm becomes the maximum-likelihood Viterbi decoding algorithm. The optimal codeword is thereby sought by exhausting all possibilities, and no computational complexity gain can be obtained at a lower noise level. Han et al. [38] proposed a true noise-level-adaptable trellis-based maximum-likelihood sequential decoder, called *maximum-likelihood soft-decision decoding algorithm* (MLSDA). The MLSDA adopts a new metric, other than the Fano metric, to guide its sequential search over a trellis for the optimal code path, which is now the code path with the minimum path metric. Derived from a variation of the Wagner rule [39], the new path metric associated with a path $\mathbf{v}_{(\ell n-1)}$ is given by

$$M_{\text{ML}}(\mathbf{v}_{(\ell n-1)} \mid \mathbf{r}_{(\ell n-1)}) = \sum_{j=0}^{\ell n-1} M_{\text{ML}}(v_j \mid r_j) \tag{9}$$

where $M_{\text{ML}}(v_j \mid r_j) = (y_j \oplus v_j) \times |\phi_j|$ is the jth-bit metric, $\mathbf{r}$ is the received vector, $\phi_j = \ln[\Pr(r_j \mid 0)/\Pr(r_j \mid 1)]$ is the jth loglikelihood ratio, and

$$y_j = \begin{cases} 1, & \text{if } \phi_j < 0 \\ 0, & \text{otherwise} \end{cases}$$

is the hard-decision output due to ϕ_j. For AWGN channels, the ML-bit metric can be simplified to $M_{\text{ML}}(v_j \mid r_j) = (y_j \oplus v_j) \times |r_j|$, where

$$y_j = \begin{cases} 1, & \text{if } r_j < 0 \\ 0, & \text{otherwise} \end{cases}$$

As described previously, the generalized stack algorithm, while examining the path merging according to a trellis structure, does not redirect the merged paths. The MLSDA, however, genuinely redirects and merges any two paths that share a common node, resulting in a stack without coexistence of crossed paths. A remarkable feature of the new ML path metric is that when a newly extended path merges with an existing path of longer length, the ML path metric of the newly extended path is always greater than or equal to the cumulative ML metric of the existing path up to the merged node. Therefore, a newly generated path that is shorter than its merged path can be immediately deleted, reducing the redirection overhead of the MLSDA only to the case in which the newly generated path and the merged existing path are equally long.[11] Thus, they merged at their end node. In such case, the

[11] Notably, for the new ML path metric, the path that survives is always the one with smaller path metric, contrary to the sequential decoding algorithm in terms of the Fano metric, in which the path with larger Fano metric survives.

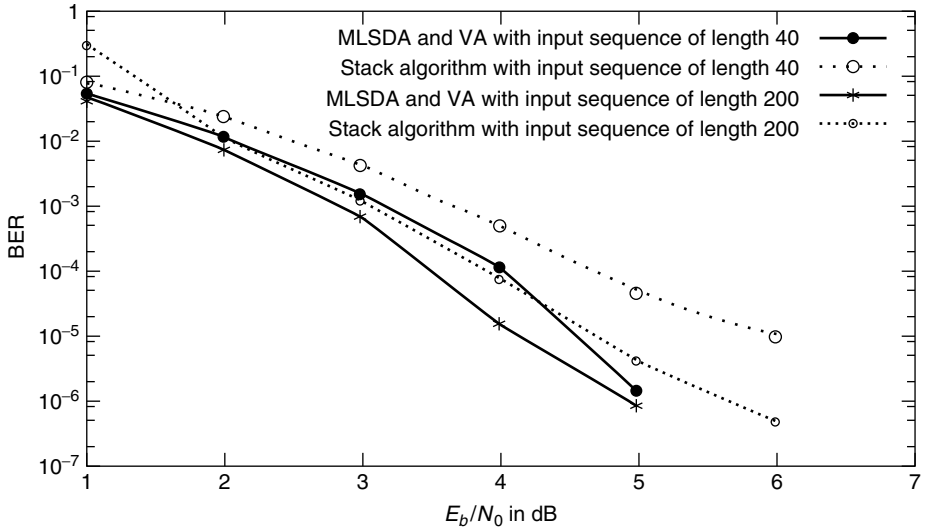

Figure 11. Bit error rates (BERs) of the MLSDA, the Viterbi algorithm (VA), and the stack algorithm for binary $(2, 1, 6)$ convolutional code with generators $g_1 = 634$ (octal), $g_2 = 564$ (octal), and input sequences of lengths 40 and 200. *Source*: Fig. 1 in Ref. 38).

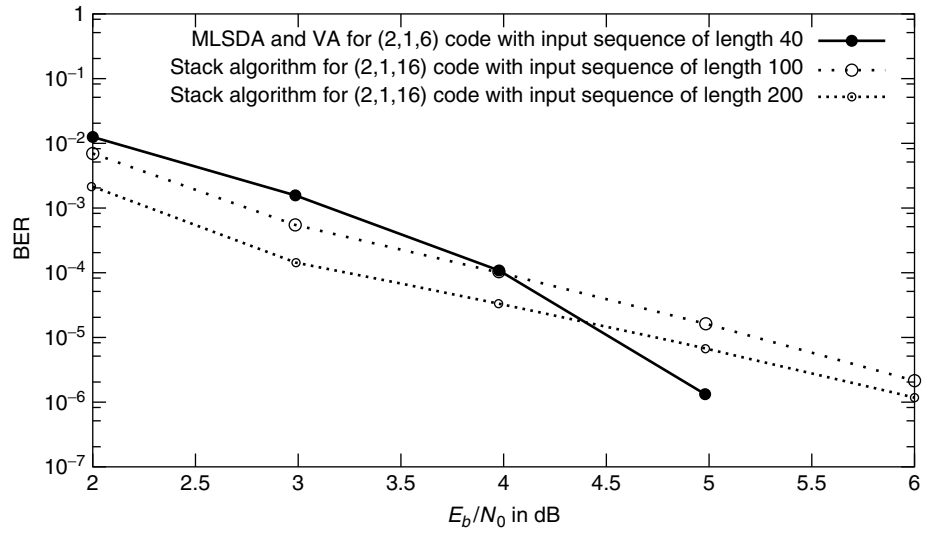

Figure 12. Bit error rates (BERs) of the MLSDA and Viterbi algorithm for binary $(2, 1, 6)$ convolutional code with generators $g_1 = 634$ (octal), $g_2 = 564$ (octal), and an input sequence of length 40. Also, BERs of the stack algorithm for binary $(2, 1, 16)$ convolutional code with generators $g_1 = 1632044, g_2 = 1145734$, and input sequences of lengths 100 and 200. (*Source*: Fig. 2 in Ref. 38).

redirection is merely a deletion of the path with larger path metric.

Figures 11 and 12 show the performances of the MLSDA for $(2, 1, 6)$ and $(2, 1, 16)$ convolutional codes transmitted over the AWGN channel. Specifically, Fig. 11 compares the bit error rate (BER) of the MLSDA with those obtained by the Viterbi and the stack algorithms. Both the MLSDA and the Viterbi algorithm yield the same BER since they are both maximum-likelihood decoders. Figure 11 also shows that the MLSDA provides around 1.5 dB advantage over the stack algorithm at BER $= 10^{-5}$, when both algorithms employ the same input sequence of length 40. Even when the length of the input sequence of the stack algorithm is extended to 200, the MLSDA with input sequence of length 40 still offers an advantage of $\sim$0.5 dB at BER $= 10^{-6}$. Figure 12 collects the empirical results concerning the MLSDA with an input sequence of length 40 for $(2, 1, 6)$ code, and the stack algorithm with input sequences of lengths 100 and 200 for $(2, 1, 16)$ code. The three curves indicate that the MLSDA with an input sequence of smaller length 40 for $(2, 1, 6)$ code provides an advantage of 1.0 dB over the stack algorithm with much longer input sequences and larger constraint length at BER $= 10^{-6}$.

These simulations lead to the conclusion that the stack algorithm normally requires a sufficiently long input sequence to converge to a low BER, which necessarily results in a long decoding delay and high demand for stack space. By adopting a new sequential decoding metric, the MLSDA can achieve the same performance using a much shorter input sequence; hence, the decoding delay and the demand for stack space can be significantly reduced. Furthermore, unlike the Fano metric, the new ML metric adopted in the MLSDA does not depend on the knowledge of the channel, such as SNR, for codes transmitted over the AWGN channel. Consequently, the MLSDA and the Viterbi algorithm share a common nature that their performance is insensitive to the accuracy of the channel SNR estimate for AWGN channels.

9. PERFORMANCE CHARACTERISTICS OF SEQUENTIAL DECODING

An important feature of sequential decoding is that the decoding time varies with the received vector, because the number of paths examined during the decoding process differs for different received vectors. The received vector, in turn, varies according to the noise statistics. The decoding complexity can therefore be legitimately viewed as a random variable whose probability distribution is defined by the statistics of the received vector.

The statistics of sequential decoding complexity have been extensively investigated using the *random coding technique* [15,36,40–44]. Instead of analyzing the complexity distribution with respect to a specific deterministic code, the average complexity distribution for a random code was analyzed. In practical applications, the convolutional codes are always deterministic in their generator polynomials. Nevertheless, taking the aspect of a random convolutional code, in which the coefficients of the generator polynomials are random, facilitates the analysis of sequential decoding complexity. The resultant average decoding complexity (where the decoding complexity is directly averaged over all possible generator polynomials) can nonetheless serve as a quantitative guide to the decoding complexity of a practical deterministic code.

In analyzing the average decoding complexity, a correct code path that corresponds to the transmitted codeword over the code tree or trellis always exists, even if the convolutional encoder is now random. Extra computation time is introduced whenever the search process of the decoder deviates from the correct code path due to a noise-distorted received vector. The incorrect paths that deviate from the correct code path can be classified according to the first node at which the incorrect and the correct code paths depart from each other. Denote by S_j the subtree that contains all incorrect paths that branch from the jth node on the correct path, where $0 \le j \le L-1$ and L is the length of the code input sequences. Then, an upper probability bound[12] on the average computational complexity C_j defined as the number of branch metric computations due to the examination of those incorrect paths in S_j can be established as

$$\Pr\{C_j \ge \mathcal{N}\} \le A\mathcal{N}^{-\rho} \tag{10}$$

for some $0 < \rho < \infty$ and any $0 \le j \le L-1$, where A is a constant that varies for different sequential decoding algorithms. The bound is independent of j because, during its derivation, L is taken to infinity such that all incorrect subtrees become identical in principle. The distribution characterized by the right-hand side of (10) is a *Pareto distribution*, and ρ is therefore named the *Pareto exponent*.

[12] The bound in (10) was first established by Savage for random *tree codes* for some integer value of ρ [41], where random tree codes constitute a super set of convolutional codes. Later, Jelinek [43] extended its validity for random tree codes to real-valued $\rho \ge 1$, satisfying (11). The validity of (10) for random convolutional codes was substantiated by Falconer [42] for $0 < \rho < 1$, and by Hashimoto and Arimoto [44] for $\rho \ge 1$.

Experimental studies indicate that the constant A usually lies between 1 and 10 [1]. The Pareto exponent ρ is uniquely determined by the code rate R using the formula

$$R = \frac{E_0(\rho)}{\rho} \tag{11}$$

for $0 < R < C$, where $E_0(\rho)$ is the *Gallager function* [45 Eq. (5.6.14)] and C is the channel capacity (cf. footnote 7). For example, the Gallager function and the channel capacity for the binary symmetric channel with crossover probability p are respectively given by

$$E_0(\rho) = \rho - (1+\rho)\log_2[p^{1/(1+\rho)} + (1-p)^{1/(1+\rho)}] \tag{12}$$

and

$$C = 1 + p\log_2(p) + (1-p)\log_2(1-p)$$

Equations (11) and (12) together imply that ρ goes to infinity as $R \downarrow 0$, and ρ approaches zero when $R \uparrow C$. Figure 13 gives the Pareto exponents for code rates $R = \frac{1}{4}, \frac{1}{3}, \frac{1}{2}, \frac{2}{3}, \frac{3}{4}$.

An argument converse to (10), due to Jacobs and Berlekamp [15], states that no sequential decoding algorithm can achieve a computational distribution better than the Pareto distribution of (10), given that no decoding error results for convolutional codes. Specifically, they showed that for a Pareto exponent that satisfies (11)

$$\Pr\{C_j \ge \mathcal{N} \mid \text{correct decoding}\} > [1 - o(\mathcal{N})]\mathcal{N}^{-\rho} \tag{13}$$

where $o(\cdot)$ is the little-o function, satisfying $o(x) \to 0$ as $x \to \infty$. The two bounds in (10) and (13) coincide only when $\mathcal{N}$ is sufficiently large.

On the basis of the multiple branching process technique [46], closed form expressions of the average computational complexity of sequential decoding were derived [47–49]. However, these closed form expressions were suited only for small $\mathcal{N}$. Inequalities (10) and (13)

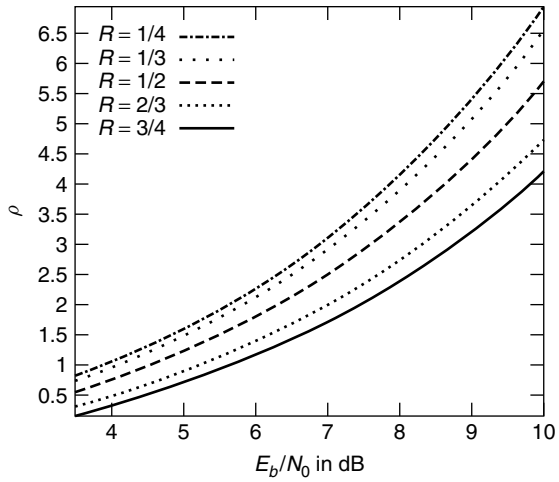

Figure 13. Pareto exponent as a function of E_b/N_0 for a BSC with crossover probability $p = \frac{1}{2}\text{erfc}(\sqrt{E_b/N_0})$, where $\text{erfc}(x) = (2/\sqrt{\pi})\int_x^\infty \exp\{-x^2\}\,dx$ is the complementary error function.

also show that the two bounds are independent of the code constraint length. This observation confirms the claim made in Section 1 that the average computational effort for sequential decoding is in principle independent of the code constraint length.

Inequalities (10) and (13) and the observation that $C_j \geq 1$ jointly yield

$$E[C_j] = \int_1^\infty \Pr\{C_j \geq \mathcal{N}\}\, d\mathcal{N} \leq \int_1^\infty A\mathcal{N}^{-\rho}\, d\mathcal{N}$$

and

$$\begin{aligned} &E[C_j \mid \text{correct decoding}] \\ &\quad = \int_1^\infty \Pr\{C_j \geq \mathcal{N} \mid \text{correct decoding}\}\, d\mathcal{N} \\ &\quad \geq \int_1^\infty [1 - o(\mathcal{N})]\mathcal{N}^{-\rho}\, d\mathcal{N} \end{aligned}$$

Therefore, if the Pareto exponent ρ is greater than unity, $E[C_j]$ is bounded from above. Conversely, if $E[C_j \mid \text{correct decoding}] < \infty$, then $\rho > 1$. Since the probability of correct decoding is very close to unity in most cases of interest, $\rho > 1$ is widely accepted as a sufficient and necessary condition for $E[C_j]$ to be bounded. This result gives rise to the term *computational cutoff rate* $R_0 = E_0(1)$, for sequential decoding.

From (11), $\rho > 1$ if, and only if, $R < R_0 = E_0(1)$, meaning that the cutoff rate R_0 is the largest code rate under which the average complexity of sequential decoding is finite. Thus, sequential decoding becomes computationally implausible once the code rate exceeds the cutoff rate R_0. This theoretical conclusion can be similarly observed from simulations.

Can the computational cutoff rate be improved? The question was answered by a proposal made by Flaconer [42] concerning the use of a hybrid coding scheme. The proposed communication system consists of an $(n_{\text{out}}, k_{\text{out}})$ outer Reed–Solomon encoder, n_{out} parallel $(n_{\text{in}}, 1, m)$ inner convolutional encoders, n_{out} parallel noisy channels, n_{out} sequential decoders for inner convolutional codes, and an algebraic decoder for the outer Reed–Solomon code. These five modules work together in the following fashion. The outer Reed–Solomon encoder encodes k_{out} input symbols into n_{out} output symbols, each of which is b bits long with the last m bits equal to zero. Then, each of n_{out} output symbol is fed into its respective binary $(n_{\text{in}}, 1, m)$ convolutional encoder in parallel, and induces $n_{\text{in}} \times b$ output code bits. Thereafter, these n_{out} $(n_{\text{in}}b)$-bit streams are simultaneously transmitted over n_{out} independent channels, where the n_{out} independent channels may be created by time-multiplexing over a single channel. On receiving n_{out} noise-distorted received vectors of dimension $n_{\text{in}}b$, the n_{out} sequential decoders reproduce the n_{out} output symbols through a sequential codeword search. If any sequential codeword search is not finished before a prespecified time, its output will be treated as an *erasure*. The final step is to use an algebraic Reed–Solomon decoder to regenerate the k_{out} input symbols, based on the n_{out} output symbols obtained from the n_{out} parallel sequential decoders.

The effective code rate of this hybrid system is

$$R_{\text{effective}} = \frac{k_{\text{out}}(b-m)}{n_{\text{out}}n_{\text{in}}b}$$

The largest effective code rate under which the hybrid system is computationally practical has been proved to improve over $E_0(1)$ [42]. Further improvement along the line of code concatenation can be found in Refs. 50 and 51.

The basis of the performance analysis for the aforementioned sequential decoding is random coding, and has nothing to do with any specific properties of the applied code, except the code rate R. Zigangirov [34] proposed to analyze the statistics of C_j for deterministic convolutional codes with an infinite memory order (i.e., $m = \infty$) in terms of recursive equations, and determined that for codes transmitted over BSCs and decoded by the tree-based stack algorithm

$$E[C_j] \leq \frac{\rho}{\rho - 1} 2^{-(-n\alpha+\beta)/(1+\rho)-k} \tag{14}$$

for $R < R_0 = E_0(1)$, where ρ is the Pareto exponent that satisfies (11) and α and β are as defined in the sentence following Eq. (4). Zigangirov's result again suggested that $E[C_j]$ is bounded for $R < R_0$, even when the deterministic convolutional codes are considered. A similar result was also established for the Fano algorithm [34].

Another code-specific estimate of sequential decoding complexity was due to Chevillat and Costello [52,53]. From simulations, they ingeniously deduced that the computational complexity of a sequential decoder is indeed related to the column distance function (CDF) of the applied code. They then established that for a convolutional code transmitted over a BSC with crossover probability p

$$\Pr\{C_j \geq \mathcal{N}\} < A N_d \exp\{-\lambda_1 d_c(\ell) + \lambda_2 \ell\} \tag{15}$$

for $R < 1 + 2p\log_2(p) + (1-2p)\log_2(1-p)$, where A, λ_1, and λ_2 are factors determined by p and code rate R; N_d is the number of length-$[n(\ell+1)]$ paths with Hamming weight equal to $d_c(\ell)$; ℓ is the integer part of $\log_{2^k}\mathcal{N}$; and $d_c(r)$ is the CDF of the applied code. They concluded that a convolutional code with a rapidly increasing CDF can yield a markedly smaller sequential decoding complexity. The outstanding issue is thus how to construct similar convolutional codes for use in sequential decoding. The issue is further explored in Section 11.

Next, the upper bounds on the bit error rate of sequential decoding are introduced. Let P_{S_j} be the probability that a path belonging to the incorrect subtree S_j is decoded as the ultimate output. Then, Chevillat and Costello [53] show that for a specific convolutional code transmitted over a BSC with crossover probability p

$$P_{S_j} < B N_f \exp\{-\gamma d_{\text{free}}\} \tag{16}$$

where B and γ are factors determined by p and code rate R, N_f is the number of code paths in S_j with Hamming weight equal to d_{free}, and d_{free} is the free distance of the applied code. The parameter γ is positive for all convolutional

codes whose free distance exceeds a lower limit determined by p and R. This result indicates that a small error probability for sequential decoding can be obtained by selecting a convolutional code with a large free distance and a small number of codewords with Hamming weight d_{free}. The free distance of a convolutional code generally grows with its constraint length. The bit error rate can therefore be made desirably low when a convolutional code with a sufficiently large constraint length is employed, as the computational complexity of sequential decoding is independent of the code constraint length. However, when a code with a large constraint length is used, the length of the input sequences must also be extended such that the effective code rate $kL/[n(L+m)]$ is closely approximated by code rate $R = k/n$. More discussion of the bit error rates of sequential decoding can be found in the literature [36,40,54].

10. BUFFER OVERFLOW AND SYSTEM CONSIDERATIONS

As already demonstrated by the hardware implementation of the Fano algorithm in Section 7, the *input buffer* at the decoder end for the temporary storage of the received vector is finite. The online decoder must therefore catch up to the input rate of the received vector such that the storage space for obsolete components of the received vector can be freed to store upcoming received components. Whenever an input buffer overflow is encountered, some of the still-in-use content in the input buffer must be forcefully written over by the new input, and the decoder must resynchronize to the new contents of the input buffer; hence input erasure occurs. The overall codeword error P_s of a sequential decoder thus becomes

$$P_s \simeq P_e + P_{\text{erasure}}$$

where P_e is the *undetected word error* under the infinite input buffer assumption and P_{erasure} is the *erasure probability*. For a code with a long constraint length and a practically sized input buffer, P_e is markedly smaller than P_{erasure}, so the overall word error is dominated by the probability of input buffer overflow. In this case, effort is reasonably focused on reducing P_{erasure}. When the code constraint length is only moderately large, a tradeoff between P_e and P_{erasure} must be made. For example, reducing the bucket spacing for the stacked bucket-enabled stack algorithm or lowering the step size for the Fano algorithm results in a smaller P_e, but increases $E[C_j]$ and hence P_{erasure}. The choice of path metrics, as indicated in Section 5, also yields a similar tradeoff between P_e and P_{erasure}. Accordingly, a balance between these two error probabilities must be maintained in practical system design.

The probability of buffer overflow can be analyzed as follows. Let B be the size of the input buffer measured in units of branches; hence the input buffer can store nB bits for an (n, k, m) convolutional code. Also let $1/T$ (bits per second) be the input rate of the received vector. Suppose that the decoder can perform μ branch metric computations in $n \times T$ seconds. Then if over μB branch computations are performed for paths in the jth incorrect subtree, the jth received branch in the input buffer must be written over by the new received branch. To simplify the analysis, assume that the entire buffer is simply reset when a buffer overflow occurs. In other words, the decoder aborts the present codeword search, and immediately begins a new search according to the new received vector. From Eq. (10), the probability of performing more than μB branch computations for paths in S_j is upper-bounded by $A(\mu B)^{-\rho}$. Hence, the erasure probability [41,55] for input sequences of length L is upper-bounded by

$$P_{\text{erasure}} \le L A (\mu B)^{-\rho} \tag{17}$$

Taking $L = 1000, A = 5, \mu = 10, B = 10^5$, and $R = \frac{1}{2}$ yields $\rho = 1.00457$ and $P_{\text{erasure}} \le 4.694 \times 10^{-3}$.

Three actions can be taken to avoid eliminating the entire received vector when the input buffer overflow occurs: (1) just inform the outer mechanism that an input erasure occurs, and let the outer mechanism take care of the decoding of the respective input sequences; (2) estimate the respective input sequences by a function mapping from the received vector to the input sequence; and (3) output the tentative decoding results obtained thus far. The previous section already demonstrated an example of the first action using the hybrid coding system. The second action can be taken whenever an input sequence to a convolutional encoder can be recovered from its codewords through a function mapping. Two typical convolutional codes whose input sequence can be directly mapped from the codewords are the systematic code and the quick-lookin code (to be introduced in the next section). A decoder can also choose to output a tentative decoded input sequence if the third action is taken. A specific example for the third action, named the *multiple stack algorithm*, is introduced in the next paragraph.

In 1977, Chevillat and Costello [56] proposed a *multiple stack algorithm* (MSA), which eliminated entirely the possibility of erasure in the sense that the decoded output is always based on the codeword search. The MSA, as its name implies, acts exactly like the stack algorithm except that it accommodates multiple stacks. During decoding, the MSA first behaves as the stack algorithm by using only its main stack of size z_{main}. When the main stack reaches its limit, the best t paths in the main stack are transferred to a smaller second stack with size $z \ll z_{\text{main}}$. Then the decoding process proceeds just like the stack algorithm, but now using the second stack. If a path reaches the end of the search tree before the second stack is filled, then the path is stored as a tentative decision, and the second stack is eliminated. The MSA then returns to the main stack that has t vacancy spaces for new paths because the top t paths have been removed. If another path reaches the end of the search tree before the main stack is filled again, the decoder compares its path metric with that of the current tentative decision, and outputs the one with larger metric, and stops. Now in case the second stack is filled before a code path is located, a third stack with the same size z is created such that the top t paths in the second stack are transferred to it. The codeword search process then proceeds over the

third stack until either a tentative decision can be made or a new stack needs to be created. Additional stacks of size z are formed whenever necessary. The decoder always compares the newly located code path with the previous tentative decision, and retains the better one. With some properly selected system parameters including z_{main}, z, t, and input buffer size, the MSA guarantees that whenever an input erasure occurs, a tentative decision is always ready for output [56]. Simulation results show that even though the stack maintenance of the MSA is more complex than the stack algorithm, the bit error rate of the former is much lower than that of the latter (see. Fig. 14). Further improvements of the MSA can be found in Refs. 57 and 58.

11. CODE CONSTRUCTION FOR SEQUENTIAL DECODING

A rapid column distance growth in CDF has been conjectured to help the early rejection of incorrect paths for sequential decoding algorithms [59]; this conjecture was later substantiated by Chevillat and Costello both empirically [52] and analytically [53]. In an effort to construct a good convolutional code for sequential decoding, Johannesson proposed [60] that the *code distance profile*, defined as $\{d_c(1), d_c(2), \ldots, d_c(m+1)\}$, can be used, instead of the entire code distance function $d_c(\cdot)$, as a "criterion" for good code construction. His suggestion greatly reduced the number of possible code designs that must be investigated.

A code $\mathcal{C}$ is said to have a better distance profile than another code $\mathcal{C}'$ with the same code rate and memory order, if there exists ℓ with $1 \le \ell \le m+1$ such that $d_c(j) = d'_c(j)$ for $1 \le j \le \ell - 1$ and $d_c(\ell) > d'_c(\ell)$, where $d_c(\cdot)$ and $d'_c(\cdot)$ are the CDFs of codes $\mathcal{C}$ and $\mathcal{C}'$, respectively. In other words, a code with a better distance profile exhibits a faster initial column distance growth in its CDF. A code is said to have an *optimal distance profile*, and is called an ODP code, if its distance profile is superior to that of any other code with the same code rate and memory order.

The searching of ODP codes was extensively studied by Johannesson and Passke [60–63]. They found that the ODP condition could be imposed on a half-rate ($R = \frac{1}{2}$) short constraint length code without penalty in the code free distance [60]; That is, the half-rate ODP code with a short constraint length can also be the code with the largest free distance of all codes with the same code rate and memory order. Tables 1 and 2 list the half-rate ODP codes for systematic codes and nonsystematic codes, respectively. Comprehensive information on ODP codes can be found in Ref. 34. These tables notably reveal that the free distance of a systematic ODP code is always inferior to that of a nonsystematic ODP code with the same memory order.

Employing ODP codes, while notably reduces the number of metric computations for sequential decoding, does not ensure erasure-free performance in practical implementation. If an erasure-free sequential decoding algorithm such as the MSA cannot be adopted due to certain practical considerations, the decoder must still force an immediate decision by just taking a *quick look* at the received vector, once input erasure occurs.

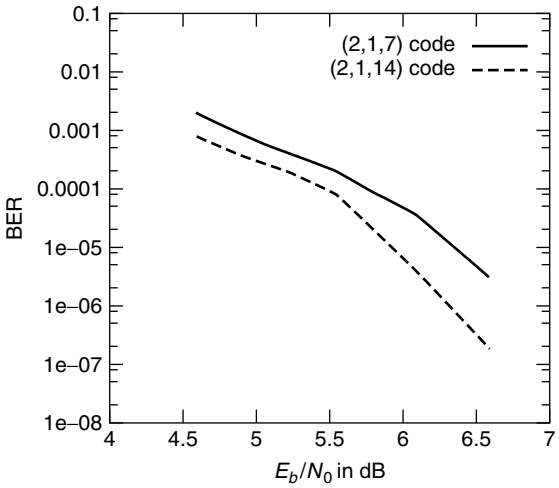

Figure 14. The MSA bit error rates (BER) for $(2, 1, 7)$ and $(2, 1, 14)$ convolutional codes with an input sequence of length 64. The system parameters for $(2, 1, 7)$ and $(2, 1, 14)$ convolutional codes are $(z_{\text{main}}, z, t) = (1024, 11, 3)$ and $(z_{\text{main}}, z, t) = (2900, 11, 3)$, respectively. The input erasure is emulated by an upper limit on branch metric computations C_{lim}, which is 1700 and 3300 for $(2, 1, 7)$ and $(2, 1, 14)$ convolutional codes, respectively. (Reproduced in part from Fig. 3 in Ref. 57).

This seems to suggest that a systematic ODP code is preferred, even if it has a smaller free distance than its nonsystematic ODP counterpart. In such case, the deficiency on the free distance of the systematic ODP codes can be compensated for by selecting a larger memory order m. However, when a convolutional code with large m is used, the length of the input sequences must be proportionally extended; otherwise the effective code rate cannot be well approximated by the convolutional code rate, and the performance to some extent degrades. This effect motivates the attempt to construct a class of nonsystematic ODP codes with the "quick look" property and a free distance superior to that of systematic codes.

Such a class of nonsystematic codes has been developed by Massey and Costello, called the *quick-lookin* (QLI) convolutional codes [59]. The generator polynomials of these half-rate QLI convolutional codes differ only in the second coefficient. Specifically, their generator polynomials satisfy $g_1(x) = g_2(x) + x$, where addition of coefficients is based on modulo-2 operation, allowing the decoder to recover the input sequence $\mathbf{u}(x)$ by summing the two output sequences $\mathbf{v}_1(x)$ and $\mathbf{v}_2(x)$ as

$$x \cdot \mathbf{u}(x) = \mathbf{v}_1(x) + \mathbf{v}_2(x) \tag{18}$$

If p is the individual bit error probability in the codeword $\mathbf{v}$, then the bit error probability due to recovering information sequence $\mathbf{u}$ from $\mathbf{v}$ through (18) is shown to be approximately $2p$ [59]. Table 3 lists the QLI ODP convolutional codes [34].

12. CONCLUSIONS

Although sequential decoding has a longer history than maximum-likelihood decoding based on the Viterbi algorithm, its practical applications are not as popular, because the highly repetitive "pipeline" nature of the Viterbi decoder makes it very suitable for hardware implementation. Furthermore, a sequential decoder usually requires a longer decoding delay (defined as the time between the receipt of a received branch and the output of its respective decoding decision) than a Viterbi decoder. Generally, the decoding delay of a sequential decoder for an (n, k, m) convolutional code is around $n \times B$, where B is the number of received branches that an input buffer can accommodate. Yet, the decoding delay of a Viterbi decoder can be made a small multiple, often ranging from 5 to 10, of $n \times m$. On the other hand, Refs. 64 and 65 showed that sequential decoding is highly sensitive to the channel parameters such as an inaccurate estimate of channel SNR and an incomplete compensation of phase noise. The Viterbi algorithm, however, proved to be robust for imperfect channel identification, again securing the superiority of the Viterbi decoder in practical applications.

Nevertheless, there are certain situations that the sequential decoding fits well, especially in decoding convolutional codes having a large constraint length.

In addition, the sequential decoder can send a timely retransmission request by detecting the occurrence of an input buffer overflow [66]. Sequential decoding has attracted some attention in the field of mobile communications [67] in which a demand of low bit error rate is required. Such applications are beyond the scope of this article, and interested readers can refer to the literature [1,68,69].

Acknowledgments

Professor Marc P. C. Fossorier of the University of Hawaii and Professor John G. Proakis are appreciated for their careful reviews and valuable comments. Mr. Tsung-Ju Wu and Mr. Tsung-Chi Lin are also appreciated for preparing the figures and checking the examples in this manuscript.

BIOGRAPHIES

Yunghsiang S. Han was born in Taipei, Taiwan, on April 24, 1962. He received the B.S. and M.S. degrees in electrical engineering from the National Tsing Hua University, Hsinchu, Taiwan, in 1984 and 1986, respectively, and the Ph.D. degree from the school of Computer and Information Science, Syracuse University, Syracuse, New York, in 1993. From 1986 to 1988 he was a Lecture at Ming-Hsin Engineering College, Hsinchu, Taiwan. He was a Teaching Assistant from 1989 to 1992 and from 1992 to 1993 a Research Assistant in the School of Computer and Information Science, Syracuse University. He is a recipient of the 1994 Syracuse University Doctoral Prize. From 1993 to 1997 he was an Associate Professor in the Department of Electronic Engineering at Hua Fan College of Humanities and Technology, Taipei Hsien, Taiwan. He is now with the Department of Computer Science and Information Engineering at National Chi Nan University, Nantou, Taiwan. He was promoted to full Professor in 1998. His research interests are in error-control coding and fault-tolerant computing.

Po-Ning Chen received the B.S. and M.S. degrees in electrical engineering from the National Tsing-Hua University in Taiwan in 1985 and 1987, respectively, and the Ph.D. degree in electrical engineering from the University of Maryland at College Park (USA) in 1994. From 1985 to 1987, he was with Image Processing Laboratory in the National Tsing-Hua University, where he worked on the recognition of Chinese characters. During 1989, he was with StarTech Engineering Inc., where he focused on the development of fingerprint recognition systems. After receiving the Ph.D. degree in 1994, he joined Wan Ta Technology Inc. as a Vice General Manager, conducting several projects on Point-of-Sale systems. In 1995, he joined the research staff at the Advanced Technology Center, Computer and Communication Laboratory, Industrial Technology Research Institute in Taiwan, where he led a project on Java-based Network Managements. Since 1996, he has been an Associate Professor in the Department of Communications Engineering at the National Chiao-Tung University, Taiwan, and became a full Professor in 2001. Dr. Chen received the 2000 Young Scholar Paper Award from Academia Sinica, Taiwan. His areas of interests are information and coding theory, large deviation theory, and distributed detection.

SERIALLY CONCATENATED CODES AND ITERATIVE ALGORITHMS

Torino (Turin), Italy

1. INTRODUCTION

In his goal to find a class of codes whose probability of error decreased exponentially at rates less than capacity, while decoding complexity increased only algebraically, Dave Forney [1] arrived at a solution consisting of the coding structure known as *concatenated code*. It consists of the cascade of an *inner* code and an *outer* code, which, in Forney's approach, would be a relatively short inner code (typically, a convolutional code) admitting simple maximum-likelihood soft decoding, and a long high-rate algebraic outer code (for most applications a nonbinary Reed–Solomon code) equipped with a powerful algebraic error correction decoding algorithm, possibly using reliability information from the inner decoder.

Initially motivated only by theoretical research interests, concatenated codes have since then evolved as a standard for those applications where very high coding gains are needed, such as (deep-)space applications, digital television broadcasting, compact disk players, and many others. Alternative solutions for concatenation have also been studied, such as using a trellis-coded modulation scheme as inner code [2], or concatenating two convolutional codes [3]. In the latter case, the inner Viterbi decoder employs a soft-output decoding algorithm to provide soft-input decisions to the outer Viterbi decoder. An interleaver was also proposed between the two encoders to separate bursts of errors produced by the inner decoder.

We find then, in a "classical" concatenated coding scheme, the main ingredients that formed the basis for the invention of "Turbo codes" [4], namely two, or more, *constituent* codes (CCs) and an *interleaver*. The novelty of Turbo codes, however, consists of the way they use the interleaver, which is embedded into the code structure to form an overall concatenated code with very large block length, and in the proposal of a parallel concatenation to achieve a higher rate for given rates of CCs. The latter advantage is obtained using systematic CCs and not transmitting the information bits entering the second encoder. In the following, we will refer to turbo codes as *parallel concatenated codes* (PCCs). The so-obtained codes have been shown to yield very high coding gains at bit error probabilities in the range 10^{-5}–10^{-7}; in particular, low bit error probabilities can be obtained at rates well beyond the channel cutoff rate, which had been regarded for long time as the "practical" capacity. Quite remarkably, this performance can be achieved by a relatively simple iterative decoding technique whose computational complexity is comparable to that needed to decode the two CCs.

After the invention of PCCs, other forms of code concatenations with interleaver have been proposed, like the serial concatenation [5] and hybrid concatenations [6,7]. This article deals with serial concatenations with interleaver in a wider sense; that is, we apply the iterative algorithm introduced in 1998 [5] for decoding serially concatenated codes (SCCs) also to systems where the two concatenated blocks represent different functions, such as intersymbol interference channel, a modulator, or a multiuser combiner.

In the first part we consider the serial concatenation of interleaved codes or *serially concatenated codes* (SCCs), called SCBC or SCCC according to the nature of CCs, that can be block (SCBC) or convolutional codes (SCCC). For this class of codes, we give analytical upper bounds to the performance of a maximum-likelihood (ML) decoder, present design guidelines leading to the optimal choice of CCs that maximize the so-called *interleaver gain* and the asymptotic code performance, and present the iterative decoding algorithm yielding results close to capacity limits with limited decoding complexity.

In the second part of the paper we extend the concept of serial concatenation, beyond the case of two codes, to systems in which two functional blocks with memory are cascaded and can be separated by an interleaver. This extension will prove that the "Turbo" principle applied to serial concatenation can have a wide variety of applications in the field of digital transmission.

Throughout the paper, a semi-tutorial approach has been adopted, and all but strictly necessary algebra and mathematical subtleties avoided. In this, we tried to stick to Einstein motto: *Everything should be made as simple as possible, but not simpler*, so as to highlight the meaning of the main properties/results while addressing the interested reader to the appropriate references.

2. SERIAL CONCATENATIONS

Figure 1 is a block diagram of a fairly general serial concatenation of three modules, M1, M2, and M3, with two interleavers I1 and I2 separating each pair of modules.

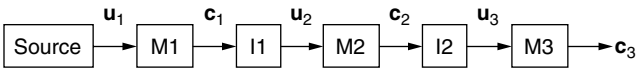

Figure 1. A general serially concatenated structure with three modules and two interleavers.

The symbols **u** and **c** may denote semiinfinite sequences, when the transmitted information flow does not possess a frame structure, or vectors containing a finite number of symbols when the information flow is delivered in a frame-by-frame basis. In the framed case, the interleavers must be *block* interleavers [8]. As we will see in Section 6, a structure like the one depicted in Fig. 1 can represent numerous systems and applications, beyond the basic one in which all modules represent encoders. In the next two sections, however, we will show how to analyze and design a serial concatenation in the particular, yet important, case of two encoders separated by one interleaver. This restriction will simplify the presentation, yet it will lead to conclusions that are applicable to a broader set of systems.

3. ANALYSIS OF SERIALLY CONCATENATED CODES WITH INTERLEAVERS

Consider the serial concatenation shown in Fig. 2. It is formed by the *outer* encoder C_o with rate $R_c^o = k/p$, and the *inner* encoder C_i with rate $R_c^i = p/n$, joined by an interleaver of size N bits, generating a serially concatenated code (SCC) C_S with rate $R_c^S = R_c^o \times R_c^i = k/n$. N will be assumed to be an integer multiple[1] of p. The outer and inner encoders are the constituent codes (CCs) of the SCC. We consider here block constituent codes, in which each code word is formed in a memoryless fashion by the encoder. This is the case when both CCs are block encoders, or when they are *terminated* [9, Chap. 11] convolutional encoders.

For large interleaver sizes, an SCC cannot be decoded as a single code using maximum-likelihood (ML) decoding [8]. Instead, as we will see later, the decoder will use a simpler, suboptimum iterative decoding algorithm based on two soft CC decoders. On the other hand, the analysis seems only be possible for ML decoding, using upper bounds that yield a great insight into the code behavior and provide valuable tools for the code design.

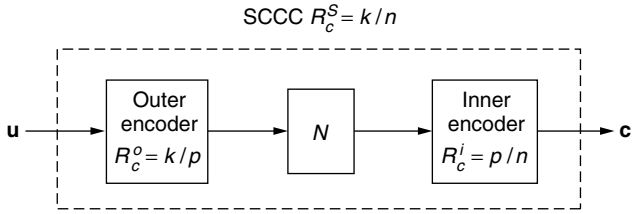

Figure 2. The serial concatenation of two encoders and one interleaver.

[1] Actually, this constraint is not necessary. We can choose in fact inner and outer codes of any rates $R_c^i = k_i/n_i$ and $R_c^o = k_o/n_o$, constraining the interleaver to be an integer multiple of the minimum common multiple of n_o and k_i, that is, $N = K \cdot mcm(n_o, k_i)$. This generalization, though, leads to more complicated expressions and is not considered in the following.

3.1. A Union Bound to the Code Error Probabilities

Upper bounds to the *word*[2] P_w and *bit*[3] P_b error probabilities for an (n, k) linear block code based on the union bound [9] under maximum-likelihood soft decoding for binary PSK (or binary PAM) transmission over an additive white Gaussian noise channel with two-sided noise power spectral density $N_0/2$ are given by

$$P_w \le \frac{1}{2} \sum_{d=d_{\min}}^{n} \sum_{w=1}^{k} A_{w,d} \operatorname{erfc}\left(\sqrt{\frac{dR_cE_b}{N_0}}\right)$$
$$P_b \le \frac{1}{2} \sum_{d=d_{\min}}^{n} \sum_{w=1}^{k} \frac{w}{k} A_{w,d} \operatorname{erfc}\left(\sqrt{\frac{dR_cE_b}{N_0}}\right) \quad (1)$$

where R_c is the code rate, E_b is the energy per *information* bit, and $A_{w,d}$ are the *input–output* coefficients of the encoder, representing the number of codewords with weight d generated by information words of weight w.

Knowledge of the coefficients $A_{w,d}$ is sufficient to evaluate the upper bound to both word and bit error probabilities, and thus we need to evaluate them for the SCC C_S, assuming that we know those of the CCs.

If N in Fig. 2 is low, we can compute the coefficients $A_{w,d}$ by letting each individual information word with weight w be first encoded by the outer encoder C_o and then, after the p bits of the outer codeword have been permuted by the interleaver, be encoded by the inner encoder C_i originating an inner codeword with a certain weight. After repeating this procedure for all the information words with weight w, we should count the inner codewords with weight d, and their number would be the value of $A_{w,d}$.

When N is large the previous operation becomes too complex, and we must resort to a different approach. As thoroughly described elsewhere [5,10], a crucial step in the analysis consists in replacing the actual interleaver that performs a permutation of the N input bits with an abstract interleaver called *uniform interleaver*, defined as a probabilistic device that maps a given input word of weight l into all distinct $\binom{N}{l}$ permutations of it with equal probability $P = 1/\binom{N}{l}$. Use of the uniform interleaver permits the computation of the "average" performance of the SCC, intended as the expectation of the performance of SCCs using the same CCs, taken over the set of all interleavers of a given size. A theorem proved in Ref. 10 guarantees the meaning fullness of the average performance, in the sense that there will always be, for each value of the signal-to-noise ratio, at least one particular interleaver yielding performance better than or equal to that of the uniform interleaver.

[2] The word error probability is defined as the probability that the decoder chooses an incorrect code word, *i.e.*, a code word different from the transmitted one.

[3] The bit error probability is defined as the probability that the decoder delivers an incorrect information bit to the user.

Define as $A_{w,d}^{C_S}$, $A_{w,l}^{C_o}$ and $A_{w,l}^{C_i}$ the input–output coefficients of the SCC C_S, outer and inner encoders, respectively; exploiting the properties of the uniform interleaver, which transforms a codeword of weight l at the output of the outer encoder into all its distinct $\binom{N}{l}$ permutations, we obtain [5]

$$A_{w,d}^{C_s} = \sum_{l=0}^{N} \frac{A_{w,l}^{C_o} \times A_{l,h}^{C_i}}{\binom{N}{l}} \tag{2}$$

This equation (2) permits an easy computation of the input-output coefficients of the SCC, and, together with (1), yields the upper bounds to word and bit error probabilities.

Example 1. Consider the rate-$\frac{1}{3}$ (nominal rate) SCC of Fig. 3 obtained concatenating a terminated rate-$\frac{1}{2}$, 4-state, recursive systematic encoders with generator matrix

$$G_o(Z) = \left[1, \frac{1+Z^2}{1+Z+Z^2}\right] \tag{3}$$

and as inner encoder a terminated 4-state, rate-$\frac{2}{3}$, recursive convolutional encoder with generator matrix

$$G_i(Z) = \begin{bmatrix} 1, 0, \dfrac{1+Z^2}{1+Z+Z^2} \\ 0, 1, \dfrac{1+Z}{1+Z+Z^2} \end{bmatrix} \tag{4}$$

Using the uniform interleaver concept, we have obtained the union bounds to the word and bit error probabilities shown in Figs. 4 and 5. The curves refer to five values of the interleaver size, corresponding to information block sizes $k = 10, 20, 40, 80, 160$. The curves show that increasing the interleaver size yields an increasing coding gain, which is more pronounced for the bit error probability. This phenomenon is known as *interleaving gain*.

Previous analysis can be generalized to n cascaded encoders separated by $n-1$ interleavers. Indeed, the ML performance of the overall encoder improves uniformly when increasing the number of CCs. On the other hand, the suboptimum iterative decoding algorithm that must be used to decode this kind of codes for complexity reasons suffers from a *bootstrap* effect that becomes more and more relevant as we increase the number of CCs. The case of three encoders, which has been proposed and analyzed [11] under the name of double serially concatenated code, seems to be the farthest one can go in practice.

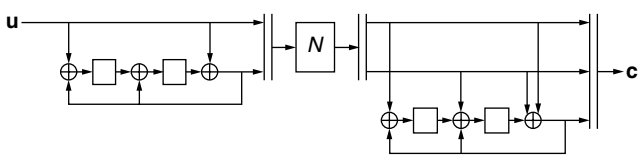

Figure 3. SCCC encoder of Example 1.

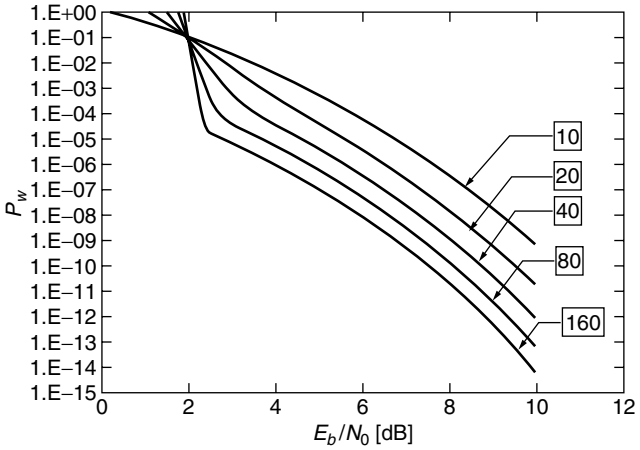

Figure 4. Word error probability bounds for the SCC of Example 1 employing as constituent encoders block codes obtained from 4-state convolutional encoders through trellis termination. The interleaver is uniform and corresponds to information words with size $k = 10, 20, 40, 80, 160$.

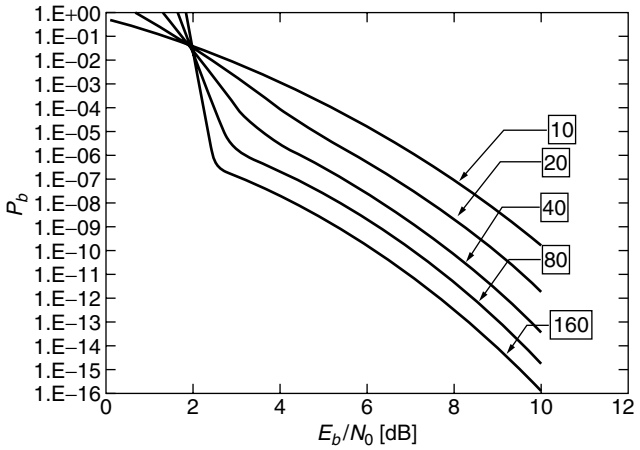

Figure 5. Bit error probability bounds for the SCC of Example 1 employing as constituent encoders block codes obtained from 4-state convolutional encoders through trellis termination. The interleaver is uniform and corresponds to information words with size $K = 10, 20, 40, 80, 160$.

4. DESIGN OF SERIALLY CONCATENATED CODES WITH INTERLEAVER

The error probability performance of concatenated codes with interleaver (and, in particular, of serially concatenated codes) under iterative decoding are invariably represented by curves like the ones depicted in Fig. 6. We can identify three different regions, for increasing values of the signal-to-noise ratio. The first one is the *non-convergence* region, where the error probability keeps high, nearly constant values. At a certain point, the *convergence abscissa*, the curves start a rather steep descent down to medium–low values of the error probability (the *waterfall region*). Finally, in the third region (the *error floor* region), the slope of the curves decreases significantly, and performance improvement are paid with

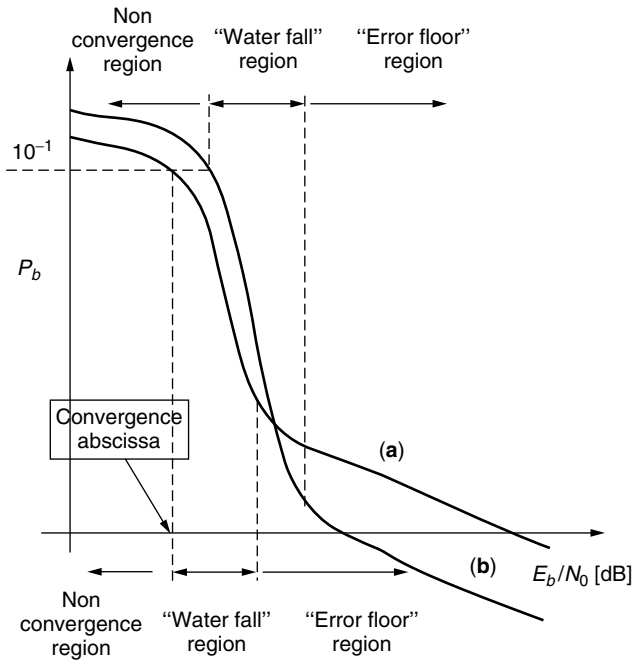

Figure 6. Qualitative behavior of P_b versus E_b/N_0 for concatenated codes with interleavers under iterative decoding.

significant energy expenses. The waterfall region is dominated by the interleaver gain, whereas the error floor region is dictated by the minimum distance of the code. In the first region, the interleaver acts through its size, whereas in the second the kind of interleaver plays a dominant role.

Any attempt to design codes like those in Fig. 2 as a whole leads to discouraging results because of its complexity. So far, only two successful design techniques have been proposed in the literature: the first relies on the previously introduced concept of uniform interleaver, and leads to design rules for the CCs that work nicely for medium–low error probabilities. After designing the CCs, one can improve the code performance by a cut-and-try approach to the interleaver design.

While the first approach is a purely analytical one, the second requires the separate simulation of the behavior of each CC, and is based on the *probability density evolution* technique ([12–14]) or on the *EXIT charts* [15]. This technique leads to codes that exhibit good performance in terms of convergence abscissa, and are suited for medium-high values of the error probability. Unfortunately, the two techniques lead to different code designs; typically, the codes designed (or, better, found) through the second technique show faster convergence of the iterative decoding algorithm, but reach sooner the error floor [see curve (a) in Fig. 6]. The opposite is true for codes designed using the first technique [see curve (b) in Fig. 6]. As a consequence, the choice depends on the quality of service requirements of the system at hand. In the following, we report the main results stemming from the first design technique, addressing the readers to the appropriate references for the second.

4.1. The ML Design

A lengthy analysis [5] shows that, for large interleavers, the union upper bound to the ML error probability of a general concatenated code with uniform interleaver can be written as

$$P \leq \frac{1}{2} \sum_{d=d_{\min}} K_d N^{\alpha(d)} \operatorname{erfc}\left(\sqrt{\frac{dR_c E_b}{N_0}}\right) \tag{5}$$

where K_d does not depend on the interleaver size N. Asymptotically, for large interleavers where $N \to \infty$, the dominant term in the summation of (5) is the one for which the exponent of N is maximum. Denoting that exponent by $\alpha_M \triangleq \max_d \alpha(d)$, and neglecting the other summation terms, yields

$$P \overset{N}{\asymp} \frac{1}{2} K_{d_M} N^{\alpha_M} \operatorname{erfc}\left(\sqrt{\frac{d_M R_c E_b}{N_0}}\right) \tag{6}$$

where $d_M = \arg\max_d [\alpha(d)]$. Negative values of α_M lead to interleaving gains, which are more pronounced for larger magnitudes of α_M. The value of α_M is different in the cases of word and bit error probabilities, and depends on the kind of code concatenation. In the following, we show its values for the bit error probability. Adding one to those values yields the α'_M values pertaining to the word error probability.

For parallel concatenated codes[4] (PCCs) [10] a necessary and sufficient condition to have $\alpha_M < 0$ is that both constituent encoders be *recursive*. In that case, we obtain

$$\begin{aligned} \alpha_M &= -1 \\ d_M &= d_{\text{free,eff}} \end{aligned} \tag{7}$$

where $d_{\text{free,eff}}$ is the *effective* free distance of the PCCC, *i.e.*, the minimum weight of codewords associated to weight 2 information words. The effective free distance of the PCCC is equal to the sum of the effective free distances of the constituent encoders, and thus the optimization of them consists in searching for recursive convolutional encoders with the largest effective free distance, and, possibly, the lowest number of codewords with weight equal to the effective free distance (number of "nearest" neighbors).

For SCCCs, a necessary and sufficient condition to have $\alpha_M < 0$ is that the inner constituent encoder be *recursive* [5]. If that is the case, we obtain

$$\alpha_M = -\left\lfloor \frac{d^o_{\text{free}} + 1}{2} \right\rfloor \tag{8}$$

$$d_M = \begin{cases} \dfrac{d^o_{\text{free}} d^i_{\text{free,eff}}}{2}, & \text{for } d^o_{\text{free}} \text{ odd} \\ \dfrac{(d^o_{\text{free}} - 3) d^i_{\text{free,eff}}}{2} + d_3, & \text{for } d^o_{\text{free}} \text{ even} \end{cases}$$

[4] For comparison purposes, we recall here the main results for the case of parallel concatenation.

where d_3 is the minimum weight of inner code words associated to input words with weight 3.

Example 2. Consider two rate-$\frac{1}{3}$ concatenated encoders. The first is a parallel concatenated convolutional encoder made up with two 4-state systematic recursive convolutional encoders derived from the generator matrix G_0 of (3). The second, instead, is the rate-$\frac{1}{3}$ SCCC of Example 1. The two concatenations use interleaver sizes such that the corresponding information block sizes coincide. Applying the union bound leads to the results reported in Fig. 7, where we plot the bit error probability versus E_b/N_0 for information block sizes equal to 100 and 1000.

The curves make apparent the difference in the interleaver gain. In particular, the parallel concatenation shows an interleaver gain going as $\alpha_M = -1$, whereas the interleaver gain of the SCCC goes as $\alpha_M = -\dfrac{d_{of}+1}{2} = -3$, being the free distance of the outer code equal to 5. This means, for $P_b = 10^{-11}$, a gain of more than 2 dB in favor of the SCCC.

For SCCs, then, the design criteria require the inner code to be recursive, and chosen so as to maximize its effective free distance. The outer encoder can be either recursive or not, and its optimization is based on the usual criterion of maximizing the free distance.

The design criterion based on the *effective* free distance (rather than simply the free distance), and the requirement for the inner constituent encoder to be recursive, is a complete novelty in the panorama of known optimum convolutional encoders, whose search had been based on feedforward encoders with the greatest free distance. The effective free distance of a convolutional encoder can be significantly greater than the free distance, and this, with the interleaver gain, explains the exceptionally good performance of SCCs in the waterfall region. In Refs. 16 and 17 upper bounds to the effective free distance and tables of good recursive convolutional encoders are reported. The findings of the more complete search for good codes matching the design criteria have also been described [18].

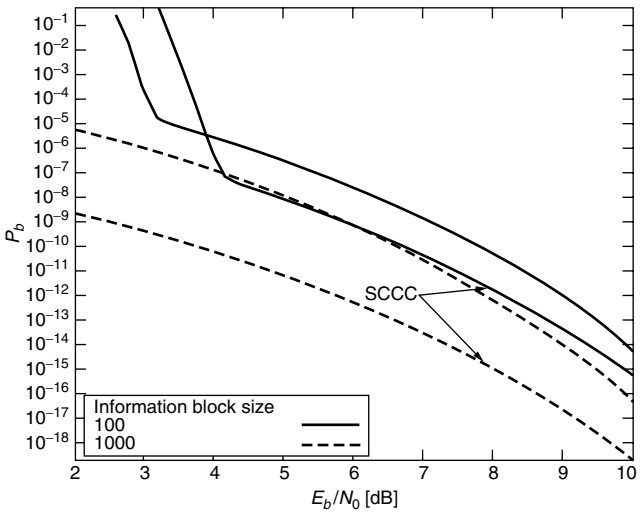

Figure 7. Comparison of serially and parallel rate-$\frac{1}{3}$ concatenated convolutional codes based on 4-state CCs with two interleaver sizes, yielding the same information block size for the two concatenations.

5. ITERATIVE DECODING OF SERIALLY CONCATENATED CODES

In this section, we present the iterative algorithm for decoding serially concatenated codes, with complexity not significantly higher than that needed to separately decode the two CCs. We assume, without loss of generality, that the constituent encoders admit a trellis representation [9].

The core of the decoding procedure consists of a block called *soft-input–soft-output* (SISO). It is a four-port device, which accepts as inputs the likelihood functions (or the corresponding likelihood ratios) of the information and code symbols labeling the edges of the code trellis, and forms as outputs an update of those likelihood functions based on the code constraints. The block SISO is used within the iterative decoding algorithm as shown in Fig. 8, where we also show the block diagram of the encoder to clarify the notations.

We will first explain in words how the algorithm works, according to the blocks of Fig. 8. Subsequently we will give the input-output relationships of the block SISO.

The symbols $\lambda(\cdot;I)$ and $\lambda(\cdot;O)$ at the input and output ports of SISO refer to the logarithmic likelihood ratios (LLRs),[5] unconstrained when the second argument is I, and modified according to the code constraints when it is O. The first argument u refers to the information symbols of the encoder, whereas c refers to code symbols. Finally, the superscript o refers to the outer encoder, and i to the inner encoder. The LLRs are defined as

$$\lambda(x;\cdot) \triangleq \log\left[\frac{P(x;\cdot)}{P(x_{\text{ref}};\cdot)}\right] \tag{9}$$

When x is a binary symbol, "0" or "1," x_{ref} is generally assumed to be the "0." When x belongs to an L-ary alphabet, we can choose as x_{ref} each one of the L symbols.

In contrast to the iterative decoding algorithm employed for PCCC decoding [19], in which only the LLRs

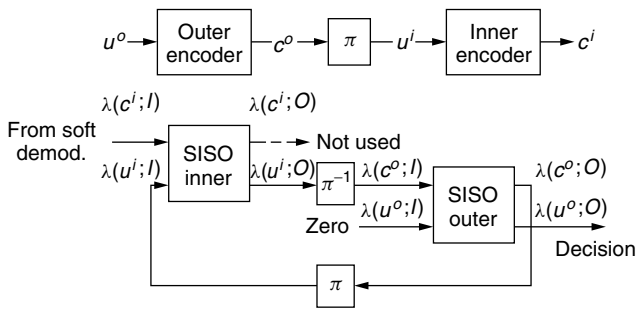

Figure 8. Block diagrams of the encoder and iterative decoder for serially concatenated convolutional codes.

[5] When the symbols are binary, only one LLR is needed; when the symbols belong to an L-ary alphabet, $L-1$ LLRs are required.

of information symbols are updated, here we must update the LLRs of both information and code symbols based on the code constraints.

During the first iteration of the SCC algorithm,[6] the block "SISO inner" is fed with the demodulator soft outputs, consisting of the LLRs of symbols received from the channels, namely, of the code symbols of the inner encoder. The second input $\lambda(u^i;I)$ of the SISO inner is set to zero during the first iteration, since no a- priori information is available on the input symbols u^i of the inner encoder.

The LLRs $\lambda(c^i;I)$ are processed by the SISO algorithm, which computes the *extrinsic* [19] LLRs of the information symbols of the inner encoder $\lambda(u^i;O)$ conditioned on the inner code constraints. The extrinsic LLRs are passed through the inverse interleaver (block labeled "π^{-1}"), whose outputs correspond to the LLRs of the code symbols of the outer code:

$$\lambda(c^o;I) = \pi^{-1}[\lambda(u^i;O)]$$

These LLRs are then fed to the block "SISO outer" in its upper entry, which corresponds to code symbols. The SISO outer, in turn, processes the LLRs $\lambda(c^o;I)$ of its unconstrained code symbols, and computes the LLRs of both code and information symbols based on the code constraints. The input $\lambda(u^o;I)$ of the SISO Outer is always set to zero, which implies assuming equally likely transmitted source information symbols. The output LLRs of information symbols (which yield the a posteriori LLRs of the SCCC information symbols) will be used in the final iteration to recover the information bits. On the other hand, the LLRs of outer code symbols, after interleaving, are fed back to the lower entry (corresponding to information symbols of the inner code) of the block SISO inner to start the second iteration. In fact we have

$$\lambda(u^i;I) = \pi[\lambda(c^o;O)]$$

5.1. Input–Output Relationships for the Block SISO

The block SISO has been described [19]. It represents a slight generalization of the BCJR algorithm [20–22]. Here, we will only recall for completeness its input–output relationships. We will refer, for notations, to the trellis section of the trellis encoder, assumed to be time invariant as we deal with convolutional codes, shown in Fig. 9, where the symbol e denotes the trellis edge, and where we have identified the information and code symbols associated to the edge e as $u(e)$, $c(e)$, and the starting and ending states of the edge e as $s^S(e)$, $s^E(e)$, respectively.

The block SISO works at *symbol* level; thus, for an (n,p) convolutional code, it operates on information symbols u belonging to an alphabet with size 2^p and on code symbols belonging to an alphabet with size 2^n. We will give the general input–output relationships, valid for both outer and inner SISOs, assuming that the information and code symbols are defined over a finite time index set $[1,\ldots,K]$.

[6] To simplify the description, we assume for now that the interleaver acts on symbols instead of bits. In practice, one often uses bit LLRs and bit interleaver, as it will be seen later.

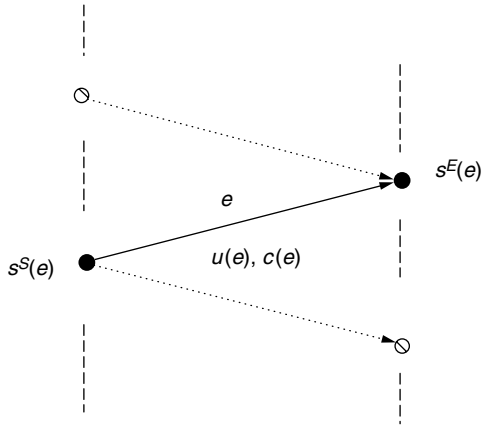

Figure 9. Trellis section defining the notations used for the description of the SISO algorithm.

At time k, $k=1,\ldots,K$, the output extrinsic LLRs are computed as

$$\lambda_k(c;O) = \max_{e:c(e)=c}{}^*\{\alpha_{k-1}[s^S(e)] + \lambda_k[u(e);I] + \beta_k[s^E(e)]\} - \max_{e:c(e)=c_{\text{ref}}}{}^*\{\alpha_{k-1}[s^S(e)] + \lambda_k[u(e);I] + \beta_k[s^E(e)]\} \tag{10}$$

$$\lambda_k(u;O) = \max_{e:u(e)=u}{}^*\{\alpha_{k-1}[s^S(e)] + \lambda_k[c(e);I] + \beta_k[s^E(e)]\} - \max_{e:u(e)=u_{\text{ref}}}{}^*\{\alpha_{k-1}[s^S(e)] + \lambda_k[c(e);I] + \beta_k[s^E(e)]\} \tag{11}$$

The name *extrinsic* given to the LLRs computed according to (10) and (11) derives from the fact that the evaluation of $\lambda_k(c;O)$ [and of $\lambda_k(u;O)$] does not depend on the corresponding simultaneous input $\lambda_k(c;I)$ [and $\lambda_k(u;I)$], so that it can be considered as an update of the input LLR based on informations coming from all homologous symbols in the sequence, except the one corresponding to the same symbol interval.

The quantities $\alpha_k(\cdot)$ and $\beta_k(\cdot)$ in (10) and (11) are obtained through the *forward* and *backward* recursions, respectively, as

$$\alpha_k(s) = \max_{c:s^E(e)=s}{}^*\{\alpha_{k-1}[s^S(e)] + \lambda_k[u(e);I] + \lambda_k[c(e);I]\}, \quad k=1,\ldots,K-1 \tag{12}$$

$$\beta_k(s) = \max_{e:s^S(e)=s}{}^*\{\beta_{k+1}[s^E(e)] + \lambda_{k+1}[u;I] + \lambda_{k+1}[c(e);I]\}, \quad k=K-1,\ldots,1 \tag{13}$$

with initial values

$$\alpha_0(s) = \begin{cases} 0 & s=S_0 \\ -\infty & \text{otherwise} \end{cases}$$

$$\beta_K(S_i) = \begin{cases} 0 & s=S_K \\ -\infty & \text{otherwise} \end{cases}$$

The operator max* performs the following operation:

$$\max_j{}^*(a_j) \triangleq \log\left[\sum_{j=1}^{J} e^{a_j}\right] \tag{14}$$

This operation, a crucial one in affecting the computational complexity of the SISO algorithm, can be performed in practice as

$$\max_j{}^*(a_j) = \max_j(a_j) + \delta(a_1, a_2, \ldots, a_J) \tag{15}$$

where $\delta(a_1, a_2, \ldots, a_J)$ is a correction term that can be computed recursively using a single-entry lookup table [19,23].

The previous description of the iterative decoder assumed that all operations were performed at *symbol* level. Quite often, however, the interleaver operates at *bit* level to be more effective. This is the case, for example, of all results presented in Sections 3–5.

Thus, to perform bit interleaving, we need to transform the symbol extrinsic LLRs obtained at the output of the first SISO into extrinsic bit LLRs, before they enter the deinterleaver. After deinterleaving, the bit LLRs need to be compacted into symbol LLRs before entering the second SISO block, and so on. These operations are performed under the assumption that the LLRs of bits forming a symbol are independent.

Assuming an (n, p) code, and denoting with $\mathbf{u} = [u_1, \ldots, u_p]$ the information symbol formed by p information bits, then the extrinsic LLR λ_i of the ith bit u_i within the symbol $\mathbf{u}$ is obtained as

$$\lambda_{kp+i}(O) = \max_{\mathbf{u}:u_i=1}{}^*[\lambda_k(\mathbf{u}; O) + \lambda_k(\mathbf{u}; I)] - \max_{\mathbf{u}:u_i=0}{}^*[\lambda_k(\mathbf{u}; O) + \lambda_k(\mathbf{u}; I)] - \lambda_{kp+i}(I) \tag{16}$$

Conversely, the extrinsic LLR of the symbol $\mathbf{u}$ is obtained from the extrinsic LLRs of its component bits u_i as

$$\lambda(\mathbf{u}) = \sum_{i=1}^{p} u_i \lambda_i \tag{17}$$

As previous description should have made clear, the SISO algorithm requires that the whole sequence had been received before starting. The reason is due to the backward recursion that starts from the (supposed known) final trellis state. As a consequence, its practical application is limited to the case where the duration of the transmission is short (K small), or, for K long, when the received sequence can be segmented into independent consecutive blocks, like for block codes or convolutional codes with trellis termination [24]. It cannot be used for continuous decoding. This constraint leads to a frame rigidity imposed to the system, and also reduces the overall code rate, because of trellis termination.

A more flexible decoding strategy is offered by modifying the algorithm in such a way that the SISO module operates on a fixed memory span, and outputs the updated LLRs after a given delay D. This algorithm, which we have called the *sliding-window soft-input/soft-output* (SW-SISO) algorithm, is fully described in Ref. 19. In all simulation results the SW-SISO algorithm has been applied.

5.2. Applications of the Decoding Algorithm

We will now use the decoding algorithm to confirm the design rules presented before, and to show the behavior of SCCC in the region of low signal-to-noise ratios (below cutoff rate). Since analytic bounds fail to give significant results in this region, no meaningful quantitative comparisons can be performed between simulated and analytic performance. However, we will show that the hierarchy of the simulation results agrees with the design considerations that had been based on the analysis.

The following aspects will be considered:

- The behavior of the decoding algorithm versus the number of decoding iterations (Section 5.2.1)
- The behavior of the decoding algorithm versus the interleaver length (Subsection 5.2.2)
- The effect of choosing a nonrecursive inner code (Section 5.2.2)
- The SCCC behavior for very low signal-to-noise ratios, to see how close serial concatenation can get to theoretical Shannon bound (Section 5.2.3)
- The comparison between SCCCs and PCCCs (Turbo codes) for the same value of the decoding delay imposed by the two schemes on the input bits (Section 5.2.4).

For all simulated SCCCs, we have used purely random interleavers.

5.2.1. Simulated Coding Gain Versus Number of Iterations. Consider the rate-$\frac{1}{3}$ SCCC1 of Example 1 employing an interleaver of length $N = 2048$. Since the interleaver operates on coded sequences produced by the outer rate-$\frac{1}{2}$ encoder, its length of 2048 bits corresponds to a delay of 1024 information bits. The simulation results are shown in Fig. 10 in terms of bit error probability versus E_b/N_0 for a number of iterations N_I ranging from 1 to 7. The nice convergence of the decoding algorithm is manifest.

5.2.2. The Effect of a Nonrecursive Inner Encoder. In Section 4 we concluded that a nonrecursive inner encoder should yield little interleaver gains. To confirm this theoretical prediction by simulation results, in Fig. 11 we plot the bit error probability versus the input decoding delay obtained by simulating a rate-$\frac{1}{3}$ SCCC that concatenates the outer encoder of Example 1 with the 4-state, nonrecursive inner encoder with generator matrix

$$G_i(Z) = \begin{bmatrix} 1+Z, & Z, & 1 \\ 1+Z, & 1, & 1+Z \end{bmatrix}$$

The curves refer to a signal-to-noise ratio $E_b/N_0 = 1.5$ dB, and to a number of iterations N_I ranging from 1 to 10. It is evident that the bit error probability reaches the floor of

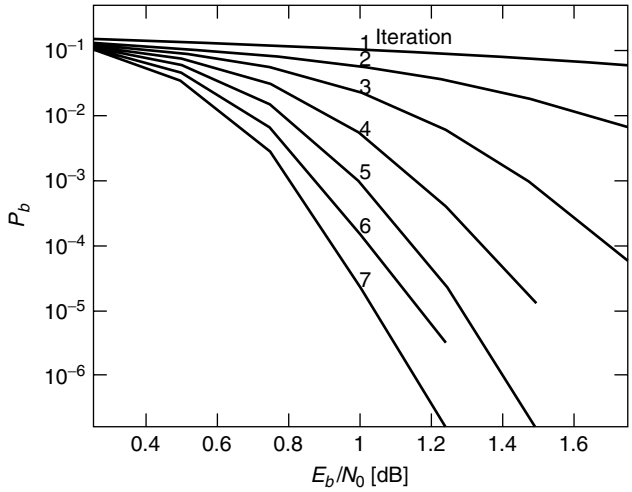

Figure 10. Simulated bit error probability versus the number of iterations for the rate-$\frac{1}{3}$ SCCC of Example 1. The decoding delay in terms of input bits due to the interleaver is 1024.

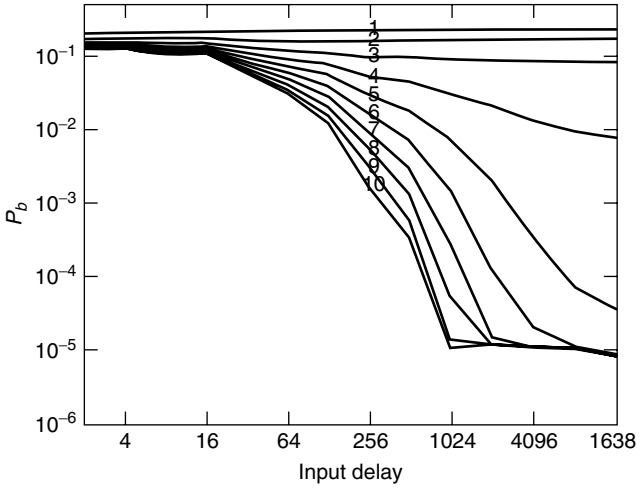

Figure 11. Simulated performance of the SCCC employing a nonrecursive inner encoder described in Section 5.2.3. The bit error probability is plotted versus input decoding delay for different number of iterations. The signal-to-noise ratio is 1.5 dB.

10^{-5} for a decoding delay greater than or equal to 1024, so that no interleaver gain takes place beyond this point. For comparison, in Fig. 12 we show the results obtained for the SCCC concatenating the 4-state, rate-$\frac{1}{2}$ nonrecursive outer encoder with generator matrix

$$G_o(Z) = [1 + Z + Z^2, 1 + Z^2]$$

with the rate-$\frac{2}{3}$ inner encoder of Example 1. The curves refer to a signal-to-noise ratio of 0.75 dB, and show the interleaver gain predicted by the analysis.

5.2.3. Approaching the Theoretical Shannon Limit. We show here the capabilities of SCCCs of yielding results close to the Shannon capacity limit. To this purpose, we have chosen a rate-$\frac{1}{4}$ concatenated scheme with very long interleaver, corresponding to an input decoding delay

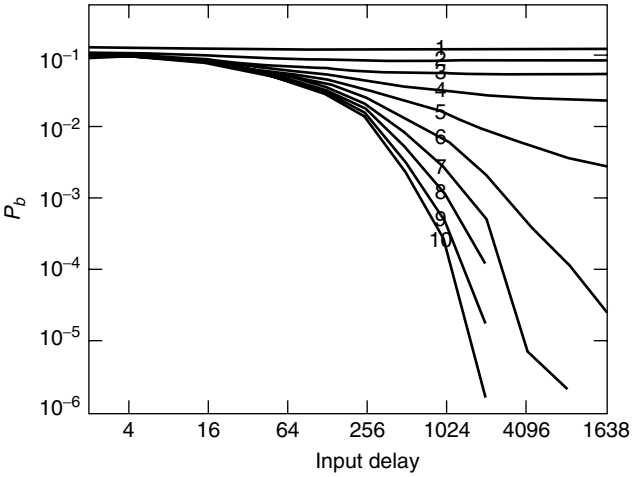

Figure 12. Simulated performance of the SCCC employing a nonrecursive outer encoder described in Section 5.2.2. The bit error probability is plotted versus input decoding delay for different number of iterations. The signal-to-noise ratio is 0.75 dB.

of 16,384. The constituent codes are 8-state codes: the outer encoder is nonrecursive, and the inner encoder is a recursive encoder. Their generating matrices are

$$G_o(Z) = [1 + Z, 1 + Z + Z^3]$$

$$G_i(Z) = \left[1, \frac{1 + Z + Z^3}{1 + Z}\right]$$

respectively. Note the feedback polynomial $(1 + Z)$ in the generator matrix of the inner encoder, which eliminates error events with odd input weights. The results in terms of bit error probability versus signal-to-noise ratio for different number of iterations are presented in Fig. 13 showing that the decoding algorithm works at $E_b/N_0 = -0.05$ dB, at 0.76 dB from the Shannon capacity limit (which is in this case equal to -0.817 dB), with very limited complexity (remember that we are using two rate-$\frac{1}{2}$ codes with 8 states).

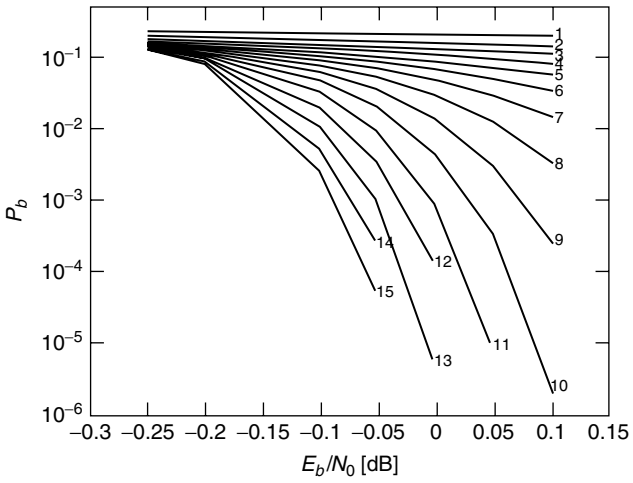

Figure 13. Simulated performance of the rate-$\frac{1}{4}$ SCCC obtained with two 8-state constituent codes and an interleaver yielding an input decoding delay equal to 16,384.

5.2.4. Comparison Between Serially and Parallel Concatenated Codes. Previous analytic results showed that serial concatenation can yield significantly higher interleaver gains and steeper asymptotic slope of the error probability curves. To check whether these advantages are retained when the codes are iteratively decoded at very low signal-to-noise ratios, we have simulated the behavior of two SCCCs and PCCCs in equal system conditions: the concatenated code rate is $\frac{1}{3}$, the CCs (same as Example 2) are 4-state recursive encoders (rates $\frac{1}{2} + \frac{1}{1}$ for PCCCs, and rates $\frac{1}{2} + \frac{2}{3}$ for the SCCCs), and the decoding delays in terms of input bits are 1024 and 16,384, respectively. In Fig. 14 we report the results, in terms of bit error probability versus signal-to-noise ratio, for the case of a decoding delay equal to 1024, after three and seven decoding iterations. As it can be seen from the curves, the PCCC outperforms the SCCC for high values of the bit error probabilities. For bit error probabilities lower than $3 \cdot 10^{-3}$ (for seven iterations), the SCCC outperform PCCC, and does not present the error floor. At 10^{-4}, SCCC has an advantage of 0.7 dB with seven iterations. Finally, in Fig. 15, we report the results for an input decoding delay of 16,384 and six and nine decoding iterations. In this case, the crossover between PCCC and SCCC happens around 10^{-5}. The advantage of SCCC at 10^{-6} is 0.5 dB with nine iterations.

As a conclusion, we can say that the advantages obtained for signal-to-noise ratios above the cutoff rate, where the union bounds can be safely applied, are retained also in the region between channel capacity and cutoff rate. Only when the system quality of service focuses on high values of bit error probability (the threshold depending on the interleaver size) the PCCC are to be preferred. PCCCs, however, present a floor to the bit error probability, which, in the most favorable case seen above, lies around 10^{-6}. This floor is much lower in the case of SCCC.

Finally, it must be recognized that the constituent codes design rules presented in Sec. 4 are based on union bound considerations, and thus yield optimum SCCCs above the cutoff rate. For system applications aiming at very low signal-to-noise ratios, close to the channel capacity (as, for example, in deep-space communications), a general statement is that complex CCs should be avoided, and CCs with low number of states (4–16) should be used. The code design in this signal-to-noise ratio region, a different design approach based on the separate simulation of the behavior of each CC, and based on the probability density evolution technique [12–14] or on the *EXIT charts* [15] must be adopted.

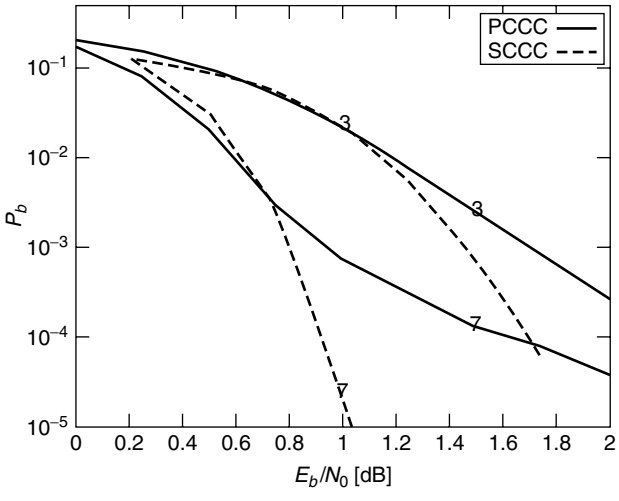

Figure 14. Comparison of the two rate-$\frac{1}{3}$ PCCCs and SCCCs of Example 2. The curves refer to three and seven iterations of the decoding algorithm and to an equal input decoding delay of 1024.

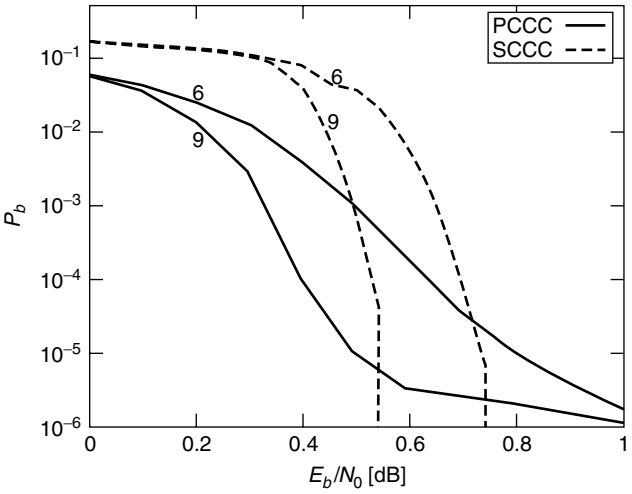

Figure 15. Comparison of the two rate-$\frac{1}{3}$ PCCCs and SCCCs of Example 2. The curves refer to three and seven iterations of the decoding algorithm and to an equal input decoding delay of 16384.

6. EXAMPLES OF SERIAL CONCATENATIONS

In this section we present a few significant examples of digital transmission systems that can be interpreted, and thus be utilized, as serial concatenations of individual modules. We will show that the serial structure fits to a set of systems well beyond the classical one constituted by two concatenated encoders with an interleaver in between.

6.1. Serial Concatenation of an Outer Encoder and an Inner Modulator

The serial concatenation of an outer encoder with rate R_c^o with an inner modulator characterized by an alphabet of $M = 2^m$ channel symbols through an interleaver is shown in Fig. 16 [25].

The binary symbols $\mathbf{u}$ emitted by the source are encoded by the outer binary encoder. The coded bits $\mathbf{c}$ are interleaved first, and then serial-to-parallel converted to m parallel bit streams $\mathbf{c_i}, \mathbf{i} = \mathbf{1}, \ldots, \mathbf{m}$. A mapper associates

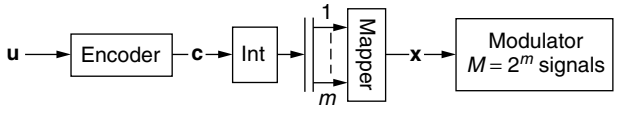

Figure 16. Block diagram of the serial concatenation of an outer encoder with an inner modulator through a bit interleaver.

each bit m-tuple to a modulator symbol x, which is then sent to the channel. The *spectral* efficiency of the scheme is related to the number of information bits per channel symbol $n_m \triangleq mR_c^o$.

A scheme like the one depicted in Fig. 16 can be detected or decoded iteratively, by considering it as a serial concatenation with interleaver. The condition to achieve improved performance through the iterative algorithm is that the mapping of m bits to a modulated signal be an operation with memory

$$\mathrm{P}[u_1, u_2, \ldots, u_m \mid r] \neq \mathrm{P}[u_1 \mid r]\mathrm{P}[u_2 \mid r] \cdots \mathrm{P}[u_m \mid r]$$

where r is the received signal.

Example 3. Consider an outer 8-state, rate-$\frac{1}{2}$ systematic recursive convolutional encoder punctured to rate $\frac{2}{3}$, followed by an interleaver with length 12,003, a mapper performing three different kind of mappings — natural, Gray mapping, or "anti-Gray" mapping — and an 8-PSK modulator. The three mappings are shown in Fig. 17. Note that the anti-Gray mapping has been chosen so as to maximize the sequence d_1, d_2, d_3, d_4, where d_w is the minimum Euclidean distance between pair of signals whose binary labels have a Hamming distance equal to w. This mapping choice is in perfect agreement with the design rule for inner encoders found in Section 4, replacing Hamming with Euclidean distances, and is the opposite with respect to Gray mapping.

The whole system is shown in Fig. 18; its receiver consists of the LLR computation on 8-PSK symbols, followed by a soft demapper that projects the symbol LLRs onto bit LLRs, the interleaver/deinterleaver and the puncturer/depuncturer pairs, and, finally, the outer SISO working on the rate-$\frac{1}{2}$ trellis. In Fig. 19 we report the bit error probability of such a scheme as a function of E_b/N_0, obtained by simulation with one to five iterations of the detection/decoding algorithm. The solid black curves refer to natural mapping, and show a 2.5-dB gain at 10^{-5}. The dashed line refers to Gray mapping, and shows that the iterations do not bring any performance improvement, although yielding better results than the first iteration with natural mapping. Finally, the solid gray curves refer to the anti-Gray mapping. With 1 iteration, this is the worst mapping; as the iterations evolve, however, the gain is very significant, and a gain of almost 4 dB over the Gray mapping is obtained at 10^{-5}, which further increases for higher E_b/N_0 because of the largest slope of the curves.

To further improve the performance, a rate-1, 2-state differential encoder could be added before the modulator, leading to the scheme of Fig. 20, in which the inner "encoder" is now recursive, as prescribed by the design rules of Section 4. Its performance has been reported elsewhere [26], and an extension to the case of intersymbol interference channels and Turbo equalization has been proposed [27].

6.2. The Encoded Continuous-Phase Modulation

Continuous-phase modulation (CPM) is a class of *constant-envelope*, *continuous-phase* modulation schemes obtained through a modulator with finite memory that can be described as a finite-state machine, or, equivalently, a trellis. Because of its attractive properties of constant envelope and bandwidth compactness, also maintained through nonlinear devices, CPM has been a subject of extensive studies and publications in the late 1970s and 1980s, and has then been applied in various radio systems, such as for example in GSM. Reference 28 contains an in-depth treatment of this subject.

A general CPM modulator can be split [29] into the cascade of a finite-state machine, the continuous-phase encoder (CPE), and a memoryless modulator (MM). Adding an outer convolutional encoder and an interleaver leads then to the system depicted in Fig. 21, where the information bits are first encoded by a convolutional encoder with rate k/n, followed by a bit interleaver with length N, and by an M-ary CPM modulator. Such a structure is capable of transmitting $(k/n)\log_2 M$

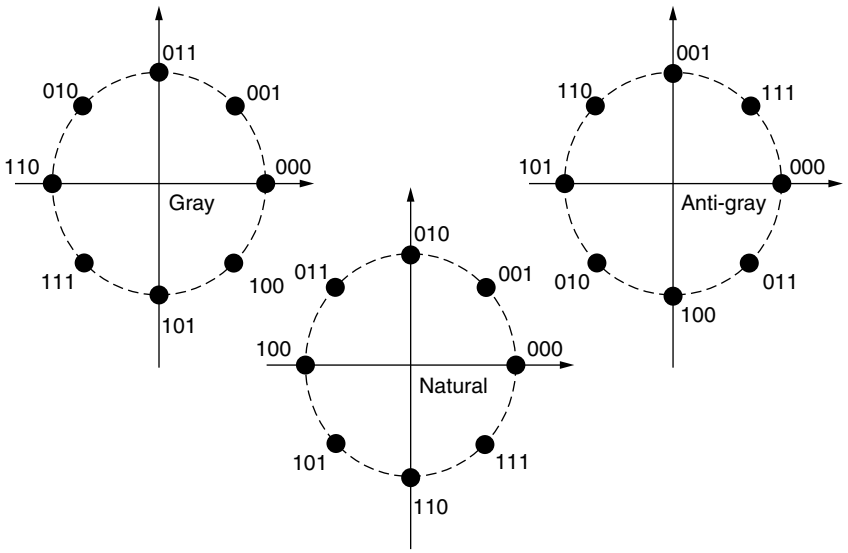

Figure 17. Three different mappings from triplets of bits to 8-PSK signals: Gray, natural, and anti-Gray.

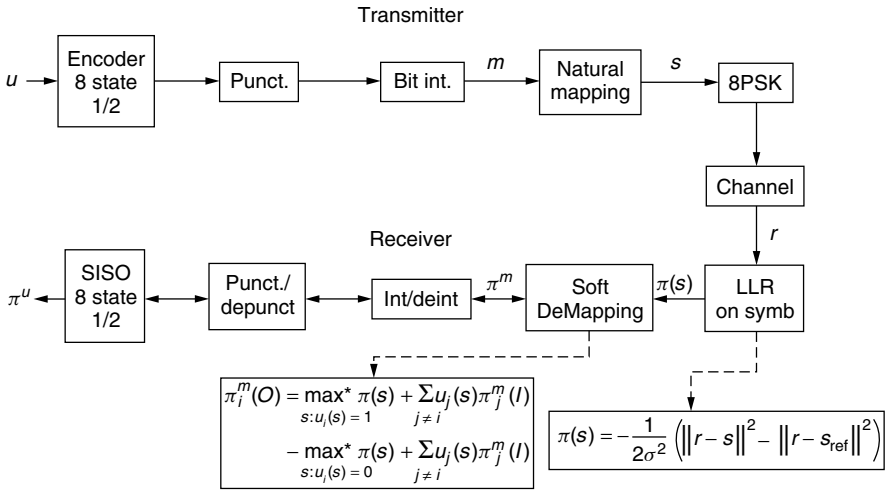

Figure 18. Block diagram of the transmitter and receiver of the serial concatenation of an outer encoder with an inner modulator through a bit interleaver.

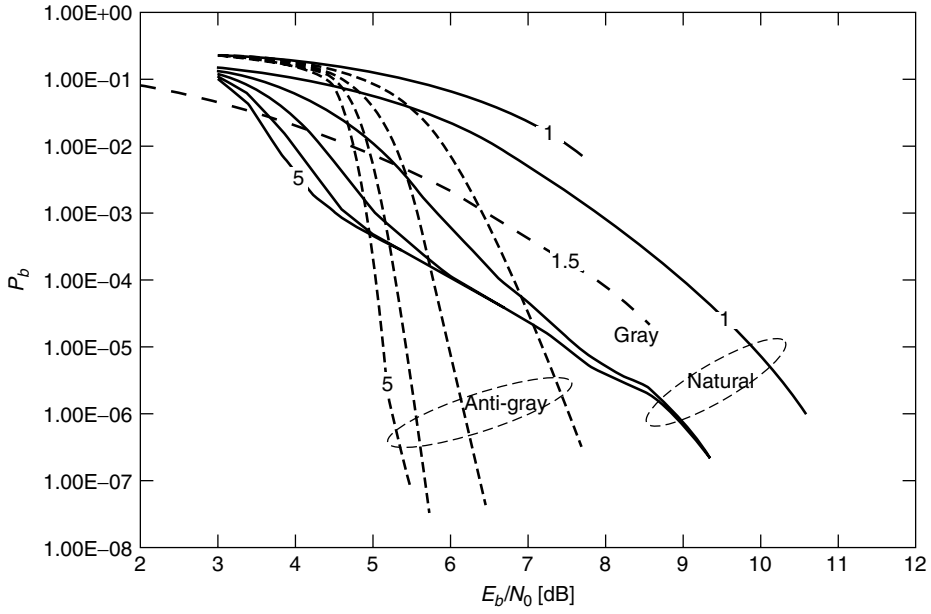

Figure 19. Bit error probability versus E_b/N_0 for the serial concatenation of Example 3. The solid black curves refer to natural mapping, the dashed one to Gray mapping, and the solid gray curves to anti-Gray mapping, with one to five iterations of the decoding algorithm.

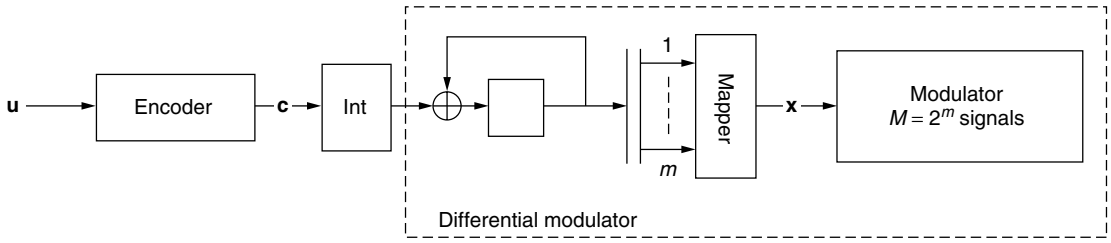

Figure 20. Block diagram of the serial concatenation of an outer encoder with an inner differential encoder and a modulator through a bit interleaver.

information bits per CPM signal, achieving a bandwidth efficiency that depends on the frequency pulse and modulation index of the CPM scheme.

According to Fig. 21, the cascade of a convolutional encoder, an interleaver, and a CPM modulator, a configuration that we will call *serially concatenated convolutional CPM* (SCC-CPM), can be seen as a particular form of serially concatenated convolutional codes with interleaver, and thus demodulated-decoded with an iterative scheme yielding high coding gains.

Example 4. Consider a coded CPM scheme (like the one depicted in Fig. 21), in which the outer encoder is a 4-state, rate-$\frac{2}{3}$ recursive systematic convolutional encoder,

and the inner module is a quarternary partial response CPM scheme [28] employing a rectangular frequency pulse with duration equal to 2 symbol intervals (the so-called 2-REC pulse) and modulation index $h = \frac{1}{3}$. Using the iterative receiver of Fig. 21, one obtains the performance shown in Fig. 22. The simulated scheme, owing to the low modulation index, has a high bandwidth efficiency, and achieves very good performance. Also, the performance improve very significantly with iterations.

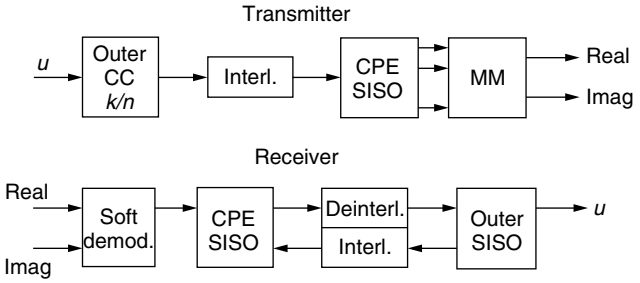

Figure 21. Block diagram of the encoded CPM transmitter and receiver.

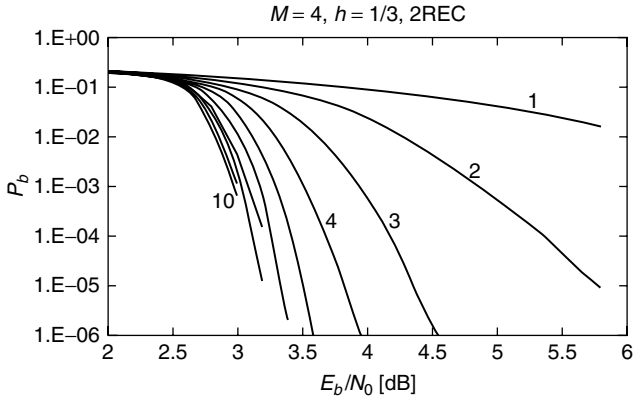

Figure 22. Bit error probability curves versus E_b/N_0 for the quaternary CPM scheme employing the 2-REC pulse with modulation index $h = \frac{1}{3}$. The outer code rate is $\frac{2}{3}$, and the interleaver size corresponds to 8190 information bits.

6.3. Serial Concatenation of an Outer Encoder with the Magnetic Recording Channel

In Fig. 23 we show the block diagram of a coded magnetic recording system based on the serial concatenation paradigm. It uses as outer code a high-rate (like $\frac{8}{9}$, $\frac{15}{16}$; this is a mandatory constraint of this applications that requires very high recording densities) terminated convolutional encoder, and as inner module the magnetic recording channel preceded by a precoder that makes it recursive. An interleaver separates the two blocks. In the same figure, the lower scheme represents the precoder/channel model. Using the Lorentzian model with an EPR4 partial response target [30], the overall magnetic channel transfer function in the transform domain is

$$G_m(Z) = 1 + Z - Z^2 - Z^3$$

It can be seen as an intersymbol interference channel with non binary (five-level) outputs, so this example becomes similar to the case of Turbo equalization [31]. The precoder is characterized by a $1/(1 \oplus Z^2)$ transfer function.

The iterative decoder (see Fig. 23, upper portion) is made by two SISOs. The inner SISO (SISO channel in the figure) is matched to the precoder/channel response, and works on non binary symbols, whereas the outer SISO works for the very high-rate $(n, n-1)$ convolutional encoder. Two solutions are possible: the first makes use of a heavily punctured rate-$\frac{1}{2}$ "mother" encoder, and the second employs unpunctured encoders. In the latter case, the complexity of the SISO, which depends on the number of edges per trellis section per decoded bit is too high, and thus a different approach must be followed, like designing a SISO that works on the $(n, 1)$ *dual* code [32]. This can be made coincident with a standard SISO, provided that its inputs be converted from LLRs to the so-called *log-reflection coefficients* (LRC in the figure).

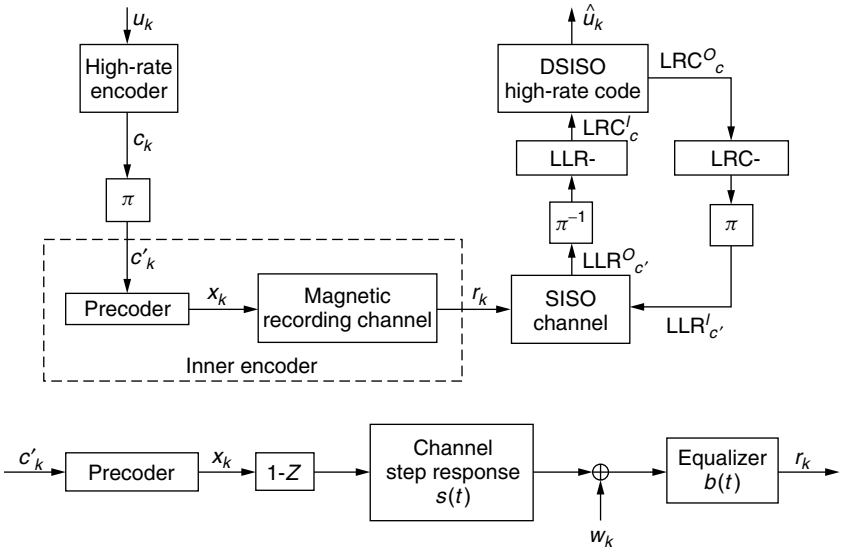

Figure 23. Block diagram of a coded magnetic recording system (upper diagram). Lorentzian model of precoder/magnetic channel (lower diagram).

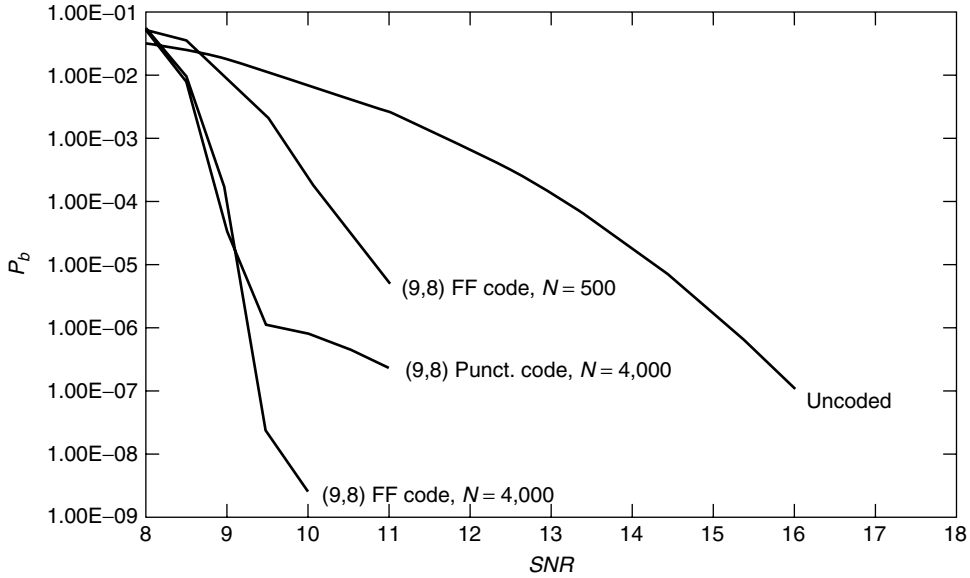

Figure 24. Bit error probability versus signal-to-noise ratio for the magnetic recording system of Fig. 23. The curves refer to the uncoded case, to the coded case employing a punctured rate-$\frac{8}{9}$ outer encoder with input block size 4000, and to the coded case using an unpunctured, optimized rate-$\frac{8}{9}$ outer encoder with block sizes 500 and 4000.

Using the iterative decoding algorithm, we have obtained the results shown in Fig. 24. The curves refer to the uncoded case, to the coded case employing a punctured rate-$\frac{8}{9}$ outer encoder with input block size 4000, and to the coded case using an unpunctured, optimized [33] rate $\frac{8}{9}$ outer encoder with block sizes 500 and 4000. A very large coding gain (6 dB for block size 4000 at 10^{-6}) can be obtained, without any significant error floor down to 10^{-9} for the unpunctured case. The punctured code, on the other hand, behaves similarly down to 10^{-6}, but shows the error floor just below. Notice that the different behavior of the two codes in the error floor region is due to the different free distance of the outer encoder, which is 2 for the punctured code (interleaver gain N^{-1}), and 3 for the unpunctured one (interleaver gain N^{-2}), in perfect agreement with the design rules of Section 4.

6.4. The Multiuser Interfered Channel

In coded code-division multiple access (CDMA) systems, K independent users first encode their information bit streams, then, after interleaving, they transmit them onto the same channel, as shown in Fig. 25. The cascade

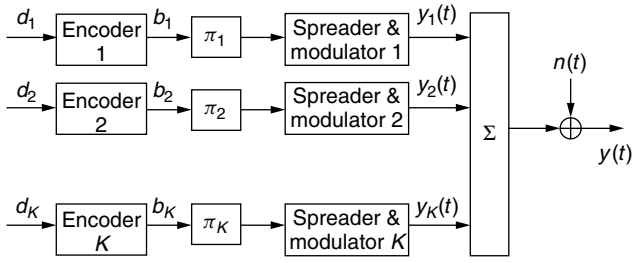

Figure 25. The CDMA transmitter with K users.

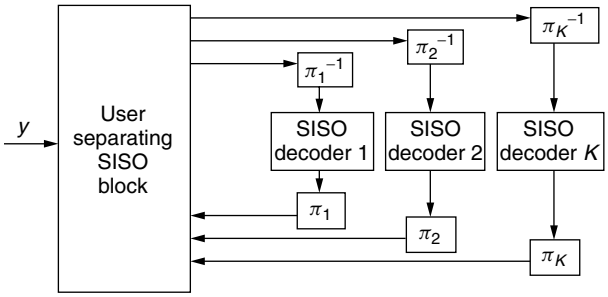

Figure 26. Turbo receiver. At every iteration, the user separator exchanges information with the decoders.

of the channel encoder, interleaver, and multiaccess channel can be viewed as a serial concatenation. As a consequence, at the receiver side, an iterative receiver can be employed, as shown in Fig. 26. A user separator, which is a soft-output version of a multiuser detector, attenuates for each user the multiaccess interference and sends K streams of soft output values to K channel decoders after deinterleaving. The decoders, in their turn, feed back with updated extrinsic LLRs the user separator, which will use the feedback information in the following iteration, to improve the user separation. In the last iteration, the decoders provide the final estimate of the K information bit streams. Figure 27 shows an example of performance along the iterations. It refers to a system with four equipower synchronous users, with correlation among any pairs equal to 0.7, and outer rate $\frac{1}{2}$, equal 16-state convolutional encoders with generator matrix

$$G_o(Z) = [1 + Z + Z^4, 1 + Z^2 + Z^3 + Z^4]$$

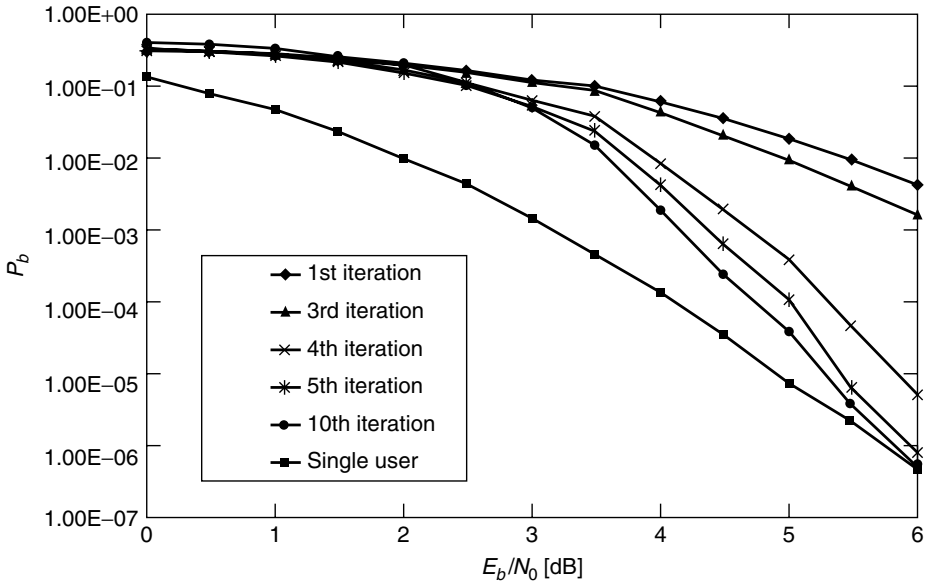

Figure 27. Results of simulation. $K = 4$ synchronous users, all with the same power. The correlation between any pair of users is 0.7. Interleaver size is 256, and the outer encoders are rate-$\frac{1}{2}$, 16-state feedforward convolutional encoders.

The interleavers are purely random interleavers with size 256. Finally, the user separator employs the algorithm described elsewhere [34].

As the curves show, the receiver tends to the single-user performance for sufficiently high signal-to-noise ratios.

7. CONCLUSIONS

In a semitutorial way avoiding all except strictly necessary mathematical developments, in this article we have described the main characteristics of serially concatenated codes with interleavers. They consist of the cascade of an outer encoder, an interleaver permuting the outer codeword bits, and an inner encoder whose input words are the permuted outer code words. Decoding is performed by an iterative technique based on two soft-input/soft-output algorithms tailored to the trellis of the outer and inner encoders. The iterative algorithm can be easily extended to other forms of concatenation, where one or both encoders are replaced with system modules with some form of memory performing different functions, like a modulator, a channel with intersymbol interference, a multiuser combiner. First, upper bounds to the *average* maximum-likelihood error probability of serially concatenated block and convolutional coding schemes have been described. Then, design guidelines for the outer and inner encoders that maximize the *interleaver* gain and the asymptotic slope of the error probability curves have been derived, together with the iterative decoding algorithm. Finally, extensions to different systems that can be seen as serial concatenations and detected or decoded accordingly have been proposed.

BIOGRAPHIES

Sergio Benedetto is a Full Professor of Digital Communications at Politecnico di Torino, Italy since 1981. He has been a Visiting Professor at University of California, Los Angeles (UCLA), at University of Canterbury, New Zealand, and is an Adjoint Professor at Ecole Nationale Superieure de Telecommunications in Paris. In 1998 he received the Italgas Prize for Scientific Research and Innovation. He has also been awarded the title of Distinguished Lecturer by the IEEE Communications Society. He has co-authored two books on probability and signal theory (in Italian), the books *Digital Transmission Theory* (Prentice-Hall, 1987), *Optical Fiber Communications* (Artech House, 1996), and *Principles of Digital Communications with Wireless Applications* (Plenum-Kluwer, 1999), and over 250 papers in leading journals and conferences. He has taught several continuing-education courses on the subject of channel coding for the UCLA Extension Program and for the CEI organization. He was the Chairman of the Communications Theory Symposium of ICC 2001, and is the Area Editor for the *IEEE Transactions on Communications for Modulation and Signal Design*. Professor Benedetto is the Chairman of the Communication Theory Committee of IEEE and a Fellow of the IEEE.

Guido Montorsi was born in Turin, Italy, on January 1, 1965. He received the Laurea in Ingegneria Elettronica in 1990 from Politecnico di Torino, Turin, Italy, with a master thesis, concerning the study and design of coding schemes for high-definition television (HDTV), developed at the RAI Research Center, Turin. In 1992 he spent the year as visiting scholar in the Department of Electrical Engineering at the Rensselaer Polytechnic Institute, Troy, NY. In 1994 he received the Ph.D. degree in telecommunications from the Dipartimento di Elettronica of Politecnico di Torino.

In December 1997 he became assistant professor at the Politecnico di Torino. In July 2001 he became Associate Professor. In 2001–2002 he spent one year in the startup company Sequoia Communications for the innovative design and implementation of a third-generation WCDMA receiver.

He is author of more than 100 papers published in international journals and conference proceedings. His interests are in the area of channel coding and wireless communications, particularly the analysis and design of concatenated coding schemes and study of iterative decoding strategies.

1. INTRODUCTION

Digital radio communications has evolved from a tiny research area to mass-market products used by millions of people worldwide. Especially the 1990s saw a tremendous development of mobile telephony. Compared to earlier analog radio systems, digital communications enables cheaper, smaller, and more complex devices through the progress in integrated digital circuit technology. Naturally, this draws increasing attention to research in digital communications.

In this article, we focus on the transmission of digital messages of any kind; thus, we do not cover how these messages are produced. They may stem from an analog source that is digitized (such as speech, audio, or video), or they may be digital in their original nature (such as text messages and computer files). It is, however, essential that the message does not contain any redundancy, that is, that it consists of digital symbols that can be considered independent and identically distributed from a statistical point of view. This normally requires some pre-processing such as speech or video coding, or data compression.

Even in digital communications, messages are converted to analog signals before transmission on a physical channel. This process, known as digital modulation, is adapted to the specific transmission medium in question, such as coaxial cables, optical fibers, or radio channels. Common digital modulation formats include binary and quadrature phase shift keying (BPSK/QPSK), quadrature amplitude modulation (QAM), frequency shift keying (FSK), and digital phase modulation (PM).

A radio transmitter normally consists of a modulator producing radiofrequency (RF) signals, a signal amplifier and an antenna. In many applications, it is both easier and cheaper to use a nonlinear amplifier than a linear one, meaning that only phase-modulated signals can be amplified without considerable distortion. Thus, modulation formats which also vary the signal amplitude (e.g., BPSK, QPSK, QAM) are not suitable in conjunction with nonlinear transmitter amplifiers. It is here that the broad class of continuous-phase modulation (CPM) schemes find their major applications [1,2]. Examples include the GSM mobile telephony standard, microwave radio links, and ground-to-satellite communications.

Reliable digital transmission can be obtained by channel coding, as discussed by Shannon [3] in his 1948 classic paper. Block codes and convolutional codes are basic channel codes that are able to lower the bit error rate (BER) in the receiver at the cost of increased complexity. More advanced codes can be constructed from these basic elements by concatenation. One such technique is Turbo coding or parallel concatenated codes (PCCs), introduced by Berrou et al. [4–7], in which two convolutional codes separated by a random interleaver (permuter) are concatenated in parallel. The two codes are decoded separately in an iterative manner (see Fig. 1). Turbo codes have been shown to perform very close to Shannon's limit, while maintaining a reasonable decoder complexity. The same is true for serially concatenated codes (SCCs) with random interleaving, as shown in Fig. 2 - as examined by Benedetto et al. [8,9]. Turbo codes are currently being introduced in the third-generation mobile system standards UMTS (Universal Mobile Telecommunications System) [10] and cdma2000 [11].

Channel coding and modulation can also be combined, as in convolutionally coded CPM. By a joint design of the code and the CPM system, improved BER performance can be obtained. This leads us to the technique of combining CPM and SCCs with random interleaving, namely, serially concatenated CPM (SCCPM) investigated by several authors [12–14]. Here, the inner (second) code in an SCC is substituted with a CPM modulator, producing a coded and interleaved CPM scheme which can be decoded iteratively (see Fig. 3). As for Turbo codes and SCCs, the use of a random interleaver leads to substantial performance gains. In this article, we describe SCCPM in detail and show some interesting performance examples.

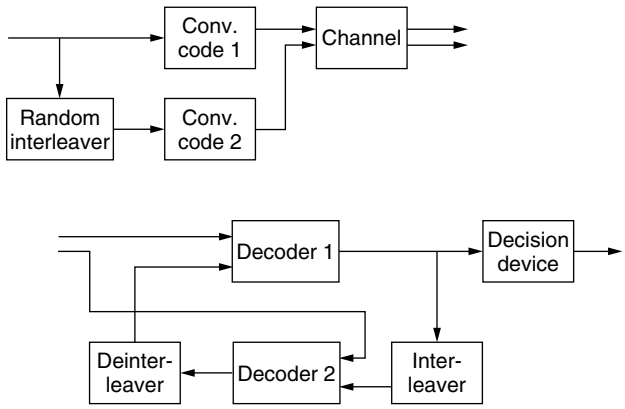

Figure 1. A typical Turbo code (PCC) with encoder (upper) and iterative decoder (lower).

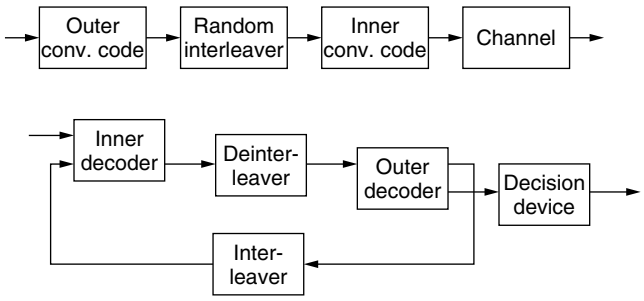

Figure 2. Serially concatenated code (SCC) with encoder (upper) and iterative decoder (lower).

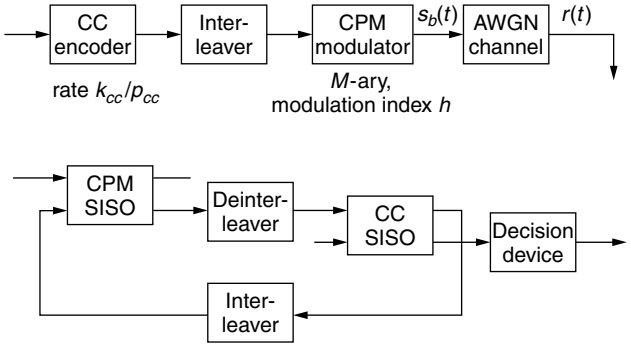

Figure 3. Serially concatenated continuous-phase modulation (SCCPM) with iterative decoding.

2. BACKGROUND

The introduction of the Turbo codes (PCCs) in 1993 [4] led to a vast research interest in concatenated convolutional codes separated by a pseudorandom bit interleaver and decoded iteratively. This technique of achieving large and nearly random codes while maintaining a simple decoder structure has found many applications, primarily where a large coding gain is desired (such as in deep-space applications or terrestrial links). The Turbo codes have shown to yield BERs around 10^{-5} at rates well beyond the channel cutoff rate, [7].

Shortly after the introduction of the turbo codes, it turned out that serially concatenated codes (SCCs) with a pseudo-random bit interleaver were equally suitable for iterative decoding [8]. It is generally understood that SCCs based on convolutional codes can give even better performance than turbo codes for low BERs (typically $<10^{-6}$) [9], while PCCs are better suited for medium-to-high BERs. Still, many concatenated coding schemes assume a simple carrier frequency modulation such as BPSK, meaning that a rate-k/n SCC transmits k/n bits per channel symbol. This bandwidth efficiency can be improved by more advanced modulation techniques such as trellis-coded modulation (TCM) [15] and continuous-phase modulation (CPM) [1,2]. Both TCM and CPM introduce memory into the transmitted signal, in a way that allows them to be described by finite-state machines similar to a convolutional code. Benedetto et al. employed TCM in an SCC with iterative decoding, such that the inner code is a recursive trellis code designed for the chosen signal set [16]. This way, it is possible to use, for example, a rate-$\frac{2}{3}$ SCC combined with an 8-PSK signal set yielding a bandwidth efficiency of 2 bits per symbol.

On the other hand, CPM is the natural choice of modulation when a constant envelope of the transmitted signal is required, such as when the transmitter amplifier is not perfectly linear. CPM was subject to vast research interest in the late 1970s and early 1980s [1], and the reader is referred to Ref. 2 for a comprehensive summary of much of that work. Later, convolutionally coded CPM was investigated as a way of improving performance while maintaining the constant envelope [17–20]. Matched codes [21] were introduced as yielding the minimum number of states in the optimum receiver when combined with CPM. The inherent modulo-2π property of the information-carrying phase in CPM has been exploited [22], such that convolutional codes over rings were combined with CPM. Since these codes showed better performance than did previous ones, much effort was put into code searches for various CPM systems [22–24].

In this article we study SCCPM, *i.e.* coded and interleaved CPM with iterative decoding. First, a brief description of CPM and how it is employed in a serially concatenated system is given (Section 3). Then, we study a transfer function bound to the BER performance, which is based on known concepts from SCCs (Section 4). This gives theoretical insights to the behavior of SCCPM in general. In Section 5, these observations are compared with numerous computer simulation results, demonstrating that the excellent performance of Turbo codes and SCCs indeed can be generalized to a trellis-coded modulation like CPM. Finally, in Section 6, bandwidth considerations are discussed and a bandwidth–performance comparison of some selected systems is presented.

3. SYSTEM DESCRIPTION

3.1. Block Diagram

Figure 3 shows a block diagram of SCCPM on an additive white Gaussian noise (AWGN) channel with iterative decoding. Independent and equiprobable information bits are encoded by a convolutional code (CC) with rate $R_{cc} = k_{cc}/p_{cc}$. For convenience, let p_{cc} be an integer multiple of $\log_2 M$, where M is the symbol alphabet size (cardinality) of the CPM system. As in Turbo codes and SCCs, bitwise block interleaving with block size N bits is employed, yielding groups of $\log_2 M$ bits that are mapped to CPM symbols using some mapping rule, such as natural mapping or gray mapping. The CPM modulator produces a constant envelope signal $s_b(t)$ that is transmitted on the AWGN channel. In this theoretical treatment, continuous transmission is assumed, thus the encoders are not reset to the zero state at the beginning of an interleaver block. The resulting concatenated code is a block code with information words of length $N \cdot R_{cc}$. (In a more practical system, blockwise decoding would be facilitated by trellis termination of both the outer CC and the inner CPM system [25], such that the encoders are enforced to the zero state at both the beginning and the end of a block. This normally leads to a small performance degradation.) In complex baseband representation, the received continuous-time signal is given by $r(t) = s_b(t) + n(t)$, where $n(t)$ is complex white Gaussian noise with double-sided power spectral density $N_0/2$.

3.2. Iterative Decoder

As in Turbo codes and SCCs, the iterative decoder consists of two *a posteriori* probability (APP) algorithms, one for the inner CPM system and one for the outer CC; more specifically, we use the bitwise sliding-window SISO algorithm proposed by Benedetto et al. [26] and formally justified by the present authors [27]. The SISO

algorithm is a nice generalization of the Bahl et al. (BCJR) algorithm [28], taking a priori probabilities of both information symbols and code symbols, and computing extrinsic APPs of both information symbols and code symbols. An extrinsic APP is an APP from which the a priori probability has been divided.

For the inner SISO, channel observations are used as a priori probabilities of the code symbols of the CPM system, as described in Section 3.4. The inner SISO then computes extrinsic APPs of the information bits of the CPM system; these are deinterleaved and used as a priori information on the code bits of the CC in the outer SISO. Applying the constraints of the CC, the outer SISO updates this information to extrinsic APPs that are interleaved and used as a priori information on the information bits of the CPM system in the next iteration. At the same time, the outer SISO computes APPs of the information bits of the CC; these are used by the decision device to select the bit with maximum APP in the last iteration. As can be seen from Fig. 3, those inputs/outputs not needed are left unconnected. A uniform distribution of the bits is assumed for an unconnected input. Note that at the first iteration, no a priori information on the CPM information bits is available in the inner SISO.

3.3. Description of CPM

Rimoldi [29] gave a concise description of CPM as the concatenation of two separate devices: a continuous-phase encoder (CPE) and a memoryless modulator (MM). He used the concept of a tilted-phase representation of CPM, which we repeat here for convenience.

Consider a CPM system with M-ary information symbols $u \in \{0, 1, \ldots, M-1\}$ transmitted every symbol interval T with energy E. To match it to the CC, let $\log_2 M$ be an integer number. The symbols are phase-modulated using a positive normalized frequency pulse $g(t)$ containing no impulses and being nonzero for L symbol intervals; thus the system is full response ($L = 1$) or partial response ($L > 1$). The phase response $q(t)$ is the integral of the frequency pulse, and it is normalized to $q(LT) = \frac{1}{2}$. The LREC and LRC families [2] are examples of frequency pulses.

The modulation index h is assumed to be rational and irreducible, $h = K/P$, since then the system can be described by a trellis [1]. The tilted-phase $\psi(t)$ during symbol interval n ($t = \tau + nT$) is given by [29]

$$\psi(\tau + nT) = \left[2\pi h \left[\sum_{i=0}^{n-L} u_i \mod P \right] + 4\pi h \sum_{i=0}^{L-1} u_{n-i} q(\tau + iT) + W(\tau) \right] \mod 2\pi \qquad 0 \le \tau < T \quad (1)$$

where $\{u_i\}$ are information symbols and the data-independent function $W(\tau)$ is given by

$$W(\tau) = \pi h (M-1) \frac{\tau}{T} - 2\pi h (M-1) \sum_{i=0}^{L-1} 9(\tau + iT) + \pi h (M-1)(L-1) \quad (2)$$

The transmitted signal during the same interval is

$$s(\tau + nT) = \mathrm{Re}\left\{ s_b(\tau + nT) \cdot \exp\left[j(2\pi f_1(\tau + nT) + \varphi_0) \right] \right\} \quad (3)$$

where $s_b(\tau + nT) = (2E/T)^{1/2} \cdot \exp[j\psi(\tau + nT)]$ is the complex baseband equivalent, $f_1 = f_0 - h(M-1)/2T$ is a shift of the center frequency f_0, and φ_0 is the initial phase of the carrier. Note from these relations that the transmitted signal during symbol interval n is completely specified by the current symbol u_n, the $L-1$ previous data symbols $u_{n-L+1}, \ldots, u_{n-1}$, and the accumulated value

$$v_n = \sum_{i=0}^{n-1} u_i \mod P \quad (4)$$

which can take only P values. Hence, in each symbol interval n, the CPE produces the code symbol (vector) $\boldsymbol{c}_n = [v_n, u_{n-L+1}, \ldots, u_n]$ to the MM, which transmits one of $P \cdot M^L$ signals $s_b(t, \boldsymbol{c}_n)$.

3.4. Channel Observations in CPM SISO Algorithm

As mentioned above, the SISO algorithm takes *a priori* probabilities of both information symbols, $\Pr(u_n = U)$, and code symbols, $\Pr(\boldsymbol{c}_n = \boldsymbol{C})$. For the inner CPM SISO, the latter are replaced by channel observations $p(\mathbf{r}_n | \mathbf{c}_n = \mathbf{C})$, where $\mathbf{r}_n$ is a sufficient statistic [30] obtained from $r(t)$. It can be shown [12] that the channel observations are proportional to $\exp[\mathrm{Re}\{r_k\}/N_0]$, where r_k is the sampled output of a filter matched to $s_b(t, \mathbf{c}_n)$,

$$r_k = \int_{nT}^{(n+1)T} r(t) s_b^*(t, \mathbf{c}_n)\, dt \quad (5)$$

and where the superscript * denotes complex conjugate. This sufficient statistic is exactly the same as when performing maximum-likelihood sequence detection (MLSD) in uncoded CPM [2], for example, using the Viterbi algorithm.

4. ANALYSIS OF SCCPM

In this section, an SCCPM system like the one in Fig. 3 is analyzed with the overall goal to demonstrate its ability to provide performance gains similar to Turbo codes and SCCs. These latter codes were analyzed through average transfer function bounds to the BER by Benedetto et al. in Refs. 6 and 9, respectively. As demonstrated in Ref. 12, this type of bound can be applied also to SCCPM. However, for all these codes, several arguments can be raised against the use of the transfer function bound:

1. Since this bound is based on a union bound, it diverges below a signal-to-noise ratio (SNR) threshold of approximately 3 dB, well above the operating point of many Turbolike systems.
2. The bound is a theoretical one in the sense that it is a bound on the average BER over all possible interleavers, each appearing with equal probability (the so-called uniform interleaver [6]). A specific

interleaver may yield substantially lower or higher BER. In fact, more recent interleaver design methods have shown improvements by orders of magnitude compared to the uniform interleaver [e.g., [31]].

3. The transfer function bound is based on optimal MLSD, which has a tremendous complexity for Turbolike systems because of their large and nearly random interleavers. The performance of the suboptimal iterative decoder can deviate substantially from MLSD, especially for low SNRs. Note that MLSD is equivalent to maximum APP sequence detection (MAPSD) because of the independent and equiprobable information bits.

Still, in this article we adhere to the transfer function bound because (1) performance above 3 dB is also of interest, and the transfer function bound is easy to obtain; (2) our primary goal is to demonstrate the Turbolike performance of SCCPM in general, as well as to compare different combinations of CCs and CPM systems; and (3) MLSD/MAPSD represents the ultimate performance limit of the system with any decoder, iterative or not. We do not address the convergence of the iterative decoder in this article, but refer the reader to other articles [e.g., 32–34,38]. The points presented above should anyway be kept in mind when bounds are compared with simulation results.

4.1. Transfer Function Bound for SCCPM

Similar to an SCC [9], the combination of a rate-R_{cc} CC, a bitwise length-N interleaver, and M-ary CPM is a block code with information words of length $k = N \cdot R_{cc}$. However, it does not possess the uniform error property, because CPM is not a linear code. Hence we cannot assume the all-zero information word to be transmitted; instead all pairs of transmitted and hypothesized (candidate) information words in the MLSD receiver must be considered. This is simplified by the fact that error events in CPM do not in general depend on the specific transmitted sequence, but only on the difference sequence between transmitted and hypothesized CPM symbols. Thus we need only enumerate the set of difference sequences in the inner CPM system, if we keep track of the fraction of transmitted sequences they correspond to. (Details of CPM error events can be found in Ref. 2.)

A union bound on the BER $P_b(e)$ in SCCPM with MLSD is

$$P_b(e) \le \frac{1}{2} \sum_{\mathcal{D}} B_{\mathcal{D}} \exp\left(-\frac{\mathcal{D} R_{cc} E_b}{2N_0}\right) \tag{6}$$

where E_b is the energy per information bit entering the CC and

$$B_{\mathcal{D}} = \sum_{w} \frac{w}{N \cdot R_{cc}} \overline{A}_{w,\mathcal{D}} \tag{7}$$

is the bit error multiplicity for error events with normalized squared Euclidean distance (NSED) $\mathcal{D}$ on the channel. The latter is assumed to be normalized to the energy per bit entering the CPM system; thus we use the same NSED as in uncoded CPM (2). $\overline{A}_{w,\mathcal{D}}$ is the number of concatenated error events with input weight w (Hamming distance $d_H(\cdot) = w$ between information words) and output weight (NSED) $\mathcal{D}$, averaged with respect to the number of transmitted codewords they correspond to. Thus $\overline{A}_{w,\mathcal{D}}$ is the input/output weight enumerating function (IOWEF), or input/output weight spectrum of the system. Assuming a uniform interleaver of length N bits, it can be shown that $\overline{A}_{w,\mathcal{D}}$ is obtained — the same as for SCCs — as

$$\overline{A}_{w,\mathcal{D}} = \sum_{l=0}^{N} \frac{A_{w,l}^{out} \cdot \overline{A}_{l,\mathcal{D}}^{in}}{\binom{N}{l}} \tag{8}$$

from the IOWEFs of the outer convolutional code and the inner CPM system. However, due to the linearity of the CC, its IOWEF need not be averaged. The denominator counts the number of distinct permutations that the uniform interleaver can produce from an output weight l codeword from the outer encoder, entering the inner CPM system as an input weight l codeword [9].

4.2. Error Events in CPM

Clearly, in concatenated and interleaved systems the input weight of error events is of interest. In the outer CC, the input weight counts the number of bit errors made during an error event, as given by the factor w in Eq. (7). But even more important, the input weight of error events in the inner CPM system determines not only which concatenated error events will be possible, but also their multiplicity, as can be seen from Eq. (8).

As an example, consider minimum shift keying (MSK) (binary 1REC, $h = \frac{1}{2}$). Error events in MSK start when the transmitted and hypothesized CPM symbols differ from each other for the first time in the block (see Fig. 4). When this occurs, there will be a Hamming distance of 1 between the bit labels of the transmitted and hypothesized symbols, that is, the input weight will increase by 1. At the same time, the NSED of the error event also will increase by 1. If the symbols differ again, the input weight and NSED will increase by the same amount, and the error event will end. However, if they do not differ, the Hamming distance will be 0 and the input weight will not increase, but the error event will continue. In this case, the NSED will increase by 2. Eventually, the symbols will differ once again, and a total input weight of 2 will be obtained, while the NSED will be any multiple of 2 depending on the length of the error event. Concluding, isolated error events in MSK will always have input weight 2, and the minimum NSED will also be 2.

For SCCs, the inner code should be a recursive systematic convolutional (RSC) code to avoid input weight 1 error events. This is because these events nullify

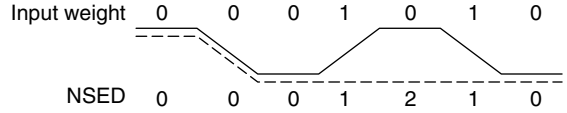

Figure 4. Input weight of an error event in MSK. Transmitted (solid) and hypothesized (dashed) symbol sequences.

the performance gain of an increased interleaver size N, the *interleaver gain* [9]. For CPM with $M > 2$, the input weight depends on the bit labeling (mapping) of the CPM symbols, including natural mapping or gray mapping. In addition, certain combinations of mapping and modulation index $h = K/P$ yield input weight 1 error events, despite the inherent recursive nature of CPM. More specifically, the following conditions apply:

- Binary ($M = 2$) CPM: integer modulation indices $h = K$. These systems are seldom used in practice.
- Quaternary ($M = 4$) CPM with natural mapping: $h = K/2$. With gray mapping: $h = K/3$.
- Octal ($M = 8$) CPM with natural mapping: $h = K/4$. With gray mapping: $h = K/3$, $h = K/5$, and $h = K/7$.
- Hexadecimal ($M = 16$) CPM with natural mapping: $h = K/8$. With gray mapping: $h = K/5$, $h = K/7$, $h = K/9$, $h = K/11$, $h = K/13$, and $h = K/15$.

Thus it is always possible to avoid input weight 1 error events, and hence to obtain interleaver gain, by a careful selection of the mapping.

4.3. Transfer Function Bound for Coded and Interleaved MSK

To find the IOWEF of the CC for all combinations of w and l, the methods described by Benedetto and Montorsi [6] or Divsalar et al. [35] can be used. The former is a recursive algorithm suitable when the output weights are integers. Regarding the inner CPM system, the IOWEF generally contains a manifold of real-valued NSEDs $\mathcal{D}$. However, for the important special case of minimum shift keying (MSK) (binary 1REC, $h = \frac{1}{2}$), all NSEDs are integers and thus the algorithm in Divsalar et al. [35] can be applied.

As an example, consider coded MSK with a uniform interleaver of length $N = 128$, 512, 2048, or 8192. The outer code is the 4-state, nonrecursive, nonsystematic rate-$\frac{1}{2}$ CC specified by the octal connection polynomial (7,5) (generating matrix $G(D) = [1 + D + D^2, 1 + D^2]$) and having free distance 5. Using the IOWEFs discussed above, Eqs. (7) and (8) give the total bit error multiplicity for each output weight $\mathcal{D}$ in the concatenated system, and Eq. (6) gives the upper bound on the average BER, shown in Fig. 5. Note the so-called divergence of the bound for E_b/N_0 (SNR) values below approximately 3 dB. This phenomenon has been observed also for Turbo codes [6] and SCCs [9], and is an inherent effect of the union bound. Above 3 dB, the bound exhibits a rather steep slope similar to those of SCCs. This promises for good practical performance, even with a suboptimal iterative decoder and a real, pseudorandom interleaver. Comparing the bounds for different interleaver sizes, it can be noted that when N increases by a factor of four, the BER bound decreases with roughly a factor 64; thus the interleaver gain appears to be approximately N^{-3}.

4.4. Detailed Analysis of Error Events

With a careful examination of the BER bound in Eqs. (6)–(8), several observations can be made regarding the behavior of SCCPM systems, when a uniform interleaver and MLSD is employed. For large SNRs, the minimum NSED $\mathcal{D}_{\min}$ dominates the bound. Thus SCCPM (as well as Turbo codes and SCCs) is no different from other coded modulation systems. However, the true strength of turbo-like systems is the spectral thinning of the distance (weight) distribution that occurs for large interleavers. This means that the lowest weights (distances) have small bit error multiplicities $B_{\mathcal{D}}$, effectively causing a displacement of the distance distribution toward larger weights. A "thin" weight spectrum gives improved BER performance for small-to-medium SNRs provided that the dominance of the exponential function in Eq. (6) is not too strong (i.e., that E_b/N_0 is not too large). As discussed

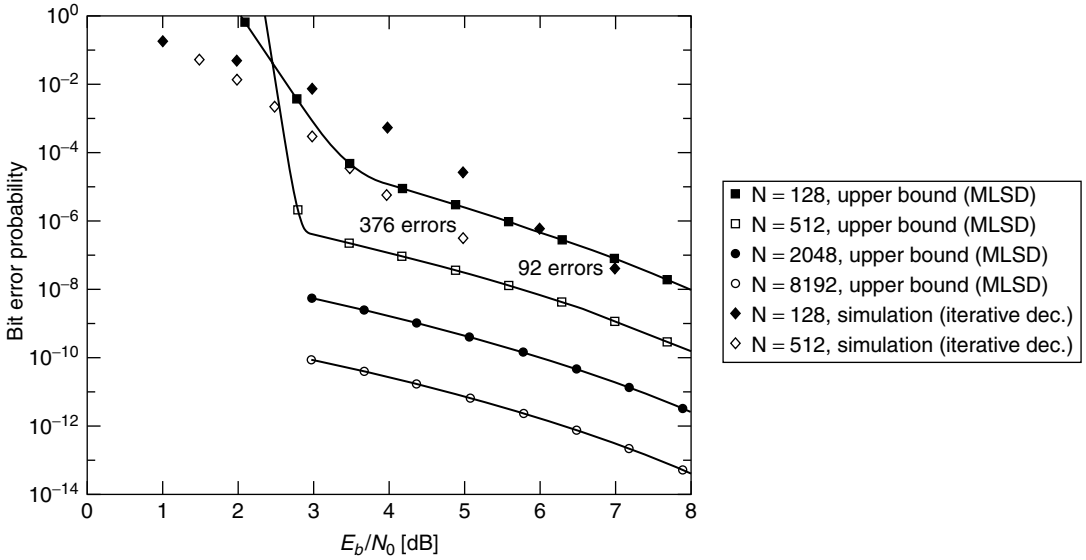

Figure 5. BER bounds and simulation results for (7,5)-coded MSK for various interleaver sizes N. The bounds for $N = 2048$ and $N = 8192$ were calculated from truncated weight spectra.

earlier, Turbolike systems have interleaver gain such that a larger interleaver decreases the bit error multiplicity [cf. Eq. (8)], and thus achieves spectral thinning.

As demonstrated for SCCs by Benedetto et al. [9], the dependency of $B_\mathcal{D}$ on the interleaver size N can be investigated with the aid of the BER bound. Specifically, $B_\mathcal{D}$ can be bounded from above, for each output weight $\mathcal{D}$, by a polynomial in N whose maximum exponent is $\alpha(\mathcal{D})$. When $\alpha(\mathcal{D}) < 0$, there is interleaver gain for the specific output weight $\mathcal{D}$. It can be shown that in general, $\alpha(\mathcal{D}_{\min}) < 0$ such that there is asymptotic (large E_b/N_0) interleaver gain.

However, the overall maximum value of the $\alpha(\mathcal{D})$, $\alpha_{\max}$, is more interesting because it determines whether there is interleaver gain over the whole SNR range. For SCCs, Benedetto et al. distinguish two separate cases [9]: (1) block and nonrecursive convolutional inner codes and (2) recursive convolutional inner codes. In case (1), input weight 1 events exist, yielding $\alpha_{\max} \geq 0$; thus, interleaver gain cannot be assured for all SNRs. In case (2), $\alpha_{\max} = -\lfloor (d_{\text{free}} + 1)/2 \rfloor < 0$ for an outer code with free distance d_{free}, because there are no input weight 1 events in the inner code. The crucial point is thus the existence of these events. We have already seen in Section 4.2 that certain CPM systems in fact do have such events — and we will also see that this affects the BER performance negatively. MSK does not have input weight 1 error events, so $\alpha_{\max} = -3$ and $B_\mathcal{D} \leq N^{-3}$ when it is combined with the (7,5) CC, for which $d_{\text{free}} = 5$. This is consistent with the bounds for different interleaver sizes in Fig. 5.

We can also study the NSED associated with $\alpha_{\max}$, $\mathcal{D}(\alpha_{\max})$, as an alternative to $\mathcal{D}_{\min}$ for small-to-medium SNRs. (For large SNRs, $\mathcal{D}_{\min}$ dominates the bound.) Let $\mathcal{D}^{\text{in}}(i)$ denote the minimum NSED for input weight i error events in the inner CPM system, and if no such event exists, let $\mathcal{D}^{\text{in}}(i) = \infty$. Thus, the classic minimum distance in CPM is the minimum of $\mathcal{D}^{\text{in}}(i)$ over all i. $\mathcal{D}^{\text{in}}(i)$ is given directly by the IOWEF of the CPM system, but it can also be obtained from a search in the difference trellis [12]. For inner CCs in SCCs, $\mathcal{D}^{\text{in}}(2)$ is called the *effective free distance* [9]. It is important since it can be shown [9] that $\mathcal{D}(\alpha_{\max})$ is given by a concatenation of input weight 2 events in the inner code, such that

$$\mathcal{D}(\alpha_{\max}) = \left\lfloor \frac{d_{\text{free}} + 1}{2} \right\rfloor \cdot \mathcal{D}^{\text{in}}(2) \tag{9}$$

(This equation is not valid when d_{free} is odd and $\mathcal{D}^{\text{in}}(3)$ is finite [12].) Clearly, performance can be improved not only by increasing the interleaver size, but also by a larger free distance in the outer CC, or a larger effective free distance in the inner CPM system. However, one should be careful with conclusions from $\mathcal{D}(\alpha_{\max})$ since it does not necessarily dominate the bound. As shown in another study [12], there are more combinations of error events that may play a role.

Example 1. Consider once again (7,5)-coded MSK. For the inner MSK system, $\mathcal{D}^{\text{in}}(2) = 2$ and $\mathcal{D}^{\text{in}}(i) = \infty$ for all other i. Hence $\mathcal{D}(\alpha_{\max}) = 6$ which coincides with $\mathcal{D}_{\min}$ for this specific system. It is interesting to note that this NSED is of the same order as that in many traditional coded CPM systems. However, the associated bit error multiplicity B_6 is overbounded by N^{-3}, which can be made as small as desired by enlarging the interleaver. This spectral thinning is not so easily obtained in traditional coded CPM.

Example 2. (7,5)-coded binary 2RC, $h = \frac{3}{4}$. Here, there are no odd input weight events in the CPM system, while $\mathcal{D}^{\text{in}}(2) = 2.66$. Therefore, $\mathcal{D}(\alpha_{\max}) = 7.97$ which is larger than $\mathcal{D}_{\min} = 5.21$. There is also a combination with $\mathcal{D} = 6.59$. The bit error multiplicities for these events are $B_{7.97} \leq N^{-3}$, $B_{6.59} \leq N^{-4}$, and $B_{5.21} \leq N^{-5}$. Thus the resulting performance is a mixture of the contributions to the bound of these events. Still, we can compare this system with Example 1 by observing that the event with lowest NSED (5.21) has a factor N^2 lower multiplicity, while the other events have larger NSEDs. Thus we can expect it to perform better than Example 1, at least above the divergence threshold around 3 dB. From the simulations in section V, this appears to be the case also for smaller SNRs.

4.5. Summary

Our observations can be summarized as follows. Note that they are generally valid only above the divergence threshold around 3 dB for systems employing a uniform interleaver and MLSD, although we will see in Section 5 that this appears to be the case also for more practical scenarios where a pseudo-random interleaver and iterative decoding is used in the low-SNR region.

- Like SCCs, SCCPM systems are capable of providing interleaver gain, if input weight 1 error events are avoided. This is always possible by a change in the mapping, such as from natural to gray, or vice versa. The order of the interleaver gain is determined by the free distance of the outer code, d_{free}.
- For a general inner CPM system, several combinations of the minimum NSEDs per input weight contribute to the BER bound. In order to compare different CPM systems, these combinations must be examined in detail for a given outer CC.
- It is always possible to avoid input weight 1 events by selecting a different mapping, specifically, natural binary instead of gray, or vice versa.

5. EXAMPLE SYSTEMS

The analysis in Section 4 is based on a union bound on the BER with MLSD, assuming a uniform interleaver. In practice, a suboptimal iterative decoder and a pseudorandom interleaver are used instead. Still, above the divergence threshold at E_b/N_0 around 3 dB, we shall see that the iterative decoder indeed performs quite close to the upper bound for MLSD. Below this value, the bound diverges and thus observations based on it may not be accurate; furthermore, the iterative decoder may not even converge toward the MLSD decision. All these points should be taken into account when performance of the iterative decoder is studied.

In this section, some examples of SCCPM systems are presented together with computer simulation results. We use (7,5)-coded MSK as our reference system, and then study the influence of other outer codes and inner CPM systems. Finally, a system with inner input weight 1 events is evaluated. In all simulations, the number of iterations[1] (8–12) as well as the delay of the sliding-window APP algorithms (10–15 symbols) are chosen such that no practical deterioration of performance could be noticed. The interleavers are chosen at random.

5.1. Reference System: (7,5)-Coded MSK

For this simple SCCPM scheme (Example 1, above), the MLSD transfer function bound is compared with simulation results for the iterative decoder in Fig. 5 for $N = 128$ and 512. For large SNRs, the actual interleaver and iterative decoding used in the simulations give slightly better performance than does the uniform interleaver in the MLSD bound, although the BER is not very accurate in the region below 10^{-6}. In fact, experience with Turbo codes tells us that most interleavers perform better than the average represented by the uniform interleaver. However, the discrepancy around the divergence threshold only be explained can by the fact that a suboptimal iterative decoder is used instead of MLSD.

Figure 6 shows more simulation results for different interleaver sizes, and also without any interleaver (i.e., a traditional coded CPM system, which was treated by Lindell [17] assuming MLSD detection). The interleaved system is evaluated using the iterative decoder (which has $4 + 2$ states) for $N = 128$, 512, 2048, 8192, and 32,768. For the noninterleaved system, both the iterative decoder and MLSD (8 states) is employed. Clearly, without interleaver, iterative decoding is inferior to MLSD by approximately 1.5 dB. At a BER of 10^{-3}, this transforms to a gain of more than 3 dB when a large interleaver is inserted.

[1] Here, and throughout the article, one decoder iteration corresponds to a pass through both the inner and the outer SISO module.

5.2. Influence of the Outer CC

According to the analysis above, the main influence of the outer code is the impact of its free distance d_{free} on the interleaver gain. Here, four different rate-$\frac{1}{2}$ outer CCs concatenated with MSK are investigated, whereby one is the reference system above. The codes are the 2-state (2,3) code, the 4-state (7,5) code, the 16-state (23,35) code, and the 64-state (133,171) code, and all codes are nonrecursive, nonsystematic convolutional codes. They have $d_{\text{free}} = 3$, 5, 7, and 10, yielding interleaver gains between N^{-2} and N^{-5}, and implying $\mathcal{D}(\alpha_{\max}) = 4$, 6, 8, and 10.

In Fig. 7, the codes are compared at an input delay of 4096 information bits ($N = 8192$). As can be seen, the required E_b/N_0 for a given BER $\geq 10^{-4}$ actually *increases* with d_{free}. This is in contrast to the analysis, where a larger d_{free} would give a larger interleaver gain. However, as pointed out earlier, this is true only above the divergence threshold, and for sufficiently large interleavers. In the

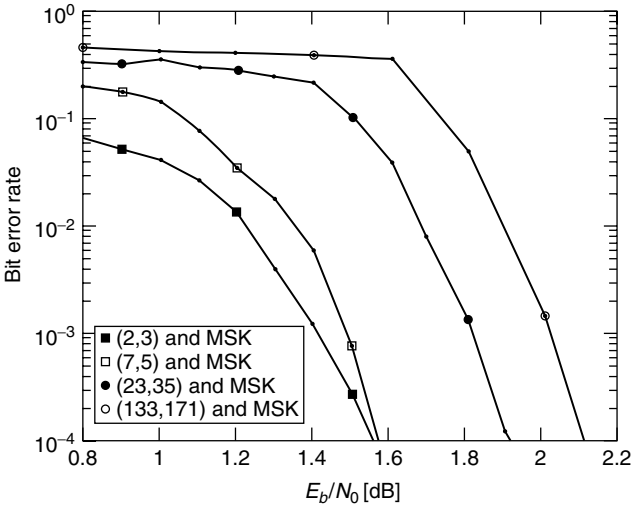

Figure 7. Simulation results for four different outer convolutional codes (CCs) with MSK, at a delay of 4096 information bits ($N = 8192$). All systems utilize the same bandwidth.

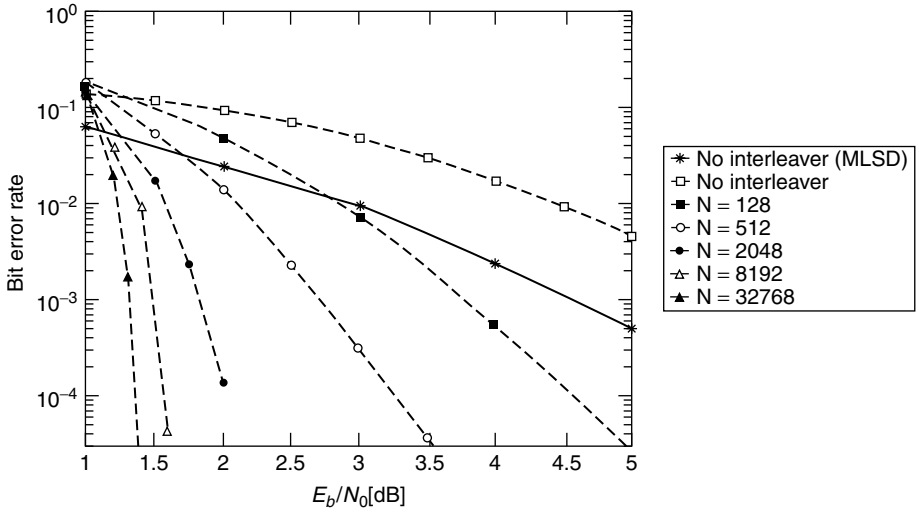

Figure 6. Simulation results for (7,5)-coded MSK ($4 + 2$ states in the iterative decoder).

low-SNR region, outer codes with more states suffer from convergence problems, as has been reported for SCCs [33]. The gain of a larger d_{free} can thus not be exploited in this SNR region. Still, it can be noticed that the 4-state code has a steeper BER slope than the 2-state code above 1.4 dB. Thus we can expect it to perform better asymptotically.

5.3. Influence of the Inner CPM System

We saw in section IV that the BER bound for SCCPM is made up of several combinations of error events in the inner CPM system, which depend on the outer CC. Therefore, in this section, we compare four different CPM systems, including MSK, concatenated through an $N = 8192$ interleaver with the same outer (7,5) CC. The systems certainly have different bandwidths, but we defer that comparison to Section 6. Their dominant error event combinations, as calculated in an earlier study [12], are shown in Table 1.

System 1 is the reference system (MSK, 2 states). System 2 is Example 2 (in Section 4) (binary 2RC, $h = \frac{3}{4}$, 8 states), which is supposed to perform better than system 1. System 3 is binary 3RC, $h = \frac{2}{3}$ (12 states), and system 4 is binary 3RC, $h = \frac{4}{5}$ (20 states). Studying the error events in Table 1 we find that system 3 should be slightly better than system 1, but worse than system 2, and that system 4 should perform about as well as system 2. These conclusions generally hold only above the divergence threshold of the BER bound, but the simulation results in Fig. 8 indicate that the relations stay the same in the low-SNR region as well, although the difference between systems 1 and 3 is larger than expected. Note that system 1 has the largest $\mathcal{D}_{\min}$, but it performs worst of these four systems.

Figure 9 shows simulation results from Ref. 36 for some SCCPM systems with $M = 4$, 8, and 16, together with system 1. The rate of the CC is adapted accordingly, such that $R_{cc} = \frac{1}{2}$, $\frac{2}{3}$, and $\frac{3}{4}$, respectively. In order to compare the systems at equal encoder delays (4096 information bits), interleaver sizes of $N = 8192$, 6144, and 5460 bits were chosen. As can be seen, increasing h and M gives improved performance, although this need not be true for arbitrary modulation indices. As demonstrated earlier [36], 3RC systems generally give worse BER performance — keeping everything else constant — than do their 2RC counterparts, but they consume less bandwidth. We will return to bandwidth in Section 6. In Fig. 9, the best BER performance is obtained by rate-$\frac{3}{4}$ coded $M = 16$ 2RC, $h = \frac{1}{2}$, which reaches BER $= 10^{-3}$ at $E_b/N_0 = 0.35$ dB. This is even better than the rate-$\frac{1}{2}$ Turbo codes with BPSK presented by Berrou et al. [4], but the bandwidth is slightly larger.

Concluding, for SCCPM systems utilizing the same outer code, performance below the divergence threshold is roughly in line with the error event analysis, and the convergence problem is not very pronounced. Still, methods of examining the convergence behavior [32–34] could give insights beyond the traditional union bound approach.

Table 1. Dominant Error Events for Some SCCPM Systems

System	$B_{\mathcal{D}} \sim N^{-5}$	$B_{\mathcal{D}} \sim N^{-4}$	$B_{\mathcal{D}} \sim N^{-3}$
1. (7,5) and binary 1REC, $h = \frac{1}{2}$ (MSK)	—	—	$B_6 \sim 480N^{-3}$
2. (7,5) and binary 2RC, $h = \frac{3}{4}$	$B_{5.21} \sim 2880N^{-5}$	$B_{6.59} \sim 1440N^{-4}$	$B_{7.97} \sim 480N^{-3}$
3. (7,5) and binary 3RC, $h = \frac{2}{3}$	—	$B_{3.55} \sim 120N^{-4}$	$B_{6.06} \sim 60N^{-3}$
4. (7,5) and binary 3RC, $h = \frac{4}{5}$	—	$B_{5.54} \sim 120N^{-4}$	—

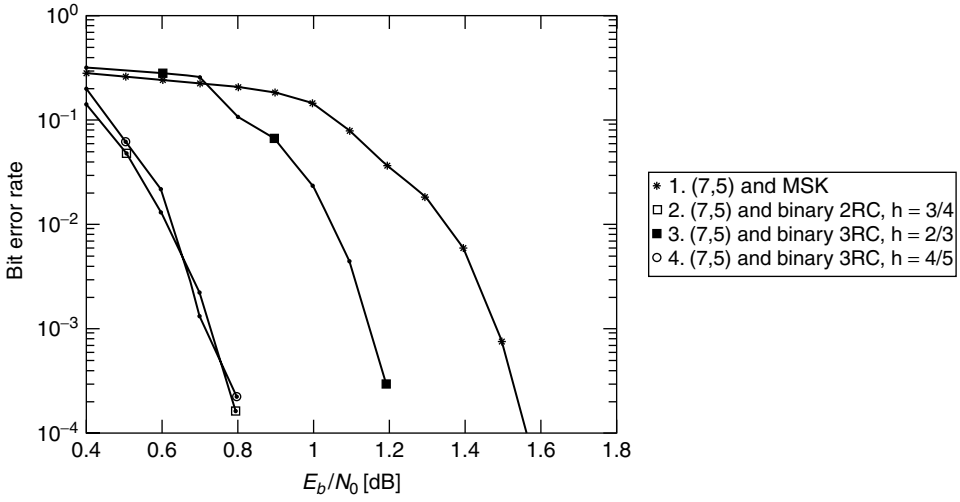

Figure 8. Simulation results for four different inner CPM systems with the (7,5) CC, at a delay of 4096 information bits ($N = 8192$). See Fig. 11 for a bandwidth comparison of these systems.

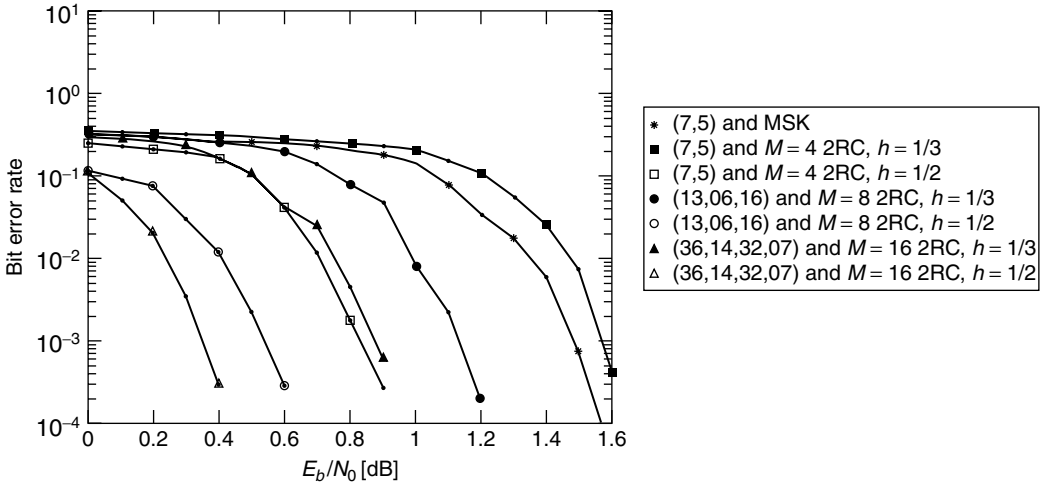

Figure 9. Simulation results for some $M = 4$, 8, and 16 SCCPM systems with rates $\frac{1}{2}$, $\frac{2}{3}$, and $\frac{3}{4}$ outer CCs, respectively, and interleaver sizes $N = 8192$, 6144, and 5460. See Fig. 11 for a bandwidth comparison of some of these systems.

5.4. Influence of Inner Input Weight 1 Error Events

It was stated in Section 4 that if the inner CPM system has input weight 1 error events, the interleaver gain would not be assured for all SNRs. We investigate this phenomenon by considering quaternary 1REC, $h = \frac{1}{3}$ with natural and gray mapping (3 states) together with the (2,3) and (7,5) outer CCs (2 and 4 states, respectively). Figure 10 shows BER simulation results with an $N = 8192$ interleaver. Clearly, the systems with Gray mapping — and thus with input weight 1 error events — do not provide any spectral thinning caused by the random interleaver; hence their BER curves have a modest slope that is due only to the distance profile in Eq. (6). Notice that for the 4-state code, gray mapping still gives better performance down to a BER of 10^{-5}.

6. POWER SPECTRAL DENSITY AND BANDWIDTH

Bandwidth is at least as important as BER performance in many communication systems. The demand for higher data rates in wireless data communications and increased capacity in digital mobile telephony networks is growing constantly. Spectrum reuse in the form of small-cell networks can meet these requirements to a certain extent, but bandwidth-efficient coding and modulation is nevertheless essential. In this section, we evaluate the bandwidth efficiency of SCCPM in general, and compare it with power efficiency (BER) for some selected examples.

For a coded CPM system without interleaving, Ho and McLane [20] have calculated the true power spectral density. However, since random bit interleaving is used in SCCPM, an accurate estimate (see also Ref. 17 and 20) of the baseband power spectral density $S(f)$ is

$$S_{\text{coded}}(f) \approx R_{cc} S_{\text{uncoded}}(R_{cc} f) \tag{10}$$

The power spectral density of the carrier-modulated SCCPM signal is given by

$$P_c(f) = \frac{P}{2}\left[S_{\text{coded}}(f - f_0) + S_{\text{coded}}(-f - f_0)\right] \tag{11}$$

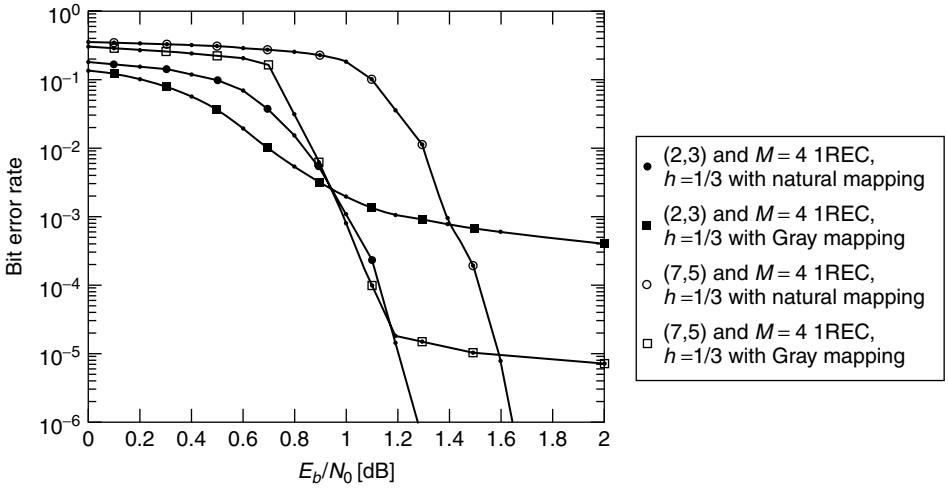

Figure 10. The effect of input weight 1 error events in the inner CPM system, $N = 8192$. Gray mapping yields such events; natural mapping does not.

where $P = E/T$ is the average transmitted signal power. Similarly, the normalized double-sided bandwidth of the coded CPM system $2B_{\text{coded}}T_b$ can be expressed in terms of the corresponding quantity of the uncoded CPM system, $2B_{\text{uncoded}}T_b$:

$$2B_{\text{coded}}T_b \approx \frac{2B_{\text{uncoded}}T_b}{R_{cc}} \tag{12}$$

Note that the rate of the CC is included in the normalized bandwidth in Eq. (12). The bandwidths are defined as 99% in-band power, equivalent with the −20 dB level in the fractional out-of-band power function [2,17]. The uncoded bandwidth of a CPM system can be calculated using the general method described in a previous publication [37].

The normalized bandwidths (bandwidth efficiencies) of some SCCPM systems are compared with their error performance in Fig. 11. Interleaver sizes corresponding to an input delay of 4096 information bits were used, namely, $N \approx 4096/R_{cc}$. Error performance is measured in terms of the required E_b/N_0 for a simulated BER of 10^{-3}, and plotted against the normalized double-sided bandwidth $2B_{\text{coded}}T_b$. Lines are used to interconnect points for similar systems but with different modulation indices. Notice that these lines do not provide any information on modulation indices in between the points. As can be seen, over the whole bandwidth range shown in Fig. 11, the lowest E_b/N_0 among these systems is obtained for the rate-$\frac{2}{3}$, (13,06,16) CC, a 6144-bit interleaver, and $M = 8$ 2RC. At $2B_{\text{coded}}T_b \approx 2.0$, it requires only 0.5 dB, and at $2B_{\text{coded}}T_b \approx 1.15$, it requires roughly 1.6 dB. The latter can be compared to uncoded MSK ($2B_{\text{coded}}T_b \approx 1.20$), which requires 7.3 dB for a BER of 10^{-3}. Thus the gain over uncoded MSK is around 5.7 dB. For smaller BERs, the gain increases because the SCCPM system has a much steeper BER slope. However, if a low-complexity system is the goal, the quaternary 1REC systems may provide a good tradeoff. The rate-$\frac{3}{4}$-coded $M = 16$ 2RC systems are not shown here because they are less power/bandwidth-efficient than are the rate-$\frac{2}{3}$-coded $M = 8$ 2RC systems, as demonstrated earlier [36].

How does SCCPM compare with a typical Turbo code with BPSK? The answer to this question depends on the bandwidth required to transmit one BPSK symbol. While theoretically, a normalized bandwidth of 1 is sufficient if signals extend over infinite time, we here assume a 99% bandwidth of 1.2 as being more practical. Then, a rate-$\frac{1}{2}$ Turbo code will have $2B_{\text{coded}}T_b = 2.4$, while typically yielding a BER of 10^{-3} at roughly 0.8 dB for an input delay of 4096 bits (Berrou et al. [4] obtained 0.6 dB with 65536 bits). This is slightly inferior to the rate-$\frac{2}{3}$-coded $M = 8$ 2RC, $h = \frac{1}{2}$ SCCPM system, which requires around 0.55 dB with $2B_{\text{coded}}T_b \approx 2$.

Finally, we compare some of the coded, noninterleaved CPM systems with MLSD, investigated by Lindell [17]. These systems have large asymptotic gains (upto dB over uncoded MSK), but here we still use simulated BER $= 10^{-3}$ as the performance measure. As can be seen from Fig. 11, SCCPM is able to provide gains of 1.5–2.0 dB at this BER level, although with increased receiver complexity. At a lower BER, the gain would increase even further because the SCCPM systems generally have a much steeper slope than do the noninterleaved systems. For example, rate-$\frac{3}{4}$ and $M = 16$ 1REC, $h = \frac{2}{13}$ with MLSD requires 5.7 dB for BER $= 10^{-5}$, while rate-$\frac{2}{3}$ and $M = 8$ 2RC, $h = \frac{1}{4}$ with a 6144-bit interleaver and iterative decoding requires 1.9 dB, yielding a gain of 3.8 dB.

7. CONCLUSIONS

SCCPM with iterative decoding is an exciting new coding and modulation technique, merging the principles of both coded CPM and Turbo codes. With the simple insertion of a random interleaver between the outer code and the CPM system, dramatic performance gains

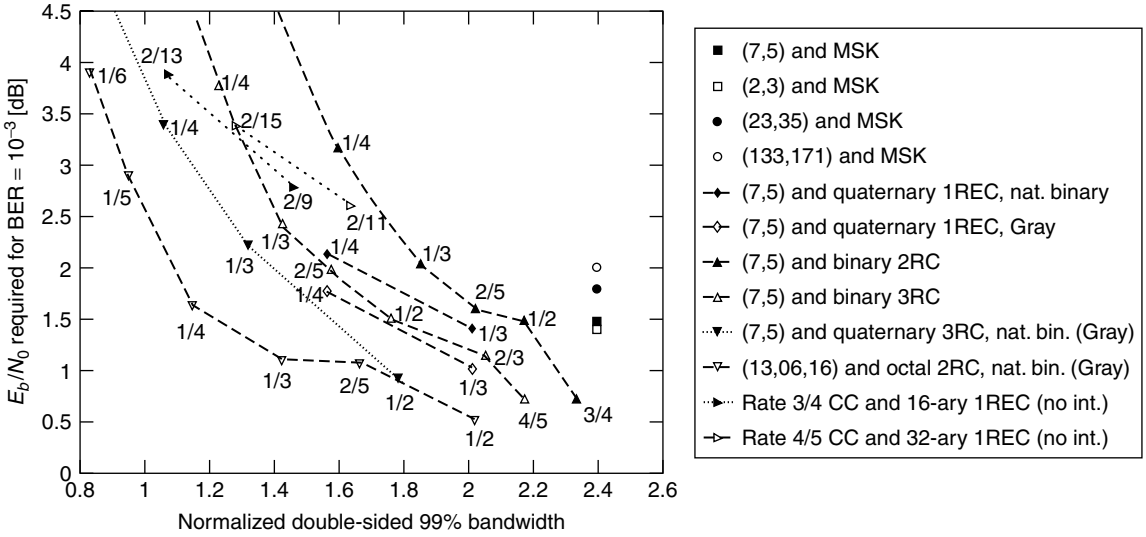

Figure 11. Bandwidth/performance comparison for an input delay of 4096 bits and BER $= 10^{-3}$. The numbers indicate modulation indices. "Nat. bin. (Gray)" refers to gray mapping only for modulation indices that yield input weight 1 error events with natural mapping.

become feasible. Since MLSD (Viterbi decoding) is practically unreasonable, this requires a rather different iterative decoder that consists of SISO algorithms for the constituent code and modulation, passing APPs between each other. This decoder is very similar to that used in SCCs with memoryless modulation.

SCCPM can be analyzed through a transfer function bound to the BER, using a number of assumptions. This includes the averaging over all possible interleavers (the uniform interleaver assumption), the use of an MLSD receiver instead of the iterative decoder, and the assumption of an SNR above 3 dB, which is the divergence threshold of the bound. Still, the transfer function bound gives theoretical insights such as the following:

1. Similar to Turbo codes and SCCs, SCCPM is capable of providing interleaver gain, the order of which is determined by the free distance of the outer CC.
2. Several error events in the inner CPM system contribute to the overall performance; hence it is difficult to give general design guidelines for the inner CPM system.
3. However, CPM systems with input weight 1 error events should be avoided since they do not give interleaver gain. This is always possible by a different choice of mapping.

Simulation results for a variety of SCCPM systems indicate that, in addition to these three conclusions, the convergence of the iterative decoder also affects performance in the low-SNR (waterfall) region. For unequal outer CCs with similar CPM systems, performance in the waterfall region actually deteriorates with increasing free distance of the outer code. This is consistent with conclusions from SCCs. On the other hand, for similar outer CCs with different CPM systems, the transfer function bound analysis appears to give satisfactory conclusions. Also, we demonstrated that CPM systems with input weight 1 error events indeed fail to provide Turbolike performance. We also demonstrated a number of higher-order SCCPM systems with $M = 4$, 8, and 16. These systems both have attractive BER performance and bandwidth efficiency. Comparing power and bandwidth efficiency, it is seen that the $M = 8$ 2RC systems are the most efficient as known today. These systems can provide gains of almost 4 dB at BER $= 10^{-5}$, at the same bandwidth, compared to the best known coded CPM systems without interleaving.

In conclusion, wherever a constant envelope of the transmitted signal is desired, SCCPM should be able to provide appealing power and bandwidth efficiencies. As of today, the decoding complexity may seem high, but we are strongly convinced that in a near future, this will not pose any major obstacles. Of course, much work remains to be done on implementation issues such as timing and carrier phase recovery, reduced sampling rates, and quantization to fix-point representation.

BIOGRAPHIES

Pär Moqvist received his M.S. and Lic.Eng. degrees in electrical engineering from Chalmers University of Technology, Göteborg, Sweden, in 1993 and 1999, respectively. In 1994, he was awarded the John Ericsson Medal for outstanding scholarship. He joined Ericsson AB in 1993 as a radio system engineer, working on the design of digital radio modems for land-mobile applications. Since 1997 he has been a Ph.D. student with the Telecommunication Theory Group at Chalmers University. His research is in the general area of signaling and detection for digital communication systems, with a current focus on iterative decoding methods.

Tor M. Aulin received his M.S. degree in electrical engineering from the University of Lund, Lund, Sweden, in 1974 and the Dr. Techn. (Ph.D.) from the Institute of Telecommunication Theory, University of Lund, Göteborg, Sweden in November 1979. He became a docent there in 1981 and he was also a visiting scientist at the ECSE Department at Rensselaer Polytechnic Institute, Troy, New York. One year was spent at the European Space Agency (ESA, ESTEC) as an ESA research fellow. In 1983, he became a research professor (docent) in information theory at Chalmers University of Technology, Göteborg, Sweden. In 1991, he formed the Telecommunication Theory group there and became a docent in computer engineering in 1995. During 1995 he was a visiting fellow at the telecommunications engineering department, Australian National University, Canberra, ACT, Australia. Some of Dr. Aulin's research interests are communication theory, combined modulation/coding strategies (such as CPM and TCM), analysis of general sequence detection strategies and digital radio channel characterization. Dr. Aulin has authored the book *Digital Phase Modulation*, Plenum Press 1986. He is a fellow of the IEEE and an editor for *IEEE Transactions on Communications* in the area of communication theory and coding. In 1997, he was awarded the prestigious Senior Individual Grant, handed over by the Prime Minister of Sweden.

SERVICES VIA MOBILITY PORTALS

DANIEL RALPH
CHRIS SHEPHARD
BTexact Technologies
Ipswich, Suffolk, United Kingdom

1. INTRODUCTION

Mobility portals look set to become the window through which the user will access a whole range of innovative services [4]. Wherever and whenever, the mobility portal will warn you, inform you or just entertain you.

There is a distinction between the mobility portal and the mobile portal, the concept of mobility extends to include terminal independence through user profiles, additional value add services such as "find me, follow me" call routing and integration with existing systems in the fixed network. The mobile portal however is being expressed as a cut-down version of existing Web-based applications such as news, weather, and email.

The explosion in use of Short Message Service (SMS) for sending text messages demonstrates a natural evolution path to WAP services on smartphone and personal digital assistant (PDA) devices. Support from many vendors has created an environment where the applications delivered through the mobile portal will increasingly substitute access through the fixed network.

However, although the Internet and mobile phones have independently been successful (see Figs. 1 and 2), this

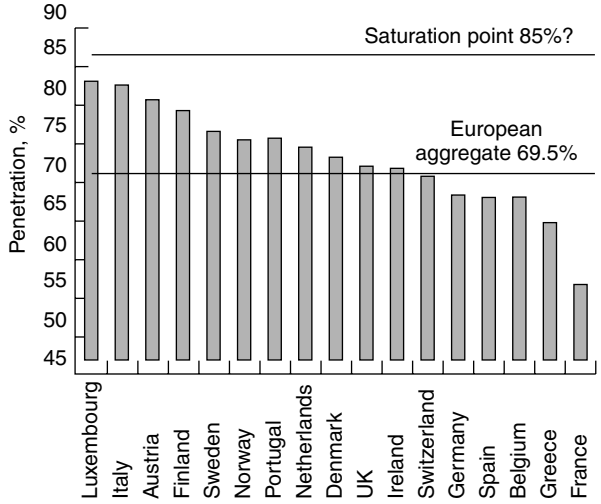

Figure 1. European mobile penetration by country, June 2001 (%) (*Source*: Morgan Stanley Research).

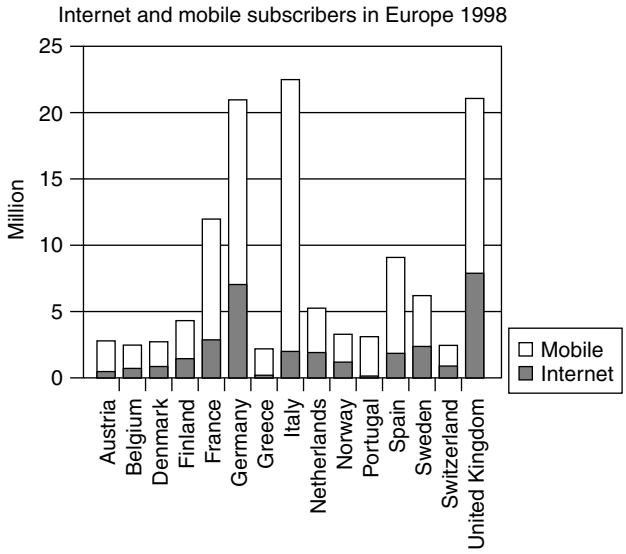

Figure 2. Internet and mobile subscribers in Europe, 1998. (*Source*: Dataquest, Mobile Communications International, Computer Industry Almanac [10]).

does not always mean that combining these technologies will also be successful. Evidence of this is clear in the combination of TV and phone technologies, both successful in their own right but the uptake of personal videophones has not happened. Mobile videophone is considered a killer application. However, it will become clear from this article that to achieve a high takeup is unlikely in the foreseeable future due to bandwidth limitations and device battery life. A more likely scenario is that a short videoclip downloaded in non–real time could be played back to the user to provide visual information.

In addition, users may subscribe to specialized information feeds for stock trading, weather, ski and snow conditions, and horoscopes. Finally, the services will offer specialized alerting through partners such as auction, travel sites, banking, and messaging providers.

2. THE RISE OF THE MOBILITY PORTAL

Without doubt the explosive growth rate of Internet users and the significance of accessing content through the use of Web-based portal services will continue. While this highlights the demand for content from the fixed network, it cannot be assumed that the same type or level of demand will be present in the mobile environment. The differences in network and device capability will require a different solution in providing content through the mobile portal.

In assessing why the mobility portal is important, it can be seen from looking across the value chain that a number of key elements are available to be exploited in delivering new mobility services:

- The existing infrastructure will support these services, in terms of both core IP networks and content availability. Whether this is from the customers Internet service provider or other content providers, it will enable the rise of the mobility portal.
- The prospect of "always on" packet-based services delivered over 2.5G and 3G networks such as GPRS and UMTS will enhance the user experience in the way content is delivered over the next-generation infrastructure provided by the mobile operator.
- The first-generation consumer equipment is readily available and supports basic web access and WAP services. This is in the form of smartphone and PDA devices.
- In the short term, existing content can be redeveloped for delivery to the smartphone or PDA device, this will enable the rapid deployment of mobile services. Although this will only be through provision of existing generic Web portal services on the mobile device, this will include search engines, personalization, snap-shot text information and basic messaging.

It is the very issue of content and what services the user will require that will determine the successful uptake of service access through the mobility portal. Figure 3 illustrates some of the anticipated benefits from a wireless portal.

Questions have to be answered to determine the customer's needs when mobile: What do they want? When? Why? Providers of mobility portals will need to assess customer requirements and actual usage to develop context awareness so as to present the most relevant content. If the network knows the weather conditions, user location, time, and whom the user is accompanied by, then this gives the network an opportunity to provide information ahead of the user requirement for this information, further developing the mobile device as a lifestyle tool [12].

Future applications need to develop the unique attributes of the mobile device. The opportunity for the network to provide location-based services, and the personal nature of the mobile device lend it to acting as a payment device.

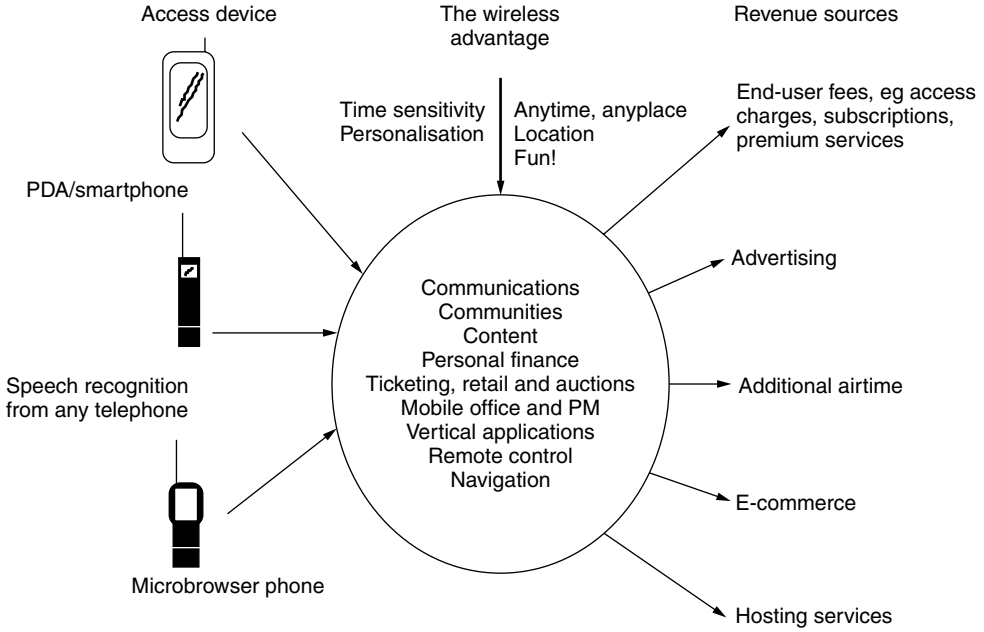

Figure 3. Benefits of a wireless portal.

3. INSIDE THE MACHINE

The current UK digital mobile network has evolved from the first-generation analog network and is based on the Global System for Mobile communications (GSM).

Network technologies are evolving toward the 3G mobile vision, this will require an evolution through extensions to the existing 2G mobile network technologies. In the near future this will involve

- GSM (2G) component technologies:
- SMS and cell broadcast
- GPRS (general packet Radio Service)
- EDGE (enhanced data rates for GSM Evolution)
- UMTS [3G] (Universal Mobile Telecommunications System)
- Bluetooth
- GPS and other location-based techniques (Mobile Positioning Protocol)
- Mobile agents and intelligent networks

The next-generation mobile system will rely heavily on emerging application technologies such as

- Wireless Application Protocol (WAP)
- XML/XSL (eXtensible Markup Language)
- JAVA Technology (Java 2 Micro Edition)
- SIM Application Toolkit
- Lightweight Efficient Application Protocol (LEAP) [1]
- Compact HTML
- XHTML

It is clear that the Internet will play a pivotal role, requiring increasing quality of service (QoS) and allowing better integration of applications across different terminals and bearers, probably using APIs to provide access to functionality.

The importance of voice must not be underestimated as a mechanism for controlling services by natural language commands, such as adding an appointment to your calendar or more simply as an alternative to typing a response to an email. Voice browsing of a mobility portal will be standardized through the use of VoiceXML and provide a development environment to deliver powerful niche applications [2].

Before service providers can offer content or applications using mobility portals, a number of issues require further consideration.

3.1. Wireless Application Protocol

Wireless Application Protocol (WAP) is a specification for a set of communication protocols to standardize the way that wireless devices, such as cellular telephones and radio transceivers, can be used for Internet access, including email, the World Wide Web, newsgroups, and Internet Relay Chat (IRC) [3].

While Internet access has been possible in the past, different manufacturers have used different technologies. In the future, devices and services that use WAP will be able to interoperate (see Fig. 4).

The WAP layers are

- Wireless application environment (WAE)
- Wireless session layer (WSP)
- Wireless transport layer (WTP)
- Wireless transport layer security (WTLS)
- Wireless datagram protocol (WDP)

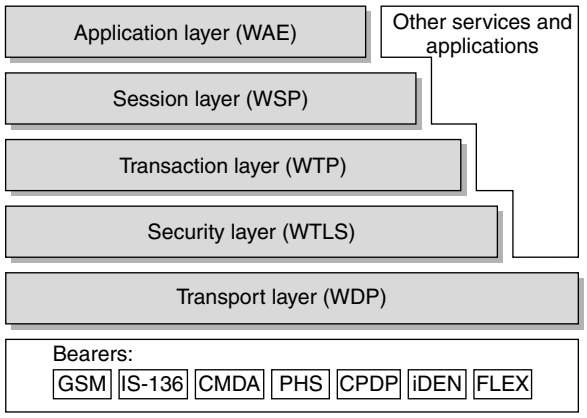

Figure 4. The WAP protocol stack.

Following independent development, four companies proposed the WAP standard: Ericsson, Motorola, Nokia, and Openwave (previously known as *phone.com*).

The use of transcoding engines (described as the HTML filter in Fig. 5) is being proposed as a "quick win" in providing services from existing Web content to the first generation of wireless terminals. This has met with limited success due to the complexity present in much of the multimedia-rich Web content. The use of JavaScript, Frames, and imagemaps causes in many cases a failure to transcode the html into a suitable WML page that can be displayed on a smartphone.

3.2. i-mode

The deployment of WAP in Europe must be contrasted with the developments in Japan, where the i-mode service has significantly better functionality. The service uses a Compact Hypertext Markup Language (CHTML) and is provided over the Personal HandyPhone System (PHS), which is a packet-based "always on" service, operating at 9.6 kbps (kilobits per second). The use of CHTML permits color graphics to be displayed or 10 lines of text, it still has limitations similar to the Wireless Markup Language as used in WAP [11].

There are many reasons for the success of i-mode. It relies on open technology, allowing any Internet site to join in; content is written in a simplified version of HTML (CHTML); and no fees are charged for placement on the i-mode portal. The services are positioned as a unique mobile service and not as "the Internet on your phone," thereby avoiding unfavorable comparisons with service from the fixed Internet. The low penetration of PCs in Japanese homes probably also helps control user expectations. Finally, NTT DoCoMo has concentrated on growing core revenues from airtime usage and has chosen not to support the service through advertising or transaction revenue.

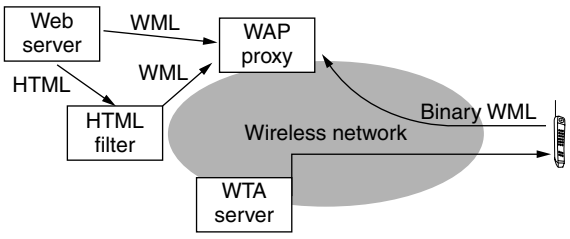

Figure 5. Example WAP network.

Mobile Internet services to compete with i-mode have now been introduced by rival operators. However, they have thus far failed to attract significant numbers of subscribers or content providers, despite offering greater bandwidth.

By being first to market, i-mode may now have an important head start, and competitors offering WAP based services cannot tap into the wealth of available i-mode content because of format incompatibilities.

i-mode is a brand name for NTT DoCoMo's Internet service. The technology and service offerings behind i-mode will continue to evolve to take advantage of improving network capabilities, including the introduction of 3rd generation mobile networks. In addition, DoCoMo has plans to roll out i-mode service in other countries, particularly in mobile networks where NTT owns a share. One example is the cooperation with Hutchinson in Hong Kong. At the same time, DoCoMo is active in the *WAP Forum*, *World Wide Web Consortium* (W3C), and Internet Engineering Task Force (IETF) whose standards, in combination, will map the way forward for a globally compatible mobile Internet.

The deployment of global mobility portals are essential to support the global traveler, they need to support the roaming capabilities of GPRS and GSM; and remove the added complexity for the user to change profiles to connect to the same services in different countries. The geographic distribution of network elements and the seamless access to services across different countries will strengthen the mobile operator's position as a service provider.

3.3. Terminals

The look and feel of the mobile device will have an impact on the user's perception of services, the usability of the device will have an impact on the usability of any service delivered over that device. Regardless of the content the portal provides, the terminal usability will prove significant in the promotion of services through mobility portals.

The types of mobile device range from the smartphone complete with NaviRoller to a pen based PDA device (see Figs. 6 and 7) and upto a subnotebook with keyboard and 1024×480 pixel display. Each of these devices has different attributes related to

- Screen size (resolution)
- Input method, such as through keyboard, touch screen, handwriting recognition
- Presence or absence of a speaker and microphone

The multiple methods for input and display are compounded by the variable and often low bit rate of mobile networks. In order to provide suitable content, device characteristics will need to be available to the service provider to allow appropriate formatting and display to

Figure 6. D503i mobile phone.

Figure 7. Next-generation PDA device with pen and speech based input, integral GPS and GPRS connectivity [9].

the range of devices outlined. The W3C have a working group on device capability and profile called Composite Capabilities/Preference Profiles (CC/PP) that is driving standards efforts to implement device profiles to enable content providers to determine device capability.

Further proposals from the Salutation consortium [6], Jini and Universal PnP (UpnP) [5] are intended to deliver service discovery and device recognition capabilities to enable the network to seek the services that the user requires and that are suitable for the terminal capability. For instance, the user may require a print service, but have available only an IrDa port with which to communicate with the printer.

The limitations of device capabilities in terms of storage and access to information will increase the need for additional support from the network. This may be provided through network based backup and synchronization services or server processing for voice recognition to authenticate to a service.

3.4. Addressing

It has been a concern for some time that the lack of IPv4 address space would prevent connections to the Internet. This problem will only become worsen with an explosion of mobile devices that have an "always on" connection to the Internet. Ultimately the proposed migration to IPv6 with its 128-bit address scheme will remove this problem with available address space for devices connected to fixed or mobile networks. The size of the IPv6 address range will allow 10^{20} addresses (or thousands of IPv6 address for every square inch of the earth.

Each mobile device that a user carries or interacts with will be uniquely identified by an IPv6 address and may well communicate to the user using Bluetooth devices connected within one's "personal bubble" or to an external network using UMTS. It is estimated that 1 billion Bluetooth addresses will be in use by 2005 [7].

The home environment is where a significant portion of this addressing will be required; in particular, the ability for devices around the home to communicate, to share information on your whereabouts, and to anticipate the family's needs. This could be extended to the fridge ordering fresh milk from the supermarket on your arrival home from holiday.

3.5. Billing

Getting information to the handset of a user is the simple part. Devising a mechanism that meets the commercial aspirations of all the players involved in making this happen is much harder. Many network operators will partner with a publisher to manage the day-to-day operations of their portal. Service providers will want recompense for the information provided.

Even in the simple case of portal provision, a number of revenue models have been developed to describe the different ways in which the value can be expressed. For example, a simple revenue share might be appropriate for a traffic-congestion report, the operator charging the user "per click" for information and passing on a share to the information provider.

Initially, WAP services are expected to be expensive to use since the tendency is to be online for a long circuit-switched data (CSD) call since features such as interactivity and selection of more information are used by the end user. With the introduction of GPRS handset the billing model is based on the number of packets sent or received by the user.

In contrast, i-mode uses an efficient micro billing system via the mobile phone bill, which makes it easy for subscribers to pay for value added services and premium sites and is also attractive for site owners, to sell information to users.

3.6. Security

There are several areas of WAP security that will need additional development to ensure the end-to-end security requirements for transactions involving payments or

instructions requiring nonrepudiation. These include what is being called "premature encryption endpoint." The WAP gateway acts as a proxy and decrypts the incoming WTLS session and encrypts as SSL3.0 for the outgoing connection to the Origin server.

The WAP specification 1.1 supports the use of certificates in a way similar to X.509 and encryption is supported at 56 and 128 bits. In the future the WAP specification will be extended to include the wireless identity module (WIM), which may be a replacement for your SIM card containing a personal digital signature to identify and authenticate the User. The addition of a crypto library will enable the developer of WAP services access to a range of functions that allow the User to digitally sign and encrypt a message before it is sent from the mobile device.

3.7. Interoperability

The provision of mobile data services in the past has always been using proprietary technologies [8]. The standardization of WAP allows developers and services to be less restricted in their range of mobile networks or mobile devices. The first release of gateway and device products have the inevitable problems associated with new technology and significantly more testing will be required between different vendors products. This is an area where the service provider can add value in providing an integrated service to an agreed level of quality and compatibility with other services.

3.8. Quality of Service

The issue of quality of service (QoS) has plagued IP networks since it became commercialized. Several IETF standards have been proposed to satisfy the user requirements, these include Resource Reservation Protocol (RSVP) with IETF Integrated Services (IntServ), Differentiated Services (Diffserv), and multiprotocol label switching (MPLS).

The mobile network suffers from QoS issues such as dropped connections, lack of resources, and reduced bandwidth due to too many users sharing the available capacity. These factors will significantly restrict the availability of mobile services that compete directly with fixed network services, such as videoconferencing or high-speed file transfer.

As users are demanding higher levels of QoS from IP networks for fixed services delivered on these networks, so, too, will the mobile user. The demand for real-time services may be sufficiently low to cause less difficulty, videostreaming can use buffering to delay the transmission. Videoconferencing cannot accept high network latency, but it may be that this is not the "killer application."

Improved quality of service will be available with the advent of 3G networks. The rollout plans for many 3G operators are progressing at a rapid pace, with statements from several outlining available data rates between 64 and 384 kbps on initial launch. With these achieving commercial service in the near future, NTT DoCoMo began trials over their installed 3G network in July 2001.

4. CONCLUSION

Future developments of the mobility portal must embrace the entire range of existing web based content if it is to succeed as the default method of access to the network. This will include all applications from gaming to mobile commerce.

Services should be designed so the relevant elements of a service are available over to the particular client device, the requirement for the network to recognize the device capability and network connection characteristics.

There will be no single "killer application" for the mobile device, although its unique attributes, including location positioning and personal nature, provide an opportunity for the mobile device to become the portal through which the user interacts whilst "on the move."

It is highly likely that WAP will be superseded by evolution of existing Internet standards, the requirement for legacy support will remain for WAP enabled mobile phone devices.

The reasons for the limited lifetime of WAP are due to

Low bandwidth
High latency
Low-resolution monochrome displays
Dropped calls and other quality of service issues
Low device processing power

All of these factors are not limitations of WAP; however, once they have been improved or overcome, the tendency will be to use existing Internet standards end to end, as opposed to the WAP architecture of creating a wireless version of these standards. Even if successful, once all devices and networks support WAP, it will cease to differentiate and therefore will not reduce subscriber churn. However, it will provide the user with convenient access to services whenever and wherever required.

With so many heavyweight carriers, equipment manufacturers and software and applications developers backing the Wireless Application Forum, a momentum is being generated that will drive WAP-based equipment and services forward into the future.

Despite the drawbacks discussed in this article, WAP certainly seems to be shaping up to play a major role in facilitating the brave new world of the personalized mobility portal. WAP is a powerful tool. It enables "anytime, anywhere" connectivity to a wealth of information, whether for leisure or business applications.

It is impossible to predict who will win between WAP and i-mode; clearly, DoCoMo has a significantly larger market share at the time of writing. However, if XML becomes the dominant content standard, there may be situations where both standards are absorbed into existing Internet protocols.

This article has demonstrated through the discussion of mobility portals some of the problems involved in providing content, applications, and filtering information to a new generation of wireless devices.

BIOGRAPHIES

Daniel Ralph joined BTexact Technologies in 1996 following a period working in the biotechnology industry. Since joining BT he has worked on projects as diverse as the deployment of the trial global VoIP network for Concert and the design and implementation of the call processing engine "powering" the network intelligence platform. He is now responsible for a number of technical developments within the arena of mobile Internet technologies. He is a graduate of the Open University, and has recently completed the BT MSc in telecommunications. He is a corporate member of the BCS.

Chris Shephard read theoretical physics at UEA and then University of Birmingham, United Kingdom. He joined BTexact Technologie in 1980 and helped to develop signaling, call control, and maintenance software for System X PSTN and ISDN switches. After two years with Siemens in Florida, where he was part of a large project designed to adapt their range of digital public switching systems (EWSD) to the USA regulatory and market requirements. He returned to BTexact Technologies where he worked initially on the development and delivery of local network switches (LA-30) and subsequently on the design and management of two European broadband ISDN projects. He then switched to the study of network centric computing and the use of thin client devices. He now works in the terminals and applications unit within Multimedia Applications where he leads a team developing XML applications.

SESSION INITIATION PROTOCOL (SIP)

HENNING SCHULZRINNE
Columbia University
New York, New York

1. OVERVIEW

The Session Initiation Protocol (SIP) is a *signaling* protocol for setting up, tearing down, and modifying multimedia sessions. These sessions can consist of any number of media, such as audio, video, and shared applications, and can be either unicast (point-to-point) or multicast. SIP does not transport media itself, but rather allows endpoints (Internet hosts) to coordinate the exchange of media.

This coordination function becomes necessary since endpoints, called *user agents* by SIP, need to discover one another even if they change their Internet address. Endpoints also need to agree on the characteristics of the session, such as the number and type of media streams, the codecs to be used for audio and video, the properties of shared applications, or the availability of quality of service (QoS) mechanisms. SIP is based on the notion that an endpoint identifier, a SIP URI, is associated with a person or telephone number. A person keeps the same SIP URI even if they change their IP address or use different devices, such as a office PC, wireless 3G phone, or traditional telephone. The ability to reach a person with different devices under the same name is sometimes referred to as *personal mobility* [1].

SIP supports five aspects of managing multimedia sessions:

User location — given a SIP URI, SIP protocol entities find all relevant end systems that are registered for that URI.

User availability — based on information in the SIP request, the called end systems indicate their willingness to participate in the session or may indicate alternate locations.

User capabilities — through protocol exchanges, both end systems learn about the media capabilities of the other side.

Session setup — if there is an intersecting set of capabilities, the called party alerts the user ("rings") and, if a human controls the endpoint, the session may get established.

Session management — SIP requests can transfer sessions to others, terminate sessions, and modify session parameters.

SIP itself does not describe the media content; rather, it relies on external protocols for this task. Currently, SIP applications almost exclusively use the Session Description Protocol (SDP) [2] for this purpose, although other mechanisms can be negotiated between session participants. A newer version of the Session Description Protocol, called SDPng, is under development [3], but it is unclear how fast it can replace SDP.

SIP messages typically, but not necessarily, travel through a sequence of intermediaries, called *SIP proxies*. These intermediaries serve many functions, from user location and providing other services to policing reachability to opening firewalls for media streams. Often, the initial message traverses all such proxies, while subsequent messages within a session are exchanged directly between the two user agents.

SIP can use a variety of network-layer and transport-layer protocols. SIP works equally well over IPv4 [4] and IPv6 [5]; the latter is particularly important for its application to next-generation wireless networks. Currently, operation has been specified for UDP [6] and TCP [7], as well as for SCTP [8,9]. For reliable transport protocols such as TCP and SCTP, SIP can also benefit from transport-layer hop-by-hop security between end systems and proxies as well as between proxies. A single SIP request may traverse a path consisting of a number of different protocols.

Unlike traditional signaling protocol approaches, SIP does not try to model services directly, but rather provide a set of interoperable building blocks that can be used to build common telephony services [10] as well as new services that are beyond the capabilities of the existing circuit-switched network.

While useful for conference establishment, the core SIP specification does not address conference control features such as floor control, specifically, the coordination of access to a shared resource. However, SIP events (Section 5.6) and possibly common remote procedure call mechanisms may be used for this purpose.

SIP is maintained by two working groups within the Internet Engineering Task Force (IETF) and is currently an Internet Proposed Standard [11]. It was published in March 1999 and reissued with corrections and enhancements in March 2002.

2. SIP USAGE

SIP was originally designed to be used with multicast multimedia conferences in the Internet, allowing participants to invite others to join the multicast group. This usage is still supported, but has been overtaken in practical importance by its use in voice over IP (VoIP) applications. Voice over IP applications using SIP can be roughly divided into four areas: enterprise, cable, landline carrier, and third-generation (3G) wireless networks. In enterprise networks, traditional analog or digital handsets are replaced by a mixture of Ethernet-connected IP phones, such as the ones pictured in Fig. 1, and software running on desktop PCs [12]. These devices then use SIP to set up internal calls or to reach a gateway operated by the enterprise, a PBX with an IP interface, or a third party.[1] This arrangement makes it easy to add devices to a local dialing plan regardless of their physical location.

Traditional landline carriers can use SIP as a rough replacement for their current backbone signaling protocols, such as ISUP. In such an arrangement, local or gateway switches offer the same analog or digital circuit-switched service to the carrier's customers, but instead of a dedicated signaling network, the carrier uses SIP to interconnect these switches. SIP has been extended to transport ISUP messages across SIP networks, so that midcall information that is relevant only to ISUP networks is not lost in the protocol translation across an ISUP-SIP-ISUP signaling path [13]. The set of specifications for facilitating the interworking of SIP and ISUP is called SIP-T [14]. This is not a different protocol, just a set of guidelines for interworking.

Cable carriers can also use SIP as the signaling protocol in the Distributed Call Signaling (DCS) version of the PacketCable specification [15]. A number of

[1] The latter arrangement is often called *IP centrex*.

Figure 1. SIP phones.

extensions [16–18] have been proposed to make DCS mimic traditional telephone behavior more closely.

Third-generation wireless networks, using both GSM-evolved and CDM2000-based wireless networks, are being standardized by the 3GGP and 3GPP2 consortia. Both have chosen SIP as the signaling protocol for multimedia sessions. For 3GPP, SIP is slated to appear in release 5 of their UMTS framework.

In addition to VoIP and multimedia session setup, SIP has also been proposed for signaling events, that is, asynchronous notifications of state changes. One of the first applications is instant messaging and presence (Section 5.6). SIP events are also useful to unify many of the features found in traditional telephone systems, such as voicemail notification, users joining and leaving conference calls, or the transmission of DTMF digits [19]. Even the use of SIP events to control home appliances have also been proposed [20].

3. RELATED PROTOCOLS

SIP is related to other signaling protocols such as H.323 [21,22] and ISUP [23]. Like these, it operates out-of-band, that is, using a two separate associations for the signaling information and the actual media data, such as voice. Unlike ISUP, SIP is designed for IP networks and for multimedia sessions. A full comparison with H.323 is beyond the scope of this article, but a number of papers offer perspectives [24–27]. Interworking between the two protocols is also possible [28].

As noted above, SIP uses the Session Description Protocol (SDP) to describe the characteristics of the multimedia streams. Typically, these multimedia sessions use RTP [29,30] to carry audio and video information across IP networks.

RTSP [31] is a related control protocol that sets up streaming media sessions. It shares some characteristics with SIP, such as the protocol format and the use of SDP, but supports the control of stored media, through requests such as pause and play, rather than setting up interactive sessions. It does not emphasize finding locations, as it is assumed that the location of multimedia objects is much more stable than those of people. RTSP can be used in a SIP-based telecommunication system for playing announcements, recording voicemail [32] and other so-called media server functionalities.

SIP can interact directly with Internet telephony gateways that translate IP voice packets into circuit-switched calls. Alternatively, these gateways, called *media gateways*, can be controlled by a media gateway controller (MGC), using a master–slave protocol such as MGCP [33] or MEGACO/H.248 [34]. The media gateway controller translates SIP requests into MGCP or H.248 requests, and vice versa. MGCs may also terminate ISUP or other PSTN signaling. MGCs are sometimes called *soft switches*, although the definition is not very precise. Unlike these media control protocols, SIP is a peer-to-peer protocol, where both endpoints are equal.

As indicated above, SIP can use telephone numbers [35] to reach destinations. Proxies can translate these numbers into SIP URIs, possibly via multiple translations, using the ENUM mechanism [36]. ENUM uses NAPTR DNS records [37] to translate a telephone number such as +1-917-555-1234 to a DNS name, here *4.3.2.1.5.5.5.7.1.9.1.enum.arpa*. This record then contains a SIP URI, for example, allowing subscribers to keep their existing telephone number as they migrate to a SIP-based telephone system.

4. PROTOCOL DESCRIPTION

4.1. Protocol Layers

SIP is an application-layer protocol, with several logical sublayers. The lowest layer describes how SIP requests and responses are encoded as messages (Section 4.4). The second layer is the transport layer, defining how clients send requests and receive responses (Section 4.3). Above this transport layer, the transaction layer deals with the notion of group of requests and responses that form a single SIP *transaction*, namely, a request, its retransmissions, and all provisional and final responses (Section 4.4). While all SIP elements (Section 4.2) share similar encoding, transport, and transaction layers, they are distinguished by their role-specific *core*.

4.2. SIP Elements

There are three principal SIP elements: user agents (UAs), proxies, and registrars. User agents can act as clients, initiating requests and receiving responses, and/or servers, receiving requests, while proxies always combine a client and a server functionality. Registrars receive only REGISTER requests and update bindings between stable names and shorter-term contact addresses (see Section 4.3). These roles are logical only, so that a single software implementation can act as a user agent and a proxy server for different requests.

Proxies can be *stateful* or *stateless*. A stateless proxy simply forwards requests and responses one by one, but does not have to concern itself with transactions or associating responses with requests. Stateful proxies are transaction-aware. Stateful proxies are needed if a single inbound request can generate multiple outbound requests going to different destinations ("forking"). Unlike a normal telephone switch, both types of proxies do not have to keep state for the duration of the call. Some proxies do keep call state, for example, for accounting purposes or to control a firewall, and are referred to as *call-stateful*. Naturally, user agents are always call-stateful. Reducing state in SIP network elements helps with scaling and improves robustness, as any host in a server farm, for example, can easily take over should one host fail (Section 4.3).

While not a different protocol element as such, it has become common to refer to back-to-back user agents (B2BUA) in creating services. B2BUAs can be thought of as two user agents where one receives a request and the other issues a related request. This arrangement can be useful for certain types of media-handling firewalls or to create services where two participants have SIP dialog with the call controller, but media are exchanged between them directly. This arrangement is called *third-party call control* [38].

4.3. Locating Users and Servers

SIP endpoints are identified by SIP URIs that are similar to email addresses. (Users may often be able to use their email address as a SIP URI.) SIP URIs can vary in specificity; they may identify a particular user at a host located at an IP address, or, more commonly, identify a user generically by name and domain. An example of the latter is *sip:alice@example.com*. Such a generic URI is then translated via one or more steps to zero or more host locations, possibly identified by SIP URIs. For example, a call to *sip:alice@example.com* may reach her at *sip:alice@128.59.16.1* and *sip:asmith592@aol.com*. SIP URIs with the "sips" scheme indicate that the destination insists on being contacted via transport-layer security (TLS) [39].

The externally visible address of a person or other endpoint is known as the *address-of-record* (AOR). A single person or SIP telephone may have several such AORs. The AOR is bound to any number of contact addresses using the SIP REGISTER method. These contact addresses are typically SIP URIs, but can be any URI, commonly including mail to URIs and http URIs. Each of the user's hosts sends periodic REGISTER request to the registrar identified by the AOR, refreshing the address bindings. For example, for the AOR *sip:alice@example.com*, all of Alice's SIP-enabled communications devices would send updates to the registrar at *example.com*. SIP registrars are one example of a SIP location service that is then used by proxies for the domain to route calls for the AOR. While less common, implementors can choose any other mechanism to populate the location service. For example, a Webpage might allow manual updates of telephone numbers or other non-SIP URIs.

SIP requests may also carry telephone URLs [40] identifying telephone numbers. An example of such a URL describing a telephone terminal in New Jersey is tel:+1-201-555-1234. However, since this URL does not identify an Internet host, a SIP entity needs to translate it to a SIP URI, either a user name or a telephone number at a particular destination domain. In the example, a SIP proxy may translate the number to *12015551234@bigcarrier.com* if it wants the call to be routed to a gateway operated by *bigcarrier.com*. The actual routing may be determined by routing protocols such as TRIP [41,42] that distribute information about the reachability of telephone numbers and their associated gateways.

When receiving an initial SIP request, a SIP proxy looks at the request URI contained in the first line of the SIP request. (In Fig. 2, this is *bob@biloxi.com*) If the domain name is managed by the proxy, the proxy maps the user name to one or more contact addresses and sends replicas of the request to those addresses, creating *branches*. The requests may be sent sequentially, after a previous branch has failed, or in parallel. This procedure is referred to as *forking* and greatly simplifies reaching one individual that may be using multiple devices to communicate. It roughly mimics, on a global scale, the operation of multiple phones in a household, all ringing at once. Each branch may also return a redirection response, indicating one or more alternate addresses to be tried. As soon as somebody picks up at one of the addresses, that SIP user agent returns a success response and the proxy sends a CANCEL request to all other active branches, terminating ringing there.

If the request URI identifies a domain not handled by the proxy, the proxy is acting as an *outbound proxy*. Outbound proxies are typically used by the initiator of the request to handle all outbound requests, regardless of destination. For example, Alice might use an outbound proxy in her home domain, *atlanta.com*. Outbound proxies may be necessary if firewall policies restrict inbound requests or might be useful to offer additional outbound services, such as custom abbreviated dialing.

Unlike HTTP, SIP URIs attempt to avoid identifying a single physical server, but rather make it possible to direct a request to one of the servers handling SIP requests for a particular domain. This approach was first taken for email, using DNS MX [43] records to list a set of mail transport agents for a domain. SIP employs a two-step process [44], where first DNS NAPTR records [37] indicate the set of transport protocols (UDP, TCP, TCP with TLS, etc.) available for the domain. For each suitable protocol, DNS SRV [45] resource records list a set of candidate servers, qualified by preference and weight. The client looking for a server picks a random server among the highest-preference group of servers, performing a simple form of client-based load balancing, albeit without load feedback.

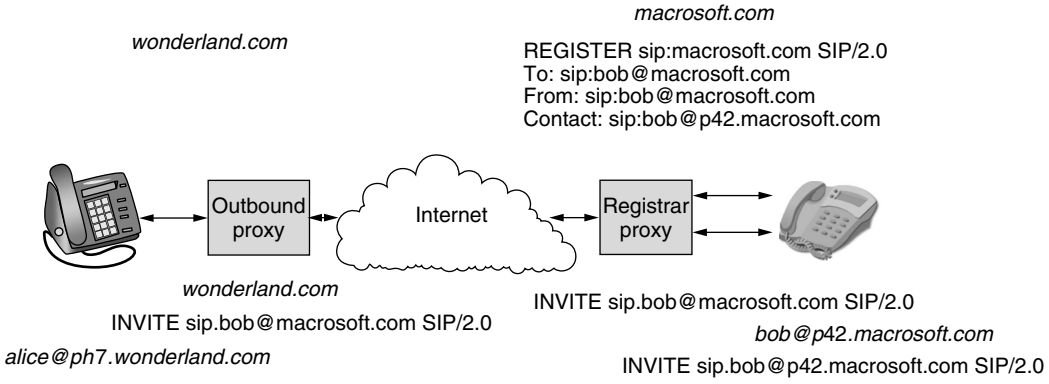

Figure 2. SIP architecture.

4.4. SIP Requests and Responses

SIP is a request-response protocol similar to HTTP. Requests and responses are expressed as plain text, consisting of a header or status line, a set of header fields and a message body. The message body can contain any information, including binary data. Just like HTTP and email, SIP uses MIME [46] to carry multiple distinct message bodies in a single request.

Each request is identified by a *method* that describes its basic functionality. The basic protocol defines six methods — INVITE, ACK, BYE for call setup and termination, OPTIONS for discovering capabilities, CANCEL for terminating pending calls, and REGISTER for establishing address bindings, but other specifications add additional methods. For example, the INFO method [47] can carry midcall ISUP PSTN call signaling information [48]. A request may trigger zero or more provisional responses that indicate call progress and one or more final responses. Each SIP method is qualified by a set of parameters expressed as header fields, similar to email or HTTP headers. Indeed, SIP inherits a large number of HTTP and email header fields.

The details of the header field syntax can be found in the protocol specification [49]. Header fields can be roughly divided into header fields that describe the message body, identify the request or response, help in routing requests, assist in authentication, negotiate protocol capabilities, and provide auxiliary information to end systems and proxies. The content-describing header fields identify the media type, language, handling, and encoding and measure the length of the body. The request is identified by components of the From, To, Call-ID and CSeq header fields. As described in Section 4.5, the Via, Record-Route, and Route header fields trace request paths and allow requests to revisit the same set of servers as a previous request. A set of header fields, mostly borrowed from HTTP [50], provide a challenge-response authentication framework, as described in Section 4.7. Headers also negotiate protocol capabilities, such as the support for media types in message bodies, human languages understood for error messages, and which protocol features are supported or required. A large set of optional header fields identify the caller or call, for example, the purpose of the call, the organization the caller or callee are affiliated with, or additional hints for the call, such as customized alerting or a Webpage related to the caller.

Responses are classified by their three-digit response code. The first digit is sufficient to identify the type of response; the first digit of "1" indicates a provisional response such as "trying" or "ringing", a first digit of "2," success; "3," a redirection; "4," a client error; "5," a server error; and "6," a global failure. (A global failure indicates that further searches for an instance of the callee are fruitless, for example, because the callee refuses to talk to the caller.)

A sample INVITE request and the corresponding final response is shown in Fig. 3. In the example, Alice, using her SIP device located at *pc33.atlanta.com*, calls Bob, at *biloxi.com*. Alice tells Bob that she can receive PCMU (that is, μ-law) audio over RTP using the AVP profile [30] at port 49172 and IP address 100.101.102.103; Bob responds to Alice that he is willing to talk and waiting to receive audio at port 33280 on address 110.111.112.113. The Call-ID field is a randomly chosen identifier for the call; the randomly chosen tags in the From and To fields identify the participants, allowing multiple terminals of Bob and Alice to be distinguished. The CSeq identifier allows Alice to unambiguously associate Bob's response with her request. The example does not show the third and final request in the call setup, with method ACK, that Alice sends to Bob to confirm that she has received Bob's "200 OK" response. The final ACK request establishes a SIP *dialog* between Alice and Bob. Only INVITE requests use an ACK request for confirmation.

As noted, SIP can operate directly on top of unreliable transport protocols such as UDP. To ensure that the call is set up, SIP implements its own retransmission mechanism. Due to forking at proxies, requests are retransmitted and acknowledged on each branch, not end to end. Requests are retransmitted at exponentially increasing intervals starting with the estimate for the round-trip time, if known, and 0.5 s if the round-trip time is unknown. The user agent client retransmits until it receives a provisional or final response or after seven retransmissions.

INVITE transactions differ somewhat in their behavior from all other requests. Non-INVITE requests are assumed to take only a small amount of time to process, so that the client simply retransmits until it gets a final response. It slows down retransmission to once every few seconds after it has received a provisional response, to deal with lost final responses. For INVITE transactions, the final answer can take tens of seconds or minutes since a human may need to answer the ringing phone. Here, the server retransmits the final response until the client confirms its receipt with an ACK request.

During the call, either Alice or Bob can send additional INVITE requests to update the media session, for example, to change the set of media or to adjust the media destination IP address. If either Alice or Bob hang up, their SIP terminal sends a BYE request to the other side. Typically, both midcall INVITE requests and the BYE request bypass any intermediate proxies since Alice and Bob now know each other's IP address.

4.5. Routing Requests and Responses

The routing of requests depends on the request URI and, for all but the first request in a dialog, on the Route header fields that may be present (see below). The response to the first request will contain a Contact header field that describes the location to send subsequent requests to. Thus, subsequent requests will contain that address as the request URI.

Route header fields lists proxies that indicated a desire to stay in the path of subsequent requests within a dialog, for example, any reINVITE requests to change session parameters or the final BYE request terminating the dialog. Requests in both directions, from caller to callee and vice versa, traverse this set of proxies. Route headers offer a functionality somewhat similar to IP source routing. A proxy that wants to see subsequent requests for a dialog

Figure 3. Sample INVITE request and response.

adds itself to the *route set* for a dialog by adding Record-Route header fields to the initial request. The callee user agent then copies those Record-Route header fields into the response. The callee also keeps the list, in the same order, as its route set. The caller reverses the list and makes that its route set. The route set is then inserted as a Route header into subsequent requests by both caller and callee in the same session. Each proxy inspects the top-most route header and uses it to find the next hop toward the destination. If the Route header names the proxy itself, the proxy removes the header field.

Responses always traverse the same set of proxy servers as the corresponding request, guided by the Via header fields inserted into the request by the proxy servers.

4.6. Extending SIP

Since VoIP and multimedia conferencing are still in their infancy, it is likely that SIP will evolve. Also, some areas where SIP is being applied have specific requirements whose fulfillment should not burden other applications. SIP was designed to be extensible while maintaining a maximum of backward compatibility. Allowing for extensions requires defining suitable behavior when an implementation discovers an unknown protocol element and the ability to ascertain the capabilities of SIP elements.

Since SIP proxies forward requests independent of their method, additional methods can be added without upgrading all proxies. SIP user agents can indicate the methods that they support in an Allow header.

User agents and proxies can add new header field types without coordination, as proxies simply copy them into outgoing requests and receiving user agents ignore unknown header fields. If a user agent client wants to ensure that a particular feature is supported by a proxy or user agent server, it adds a Require header field indicating the name of the feature. In turn, the client or server can summarize its own capabilities with the Supported header field.

4.7. SIP Security

SIP poses a number of security challenges. It carries potentially sensitive information, such as subject information about calls, media encryption keys, and reachability information. The existence of communication relationships themselves may be considered private. Registrations need to be protected against malicious modifications, as such modifications would allow the attacker to redirect requests to any location. Also, attackers must be prevented from injecting requests into existing calls, as those fake requests could be used to terminate or redirect the call. The security challenges are increased by the use of proxies that may be operated by either the caller's network provider, the callee's network provider, or possibly the operator of the network being visited by either caller or callee.

Since it must be possible to make calls to parties with whom the caller does not have a preexisting security relationship, standard shared secret security is of only limited use. A public key infrastructure for large user populations does not currently exist, but organizations can easily obtain public key certificates, for example, for Web servers.

Given those constraints, SIP uses three security mechanisms, namely transport-layer security (TLS) [39,51], digest authentication [52], and secure/multipurpose Internet mail extensions (S/MIME) [53]. Naturally, IPsec can be deployed as well, but it is effectively invisible to SIP. TLS protects exchanges "hop by hop," that is, between user agent and proxy or registrar, and between proxies. With standard server certificates, the user agent can ascertain the identity of the registrar or proxy. Digest authentication is a challenge–response authentication protocol based on a shared secret. It is commonly used to protect registrations, although it offers header integrity only in combination with TLS. Finally, S/MIME is used in a fashion similar to email, but encapsulating the SIP message parts that are to be encrypted or signed in an outer SIP wrapper that remains visible to proxies. For encryption, S/MIME requires that the sender knows the recipients public key or has access to a shared public key infrastructure.

5. SIP EXTENSIONS

The IETF is extending SIP in a variety of ways to accommodate special requirements. Many of the extensions are motivated by the need to interoperate with the PSTN, but a major extension, SIP events (Section 5.6), offers new services and extends SIP to provide event notification. SIP extensions are designed to be backward-compatible, so that peers can establish sessions, with possibly reduced functionality, even if one or both of them do not support a particular extension. Many extensions are specific to particular deployment scenarios or applications and thus are likely to be supported by only a subset of implementations.

5.1. Session Keep-Alive

Once a SIP dialog has been established, the two peers have no direct way to discover if the other one has crashed or has been disconnected from the network. Usually, the lack of media data may provide a clue, but, unlike the situation in traditional phone calls, SIP sessions can persist even if no media are being exchanged. In circumstances where endpoints want to remove state if the other side is no longer reachable, the SIP session timer mechanism [54] has been proposed. The initial INVITE request indicates how often the caller would like the session to be refreshed. The callee can claim the role of refresher or leave this to the caller. The party responsible for refreshes periodically issues another INVITE request. If it receives no response, it terminates the call. Similarly, the party expecting periodic reINVITE requests will terminate the call if they are not forthcoming. The session interval can be lowered by proxies en route, but proxies can reject session intervals that are too short.

As with TCP liveness detection, SIP session timers must be used with caution, as they may unnecessarily terminate a long-lived session during brief network outages.

5.2. Conferencing

SIP supports a variety of multiparty conferencing architectures, including Internet multicast, end-system mixing, dialin conference servers, ad hoc centralized conferences, dialout conferences, or centralized signaling with peer-to-peer or multicast media [55,56]. For multicast and end-system mixing, there are no special servers. However, multicast is not yet widely available in the Internet; end-system mixing is likely to scale only to modest-size conferences, since one of the participants needs to send a mixed audio- or videostream to all other participants. The most common architectures are likely to be dialin and dialout conferences with a centralized conference server, or possibly a hierarchy of such servers.

Conferences are treated just like normal users; they are addressed using SIP URLs such as *sip:staff-meeting@example.com*. For ad hoc conferences, the initiator sends an INVITE request to the conference bridge, with a randomly chosen conference identifier.

The manner of adding users depends on the conference model. For multicast and end-system mixed conferences, regular INVITE requests suffice. For dialin conferences, conference members can ask others to join the conference by issuing a REFER request to the candidate member.

5.3. Multiparty Calls

A number of common telephony features, such as call waiting, blind and attended transfer, conference calls, call parking, call pickup, music on hold, call monitoring, barge-in, whispered call waiting, and single-line extensions, or Internet-oriented features such as presence-enabled conferencing all generally involve multiple participants, both human and machines (media servers). Often, media of these participants are mixed.

Many of these features can be implemented using third-party call control [38], where a central controller maintains and terminates dialogs, using INVITE, reINVITE, and BYE, with the participants and mixes media as appropriate. This approach has the advantage that it requires only basic SIP capabilities in the end systems, but it means that features have to implemented in a single point for each call.

Alternatively, a peer-to-peer approach can be used [57], where all functionality is implemented "at the edges," that is, by terminals. This approach requires a set of primitives to replace an existing dialog, join an existing dialog with another one, perform media replication by the media origin, and allow a user agent to ask another user agent to send a request on its behalf. The latter functionality is accomplished with the REFER request [58] that asks the recipient to construct another SIP request. The SIP request and its parameters and contained in the Refer-To header as a SIP URI.

5.4. Caller Preferences

In SIP, terminal addresses often identify a generic destination, such as a person, and not a particular terminal or phonejack. Thus, it is helpful to provide the caller with the ability to indicate which of the devices reachable by a particular SIP URI the caller would prefer to reach. This preference is expressed through properties that the destination should have, not its address [59]. For example, the caller can indicate a desire to reach voicemail instead of a human being, might prefer not to talk to a mobile phone or might like to be connected to a Chinese-speaking operator. SIP proxies then use this information in making call routing decisions.

5.5. Quality of Service

Since SIP requests do not necessarily traverse the same route as the data packets for the session they establish, SIP cannot directly control quality of service on the data path. Instead, this is left to mechanisms such as the Resource Reservation Protocol (RSVP) [60] or differentiated services. However, SIP can help negotiate the use of such mechanisms and determine when the resource reservation has succeeded. This is needed to prevent scenarios where the called phone rings, but then the resource reservation fails because of lack of network bandwidth, leading to a call without media or with only best-effort media streams. An additional SIP method, COMET (condition met), signals the successful completion of the resource reservation [61].

5.6. SIP for Events, Presence, and Instant Messaging

Events, that is, changes in state, are a useful abstraction in many telecommunication services. Examples include automatic callback, message waiting, and multi party conference management. Also, they underlie the notion of presence (usually combined with instance messaging) that has become a popular Internet service. Event notifications are often approximated by email messages, but since email is picked up only by the recipient, there can be a large and unpredictable latency between the event notification and its receipt. SIP can readily be extended to signal events. Here, SIP follows the common subscribe–publish model. A SIP entity sends a SIP SUBSCRIBE request to the source of the events. The subscriber is then notified, using NOTIFY, each time the event occurs. The subscription has a limited lifetime and needs to be refreshed before it expires.

SIP is suitable since many of the same properties needed for setting up calls apply. For example, the destination of the event subscription and event notification should be identified by a long-term address, while the actual destination may change network addresses.

Beyond signaling events related to SIP sessions, SIP events have also been defined for describing the presence state of a user [62], that is, whether the user is available to communicate by phone, SIP call, text chat, or other means. Since this information needs to be available even if the user terminal is not connected to the network, a presence agent acts as a standin for the user. It also merges presence information from multiple devices. The presence agent can use information from SIP binding updates (REGISTER) to detect changes in presence state.

5.7. Programming SIP Services

While not part of the protocol specification itself, there have been a number of proposals on how to program SIP-based proxies and end systems. Among these are JAIN SIP, SIP servlets [63], sip-cgi [64], and the Call Processing Language (CPL) [65,66]. JAIN SIP is a Java API that allows to construct SIP messages and extract information about SIP headers and responses. SIP servlets are similar to Java servlets for Web servers, offering a model where the servlet handles a full transaction. Sip-cgi attempts to transfer the cgi programming model found in Web servers to SIP proxies. SIP requests are passed as environment variables to scripts or programs, with each request causing a new process to be invoked. The scripts can be written in any language, including such common Web services scripting languages such as Perl, Python, or Tcl. Unlike HTTP requests, which are completely stateless, sip-cgi offers some support for associating multiple requests and responses within the same transaction. The script is responsible for parsing SIP headers and generating responses, but can simplify its task by invoking default behaviors.

CPL is an XML-based tree for handling a SIP transaction in proxies. It is useful primarily for call routing, admission, rejection, and logging. Each transaction is logically handled by a single CPL script, acting as a form of decision tree. The traversal of the tree can depend on the status responses returned by branches. Extensions of CPL to presence services and to end-system services are in progress. For voice-oriented services, voice menu systems such as VoiceXML are available.

5.8. SIP Performance

There currently is no generally accepted, standard way to measure the performance of SIP clients and servers. However, SIPstone [67] has been proposed as a simple metric for common operations, such as calls and registrations.

5.9. Emergency Services

One of the principal functions of the existing PSTN is to summon emergency help. In many countries, a system has emerged where callers can call a single, nationwide emergency number, such as 911 in the United States or 112 in many parts of Europe. The call is then directed to the nearest emergency call center, where the dispatcher

can see the caller's geographic location on her console. A similar architecture has been proposed for SIP [68], with a global emergency identifier, "sos," and a special proxy that maps user location to the nearest emergency call center. Unlike in the PSTN, the user location cannot be directly determined from the device address, as IP subnets can span large geographic regions, particularly with virtual private networks and dialup connections.

5.10. Configuring SIP Networks

SIP attempts to make it possible to set up a SIP network with minimal manual configuration. It is sufficient for a SIP device to know the address-of-record of its owner. The domain part of that address identifies the registrar for the owner. If desired, an outbound proxy can be discovered using DHCP [69]. Configuring other parameters, such as dial plans or SIP protocol timing parameters, is currently under discussion [70].

6. SUMMARY AND CONCLUSION

SIP is a signaling protocol that allows peers to establish multimedia sessions across the Internet. Since some of the requirements, such as mapping from long-term stable user identities to addresses, are similar, SIP can also be used to convey events to users, including changes of presence information. SIP is currently used primarily by voice over IP applications. A number of extensions have been standardized, with many more under discussion.

BIOGRAPHY

Henning Schulzrinne received his undergraduate degree in economics and electrical engineering from the Darmstadt University of Technology, Germany, his M.S.E.E. degree as a Fulbright scholar from the University of Cincinnati, Ohio, and his Ph.D. degree from the University of Massachusetts in Amherst, Massachusetts. He was a member of the technical staff at AT&T Bell Laboratories, Murray Hill and an associate department head at GMD-Fokus (Berlin), before joining the Computer Science and Electrical Engineering Departments at Columbia University, New York. His research interests encompass real-time, multimedia network services in the Internet and modeling and performance evaluation.

He is a division editor of the *Journal of Communications and Networks* and an editor of the *IEEE/ACM Transactions on Networking* and former editor of the *IEEE Internet Computing Magazine* and *IEEE Transactions on Image Processing*. He is member of the Board of Governors of the IEEE Communications Society and the ACM SIGCOMM Executive Committee, former chair of the IEEE Communications Society Technical Committees on Computer Communications and the Internet, and has been technical program chair of Global Internet, Infocom, NOSSDAV, and IPtel. He also was a member of the Internet Architecture Board (IAB).

Protocols codeveloped by him are now Internet standards, used by almost all Internet telephony and multimedia applications. His research interests include Internet multimedia systems, quality of service, and performance evaluation.

1. INTRODUCTION

Since the early 1980s, the underwater acoustic (UWA) communications technology has progressed significantly. Communication systems with increased bit rate and reliability now enable real-time point-to-point links between underwater nodes such as ocean-bottom sensors and autonomous underwater vehicles (AUVs). Current research is focused on combining various point-to-point links within a network structure to meet the emerging demand for applications such as environmental data collection, offshore exploration, pollution monitoring, and military surveillance [1].

The traditional approach for ocean-bottom or ocean-column monitoring is to deploy oceanographic sensors, record the data, and recover the instruments. This approach has several disadvantages:

- The recorded data cannot be recovered until the end of the mission, which can be several months.
- There is no interactive communication between the underwater instruments and the onshore user. Therefore, it is not possible to reconfigure the system as interesting events occur.
- If a failure occurs before recovery, data acquisition may stop, or all the data may be lost.

The long delay between data acquisition and recovery can be reduced by using expendable or reusable communication probes as in the EMMA [2] and GEOSTAR [3] systems. Both systems have ocean-bottom sensors and a number of probes that have radiocommunication equipment. The data collected by sensors are carried to the surface with probes at preprogrammed intervals or as soon as some interesting events occur. After surfacing, the probe sends the data to an onshore user via satellite. The release of the probes can also be forced by sending acoustic signals from a nearby ship. These systems provide quasi-real-time data collection. However, lack of bidirectional communication links and the high cost of probes limit their usage.

The ideal solution for real-time monitoring of selected ocean areas for long periods of time is to connect various instruments through wireless links within a network structure. Basic underwater acoustic networks are formed by establishing bidirectional acoustic communication between nodes such as autonomous underwater vehicles (AUVs) and fixed sensors. An RF link connects the network to a surface station that can be further connected to terrestrial networks, such as the Internet, through an RF link. Onshore users can extract real-time data from multiple distant underwater instruments. After evaluating the obtained data, they can send control messages to individual instruments. Since data is not stored in the underwater instruments, data loss is prevented as long as isolated node failures can be circumvented by reconfiguring the network.

A major constraint of UWA networks is the limited energy supply. Whereas the batteries of a wireless modem can be easily replaced on land-based systems, the replacement of an underwater modem battery involves ship time and retrieval of the modem from the ocean bottom, which is costly and time-consuming. Therefore, transmission energy is precious in underwater applications. Network protocols should conserve energy by reducing the number of retransmissions, powering down between transactions, and minimizing the energy required per transmission.

* This work was supported by the Multidisciplinary University Research Initiative (MURI) under the Office of Naval Research Contract N00014-00-1-0564, by Small-Business Innovative Research (SBIR) Program, and by ONR 321.

Some underwater applications require that the network be deployed quickly without substantial planning, such as in rescue and recovery missions. Therefore, the network should be able to determine the node locations and configure itself automatically to provide an efficient data communication environment. Also, if the channel conditions change or some of the nodes fail during the mission, the network should be capable of reconfiguring itself dynamically to continue its operation.

2. UNDERWATER ACOUSTIC COMMUNICATIONS

Unlike digital communications through radio channels where data are transmitted by means of electromagnetic waves, acoustic waves are used primarily in underwater channels. The propagation speed of acoustic waves in UWA channels is five orders of magnitude less than that of radiowaves. This low propagation speed increases the latency of a packet network.

The available bandwidth of an UWA channel depends critically on transmission loss, which increases with both range and frequency, and severely limits the available bandwidth [4,5]. For example, long-range systems that operate over several tens of kilometers may have a bandwidth of only a few kilohertz, while a short-range system operating over several tens of meters may have more than a 100 kHz bandwidth [6]. Within this limited bandwidth, the acoustic signals are subject to time-varying multipath [4], which may result in severe intersymbol interference (ISI) and large Doppler shifts and spreads, relative to radio channels, especially in shallow-water channels. Multipath propagation and Doppler effects degrade of acoustic signals and limit the data throughput. Special processing techniques are needed to combat these channel impairments.

Until the year 1990, as a result of the challenging characteristics of UWA channels, modem development was focused on employing noncoherent frequency shift keying (FSK) signals for achieving reliable communication. Since FSK demodulation is based on energy detection, it does not require phase tracking, which is a very difficult task in high Doppler spread environments. The multipath effects are eliminated by inserting guard periods between successive pulses to ensure that all the reverberation vanishes before each subsequent pulse is to be received. In addition, to avoid Doppler effects, some guard bands are employed between frequency tones. By varying the values of the guard bands, the communication signals can be matched to the channel characteristics, providing an adaptive modem structure. Table 1 presents some data on the noncoherent FSK modems described in the literature.

Although noncoherent FSK systems are effective in UWA channels, their low bandwidth efficiency makes them inappropriate for high-data-rate applications such as multiuser networks. The need for high-throughput, long-range systems has resulted in a focus toward coherent modulation techniques.

Today, with the availability of powerful digital signal processing devices, we are able to employ fully coherent PSK modulation in underwater communications. Equalizers are used to undo the effects of ISI, instead of trying to avoid or suppress it. When combined with explicit phase tracking loops, such as phase-locked loops (PLLs), decision feedback equalizers can provide high data throughput [7]. Other similar structures that use transversal filters and various adaptation algorithms are also reported in the literature. Coherent systems are summarized in Table 1.

Table 1. Summary of Performance Metrics for Some UWA Modems Presented in the Literature [5]

Type	Year	Data Rate (bps)	Bandwidth (kHz)	Range (km)[a]
FSK	1984	1200	5	3.0_S
FSK	1991	1250	10	2.0_D
FSK	1997	2400–600	5	10.0_D–5.0_S
Coherent	1989	500,000	125	0.06_D
Coherent	1993	600–300	0.3–1	89_S–203_D
Coherent	1994	20	20	0.9_S
Coherent	1998	1670–6700	2–10	4.0_S–2.0_S

[a] Subscript S indicates a shallow-water result; D indicates a deep-water result, generally a vertical channel.

Current research is focused on DSP algorithms with decreased complexity and multiuser modems that can operate in a network environment.

3. UNDERWATER ACOUSTIC NETWORKS

Information networks are designed in the form of a layered architecture [8]. The first three layers of this hierarchical structure are the physical layer, the data-link control layer, and the network layer.

The function of physical layer is to create a virtual link for transmitting a sequence of logical information (bits 0 and 1) between pairs of nodes. The information bits are converted into acoustic signals (in case of UWA networks), which are transmitted through the acoustic channel. At the receiving node, the physical layer converts the channel corrupted signals back into logical bits. The modem structures that can be used in the physical layer of an acoustic network were discussed in the previous section.

The second layer in the hierarchical structure is the *data-link control* (DLC) layer, which is responsible for converting the unreliable bit pipe of the physical layer into a higher-level error-free link. For this purpose DLC employs two mechanisms: framing and error correction control. Framing is accomplished by adding header information, which consists of a synchronization preamble, with source and destination addresses at the beginning of the information sequence, and cyclic redundancy check (CRC) bits at the end. The CRC bits are formed from the bits in the packet and are used for error correction control.

At the receiver side, the DLC performs a check using the CRC field to detect errors in a packet. If the CRC fails, it may ask for a retransmission depending on the automatic repeat request (also known as the Automatic Repeat reQuest) (ARQ) protocol. Some widely used ARQ schemes are stop and wait, go-back-N, and selective repeat. These protocols control the logical sequence of transmitting packets between two nodes

and acknowledging the correctly received packets. ARQ procedures form the logical link control (LLC) sublayer of the DLC. If the network is based on multiaccess links, rather than point-to-point links, additional measures must be taken to orchestrate the access of multiple sources to the same medium. These measures are called *media access control* (MAC). Commonly used MAC protocols are the ALOHA protocol, the carrier sense media access (CSMA) protocols, and token protocols. These protocols form the MAC sublayer of DLC.

The layer above the DLC layer is the network layer. The main function of the network layer is to transfer information packets to their final destination, which is called *routing*. Routing involves finding a path through the network and forwarding the packets from the source to the destination along this path. If a route is established at the beginning of a transaction and all the packets follow this path, the network is called a *virtual circuit-switching network*. If a new path is determined for each packet of the same transaction, the network employs datagram switching. In case of datagram switching, packets may arrive to the destination out of order. Therefore, the network layer should reorder the packets before passing them to a higher level.

The network layer selects optimal routes by minimizing the end-to-end path distance. The distance metric can be the delay, the number of hops, required energy, or some other "distance" measure. Some well-known static routing algorithms are the Dijkstra algorithm and the Bellman–Ford algorithm. In dynamic environments, the routes provided by these static algorithms are modified as the "distance" metrics change.

In the following paragraphs, we review the methods and protocols used in the DLC layer and network layer, together with their applicability to UWA networks. We also discuss possible network topologies, which is an important constraint in designing a network protocol.

3.1. Network Topologies

Three basic topologies can be used to interconnect network nodes: centralized, distributed, and multihop [9]. In a *centralized* network, the communication between nodes takes place through a central station, which is sometimes called the "hub" of the network. The network is connected to a backbone at this central station. This configuration is suitable for deep-water networks, where a surface buoy with both an acoustic and an RF modem acts as the hub and controls the communication to and from ocean-bottom instruments. A major disadvantage of this configuration is the presence of a single failure point [9]. If the hub fails, the entire network shuts down. Also, because of the limited range of a single modem, the network cannot cover large areas.

The next two topologies support peer-to-peer links. A fully connected peer-to-peer topology provides point-to-point links between every node of the network. Such a topology eliminates the need for routing. However, the output power needed for communicating with widely separated nodes is excessive. Also, a node that is trying to send packets to a far-end node can overpower and interfere with communication between neighboring nodes, which is called the *near–far problem* [9].

Multihop peer-to-peer networks are formed by establishing communication links only between neighboring nodes. Messages are transferred from source to destination by hopping packets along a multinode route. Routing of the messages is handled by intelligent algorithms that can adapt to changing conditions. Multihop networks can cover relatively larger areas since the range of the network is determined by the number of nodes rather than the modem range.

One of the UWA network design goals is to minimize the energy consumption while providing reliable connectivity between the nodes in the network and the backbone. Network topology is an important parameter that determines the energy consumption [10]. A simplified scenario in which a number of nodes and a master node arranged linearly along a line is considered. The nodes are uniformly distributed, and each node tries to send its packets to the master node. Two extreme communication strategies are possible in this scenario. In the first strategy, each node has direct access to the master node (fully connected topology). In the second strategy, each node transmits only to its nearest neighbor, who then relays the information toward the master node (multihop peer-to-peer topology). The energy consumption curves for both of these cases is plotted as a function of the total distance spanned by the network shown in Fig. 1. Dashed curves represent the case of direct access, which obviously requires more energy. For direct access, inclusion of each additional node results in an increase in total energy. For relaying, the situation is reversed; inclusion of each additional node decreases the total energy consumption because the additional node serves as an additional relay along the same distance.

Hence, the strategy that minimizes energy consumption is multihop peer-to-peer topology. The price paid for the decrease in energy consumption is the need for a sophisticated communication protocol and an increase in packet delay. Therefore, special attention should be given to applications that are sensitive to delays.

3.2. Multiple-Access Methods

In many information networks, communication is bursty, and the amount of time a user spends transmitting over the channel is usually smaller than the amount of time it remains idle. Thus, network users should share the available frequency and time in an efficient manner by means of a multiple access method. Frequency-division multiple access (FDMA) divides the available frequency band into subbands and assigns each subband to an individual user. Because of the severe bandwidth limitations and vulnerability of narrowband systems to fading, FDMA systems do not provide an efficient solution for UWA applications. Instead of dividing the frequency band, time-division multiple access (TDMA) divides a time interval, called a "frame," into time slots. Collision of packets from adjacent time slots is prevented by including guard times that are proportional to the propagation delay present in the channel. TDMA systems require very precise synchronization for proper utilization of the time

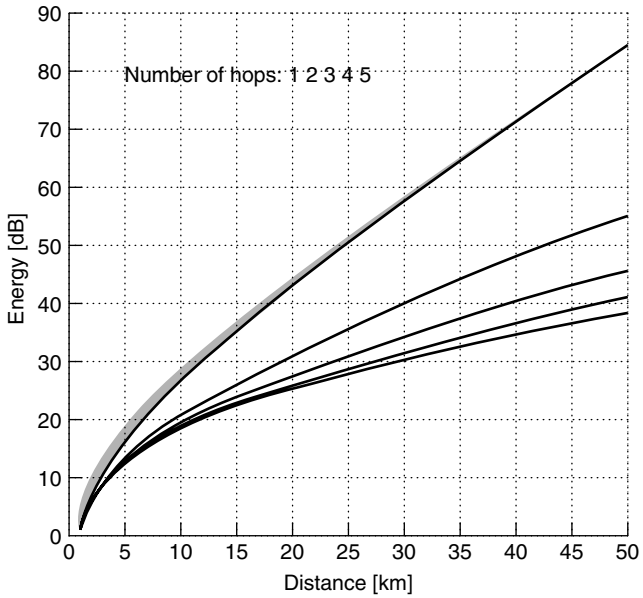

Figure 1. Total (normalized) energy needed to transmit a packet from each network node to the master node. Solid curves represent relaying; dotted curves represent direct access. The parameter on the curves is the number of hops. For relaying, the number of hops increases fro the top curve downward; although more packets are sent when there are more hops, total energy consumption is lower. For direct access, there is little difference between the curves, and the situation is reversed: the number of hops increases from 1 for the lowest energy consumption to 5 for the highest.

slots. High latency present in UWA channels requires long guard times that limits the efficiency of TDMA. Also, establishing a common timing reference is a difficult task. Code-division multiple access (CDMA) allows multiple users to transmit simultaneously over the entire frequency band. Signals from different users are distinguished by means of pseudonoise (PN)codes that are used for spreading the user messages. The large bandwidth of CDMA channels provides resistance to frequency-selective fading and exploits the time diversity present in the UWA channel by employing RAKE filters at the receiver in the case of DS-CDMA (direct-sequence CDMA) [11]. Spread-spectrum signals can be used for resolving collisions at the receiver by using multiuser detectors [12]. In this way, the number of retransmissions and energy requirements of the system can be reduced. This property both reduces battery consumption and increases the throughput of the network. Also, the power requirement of CDMA systems may be less than one-tenth that of TDMA [13]. In conclusion, CDMA appears to be a promising multiple-access technique for shallow-water acoustic networks.

3.3. Media Access Control (MAC) Protocols

Since the number of channels (time frames, frequency bands, or spreading codes) offered by a multiple access method can be much less than the total number of users in a network environment, the same channel is assigned to more than one user. If these users access the channel at the same time, their signals overlap and may be lost (packet collision). Likewise, most underwater acoustic modems are half-duplex in nature, and signals arriving during a transmission are lost, and must also be treated as packet collisions. Media access control (MAC) protocols are used to avoid information loss as a result of packet collisions.

A group of MAC protocols, such as the ALOHA protocol, do not try to prevent collisions but detect collisions and retransmit lost packets. The original ALOHA protocol is based on random access of users to the medium [14]. Whenever a user has information to send, it transmits it immediately. An acknowledgment (ACK) is sent back by the receiver if the packet is received without errors. Because of the arbitrary transmission times, collisions occur and packets are lost. Slotted ALOHA is an enhanced version of the ALOHA protocol, where the time frame is divided into time slots. When a node wants to send a packet, it waits until the next time slot and then begins transmission. Restricting packet transmission to predetermined time slots decreases the probability of collisions [9]. As in the case of TDMA, the ALOHA protocol is inefficient for UWA environment due to slow propagation. Also, the need for retransmissions increases the power consumption of the network nodes and reduces the lifetime of the network.

The number of retransmissions can be reduced if the MAC protocol uses a priori information about the channel state. The media access methods based on this idea are called *carrier sense multiple access* (CSMA) [9]. Details and various forms of this method can be found in papers by Kleinrock and Tobagi [15–18]. The CSMA method tries to avoid the collisions by listening for a carrier in the vicinity of the transmitter. However, this approach does not avoid collisions at the receiver [19]. Let us consider a network formed by three users as shown in Fig. 2. The circles around each node show the communication range of that node. Assume that node A is sending a packet to node B. At the same time, node C listens to the channel and because it is out of the range of A and does not detect the carrier of A, it begins transmission. This creates a collision at B, which is the receiver node. Node A was hidden from node C. This situation is called the "hidden node" scenario [19]. To enable B to hear both messages, node C should defer its transmission. However, if the destination of the packet of C is not B, there is no reason to defer the transmission, provided that node B has the capability to deal with the interference generated by the signal from C [19]. In the case of B sending a packet to A,

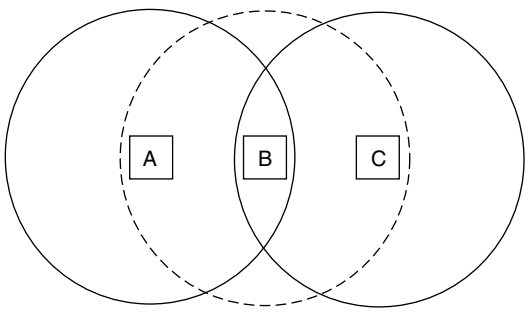

Figure 2. Node A can communicated with node B, but not with node C. Node B can communicated with both A and C.

node C detects a carrier. This creates an "exposed node" situation, where C is exposed to node B.

CSMA cannot solve these problems without adding a guard time between transmissions that is proportional to the maximum propagation time present in the network. The extensive propagation delays in underwater channels can cause this method to become very inefficient. If we consider an underwater acoustic network with a maximum range of 10 km, a data rate of 1 kbps, and a packet size of 1000 bits, the transmission delay and the maximum propagation delay become 1 and 6.7 s, respectively. In this situation, most of the time the channel will be idle, which results in low throughput.

The multiple access with collision avoidance (MACA) protocol was proposed by Karn [20] to detect collisions at the receiver as an alternative to CSMA. This protocol uses two signaling packets: "request to send" (RTS) and "clear to send" (CTS). When node A wants to send a message to B, it first issues an RTS command that contains the length of the message that is to be sent. If B receives the RTS, it sends back a CTS command that also contains the length of the message. As soon as A receives CTS, it begins transmission of the data packet. A node that overhears an RTS (C in this case) defers long enough to let node A receive the corresponding CTS. Also, any node that overhears a CTS defers its transmission for the length of the data packet to avoid collision. If a node overhears an RTS but not a CTS, it decides that it is out of range of the receiver, and transmits its own packet. Therefore, this protocol can solve both the hidden- and the exposed-node problems. The nodes can probe the channel during the RTS–CTS exchange [20]. The channel state information can be used to set the physical-layer parameters, such as output power and modulation type, These properties of the MACA protocol are essential for efficient UWA network design. MACA provides information for reliable communication with minimum energy consumption and can prevent collisions before they occur. The RTS–CTS exchange adds overhead but the reduction of retransmissions can compensate for this increase.

The MACAW protocol was proposed by Bharghavan [19] to improve performance and reliability of the MACA protocol. Instead of creating error-free, reliable point-to-point links with the DLC layer by use of acknowledgments, the MACA protocol ensures the reliability of the end-to-end link with the network layer. If some packets of a message are lost because of errors, the final destination node will ask the originating source to retransmit the lost packets. On highly reliable links, this approach increases throughput, since it eliminates the need to send individual acknowledgments for each hop. In case of poor-quality communication channels, a message will most probably contain erroneous packets. Recovering the errors in the data packet at the network layer will require excessive delay. Generally, error correction is better performed at the data-link layer for channels of low reliability, such as radio or shallow-water acoustic channels. For this purpose, an ACK packet is transmitted after each successful transaction. Including an extra packet in the transaction increases the overhead, which decreases the throughput. However, it has been shown [19] that, for radio channels, the gain in throughput exceeds the increase in overhead. This result may also apply to UWA channels. The MACAW protocol ignores power control and asymmetries that can occur. Its performance under power control needs to be investigated. Also, the effect of adding more overhead to the protocol in an environment where propagation delays are excessive needs to be assessed.

Deng and Haas [21] show that the performance of protocols based on RTS–CTS exchange can degrade as a result of the collision of control packets (RTS–CTS), especially in the case of high propagation and transmission delay. The dual-busy-tone multiple access (DBTMA) protocol is proposed to reduce the packet collision probability. In this protocol, the single shared channel is divided into two subchannels: a data channel and a control channel. Control packets are transmitted on the control channel, while data are carried on the data channel. In addition, two out-of-band tones are introduced to indicate that a node is transmitting on the data channel (BT_t) and a node is receiving on the data channel (BT_r). Researchers face two important limitations for employment of this protocol in an UWA network where energy and bandwidth are scarce: (1) the use of additional tones increases the energy consumption of network nodes, and (2) the divided bandwidth decreases the data throughput of nodes. However, because of the reduced number of collisions, the total energy consumption may be reduced, while network throughput can be increased.

3.4. Automatic Repeat Request (ARQ) Methods

Automatic repeat request (ARQ) is used in the data-link control layer to request the retransmission of erroneous packets. The simplest ARQ scheme that can be directly employed in a half-duplex UWA channel is the stop-and-wait ARQ, where the source of the packet waits for an ACK from the destination node for the confirmation of error-free packet transmission. Since the channel is not utilized during the round-trip propagation time, this ARQ scheme has low throughput. In go-back-N and selective-repeat ARQ schemes, nodes transmit packets and receive ACKs at the same time, and therefore require full-duplex links. Dividing the limited bandwidth of the UWA channels into two channels for full-duplex operation can significantly reduce the data rate of the physical layer. However, the effect on the overall network throughput needs to be investigated.

The selective-repeat ARQ scheme can be modified to work on half-duplex UWA channels. Instead of acknowledging each packet individually at reception time, the receiver will wait for N packet durations and send an ACK packet with the identification number of packets received without errors. Accordingly, the source of the packets will send N packets and wait for the ACK. Then, the source will send another group of N packets that contains the unacknowledged packets and new packets.

Acknowledgments can be handled in two possible ways. In the first approach, which is called *positive acknowledgment*, on reception of an error-free packet, the destination node will send an ACK packet to the source node. If the source does not receive an ACK packet before

a preset timeout duration, it will retransmit the data packet. In the case of a *negative acknowledgment*, the destination sends a packet if it receives a corrupted packet or does not receive a scheduled data packet. A negative acknowledgment may help conserve energy by eliminating the need to send explicit ACK packets and retransmission of data packets in case of a lost ACK packet. When combined with a MACA-type MAC protocol, the negative acknowledgment scheme may provide highly reliable point-to-point links due to the information obtained during RTS–CTS exchange as discussed in Section 3.3.

3.5. Routing Algorithms

As previously indicated, there are two basic methods used for routing packets through an information network: *virtual circuit* routing, where all the packets of a transaction follow the same path through the network, and *datagram* routing, where packets are allowed to pass through different paths. Networks using virtual circuits decide on the path of the communication at the beginning of the transaction. In datagram switching, each node that is involved in the transaction makes a routing decision, which is to determine the next hop of the packet.

Many of the routing methods are based on the *shortest-path* algorithm. In this method, each link in the network is assigned a cost that is a function of the physical distance and the level of congestion. The routing algorithm tries to find the shortest path, that is, the path with lowest cost, from a source node to a destination node. In a distributed implementation each node determines the cost of sending a data packet to its neighbors and shares this information with the other nodes of the network. In this way, every node maintains a database that reflects the cost of possible routes.

For routing, let us consider the most general problem where network nodes are allowed to move. This situation can be viewed as an underwater network with both fixed ocean-bottom sensors and AUVs. The instruments temporarily form a network without the aid of any preexisting infrastructure. These types of networks are called *ad hoc networks* [22].

In ad hoc networks the main problem is to obtain the most recent state of each individual link in the network, so as to decide on the best route for a packet. However, if the communication medium is highly variable as in the shallow-water acoustic channel, the number of routing updates can be very high. Current research on routing focuses on reducing the overhead added by routing messages while at the same time finding the best path, which are two conflicting requirements. Broch et al. [23] compared four ad hoc network routing protocols presented in the literature:

- Destination sequence distance vector (DSDV) [24]
- Temporally ordered routing algorithm (TORA) [25]
- Dynamic source routing (DSR) [26]
- Ad hoc on-demand distance vector (AODV) [27]

DSDV maintains a list of *next hops* for each destination node that belongs to the shortest-distance route. The protocol requires each node to periodically broadcast routing updates to maintain routing tables.

TORA is a distributed routing algorithm. The routes are discovered on demand. This protocol can provide multiple routes to a destination very quickly. The route optimality is considered as a second priority, and the routing overhead is reduced.

DSR employs source routing; that is, the route of each packet is included in its header. Each intermediate node that receives the packet checks the header for the next hop and forwards the packet. This eliminates the need for intermediate nodes to maintain best routing information to route the packets.

AODV uses the on-demand route discovery and maintenance characteristic of DSR and employs them in a hop-by-hop routing scheme instead of source routing. Also, periodic updates are used in this protocol.

In a mobile radio environment DSR provides the best performance in terms of reliability, routing overhead, and path optimality [23]. The effect of long propagation delays and channel asymmetries caused by power control are issues that need to be addressed when considering application of these network routing protocols to UWA channels.

4. EVOLUTION OF UWA NETWORKS

Two types of applications have guided the evolution of underwater networks so far: gathering of environmental data and surveillance of an underwater area. In the first case, the network consists of several types of sensors, some mounted on fixed moorings and others mounted on moving vehicles. This type of network is called an *autonomous ocean sampling network* (AOSN), where the word "sampling" implies collecting the samples of oceanographic parameters such as temperature, salinity, and underwater currents. For surveillance applications, the network consists of a larger number of sensors, typically bottom-mounted or on slowly crawling robots, that can be quickly deployed, and whose task is to map a shallow-water area. In particular, mapping may focus on detection of warfare objects. An example of such a network, called *Seaweb*, will be described in more detail in Section 5.

An AOSN is formed by a number of autonomous underwater vehicles (AUVs), moorings, and surface buoys. The AUVs traverse an ocean area spanned by the network nodes (moorings and surface buoys) collecting scientific data. The coordination of the AUVs is handled from a central location, which can be either at one of the network nodes and/or on shore. AUVs relay key observations and their status to the central location. After evaluating the incoming data, the central location sends control signals to the AUVs through the network nodes. The acoustic communication between the AUVs and the network nodes is designed so that it does not require high data throughput. More complete data sets are transferred to the onshore control center through a radio channel when AUVs dock to a mooring. The control center is connected to a backbone such as the Internet, so that a scientist can reach the sampling network in real time. An important

limitation observed during the tests of the AOSN was the impossibility for the AUVs to instantly respond to commands due to the high-latency environment [28]. As a result of the highly variable acoustic channel, network connections to AUVs were occasionally lost. Therefore, some level of automation is needed in the AUVs to avoid disastrous events, which may occur if the last command sent to an AUV directs it toward an obstacle and the connection is lost.

A deep-water acoustic local-area network (ALAN) was deployed in Monterey Canyon, California, for long-term data acquisition and ocean monitoring from multiple ocean-bottom sources [1]. A centralized network topology was employed with a hub on the surface. The MAC protocol was based on TDMA, where time slots were determined adaptively on the basis of estimated latency. Because this protocol relies on correct estimation of the round-trip propagation times, any error in the estimation process decreases the throughput of the system by causing retransmissions.

The evolution of research on underwater acoustic networks has followed the usual layered architecture. Most work to date has been performed on the physical layer and multiple-access techniques. The data-link-layer protocols have been addressed to a lesser extent, and the work has only begun on the network layer and routing algorithms [5]. In all of these areas, the focus of research has been on adapting the well-known theoretical concepts to the requirements and constraints of the underwater acoustic channels.

Typically, packet transmission in a store-and-forward network is considered in most of the underwater acoustic networks. The design of automatic repeat request (ARQ) protocols is influenced by the long propagation times in underwater channels. Talavage et al. [29] proposed a shallow-water acoustic local-area network (S-ALAN) protocol, which is a modified version of ARPA-supported packet radio network (PRN) protocol. The S-ALAN differs from PRN in the routing algorithm and the data transmission medium. In contrast to PRN, which uses datagram switching over a single channel, S-ALAN employs virtual circuit switching using three separate channels (frequency bands) and selective-repeat ARQ. When a network node gathers enough information to send to the control center, it issues a request to set up a virtual circuit. When the setup request reaches the destination node, the destination node assigns transmit data, receive data, and acknowledgment channels for all the nodes in the virtual circuit and reports the final configuration back to the source node. The use of three separate channels enables the network to fully utilize the ARQ scheme.

A peer-to-peer communication protocol has been developed to control AUVs [30] based on carrier sense multiple access with collision avoidance (CSMA/CA). Since the CSMA/CA protocol relies on acknowledgments, the channel remains idle for an amount proportional to the round-trip propagation time. Because of the long propagation delays in UWA channels, this protocol has a low throughput. On the other hand, it is highly reliable.

A media access protocol proposed for shallow-water acoustic networks is presented in Ref. 10. The protocol is based on the MACA protocol and employs a stop-and-wait ARQ scheme. The RTS–CTS exchange is used to determine the channel conditions, and this information is used to set the acoustic modem parameters such as output power level. The details of this network are given in the following section.

The routing optimization problem for a shallow-water acoustic network is addressed in Ref. 31. The genetic algorithm based routing protocol tries to maximize the lifetime of the battery-powered network by minimizing the total energy consumption of the network. The minimum energy required to establish reliable communication between two nodes is used as the link distance metric. A master node collects the link cost information from the network nodes, determines optimum routes, and sends the routing information back to the nodes. The authors showed that the optimization algorithm favors multihop links at the expense of increased delay.

5. SEAWEB

Seaweb is an acoustic network for communications and navigation of deployable autonomous undersea systems [32]. The U.S. Navy incorporated Seaweb networking in the June 2001 Fleet Battle Experiment India (FBE-I). The Seaweb installation charted in Fig. 3 was part of the overall FBE-I joint forces architecture for command, control, communications, computers, intelligence, surveillance, and reconnaissance (C4ISR) providing wide-area connectivity, enhanced bandwidth, and reachback capability. Seaweb reliably supported asynchronous networking for an improved 688-class (688I) fast-attack nuclear submarine mobile node and two deployable autonomous distributed system (DADS) nodes. Two moored radio-acoustic communications (racom) buoy gateway nodes provided line-of-sight radio links to a shore station having terrestrial Internet connection to an antisubmarine warfare (ASW) command center (ASWCC) located ashore. In addition, 10 undersea repeater nodes highlighted the flexible architecture, indicating expandability and potential area coverage. The network performed reliably with no hardware failures and no lost transmissions. Seaweb supported Internet Protocol (IP) delivery of automated ASW contact reports from the DADS sensors to shore, and command and control (C2) on the IP backlink. Naval messages to and from the submarine via Seaweb protocols permitted assured access at tactical depth. The 15-node FBE-I Seaweb system extended Naval network-centric operations into the undersea battlespace. Analysts executed numerous communication and navigation tests, and proved that the FBE-I network design was overly conservative and could have supported even greater area coverage and traffic load.

5.1. Concept of Operations

Telesonar wireless acoustic links interconnect distributed undersea instruments, potentially integrating them as a unified resource. Seaweb is the realization of an undersea telesonar network [10] of fixed and mobile nodes, with various interfaces to manned command centers.

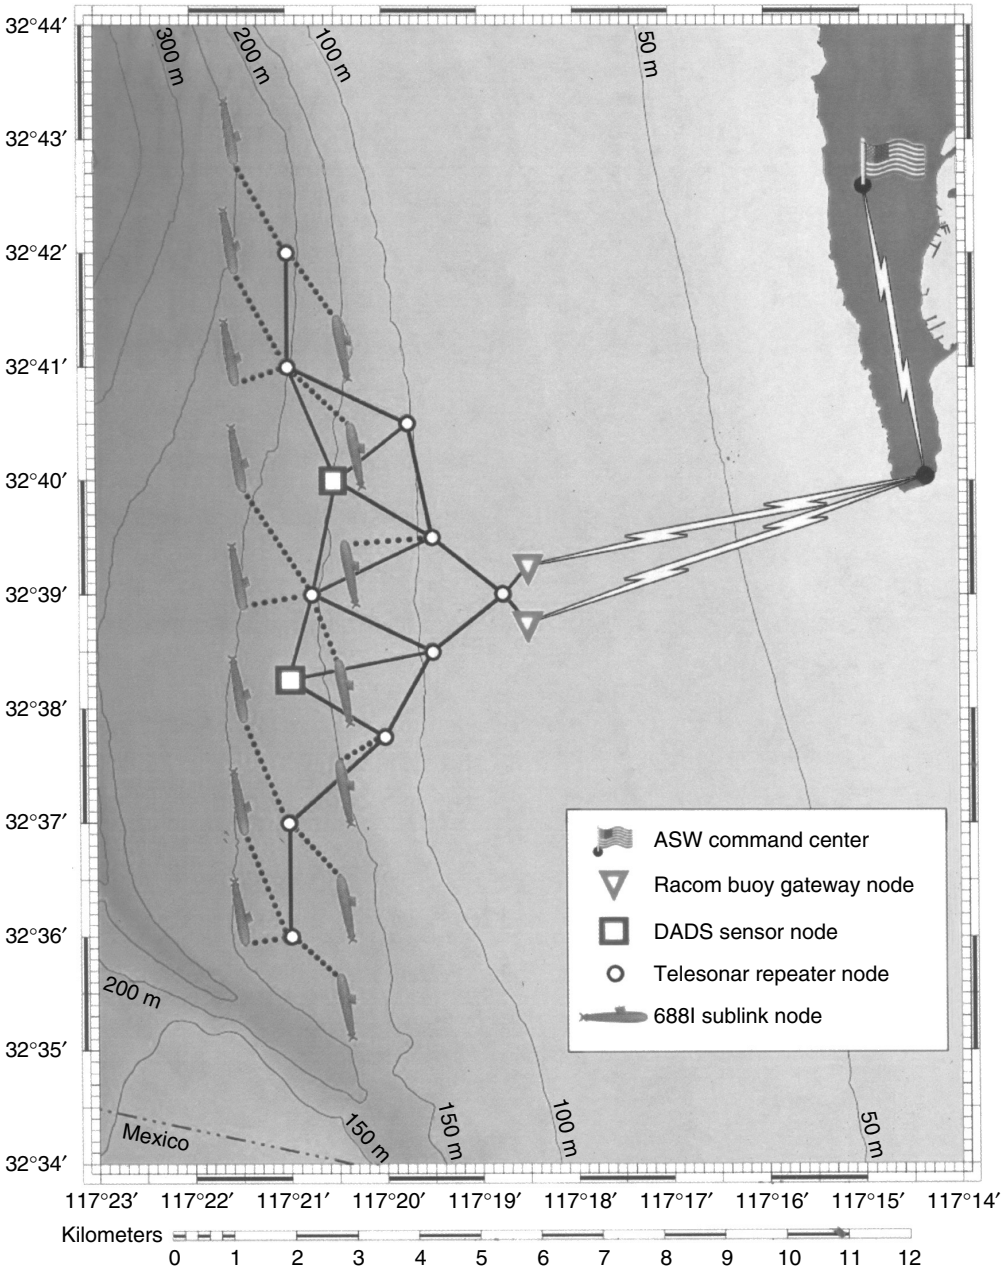

Figure 3. The FBE-I Seaweb network was a 14-node undersea grid. Two nodes were prototype deployable autonomous distributed system (DADS) sensors for littoral ASW, and two nodes were moored radio/acoustic communications (racom) gateway nodes. A mobile submarine node with sublink capacity had full interoperability with the Seaweb network. An ASW command center served as the ashore site. U.S. Navy personnel exercised the complete Seaweb installation for 4 days with high reliability and no component failures.

The architectural flexibility afforded by Seaweb wireless connections permits the network designer to allocate an arbitrary mix of node types with a node density and area coverage appropriate for the given telesonar propagation conditions and for the mission at hand. The concept of operations assumes that the majority of network nodes are inexpensive, autonomous, battery-limited devices deployed from submarine, ship, and aircraft, or from unmanned undersea vehicles (UUVs) and unmanned aerial vehicles (UAVs).

Seaweb networks support asynchronous data communications from autonomous nodes to command centers. On the backlink, Seaweb allows remote command and control of instruments associated with the autonomous nodes. Additionally, network activity supports acoustic navigation and geolocalization of undersea nodes as a natural byproduct of telesonar ranging signals. More generally, Seaweb networking permits wireless transmissions between member nodes in the network using established routes or via an intervening cellular node.

Seaweb enables future Naval capabilities in littoral ASW and undersea autonomous operations. A significant dual use of Seaweb is communication and navigation for oceanographic surveys and environmental assessment. Certainly, a major potential benefit of the technology is cross-system, cross-platform, cross-mission interoperability, providing enormous added value to otherwise solitary systems. For example, a UUV mobile node operating within a grid of fixed sensor nodes benefits from the established network topology for situational awareness, navigation, and communications via gateway nodes to distant command centers. Conversely, UUVs add value to the fixed grid for sensor deployment, search, survey, water-column sampling, popup racom gateway communications, and other functions.

The initial motivation for Seaweb is a requirement for wide-area surveillance in littoral waters. These sensors operate in 50- to 300-m waters with node spacing of 2–5 km. Sensor nodes generate concise ASW contact reports that Seaweb routes to a master node for field-level data fusion [33]. Primary network packets are contact reports with about 1000 information bits [34]. Sensor nodes asynchronously produce these packets at a variable rate dependent on the receiver operating characteristics (ROCs) for a particular sensor suite and mission. The master node communicates with manned command centers via encrypted gateway nodes such as a racom sea-surface buoy linked with space satellite networks. Following ad hoc deployments, the Seaweb network self-organizes, including node identification, clock synchronization on the order of 0.1–1.0 s, node geolocalization on the order of 100 m, assimilation of new nodes, and self-healing following node failures.

As a fixed grid of inexpensive interoperable sensor nodes and repeater nodes, this is the most fundamental Seaweb operating mode based on a stable topology that periodically adjusts itself to optimize overall network endurance and quality of service (QoS). The fixed Seaweb topology provides an underlying cellular network suited for supporting an AOSN [35], including communication and navigation for UUV mobile nodes. The cellular architecture likewise provides seamless connectivity for submarine operations at speed and depth in a manner not unlike those for terrestrial cellular telephone service for automobiles.

5.2. Developmental Approach

The concept of operations emphasizes simplicity, efficiency, reliability, and security, and these attributes therefore govern the design philosophy for Seaweb development. Research is advancing telesonar modem technology for reliable underwater signaling by addressing the issues of (1) adverse transmission channels, (2) asynchronous networking, (3) battery energy efficiency, (4) transmission security, and (5) cost.

Despite a concept of operations emphasizing simplicity, Seaweb is a multifaceted system, and its development is a grand challenge. The high cost of sea testing and the need for many prototype nodes motivate extensive engineering system analysis. Simulations using an optimized network engineering tool (OPNET) with simplified ocean acoustic propagation assumptions permit laboratory refinement of networking protocols [34] and initialization methods [36]. Meanwhile, controlled experimentation in actual ocean conditions incrementally advances telesonar signaling technology [37].

Seaweb development balances the desire for rapid increases in capability and the need for stable operation in support of applications that are themselves developmental. This balance is achieved by an annual cycle culminating with the late-summer Seaweb experiment (Seaweb '98, Seaweb '99, Seaweb 2000, etc.).

The objective of the annual Seaweb experiments is to exercise telesonar modems in networked configurations where various modulation and networking algorithms can be assessed. In the long term, the goal is to provide for a self-configuring network of distributed assets, with network links automatically adapting to the prevailing environment through selection of the optimum transmit parameters. A full year of hardware improvements and in-air network testing helps ensure that the incremental developments tested at sea will provide tractable progress and mitigate overall developmental risk. In preparation for Seaweb experimentation, multiple contributing projects conduct relevant research during the first three-quarters of the fiscal year. The fourth-quarter Seaweb experiment then implements and tests the results from these research activities with a concentration of resources in prolonged ocean experiments. The products of the annual Seaweb experiment are major capability upgrades for integrated Seaweb server software, telesonar modem Seaweb firmware, and telesonar modem hardware. The annual Seaweb experiment also transitions these upgrades into participating application systems. After the annual Seaweb experiment yields a stable level of functionality, the firmware product can be further exercised and refinements instituted during system testing and by spinoff applications throughout the year. For example, in year 2001, Seaweb 2000 technology enabled the March–June FRONT-3 ocean observatory on the continental shelf east of Long Island, New York [38]. These applications afford valuable long-term performance data that are not obtainable during Seaweb experiments when algorithms are in flux and deployed modems are receiving frequent firmware upgrades. At the conclusion of the Seaweb experiment, the upgraded Seaweb capability reaches stability suitable for use with the continuing development of the various application systems during the following year. Meanwhile, the annual cycle repeats, beginning with research and preparations for the next Seaweb experiment. And so, Seaweb capability increases in an incremental manner.

The Seaweb architecture of interest includes the physical layer, the media access control (MAC) layer, and the network layer. These most fundamental layers of communications functionality support higher layers, collectively identified here as the "client" layer. The client layer tends to be application-specific and is not the direct responsibility of telesonar modems or the Seaweb network.

5.3. Telesonar Modems and the Physical Layer

The U.S. Navy has been developing *telesonar* modems designed to function at low bit rates with high reliability and modest processing [39,40]. The basis for this approach is the need for low-cost, energy-efficient workhorse modems suitable for the development of networking technologies [41]. From an interoperability perspective, the low-bit-rate modem offers the lowest common denominator for cross-system networks that may include low-cost, expendable nodes [42,43]. As a pair of modems establishes a low-bit-rate link, they may adaptively negotiate higher-bit-rate modulations if warranted by favorable propagation and available processing resources.

The present telesonar modem [44] normally uses 5 kHz of acoustic bandwidth encompassing 120 discrete MFSK bins and 8 tracking bins [45]. A basic 1-of-4 MFSK modulation carries 2400 bps but lacks data protection and error correction coding (ECC). A constraint-length-9, rate-$\frac{1}{2}$ convolutional code very effectively corrects bit errors by representing binary information across multiple symbols; the rate-$\frac{1}{2}$ reduces throughput by a factor of 2. For protection against multipath-induced inter-symbol interference (ISI), the MFSK chip duration may be lengthened; the modem allows for a doubling from 25 to 50 ms, resulting in another factor of 2 reduction in bit rate. A "Doppler-tolerant" mode skips alternate MFSK bins to allow greater latitude for tracking Doppler shifts caused by node-to-node range rate. The Doppler-tolerant mode also increases robustness by doubling the acoustic energy per chip, but it also causes another halving in bit rate. Finally, a Hadamard MFSK modulation carries 6 Hadamard codewords of 20 tones each. Interleaving the codewords across the band increases immunity to frequency-selective fading, and Hadamard coding yields a frequency diversity factor of 5 for adverse channels having low or modest spectral coherence. Hadamard signaling is effective in channels having frequency-selective fading or narrowband noise. Any combination of the above mentioned options is possible. For FBE-I, a conservative modulation choice combined Hadamard MFSK, rate-$\frac{1}{2}$ convolutional coding, and 50-ms chip lengths to yield a net 300 bps information rate.

For all operational modes, receiving modems process the data noncoherently using a fixed-point TMS320C5410 DSP. Directional transducers can further enhance the performance of these devices [46,47]. The present telesonar modem includes provision for a watchdog function hosted aboard a microchip independent of the DSP. The watchdog resets the DSP on detection of supply voltage drops or on cessation of DSP activity pulses. The watchdog provides a high level of fault tolerance and permits experimental modems to continue functioning in spite of system errors. A watchdog reset triggers the logging of additional diagnostics for thorough troubleshooting after modem recovery.

Low-bandwidth, half-duplex, high-latency telesonar links limit Seaweb quality of service (QoS). Occasional outages from poor propagation or elevated noise levels can disrupt telesonar links [48]. Ultimately, the available energy supply dictates service life, and battery-limited nodes must be energy-conserving [49]. Moreover, Seaweb must ensure transmission security by operating with low bit-energy per noise-spectral-density (E_b/N_0) and by otherwise limiting interception by unauthorized receivers.

Spread-spectrum modulation is consistent with the desire for asynchronous multiple access to the physical channel using CDMA networking [50]. Nevertheless, the Seaweb concept does not exclude TDMA or FDMA methods and is in fact pursuing hybrid schemes suited to the physical-layer constraints. In a data transfer, for example, a concise asynchronous CDMA dialog could queue data packets for transmission during a time slot or within a frequency band such that multiaccess interference (MAI) collisions are avoided altogether.

At the physical layer, an understanding of the transmission channel is obtained through at sea measurements [51] and numerical propagation models [52]. Knowledge of the fundamental constraints on telesonar signaling translates into increasingly sophisticated modems [53]. DSP-based modulators and demodulators permit the application of modern digital communications techniques to exploit the unique aspects of the underwater channel. To aid understanding of telesonar performance, modems automatically log physical-layer diagnostics, including signal-to-noise ratio (SNR), automatic gain control (AGC), bit error rate (BER), and the number of corrected and uncorrected errors.

5.4. Handshake Protocols and the MAC Layer

Developmental Seaweb modem firmware implements the core features of a compact, structured protocol for secure, low-power, point-to-point, connectivity. The protocol efficiently maps MAC-layer functionality onto a physical layer based on channel-tolerant, 64-bit utility packets and channel-adaptive, arbitrary-length data packets. Seaweb firmware implements utility packet types using the basic Hadamard MFSK physical layer. These utility packet formats permit data transfers and node-to-node ranging. A richer set of available utility packets is being investigated with OPNET simulations prior to modem implementation, but seven core utility packets provided substantial networking capability for FBE-I.

The telesonar handshake protocol is suited to wireless half-duplex networking with slow propagation. Handshaking [20] asynchronously establishes adaptive telesonar links [54]. The initial handshake consists of the transmitter sending a request-to-send (RTS) packet and the receiver replying with a clear-to-send (CTS) packet. A busy signal (BSY) packet may be issued in response to an RTS when the receiver node decides to defer data reception in favor of other traffic. Following a successful RTS–CTS handshake, the data packet(s) are sent. This RTS–CTS round trip establishes the communications link and probes the channel to gauge optimal transmit power. Future firmware enhancements will support power control and the adaptive choice of data modulation method, with selection based on channel estimates derived from the RTS role as a probe signal. Telesonar links eventually will be environmentally adaptive [55], with provision for bidirectional asymmetry. Handshaking permits addressing, ranging, channel estimation, adaptive modulation, and power control.

The Seaweb 2000 core protocol implemented stop-and-wait ARQ scheme by providing either positive or negative acknowledgment of a data message. The choice of acknowledgment type depends on the traffic patterns associated with a particular network mission. Handshaking provided the means for resolving packet collisions automatically using retries from the transmitter or automatic repeat request (ARQ) packets from the receiver. For FBE-I, a purely negative acknowledgment was supported by the modem, implemented as an ARQ utility packet. At the client layer, the DADS client system supports positive acknowledgment through its IP implementation. Figure 4 illustrates the MAC layer protocol.

If two nodes send an RTS to each other, unnecessary retries may occur because both nodes will ignore the received RTS command. Each node will then wait for the other node to send a CTS for a timeout duration, and retransmit their RTS packet. This problem is solved by assigning priority to the packets that are directed towards the master node, as explained below (Fig. 5).

Assume that node A is a lower level node than node B; that is, Node A is the parent of B. Node A and node B both send RTS to each other. As a result of transmission delays, packets arrive to their destinations while both nodes are waiting for a CTS packet. When node B receives the RTS, it notices that the packet is from its own destination, node A. Node B checks whether node A is its parent or child. Since node A is its parent, node B has the priority and sends a CTS packet immediately. By that time, node A receives the RTS of node B, does the same check and decides that it should wait for node B to complete its data transmission, since node B is its child. Therefore, node A puts its own data packet into a queue and waits for the CTS packet of node B.

Future implementations of Seaweb firmware will retain the purely negative acknowledgment approach, as analysis has shown this to be the appropriate MAC layer implementation for long-latency, half-duplex links. For communications requiring positive acknowledgments, the Seaweb 2001 firmware includes provision for efficient delivery of a receipt (RCPT) utility packet from the destination node to the source node.

The RTS–CTS approach anticipates eventual implementation of adaptive modulation and secure addressing. The initiating node transmits a RTS waveform with a frequency-hopped, spread-spectrum (FHSS) [44] pattern or direct-sequence spread-spectrum (DSSS) [11] pseudo-random carrier uniquely addressing the intended receiver.

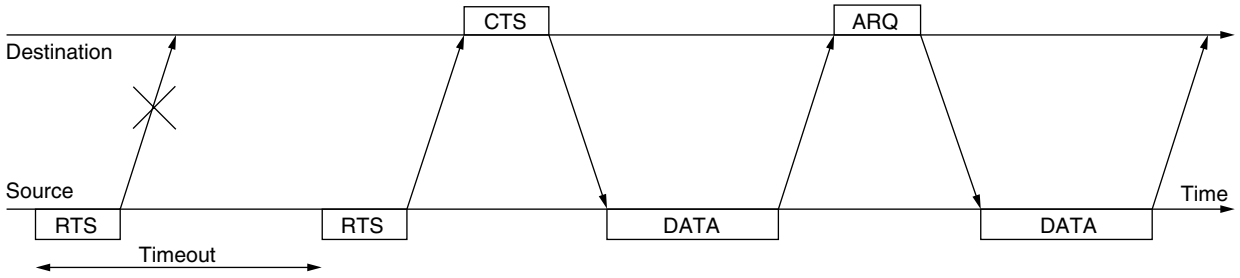

Figure 4. The source node starts the MAC layer handshake protocol by sending an RTS packet to the destination node. If the RTS packet is lost in the channel, the source node retransmits the RTS packet after a timeout duration equal to the round-trip time of an header-only packet (e.g., RTS, CTS, or ARQ), and calculated using the range information in the neighboring tables. When the destination node receives the RTS, it replies with a CTS packet. On receipt of the CTS packet by the source, the DATA packet, which contains a header and the information, is sent to the destination. The destination node issues an ARQ packet if it does not receive the DATA packet before a timeout occurs.

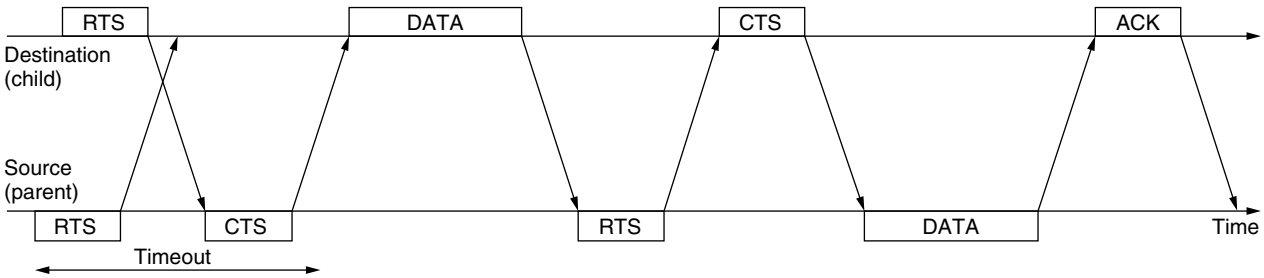

Figure 5. If two nodes send RTS packets to each other with some delay, both nodes receive the packets. When they recognize that the RTS is received from their destination, they check for the priority of the nodes. Higer-level nodes, or children, have higher priority. Therefore, the parent node sends CTS telling the child to send its data. When the parent receives the data, it replies with an RTS, which also act as an acknowledgments. Then the parent sends its data to the child. This example uses positive acknowledgments (ACK).

(Alternatively, the initiating node may transmit a universal code for broadcasting or when establishing links with unknown nodes.) The addressed node detects the request and awakens from an energy-conserving sleep state to demodulate. Further processing of the RTS signal can provide an estimate of the channel scattering function and signal excess. An adaptive power-control technique determines the source level that will deliver sufficient but not excessive SNR. The addressed node then acknowledges receipt with a FHSS or DSSS acoustic response. This CTS reply specifies appropriate modulation parameters for the ensuing message packets based upon the measured channel conditions. Following this RTS–CTS handshake, the initiating node transmits the data packet(s) with nearly optimal bit rate, modulation, coding, and source level.

5.5. Seaweb Server and the Network Layer

The Seaweb backbone is a set of autonomous, stationary nodes (e.g., deployable surveillance sensors, repeaters). Seaweb peripherals are mobile nodes (e.g., UUVs, including swimmers, gliders, and crawlers) and specialized nodes (e.g., bistatic sonar projectors). Seaweb gateways provide connections to command centers submerged, afloat, aloft, and ashore. Telesonar-equipped gateway nodes interface Seaweb to terrestrial, airborne, and space-based networks. For example, a telesonobuoy serves as a racom interface permitting satellites and maritime patrol aircraft to access submerged, autonomous systems. Similarly, submarines can access Seaweb with telesonar signaling through the underwater telephone band or other high-frequency sonar [56]. Seaweb provides the submarine commander digital connectivity at speed and depth with bidirectional access to all Seaweb-linked resources and distant gateways.

At the physical and MAC layers, adaptive modulation and power control are keys to maximizing both channel capacity (bps) and channel efficiency (bit-kilometer/joule). At the network layer, careful selection of routing is required to minimize transmit energy, latency, and net energy consumption, and to maximize reliability and security. Seaweb experimentation underscores the differences between acoustic networks and conventional networks. Limited power, small bandwidth, and propagation latencies dictate that the Seaweb network layer be simple and efficient. For compatibility with Seaweb networks, the higher client layers must utilize lookup tables, data compression, forward error correction, and data filtering to minimize packet sizes and retransmissions, and to avoid congestion at the network layer.

A very significant development was the introduction of the Seaweb server [57]. A Seaweb server resides at manned command centers and is the graphical user interface to the undersea network. It interprets, formats, and routes downlink traffic destined for undersea nodes. On the uplink, it archives incoming data packets produced by the network, retrieves the information for an operator, and provides Web-based read-only database access for client users. The server manages Seaweb gateways and member nodes. It monitors, displays, and logs the network status. The server manages the network routing tables and neighbor tables and ensures network interoperability. Seaweb '99 modem firmware permitted the server to remotely reconfigure routing topologies, a foreshadowing of future self-configuration and dynamic network control. The Seaweb server is a suite of software programs implemented under Linux on a laptop PC with a LabVIEW graphical user interface. A single designated "super" server controls and reconfigures the network.

Network supervisory algorithms can execute either at an autonomous master node or at the Seaweb server. Seaweb provides for graceful failure of network nodes, addition of new nodes, and assimilation of mobile nodes. Essential byproducts of the telesonar link are range measurement, range rate measurement, and clock synchronization. Collectively, these features will support network initialization, node localization, route configuration, resource optimization, and maintenance.

Node-to-node ranging employed a new implementation of a round-trip travel time measurement algorithm with 0.1-ms resolution linked to the DSP clock rate.

As a network analysis aid, all modems now include a data-logging feature. All output generated by the telesonar modem and normally available via direct serial connection is logged to an internal buffer. Thus, the behavior of autonomous nodes can be studied in great detail after recovery from sea. Seaweb 2000 firmware logs diagnostics related to channel estimation (SNR, multipath duration, range rate, etc.), demodulation statistics (BER, AGC, intermediate decoding results, power level, etc.), and networking (data packet source, data packet sink, routing path, etc.). For Seaweb applications, the data-logging feature can also support the archiving of data until such time that an adjacent node is able to download the data. For example, a designated sink node operating without access to a gateway node can collect all packets forwarded from the network and telemeter them to a command center when interrogated by a gateway (such as a ship arriving on station for just such a data download).

Since the network in consideration is an ad hoc network, an initialization algorithm is needed to establish preliminary connections autonomously. This algorithm is based on polling, and as such it guarantees connectivity to all the nodes that are acoustically reachable by at least one of their nearest neighbors. During initialization, the nodes create *neighbor tables*. These tables contain a list of each node's neighbors and a quality measure of their link, which can be the received SNR from the corresponding neighbor. The neighbor tables are then collected by the master node and a routing tree is formed. Table 2 is an example node table for node 3 of the network given in Fig. 6.

The master node decides on the primary (and secondary) routes to each destination, with routing optimization based on the genetic algorithm. Initialization ends when the master node sends primary routes to the nodes. The initialization algorithm provides either a single set of connections, or multiple connections between the nodes. Multiple connections are desirable to provide greater robustness to failures. A possible routing tree with backup routes for the network of Fig. 6 is given in Fig. 7.

Optimum routes are determined with the help of a genetic algorithm-based routing protocol [31]. The routing protocol tries to maximize the lifetime of the

Table 2. Node Table[a] of Node 3 for Network Given in Fig. 6

Neighbor ID	Range (km)	Output Power (dB)
1	6	−9 dB
2	7	−9 dB
4	9	−3 dB

[a] This table contains the ID of the nodes with which node 3 can communicate with a direct link. For each neighbor, the range of the node and the minimum output power required to communicate with that node are entered. The output power is in decibels with respect to the maximum output power of the modem. Because of the channel characteristics, nodes at different ranges may require the same amount of output power.

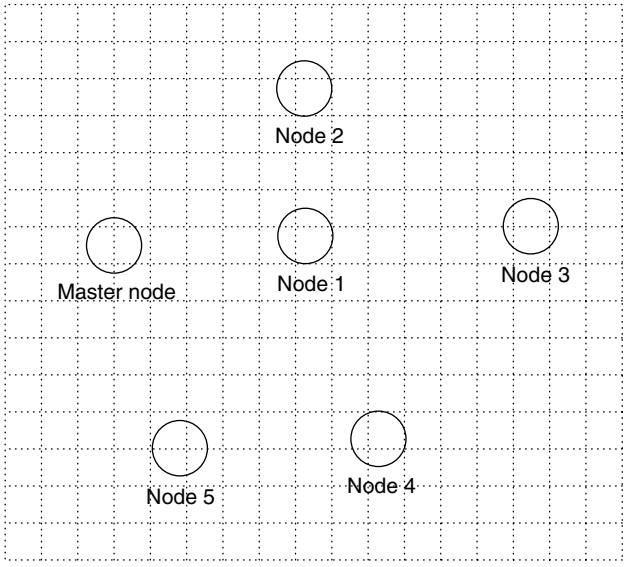

Figure 6. The network consists of a master node and five sensor nodes. The sensor nodes send information packets to the master node, which is the connection point of the network to a backbone. The master node can also send control packets to the sensor nodes.

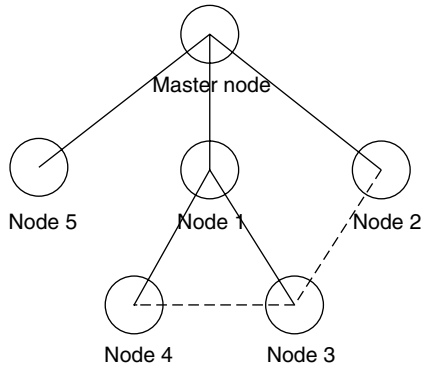

Figure 7. The routing tree is created by the master node. The master node is at the top of the tree. Sensor nodes are the leafs. Nodes 1, 2, and 5 are the children of the master node and form the first layer of the network. Node 1 is the parent of nodes 3 and 4, which form the second layer of the network. Dashed lines represent backup links that can be used in case of a failed link.

battery-powered network by minimizing the total energy consumption of the network. The minimum energy required to establish reliable communication between two nodes is used as the link distance metric. A master node collects the link cost information from the network nodes, determines optimum routes, and sends the routing information back to the nodes. The optimization algorithm favors multihop links at the expense of increased delay.

The performance of acoustic links between nodes can degrade, and even a link can be permanently lost as a result of node failure. In such cases, the network should be able to adapt itself to the changing conditions without interrupting the packet transfer. This robustness can be obtained by updating the routes periodically.

In the current implementation, the network tables are created manually at the Seaweb server with the help of the ranging packets. Also, the initial routes and updates are determined and reported to the network nodes manually through the Seaweb server.

6. CONCLUDING REMARKS

In this article, we presented an overview of basic principles and constraints in the design of reliable shallow-water acoustic networks that may be used for transmitting data from a variety of undersea sensors to onshore facilities. Major impediments in the design of such networks were considered, including (1) severe power limitations imposed by battery power; (2) severe bandwidth limitations; and (3) channel characteristics, including long propagation times, multipath, and signal fading. Multiple-access methods, network protocols, and routing algorithms were also considered.

Of the multiple-access methods considered, it appears that CDMA, achieved either by frequency hopping or by direct sequence, provides the most robust method for the underwater network environment. Currently under development are modems that utilize these types of spread-spectrum signals to provide the multiple-access capability to the various nodes in the network. Simultaneously with current modem development, there are several investigations on the design of routing algorithms and network protocols.

The design example of the shallow-water network employed in Seaweb embodies the power and bandwidth constraints that are so important in digital communication through underwater acoustic channels. As an information system compatible with low bandwidth, high latency, and variable quality of service, Seaweb offers a blueprint for the development of future shallow-water acoustic networks. Experimental data that will be collected in the near future will be used to assess the performance of the network and possibly validate a number of assumptions and tradeoffs included in the design. Over the next decade (at the time of writing), significant improvements are anticipated in the design and implementation of shallow water acoustic networks as more experience is gained through at-sea experiments and network simulations.

BIOGRAPHIES

Dr. John G. Proakis received the B.S.E.E. from the University of Cincinnati in 1959, the M.S.E.E. from MIT in 1961, and the Ph.D. from Harvard University in 1967. He is an Adjunct Professor at the University of California at San Diego and a Professor Emeritus at Northeastern University. He was a faculty member at Northeastern University from 1969 through 1998 and held the following academic positions: Associate Professor of Electrical Engineering, 1969–1976; Professor of Electrical Engineering, 1976–1998; Associate Dean of the College of Engineering and Director of the Graduate School of Engineering, 1982–1984; Interim Dean of the College of Engineering, 1992–1993; Chairman of the Department of Electrical and Computer Engineering, 1984–1997. Prior to joining Northeastern University, he worked at GTE Laboratories and the MIT Lincoln Laboratory.

His professional experience and interests are in the general areas of digital communications and digital signal processing and more specifically, in adaptive filtering, adaptive communication systems and adaptive equalization techniques, communication through fading multipath channels, radar detection, signal parameter estimation, communication systems modeling and simulation, optimization techniques, and statistical analysis. He is active in research in the areas of digital communications and digital signal processing and has taught undergraduate and graduate courses in communications, circuit analysis, control systems, probability, stochastic processes, discrete systems, and digital signal processing. He is the author of the book *Digital Communications* (McGraw-Hill, New York: 1983, first edition; 1989, second edition; 1995, third edition; 2001, fourth edition), and co-author of the books *Introduction to Digital Signal Processing* (Macmillan, New York: 1988, first edition; 1992, second edition; 1996, third edition), *Digital Signal Processing Laboratory* (Prentice-Hall, Englewood Cliffs, NJ, 1991); *Advanced Digital Signal Processing* (Macmillan, New York, 1992), *Algorithms for Statistical Signal Processing* (Prentice-Hall, Englewood Cliffs, NJ, 2002), *Discrete-Time Processing of Speech Signals* (Macmillan, New York, 1992, IEEE Press, New York, 2000), *Communication Systems Engineering* (Prentice-Hall, Englewood Cliffs, NJ: 1994, first edition; 2002, second edition), *Digital Signal Processing Using MATLAB V.4* (Brooks/Cole-Thomson Learning, Boston, 1997, 2000), and *Contemporary Communication Systems Using MATLAB* (Brooks/Cole-Thomson Learning, Boston, 1998, 2000). Dr. Proakis is a Fellow of the IEEE. He holds five patents and has published over 150 papers.

Joseph A. Rice joined the Naval Postgraduate School's Physics Department in 2001 as the SPAWAR Systems Center San Diego Engineering Acoustics Chair. He is Principal Investigator for numerous ONR projects and tasks collectively performed as the Seaweb Initiative. He is the Technical POC for three SBIR contracts producing undersea acoustic modems, networks, and directional transducers. He has been a U.S. Navy research engineer since 1981, developing digital signal processing and numerical modeling concepts for solving undersea acoustics problems. He received the U.S. Navy Meritorious Civilian Service Award for experimental demonstration of undersea acoustic matched-field processing (MFP) during the Swellex acoustic propagation studies. He is interested in acoustic localization and navigation, having developed the prototype array element localization (PAEL) sonobuoy and associated processing for the Sonobuoy Thinned Random Array Program (STRAP). He holds a B.A. in Mathematics and a B.S. in Engineering Science, both from the University of Cincinnati. He holds an M.S.E.E. in Applied Ocean Science from UCSD. He is a member of IEEE and ASA.

Ethem M. Sozer received his B.S. and M.S. degrees in Electrical Engineering from the Middle East Technical University, Ankara, Turkey, in 1994 and 1997, respectively. He is working toward his Ph.D. in Electrical Engineering at Northeastern University, Boston. His research interests include iterative equalization techniques, underwater acoustic communications, and underwater acoustic networks. He is currently working for Delphi Communication Systems, Inc, Maynard, Maryland.

Milica Stojanovic graduated from the University of Belgrade, Belgrade, Yugoslavia, in 1988, and received the M.S. and Ph.D. degrees in Electrical Engineering from Northeastern University, Boston, in 1991 and 1993, respectively. She is a Principal Research Scientist at the Massachusetts Institute of Technology, and a Guest Investigator at the Woods Hole Oceanographic Institution. Her research interests include digital communications theory and statistical signal processing and their applications to wireless communication systems.

1. CONSTELLATION SHAPING

Constellation shaping [1,2] is a technique that improves the efficiency of high-rate digital communications by reducing the average power without compromising the data rate or bit error rate. It can provide moderate gain (called *shaping gain*) of up to 1.53 dB on top of any coding gain (such as by using convolutional codes) with modest complexity. For instance, it is used in the V.34 high-rate analog voiceband modem standard to reduce the average power of the QAM constellation.

The concept and purpose of shaping is easily illustrated by the following simple example. Consider two 256-QAM constellations (see Figs. 1 and 2). Both constellations have the same number of distinct points, allowing 8 bits to be transmitted with each symbol. The error rate is primarily a function of the distance between constellation points, so it is virtually identical for both constellations. However, the average energy is reduced from 170 to 162.75 by choosing

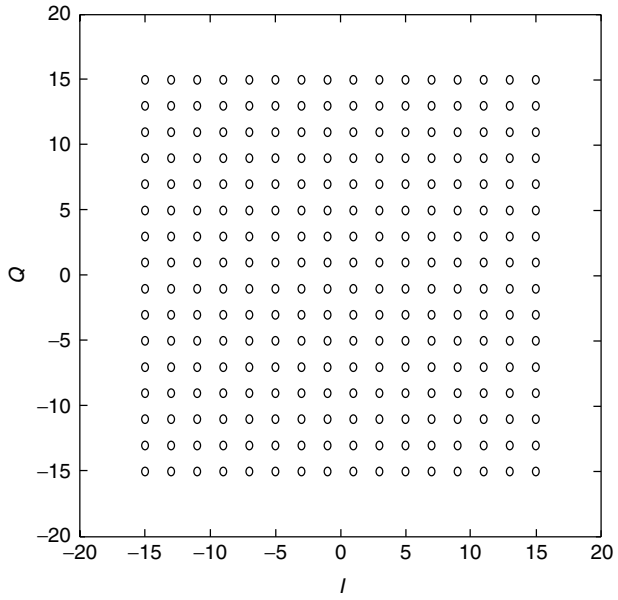

Figure 1. The original (unshaped) 256-QAM constellation has an average energy of 170.

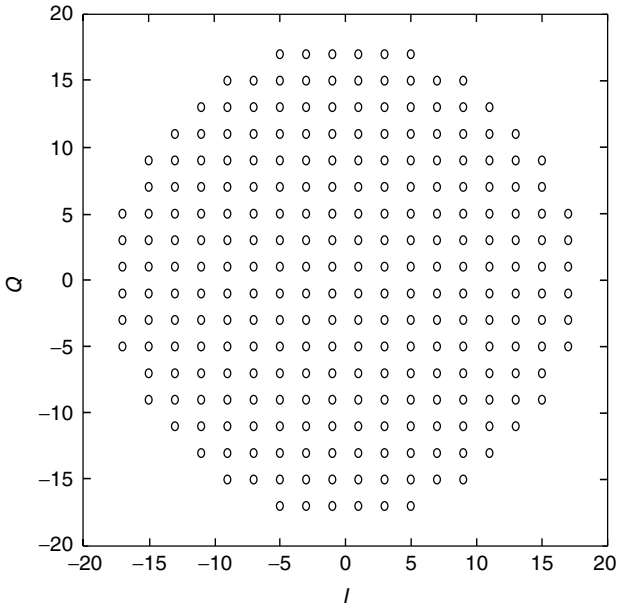

Figure 2. The shaped 256-QAM constellation has an average energy of 162.75 — a reduction of 0.379 dB.

a circular boundary instead of a square one. The reduction in average power is 0.379 dB without compromising the data rate or bit error rate.

Higher-dimensional constellations can provide even more average power reduction (up to 1.53 dB) [1–3]. For example, V.34 modems use a 16-dimensional constellation that provides about 1 dB of average power reduction. The idea is essentially the same as for two dimensions; conceptually, a block of N successive complex-valued symbols are grouped into a single $2N$-dimensional "hypersymbol," and a "hyperconstellation" in this space encodes a large number of bits simultaneously. Use of an approximately hyperspherical constellation with the same distance between constellation points reduces the average energy while preserving the same noise margin.

The primary practical challenge of shaping is to efficiently index the very large number of points in a high-dimensional, shaped constellation. Beyond two dimensions, simple tabulation becomes infeasible. Shell mapping is an efficient algebraic technique for performing this mapping that allows shaping to be used in practical communication systems. Shell mapping groups constellation points of roughly equal energy from a quadrature (QAM) constellation into concentric rings, or shells. A block of successive QAM symbols jointly code a large number of bits, which are divided into two groups: those mapped to the particular constellation points within the chosen shell for each QAM symbol, and another set of bits that indicates the combination of shells used for that block. For example, a system encoding an average rate of 6 bits per QAM symbol might use a block of eight symbols with 16 constellation points per shell; in this case, $8 \times 4 = 32$ bits would be encoded in the specific constellation point used within the shells selected for the eight successive QAM symbols, and the remaining 16 bits map to the 2^{16}th lowest-energy combinations of shells for the block. The total rate per eight symbols is thus $32 + 16 = 48$, for an average rate of 6 bits per QAM symbol. Shell mapping is a mathematical algorithm that efficiently identifies and indexes the lowest-energy sets of shells in a block of several successive QAM symbols using a technique based on combinatorics, generating functions, and finite-field algebra.

2. SHELL MAPPING

Shell mapping provides an efficient way to index lattice points inside a regular solid (such as a hypersphere or a hyperdiamond). It was first used in reducing the average power of QAM-based modems, in which it divides a QAM constellation into concentric rings with equal areas. A certain number of input bits are used to select the rings from which the constellation points will be chosen. A method due to Laroia [3] is used in the V.34 modems. We present a general version of this algorithm from a combinatorial viewpoint.

We use superscript $^{(N)}$ to indicate the dimension of a particular quantity. (The superscript may be suppressed if the dimension is 1.) Bold face represents a vector or a collection of lower-dimensional quantities. A subscript is used to differentiate different quantities of the same dimensionality. For example, the ith ring index is denoted as s_i [or $s_i^{(1)}$], and the N-element combination is denoted as $\mathbf{s}^{(N)} = (s_1, s_2, \ldots, s_N)$.

2.1. Generating Function

In combinatorics [4,5], a generating function is defined as a formal series

$$g(x) = a_0 + a_1 x + \cdots + a_N x^N \tag{1}$$

Generating functions are often used to solve problems involving a collection of objects with costs. We illustrate the method of generating functions with an example.

Example 1. How many ways are there to add three integers from the set of $\{0, 1, 2, 3\}$ such that the sum equals C? To solve this via the generating function, we first define

$$g^{(1)}(x) = 1 + x + x^2 + x^3 \tag{2}$$

The power of each coefficient represents the value of the first number. Then, $g^{(3)}(x) = [g^{(1)}(x)]^3 = 1 + 3x + 6x^2 + 10x^3 + 12x^4 + 12x^5 + 10x^6 + 6x^7 + 3x^8 + x^9$ represents the generating function of the three-integer sum. There is one three-integer combination that adds up to 0 (or 9), three combinations that add up to 1 (or 8), and so on. Table 1 lists the combinations that result in those costs and the corresponding terms in the generating function.

The exponent of the terms indicates the *cost* of selecting a certain object, and the coefficients of the terms denote the *number* of combinations that achieve a particular cost. To compute the N-element generating function, one simply multiplies the generating polynomial N times and locates the coefficient for the term representing the desired cost.

Table 1. Each Term in the Generating Function and Its Associated Inputs and Outputs

Terms in $g^{(3)}(x)$	Combinations
1	(0, 0, 0)
$3x$	(1, 0, 0), (0, 1, 0), (0, 0, 1)
$6x^2$	(1, 1, 0), (0, 1, 1), (1, 0, 1), (2, 0, 0), (0, 2, 0), (0, 0, 2)
$10x^3$	(1, 1, 1), (2, 1, 0), (2, 0, 1), (0, 2, 1), (1, 2, 0), (0, 1, 2), (1, 0, 2), (3, 0, 0), (0, 3, 0), (0, 0, 3)
$12x^4$	(0, 1, 3), (0, 3, 1), (3, 0, 1), (1, 1, 2), (1, 2, 1), (2, 1, 1), (1, 0, 3), (1, 3, 0), (3, 1, 0), (2, 2, 0), (2, 0, 2), (0, 2, 2)
$12x^5$	(3, 2, 0), (3, 0, 2), (0, 3, 2), (2, 2, 1), (2, 1, 2), (1, 2, 2), (2, 3, 0), (2, 0, 3), (0, 2, 3), (1, 1, 3), (1, 3, 1), (3, 1, 1)
$10x^6$	(2, 2, 2), (1, 2, 3), (1, 3, 2), (2, 1, 3), (2, 3, 1), (3, 1, 2), (3, 2, 1), (3, 3, 0), (3, 0, 3), (0, 3, 3)
$6x^7$	(3, 3, 1), (3, 1, 3), (1, 3, 3), (3, 2, 2), (2, 3, 2), (2, 2, 3)
$3x^8$	(3, 3, 2), (3, 2, 3), (2, 3, 3)
x^9	(3, 3, 3)

2.2. Indexing Algorithm for Sets with Integral Summable Cost

The method of generating functions has been used to solve numerous counting problems. However, for this article, we focus on a specific class of problems.

Let S be a set of objects. Let each element $s \in S$ have an integral cost of $|s|$. Denote the cost of an N-element combination, $\mathbf{s}^{(N)} = (s_1 \cdots s_N) \in S^N$, as

$$|\mathbf{s}^{(N)}| = \sum_{i=1}^{N} |s_i| \tag{3}$$

It is important that the cost of an element take on integral values and that the cost of an N-element combination be the sum of the cost of individual elements. Equation (3) has the same form as the l_1-norm and often leads to geometrical interpretation.

Example 2. In the previous example, $S = \{0, 1, 2, 3\}$ and $|s| = s$. Therefore

$$|\mathbf{s}^{(N)}| = \sum_{i=1}^{N} |s_i| = \|\mathbf{s}^{(N)}\|_1 \tag{4}$$

Graphically, $\|\mathbf{s}^{(N)}\|_1 = c$ depicts a hyperplane in the all-positive quadrant.[1] We denote

$$S_c^{(N)} = \{\mathbf{s}^{(N)} \in S^N : |\mathbf{s}^{(N)}| = c\} \tag{5}$$

We illustrate the first four hyperplanes, $S_0^{(3)}$, $S_1^{(3)}$, $S_2^{(3)}$, and $S_3^{(3)}$, with the lattice points that belong to each hyperplane shown in Fig. 3. The lattice points on $S_c^{(3)}$ represent three-integer combinations that sum up to c. Each layer corresponds to a term in $g^{(3)}(x)$.

We assume that it is desirable to select N-element combinations within a certain range of costs. From this point on, we assume (without loss of generality) that the cost is nonnegative. This assumption implies that the generating functions will consist only of terms x^n where $n \in \{0\} \cup \mathbb{Z}^+$.

[1] Strictly speaking, the set defined is not a hyperplane, but rather a set of lattice points that lie on a common hyperplane. Throughout this article; however, we loosely use the term "hyperplane" to denote a set of lattice points on a common hyperplane.

2.3. Counting the Sets

First, we count the number of combinations that satisfy the cost constraint. To that end, we define the one-element generating function

$$g^{(1)}(x) = \sum_{i=\min_{s\in S}|s|}^{\max_{s\in S}|s|} a_i x^i \tag{6}$$

where a_i represents the number of elements in S that have the cost of i. Next, we compute the N-element generating function

$$g^{(N)}(x) = [g^{(1)}(x)]^N = \sum_i a_i^{(N)} x^i \tag{7}$$

where $a_i^{(N)}$ represents the number of N-element combinations in S^N that have the cost of i. To seek the number of combinations within a cost range, we can sum the coefficients over the range $C_l \le |\mathbf{s}^{(N)}| \le C_h$ as

$$K = \sum_{i=C_l}^{C_h} a_i^{(N)} \tag{8}$$

2.4. Mapping Algorithm

A mapping procedure from an input value to an N-element combination is needed in an actual communication system. Suppose that there are K N-element combinations that satisfy the cost constraint. Let R be an input integer from the set $I^{(N)} = \{i \in \mathbb{Z} : 0 \le i < K\}$, and let the set of the K N-element combinations be $S^{(N)} = \{\mathbf{s} \in S^N : C_l \le |\mathbf{s}| \le C_h\}$. The goal is to find a bijective mapping, $\mathbf{f} : I^{(N)} \to S^{(N)}$. The basic approach is to decompose the N-dimensional problem into multiple lower-dimensional problems. Specifically, Laroia [3] provides a way to decompose the N-dimensional problem into two $\frac{N}{2}$-dimensional problems and another way to decompose the problem into a 1D (one-dimensional) problem and an $(N-1)$-dimensional problem. Arbitrary decompositions

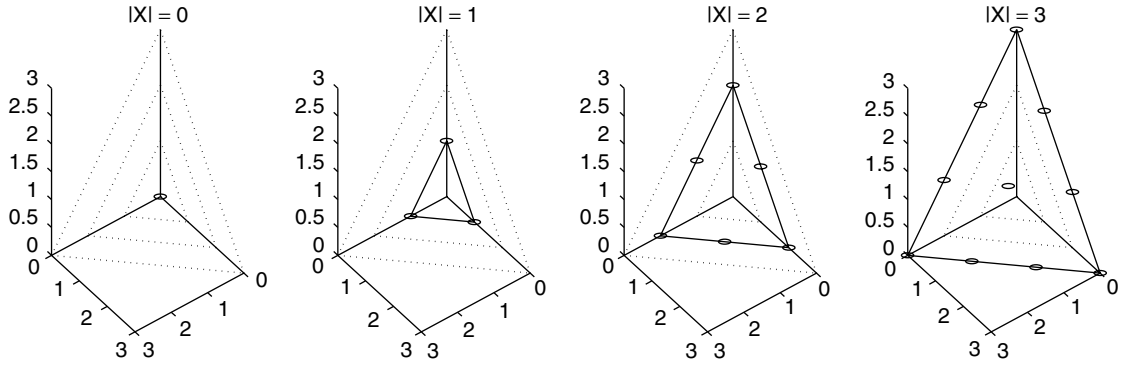

Figure 3. The layering of the generating function.

offering different trade-offs between computational cost and memory requirements can be found in Ref. 6.

2.5. Identifying the Cost of the Combination

First, we partition $S^{(N)}$ into a set of hyperplanes, $\{S_c^{(N)}\}_{c=C_l}^{C_h}$. Since these hyperplanes are parallel, they are also disjoint.[2] Thus, the $S^{(N)}$ set is partitioned into

$$S^{(N)} = S_{C_l}^{(N)} \cup S_{C_l+1}^{(N)} \cup \cdots \cup S_{C_h}^{(N)} \tag{9}$$

Next, we associate ranges of integers from $I^{(N)}$ to these N-dimensional hyperplanes. This is done by successively assigning the set of $a_c^{(N)}$ lowest available input integers in $I^{(N)}$ to the hyperplane of cost c, $S_c^{(N)}$. At the end of this process, we associate each input $R \in I^{(N)}$ to one of the $S_c^{(N)}$. If the input R is associated with $S_c^{(N)}$, we define the N-D *cost* of the input R as

$$C^{(N)} \triangleq |\mathbf{f}(R)| = c \tag{10}$$

This is called the N-dimensional cost because all N-element combinations $\mathbf{s}^{(N)}$ from this hyperplane have the cost $|\mathbf{s}^{(N)}|$ of $C^{(N)}$. Next, we partition the input set into

$$I_c^{(N)} = \{r \in I^{(N)} : \mathbf{f}(r) \in S_i^{(N)}\} \tag{11}$$

In other words, $I_c^{(N)}$ is the subset $I^{(N)}$ that is associated with $S_c^{(N)}$. Since each input is associated to only one hyperplane, the collection of $I_c^{(N)}$'s is disjoint, and we can write

$$I^{(N)} = \cup_c I_c^{(N)} \tag{12}$$

From the example above, it is easy to see that each $I_c^{(N)}$ consists of a range of consecutive integers. We define the N-dimensional *residue* as

$$R^{(N)} = R - \min I_{C^{(N)}}^{(N)} \tag{13}$$

Physically, $R^{(N)}$ uniquely indices a combination in $S_{C^{(N)}}^{(N)}$. (The uniqueness can be shown from the fact that $0 \le R^{(N)} < a_{C^{(N)}}^{(N)}$.) So far, we have created a mapping $(g_c, g_s) : I^{(N)} \to \mathbb{Z} \times \mathbb{Z}$ that maps an input to an N-dimensional cost and an N-dimensional residue. The cost selects the hyperplane $S_{C^{(N)}}^{(N)}$, and the residue points to an N-element combination in $S_{C^{(N)}}^{(N)}$.

Example 3. From Example 2, we have $N = 3$, $S = \{0, 1, 2, 3\}$, $|s| = s$, $C_l = 0$, and $C_h = 3$. Also, let the input $R = 14$. We have

$$K = \sum_{i=C_l}^{C_h} a_i^{(N)} = \sum_{i=0}^{3} a_i^{(3)} \tag{14}$$

$$= \begin{array}{ccccccc} 1 & + & 3 & + & 6 & + & 10 \\ \updownarrow & & \updownarrow & & \updownarrow & & \updownarrow \\ x^0 & & x^1 & & x^2 & & x^3 \end{array} \tag{15}$$

$$= 20 \tag{16}$$

[2] Again, what we mean here is that since the two sets lie on two parallel hyperplanes, there is no element that belongs to both sets.

We associate the range of input to the subset of outputs as

$$\begin{aligned} I_0^{(3)} &= \{0\} \to S_0^{(3)} \\ I_1^{(3)} &= \{1, 2, 3\} \to S_1^{(3)} \\ I_2^{(3)} &= \{4, 5, \ldots, 9\} \to S_2^{(3)} \\ I_3^{(3)} &= \{10, 11, \ldots, 19\} \to S_3^{(3)} \end{aligned} \tag{17}$$

From (17), we find that $R = 14$ belongs to the range of 10–19. This means $C^{(3)} = 3$ and $R^{(3)} = 14 - 10 = 4$ [or we are now considering the fifth combination in the hyperplane of $|\mathbf{s}^{(3)}| = C^{(3)} = 3$; see Fig. 3].

2.6. Decomposition of the Problem

We decompose the N-dimensional problem into a P-dimensional problem and a Q-dimensional problem. The idea is to split $(C^{(N)}, R^{(N)})$ into $(C^{(P)}, R^{(P)})$, and $(C^{(Q)}, R^{(Q)})$. The obvious constraint is that $P + Q = N$.

Now, we perform the actual decomposition of the problem. We break up the N-dimensional hyperplane into the union of a collection of Cartesian product sets of P-dimensional and Q-dimensional hyperplanes, where $Q = N - P$.[3] For $\forall c \in \mathbb{Z}$, we can write

$$\begin{aligned} S_c^{(N)} &= (S_0^{(P)} \times S_c^{(Q)}) \cup (S_1^{(P)} \times S_{c-1}^{(Q)}) \cup \cdots \cup (S_c^{(P)} \times S_0^{(Q)}) \\ &= \bigcup_{i=0}^{c} (S_i^{(P)} \times S_{c-i}^{(Q)}) \end{aligned} \tag{18}$$

Since all product sets on the right side are disjoint, we can relate the size of these sets as follows:

$$\begin{aligned} |S_c^{(N)}| &= |S_0^{(P)}| \cdot |S_c^{(Q)}| + |S_1^{(P)}| \cdot |S_{c-1}^{(Q)}| + \cdots + |S_c^{(P)}| \cdot |S_0^{(Q)}| \\ &= \sum_{i=0}^{c} |S_i^{(P)}| \cdot |S_{c-i}^{(Q)}| \end{aligned} \tag{19}$$

We may also reach the following conclusion by noting that $a_i^{(n)} = |S_i^{(n)}|$ and

$$a_c^{(N)} = \sum_{i=0}^{c} a_i^{(P)} a_{c-i}^{(Q)} \tag{20}$$

In other words, (19) simply states the rule for evaluating the coefficients of $g^{(N)}(x)$ from the coefficients of $g^{(P)}(x)$ and $g^{(Q)}(x)$. Now, we partition the hyperplane $S_c^{(N)}$ into a collection of Cartesian product sets of lower-dimensional hyperplanes. Meanwhile, we partition the corresponding input range, $I_c^{(N)}$, similar to the way described above. The $|S_0^{(P)} \times S_c^{(Q)}| = |S_i^{(P)}| \cdot |S_{c-i}^{(Q)}|$ lowest available integers in $I_c^{(N)}$ are assigned to the Cartesian-product set, $S_i^{(P)} \times S_{c-i}^{(Q)}$. This range of input is denoted as $I_{i,c-i}^{(N)}$. Once again, we have

$$I_c^{(N)} = \bigcup_{i=0}^{c} I_{i,c-i}^{(N)} \tag{21}$$

[3] As mentioned earlier, usually $P = N - P = N/2$. However, for the sake of visual illustration, we choose N to be 3, which is not a power of 2. The shell mapper still operates properly; however, it is less efficient.

Once we decide that an input R is within $I^{(N)}_{i,C^{(N)}-i}$ and is associated with $S^{(P)}_i \times S^{(Q)}_{C^{(N)}-i}$, we have split the cost into

$$C^{(P)} = |\mathbf{s}^{(P)}| = i \tag{22}$$

$$C^{(Q)} = |s^{(Q)}| = C^{(N)} - i \tag{23}$$

In addition, we need to adjust the residue so that it now indexes a combination in $S^{(P)}_i \times S^{(Q)}_{C^{(N)}-i}$ instead of $S^{(N)}_{C^{(N)}}$. This is done by subtracting from $R^{(N)}$ the smallest value in $Z^{(N)}_{i,C^{(N)}-i}$. Now a residue of 0 indicates the first combination in $S^{(P)}_i \times S^{(Q)}_{c-i}$. We denote the new residue as

$$R^{(N)}_{i,c-i} = R^{(N)} - (\min I^{(N)}_{i,c-i} - \min I^{(N)}_c) = R - \min I^{(N)}_{i,c-i} \tag{24}$$

where $c = C^{(N)}$ in our specific case.

Example 4. Continuing with our previous example of $S = \{0, 1, 2, 3\}$, $N = 3$, $C_l = 0$, $C_h = 3$, $K = 20$, and $R = 14$, recall that $(C^{(3)}, R^{(3)}) = (3, 4)$. We now search for the Cartesian product set with which the input is associated. Let $P = 2$, and $Q = N - P = 1$. We associate the input range $I^{(3)}$ to the Cartesian product sets as

$$\begin{aligned} I^{(3)}_{0,3} &= \{10\} \rightarrow S^{(2)}_0 \times S^{(1)}_3 \\ I^{(3)}_{1,2} &= \{11, 12\} \rightarrow S^{(2)}_1 \times S^{(1)}_2 \\ I^{(3)}_{2,1} &= \{13, 14, 15\} \rightarrow S^{(2)}_2 \times S^{(1)}_1 \\ I^{(3)}_{3,0} &= \{16, 17, 18, 19\} \rightarrow S^{(2)}_3 \times S^{(1)}_0 \end{aligned} \tag{25}$$

We search in the following order: $S^{(2)}_0 \times S^{(1)}_3$, $S^{(2)}_1 \times S^{(1)}_2$, and then $S^{(2)}_2 \times S^{(1)}_1$. The search sequence is graphically depicted in Fig. 4. We find that $R = 14$ belongs to $I^{(3)}_{2,1}$. Thus, the two costs are $C^{(2)} = 2$, $C^{(1)}_3 = 1$.

In order to complete the decomposition into two lower-dimensional problems, we need two residues, $R^{(P)}$ and $R^{(Q)}$, for the two costs, $C^{(P)}$ and $C^{(Q)}$. Observe that there are several constraints. First, $R^{(P)}$ (or $R^{(Q)}$) is an index to a P-element (or Q-element) combination in $S^{(P)}_{C^{(P)}}$ (or $S^{(Q)}_{C^{(Q)}}$). Thus, $R^{(P)}$ and $R^{(Q)}$ must satisfy the following inequalities:

$$0 \le R^{(P)} < |S^{(P)}_{C^{(P)}}| \tag{26}$$

$$0 \le R^{(Q)} < |S^{(Q)}_{C^{(Q)}}| \tag{27}$$

In addition, the mapping of $|S^{(P)}_{C^{(P)}}| \cdot |S^{(Q)}_{C^{(Q)}}|$ values of $R^{(N)}_{C^{(P)},C^{(Q)}}$ to $(R^{(P)}, R^{(Q)})$ must be bijective. One such mapping is

$$\mathbf{g}_{|S^{(P)}_{C^{(P)}}|}(R^{(N)}) = \left(R^{(N)}_{C^{(P)},C^{(Q)}} \bmod |S^{(P)}_{C^{(P)}}|, \left\lfloor \frac{R^{(N)}_{C^{(P)},C^{(Q)}}}{|S^{(P)}_{C^{(P)}}|} \right\rfloor \right) \tag{28}$$

This is the same as arranging the $|S^{(P)}_{C^{(P)}}| \cdot |S^{(Q)}_{C^{(Q)}}|$ values of $R^{(N)}$ into an $|S^{(P)}_{C^{(P)}}|$-column $\times$ $|S^{(Q)}_{C^{(Q)}}|$-row array. Then, the column and row index of each array element are taken as $R^{(P)}_1$ and $R^{(Q)}$, respectively. Now, we have transformed $(C^{(N)}, R^{(N)})$ into $(C^{(P)}, R^{(P)})$ and $(C^{(Q)}, C^{(Q)})$. We may recursively apply the procedure to each cost–residue pair. Eventually, the dimension of the cost (and residue) will become 1. If $a^{(1)}_{C^{(1)}} = 1$, we are guaranteed that $R^{(1)} = 0$, signifying the first (and only) element in S with the cost $C^{(1)}$. If $a^{(1)}_{C^{(1)}} > 1$, it is possible that $R^{(1)} > 0$. In that case, we must resort to a lookup table to find the specific element in S.

Example 5. To conclude this section, we finish the shell mapping of the input $R = 14$. Note that $R = 14$ is the second combination ($R^{(3)}_{C^{(2)},C^{(1)}} = 1$) in $S^{(2)}_{C^{(2)}} \times S^{(1)}_{C^{(1)}}$, so the lower-dimensional residues should be

$$R^{(2)} = 1 \bmod 3 = 1 \tag{29}$$

$$R^{(1)} = \lfloor \tfrac{1}{3} \rfloor = 0 \tag{30}$$

We perform the same decomposition procedure on the cost-residue pair of $(C^{(2)}, R^{(2)}) = (2, 2)$. We know that $S^{(2)}_{C^{(2)}} = S^{(2)}_2 = (S^{(1)}_0 \times S^{(1)}_2) \cup (S^{(1)}_1 \times S^{(1)}_1) \cup (S^{(1)}_2 \times S^{(1)}_0)$. Since $S^{(1)}_i$ is a simple point in one dimension, $S^{(1)}_i \times S^{(1)}_j$ is a 2D point. We can also derive this fact from $|S^{(1)}_i \times S^{(1)}_j| = |S^{(1)}_i| \cdot |S^{(1)}_j| = 1 \cdot 1 = 1$. In addition, we know from the generating function $g^{(2)}(x)$ that $|S^{(2)}_{C^{(2)}}| = 3$. On the other hand, from Eq. (19), we have

$$\begin{aligned} |S^{(2)}_{C^{(2)}}| &= |S^{(1)}_0 \times S^{(1)}_2| + |S^{(1)}_1 \times S^{(1)}_1| + |S^{(1)}_2 \times S^{(1)}_0| \\ &= |S^{(1)}_0| \cdot |S^{(1)}_2| + |S^{(1)}_1| \cdot |S^{(1)}_1| + |S^{(1)}_2| \cdot |S^{(1)}_0| \\ &= 1 + 1 + 1 = 3 \end{aligned} \tag{31}$$

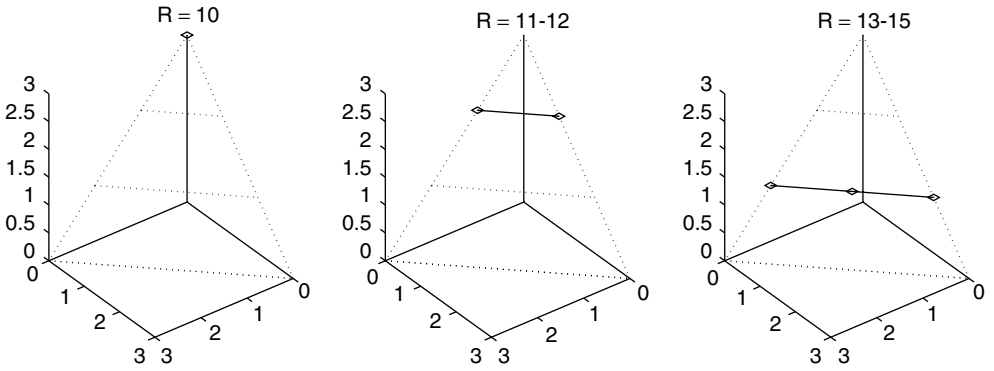

Figure 4. Decomposition of $S^{(3)}_3$ into a collection of Cartesian-product sets.

The corresponding input partitioning is

$$\begin{aligned} I_{0,2}^{(2)} &= \{13\} \rightarrow S_0^{(1)} \times S_2^{(1)} \\ I_{1,1}^{(2)} &= \{14\} \rightarrow S_1^{(1)} \times S_1^{(1)} \\ I_{2,0}^{(2)} &= \{15\} \rightarrow S_2^{(1)} \times S_0^{(1)} \end{aligned} \tag{32}$$

Thus, we have three Cartesian product sets, each with only one element. Since we are seeking the second combination ($R^{(2)} = 1$), we split the 2D cost $C^{(2)}$ into

$$C_1^{(1)} = 1 \tag{33}$$

$$C_2^{(1)} = 2 - 1 = 1 \tag{34}$$

The residue $R^{(2)}$ is reduced to

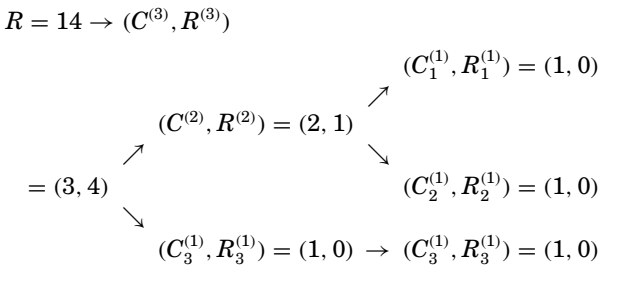
$$\begin{aligned} R_{1,1}^{(2)} &= R^{(2)} - (\min I_{1,1}^{(2)} - \min I_2^{(2)}) \\ &= 1 - (14 - 13) = 0 \end{aligned} \tag{35}$$

$$R_1^{(1)} = R_{1,1}^{(2)} \bmod |S_1^{(1)}| = 0 \bmod 1 = 0 \tag{36}$$

$$R_2^{(1)} = \left\lfloor \frac{R_{1,1}^{(2)}}{|S_1^{(1)}|} \right\rfloor = \left\lfloor \frac{0}{1} \right\rfloor = 0 \tag{37}$$

The final cost-residue pairs are $(C_1^{(1)}, R_1^{(1)}) = (1, 0)$, $(C_2^{(1)}, R_2^{(1)}) = (1, 0)$, and $(C_3^{(1)}, R_3^{(3)}) = (1, 0)$. We may now find the elements that correspond to each cost-residue pair. For example, we need to find the first combination with the cost of 1 for $(C_1^{(1)}, R_1^{(1)})$. Coincidentally, the elements have the same value as the costs. Now, the three 1D costs form the final combination $\mathbf{s}^{(3)} = (C_1^{(1)}, C_2^{(1)}, C_3^{(1)}) = (1, 1, 1)$. The answer is verified graphically in Fig. 5.

The decomposition results in a tree diagram as



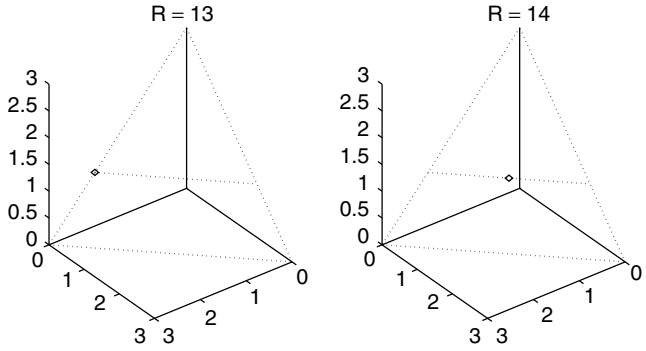


Figure 5. Decomposition of $S_2^{(2)}$ into individual lattice points. The final answer is $s^{(3)} = (1, 1, 1)$.

Note that at each column all costs sum up to 3 ($3 = 2 + 1 = 1 + 1 + 1$). Algebraically, this is equivalent to the decomposition of $g^{(3)}(x) \rightarrow g^{(2)}(x) \cdot g^{(1)}(x) \rightarrow g^{(1)}(x) \cdot g^{(1)}(x) \cdot g^{(1)}(x)$.

2.7. Demapping Algorithm

The demapping operation is the inverse operation of the mapping process. We solve for the inverse of each step and reverse the order of the steps. It is simpler than the mapping process in the sense that there is no need to search for the proper-cost decomposition.

First, given a vector $\mathbf{s}^{(N)} = (s_1 \cdots s_N)$, we find (usually via lookup tables) $\{(C_i^{(1)}, R_i^{(1)})\}_{i=1}^{N}$ such that s_i is the $(R_i^{(1)} + 1)$-th element in S with a cost of $C_i^{(1)}$. Next, for each pair of cost–residue pairs, $(C^{(P)}, R^{(P)})$ and $(C^{(Q)}, R^{(Q)})$, we combine the costs by

$$C^{(P+Q)} = C^{(P)} + C^{(Q)} \tag{38}$$

and the residues by

$$R_{C^{(P)}, C^{(Q)}}^{(P+Q)} = |S_{C^{(P)}}^{(P)}| R^{(Q)} + R^{(P)} \tag{39}$$

$$R^{(P+Q)} = R_{C^{(P)}, C^{(Q)}}^{(P+Q)} + (\min I_{C^{(P)}, C^{(Q)}}^{(P+Q)} - \min I_{C^{(P+Q)}}^{(P+Q)}) \tag{40}$$

We repeatedly apply this procedure until we combine all cost–residue pairs to one pair: $(C^{(N)}, R^{(N)})$. Then, the original index can be recovered by

$$R = \sum_{i=0}^{C^{(N)}} g^{(N)}(i) + R^{(N)} \tag{41}$$

3. APPLICATION AND PRACTICAL CONSIDERATION

Shell mapping can be applied in situations in which the cost (i.e., energy in the case of constellation shaping) per ring is proportional to the ring index and the total cost is the sum of the individual ring costs. This is nearly exact for large-QAM constellations subdivided into many rings. The shaping gain from shell mapping tends to improve as the number of rings increases, thereby reducing the number of symbols in each ring. However, the complexity and cost of shell mapping also increases with the number of rings, so practical systems make a judicious trade-off between the accuracy of the approximation and the number of rings. For example, the V.34 modem standard uses 8 rings of QAM symbols to create a 16-dimensional-shaped constellation. Each QAM symbol is divided into as many as 16 rings from a constellation as large as 1664-QAM.

The maximal shaping gain is obtained asymptotically as the number of dimensions grows arbitrarily large. However, the complexity of the shell mapping algorithm also grows with the dimension, so practical systems select a moderate block size. For example, the V.34 modem uses 16-dimensional blocks; larger block sizes provide incremental performance benefits at the cost of rapidly increasing complexity.

Shell mapping reduces the average energy of a block of QAM symbols by using only the 2^b combinations of

rings with the lowest total energies over the block. For instance, it would not use the high-energy constellation points for every QAM symbol in a single block. To provide the freedom to reject high-energy combinations of symbols, at least a modest overdeterminacy in the individual QAM constellations is required. For example, if a data rate of 8 bits per QAM symbol is desired, a shell-mapped QAM constellation of more than 256 points is required to support shaping. The larger constellation increases both complexity and the peak-to-average power ratio, however, so some compromise between expansion and reduced shaping gain is generally made. Factors of 1.2–1.5 times the base size are usually sufficient to realize most of the available shaping gain.

The ITU V.34 modem standard includes shell mapping. It uses eight successive QAM symbols to create a 16-dimensional-shaped constellation. Each QAM symbol is divided into as many as 16 rings from a base constellation as large as 1664-QAM. The incoming bit stream is segmented into blocks of bits. Within each block, a portion are used for the trellis coder. The output selects one of four QAM constellations. Some bits are sent to the shell mapper, which yields eight ring indices. The remaining bits are used to select the actual constellation points within each ring.

BIOGRAPHY

Douglas L. Jones received th B.S.E.E., M.S.E.E., and Ph.D. degrees from Rice University in 1983, 1985, and 1987, respectively. During the 1987–1988 academic year, he was at the University of Erlangen — Nuremberg in Germany on a Fulbright postdoctoral fellowship. Since 1988, he has been with the University of Illinois at Urbana — Champaign, where he is currently a Professor in Electrical and Computer Engineering, the Coordinated Science Laboratory, and the Beckman Institute. In the Spring semester of 1999 he served as the Texas Instruments Visiting Professor at Rice University. He is an author of the laboratory textbook *A Digital Signal Processing Laboratory Using the TMS32010*, over 150 conference and journal publications, and several patents. His research interests are in digital signal processing and communications, including nonstationary signal analysis, adaptive processing, multisensor data processing, OFDM, and various applications such as advanced hearing aids.

SIGMA-DELTA CONVERTERS IN COMMUNICATION SYSTEMS

FRED HARRIS
San Diego State University
San Diego, California

1. THE WHY OF SIGMA-DELTA CONVERTERS

Correlation between a sequence of sample values can be used to quantize, to a specified fidelity, a signal with significantly fewer bits per sample than that required by an instantaneous quantizer. The sigma-delta (Σ-Δ) converter uses feedback to shape the quantizing noise spectrum of an oversampled low-resolution quantizer to obtain low levels of in-band noise in exchange for higher levels of out-of-band-noise. In effect, the quantizer arranges for the quantizing noise spectrum and input signal spectrum to occupy nearly distinct spectral regions. Filtering that rejects the out-of-band-shaped quantizing noise converts the signal correlation to additional bits by the ratio of coherent gain to incoherent gain of the filtering process.

A major application of the sigma-delta process is in the area of analog-to-digital conversion, particularly in the conversion of audio signals, of instrumentation signals, and modem input signals. High-performance converters operating with 1-bit quantizers at an input rate 64 times the desired output rate of 100 kHz can supply 24-bit samples with 120 dB SNR (signal-to-noise ratio). The second major application of the Σ-Δ process has been in the area of digital-to-analog conversion for audio signals, control signals, and modem output signals. It is standard practice to use multirate digital filters to raise the sample rate of a 16-bit sampled data signal by a factor of 64, say, from 48 kHz to 3.072 MHz, then convert the 16-bit data samples to 1-bit data samples with a digital Σ-Δ converter, which is then presented to a 1-bit DAC for conversion to an analog signal.

The enhanced analog-to-digital conversion application uses analog sampled data components in the Σ-Δ modulator. These are implemented with switched capacitor or continuous-time integrators, a pair of low-resolution A-to-D (A/D) and D-to-A (D/A) converters in the feedforward–feedback path, and digital filters to reduce noise bandwidth and signal sample rate. By way of comparison, the enhanced D/A conversion application uses standard digital signal processing blocks in its Σ-Δ modulator. It also uses standard DSP blocks to raise the sample rate, a single low-resolution D/A converter to form an analog signal, and analog filters to reduce the noise bandwidth.

The third major application of the Σ-Δ process is in the area of digital-to-digital (D/D) conversion. In this

application, the input signal, collected and quantized with a conventional A/D, is pre-processed with a digital Σ-Δ to reduce the number of bits required to represent the signal in the bandwidth to be extracted by subsequent processing. The Σ-Δ modulator shapes the quantizing noise spectrum to preserve low noise levels over the frequency span of the passband while permitting significant increase of noise level in the frequency span of the stopband of the subsequent digital filter. Processing resources, such as multiplier widths required to implement digital filters after the digital Σ-Δ modulator, are reduced considerably. Reduction in data bit width from 16 to 4 bits can convert filter multipliers to lookup tables for FPGA implementations, while reductions from 16 bits to 1 bit permits arbitrary FIR filtering with no multipliers at all.

Processing flow diagrams matching the three applications we have described are shown in Fig. 1. The material covered in the remainder of this presentation will be

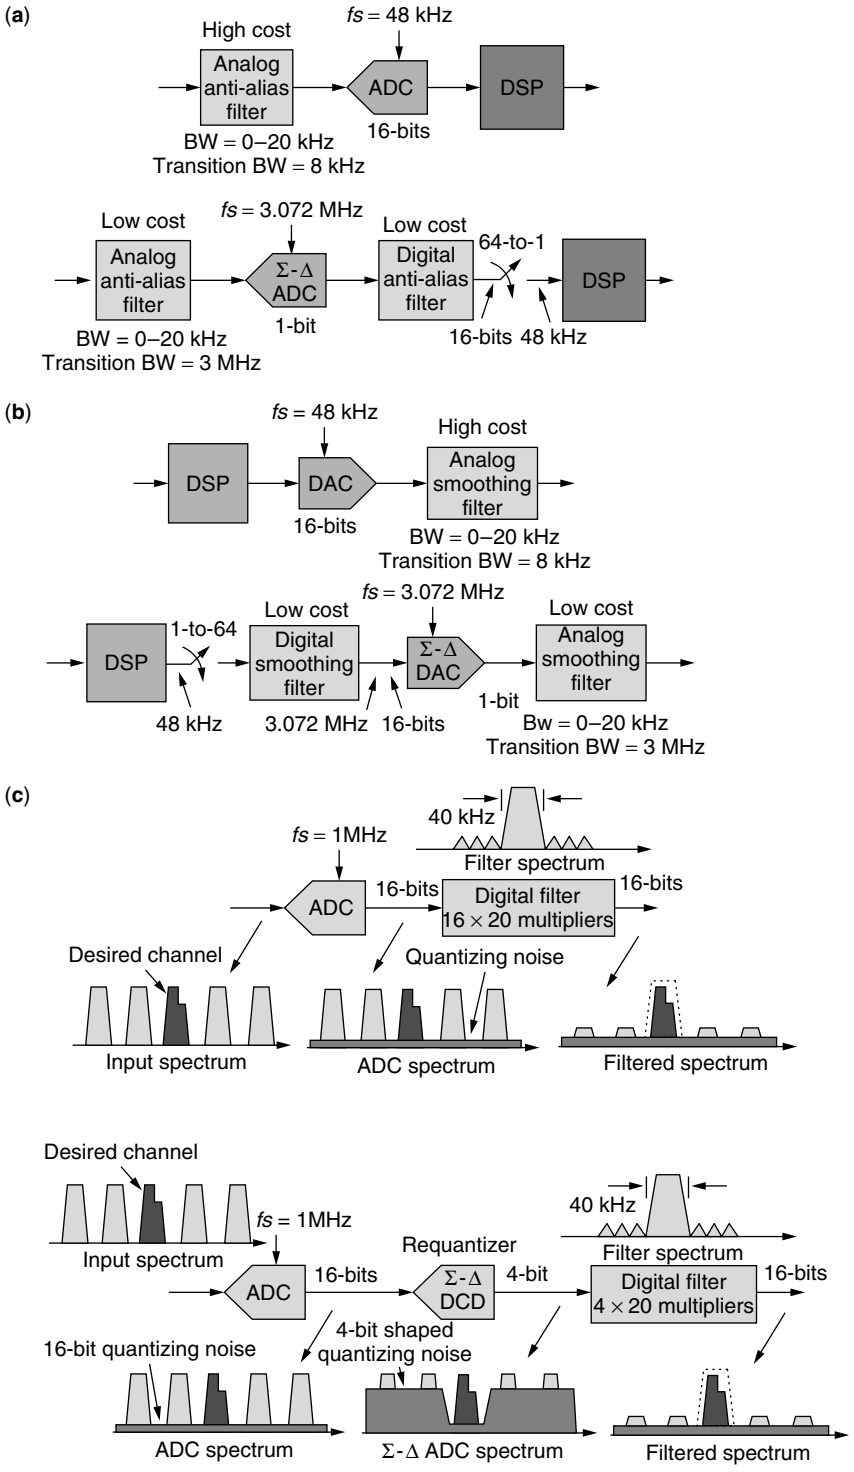

Figure 1. (**a**) A/D conversion with memoryless converter compared to oversampled sigma-delta A/D modulator with low-cost digital filter; (**b**) D/A conversion with memoryless converter compared to low-cost digital filter with oversampled sigma-delta D/A modulator; (**c**) digital signal processing of sampled data with full-bandwidth A/D conversion compared to processing with sigma-delta preprocessed bandwidth-limited data.

generic descriptions of the Σ-Δ process without regard to implementation. Applications presented near the end of this article will emphasize the third application, with use of the all-DSP digital-to-digital process in communication systems.

2. BACKGROUND

We start by reviewing the model of the ideal amplitude quantizer that performs instantaneous mapping from input amplitude x to output amplitude x_q in accord with a specified input–output profile $x_q = Q(x)$. As shown in Eq. (1) and in Fig. 2, the difference between the input and output of the quantizer represents an error, and to control the size of this error, the profile should be close to the errorless profile $x_q = x$, the unit slope line through the origin.

$$x_q = Q(x)$$
$$e_q = Q(x) - x = x_q - x \tag{1}$$

The quantization profile, reminiscent of a staircase, is defined by the locations of its treads and risers. Figure 2 shows the nonlinear mapping profile and the error profile of a uniform quantizer, one exhibiting equally spaced treads and risers. Such a quantizer is described as being a uniform or, paradoxically, a linear quantizer.

Note from the error profile that the quantization error is a deterministic and nonlinear function of the input signal level with a known error for a known input. A linear model of the quantizer is that of a zero-mean, independent, uniformly distributed, white-noise source added to each input sample. Both models are shown in Fig. 3. The linear model is often substituted for the nonlinear model for ease of analysis. In our subsequent discussions, we make this substitution with the awareness that this may a poor representation of the quantizing noise when the number of output levels is less than 16, or when the input samples are highly correlated. These are precisely the conditions we encounter in the Σ-Δ process. It is for this reason that simple linear analysis of a Σ-Δ system does not predict nonlinear modes of behavior, which we discuss in a later section.

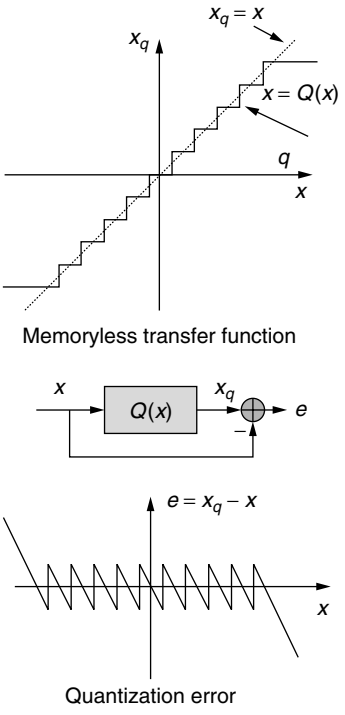

Figure 2. Quantization profile and error profile for uniform quantizer.

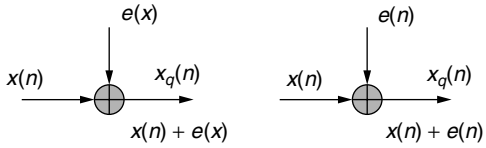

Figure 3. Nonlinear model and linear additive model of quantizer.

The noise in the linear additive noise model of the quantizer is uniformly distributed over a quantile interval of width q, from which we can compute the mean-square quantizing noise as shown in Eq. (2) to be $q^2/12$. We can similarly identify the mean-square level of the signal component at the quantizer output for any input amplitude distribution. The simplest such distribution is uniform over the range of $-Mq$ to $+Mq$, where M is the maximum number of positive and negative quantile increments. The mean-square signal level for this distribution is shown in Eq. (3) to be $(2Mq)^2/12$:

$$\sigma_q^2 = \int_{-q/2}^{+q/2} e^2 f_q(e)\, de = \frac{1}{q}\int_{-q/2}^{+q/2} e^2\, de = \frac{q^2}{12} \tag{2}$$

$$\sigma_s^2 = \int_{-Mq}^{+Mq} s^2 f_s(s)\, ds = \frac{1}{2Mq}\int_{-Mq}^{+Mq} s^2\, ds = \frac{(2M)^2 q^2}{12} \tag{3}$$

The signal : quantizing noise ratio of the quantizer is shown in Eq. (4) to be $(2M)^2$. Equation (4) also shows that when we replace $2M$, the number of levels in a quantizer with a power of 2 of the form 2^b, the SNR is 2^{2b}. Finally we see that the SNR in decibels is seen to be $6b$ dB, from which we obtain the standard quantizer rule of 6 dB per bit. The SNR of a quantizer, for any input amplitude distribution, is of the form shown in Eq. (5), where the offset factor $K_{\text{density}}(\sigma^2)$, is a parameter that varies with amplitude density and signal variance. K_{density} is negative for most densities and becomes more so as we decrease the input signal variance relative to quantizer dynamic range.

The primary message presented by Eq. (5) is that quantizer fidelity or SNR can be purchased with a linear quantizer by increasing the number of bits involved in the quantization process. The first rule of quantizing is: "If you want a higher fidelity representation of the signal, get more bits." In the next section we derive a corollary to this rule: "If you can't get more bits, get correlated samples and convert them to more bits."

$$\text{SNR} = \frac{\sigma_s^2}{\sigma_q^2} = \frac{(2M)^2 q^2/12}{q^2/12} = (2M)^2 = (2^b)^2 = 2^{2b}$$

$$\begin{aligned}\mathrm{SNR}_{\mathrm{dB}} &= 10\log_{10}(\mathrm{SNR}) = 10\log_{10}(2^{2b}) \qquad (4)\\ &= 20b\log_{10}(2) = 6b \text{ dB}\end{aligned}$$

$$\mathrm{SNR}_{\mathrm{dB}} = 6b + K_{\mathrm{density}}(\sigma^2) \qquad (5)$$

3. SIGMA-DELTA MODEL

The model of a Σ-Δ converter can be derived from a number of equivalent perspectives; the two most common are that of an error feedback modulator and that of a standard two-input one-output feedback loop. We first examine the error feedback model and then convert this model to other feedback models. Figure 4 presents the structure of a noise feedback modulator or coder. The coder consists of a prediction filter that computes, from previous quantization errors, an estimate $\hat{q}(n)$ of the next quantization error $q(n)$. This estimate is subtracted from the input and presented to the internal quantizer that adds the actual quantization error, $q(n)$, an error modeled as an additive noise source. The size of this added error is computed as the difference between the output and input of the quantizer and is delivered to the predictor filter for use in the next prediction cycle. From Fig. 4, we can determine the input and output of the quantizer that is shown in Eq. (6).

$$\begin{aligned}&\text{Quantizer input:} && x(n) - \hat{q}(n)\\ &\text{Quantizer output:} && y(n) = [x(n) - \hat{q}(n)] + q(n) \qquad (6)\\ & && = x(n) + [q(n) - \hat{q}(n)]\end{aligned}$$

The transfer function of the noise feedback coder is presented in Eq. (7). Here we see that the output of the system contains the signal input to the system, $X(Z)$, plus a filtered version of the noise input $Q(Z)[1 - P(Z)]$. The term $[1 - P(Z)]$ is denoted the noise transfer function (NTF):

$$\begin{aligned}Y(Z) &= X(Z) + [Q(Z) - \hat{Q}(Z)]\\ &= X(Z) + Q(Z)[1 - P(Z)] \qquad (7)\end{aligned}$$

Rather than continuing with this general model with arbitrary $P(Z)$, we choose to examine a specific example, in particular, the simplest prediction filter from which we will derive insight and guidance to other filter structures. We reason as follows. We want the output $\hat{q}(n)$ of the prediction filter to be a good approximation of $q(n)$, and further we want the computational burden required to perform the prediction to be small. We can realize these conditions if the successive samples of the error are highly correlated and, of course, we obtain high correlation when the input signal is significantly oversampled. This is the justification for the requirement to deliver over sampled data to the Σ-Δ converter. It is common, for instance, for the input data to be sampled at 64 times the signal's Nyquist rate. With significant oversampling, we can easily argue that the correlation between successive input samples is high and consequently the correlation between successive quantization errors is also high. For this condition, a good approximation of the next quantization error $\hat{q}(n)$ is the previous error $q(n-1)$, and the filter that supplies the delayed noise sample is $P(Z) = Z^{-1}$. Figure 5 shows the noise feedback coder with the prediction filter replaced with a single delay element Z^{-1}.

We note that there are two feedback loops in Fig. 5. The first loop starts at the input summing junction, negotiates the lower summing junction, and passes through the delay line back to the input junction. The second loop starts at the input summing junction, passes through the quantizer summing junction, the sign reversal of the lower summing junction, through the delay line and back to the input summing junction. Figure 6 presents the noise feedback quantizer redrawn to explicitly show the two loops just traversed, and then recognizing that the minor loop is a digital integrator, replacing it with the transfer function $Z/(Z-1)$. This figure is the conventional model of a Σ-Δ converter comprising an integrator and quantizer in a feedback loop.

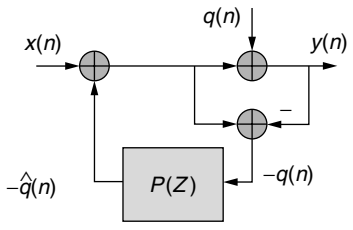

Figure 4. Simple model of noise feedback quantizer.

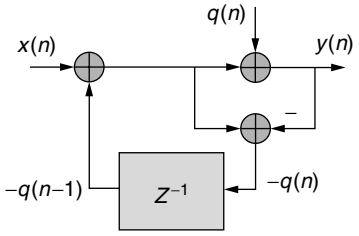

Figure 5. Noise feedback quantizer with delay-line predictor.

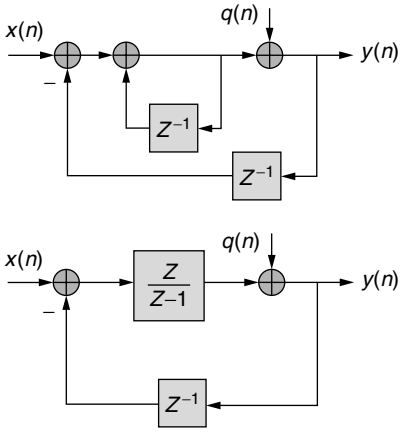

Figure 6. Noise feedback quantizer drawn with inner and outer feedback loops and with inner loop, a digital integrator represented by its transfer function.

Replacing $P(Z)$ with Z^{-1} in Eq. (7) leads to Eq. (8), which describes the input–output relationship of the Σ-Δ converter. Note that the NTF for the quantizing noise input is that of a simple differentiator $[1 - Z^{-1}]$ and that this filter has a transmission zero at $Z = 1$ or at DC. The pole-zero diagram of this NTF and its power spectral response along with the spectra of a typical input signal is shown in Fig. 7. The power spectral response of the NTF is derived in Eq. (9), where sampled data frequency is denoted by the parameter θ, where $\theta = \omega T = 2\pi(f/fs)$ and has units of radians per sample.

$$\begin{aligned} Y(Z) &= X(Z) + Q(Z)[1 - Z^{-1}] \\ &= X(Z) + Q(Z)\left[\frac{Z-1}{Z}\right] \end{aligned} \tag{8}$$

$$\begin{aligned} |\mathrm{NTF}(\theta)|^2 &= \left[\frac{e^{j\theta}-1}{e^{j\theta}}\right]\left[\frac{e^{-j\theta}-1}{e^{-j\theta}}\right] \\ &= 2[1-\cos(\theta)] = 4\sin^2(\theta/2) \end{aligned} \tag{9}$$

In Fig. 7, note that the zero of the NTF is located at DC, which suppressed the quantization noise in the neighborhood of DC. The signal spectral is restricted by the significant oversampling to reside in a small neighborhood of DC with two-sided width on the order of 1.5% of the sample rate. The combination of the over sampling and noise spectral shaping has arranged, to first order, for the signal and the noise spectra to occupy distinct spectral intervals. The signal spectra can be retrieved from the composite signal by a lowpass filter that passes the signal but rejects the noise residing beyond the signal bandwidth. Increasing the number of NTF zeros in the signal bandwidth can further improve the in-band noise suppression. We will examine Σ-Δ converters with multiple NTF zeros. The zeros of the NTF significantly suppress the quantizer noise levels of a quantizer embedded in Σ-Δ, consequently, low levels of output quantizing noise can be obtained from quantizers with relatively large levels of input quantizing noise. Most Σ-Δ converters are designed to operate with 1-bit quantizers with a number of high-performance converters operating with 4-bit quantizers.

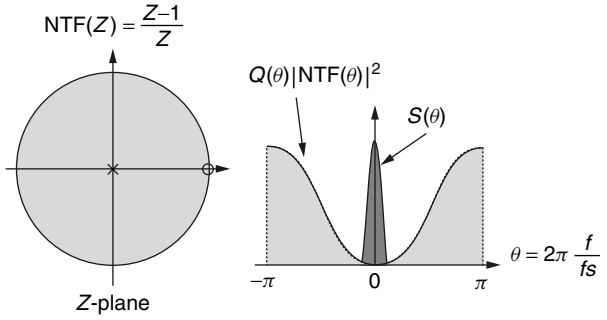

Figure 7. Pole-zero diagram of noise transfer function and power spectrum of input signal and of quantizing noise shaped by NTF.

4. NOISE PERFORMANCE OF SIGMA-DELTA CONVERTERS

We now review how filtering an oversampled and quantized data signal can improve that signal's quantizing SNR. The spectrum of nonshaped quantizing noise is uniformly distributed over a spectral width equal to the sample rate. If the signal is oversampled, say, by a factor of 2, half the quantizing noise power is in-band and half the noise power is out-of-band. We can pass the oversampled signal through a half-band filter without affecting the signal but effectively rejecting half the noise power. Rejecting half the noise bandwidth improves the signal to quantizing noise ratio by 3 dB. Quantizing noise is measured at 6 dB per bit, so reducing the noise bandwidth of uniformly distributed noise by a factor 2 improves the SNR by half a bit. To realize a 1-bit improvement in SNR, a signal would have to be oversampled by a factor of 4 and have its quantizing noise bandwidth reduced by the same factor of 4.

We now address the relationship between the SNR of a Σ-Δ converter with a shaped noise spectrum and its oversample ratio. In many modulators, the NTF of the Σ-Δ contains one or more zeros located at DC. We expand the power spectral response of a single-zero NTF in a Taylor series about DC and truncate the series after the first nonzero term to obtain an approximation to the filter response valid in the neighborhood of the signal spectrum:

$$\begin{aligned} |\mathrm{NTF}(\theta)|^2 &= 4\sin^2\frac{\theta}{2} = 2[1-\cos(\theta)] \\ &= 2\left\{1-\left[1-\frac{\theta^2}{2!}+\cdots+\right]\right\} = \theta^2 \end{aligned} \tag{10}$$

The fraction of the shaped noise spectrum that contributes to the final output of the Σ-Δ converter is that part that survives the filtering operation of the lowpass filter following the initial conversion process. The noise contained in the filter bandwidth is

$$\sigma_q^2 = \frac{N_0}{2}\int_{-\theta_{\mathrm{BW}}}^{\theta_{\mathrm{BW}}}\theta^2 d\theta = \frac{N_0}{2}\frac{1}{3}\theta^3\Big|_{\theta=-\theta_{\mathrm{BW}}}^{\theta=\theta_{\mathrm{BW}}} = \frac{N_0}{3}(\theta_{\mathrm{BW}})^3 \tag{11}$$

where we see that the noise contained in the filtered Σ-Δ output is proportional to the cube of the ratio of bandwidth-to-sample rate. If we reduce this ratio by a factor of 2, the noise contribution is reduced by a factor of 8, or by 9 dB, or equivalently by an improvement of 1.5 bits. Figure 8 illustrates how reduction in bandwidth (relative to sample rate) effects the reduction in output noise. Table 1 lists the rate at which the output SNR increases as a function of oversample ratio for a quantizer with 0, 1, 2, and 3 zeros in the NTF. The next section describes architectures for Σ-Δ converters that have NTFs with multiple zeros.

Figure 9 presents the power spectrum of a Σ-Δ's two-zero noise transfer function along with the spectrum of its 1-bit time series formed when processing an input signal containing two in-band sinusoids. Figure 10 show a segment of the input time series overlaid with the corresponding one-bit output series as well as the spectrum obtained by filtering the one-bit output series of the Σ-Δ

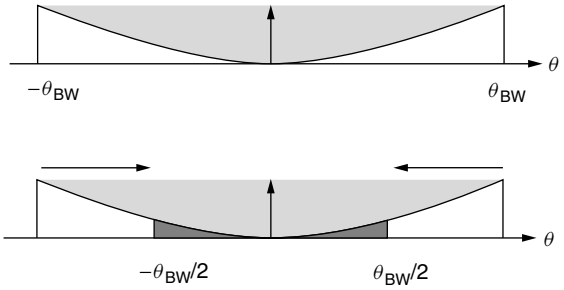

Figure 8. Area under spectrally shaped noise for two different ratios of output bandwidth-to-sample rate ratio.

converter. Note that the normalized bandwidth of the modulator and filter is $\frac{1}{100}$th of the input sample rate, a ratio equal to 6.64 octaves. From Table 1 we see that a 2-zero NTF exhibits a noise processing gain of 15 dB per oversampling octave, from which we expect a 6.64 × 15-dB or 99.6-dB improvement in SNR. With the spectrum normalized to the peak response of the windowed FFT (fast Fourier transform) we observe that the noise level of the filtered output is on the order of 98–105 dB with 103.6 dB as the actual SNR determined by integrating over the filter bandwidth.

5. SIGMA-DELTA ARCHITECTURES

A small number of common structures describe the architecture of the majority of Σ-Δ converters. We now examine the design philosophy common to many of these architectures. Most Σ-Δ architectures are formed about a feedback loop containing a loop filter and low-resolution quantizer that forms an oversampled, spectrally shaped data sequence that is processed by an external band-limiting filter to reject out-of-band noise. The feedback loop of the Σ-Δ quantizer is called the "Σ-Δ modulator," which, when combined with the filter, forms the sigma-delta converter.

Figure 11 is an extension of the redrawn noise feedback structure of Fig. 6 that cast the Σ-Δ as a two-input one-output feedback system. That first system employed an integrator and quantizer in a unity feedback control loop. What we have done here is replace the feedback integrator with an arbitrary filter $H(Z)$ and have also placed filter $G(Z)$ in the input path to enable private zeros for the input signal. We now consider appropriate constraints for the two filters to obtain the desired Σ-Δ performance.

As shown in Eq. (12), the transfer functions from the two inputs, $X(Z)$ and $Q(Z)$, to the common output $Y(Z)$ is computed as their distinct forward gains divide by one minus the loop gain:

$$Y(Z) = \frac{G(Z)}{1+H(Z)}X(Z) + \frac{1}{1+H(Z)}Q(Z) \tag{12}$$

The transfer functions of $H(Z)$ and $G(Z)$ are ratios of numerators to a common denominator polynomial defined by $N_1(Z)/D_1(Z)$ and $N_2(Z)/D_1(Z)$, respectively. Substituting these ratios in Eq. (12) leads to Eq. (13), and clearing the resulting denominators results in Eq. (14):

$$Y(Z) = \frac{N_2(Z)/D_1(Z)}{1+N_1(Z)/D_1(Z)}X(Z) + \frac{1}{1+N_1(Z)/D_1(Z)}Q(Z) \tag{13}$$

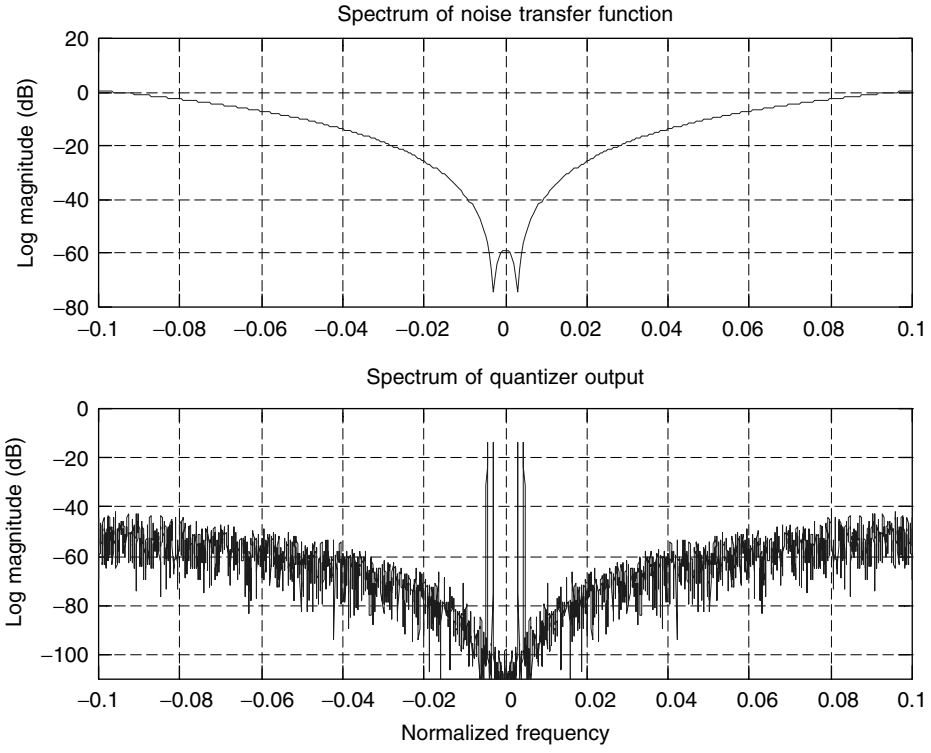

Figure 9. Noise transfer function of a 2-zero sigma-delta modulator and power spectrum of the output series obtained from modulator.

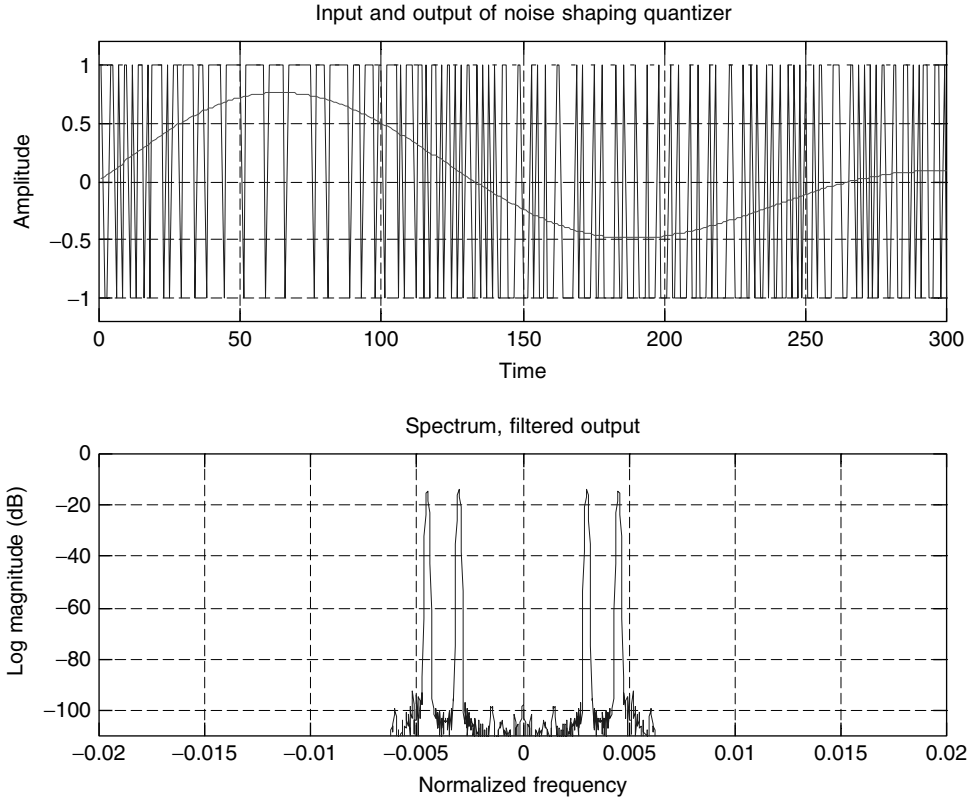

Figure 10. Segment of input and 1-bit output time series and power spectrum of filtered 1-bit output series from modulator.

$$Y(Z) = \frac{N_2(Z)}{D_1(Z) + N_1(Z)} X(Z) + \frac{D_1(Z)}{D_1(Z) + N_1(Z)} Q(Z) \tag{14}$$

5.1. MULTIPLE FEEDBACK LOOPS

We identify the two transfer functions shown in Eq. (14) as the signal transfer function (STF) and as the noise transfer function (NTF), respectively. As expected, the poles, $D(Z)$, of the loop filter transfer function become the zeros of the NTF. To assure good stopband performance of the NTF, $D(Z)$ must have its roots on the unit circle in the signal passband. Poles located at $Z = 1$, obtained by local feedback, form integrators that lead to the desired NTF zeros. Local feedback between the integrators can redistribute the zeros along the unit circle to realize an equal-ripple stopband to exchange excess attenuation for wider stopband bandwidth. Typical NTFs that can be realized with the structure of Eq. (14) are illustrated in Eq. (15); by way of example, these NTFs are third-order NTFs implementing Chebyshev (also transliterated as Tchebyschev), Butterworth, and derivative stopbands. These NTFs have distributed zeros and active poles, repeated zeros and active poles, and repeated zeros with inactive poles; "active" poles are finite poles that affect the spectral magnitude response, and hence are finite poles not at the origin. The frequency responses of these sample NTFs are shown in Fig. 12, where we see that the active poles have the desirable effect of reducing the

Table 1. Improvement in Quantizer SNR in dB and Effective Number of Bits for Each Doubling of Sample Rate Relative to Signal Bandwidth for Sigma-Delta Converters with 0, 1, 2, and 3 Noise Transfer Function Zeros

Number of NTF Zeros	SNR Improvement	
0	3 dB/double	0.5 bit/double
1	9 dB/double	1.5 bit/double
2	15 dB/double	2.5 bit/double
4	21 dB/double	3.5 bit/double

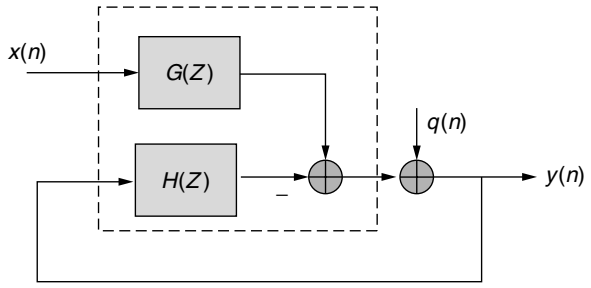

Figure 11. Two-input one-output feedback model of sigma-delta modulator.

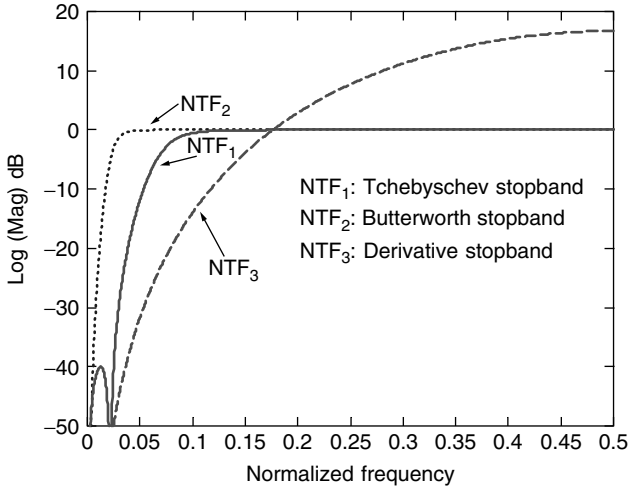

Figure 12. Spectral responses of typical noise transfer functions.

high-frequency gain of the NTF and that the distributed zeros widens the stopband bandwidth of the NTF.

$$\begin{aligned} \mathrm{NTF}_1 &= \frac{(Z-1)(Z^2+c_1Z+1)}{(Z-1)^3+(Z^2+b_1Z+b_2)} \\ \mathrm{NTF}_2 &= \frac{(Z-1)^3}{(Z-1)^3+(Z^2+b_1Z+b_2)} \\ \mathrm{NTF}_2 &= \frac{(Z-1)^3}{Z^3} \end{aligned} \tag{15}$$

The zeros $N_1(Z)$ of the feedback filter $G(Z)$ are selected so that the system poles match a selected prototype transfer function such as an elliptic, Chebyshev, or Butterworth stopband filter.

Figure 13a shows a three-stage version of the general multiple feedback–feedforward filter structure with local feedback forming the discrete integrators. The integrator poles become, via the major feedback loops, the desired NTF zeros. In this configuration, the input data $x(n)$ enter the filter through the feedforward path while the output data $y(n)$ leave the filter at the feedback path. Figure 13b presents the dual three-stage version of the pole structure presented in Fig. 13a. Here the input data $x(n)$ enter the filter at the feedback path while the output data $y(n)$ also leave the filter at the feedback path in which the quantizer must reside. This form of the filter does not offer a feedforward path to form private zeros for the signal transfer function.

5.2. Cascade Converters

The second major architecture for Σ-Δ modulators is that of cascade low-order Σ-Δ modulators. The cascade form is called a MASH converter, for *multiple sample and holds*, a description of the analog implementation. The low-order modulators can be formed by any structure but is usually implemented with one or two integrator loops and a 1-bit quantizer as originally shown in Fig. 6. We derived the expression for the output of the first stage of a single-loop modulator in Eq. (8). The output contains the loop's quantizer noise differentiated by the loop NTF. We obtain an improved NTF by the use of a second Σ-Δ modulator to measure and cancel the noise of the first modulator. This structure is shown in Fig. 14.

The Z transform of the first loop's output is shown in Eq. (16), and that of the second loop's output is shown in Eq. (17). Note that the first output contains $Q_1(Z)[1-Z^{-1}]$, the first loop's noise filtered by the loop NTF, a derivative, while the second output contains $Q_1(Z)$, the first loop's noise without the derivative. Applying a derivative as a $(1-Z^{-1})$ operator to the output of the second loop leads to the terms shown in Eq. (18), and forming the sum of $y_1(n)$ and $[y_2(n)-y_2(n-1)]$ leads to the terms shown in Eq. (19):

$$Y_1(Z) = X(Z) + [1-Z^{-1}]Q_1(Z) \tag{16}$$

$$Y_2(Z) = -Q_1(Z) + [1-Z^{-1}]Q_2(Z) \tag{17}$$

$$[1-Z^{-1}]Y_2(Z) = -[1-Z^{-1}]Q_1(Z) + [1-Z^{-1}]^2Q_2(Z) \tag{18}$$

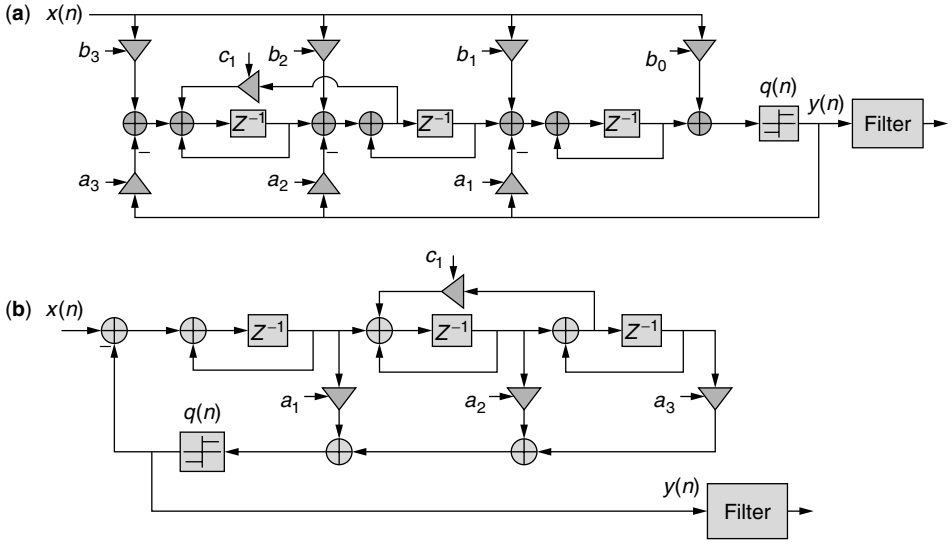

Figure 13. (**a**) Three-stage example of feedback–feedforward filter using cascade discrete integrators: zeros formed at input, poles formed at output; (**b**) dual three-stage example of feedback using cascade discrete integrators: poles formed at input.

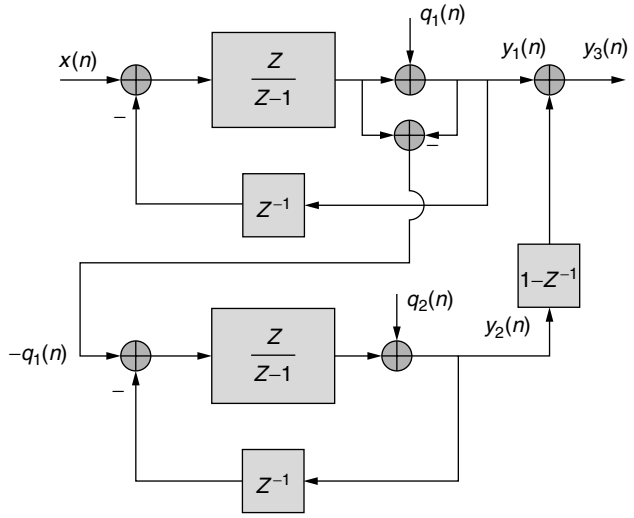

Figure 14. Cascade single-loop, single-bit sigma-delta modulators.

$$\begin{aligned} Y_1(Z) + [1 - Z^{-1}]Y_2(Z) &= X(Z) + [1 - Z^{-1}]Q_1(Z) \\ &\quad + \{-[1 - Z^{-1}]Q_1(Z) \\ &\quad + [1 - Z^{-1}]^2 Q_2(Z)\} \\ &= X(Z) + [1 - Z^{-1}]^2 Q_2(Z) \end{aligned} \tag{19}$$

The output of the cascade modulators contains the input $X(Z)$ and the doubly differentiated noise $Q_2(Z)[1 - Z^{-1}]^2$ of the second modulator loop. The double zero in the NTF has the effect of further suppressing the in-band quantization noise, which improves the output SNR for a given over sample rate. The process of canceling the first loop's noise with differentiated output of the second loop results in bit growth due to the two summations. If each of loop uses a 1-bit quantizer, the modulator outputs are ± 1. The output of the discrete derivative contains the three levels, 0 and ± 2, and the output of the sum of the two paths contains the four levels, ± 1 and ± 3. The result of combining the output of the cascade 1-bit modulators results in an equivalent 2-bit modulator. The cascade can be extended to include three stages by using a third Σ-Δ modulator to measure and cancel the noise of the second Σ-Δ modulator. The output of the third stage is double differentiated and added to the output of the two-stage cascade, which replaces the doubly differentiated second stage noise with the triply differentiated third-stage noise. Here again, the double derivative of a 1-bit sequence results in an increased output bit width. The output levels of the three cascade modulators are ± 1, ± 3, ± 5, and ± 7, the equivalent of a 3-bit modulator. Figure 15a–c presents the time series and the spectrum obtained from successive stages of a cascade of three single-loop modulators. Note the bit growth at each successive output and the enhanced depth of spectral noise suppression with the increased number of NTF zeros of the cascade modulator. For comparison, Fig. 15d presents the time series and spectrum from a single 3-loop, 3-bit sigma delta modulator. The spectral responses of the two 3-loop systems are essentially the same even though the time series from the two systems are very different.

5.3. Noise Prediction Loops

The third and the last major architecture for a Σ-Δ modulators is an enhanced version of the prediction filter introduced as our first model of the Σ-Δ modulator and presented in Fig. 4. We initially replaced the prediction filter with a delay element Z^{-1}, and then elected to operate the loop at rates far in excess of the signal Nyquist rate to assure high correlation between successive errors. We now return to this structure and describe one technique of designing efficient prediction filters, which permit significant reduction in the system over sample rate.

The design of a prediction filter that forms successive estimates of the next input sample is a standard task in signal estimation. The optimum prediction filter processes a sequence of N successive input samples with weights that minimize the mean-squared error between the prediction of the next sample and the ensuing measurement of that sample. This structure is expressed in Eq. (20) and shown in Fig. 16:

$$\begin{aligned} \hat{q}(n) &= \sum_{k=1}^{N} b(k) q(n-k) \\ e(n) &= q(n) - \hat{q}(n) \end{aligned} \tag{20}$$

The process of minimizing the mean-squared error leads to the standard normal equations shown in Eq. (21a) along with the augmented power of the prediction error shown in Eq. (21b). The set of N normal equations can be represented in matrix form as shown in Eq. (22), where the column vector $\overline{b}$ of dimension $(N+1)$ is the augmented coefficient vector $\{1 - b_1 - b_2 \cdots - b_N\}^T$, and the column vector $\overline{r}_e$ is the error correlation vector:

$$r_{qq}(m) = \sum_{k=1}^{N} b(k) r_{qq}(m-k) \quad m = 1, 2, 3, \ldots, N \tag{21a}$$

$$r_{ee}(0) = r_{qq}(0) - \sum_{k=1}^{N} b(k) r_{qq}(k) \tag{21b}$$

$$\begin{bmatrix} r_{qq}(0) & r_{qq}(1) & \cdots & \cdots & r_{qq}(N-1) \\ r_{qq}(1) & r_{qq}(0) & \cdots & \cdots & r_{qq}(N-21) \\ \vdots & \vdots & \cdots & \cdots & \vdots \\ \vdots & \vdots & \cdots & \cdots & \vdots \\ r_{qq}(N-1) & r_{qq}(N-2) & \cdots & \cdots & r_{qq}(0) \end{bmatrix} \times \begin{bmatrix} 1 \\ -b(1) \\ \vdots \\ \vdots \\ -b(N) \end{bmatrix} = \begin{bmatrix} r_{ee}(1) \\ 0 \\ \vdots \\ \vdots \\ 0 \end{bmatrix} \tag{22}$$

Equation (22) can be written concisely in vector–matrix form as shown in Eq. (23) and then solved for the optimum weights as shown in Eq. (24):

$$\mathbf{R}_{qq}\overline{\boldsymbol{b}} = \overline{\boldsymbol{r}}_e \tag{23}$$

$$\overline{\boldsymbol{b}} = \mathbf{R}_{qq}^{-1}\overline{\boldsymbol{r}}_e \tag{24}$$

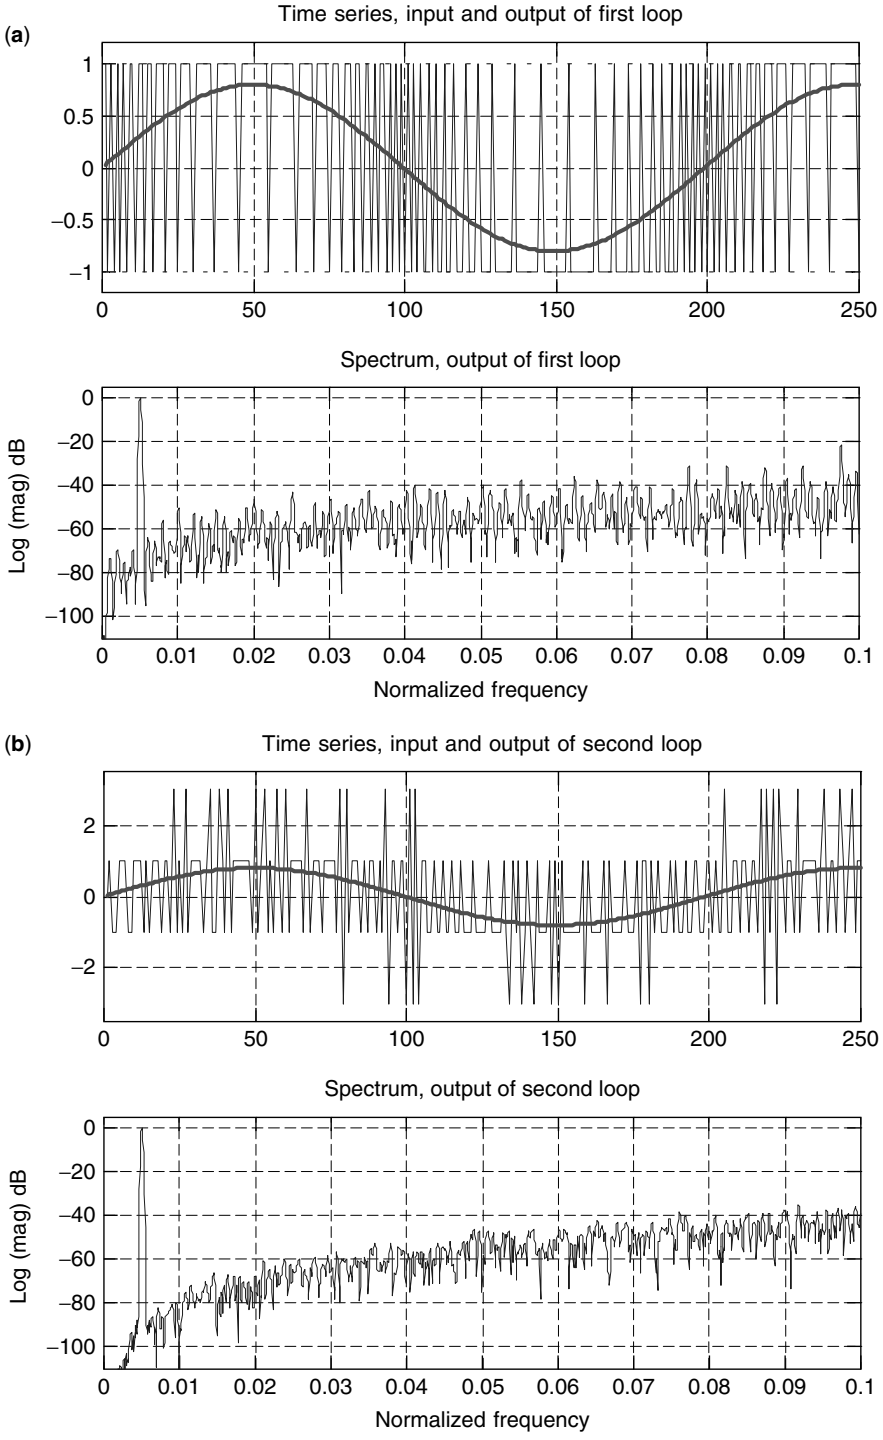

Figure 15. (**a**) Time series and spectral response of (**a**) first 1-bit modulator; (**b**) two-cascade 1-bit modulators; (**c**) three-cascade 1-bit modulators; and (**d**) 3-zero 3-bit modulator.

We have no problem with the existence of, and the process for, computing the weight set that minimizes the mean squared error for a given signal from which we can extract the second-order statistics. The problem is that we do not know the signal a priori hence do not have the required signal statistics. We fall back to a minimax solution, that of finding the solution for the signal with the worst statistics and apply that solution to the arbitrary signal. This signal is band limited white noise, and of course it is the band limiting that permits the successful prediction. The power spectrum of the bandlimited noise is shown in Fig. 17 and expressed as follows:

$$P_{qq}(\theta) = \begin{cases} 1 & -\theta_0 \le \theta \le \theta_0 \\ 0 & \text{elsewhere} \end{cases} \tag{25}$$

The correlation function of the modeled band-limited white noise, found as the inverse DTFT of Eq. (25), is

$$r_{qq}(n) = \frac{\theta_0}{\pi} \frac{\sin(n\theta_0)}{(n\theta_0)} \tag{26}$$

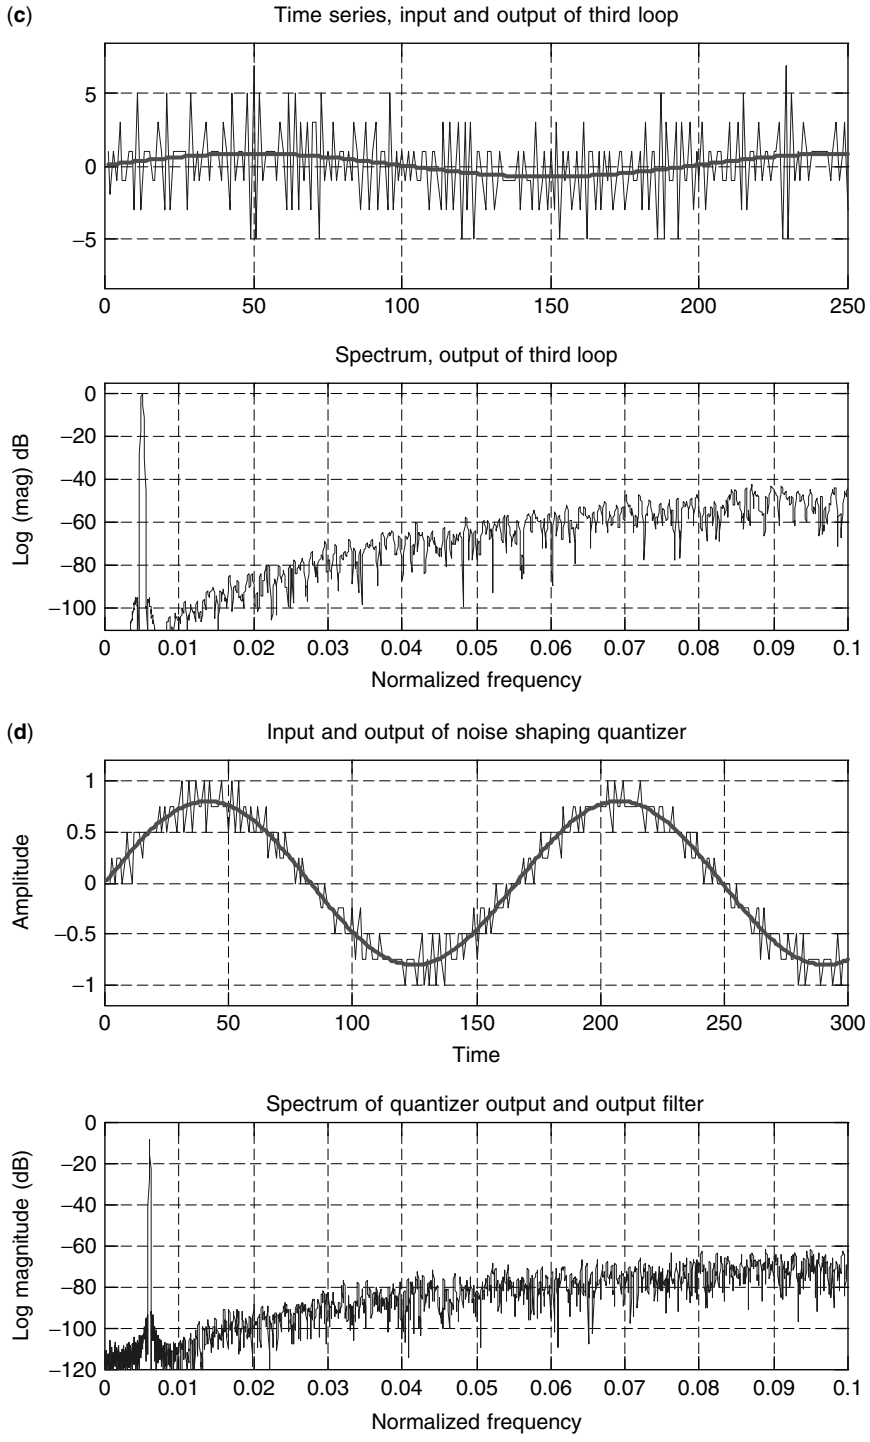

Figure 15. (*Continued*)

Using sample values of the correlation function presented in Eq. (26) to solve for the optimum weights of Eq. (24) leads to an ill-conditioned correlation matrix and to a set of weights with a large spread of coefficient values. This large spread is undesirable, and is due to the fact the optimum predictor is also the whitening filter. This filter tries to whiten the spectrum, and since there is no energy in the out-of-band region of Eq. (25), the filter can and does set arbitrarily large gains in this region. To control the out-of-band spectral gain of the predictor, we overlay the entire frequency band with a low-level white-noise spectrum of amplitude ε, modifying Eq. (25) to take the following form:

$$P_{qq}(\theta) = \begin{cases} 1+\varepsilon & -\theta_0 \le \theta \le \theta_0 \\ \varepsilon & \text{elsewhere} \end{cases} \tag{27}$$

The modified power spectrum has the following correlation function:

$$r_{qq}(n) = \frac{\theta_0}{\pi}\frac{\sin(n\theta_0)}{(n\theta_0)} + \varepsilon\delta(n) \tag{28}$$

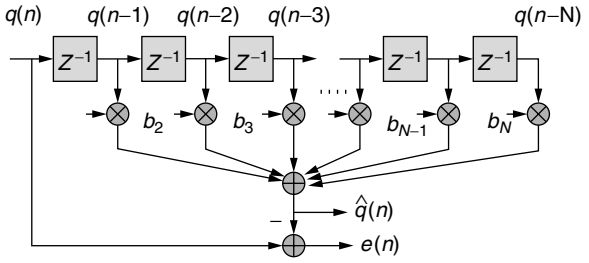

Figure 16. Tapped delay-line prediction filter.

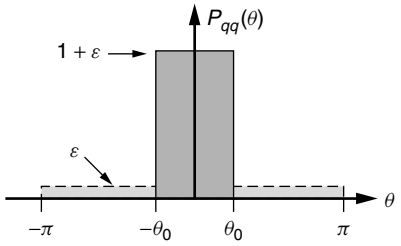

Figure 17. Power spectrum of band-limited white noise with ε white-noise overlay.

The effect of the added low-level white noise is to improve the condition number of the correlation matrix by adding the small value ε to the diagonal terms of the matrix. Adjustment of this parameter is an effective way to control out-of-band gain to improve the modulator stability margin.

Figure 18a presents the spectrum of a 20% bandwidth 10-tap prediction filter designed with the conditioning parameter $\varepsilon = 10^{-5}$. This is an unusually wide bandwidth Σ-Δ modulator with sample rate only 5 times the signal's Nyquist rate. Also shown is the spectrum formed from the Σ-Δ modulator 4-bit output sequence obtained with this prediction filter. Figure 18b shows a segment of the input series and the 4-bit output series from this modulator as well as a zoom to the passband of the output signal spectrum.

5.4. Bandpass Sigma-Delta Modulators

The Σ-Δ modulators we have examined thus far have been baseband since they were originally designed around the spectral characteristics of the pole of a digital integrator. The standard method for quantizing a passband signal involves a downconversion of the center frequency to baseband with a pair of quadrature mixers, a pair of filters to remove the sum frequencies formed by the mixing operation, and finally quantization with a pair of matched converters. It is logical to perform this translation when the Σ-Δ modulator is the conversion device, since the NTF zeros reside at base band. As expected, two converters are required to service the complex base band process. Another option is to move the NTF zeros from baseband to the center frequency of the narrowband input and perform the desired conversions with the signal residing at a low intermediate frequency.

When we move the sigma-delta integrator poles from the neighborhood of zero frequency, the resultant poles are called *resonators*. A resonator formed by structures with real coefficients exhibits both positive- and negative-frequency images, and hence requires twice the number of integrators to build the positive- and the negative-frequency NTF zeros. Doubling the number of integrators is equivalent to building and using two filters in a pair of modulators, so the increase in implementation complexity is not a concern. Feedback around resonator pole pairs results in NTF spectral zeros at these locations; hence a Σ-Δ modulator can be designed to operate at any frequency within the spectral span defined by the sample rate. Rather than pursue the straightforward synthesis problem, we consider techniques that can be applied directly to the structure of the prototype baseband modulator. A number of such techniques can be used to translate the poles of a baseband prototype modulator to an arbitrary center frequency.

We can effect a frequency transformation of an existing filter structure by replacing all-pass networks in the structure with another all-pass network. The simplest such transformation, shown in Eq. (29), replaces a delay line, represented by Z^{-1}, with a phase rotated delay line, represented by $Z^{-1}e^{j\theta}$. When applied to the delays in a filter, the spectral response of the filter is translated to the center frequency θ radians per sample. This relationship, shown in Eq. (30), is known as the *modulation property* of the Z transform:

$$Z^{-1} \Rightarrow Z^{-1}e^{j\theta} \tag{29}$$

$$\text{If} \quad h(n) \Leftrightarrow H(Z)$$

$$\text{Then} \quad h(n)e^{jn\theta} \Leftrightarrow H(Ze^{-j\theta}) \tag{30}$$

Figure 19 is a third-order multiple feedback Σ-Δ modulator with the tuning substitution described in Eq. (29) converting the prototype integrators into complex resonators. This substitution results in complex data due to the complex scalars, requiring the use of complex registers in place of the delay lines of the prototype, and similarly, the need for two real quantizers in place of the original quantizer. Figure 20 shows the frequency response of time series obtained from a baseband prototype, from a complex resonated version, and from a real resonated version of the 3-loop, 1-bit modulator presented in Fig. 19. The real resonator version is described next.

One might object to the computational burden due to the use of a complex phase rotator in each complex resonator, but remember that the scalar phase rotators replace the pair of input mixers and the DDS required for the downconversion. Judicious choice of center frequency can also lead to trivial operators that replace the complex phase rotators. In particular, when the center frequency is the quarter-sample rate, the phase rotator defaults to $\exp(j\,\pi/2)$ or j, a simple data transfer and possible sign reversal between registers.

A related all-pass transformation that can be applied directly to the baseband prototype modulator is the lowpass to bandpass transformation shown in Eq. (31). This transformation appends to each delay element in the filter a sign change, and an all-pass tuning filter with a parameter $c = \cos(\theta c)$, where θc is the center frequency.

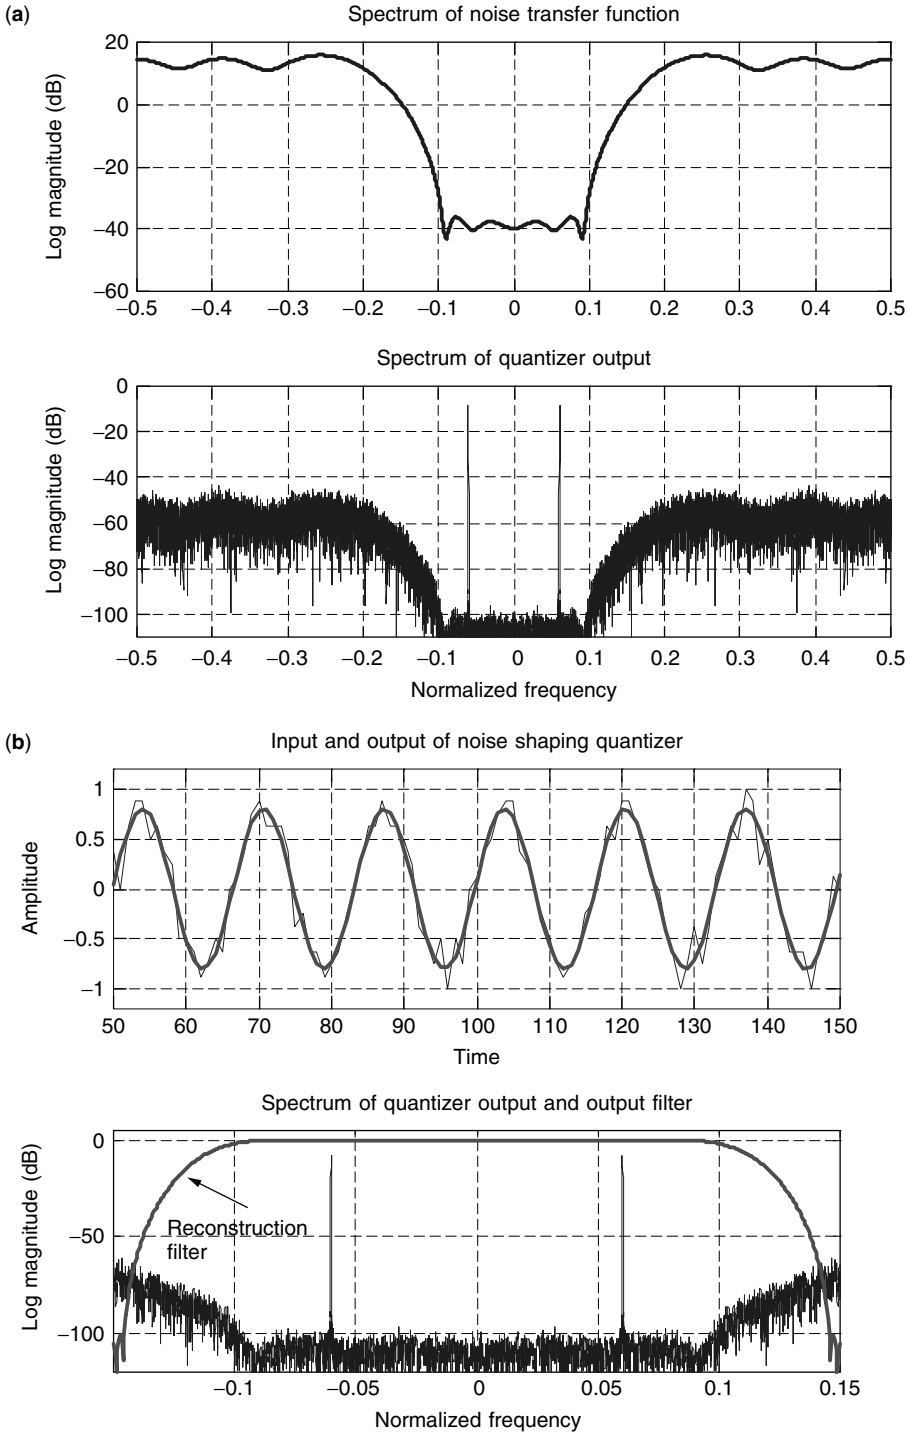

Figure 18. (**a**) Spectrum of noise transfer function obtained with 10-tap prediction filter and spectrum of sigma-delta output 4-bit series; (**b**) segment of input and output time series obtained with 10-tap prediction filter with 4-bit sigma-delta modulator and detail of output series spectrum.

The most common form of this frequency transformation is the default case $\theta c = \pi/2$, which sets c to zero, and consequently replaces Z^{-1} with $-Z^{-2}$. This substitution results in two delays with negative feedback in place of the baseband integrators:

$$\frac{1}{Z} \Rightarrow -\frac{1}{Z}\frac{1-cZ}{Z-c}, \qquad \text{where} \quad c = \cos(\theta_c) \tag{31}$$

Figure 21 illustrates the progression from the base band integrator, through the quarter-sample rate resonator, to the arbitrary all-pass tuned resonator. The lowpass to bandpass generalized delay in the tuning resonator requires two delays, two additions, and a single multiplier to implement both numerator and denominator as well as the cascade delay shown in Eq. (31). The third subplot of Fig. 19 presents the spectrum of a time series formed by the all-pass tuned variant of the modulator shown in Fig. 18.

As a final note on resonated Σ-Δ modulators, we comment that the predictive noise filters of the previous

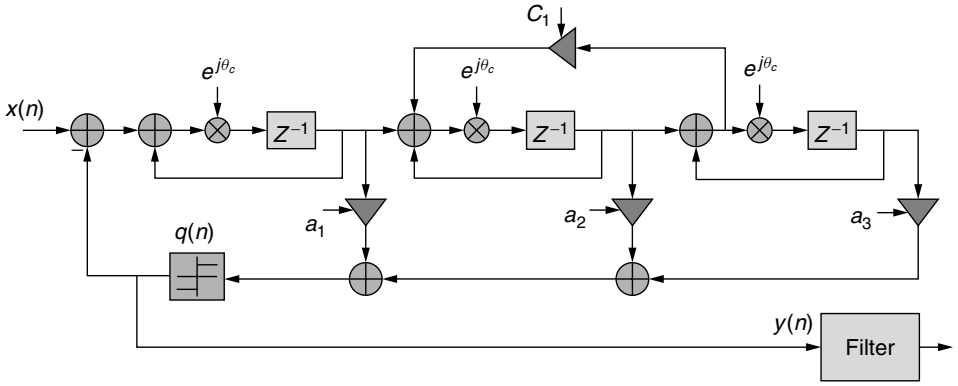

Figure 19. Bandpass sigma-delta converter with complex, phase-rotated resonators.

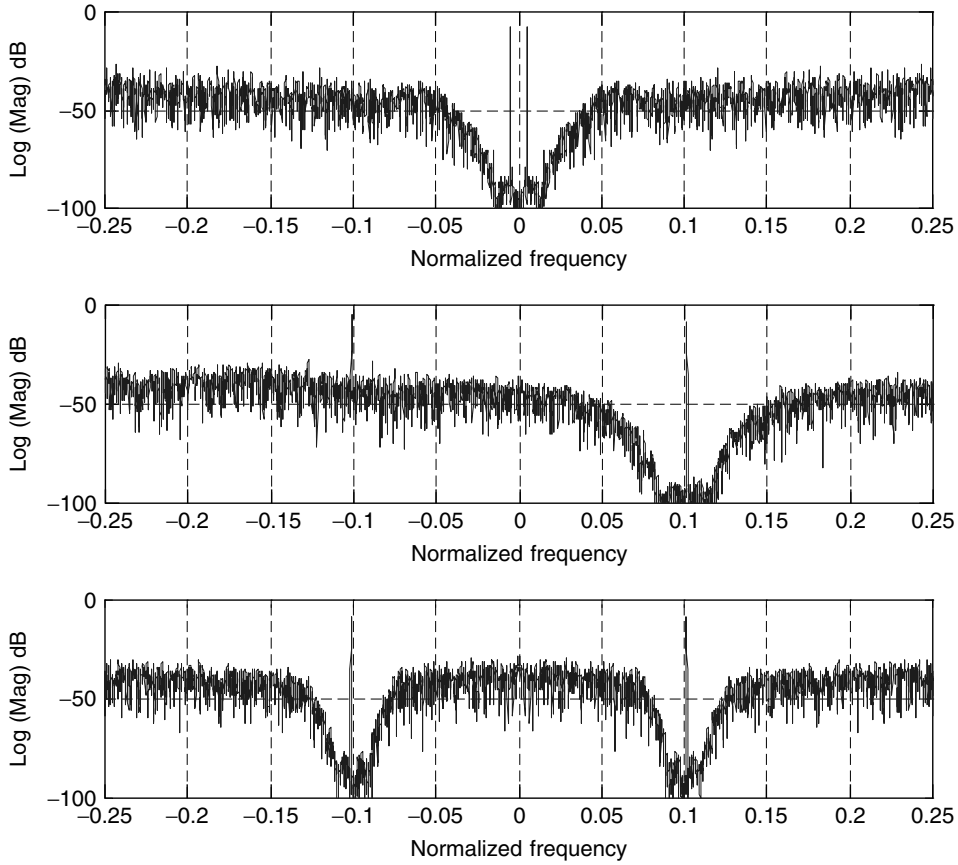

Figure 20. Spectrum of time series from 3-loop, 1-bit baseband prototype, from complex resonator, and from real resonator versions of prototype modulator.

section can also be trivially tuned to become bandpass Σ-Δ modulators. We manage this by spectrally shifting, as a symmetric or asymmetric translation, the spectra of the band-limited noise power spectrum in Eq. (27) used to define the correlation sequence of Eq. (28). As a consequence of this translation, the filter designed by the normal equation will be have a bandstop NTF rather than a baseband NTF.

6. STABILITY CONSIDERATIONS

We now address models of the quantizer in the Σ-Δ modulator. Our first order model of the quantizer is that

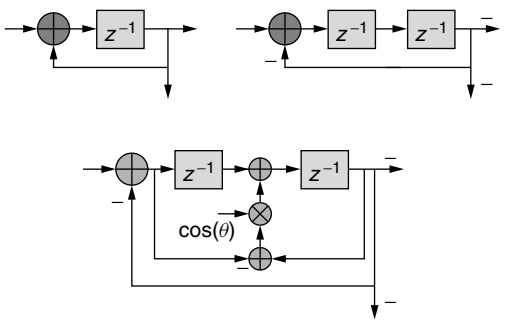

Figure 21. Prototype integrator, quarter-sample rate resonator, and all-pass tuned arbitrary frequency resonator.

of an independent additive noise source, the standard approximation used in a memoryless quantizer. When we have a small number of quantization levels, this model is poor because of the high correlation between the quantized signal and the quantization error. The quality of the model is improved by adding a random dither signal to the data samples prior to the quantization process. When embedded in a feedback loop, the model must also include a gain that may be amplitude-dependent. One linear model of the nonlinear quantizer $Q[u(n)]$ is shown in Fig. 22, where the input signal $u(n)$ is partitioned into two components, $u_{DC}(n)$ and $u_{AC}(n)$, subjected to their separate gains of K_0 and K_1 and then added to the additive noise source. Reasonable questions to ask are (1) whether this is a valid model and (2) over what range of input signal amplitudes is this a valid model.

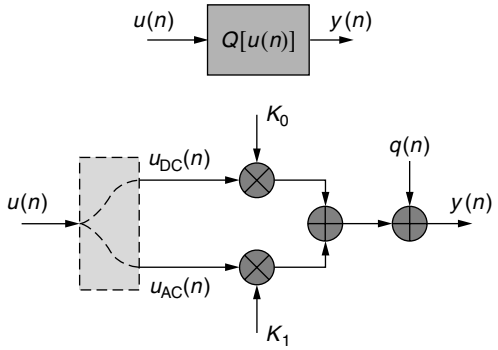

Figure 22. Linear model of quantizer in sigma-delta modulator feedback loop.

We answer the first question, concerning model validity by operating two 3-loop feedback models, one containing a standard 1-bit quantizer, and one an additive noise source in place of the quantizer. Figure 23a presents the

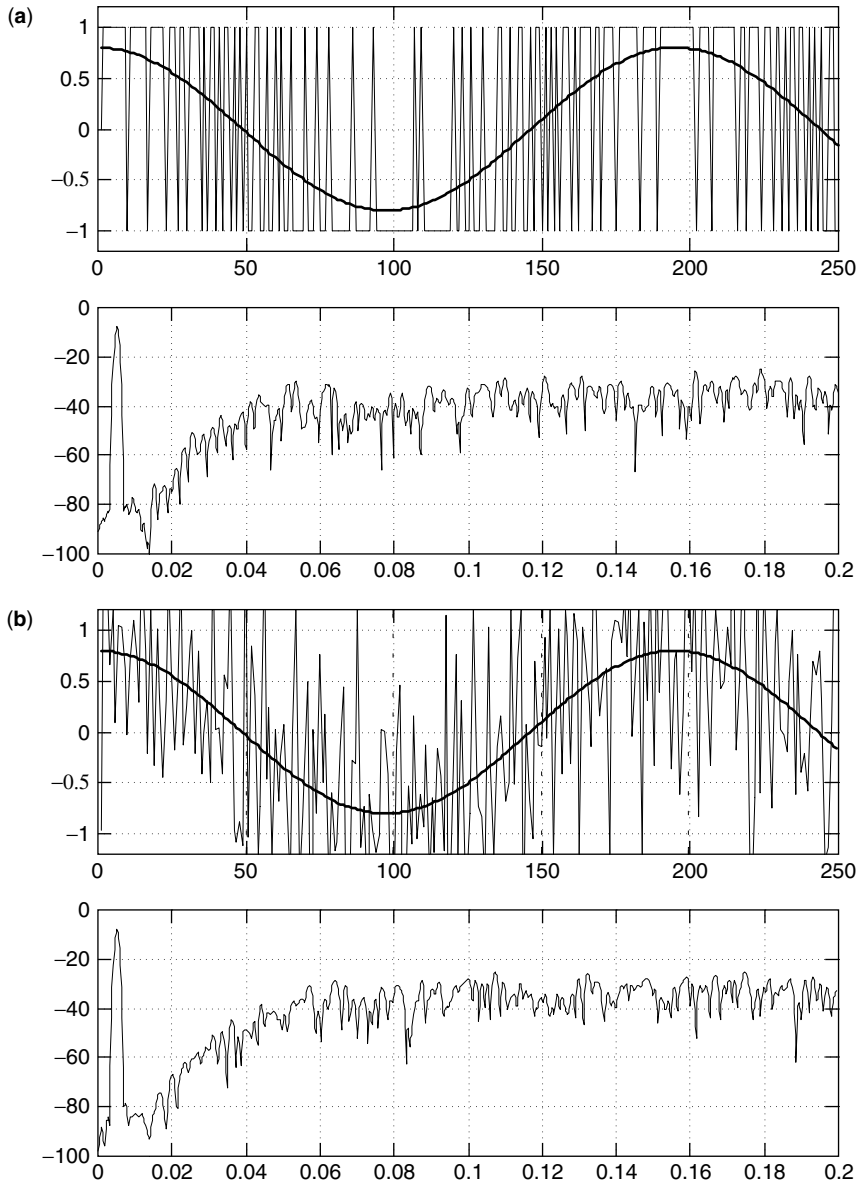

Figure 23. Input and output time series, and output spectra of a (**a**) 3-loop, 1-bit sigma-delta modulator and (**b**) 3-loop, linear additive noise model of sigma-delta modulator.

input and output time sequences with associated output spectrum of the 3-loop, 1-bit modulator. Figure 23b shows the corresponding figures for the same system containing the additive noise source with comparable variance. As projected, the spectra of the two loops is identical; the shaped inserted noise has the same spectrum as the shaped quantization noise. It is interesting to see how well the feedback loop suppresses the nonlinear quantizer behavior, enabling the linearized model to approximate the performance of the nonlinear system.

The next question we address is the range of input amplitudes for which the linearized model is a valid description of the nonlinear system. The standard approach to this inquiry is to collect statistics on the maximum level of the modulator's internal registers as a function of the input signal level. Figure 24a presents curves showing the maximum register levels observed in a 3-loop, 1-bit Σ-Δ modulator for test runs of length 16,384 samples with fixed (DC) levels over the range of 0–1, where 1 is the full-scale 1-bit quantizer output level. Also shown are the maximum register levels as a function of fixed input levels for the linear model of the loop with the inserted noise rather than quantizing noise. We note that the quantized loop and the linear model exhibit similar responses for fixed DC input levels spanning the range 0 to 0.6, and that the quantized loop exhibits poor stability for input signal levels beyond 0.6 and in fact becomes unstable at approximately 0.74.

Figure 24b presents a set of similar curves for the maximum register levels observed in the same 3-loop,

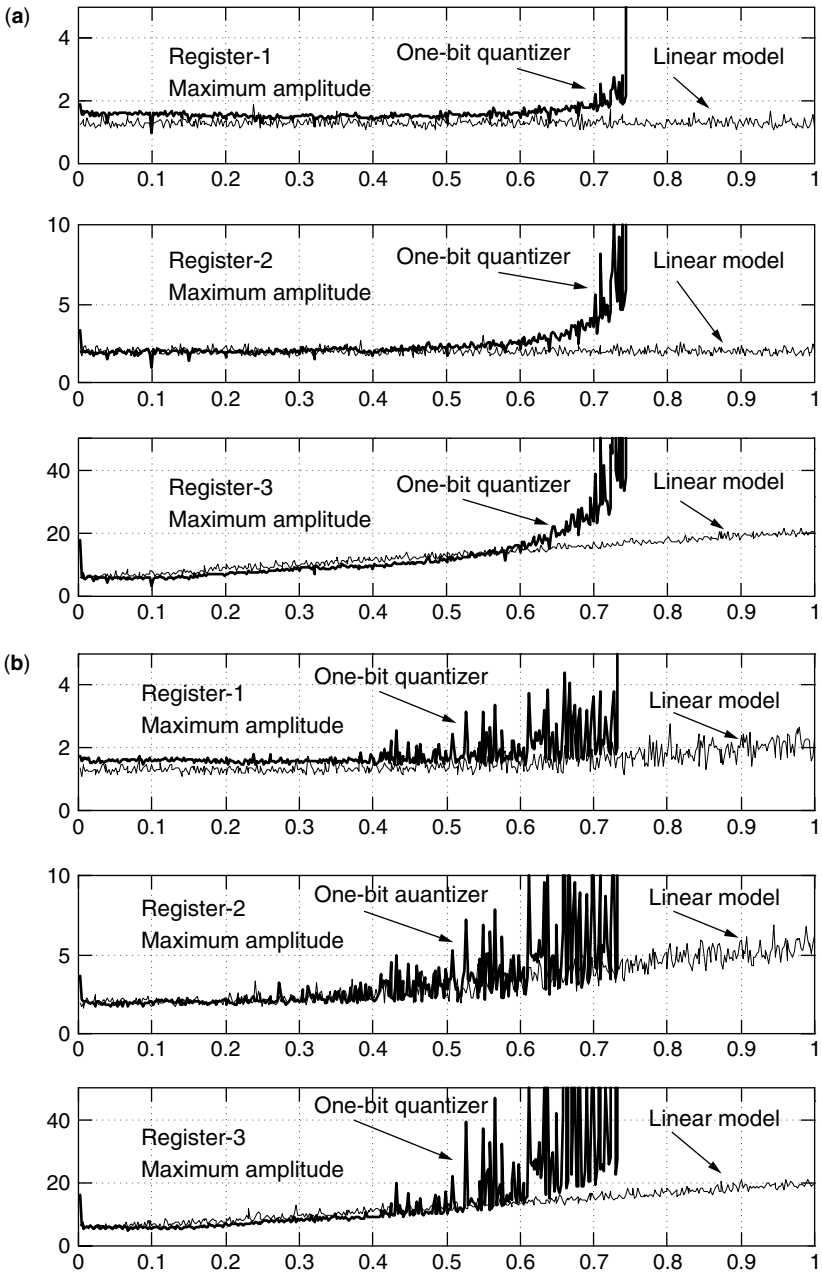

Figure 24. Amplitudes of internal states of 3-loop sigma-delta modulator and linearized noise model as function of (**a**) DC input level and (**b**) in-band AC input level.

1-bit Σ-Δ modulator for the same measurement conditions except that the input signal is an in-band sinusoid with fixed amplitude levels varied over the range of 0–1. As in the companion figure, also shown are the maximum register levels as a function of input levels for the linear model of the loop. We note that the quantized loop and the linear model exhibit similar responses for fixed AC input levels spanning the reduced range 0–0.4, with the quantized loop exhibiting increasingly poorer stability for input signal levels in the range 0.4–0.74 and in fact becoming unstable at 0.74. Note that the range of input AC levels for which the internal states avoid instability is smaller than the range of input DC levels. It is standard practice to restrict the range of input levels to half the input range to avoid the operating at the edge of unstable behavior.

The relationship that couples the instability of the sigma-delta modulator to the amplitude of the input resides in the fact that the linear model gain terms, K_0 and K_1, introduced in Fig. 22, decrease as the input amplitude increases. We can include the gain K_1 in the closed-loop expression for the noise transfer function, as shown in Eq. (32) to illustrate how the denominator of the transfer function changes with K_1, and hence varies with the input amplitude. From conventional feedback analysis we see that the closed-loop zeros are the open-loop poles, and that as K_1 varies from 0 to 1, the closed root poles migrate from the closed root zeros to the unity-gain closed root poles. The locus of the root migration as a function of K_1 is shown in Fig. 25. Note that for values of K_1 less than 0.276, the system poles are outside of the unit circle and the system is unstable:

$$\mathrm{NTF}(Z) = \frac{1}{1 + K_1 N(Z)/D(Z)} = \frac{D(Z)}{D(Z) + K_1 N(Z)} \qquad (32)$$

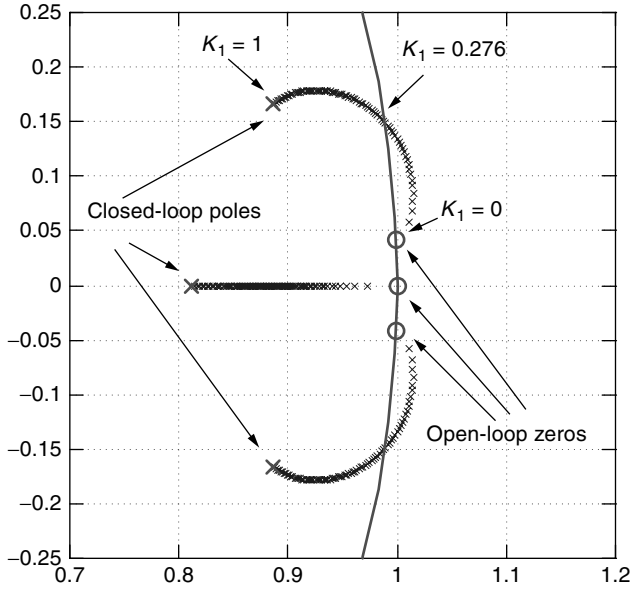

Figure 25. Root locus of closed-loop poles for third-order sigma-delta modulator demonstrating cause of instability as quantizer gain K_1 is reduced.

7. DIGITAL SIGNAL PROCESSING APPLICATIONS OF SIGMA-DELTA CONVERTERS

7.1. Σ-Δ Modulator in Data Preprocessor

The Σ-Δ converter can be used to improve the fidelity of any quantization process in a DSP system, many of which occur naturally and many by virtue of enlightened design. In the spirit of the latter option, the Σ-Δ modulator can be used as a preprocessor in any filtering task for which the filter bandwidth is a small fraction of its sample rate. Under this condition, the bandwidth of interest is already oversampled and can be requantized to a smaller number of bits to reduce the arithmetic resources required for the ensuing filtering process. One example we cite is that of a digital FIR filter to extract a downconverted 0.6-MHz-wide color subcarrier of a composite 6-MHz-wide NTSC signal sampled at 12.0 MHz. We note that the signal bandwidth processed by the filter is already oversampled by a factor of 20 occupying only 5% of the sample rate. The Σ-Δ can requantize the data from 10 bits to 1 bit with a shaped noise spectrum. The shaped noise spectrum preserves the quantizing noise level of the input signal in the signal bandwidth while permitting increased quantizing noise levels in the band to be rejected by the filtering process. Block diagrams of the two approaches to this processing task, conventional and sigma-delta preprocessing, are shown in Fig. 26. Here, a 4-tap preprocessor converts the 10-bit data to 1-bit so that the following 80-tap filter can be implemented without multiplies. Figure 27 shows the input and output time series as well as the output spectrum of the preprocessor. As expected, the 1-bit process successfully preserves the signal fidelity in the important band, the band processed by the filter.

7.2. Σ-Δ Modulator in DC Canceler

A second application of the Σ-Δ modulator as a DSP preprocessor is its insertion in the common signal task of canceling DC. DC components are generated and inserted in the signal a number of mechanisms, these include analog insertion due to untrimmed offsets in A/D converters, and digital insertion due to arithmetic truncation of two's-complement products and summations in various signal processing operations. The bias, or DC offset, on the order of a fraction of a bit per sample, does not appears to be a problem at first glance, but in

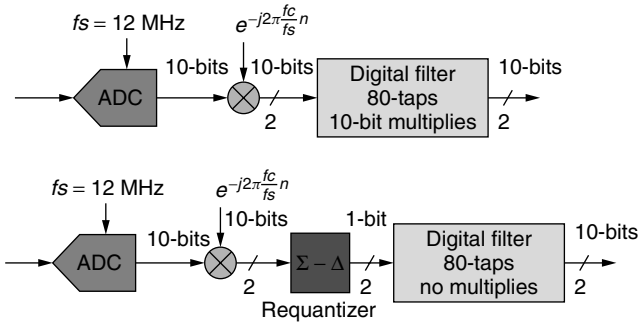

Figure 26. Narrowband processing with conventional and unconventional sigma-delta preprocess filtering.

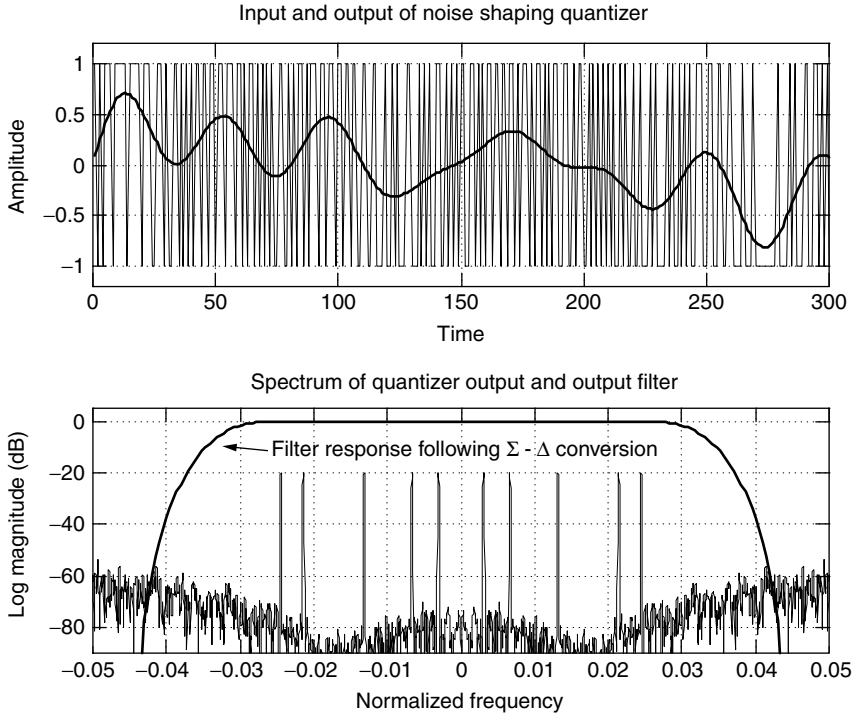

Figure 27. Time series and spectrum of signal preprocess quantized to 1 bit for reduced workload in subsequent filtering process.

fact becomes a problem when the samples are coherently processed. The fractional bit offset can grow to a many-bit offset as the signal experiences the coherent gain of subsequent filters as they reduce signal bandwidth. In some applications, the DC is of no consequence and can be ignored, but in others, the DC offset must be removed early in the signal processing path. We do this to preserve the dynamic range of a fixed-point data set and in digital receivers to avoid decision biases in the detection process following matched-filter processing.

Removal of the DC is performed by a DC notch filter usually implemented as a DC canceler of the form shown in Fig. 28. The integrator in the feedback loop of the filter becomes the transmission zero of this filter that also exhibits a nearby pole at $Z = (1 - \mu)$. The notch filter has the transfer function shown in Eq. (33), and we note that the distance, μ, between the zero and pole defines the bandwidth of the notch. The parameter μ is a small binary number, on the order of 2^{-10}, implemented by a right data shift. The integrator estimates the DC in the series, and the filter subtracts the DC from the input sequence. In order to cancel a DC term whose value is a fraction of a bit, the output of the canceler filter must grow additional bits to the right of the input data's binary point. On leaving the canceler, the lower-order data bits are discarded by the output quantizer that returns the number of output bits to the number of input bits for the benefit of subsequent arithmetic processing. This quantization discards the fractional part of the correction inserted by the canceler, so that the combined canceler and quantizer is capable of rejecting only the integer number of bits of the DC offset:

$$H(Z) = \frac{Z - 1}{Z - (1 - \mu)} \tag{33}$$

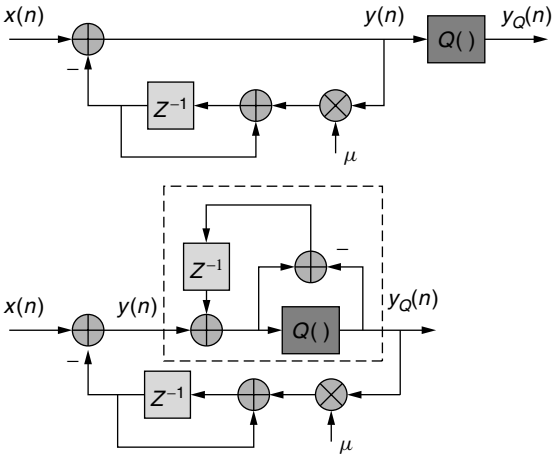

Figure 28. DC canceler with integrator in feedback path and external quantizer and same DC canceler with internal quantizer with noise feedback loop.

To preserve the fractional part of the corrected DC cancellation, we move the quantizer into the feedback loop and wrap a noise feedback loop around the quantizer. This modified structure is shown in the lower section of Fig. 28. The noise feedback quantizer can be placed in either the feedforward or in the feedback portion of the noise canceler. Figure 29 shows the spectrum of the input and output of the DC canceler before and after the external quantizer. We see the DC term present in the input spectrum and its absence in the output spectrum. A DC term is reinserted at the output of the external quantizer as the data samples are returned to 8-bit datawords. In the last figure we note that the internal quantizer with its

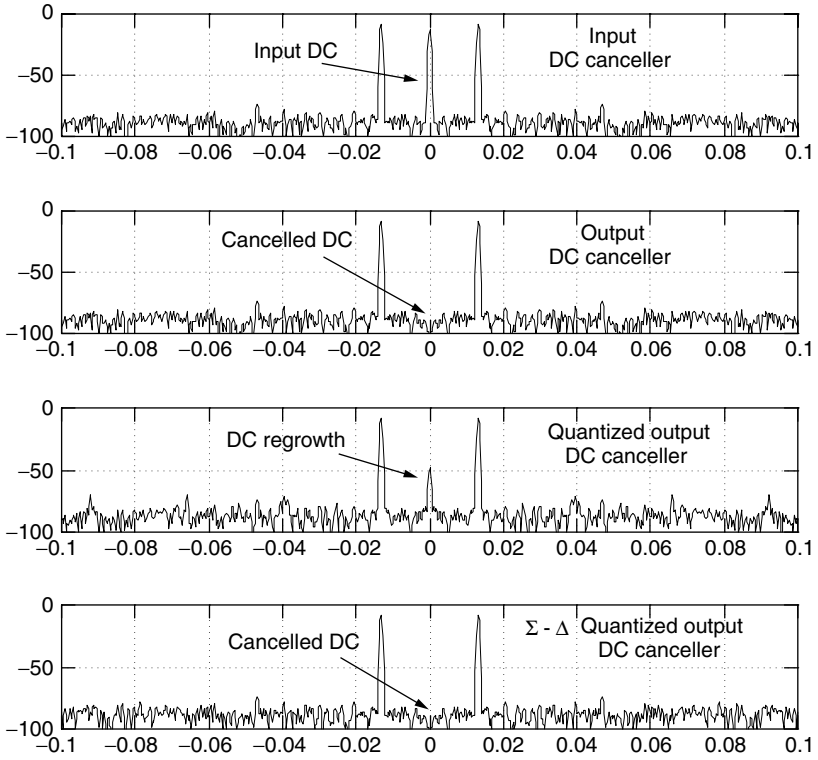

Figure 29. Spectra of input and output of DC canceler, and then output of canceler with 8-bit external quantizer and 8-bit internal noise feedback quantizer.

noise feedback loop does not reinsert the DC as the data are truncated to 8 bits.

7.3. Σ-Δ Regulator in DDS

The last example we cite for the use of a Σ-Δ requantizer is in a direct digital synthesizer (DDS). The DDS uses a fine-resolution overflowing phase accumulator to synthesize a specified phase–time profile for an output complex sinusoid. In a typical system, the output phase word, drawn from a 32-bit accumulator, is quantized to an 8-bit word used as an address to access the sine–cosine values stored in its lookup table. This structure is shown as the first of the three block diagrams in Fig. 30. The quantization forms a correlated error sequence, in fact a sawtooth-shaped periodic phase error of peak amplitude equal to the least significant output bit. The phase error sequence, the difference between the input and output of the quantizer, is shown as the top segment of Fig. 31. This error sequence phase-modulates the output sinusoid, generating an undesired set of line spectra centered about the output center frequency. The amplitude of the maximum phase modulation spurious line is 6 dB per address bit below the desired spectral line. The first curve of Fig. 32 presents the spectrum formed from an 8-bit lookup table containing 16-bit values of sine and cosine of the table address. We can clearly see the line structure and the −48-dB phase modulation spurious tone.

The spectral line structure related to the periodic phase error is undesirable, and the standard remedy to suppress this line structure is the use of additive dither to break up the regularity of the error sequence. The second block diagram of Fig. 30 illustrates the location for the dither

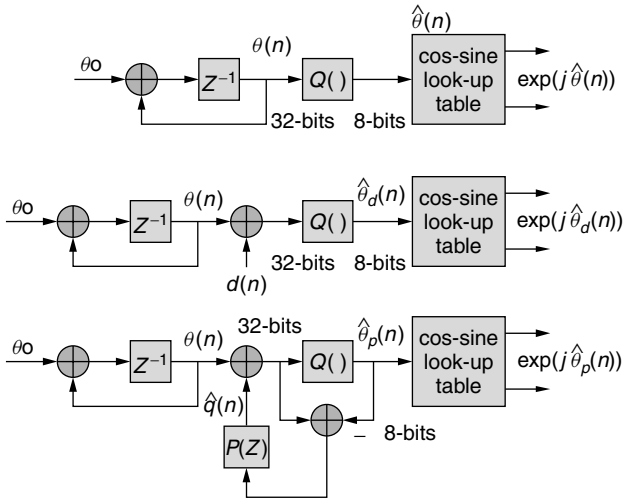

Figure 30. DDS quantization options for table addresses: option 1 — truncation; option 2 — dithered truncation; option 3 — noise feedback truncation.

insertion, the corresponding curve in Fig. 31 shows the dithered phase error structure, and the related curve in Fig. 32 shows the spectrum of the time series generated by the dithered address process. A proper dither suppresses the line structure and pulls the average phase noise level down by 12 dB or 2 bits, in this example from −48 to −60 dB.

It is an easy transition to replace the addition of random dither prior to the quantization process by the addition of correlated dither formed in a noise feedback

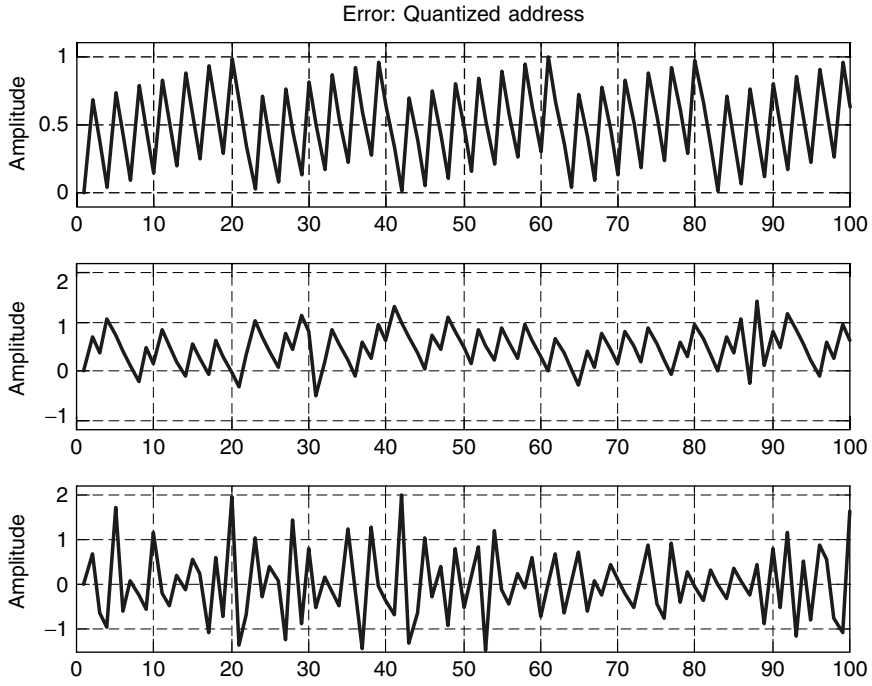

Figure 31. DDS phase error sequences obtained by different quantization options: option 1—truncation; option 2—dithered truncation; option 3—noise feedback truncation.

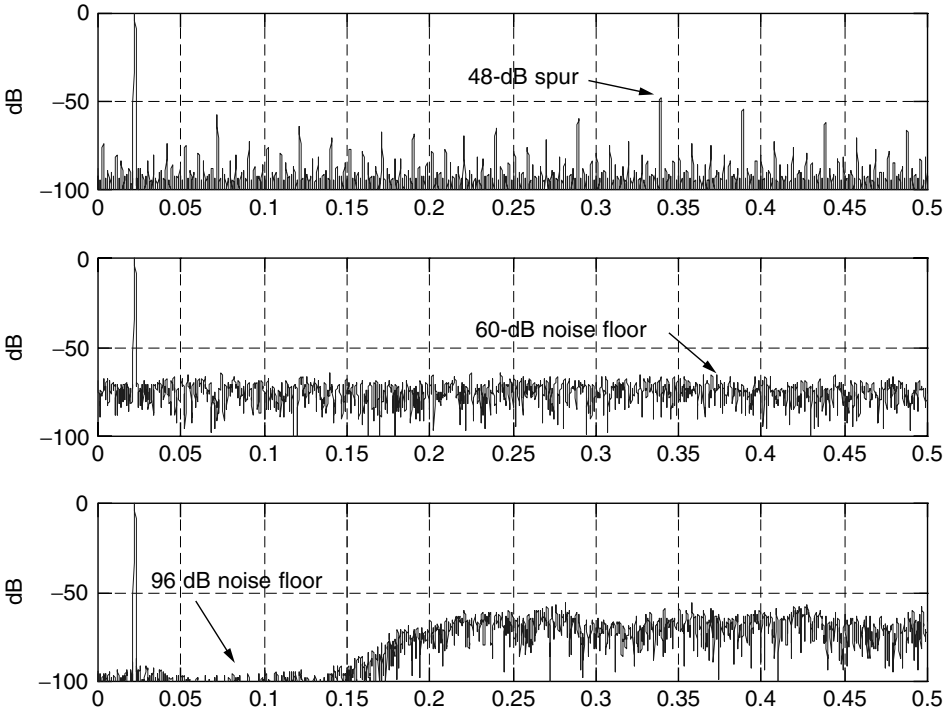

Figure 32. Spectrum of sinusoids obtained from 8-bit table with different quantization options: option 1—truncation; option 2—dithered truncation; option 3—noise feedback truncation.

loop. The third block diagram of Fig. 30 illustrates this option. The corresponding segment of Fig. 31 presents the dithered phase error generated by a 10-tap prediction filter designed using the normal equations presented in Eqs. (22)–(28) to obtain a noise suppression bandwidth equal to 25% of the sample rate. The shaped noise spectrum shown in the third segment of Fig. 32 illustrates a dramatic improvement in the level of phase noise modulation. The in-band level has been pulled down from −60 to −96 dB with rather small increases in out-of-band spectral level. This option of using the sigma-delta loop to manipulate addresses rather than signal amplitude leads to SNR improvements comparable to that available from a dithered 14-bit table with data samples extracted from an 8-bit table. Shorter tables, and predictors with smaller fractional bandwidth can form sinusoids at arbitrary center frequencies exhibiting remarkable fidelity over restricted close-in bandwidths.

8. CLOSING COMMENTS

We have reviewed the theory of operation of noise feedback, hence noise shaping, quantizers commonly called *sigma-delta modulators*. A number of architecture variants were described and their performance illustrated by examining spectra of their output series. Sigma-delta modulator architectures were described that reflect three primary design perspectives: cascade integrators, predictive feedback, and combinations of multiple simple modulators. The cascade integrator model uses minor-loop feedback to place and distribute open-loop poles on the unit circle and then major-loop feedback through a low-resolution quantizer to convert these poles to closed-loop noise transfer function zeros. The noise feedback model measures the quantizing error and uses band-limited prediction filters to predict and precancel the next value of quantizing noise contained within a selected segment of input bandwidth. The cascade models use a succession of low-order modulators to synthesize a high-order modulator. This is accomplished by measuring and canceling the shaped quantizing noise from previous stages with enhanced-shaped noise from later stages.

The tradeoff between oversample ratios, quantization SNR improvement, and order of feedback filter was described for multiple zero NTF. We examined narrow-band resonator-based models of the Σ-Δ process. In particular, we limited our discussion to transformations of baseband prototype systems that support tunable variants of existing systems. Feedback stability considerations were examined to explain the divergence of behavior between the linear and nonlinear models of the Σ-Δ modulator. Finally, a number of Σ-Δ applications were presented and illustrated in which the requantization process was enhanced or invoked to improve the performance of standard DSP-based signal processing tasks.

Material not addressed in this presentation included design and implementation of digital resampling filters that normally accompany the modulator when it is used in A/D and D/A applications. Here the emphasis was the embedding of the Σ-Δ modulator in a DSP system environment. Consistent with this emphasis, analog implementations of the noise feedback process were also intentionally not addressed in this review article.

BIOGRAPHY

Fred J. Harris received the B.S. degree in Electrical Engineering in 1961 from the Polytechnic Institute of Brooklyn, the M.S. degree in Electrical Engineering in 1967 from San Diego State University, and pursued Ph.D. work in electrical engineering from 1967 to 1971 at the University of California at San Diego. Since 1967 he has taught at San Diego State University, were he occupies the CUBIC Corp. Signal Processing Chair. Teaching and research areas include digital signal processing, multirate signal processing, communication systems, source coding, and modem design. He holds a number of patents involving multirate signal processing for satellite and cable modems as well as for sigma-delta implementations. He has contributed to a number of texts and handbooks on various aspects of signal processing. He is the traditional absentminded professor and drives secretaries and editors to distraction by requesting lowercase letters when spelling his name. He roams the world collecting old toys and sliderules and riding old railways.

1. INTRODUCTION

The main driving force of progress in magnetic-recording technology has been the need for vast and reliable storage. In the past four decades, the areal density of disk drives has increased ten million fold, leading to dramatic reductions in storage cost. In particular, the storage densities of high-end disk drives have been growing at a compound growth rate of 60% annually, starting in 1991. This is due to the introduction of the magnetoresistive (MR) recording head, and the advances in high-performance data and servo channels, as well as in VLSI technology [1]. Today's commercial disk drives use longitudinal recording and can store information at a density of approximately 50 Gbits per square inch. This unprecedented areal density is achieved while maintaining the stringent on-track error rate requirements of 10^{-8} to 10^{-9} before outer error-correction coding.

It is expected that this phenomenal growth in areal density of longitudinal recording will slow down because of the superparamagnetic effect [1]. This has increased research and development efforts in perpendicular recording, which since its inception [2,3] has promised to achieve much higher areal densities than longitudinal recording can. Although indications exist that perpendicular recording may be able to achieve ultra-high areal densities, the most recent laboratory demonstrations indicate that longitudinal recording is still marginally ahead of its perpendicular counterpart. Ultimately, perpendicular recording promises areal densities that are about four to five times higher than those of longitudinal recording [4,5]. However, there are considerable engineering challenges associated with the realization of this promise [6]. A transition from longitudinal to perpendicular recording would involve changes in various disk-drive subsystems, including the head, disk, head/disk interface, and servo. It is expected, however, that from a signal-processing and coding architecture point of view, the read electronics will not undergo substantial changes.

Although advances in head and media technologies have historically been the driving force behind areal density growth, digital signal processing and coding are increasingly recognized as a cost-efficient approach in achieving substantial areal density gains while preserving the high reliability of disk drives. The general similarity of the write/read process in a hard-disk drive to transmission and reception in communication systems has led to the adoption of adaptive equalization and coding techniques to the magnetic-recording channel. The classical communication channel perspective can be applied not only to study equalization, detection, and both inner and outer coding strategies but also to estimate the ultimate information-theoretic limits of longitudinal and perpendicular recording [7–9].

In the past decade, several digital signal-processing and coding techniques have been introduced into hard-disk drives to improve the error-rate performance at ever increasing normalized linear densities as well as to reduce manufacturing and servicing costs. In the early 1990s, partial-response class-4 (PR4) shaping in conjunction with maximum-likelihood sequence detection [10] replaced the peak detection systems employing run-length-limited (RLL) (d, k)-constrained codes, and paved the way for future applications of advanced coding and signal-processing techniques. For example, at moderate storage densities, the introduction of partial-response maximum-likelihood detection (PRML) [10] requires a new class of inner constrained codes. This class of codes, collectively known as PRML(G, I) codes, facilitates timing recovery and gain control, and limits the path memory length of the sequence detector. At higher normalized linear recording densities, generalized partial-response (PR) polynomials with real coefficients reduce noise enhancement at the equalizer output. In particular, shaping polynomials of the form $(1 - D)(1 + p(D))$ and $(1 - D^2)(1 + p(D))$, where D represents the unit delay and $p(D) = \sum_{\ell=1}^{L} p_\ell D^\ell$ is a finite impulse response predictor filter with real coefficients $\{p_\ell\}$, are significant in practice. Generalized PR channels in conjunction with sequence detection give rise to noise-predictive maximum-likelihood (NPML) systems [11–15]. The extension of the NPML detection scheme to handle data-dependent medium noise was proposed in [16–20].

Parallel to the developments on NPML detection for magnetic recording, maximum transition run (MTR) (j, k) codes were introduced as a means to provide coding gains for extended partial response (E^2PR) channels [21]. The theoretical underpinning of this new class of codes and practical constructions of codes that deal with the problem of quasi-catastrophic error propagation are presented in Ref. [22]. The unifying theory presented in Ref. [22] led to an exhaustive characterization of quasi-catastrophic error-propagation-free MTR codes, called MTR(j, k, t) codes, and revealed a connection between the conventional PRML(G, I)-constrained codes used in disk drives and the recently discovered MTR codes.

More recently, constrained codes, such as the PRML(G, I) and MTR(j, k, t) codes, have been combined with multiparity block codes to improve the bit error rate performance of the inner channel even further — at the expense, sometimes, of a slight decrease in code rate. These multiparity linear inner codes deliver substantial gains in performance when decoded by a so-called *soft* post-processor that follows the NPML detector and utilizes some form of reliability information [23–28]. Currently, a 16-state NPML detector for a generalized PR channel with a first-order null at dc followed by a post-processor for soft decoding of a combined multiparity/constrained code represents the de facto industry standard.

In this article the state of the art in signal processing and constrained coding for hard-disk drives is reviewed, with emphasis on the techniques that have been used in commercial systems. In Section 2 the magnetic recording system as a communications channel is introduced, and the various sources of noise are presented. In Section 3 the three families of modulation codes, namely, RLL(d, k), PRML(G, I), and MTR(j, k, t), that have predominantly been used in storage systems are discussed, and the latest developments on combined modulation/parity codes are presented. In Section 4 equalization and detection techniques are discussed, with emphasis on the PRML and NPML detection, and performance results are given. The soft-decoding methods for the combined modulation/parity codes via post-processors are presented in Section 5, and the NPML detector for data-dependent noise is reviewed in Section 6. Finally, Section 7 contains a brief discussion of future trends in signal processing and coding for magnetic storage.

2. MAGNETIC-RECORDING SYSTEM

2.1. Saturation Recording

In hard-disk drives, data is stored by longitudinal magnetization of a layer of magnetic media that has been deposited on a rigid disk. The data is recorded in concentric circles, called *tracks*, by applying an external field using a write head flying over the spinning disk. In general, the recording process is nonlinear, primarily because of the nonlinear nature of the magnetic medium. However, if the applied field exceeds a critical value the magnetization is

completely polarized in one direction. Therefore, at any point along a track, the magnetization can, in principle, be uniformly polarized in one of two possible directions, reflecting a recorded "0" or "1." This approach to storing information is referred to as saturation recording.

Writing is most commonly performed by inductive heads. When a current is applied, a magnetic field is generated through the head and across its gap. Depending on the amplitude of the applied current, the fringe field that escapes the gap can be strong enough to saturate the magnetic medium. By reversing the polarity of the current flowing through the coil, which is wound around the head, the direction of the magnetic field and consequently the direction of the magnetization of the medium are reversed. The size of the magnetization pattern depends on the rate by which the polarity of the current through the write head changes (data rate) and on the spinning velocity of the disk.

Magnetoresistive (MR) heads have become the prevailing magnetic-recording sensor for reading back the stored information because of the higher sensitivity and lower noise than the inductive heads. The term *magnetoresistive* refers to the physical phenomenon in which the resistivity of a metal changes in the presence of a magnetic field. Therefore, as the MR head flies over a spinning disk, the changes in the magnetic field emanating from the disk translate into changes of the resistivity of the head and consequently into changes of the voltage across the head. Because the MR head directly measures the flux from the medium, the head signal is independent of the velocity of the disk. As a consequence, the MR-head readback signal is as strong for high-RPM (revolutions per minute) server-class drives as it is for slowly rotating, mobile hard-disk drives.

2.2. A Communications Channel

One may consider a magnetic-recording system as a communications channel in which information, rather than being transmitted from one point in space to another, is stored at one point in time and retrieved at another. The objective in magnetic recording is to maximize the rate at which data is stored and retrieved as well as to maximize the density of the information stored per square inch of disk space. Figure 1 shows the general architecture of the recording system in commercial magnetic hard-disk drives.

User data are organized in sectors, with each sector typically containing 512 8-bit bytes. Upon a write request, the data are organized into sectors and fed into a Reed–Solomon (RS) encoder. The RS codewords are first byte-interleaved and then encoded by a constrained or modulation code. In storage systems, the latter code imposes constraints on the data stream being stored in the medium. In magnetic storage, modulation or constrained codes are used, for example, to facilitate the operation of the conventional peak detector, to provide timing information and eliminate quasi-catastrophic error propagation in sequence detection, or to eliminate certain predominant error events and increase the Euclidean distance between output sequences as seen by certain types of sequence detectors. Modulation codes usually employ a precoder, either of the form $1/(1 \oplus D)$ (in the RLL and MTR cases) or $1/(1 \oplus D^2)$ (in the (G, I) case), where $\oplus$ denotes modulo-2 addition. The main function of the precoder is to facilitate modulation code design. In today's recording systems the modulation encoder is followed by a parity encoder that usually appends one, two, three, or four parity bits to the modulation codeword. The output of

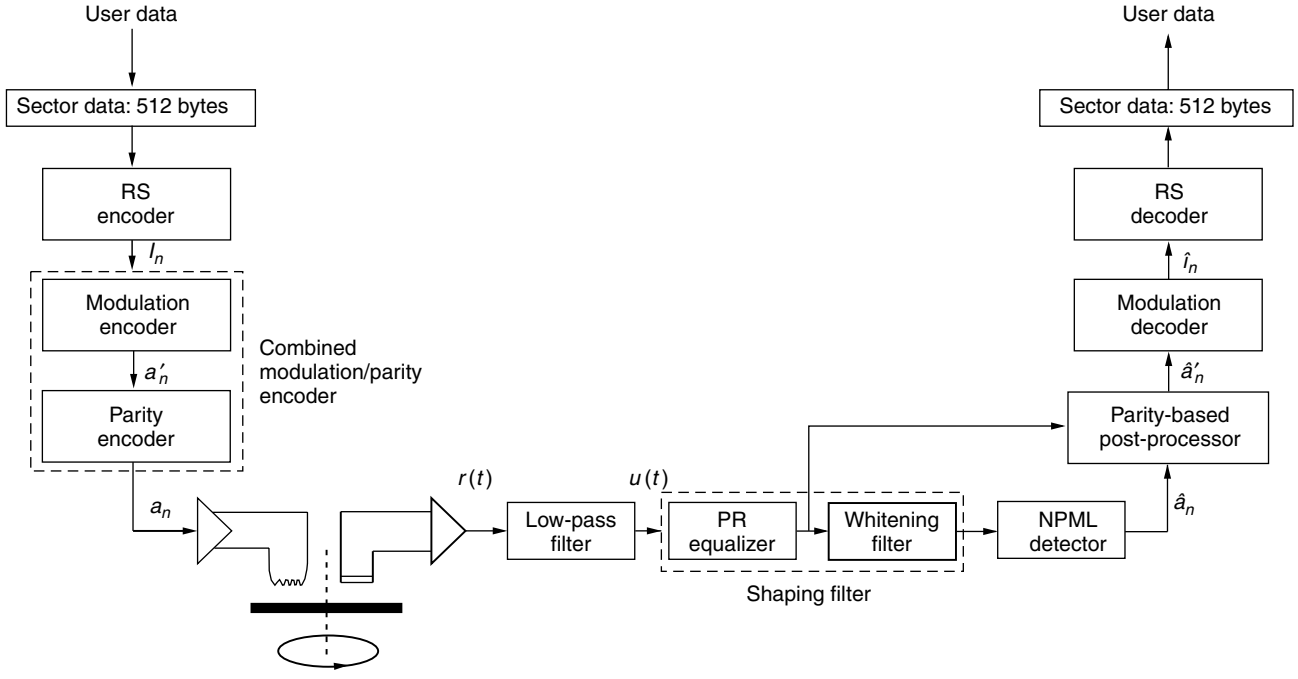

Figure 1. Recording system architecture.

the parity encoder is finally mapped into two-level channel input symbols, $a_i \in \{+1, -1\}$. These are the symbols that are actually being stored in the magnetic medium. The symbol sequence is first converted into current levels by the write head driver, and then the head stores the resulting sequence of rectangular pulses on disk tracks in the form of a series of transitions or magnetization waveforms.

For completeness, it is worthwhile to mention that there are two different formats for mapping the binary data sequence at the output of the modulation encoder to write current waveforms as shown in Fig. 2. In non-return-to-zero inverted (NRZI) recording, a binary 1 corresponds to a change in polarity of the write current, whereas a binary 0 corresponds to no change in polarity of the write current. In non-return-to-zero (NRZ) recording, the binary information sequence is mapped directly to the amplitude level of the write current waveform. From the signaling point of view, these two recording formats are related via the simple $1/(1 \oplus D)$ precoding function as shown in Fig. 3. As can be seen, the current waveform corresponding to NRZI recording of a particular data-input sequence is identical to the NRZ current waveform of the $1/(1 \oplus D)$ precoded data-input sequence. The NRZI recording format played an important role for peak-detection systems, whereas in today's sequence-detection systems, NRZ is the preferred recording format.

To read the data back from the hard disk, a read head is used that senses the changes of the magnetic flux that reflect the changes in polarity of the data sequence stored.

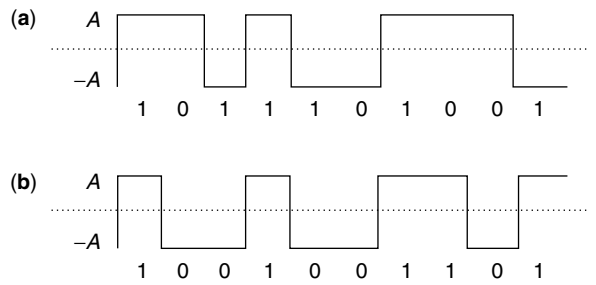

Figure 2. (**a**) NRZI and (**b**) NRZ signals.

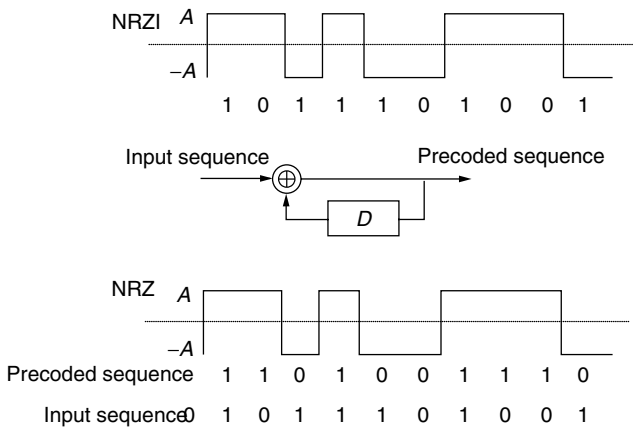

Figure 3. Relationship of NRZI and NRZ.

For an isolated positive transition, the response of the read head is a pulse $s(t)$, which is referred to as the isolated transition response. Analytically this isolated transition or step response is very well approximated by the Lorentzian pulse

$$s(t) = \frac{A}{1 + (2t/\mathrm{PW50})^2} \tag{1}$$

where A is the peak amplitude and PW50 denotes the width of the pulse at its 50% amplitude level. The value of PW50 depends on the physical width of the written transition, the characteristics of the magnetic medium, and the flying height of the head. Figure 4 shows the Lorenztian pulse response as well as the response to an isolated transition known as the Potter pulse [29] for the same value of PW50 and $A = 1$. The Lorentzian pulse is a single-parameter model, whereas the Potter pulse depends on the geometry of the head, the head-to-medium spacing, and the transition parameter [30, Chapter 6]. The Potter analytical pulse appears to be more appropriate for modeling the response of a MR head [30].

The data signal is read back via a low-pass filter (LPF) and a variable gain amplifier (VGA) as an analog signal, $r(t)$. The signal $r(t)$ is sampled periodically at times $t = iT$ to obtain a sequence of samples. The functions of the sampling device and VGA unit are controlled by the timing recovery and gain control loops, respectively. The sequence of samples is first shaped into a suitable PR signal format by the equalizer. The whitening filter then whitens the total distortion at the output of the equalizer, and the NPML sequence detector provides an initial estimate, $\hat{a}_i$, of the channel input symbols. Note that the functions of the PR equalizer and the whitening filter can be combined into a single filter. The initial estimate of the encoded data $\hat{a}_i$ coupled with the equalizer output, that is, hard and soft information, is fed to a noise-predictive parity-based post-processor. The post-processor is a suboptimum soft decision decoder for the parity code that corrects a specified number of the most likely error events at the output of the NPML detector by exploiting the parity information in the incoming sequence. The post-processor produces

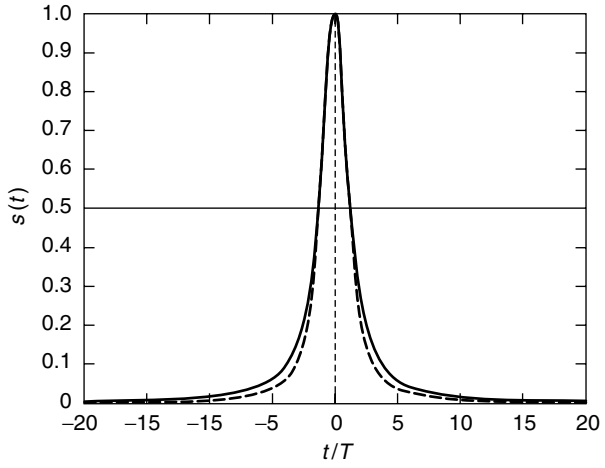

Figure 4. Isolated transition response in a magnetic-recording system. Solid line: Lorentzian pulse, dashed line: Potter pulse.

the final estimate $\hat{a}_i'$ of the modulation-encoded symbols. This sequence is fed to the modulation decoder, which delivers the final decisions. The overall performance of the recording system is very sensitive to error propagation at the modulation decoder. Thus, in practice, the design of modulation decoders with limited error propagation is crucial. Finally, after byte-deinterleaving, the RS decoder corrects any residual errors to obtain a highly reliable estimate of the original user data stored.

2.3. Linear Intersymbol-Interference Channel Model

As mentioned above, the two-level channel-input sequence, $\{a_i\}$, modulates a current source to produce a rectangular current waveform with amplitude -1 or $+1$. This rectangular current waveform can be viewed as the input to the write-head/medium/read-head assembly that produces an output voltage waveform that in essence is the differentiated and low-pass-filtered version of the input waveform corrupted by noise [31,32]. Experimental data have demonstrated that with write precompensation of magnetization transition shifts, the readback waveform is very well approximated by the sum of the appropriate series of isolated transition responses. Adopting therefore a linear model for the write/read process on a magnetic disk, the readback waveform $r(t)$ can be expressed as [31,32]

$$r(t) = \frac{d}{dt}\left[\sum_i a_i \Pi(t - iT)\right] \circledast s(t) + \eta_e(t) \tag{2}$$

where $\Pi(t)$ is a unit-amplitude rectangular pulse of duration T, $s(t)$ is the isolated transition or step response, $\eta_e(t)$ represents the additive white Gaussian electronics noise arising from read head and preamplifier, and $\circledast$ denotes convolution. The effect of medium noise in the case of well-dispersed particulate media can be taken into account by considering a second additive white Gaussian source, $\eta_m(t)$, at the channel input [33]. In this case the model in Eq. (2) becomes

$$r(t) = \frac{d}{dt}\left[\sum_i a_i \Pi(t - iT) + \eta_m(t)\right] \circledast s(t) + \eta_e(t) \tag{3}$$

It can readily be seen that the readback signal can equivalently be expressed as

$$r(t) = \sum_i a_i [s(t - iT) - s(t - T - iT)] + \eta(t) \tag{4}$$

where

$$\eta(t) = \frac{d\eta_m(t)}{dt} \circledast s(t) + \eta_e(t) \tag{5}$$

and $\dfrac{d\eta_m(t)}{dt} \circledast s(t)$ represents the medium-noise contribution to the total noise. Equation (4) describes a pulse-amplitude-modulated waveform of a binary data sequence $\{a_i\}$ transmitted at a rate of $1/T$ through a dispersive linear channel with effective impulse response $h(t) = s(t) - s(t - T)$ and received in the presence of additive noise. In a magnetic-recording system, the impulse response $h(t)$, which represents the effective impulse response of the overall magnetic-recording channel, is called pulse response because it corresponds to the response of the head/medium to a rectangular pulse. Furthermore, the quantity $D_c = \mathrm{PW50}/T$ is called normalized linear density. For a given PW50, the smaller the symbol interval T, that is, the closer the transitions, the higher the value of D_c, which implies the larger the linear density of the recording system. Conversely, the smaller the symbol interval T, the higher the interaction and overlap between the pulses, which gives rise to intersymbol interference (ISI) in a sequence of data symbols. Today's high-performance digital magnetic-recording systems operate at normalized linear densities in the range of $2.5 \le D_c \le 3.5$, where severe ISI is present in the readback signal. In such a case, the recovery of the data sequence from the readback signal requires advanced equalization and detection techniques that compensate for the presence of ISI.

Alternatively, the readback signal may be expressed in the equivalent form:

$$r(t) = \sum_i b_i s(t - iT) + \eta(t) \tag{6}$$

where $b_i = a_i - a_{i-1}$. In this case the symbol sequence $\{b_i\}$ takes values from the ternary alphabet $\{+2, 0, -2\}$. Figure 5 shows a linear ISI model of the magnetic-recording channel, where $s'(t)$ denotes the first derivative of the isolated transition response $s(t)$. The encoded NRZ data symbols a_n are passed through a $1 - D$ filter. A nonzero output of this filter corresponds to a positive or negative transition of the write current and, consequently, a transition in the magnetization pattern on the disk. The output of the $1 - D$ filter is then fed to a linear filter with impulse response $s(t)$, representing a Lorentzian, Potter, or any other analytic or experimental read-head response to an isolated transition. Finally, the readback signal is generated by adding white and colored Gaussian noise.

In the frequency domain, the overall response of the linear model may be expressed as $H(f) = S(f)[1 - e^{-j2\pi fT}]$, where $S(f)$ indicates the Fourier transform of the isolated transition response. The frequency response characteristics $H(f)$, plotted as a function of the normalized frequency fT and with D_c as a parameter, are illustrated in Fig. 6. As expected, the frequency response exhibits a spectral null at $f = 0$ because of the factor $[1 - e^{-j2\pi fT}]$. Furthermore, there is substantial high-frequency attenuation, which increases as the linear normalized density D_c is increased.

So far a linear channel model has been assumed, that is, the noise-free readback signal can be derived by linear

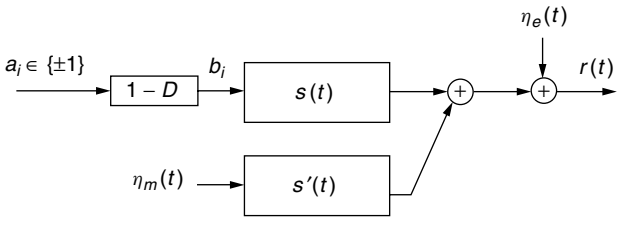

Figure 5. Linear ISI model for a magnetic-recording system.

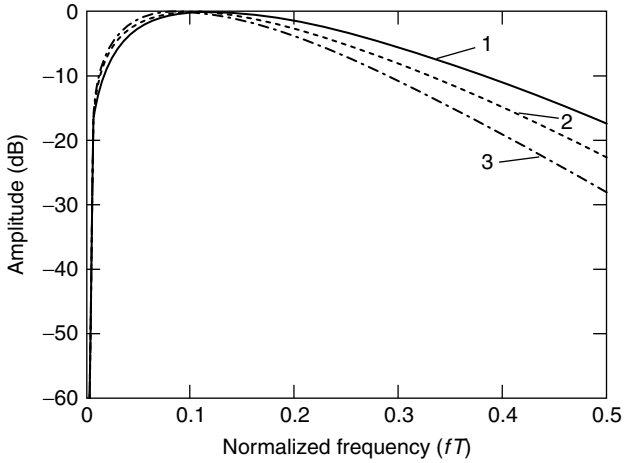

Figure 6. Frequency response to a square pulse of duration T. Curve 1: PW50/$T = 2.5$; curve 2: PW50/$T = 3.0$, and curve 3: PW50/$T = 3.5$.

superposition of isolated step responses, and the noise sources are stationary and additive. At high recording densities, the noise tends to be colored and enhanced by the linear equalizer, the nonstationary data-dependent noise becomes more dominant, and the signal becomes inherently nonlinear. Finally, today's recording systems employ thin-film media, which are dominated, as we will see below, by nonadditive noise sources.

2.4. The Microtrack Model

Recording systems using thin-film media may also exhibit a nonadditive noise known as transition noise. In general, the transition noise is due to fluctuations concentrated close to the recorded transition centers and is attributed to the random microstructural properties of the grains in thin-film recording media [34]. The effect of transition noise on equalization and data detection is more difficult to analyze than that of Gaussian noise owing to its nonstationary and data-dependent characteristics. A simple model for transition noise can be obtained by modeling the width and the position of the isolated transition response as random variables. Taking a Taylor series expansion with respect to small random deviations from the nominal value in the position and width, we can arrive at a channel model with multiplicative position jitter and pulse-widening noise sources [35].

The microtrack model developed in [18] is more general and allows a rather accurate modeling of the noise that occurs when a transition is written in thin-film magnetic-recording media. This model imitates the random zigzag effects when a transition is written. The random zigzag form of a transition is captured by dividing the recording track into N equally-sized microtracks. Figure 7 shows a track modeled by $N = 4$ microtracks, where the vertical dashed lines indicate the ideal positions of two consecutive transitions. The arrows show the direction of magnetization, whereas the short vertical lines on each microtrack indicate the corresponding positions of an instantaneous magnetization reversal. The positions of these instantaneous reversals or flips follow a specified probability density function and are chosen independently for each microtrack. Therefore, if $s(t)$ is the response to an ideal isolated transition across the entire track, then the response of the ℓ-th microtrack to a magnetization reversal at position τ_ℓ is $s(t - \tau_\ell)/N$ [18]. The noiseless output of the magnetic-recording channel to a single transition is then given by

$$\hat{s}(t) = \frac{1}{N} \sum_{\ell=1}^{N} s(t - \tau_\ell) \tag{7}$$

where τ_ℓ is the random shift associated with the ℓ-th microtrack. This random shift or jitter, τ_ℓ, is modeled as an independent and identically distributed (i.i.d.) process according to the derivative of the average cross-track magnetization profile. If the average cross-track magnetization profile has a *tanh*-shape, the jitter probability density function (pdf) is given by [34]

$$p_\tau(\tau) = \frac{1}{\pi a} \operatorname{sech}^2\left(\frac{2\tau}{\pi a}\right) = \frac{1}{\pi a} / \cosh^2\left(\frac{2\tau}{\pi a}\right) \tag{8}$$

In the case of an *erf*-shaped cross-track magnetization profile, the pdf is given by [18]

$$p_\tau(\tau) = \frac{1}{\pi a} \exp\left\{-\left(\frac{\tau}{a\sqrt{\pi}}\right)^2\right\} \tag{9}$$

In both cases a is known as the transition-width parameter, a quantity usually determined experimentally.

The microtrack model is specified by two parameters: the number of microtracks N and the transition-width parameter a. In its more general form, a third parameter, L_e, can be introduced that characterizes partial erasure and its effects. This parameter specifies the threshold below which two adjacent transitions on the same microtrack erase each other [18], see Fig. 7. The microtrack model allows a separate analysis of the write process and the transition noise. The measure of goodness of the write process is the steepness of the cross-magnetization profile. This steepness depends on the transition-width parameter a. An ideal transition

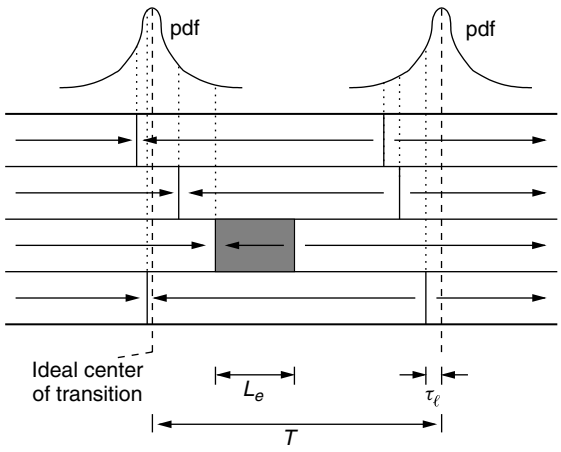

Figure 7. Microtrack model with $N = 4$ microtracks and erasure on the second microtrack.

has width zero, that is, all magnetic particles change their polarization at the same location. However, real transitions exhibit a *tanh*-shape, an *erf*-shape, or another experimentally determined cross-polarization profile. The transition- or data-dependent medium noise produced by the microtrack model is the difference between the actual output and the expected or average output with respect to the jitter distribution, that is, $\hat{s}(t) - E[\hat{s}(t)]$. As the number of microtracks increases, the transition noise decreases. By allowing $N \to \infty$ then $\hat{s}(t) \to E[\hat{s}(t)] = s(t) * p_\tau(t)$, and the transition noise is zero. In this case only electronics noise and the nonideal write process affect the performance of the magnetic-recording system via the transition-width parameter a. Another way to eliminate the effects of transition noise is to set $a = 0$. In this case $E[\hat{s}(t)] = s(t)$, and the magnetic-recording system behaves according to the linear ISI model described above.

Using Taylor's series expansion and keeping only the first two predominant terms, the transition noise for a single transition can be approximated by [18]

$$\begin{aligned}\hat{s}(t) - E[\hat{s}(t)] &= -s'(t)\left[\frac{1}{N}\sum_{\ell=1}^{N}\tau_\ell\right] \\ &\quad + s''(t)\left[\frac{1}{2N}\sum_{\ell=1}^{N}\tau_\ell^2 - \frac{1}{2}E[\tau_\ell^2]\right] \\ &\quad + \cdots \simeq s'(t)n_1 + s''(t)n_2\end{aligned} \tag{10}$$

where $n_1 = \dfrac{1}{N}\sum_{\ell=1}^{N}\tau_\ell$ and $n_2 = \dfrac{1}{2N}\sum_{\ell=1}^{N}\tau_\ell^2 - \dfrac{1}{2}E[\tau_\ell^2]$ are zero-mean random variables [18]. The random variable n_1 controls the amount of position jitter noise and is referred to as the position jitter variable, whereas the random variable n_2 controls the amount of pulse-width variation noise and is referred to as the width variable.

In general, the readback signal according to the microtrack model is expressed as

$$r(t) = \frac{1}{N}\sum_i b_i \sum_{\ell=1}^{N} s(t - iT - \tau_{\ell,i}) + \eta_e(t) \tag{11}$$

where $\tau_{\ell,i}$ is the random shift or jitter associated with the ℓ-th microtrack at the i-th symbol interval, and $\eta_e(t)$ represents additive white Gaussian noise (AWGN) characterized by its one-sided power spectral density N_0. Thus, the behavior of the magnetic-recording system can be described by the five-parameter (PW50/T, N, L_e, a, and N_0) model as shown in Fig. 8. Although for the magnetic-recording channel this model is quite versatile and encompasses the effects of both medium noise in thin-film media and electronics noise, the linear ISI model with additive Gaussian noise is still commonly used to estimate the performance of detection and coding schemes, even at ultra-high densities, and yields very accurate results.

3. MODULATION CODES

The basic principles of modulation coding, also known as coding for input-constrained channels, was established in the classic study of discrete noiseless channels [36]. With modulation coding a desired constraint is imposed on the data-input sequence so that the encoded data stream satisfies certain properties in the time or frequency domain. These codes are very important in digital-recording devices and have become ubiquitous in all data-storage applications [37].

A constrained system is represented by a labeled, directed graph, or a finite-state transition diagram (FSTD). An FSTD consists of states (or vertices) and labeled, directed transitions between states such that the allowable constrained sequences are precisely the sequences obtained by traversing paths of the diagram. The FSTD is called deterministic if at each state all outgoing transitions have distinct labels. The capacity of a constrained set of sequences represents the maximum achievable code rate of an encoder generating sequences satisfying the underlying constraint. It is given by $\log_2 \lambda_{\max}(A)$, where $\lambda_{\max}(A)$ is the largest real eigenvalue of the adjacency matrix associated with a deterministic FSTD that represents the constrained set of sequences. Among the various methods for constructing modulation codes, the state-splitting algorithm in [38] provides a systematic approach to designing finite-state encoders and sliding-block decoders for finite-type constrained systems. In practice, however, the right choices must be made during the code-construction procedure, irrespective of the approach used for code design. For example, quite often look-ahead coding techniques yield more efficient designs than the systematic state-splitting approach does. A more detailed treatment of finite-state modulation codes and their application to digital data recording can be found in [37,39].

In this section the most important classes of modulation codes will be reviewed, with emphasis on the application to magnetic recording, in particular, to hard-disk drives. Finally, the combination of the PRML(G, I) and MTR(j, k, t) codes with parity block codes in order to improve the bit error rate performance will also be discussed.

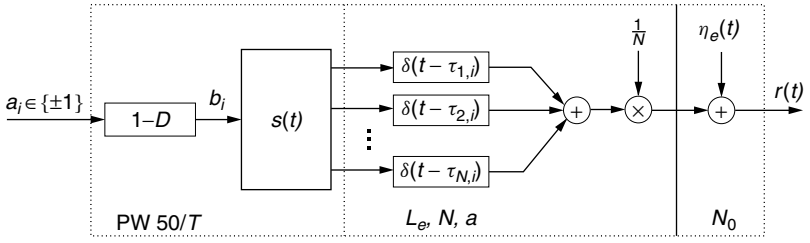

Figure 8. Data-dependent noise channel model for a magnetic-recording system. From [9], ©; IEEE 2002.

3.1. RLL(d, k) Codes

Modulation codes that impose a restriction on the number of consecutive 1s and 0s in the encoded data sequence are generally called RLL(d, k) codes. The code parameters d and k are nonnegative integers with k always larger than d, where d indicates the minimum number of 0s between two 1s and k indicates the maximum number of zeros between two 1s. At low-linear recording densities, peak-detection systems employing RLL(d, k)-constrained codes have been predominant in digital magnetic storage. RLL(d, k) codes reduce the effect of pulse interference and prevent the loss of clock synchronization. When used with the NRZ recording format, the d-constraint has the effect of spreading the transitions by at least $d + 1$ symbols further apart, thereby minimizing intersymbol interference and nonlinear distortion. The k-constraint sets an upper limit on the run of identical symbols to $k + 1$ so that useful timing information can always be extracted from the readback signal.

The set of sequences that satisfy the (d, k) constraints can be generated by the FSTD shown in Fig. 9. For (d, k)-constrained sequences the capacity can be computed as the base-2 logarithm of the largest real solution of one of the following equations [40]:

$$x^{k+2} - x^{k+1} - x^{k+1-d} = 1, \qquad k < \infty \tag{12}$$
$$x^{d+1} - x^{d} = 1, \qquad k = \infty,$$

Table 1 lists the capacity Cap(RLL(d, k)) for various values of d and k. The use of (d, k)-constrained sequences, with $d \geq 1$, allows the information density along a track to be increased while keeping the separation between adjacent recorded transitions fixed. The quantity $(d + 1)$Cap(RLL(d, k)), called the density ratio or packing density [37,41], is a direct measure of the increase in linear recording density as a function of d and of the capacity of the (d, k)-constrained sequences. Clearly, the packing density can be made arbitrarily large by increasing d. Conversely, large values of d lead to codes with very low rate, which implies high-recording symbol rates, and thus renders these codes impractical for storage systems that are limited by the clock speed. Moreover, large values of d lead to a more sensitive timing and detection window. In practical recording systems, codes with $d \leq 2$ have been used. In particular, the rate-2/3 RLL$(1, 7)$ (packing density of 4/3) and rate-1/2 RLL $(2, 7)$ (packing density of 3/2) codes have been widely used in the digital-recording industry at low-normalized densities around $D_c \simeq 1$ [37].

There are several approaches for constructing a rate-2/3 RLL$(1, 7)$ code. The simple construction in Ref. [42] is based on the code assignment of Table 2. Freely concatenating any of the four codewords from this list would violate the $d = 1$ constraint at codeword boundaries. The substitutions given in Table 3 avoid the violations at code boundaries and give rise to a *look-ahead encoder* and *sliding-block decoder*. The encoding table of the other popular rate-1/2 RLL$(2, 7)$ code is illustrated in Table 4.

3.2. PRML(G, I) Codes

The PRML scheme introduced in the early 1990s to advanced hard-disk drives operating at moderate linear recording densities, that is, approximately in the range $1.5 \leq D_c \leq 2.3$, requires a different type of constraint called (G, I) constraint [10,41]. The need for this new constraint is twofold. First, long runs of zero samples (noise-free samples) at the PR4 equalizer output can degrade the tracking performance of the timing recovery

and gain control loops. Thus, as in peak detection systems and the k-constraint described above, it is necessary to introduce a global constraint G to limit the number of zero samples at the equalizer output. Second, another constraint is necessary to limit the path memory requirements and hence force a finite decision delay in PRML detection, without incurring any significant performance degradation in the sequence of estimates produced by the detector. This constraint, referred to as the I-constraint, is related to the so-called quasi-catastrophic error propagation of PR systems [43], and imposes a limitation on the length of runs of zero samples in each of the odd and even interleaved subsequences at the PR4 equalizer output. In general, a trellis is called quasi-catastrophic if there are distinct states for which some of the output sequences starting from these states are identical and the total probability of all such indistinguishable output sequences is zero [43].

The issue of undesired sequences and the application of PRML(G, I) codes to eliminate them are more general and not restricted to PR4 shaping only. The above discussion has indicated that long strings of zeros at the PR4 channel output as well as in each of the subsequences of even and odd bit positions at the PR4 channel output constitute a set of undesired sequences that need to be eliminated. It can readily be shown that the same holds for all types of generalized PR shaping polynomials of the form $(1-D)^m(1+D)^n(1+p(D)), n, m \geq 1$, where $p(D)$ has no roots on the unit circle [22].

To facilitate the timing and gain control algorithms, in general only those channel input sequences need to be eliminated that have spectral energy at the frequencies where the generalized PR polynomial used for shaping has spectral nulls. For example, for shaping polynomials of the form $(1-D)^m(1+p(D)), m \geq 1$, exhibiting and m-th order spectral null at dc, the channel input sequences $(+1)$ and (-1) with a spectral null at dc should be eliminated. The notation (S) indicates the sequence obtained by periodically repeating the string S infinitely many times, e.g., $(ab) = ababab\cdots$. The k-constraint presented above limits the maximum length of 0s at the input of the $1/(1 \oplus D)$ precoder to k or, equivalently, the length of channel input patterns (after precoding) of type $(+1)$, (-1) to $k+1$. Similarly, it can readily be seen that for an arbitrary channel-shaping polynomial with spectral nulls at both the dc and the Nyquist frequency, the channel input sequences $(+1-1)$ and $(-1+1)$ with a spectral null at the Nyquist frequency should also be eliminated. For example, for channel-shaping polynomials of the form $(1-D^2)(1+p(D))$, the channel input sequences $(+1)$, (-1), with a spectral line at dc, as well as the sequences $(+1-1)$, $(-1+1)$, with a spectral line at the Nyquist frequency, should be eliminated. The G-constraint mentioned above limits the maximum length of 0s at the input of the $1/(1 \oplus D^2)$ precoder to G or, equivalently, the maximum length of channel input patterns of all four types $(+1)$, (-1), $(+1-1)$ and $(-1+1)$ to $G+2$ [22].

In connection with the PR4 shaping polynomial above, we have seen that another desirable code property is the elimination of quasi-catastrophic error propagation, which is inherent in maximum likelihood sequence detection of any generalized PR channel with spectral nulls [43]. This property allows the path memory size of the sequence detector to be reduced without degrading its bit error rate performance. Quasi-catastrophic error propagation is prevented by eliminating all channel-input error sequences $\{\varepsilon_i\} = \{a_i - \hat{a}_i\}$ that have spectral energy at those frequencies where the channel has spectral nulls. For generalized PR polynominals of the form $(1-D)^m(1+p(D)), m \geq 1$, the k-constraint at the input of a $1/(1 \oplus D)$ precoder is sufficient to eliminate quasi-catastrophic error propagation, because it limits the maximum length of channel-input error patterns of type $(+2)$, (-2) to $k+1x$. Conversely, for shaping polynominals that also exhibit spectral nulls at the Nyquist frequency, such as for example the shaping polynominal $(1-D^2)(1+p(D))$, which is very often used in practical systems, more channel-input error patterns need to be eliminated. Specifically, it can readily be seen that in this case it is necessary, and sufficient, to limit the maximum length of channel-input error patterns of the type $(+2)$, (-2), $(+2\,-2)$, $(-2\,+2)$, $(+2\,0)$, $(0\,+2)$, $(-2\,0)$, $(0\,-2)$. In general, these channel-input patterns exhaustively characterize the undesired quasi-catastrophic sequences for arbitrary shaping polynomials of the form $(1-D)^m(1+D)^n(1+p(D))$, where $n, m \geq 1$ (see also [44]). The I-constraint discussed above at the input of a $1/(1 \oplus D^2)$ precoder limits the maximum length of channel-input error patterns of type $(+2)$, (-2), $(+2\,-2)$, $(-2\,+2)$ to $2I+2$, and of type $(+2\,0)$, $(0\,+2)$, $(-2\,0)$, $(0\,-2)$ to $2I+3$. Note that an additional G-constraint, $G \leq 2I$, further reduces the maximum length of error patterns of type $(+2)$, (-2), $(+2\,-2)$, $(-2\,+2)$ [22].

The most widely used code rates for PRML(G, I) codes in the industry have been 8/9 and 16/17. The optimal block lists of length 9 for constructing block-encodable/decodable rate-8/9 PRML$(4, 4)$ and rate-8/9 PRML$(3, 6)$ codes can be found in [45]. By slightly relaxing the G and I parameters, it was also possible to construct a rate-16/17 PRML$(6, 6)$ code [46].

3.3. MTR Codes

The MTR(j, k) codes introduced in [21] result in a direct coding gain or improved performance by eliminating some of the predominant error events in conjunction with sequence detection. In addition to the benefits of an enhanced coding gain, MTR codes are useful in controlling nonlinear phenomena associated with the fast switching of the write head. More specifically, the MTR constraints are characterized by the parameters j, the maximum number of consecutive 1s that can occur, and k, the maximum number of zeros that can occur. Figure 10 shows the FSTDs generating sequences according to the MTR$(j = 2, k = \infty)$ and MTR$(j = 3, k = \infty)$ constraints. The FSTD of the MTR$(j = 2, k = 5)$ constraint is illustrated in Fig. 11. It can readily be verified that in all sequences obtained by traversing the paths of the diagram in Fig. 11, the consecutive runs of 1s are limited to two. Also, the runs of consecutive 0s are limited to five for timing-recovery purposes. The capacities of these FSTDs are Cap(MTR$(j = 2, k = 5)) = 0.8578$, Cap(MTR$(j = 2, k = \infty)) = 0.8791$, and Cap(MTR$(j = 3, k = \infty)) = 0.9468$.

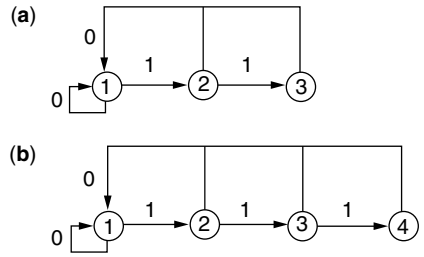

Figure 10. FSTDs for (**a**) MTR($j = 2, k = \infty$) and (**b**) MTR($j = 3$, $k = \infty$) constrained sequences.

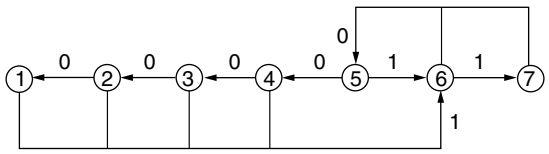

Figure 11. FSTD for MTR($j = 2, k = 5$) constrained sequences.

In general, MTR(j, k) codes do not avoid quasi-catastrophic error propagation in sequence detectors for PR polynomials with spectral nulls at both dc and the Nyquist frequency. The k-constraint avoids channel-input error sequences that have spectral energy only at dc, whereas the j-constraint avoids channel-input error sequences that have spectral energy only at the Nyquist frequency. Therefore, an additional constraint is needed to limit the maximum length of channel-input error sequences of type $(+2\,0)$, $(0\,+2)$, $(-2\,0)$, $(0\,-2)$ that have spectral energy at both dc and the Nyquist frequency. This new constraint for MTR codes, known as the *twins* or t-constraint, has been introduced in [22]. In simple terms the MTR encoder satisfies a t-constraint if it does not allow $t + 1$ consecutive pairs of 0s or 1s (twins). For example if $t = 8$ then nine consecutive twins are not allowed, that is, the string 00 00 11 00 00 00 11 00 11 is not allowed. Sequences that satisfy the t-constraint and at the same time are j- and k-constrained are denoted by MTR(j, k, t) [22]. The derivation of the deterministic FSTD that describes the MTR(j, k, t) constraint is presented in [22]. Figure 12 illustrates a 30-state labeled directed graph for the MTR($j = 2, k = 7, t = 4$) constraint. The capacity of this FSTD is Cap(MTR($j = 2, k = 7, t = 4$) = 0.8591. Tables 5 and 6 list the capacities Cap(MTR($j = 2, k, t$)) and Cap(MTR($j = 3, k, t$)) for various values of the parameters k and t. Codes based on the MTR(j, k, t) constraints eliminate the problem of error propagation in sequence detection for all PR shaping polynomials of the form $(1 - D)^m(1 + D)^n(1 + p(D))$, $m, n \geq 1$. Note that this class of PR polynomials includes PR4, EPR4 (extended PR4), and E^{2}PR4, (extended-square PR4) corresponding to $(1 - D^2)$, $(1 - D^2)(1 + D)$, and $(1 - D^2)(1 + D)^2$ shaping polynomials, respectively, which have been very important in practical systems. For shaping polynomials with memory greater than $j + 1$, the j-constraint can readily be incorporated into the detector to reduce the number of states or branches in the trellis, and to increase the capacity by allowing new potential sequences which were forbidden in MTR(j, k, t) [22].

In a NRZI format the j-constraint imposes a limit on the maximum number of consecutive transitions in the write current. In particular, the original MTR$(j = 2, k)$ codes that do not allow three consecutive transitions to appear in any encoded sequence have the interesting property of eliminating bit patterns that cause the most common error events in sequence detection. Figure 13 shows typical error patterns that are eliminated by these codes. These error patterns correspond to the NRZ error events of the form $\{\pm 2, \mp 2, \pm 2\}$. It can easily be seen that error bursts of the form $\{\pm 2, \mp 2, \pm 2, \ldots\}$ and length greater than three are also eliminated by the $j = 2$ constraint. These error events correspond to mistaking the polarity of an alternating write current for three or more channel symbol intervals. However, the distance gain realized by eliminating these error events is offset by a significant rate loss penalty. In particular, the maximum possible code rates for the original MTR$(j = 2, k)$ constraint [21]

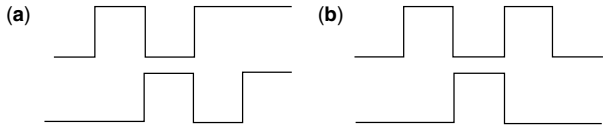

Figure 13. Error patterns eliminated by the $j = 2$ constraint. (**a**) Tribit shift, (**b**) quadbit to dibit.

and the MTR$(j = 2, k, t)$ constraint [22] are less than 8/9, leading to an unacceptable loss of performance due to the low code rate. Time-varying constraints, in which $j = 2$ is observed only at even bit positions (referred to as MTR $j = 2, 3$ constraints), permit the design of higher-rate MTR codes while maintaining their distance gain. The rates of the codes that have been designed to satisfy time-varying MTR$(j = 2, 3, k)$ constraints are 8/9 [47], and slightly higher [48,49]. These rates are still not adequately high for magnetic-recording applications.

An alternative coding strategy is to allow the error event $\{\pm 2, \mp 2, \pm 2\}$ to occur partially and to eliminate all other error events that correspond to mistaking the polarity of an alternating write current for four or more channel symbol intervals. In this way higher-rate codes can be constructed, thereby reducing the signal-to-noise ratio (SNR) penalty due to rate loss. For example, by using a $j = 3$ constraint in conjunction with a j-constrained trellis, all error events of the type $\{\pm 2, \mp 2, \pm 2, \mp 2, \}$, $\{\pm 2, \mp 2, \pm 2, \mp 2, \pm 2\}$, and so on are eliminated. Moreover, also the error event $\{\pm 2, \mp 2, \pm 2\}$ is partially eliminated because the quadbit-to-dibit error cannot occur (see Fig. 13). The rate-16/17 MTR$(j = 3, k = 12, t = 16)$ look-ahead code and the time-varying MTR$(j = 3, 4, k = 18, t = 14)$ block code, described in [22], have this interesting performance-enhancing property and have been implemented in various magnetic-recording systems. The construction of the rate-16/17 block-encodable/decodable MTR$(j = 3, 4, k = 18, t = 14)$ code, as described in [22], will be outlined briefly because of its practical significance. It can be verified that there are in total $65753 > 2^{16}$ potential codewords that can be generated by starting in state two in Fig. 10b, making 17 transitions and terminating in states one, two, or three. Among these codewords there are 199 codewords that begin or end with 10 zeros. After discarding these codewords and 17 more codewords that start with the first 15 bits of one of the strings (1001), (0110), (0011), (1100), or end with the first 16 bits of one of the strings (1001), (0110), (0011), or (1100), a set of 65537 codewords is obtained. These 17-bit codewords can be freely concatenated without violating the $j = 3$ constraint except at the border of two codewords, where the constraint is relaxed to $j = 4$. Furthermore, $k = 18$ and $t = 14$ is obtained.

In general, the performance-enhancing features of the class of high-rate MTR codes render them very attractive compared with conventional PRML(G, I) codes. Of course, ultimately, the coding gain of an MTR code is determined by the tradeoff among various factors such as rate loss, error propagation at the MTR decoder, and performance-improving properties of the MTR code. Finally, it is worthwhile mentioning that for a long time the conventional (G, I) and MTR constraints were discussed separately in the literature, and no connection was made between them. Very recently a theoretical result was presented in [22] showing that the precoded (G, I) constraints are a subclass of the precoded MTR constraints. This very interesting property allows an alternative code-construction methodology for (G, I) codes that is based on employing the $1/(1 \oplus D)$ precoder used by MTR codes.

3.4. Combined Modulation/Parity Codes

As discussed above, PR shaping for the magnetic-recording channel was normally used in conjunction with byte-oriented PRML(G, I) or MTR(j, k, t) modulation codes to aid timing recovery and gain control, to limit the path memory length, and to enhance the performance of the sequence detector. Until recently, these codes have been widely used in the disk-drive industry since the introduction of PR4 and maximum likelihood sequence detection more than ten years ago [10].

Because of the channel memory and the slight noise coloration, sequence detection produces some error patterns more frequently than others. These predominant error patterns or error events at the sequence detector output depend on the generalized PR shaping polynomial, the noise blend, and the normalized linear recording density D_c. For example, Table 7 shows the error events at the 16-state NPML detector output in the case of electronics noise only and $D_c = 3.4$. A shorthand notation to represent ternary error events has been used. For example, $\{+, -, +\}$ is used to denote the events $\{+2, -2, +2\}$ and $\{-2, +2, -2\}$. At high-recording linear densities, the predominant error event is of the type $\{+, -, +\}$. Simulation and experimental data have shown that at low and moderate linear densities the error event $\{+\}$ predominates. Note that the relative percentage of the various error events also depends on the noise conditions, that is, the noise blend between electronics, transition, and colored stationary media noise. These observations suggested the use of modulation codes combined with multiparity block codes to improve performance even further, but at the expense of a slight decrease in code rate. The basic concept is to use parity to detect the presence of an error event from a list of predominant error events. Decoding is achieved by a technique that combines syndrome and soft-decision decoding and is known in the industry as parity-based post-processing [23–28]. A combined modulation/parity code is constructed from a

Table 7. Error Events at NPML Detector Output (PW50/T = 3.4)

Error Events	Relative Frequency
$+-+$	62%
$+$	15%
$+-$	10%
$+-+-+$	4%
$+-+-$	2%
$+\,0\,0+$	1%
$+-+-+-$	1%
other	5%

(G, I) or MTR code by adding parity bits to the (G, I) or MTR codewords. Specifically, the design aims at single or double error-event detection from a prespecified list of error events so that the probability of miscorrection is minimum. Practical reasons, such as complexity and decoding delay, dictate the use of a short list of error events and short codes. Therefore, to keep the code-rate as high as possible, only a small number of parity bits may be used. Typically, the (G, I) codewords are extended by one to four parity bits. In [27] an elaborate approach to designing error-event detection codes is proposed. The code construction methodology is based on a recursive approach for building the parity-check matrix by adding one column at a time. A new column is added to the parity-check matrix if and only if the prespecified error-event detection capability is satisfied [27].

The approach adopted in [23,25,26,28] is based on simple polynomial codes characterized by their generator polynomial $g_c(D)$, whose degree specifies the total number of parity bits. The single-parity code $g_c(D) = 1 \oplus D$ ensures that there is an even number of 1s in the codeword. It can therefore detect error events of odd length. The double-parity code with $g_c(D) = 1 \oplus D^2$ adds two parity bits such that both odd and even interleaves of the codeword have an even number of 1s. The polynomial codes with primitive generator polynomials $g_c(D) = 1 \oplus D \oplus D^3$ and $g_c(D) = 1 \oplus D \oplus D^4$ add three and four parity bits, respectively. In all cases the combined modulation/parity code satisfies the prespecified (G, I) constraint. Examples of combined modulation/parity codes proposed in the literature include rate-32/35 PRML$(G = 7, I = 7)$ single-parity bit code [23], and rate-64/66, -64/67, -64/68, and -64/69 PRML(G, I) single-parity, dual-parity, triple-parity, and quadruple-parity codes, respectively, [25,26,28]. Moreover, longer block-length rate-96/101 and -96/102 PRML(G, I) triple-parity and quadruple-parity codes, respectively, have been discussed in [24–26].

An alternative design approach is to use performance-enhancing MTR modulation codes instead of the simple (G, I) codes. For example, the time-varying MTR$(j = 3, 4, k = 18, t = 14)$ block code presented above eliminates all error events of the type $\{\pm 2, \mp 2, \pm 2, \mp 2\}$, $\{\pm 2, \mp 2, \pm 2, \mp 2, \pm 2\}$, and so on. More important, this code also eliminates almost 50% of the error events of the type $\{\pm 2, \mp 2, \pm 2\}$. Therefore, two parity bits are adequate to detect the remaining predominant error events $\{\pm 2, \mp 2, \pm 2\}$, $\{\pm 2\}$, $\{\pm 2, \mp 2\}$, and $\{\pm 2, 0, 0, \pm 2\}$. By concatenating six 17-bit MTR$(j = 3, 4, k = 18, t = 14)$ codewords and inserting two parity bits in appropriate locations a rate-96/104 MTR$(j = 3, 4, k = 18, t = 14)$ dual-parity code is obtained.

4. EQUALIZATION AND DETECTION TECHNIQUES

The role of advanced signal processing has been crucial in increasing the areal density in magnetic storage devices. Until the beginning of the past decade, all commercially available disk-drive systems used analog peak detection. A peak detector operates on the analog readback signal to detect the presence of a pulse within a sliding observation window. At low linear densities, the location of peaks in the readback waveform will closely correspond to the location of the transitions in the input current waveform. Therefore, with an accurate clock signal, the recorded data pattern can in principle be reconstructed by correctly determining the pulse positions in the readback waveform. For a long time, peak detectors combined with RLL(d, k) modulation codes, which improve missing-bit errors by spacing transitions further apart, provided a low-cost detection strategy.

Recent advances in VLSI technologies and the need for ever higher areal densities paved the way for advanced signal-processing techniques, including maximum-likelihood sequence detection (MLSD) or near-MLSD schemes. The noise in hard-disk drive systems is a combination of electronics noise, colored stationary media noise, and transition noise. Although the first two noise sources can be treated as additive and Gaussian sources, the third is data-dependent, non-Gaussian and nonadditive.

For the purpose of introducing the optimum detection scheme for the readback signal, we will first consider the linear ISI model for the magnetic-recording system shown in Fig. 5. In this case, it can readily be shown [50,51] that the optimum signal processing and detection method consists of a filter matched to the pulse response, $h(t)$, a symbol-rate sampler, a whitening filter, and a MLSD as shown in Fig. 14. The output of the symbol-rate sampler will then be

$$u_i = \sum_{\ell} a_\ell R_h(i - \ell) + \nu_i \tag{13}$$

where $R_h(i)$ is the sampled autocorrelation function of $h(t)$ defined by

$$R_h(i) = \int_{-\infty}^{+\infty} h(t)h(t + iT)\,dt \tag{14}$$

$1/T$ is the rate at which the encoded date are written in the magnetic medium, and $\{\nu_i\}$ is the additive noise sequence given by

$$\nu_i = \int_{-\infty}^{+\infty} \eta(t)h(t - iT)\,dt \tag{15}$$

In Fig. 14, the binary modulation-encoded data sequence $\{a_i\}$ is represented by the D-transform $a(D) = \sum_i a_i D^i$ and

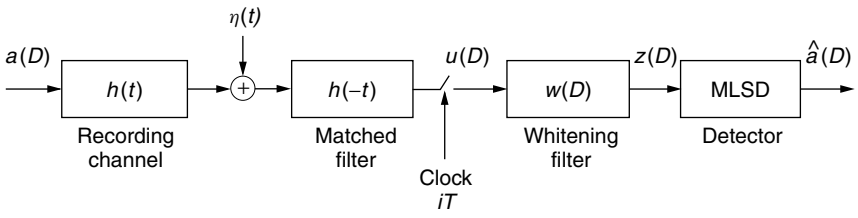

Figure 14. Magnetic-recording system with optimum signal processing and MLSD detection.

has power spectral density $S_a(D)$. Also the D-transform of the symbol-rate sampler output sequence $\{u_i\}$ is denoted by

$$u(D) = a(D)S_h(D) + \nu(D) \tag{16}$$

where $S_h(D)$ indicates the D-transform of the sampled autocorrelation function $R_h(i)$. By observing Eq. (15) it can readily be seen that the power spectral density of the noise sequence $\{\nu_i\}$ is $S_\nu(D) = S_\eta(D)S_h(D)$, where $S_\eta(D)$ denotes the D-transform of the sampled autocorrelation function $R_\eta(i)$ of the additive Gaussian process $\eta(t)$, that is, $R_\eta(i) = \int_{-\infty}^{+\infty} \eta(t)\eta(t+iT)\,dt$. Note that if the only noise source is the electronics noise due to the read head and preamplifier, then $S_\nu(D) = N_0\, S_h(D)$.

After symbol-rate sampling, the sequence at the output of the matched filter enters the whitening filter with transfer function $w(D)$. The output of the whitening filter is given by

$$z(D) = a(D)S_h(D)w(D) + \nu(D)w(D) = a(D)g(D) + e(D) \tag{17}$$

Observe that the desired signal component is affected by ISI through the overall transfer function $g(D) = S_h(D)w(D)$. Although it appears that the ISI may affect an infinite number of previously recorded symbols, in practice only a finite number of terms of $g(D)$ play a role in the sequence-detection process. This allows modeling the digital magnetic-recording system by an equivalent discrete-time finite-impulse-response (FIR) model with a minimum-phase transfer function $g(D)$ [52], where

$$g(D) = \sum_{\ell=0}^{M} g_\ell D^\ell \tag{18}$$

The MLSD that follows the whitening filter determines the most likely recorded sequence $\hat{a}(D)$ based on the observed sequence $z(D)$. It is well known that the MLSD is efficiently implemented with the Viterbi algorithm, whose complexity increases exponentially with the memory length. For an ISI span of M symbols, the state complexity of the optimum MLSD is 2^M. At low-linear recording densities, M may extend to only a few symbols. However, for $D_c > 3$, the ISI may extend to eight or even more symbols.

The optimum detector in the presence of ISI and additive Gaussian noise could therefore be prohibitively complex to implement because of its excessive state complexity. To circumvent this problem, a variety of suboptimal lower-complexity schemes have been developed aiming at reducing the span of ISI and consequently the complexity of the resulting MLSD. PR shaping to prescribed ISI targets has been very early recognized as an affective way to reduce the channel memory and also match the overall channel frequency response. In the following sections the most important suboptimum detection schemes will be reviewed, with emphasis on the ones that have extensively been used in high-performance direct-access storage devices.

4.1. PRML Detection

Partial response techniques for the magnetic-recording channel are similar to those that have been used in digital communication systems [50]. According to these techniques, the overall channel is shaped to some prescribed ISI pattern for which simple detection methods are known. The similarity between the pulse response in a magnetic-recording system and certain PR shapes was first noted in [53]. In particular, it was observed that at recording densities corresponding to $D_c \approx 2$, the frequency-domain representation of the Lorentzian pulse response closely resembles that of a linear filter with impulse response given by

$$f(t) = \operatorname{sinc}\left(\frac{t}{T}\right) - \operatorname{sinc}\left(\frac{t-2T}{T}\right) \tag{19}$$

where $\operatorname{sinc}(t) = \sin(\pi t)/\pi t$. It can readily be seen that at all times that are multiples of T, the value of the function $f(t)$ is zero except at times $t = 0$ and $t = 2T$, where the function takes the values $+1$ and -1, respectively. The discrete-time representation of this recording channel model corresponds to an overall noiseless input–output relationship given by

$$x_i = a_i - a_{i-2} \tag{20}$$

In D-transform notation, the input–output relationship becomes

$$x(D) = a(D)f(D) = a(D)(1 - D^2) \tag{21}$$

where the overall transfer function $f(D) = 1 - D^2$ is known in the literature as partial-response class-4 or PR4 shape. For higher linear recording densities, PR polynomials of the form

$$f_N(D) = (1 - D)(1 + D)^N \qquad N \geq 1 \tag{22}$$

are more suitable because their spectral characteristics match the spectral characteristics of the magnetic-recording channel better [54]. Clearly, the frequency response corresponding to $f_N(D)$ exhibits a spectral null at zero frequency and an N-th order null at the Nyquist frequency. Moreover, the PR4 polynomial corresponds to $N = 1$, whereas the PR polynomials with $N > 1$ are referred to as *extended* PR4 polynomials and are denoted as $\mathrm{E^{N-1}PR4}$. The PR4 and EPR4 shaping polynomials have been used extensively in hard-disk drives.

Simple linear equalization techniques may be employed to yield a prescribed PR shape. After symbol-rate sampling at the output of the matched filter, the samples enter a PR equalizer with transfer function $c(D)$, as shown in Fig. 15. The coefficients of the PR equalizer $\{c_\ell\}$ are optimized such that the overall transfer function, including channel and matched filter, closely matches a desired PR polynomial, that is,

$$c(D) = \frac{f_N(D)}{S_h(D)} \tag{23}$$

This equalizer is called zero-forcing linear equalizer, and shapes the incoming sequence $\{u_\ell\}$ according to any of the PR polynomials given by Eq. (22). If the magnetic-recording channel with additive Gaussian noise

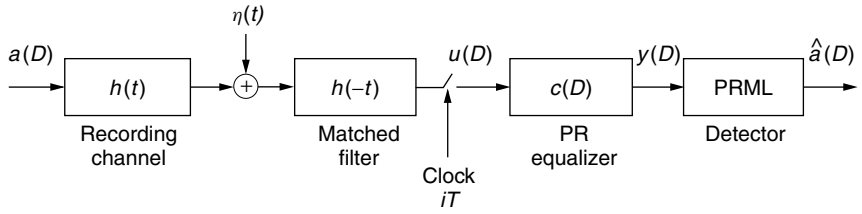

Figure 15. Magnetic-recording system with PRML detection.

is equalized to a PR target $f_N(D)$, the signal at the input of the detector becomes

$$\begin{aligned} y(D) &= a(D)S_h(D)c(D) + \nu(D)c(D) \\ &= a(D)f_N(D) + n(D) = x(D) + n(D) \end{aligned} \tag{24}$$

Thus, the zero-forcing linear equalizer limits the span of ISI to a small number of symbols, allowing an implementation of the MLSD for the desired PR target $f_N(D)$ with a small number of states.

After zero-forcing linear equalization, the noise sequence $n(D)$ is a discrete-time filtered version of the additive Gaussian noise $\eta(t)$. The power spectral density of $n(D)$ is

$$S_n(D) = \frac{f_N(D)f_N(D^{-1})}{S_h(D)} S_\eta(D) \tag{25}$$

Therefore, the variance of the noise sequence $\{n_i\}$ is

$$\sigma_n^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi} S_n(e^{jw})\,dw = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{|f_N(e^{jw})|^2}{S_h(e^{jw})} S_\eta(e^{jw})\,dw \tag{26}$$

This variance is a measure of the noise power at the input to the detector. Given that the noise sequence $n(D)$ is Gaussian and assuming that it also is an i.i.d. sequence of random variables (a reasonable assumption provided the selected PR target closely matches the magnetic-recording channel characteristics at the specified linear recording density), the most likely recorded sequence $\hat{a}(D)$ is the one that minimizes the squared Euclidean distance between the equalized sequence $y(D)$ and the noiseless sequence $x(D) = a(D)f_N(D)$. Equivalently,

$$\begin{aligned} \hat{a}(D) &= \arg\min_{a(D)} \|y(D) - x(D)\|^2 \\ &= \arg\min_{a(D)} \|y(D) - a(D)f_N(D)\|^2 \end{aligned} \tag{27}$$

The minimization in Eq. (27) can be efficiently achieved using the Viterbi algorithm. The combination of PR equalization techniques with MLSD is known in the industry as PRML detection [10]. The Viterbi algorithm is usually described via a finite-state transition diagram that evolves in time, known as the trellis diagram. The implementation complexity of the Viterbi algorithm depends on the number of states of the corresponding trellis. A $E^{N-1}PR4$ shaping polynomial gives rise to a trellis with 2^{N+1} states. In the case of PR4 and EPR4, the number of states is four and eight, respectively.

The application of the Viterbi algorithm for a PR4 shaped magnetic-recording channel was first proposed in [55], where it was also shown that a potential gain of 3 dB could be achieved using this dynamic programming procedure. The state complexity of a PR4-based detector can be further reduced by noting that the Euclidean metric in Eq. (27) can be split into two terms: one involving the odd indices and the other the even indices. Thus, in this special case, the Viterbi algorithm can be applied to two independent 2-state trellises operating on the even and odd PR4-equalized subsequences $\{y_{2i}\}$ and $\{y_{2i+1}\}$, respectively [10,56]. The Viterbi algorithm on each of the two 2-state trellises shown in Fig. 16 can be further simplified substantially by considering only the difference between the two survivor metrics and thus transforming the algorithm into a dynamic-threshold computation scheme ([10,56], and references therein). All these simplifications inherent in PR4 shaping led to the incorporation of the PR4-based PRML detection technology into magnetic hard-disk drives as well as magnetic tape systems. It was first introduced in the early 1990s in a commercial 5.25-inch IBM disk drive. The PR4-based PRML technology had a tremendous impact in the hard-disk drive industry and became the de-facto standard. Analytical studies, simulation results, and experimental data have shown that PR4-based PRML systems offer a 30–50% increase in linear recording density over RLL(2, 7) or RLL(1, 7) peak detection systems.

At higher linear recording densities, that is, $D_c > 2$, the linear PR4 equalizer leads to substantial noise enhancement, which increasingly affects the performance of the PRML system. EPR4 shaping alleviates this problem, to a certain extent, but increases the memory of the shaping polynomial to three and hence the number of states in the corresponding trellis to eight. Like PR4 shaping, the EPR4 polynomial exhibits spectral nulls at zero and the Nyquist frequencies; therefore, the magnetic-recording system would require similar PRML(G, I) codes

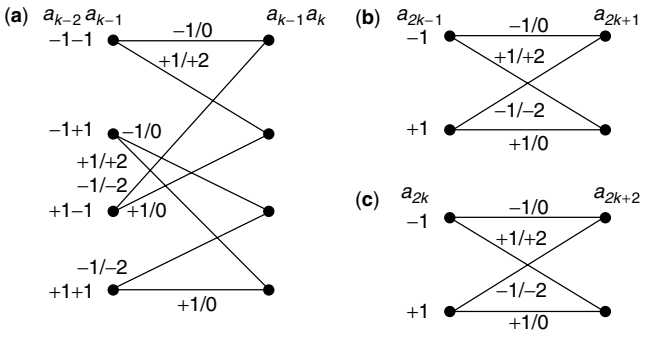

Figure 16. (**a**) 4-state PR4 trellis diagram. (**b**) 2-state odd and (**c**) 2-state even interleaved $1 - D$ trellis.

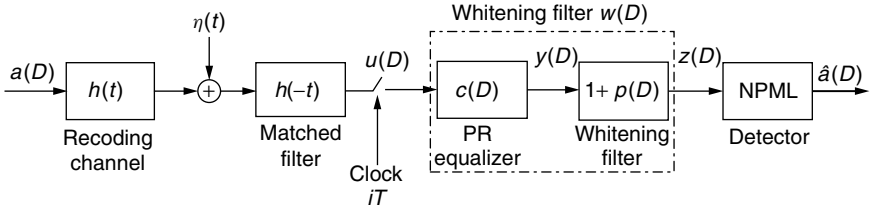

Figure 17. Magnetic-recording system with NPML detection.

to eliminate quasi-catastrophic error propagation, limit the path memory length, and facilitate timing and gain control. EPR4-based PRML systems achieve an additional 15% increase in linear recording density over PR4-based PRML systems, and the scheme has been used by some disk-drive manufactures for a limited period of time. Higher-order PR polynomials, that is, $N > 2$, although suitable for magnetic recording from the shaping characteristics point of view, do not achieve the matched filter bound and thus are of less interest. Hence, generalized PR polynomials in which the coefficients of the desired target response are nonintegers became significant in practical systems.

4.2. NPML Detection

In the absence of noise enhancement and noise correlation, the PRML sequence detector performs maximum-likelihood sequence detection. But there is an obvious loss of optimality associated with linear PR equalization as the operating point moves to higher linear recording densities. Clearly, a very close match between the desired target polynomial and the physical channel will guarantee that this loss will be minimal. An effective way to achieve near optimal performance independent of the operating point — in terms of linear recording density — and the noise conditions is via noise prediction. In particular, the power of the noise sequence $n(D)$ at the output of the PR linear equalizer can be minimized by using an infinitely long predictor. A linear predictor with coefficients $\{p_\ell\}$ operating on the noise sequence $n(D)$ will produce the estimate $\hat{n}(D)$, where the prediction-error sequence is given by

$$e(D) = n(D) + \hat{n}(D) = n(D)(1 + p(D)) \tag{28}$$

The optimum predictor $p(D) = p_1 D + p_2 D^2 + \cdots$, which minimizes the mean-square error $E\{|e_i|^2\}$ is given by $p(D) = q(D)/q_0 - 1$, where $q(D)$ is the minimum phase causal factor of $1/S_n(D)$ in Eq. (25). Using results from prediction theory, one readily obtains the minimum achievable mean-square error, which is also the variance of the white noise sequence at the output of the whitening filter $1 + p(D)$ shown in Fig. 17 and is given by [11]

$$\sigma_e^2 = \exp\left\{\frac{1}{2\pi}\int_{-\pi}^{\pi} \ln \frac{S_\eta(e^{j\omega})}{S_h(e^{j\omega})}\, d\omega\right\} \tag{29}$$

Assuming that the additive noise process before matched-filtering is white and Gaussian with power spectral density $S_\eta(D) = N_0$, that is, the case of electronics noise only, Eq. (29) reduces to an expression that is identical to the minimum mean-square error (MMSE) of an infinitely long zero-forcing decision-feedback equalizer (DFE). Thus, the combination of the PR linear equalizer with the infinitely long noise predictor, shown in Fig. 17, is equivalent to the forward filter of a zero-forcing DFE, which in turn is the optimum whitening filter $w(D)$ of the MLSD [57]. Hence,

$$w(D) = c(D)(1 + p(D)) \tag{30}$$

and the sequence at the input of the detector becomes

$$z(D) = a(D)f(D)(1 + p(D)) + e(D) \tag{31}$$

where $e(D)$ is an AWGN sequence with variance given by Eq. (29). Note that in general the linear PR equalizer $\{c_\ell\}$ can be optimized so that the coefficients of the desired target $\{f_k\}$ can take any arbitrary value, that is,

$$f(D) = \sum_{\ell=0}^{K} f_\ell D^\ell \tag{32}$$

If $f_0 = 1$ and $f(D)$ is minimum phase, then the variance of the noise at the output of the whitening filter is still given by Eq. (29) [11].

So far, the zero-forcing criterion for obtaining the equalizer coefficients $\{c_\ell\}$ has been considered for the development of the NPML detection technique. Similar results can be obtained by using the MMSE criterion for optimizing the linear PR equalizer. For more details on this topic the reader is referred to [11].

The important result of Eq. (31) is that with this method the desired generalized PR target can be factored into two terms. The first factor contains spectral nulls or near nulls at selected frequencies, reflecting the nulls or near nulls of the physical magnetic-recording channel. The second factor, without roots on the unit circle, is optimized depending on the linear recording density and noise conditions. Note that spectral nulls at frequencies $f = 0$ and $f = 1/2T$ play an important role in practical systems because they render the sequence detector insensitive to dc offsets and disturbances around the Nyquist frequency.

An infinitely long predictor filter would lead to a sequence detector structure that requires an unbounded number of states. Finite-length predictors and, in particular, shaping polynomials of the form $g(D) = (1 - D)(1 + p(D))$ with a spectral null at dc and $g(D) = (1 - D^2)(1 + p(D))$ with spectral nulls at both dc and the Nyquist frequency, where $p(D) = \sum_{\ell=1}^{L} p_\ell D^\ell$ is the transfer function of a predictor of finite order L, render the noise at the input of the sequence detector approximately white. This class of generalized PR polynomials, which

is significant in practical applications, as well as any generalized PR shaping polynominal of the form $g(D) = f(D)(1 + p(D))$, when combined with sequence detection, give rise to NPML systems [11,12,14,15]. For a generalized PR target characterized by the polynomial $g(D) = (1 - D)(1 + p(D))$, the effective ISI memory of the system is limited to $M = L + 1$ symbols, and the NPML detector performs maximum-likelihood sequence detection using the 2^{L+1}-state trellis corresponding to $g(D)$. The same holds for generalized PR targets of the form $g(D) = (1 - D^2)(1 + p(D))$. In this case the effective ISI memory of the system is limited to $M = L + 2$ symbols, and the NPML detector performs maximum-likelihood sequence detection using the 2^{L+2}-state trellis corresponding to $g(D)$. Finally, if $g(D) = f(D)(1 + p(D))$, then the effective memory of the system is limited to $M = L + K$, giving rise to a 2^{L+K}-state NPML detector. In any case, the NPML detector is efficiently implemented by using the Viterbi algorithm, which recursively computes

$$\hat{a}(D) = \arg \min_{a(D)} \|z(D) - a(D)g(D)\|^2 \tag{33}$$

For large values of L, which implies white Gaussian noise at the output of the predictor filter, the performance of NPML may be determined by the technique described in [52]. At high SNR, the probability of error for NPML detection can be approximated by

$$P_b \approx K_0 Q\left(\frac{d_{\min}}{2\sigma_e}\right) \tag{34}$$

where $d^2_{\min}$ is the minimum Euclidean distance of an error event, σ_e^2 is the variance of the AWGN at the output of the predictor given in Eq. (29), and K_0 is a constant.

The variance σ_e^2 of the noise is a measure of performance because it represents the effective SNR at the input to the NPML detector. It is plotted in Fig. 18 as a function of the normalized linear density D_c for selected generalized PR shaping polynomials. The system is only affected by electronics noise, and the SNR is assumed constant at 25 dB. Curve 1 corresponds to the case of an infinitely long whitening filter $w(D)$. Curves 2 and 3 correspond to the memory-four shaping polynomials $g(D) = (1 - D^2)(1 + p_1 D + p_2 D^2)$ and $g(D) = (1 - D)(1 + 0.75D)(1 + p_1 D + p_2 D^2)$, respectively. Finally, curve 4 corresponds to a memory-six shaping polynomial assuming a PR4 equalizer followed by a four-coefficient predictor. In all cases a simple 5-pole Butterworth filter instead of a matched filter has been assumed. Furthermore, the results for curves 2 and 4 have been obtained by using a linear PR4 equalizer with 10 coefficients, whereas those for curve 3 have been obtained by using a $(1 - D)(1 + 0.75D)$ 10-coefficient PR linear equalizer. As can be seen a memory 4-target giving rise to a 16-state NPML detector is uniformly good for $2 \le D_c \le 3.6$. In fact, the variance of the noise at the input of the 16-state NPML detector is at most 1.2 dB worse than the variance of an infinitely long whitening filter. The class of 16-state NPML detectors associated with order $L = 3$ predictor filters $(g(D) = (1 - D)(1 + p_1 D + p_2 D^2 + p_3 D^3))$ or order $L = 2$ predictor filters $(g(D) = (1 - D^2)(1 + p_1 D + p_2 D^2))$ provide significant performance gains over the E^2PR4 shaping polynomial and is currently the state-of-the-art detection scheme in the hard-disk drive industry.

In practical applications a simple low-pass filter is used instead of a matched filter. Furthermore, the PR equalizer can be implemented as a FIR digital filter or a continuous-time filter before sampling. There are many commercial products that have used the latter approach, but today most of the hard-disk drives use discrete-time FIR equalization techniques. For known channel characteristics, the coefficients of the finite-length PR equalizer and predictor can be obtained by solving two sets of equations separately. In a first step the optimum coefficients of a finite-length PR equalizer according to the MMSE or zero-forcing criterion are obtained [50]. The predictor coefficients are then the solution of the well-known normal equations. An alternative approach is to combine the PR equalizer and the predictor into a single whitening filter and obtain its coefficients together with the NPML detector target by using a joint optimization procedure. Such an approach is reminiscent of the computation of the coefficients of a PR DFE [11,58]. To cope with the slow variations of the magnetic-recording channel as well as with the need for different sets of coefficients depending on whether the outer or the inner tracks are read back, standard adaptation algorithms can be applied. In some commercial hard-disk drives, the whitening-filter

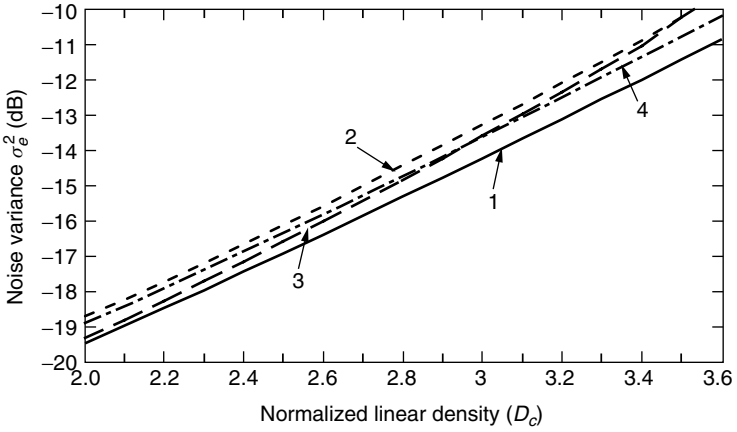

Figure 18. Noise variance at NPML detector input as a function of D_c for a Lorentzian channel with AWGN and an SNR of 25 dB. Curve 1: infinitely long whitening filter $w(D)$; curve 2: $g(D) = (1 - D^2)(1 + p_1 D + p_2 D^2)$; curve 3: $g(D) = (1 - D)(1 + 0.75D)(1 + p_1 D + p_2 D^2)$, and curve 4: $g(D) = (1 - D^2)(1 + p_1 D + p_2 D^2 + p_3 D^3 + p_4 D^4)$.

(PR equalizer/predictor) coefficients are trained during manufacturing, and large sets of coefficients are obtained reflecting the various operating conditions. These sets of coefficients are stored and frozen before shipping the products. Other commercial products have the capability to retrain the whitening filter and NPML detector target adaptively in real time.

4.3. Other Detection Techniques

Several other techniques to increase the areal recording density have been proposed. One of these, which is well known in the field of digital communications, is DFE [50]. The DFE does not force the overall transfer function to a prescribed target, and thus suffers from less noise enhancement than PRML techniques. In fact, the response at the output of the forward section of a DFE could be viewed as a particular form of generalized PR polynomial that matches the magnetic-recording channel characteristics very well. It has already been pointed out above that the forward section of an infinitely long zero-forcing DFE is equivalent to the whitening filter of the optimum MLSD. The feedback section of the DFE using past decisions cancels the causal ISI and a simple threshold symbol-by-symbol detector provides the final decision. Application of DFE to storage channels has been studied in [59]. An adaptive DFE with look-up table implementation of the feedback section (RAM-DFE) has been proposed in [60,61]. By using a dynamic procedure to update the contents of the RAM, a RAM-DFE can also effectively counter nonlinear distortion. Prototype DFE chips for the magnetic-recording channel have been developed in the past [62] but this approach did not enjoy commercial success primarily because of the problem of error propagation.

Another technique that has attracted considerable attention is the fixed-delay tree-search approach with decision feedback (FDTS/DF) [31]. The FDTS/DF employs the forward section of a DFE to create a minimum phase causal response with most of the energy of the causal ISI concentrated in the first few terms. If M is the total span of ISI, the last $M-\tau$ ISI terms are canceled by a feedback mechanism similar to a DFE arrangement, whereas the first τ ISI terms are being processed by a detector structure that searches into a tree with $2^{\tau+1}$ branches. Clearly, the feedback cancellation scheme works properly provided that the FDTS/DF detector releases decisions with a delay of τ symbols. Thus, the detector looks ahead τ steps into the tree, and computes the $2^{\tau+1}$ Euclidean metrics associated with all the look-ahead paths in the tree. These metrics are then used to decide whether the symbol at the root of the tree should be $+1$ or -1. This scheme is a derivative of the delay-constrained optimal detector approach presented in [63]. The application of noise-predictive PR equalization schemes in conjunction with FDTS has been studied in [12].

Finally, reduced-state sequence-detection schemes [64–66] have also extensively been studied for application in the magnetic-recording channel ([12,25] and references therein). For example, it can readily be seen that the NPML detectors can be viewed as a family of reduce-state detectors with imbedded feedback. They also exist in a form in which the decision-feedback path can be realized by simple table look-up operations, whereby the contents of these tables can be updated as a function of the operating conditions [12]. Analytical and experimental studies have shown that a judicious tradeoff between performance and state complexity leads to practical schemes with considerable performance gains. Thus, reduced-state approaches appear promising for increasing the linear density even further.

5. PARITY-BASED POST-PROCESSING

In generalized PR systems combined with sequence detection a short list of error events dominates. In general, post-processors are suboptimum reduced-complexity receiver structures that improve error-rate performance by correcting the most likely error events at the output of the sequence detector. The use of a post-processor requires a modest increase in implementation complexity. Based on the short list of preselected error events the post-processor computes the log-likelihood ratio (LLR) of each of these selected error events at each point in time. These LLRs are then used to decide the type and the location of the most likely error event to be corrected. The LLR corresponding to the i-th error event in the list, $\varepsilon_i(D)$, is computed as the difference of the following Euclidean metrics

$$\begin{aligned}\mathrm{LRR}(\varepsilon_i(D)) = \|(z(D) - \hat{a}(D)g(D)\|^2 - \|z(D) \\ - (\hat{a}(D) + \varepsilon_i(D))g(D)\|^2 \end{aligned} \tag{35}$$

where $\|z(D) - \hat{a}(D)g(D)\|^2$ is the Euclidean distance between the noisy sequence at the input of the sequence detector, $z(D)$ and the sequence $\hat{a}(D)g(D)$ generated by using final decisions produced by the sequence detector, whereas $\|z(D) - (\hat{a}(D) + \varepsilon_i(D))g(D)\|^2$ is the Euclidean distance between the noisy sequence at the input of the sequence detector, $z(D)$ and the sequence $(\hat{a}(D) + \varepsilon_i(D))g(D)$ generated by an alternative data sequence that includes the specific error pattern.

As can be seen, the LLRs computed according to Eq. (35) use the same metric as the NPML detector does. A post-processor using such a soft metric is also referred to as noise-predictive post-processor. Noise-predictive post-processors are reminiscent of the *one-shot* optimum receiver structures in communications theory [67], and can have threshold-based or parity-based triggering mechanisms [23–28,68,69]. In general, threshold-based post-processing schemes do not suffer from rate loss, whereas parity-based post-processing schemes do. However the parity-based triggering mechanism for initiating error-event correction may be more robust in certain situations.

In a parity-based post-processing scheme typically a single or double error event within a codeword is corrected. After NPML detection and during the symbol-by-symbol processing of each codeword, a short list of the most likely error events is maintained and continuously updated together with the associated error type, polarity, and location. Once the entire codeword has been received and the short list finalized, the LLRs and the syndromes of all combinations of error events are computed. Finally,

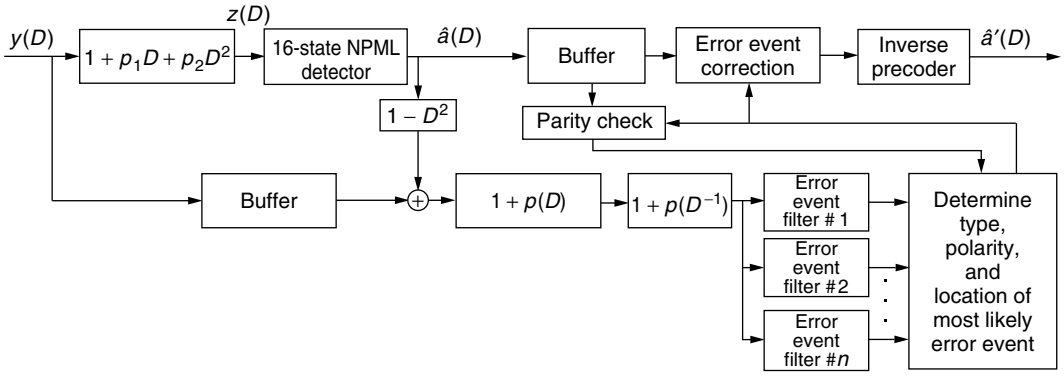

Figure 19. 16-state NPML detector and noise-predictive parity-based post-processor. From [26], © IEEE 2001.

after rejecting error-event candidates that violate certain conditions, such as for example those that do not produce valid syndromes, the single (double) error event with the minimum LLRs is (are) corrected. Figure 19 shows the block diagram of the 16-state NPML detector in tandem with a parity-based post-processor.

Figure 20 illustrates the performance of various modulation/parity codes after 16-state NPML detection and parity-based post-processing. These results have been obtained via computer simulations assuming the Lorentzian channel model and electronics noise. The user linear density is set to $\mathrm{PW50}/Tu = 3.2$. The channel density D_c depends on the rate of the code. The front-end filter is a five-pole low-pass Butterworth filter with 3-dB cutoff frequency at 55% of the channel symbol rate. The equalizer is a 10-coefficient PR4-shaping zero-forcing equalizer. Curve 1 shows the performance of a 16-state NPML detector in conjunction with a rate-32/34 PRML(G, I) single-parity code and a post-processor that detects and corrects the three types of error events $\{\pm 2\}$, $\{\pm 2, \mp 2, \pm 2\}$, and $\{\pm 2, \mp 2, \pm 2, \mp 2, \pm 2\}$. Curve 2 indicates the performance of the 16-state NPML detector in conjunction with a rate-96/102 PRML(G, I) code with quadruple-parity and a post-processor that detects and corrects seven types of error events. Finally, curve 3 corresponds to the performance of the 16-state NPML detector in conjunction with rate-96/104 MTR$(j = 3, 4, k = 18, t = 14)$ code with dual-parity and a post-processor that detects and corrects the four types of error events $\{\pm 2\}$, $\{\pm 2, \mp 2, \pm 2\}$, and $\{\pm 2, 0, 0, \pm 2\}$, and $\{\pm 2, \mp 2, \pm 2, \mp 2\}$. As can be seen, the rate-96/104 MTR-based code outperforms the rate-32/34 and -96/102 (G, I)-based codes by 1.3 and 0.7 dB, respectively, although it is approximately 2% less efficient. The difference in performance between the rate-96/104 MTR-based and rate-96/102 (G, I)-based codes is less pronounced under data-dependent medium noise conditions. This is attributed to the fact that in such a case, even at very high linear densities, the error $\{\pm 2\}$ is the predominant error event and the MTR constraints are not very effective.

Figure 21 shows the evolution of the various architectures that have been used over the past decade by various disk-drive manufactures. In particular, it shows the SNR requirements for achieving a symbol-error rate of 10^{-6} after the parity-based post-processor as a function of the normalized linear density D_c. Curve 1 corresponds to the conventional PRML architecture. It shows the performance of the 2-state interleaved PR4-based PRML

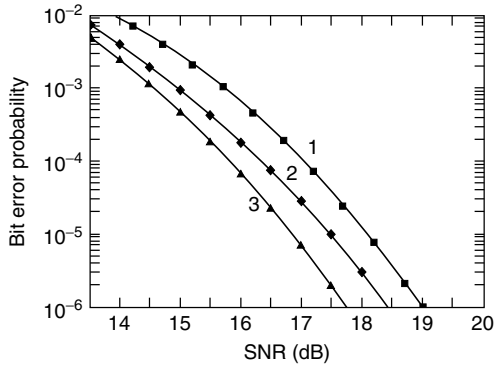

Figure 20. Bit-error rate performance after post-processing for a Lorentzian channel with $\mathrm{PW50}/Tu = 3.2$, AWGN, and a 16-state NPML detector. Curve 1: rate-32/34 PRML(G, I), 1 parity bit; curve 2: rate-96/102 PRML(G, I), 4 parity bits, and curve 3: rate-96/104 MTR(j, k, t), 2 parity bits.

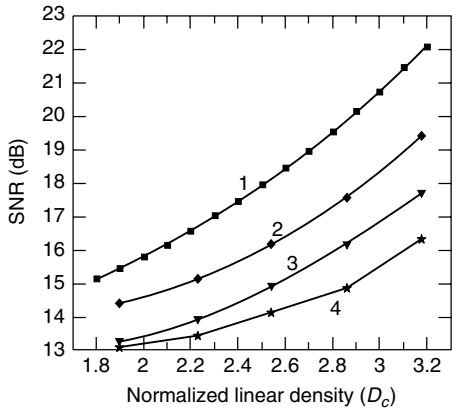

Figure 21. SNR requirements as a function of D_c for a Lorentzian channel with AWGN. Error probability $P_b = 10^{-6}$. Curve 1: PRML architecture, rate-16/17 PRML(G, I); curve 2: EPRML architecture, rate-32/34 PRML(G, I), 1 parity bit; curve 3: NPML architecture, rate-32/34 PRML(G, I), 1 parity bit, and curve 4: NPML architecture, rate-96/104 MTR(j, k, t), 2 parity bits.

detector in conjunction with a rate-16/17 PRML(G, I) constrained code. Curve 2 corresponds to the EPRML architecture. In this architecture the detector is based on the EPR4 shaping polynomial giving rise to an 8-state trellis. The inner code is a rate-32/34 PRML(G, I) constrained code and includes a single parity bit. Curve 2 demonstrates the benefit of the higher-order shaping polynomial as well as of the combined constrained/parity inner code, in particular at high linear recording densities, where a gain of approx. 2.5 dB over the conventional PRML scheme is obtained. Finally, curves 3 and 4 correspond to the NPML architecture, which has only recently been introduced in hard-disk drive products. The shaping polynomial is based on a 2-coefficient predictor and has spectral nulls at both the dc and the Nyquist frequency. Curve 3 shows the performance of the 16-state NPML detector in conjunction with the single-parity rate-32/34 PRML(G, I) constrained code, whereas curve 4 illustrates the performance of the 16-state NPML detector in conjunction with the dual-parity rate-96/104 MTR$(j = 3, 4, k = 18, t = 14)$ code. As can be seen, the 16-state NPML detector in conjunction with the rate-96/104 MTR-based dual-parity code, provides a 5.5 dB gain over the conventional PR4-based PRML detection with the rate-16/17 PRML(G, I) code at $D_c = 3.2$. Alternatively, the current NPML system architecture provides a 55% linear recording density increase over the conventional PR4-based PRML architecture.

6. DATA-DEPENDENT NPML DETECTION

Today's hard-disk drive devices employ thin-film media that appear primarily to exhibit nonstationary data-dependent transition or medium noise as opposed to colored stationary medium noise. Improvements on the quality of the readback head as well as the incorporation of low-noise preamplifiers may render the data-dependent medium noise a significant component of the total noise affecting the performance of the magnetic-recording system. Because the medium noise is correlated and data-dependent, information about the noise and data patterns in past samples can provide information about the noise in the current sample. Thus, the concept of noise prediction for stationary Gaussian noise sources developed in [11] can be naturally extended to the case where the noise characteristics depend highly on the local data patterns [16,18].

By modeling the data-dependent noise as a finite-order Markov process, the optimum MLSD for channels with ISI has been derived in [17,19]. In particular, it has been shown that when the data-dependent noise is conditionally Gauss–Markov, the branch metrics can be computed from the conditional second-order statistics of the noise process. In other words, the optimum MLSD can be implemented efficiently by using the Viterbi algorithm, where the branch-metric computation involves data-dependent noise prediction. Because both predictor coefficients and prediction error depend on the local data pattern, the resulting structure has been called data-dependent NPML detector [20]. In real systems, the data-dependent medium noise is not a strictly Markov noise process, and clearly the data-dependent NPML detector is only a near-MLSD structure. Nevertheless, physical models for data-dependent medium noise such as the one developed in [35] or the more accurate microtrack model [18] can be used to investigate the impact of the model parameters on the data-dependent Markov assumption and the performance of the NPML detector.

Let $\{y_i\}$ be the sequence of samples at the output of the PR linear equalizer with target $f(D)$. Then

$$y_i = x_i + n_i(a) = a_i + \sum_{\ell=1}^{K} f_\ell a_{i-\ell} + n_i(a) \tag{36}$$

where the noise sample $n_i(a)$ at time instance iT is assumed to be a zero-mean Gaussian random variable with statistics depending on the data sequence $a \triangleq \{a_i\}$. Figure 22 shows an example of a channel with ISI that spans K symbols and data-dependent Gauss–Markov noise. This model corresponds to Eq. (36), where the additive noise is generated by a L-order autoregressive filter whose coefficients depend on the last $K + 1$ recorded data symbols $a_i^{i-K} = \{a_i, a_{i-1}, \ldots, a_{i-K}\}$. In this case the correlated and data-dependent noise sample is given by

$$n_i = \sigma_e(a_i^{i-K})\upsilon_i - \sum_{\ell=1}^{L} p_\ell(a_i^{i-K}) n_{i-\ell} \tag{37}$$

where $\{\upsilon_i\}$ denotes a zero-mean unit-variance white Gaussian noise sequence, $\sigma_e(a_i^{i-K})$ indicates the data-dependent standard deviation, and $\{p_\ell(a_i^{i-K})\}$ represents the data-dependent coefficients of the autoregressive filter. Clearly, there are 2^{K+1} sets of filter coefficients, and the total memory of the model is $K + L$, giving rise to a trellis with 2^{K+L} states. A Viterbi algorithm, whose branch metrics have been modified to account for the data-dependent correlated noise, can operate on this trellis to estimate recursively the most likely recorded data sequence $\{a_i\}$. The implementation of this algorithm is very similar to the standard Viterbi algorithm for NPML detection described above. The main difference is that in the computation of the branch metrics, a window of observed values $y_i^{i-L} = \{y_i, y_{i-1}, \ldots, y_{i-L}\}$ is used, instead of just one sample z_i, which is the output of a "global"

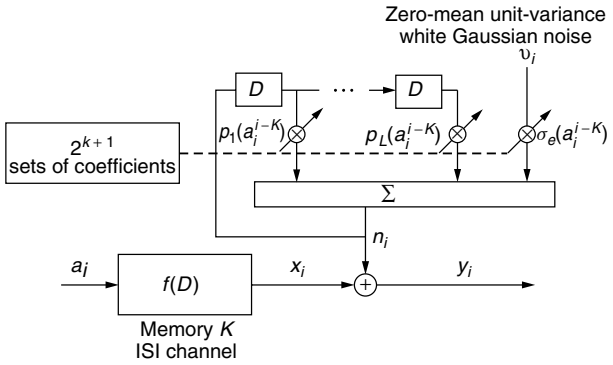

Figure 22. Block diagram of ISI channel with Gauss–Markov data-dependent noise.

whitening/prediction filter. The optimality of this approach for the Gauss–Markov noise case was shown in [19].

Let $\xi_i \triangleq a_i^{i-K-L} = \{a_i, a_{i-1}, \ldots, a_{i-K-L}\}$ denote a transition on the 2^{K+L}-state trellis. Then, assuming Gaussian data-dependent noise, the branch metric associated with transition ξ_i is given by

$$\gamma_i(\xi_i) = \ln \sigma_e^2(a_i^{i-K}) + \frac{[y_i - x_i + \hat{n}_i(\xi_i)]^2}{2\sigma_e^2(a_i^{i-K})} \tag{38}$$

where $\hat{n}_i(\xi_i)$ is a data-dependent predicted value of the current noise sample n_i, based on the past L noise samples $\{n_{i-1}, n_{i-2}, \ldots, n_{i-L}\}$, that is,

$$\hat{n}_i(\xi_i) = \sum_{\ell=1}^{L} p_\ell(a_i^{i-K})(y_{i-\ell} - x_{i-\ell}) = \sum_{\ell=1}^{L} p_\ell(a_i^{i-K}) n_{i-\ell} \tag{39}$$

and $\sigma_e^2(a_i^{i-K})$ represents the data-dependent variance of the prediction error. If the additive noise is correlated and Gaussian and does not depend on the data pattern, then $\{p_l(a_i^{i-K})\}$ and $\sigma_e^2(a_i^{i-K}) = \sigma_e^2$. In such a case, the data-dependent NPML detection structure reduces to the NPML detection technique presented above.

A finite-length predictor filter with coefficients that depend on a particular data pattern can be obtained by applying the normal equations separately and conditioned on each of the 2^{K+1} possible data patterns a_i^{i-K} that affect the noise process. For this purpose, the noise process can be characterized by 2^{K+1} autocorrelation functions of the form

$$R_n(l \mid a_i^{i-K}) = E\{n_i n_{i-\ell} \mid a_i^{i-K}\} \tag{40}$$

where the expectation is taken not only with respect to the noise statistics but also with respect to the data symbols that are not included in the conditioning. Using the autocorrelation functions described by Eq. (40), a set of 2^{K+1} L-th order prediction filters $\{p_l(a_i^{i-K})\}$ can be obtained together with their corresponding prediction errors $\sigma_e^2(a_i^{i-K})$, which can then be used in the branch metric computation of Eq. (38).

In practical systems the noise autocorrelation function can be estimated based on training patterns and statistical averaging, which can be performed during the manufacturing process of the disk drive. To avoid matrix inversions and the numerical problems associated with ill-conditioned matrices, an alternative approach is to use standard adaptation procedures to learn the set of noise predictor coefficients and noise prediction error-variances conditioned on the local data patterns [20]. Finally, note that the reduced-state sequence detection schemes discussed in connection with NPML detection can also be applied to data-dependent NPML, providing a significant reduction of implementation complexity.

Figure 23 illustrates the performance of two 16-state NPML detection schemes in the presence of nonstationary data-dependent medium noise. These results have been obtained via computer simulations assuming the microtrack channel model with a transition-width parameter of $a = 0.15$, and no electronics or any other source of stationary noise. In this case the system is affected by 100% data-dependent medium noise. The user linear recording density is set to PW50/$Tu = 3.6$. In both cases a rate-96/102 PRML(G, I) has been used, resulting in a normalized channel linear density of $D_c = 3.825$. The front-end filter is a five-pole low-pass Butterworth filter with 3-dB cutoff frequency at 55% of the channel symbol rate. The equalizer is a 10-coefficient PR4-shaping zero-forcing equalizer. Curve 1 shows the performance of a 16-state NPML detector whose branch metric computation uses the same set of predictor coefficients optimized as if the system were affected by stationary Gaussian noise only. Curve 2 indicates the performance of the data-dependent 16-state NPML detector whose branch metrics have been modified according to Eq. (38) to account for the presence of 100% data-dependent noise. As can be seen, the data-dependent NPML detector yields a gain of 1.3 dB at a symbol error rate of 10^{-5}. Note however that 100% data-dependent medium noise is not a realistic scenario in today's hard-disk drives, and therefore the gains expected by using a more complex data-dependent NPML detection scheme are less pronounced.

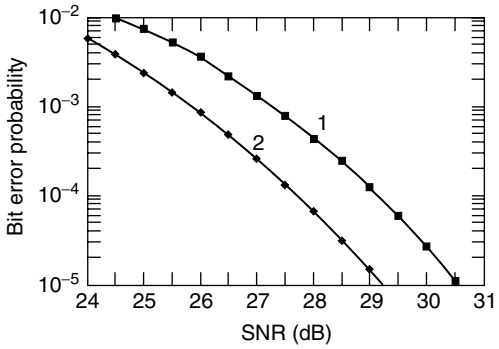

Figure 23. Bit-error rate performance for microtrack channel with PW50/$Tu = 3.6$, $a = 0.15$, and 100% data-dependent medium noise. Curve 1: 16-state NPML detector, and curve 2: 16-state data-dependent NPML detector.

7. FUTURE TRENDS

Currently, MTR or (G, I) codes combined with multiparity block codes, and 16-state NPML detection for generalized PR shaping channels, followed by a post-processor for soft decoding of the combined multiparity/constrained code, represent the state of the art in the industry. Outer error-correction coding has also played an important role in achieving high data integrity in magnetic-recording systems. In hard-disk drives, interleaved byte-oriented RS coding is currently the standard outer coding scheme. In the future, RS symbols with more than eight bits and sector sizes having a length of more than 512 8-bit bytes will have a significant impact on efforts to improve performance and push areal density even further.

The recent advances in coding theory and in particular the introduction of Turbo codes in the mid-1990s and the rediscovery of the powerful low-density parity check (LDPC), hold the promise to push the areal density to the ultimate limit for given magnetic-recording components. In spite of the current limit of the sector-size in a hard-disk drive to 512 bytes, which constrains the block size of an

outer code, and the high code-rate requirements, it has been shown that LDPC or Turbo codes with rather simple iterative decoding schemes can achieve a gain of more than 2 dB over existing systems and bring performance to within 1.5 dB of the ultimate information-theoretic limit: the capacity.

However, despite progress in the area of reduced-complexity detection and decoding algorithms, Turbo equalization structures with iterative detectors/decoders have not yet found their way into digital recording systems because of the still unfavorable tradeoff between performance, implementation complexity, and latency. The design of high-rate, short-block-length Turbo-like codes for recording systems remains an area of active research.

BIOGRAPHY

Evangelos S. Eleftheriou received as B.S. degree in electrical engineering from the University of Patras, Greece, in 1979, and M.Eng. and Ph.D. degrees in electrical engineering from Carleton University, Ottawa, Canada, in 1981 and 1985, respectively. He joined the IBM Zurich Research Laboratory in Rüschlikon, Switzerland, in 1986, where he has been working in the areas of high-speed voice-band data modems, wireless communications, and coding and signal processing for the magnetic recording channel. Since 1998, he has managed the magnetic recording and wired transmission activities at the IBM Zurich Research Laboratory.

His primary research interests lie in the areas of communications and information theory, particularly signal processing and coding for recording and transmission systems. He holds more than 30 patents (granted and pending applications) in the areas of coding and detection for transmission and digital recording systems. He was editor of the IEEE Transactions on Communications from 1994 to 1999 in the area of Equalization and Coding. He was guest editor of the *IEEE Journal on Selected Areas of Communications* special issue, "The Turbo Principle: From Theory to Practice."

SIGNAL QUALITY MONITORING IN OPTICAL NETWORKS

IPPEI SHAKE
NTT Corporation
Kanagawa, Japan

1. INTRODUCTION

Signal quality monitoring is an important issue in relation to the design, operation, and maintenance of optical transport networks. From a network operator's point of view, monitoring techniques are required to provide connections, undertake protection and/or restoration, perform maintenance, and establish service level agreements. To realize these functions, the monitoring techniques should be able to offer the following: in-service (nonintrusive) measurement, signal deterioration detection [both signal-to-noise ratio (SNR) degradation and waveform distortion], fault isolation (locate faulty sections or nodes), transparency and scalability (irrespective of the signal bit rate and signal format), and simplicity (small size and low cost).

There are several approaches, including both digital and analog techniques, that make it possible to detect various types of impairment. Bit error rate (BER) measurement is a fundamental method for evaluating end-to-end signal quality, but it is not a practical solution for optical networks because it requires clock and data synchronization between transmitters and receivers. Error block detection or error counting utilizing a SONET/SDH frame or other frame is currently a practical solution for optical networks. However, these techniques fail to satisfy the aforementioned requirements for performance monitoring, for instance, transparency in an optical transport network (OTN). Several approaches have recently been proposed to overcome this problem. These techniques include optical SNR or power evaluation with optical/electrical spectrum measurement, pilot tone detection, pseudo-BER estimation or error monitoring using variable decision circuits, and a statistical method using histogram evaluation accompanied by synchronous or asynchronous eye diagram measurement. A fundamental performance monitoring parameter of any digital transmission system is its end-to-end BER. However, the BER can be correctly evaluated only with an out-of-service BER measurement by using a known test bit pattern in place of the real signal. By contrast, in-service measurement can provide only rough estimates through the measurement of digital parameters [e.g., BER estimation, error block detection, and error count in forward error correction (FEC) or analog parameters (e.g., optical SNR, optical/electrical spectrum, and Q-factor)].

2. PERFORMANCE MONITORING UTILIZING DIGITAL PARAMETERS

2.1. Digital Frame Based Technique

2.1.1. Bit Interleaved Parity (SONET/SDH). Error block detection is a digital technique for the end-to-end performance monitoring of optical channels. The error block is detected by means of an error detection code, for example, bit interleaved parity (BIP) in a SONET/SDH frame [1]. A BIP code that consists of X bits is called a BIP-X code. The BIP-X code is written as part of the overhead of the following payload. The data sequence to be monitored is divided into sequences, each of which is X bits long, the even parity of the nth bit (n is an integer between 1 and X) of all the X bits sequences is written in the nth bit of the BIP-X code. These procedures are undertaken at the transmitter end first. Then, at the receiver end, the BIP code is calculated again over each frame using the same procedure and compared with the transmitted code. This technique can only be used to monitor odd numbers of bit errors because it uses a BIP code in which an even parity is written over long sequences of data. This means that BIP-X is valid when the BER is low enough to cause only 1 bit error in the nth bit of all the X bit sequences.

2.1.2. Digital Wrapper. The digital wrapper is a SONET/SDH-based frame format technology in OTN [1]. This frame includes not only data and a channel header but also the forward error correction (FEC) code. The FEC makes it possible to correct bit errors that occur in the transmission line at the receiver by sending an additional bit sequence with data and channel header sequences. FEC is a powerful technology for long-haul high-speed optical transmission because of this real-time error correction capability. From the viewpoint of performance monitoring, the FEC procedure can provide us with the number of errors. This frame typically is used on a link per link basis, so it should not be used for end-to-end performance monitoring.

2.1.3. Others. Other frame format technologies have been developed for wide area networks (WAN), although most are also SONET-based. For example, 10 Gbit/s Ethernet (IEEE802.3ae) for WAN (WAN-PHY) has an operation, administration, management, and provisioning function based on SONET technology. Another extension of the 10 Gbit/s Ethernet frame for WAN has also been proposed.

2.2. Pseudo BER Estimation Using Variable Decision Circuit

When the system BER is too low to be measured within a reasonable amount of time, it is necessary to estimate the BER or other parameters representing signal quality. This subsection introduces one BER estimation approach that uses a variable decision circuit [2]. The decision level is changed step by step from a low amplitude to a high amplitude through the whole eye opening. The BER is measured only when the decision levels are relatively low or high. This is because the decision level is directly related to the BER, as shown in the following equation (with a Gaussian assumption),

$$\mathrm{BER} = (1/2)\mathrm{erfc}(Q/\sqrt{2}),\ Q = (\mu_1 - V_t)/\sigma_1 = (V_t - \mu_0)/\sigma_0 \quad (1)$$

where μ_i and σ_i are the mean and the standard deviation of mark ($i = 1$) and space ($i = 0$) noise levels, respectively, and V_t is the decision level. The BER becomes relatively high when the decision level is lower or higher than the

optimum level, and the measurement can be finished in a sufficiently short time. BER data are then plotted on a graph, where the vertical axis is the BER and the horizontal axis is the decision level. There are two linear fitting curves in the figure. Finally, the lowest BER is estimated by extracting the intersection of these two fitting curves.

This method is useful because a very low BER can be easily estimated within a reasonable amount of time. However, its use of BER measurement means that it requires data synchronization between the transmitter and receiver.

Recently, a new approach has been proposed as an application of this method, which resolves the problem of data synchronization by using two decision circuits [3,4]. The receiver equipment uses these two decision circuits. The first is used for a working channel with a fixed decision level and the second is used for measurement with a variable decision level. The received signal is divided into two, launched into these two decision circuits, and then the two logical outputs from the two circuits are combined with an exclusive OR gate (EXOR). The EXOR output is interpreted as the BER (Fig. 1). This provides a pseudo-BER estimation because the result from the fixed decision level is used as the reference data instead of the bit sequence of a real data code. Using these estimated BER values, we can estimate the lowest BER value by employing the same procedure as [2] (extracting the intersection of the fitting curve). The merit of this method is that it requires no knowledge of the transmitted bit sequences, and the performance of the data regeneration process in the master decision circuit is not degraded by the monitoring function.

By counting the bit error number, we also can estimate the amplitude histograms [3]. When the decision level of the second decision circuit is changed step by step through the whole eye opening, the number of "1" events counted at EXOR is recognized as the pseudo-error probability, which is the number of events whose amplitude is between the decision levels of the first and second decision circuits. The amplitude histograms are given by the absolute value of the derivation of this distribution, which is the same as that obtained by the synchronous sampling measurement. The Q-factor is evaluated using the amplitude histograms.

EXOR can be eliminated to realize the same function [3]. By counting "1" events at both the first (fixed decision level) and second (variable decision level) decision circuits while counting the clock period, and subtracting the number of "1" events, we can recognize the difference between a "1" event of the first and second decision circuits. Then the deviation of the probability curve of the difference also provides the amplitude histograms.

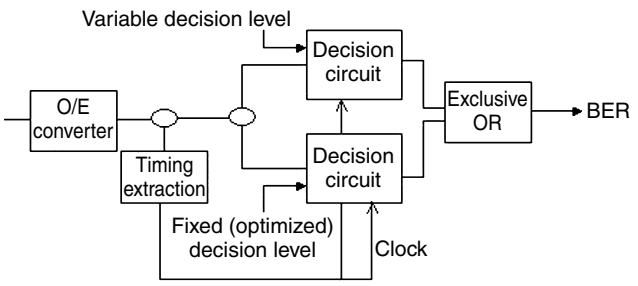

Figure 1. Typical configuration for dual decision circuits technique.

If the profile of the amplitude histograms does not change in the measurement time, the amplitude histograms can be estimated by using one decision circuit and a clock counter [5]. As a single decision circuit with a variable decision level does not have a reference, the error counter cannot reflect the influence of the amplitude fluctuation of each bit. This method is particularly advantageous with regard to BER measurement or error block detection, although it still requires timing extraction, which might depend on the signal format, bit rate, and/or modulation format.

3. ANALOG PARAMETERS

3.1. Statistical Method Using Histogram Evaluation

A method for signal quality monitoring that will provide a good measure of signal quality without the complexity of termination has long been desired and studied. Amplitude histogram estimation using a variable decision level (Section 2) can be recognized as a statistical method, but in this section, I focus on amplitude histogram evaluation using a sampling technique. Q-factor evaluation using synchronous sampling is more of a statistical method than a variable decision circuit technique because the sampling rate typically is low compared with the signal bit rate. However, Q-factor evaluation using the sampling technique is also a useful method when the system BER is too low to be measured within a reasonable amount of time, because it can be used for high bit rate signals, for which no decision circuit is used.

The amplitude histogram of an optical binary signal is obtained from an eye-diagram measured by the synchronous sampling technique. An amplitude histogram exhibits amplitude distributions at both mark and space levels at a fixed timing phase where the eye opening is at its maximum (Fig. 2a). The Q-factor at a fixed timing phase t ($Q(t_0)$) is estimated from the amplitude histogram, which is generally generated at timing phase t in the pattern as opposed to the data eye. It is defined as

$$Q(t_0) = |\mu_1(t) - \mu_0(t)|/(\sigma_1(t) + \sigma_0(t)) \tag{2}$$

where $\mu_i(t)$ and $\sigma_i(t)$ are the mean and standard deviation of the mark ($i = 1$) and space ($i = 0$) levels at t, respectively. The Q-factor (Q) is analytically related to the BER on a Gaussian assumption due to the equation defined by (1).

When the BER is low (e.g., $< 10^{-7}$), the theoretical value of Q is almost the same as the measured $Q(t_0)$ value:

$$Q(t_0) \sim Q \tag{3}$$

Eye monitoring using synchronous electrical sampling is conventionally undertaken with a digital sampling oscilloscope. However, the signal bit rate is limited by the O/E conversion bandwidth. Recently, an optical sampling

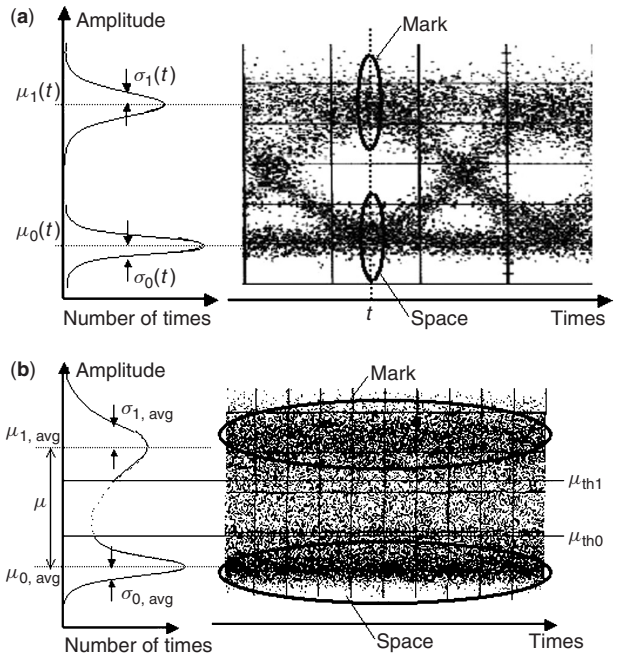

Figure 2. (**a**) Amplitude histograms at a fixed timing phase t of eye diagrams obtained by synchronous sampling; (**b**) amplitude histograms obtained by asynchronous sampling.

technique has been developed that has a temporal resolution of less than 1 ps and which overcomes the bit rate limitation [6]. Signal quality evaluation using eye diagrams obtained by means of optical sampling has also been reported [7,8]. The noise characteristics of optical amplifier systems do not have a Gaussian distribution. The analysis of non-Gaussian distributions is discussed in Ref. 9. Evaluations of crosstalk due to chromatic dispersion using histograms obtained by electrical sampling are presented in Ref. 10.

As mentioned previously, a statistical method using synchronous sampling is a useful technique for Q-factor evaluation. However, all sampling-based methods require synchronization and then some analysis, which makes them similar to protocol-aware termination in terms of cost and complexity. In fact, synchronous sampling also requires timing extraction using complex equipment that is specific to each BER and each format. Recently, the situation has begun to change. A simple, asynchronous histogram method was developed for Q-factor measurement [11]. Performance can be monitored at different monitoring points such as optical line repeaters, regenerators, or optical switching nodes (requires premeasurement). In other words, this method is expected to be applied to monitoring points where electrical termination is impossible. If we consider the all-optical network of the future, an optical switching node that has an all-optical switch will require performance monitoring without electrical termination.

Here, the averaged Q-factor (Q_{avg}) measurement obtained through asynchronous sampling is presented [11]. The asynchronous amplitude histogram is obtained from an eye-diagram measured by asynchronous optical sampling (Fig. 2b). Of the sampling points that constituted the histogram, it is determined that a set of points whose level is higher than a predetermined threshold level, μ_{th1}, belongs to level "mark" (i.e., "1"), while a set of points whose level is lower than a predetermined threshold level, μ_{th0} belongs to level "space" (i.e., "0"). Q_{avg} is defined by

$$Q_{avg} = |\mu_{1,avg} - \mu_{0,avg}|/(\sigma_{1,avg} + \sigma_{0,avg}) \tag{4}$$

where $\mu_{i,avg}$ and $\sigma_{i,avg}$ are the mean and standard deviation of the mark ($i = 1$) and space ($i = 0$) level distributions, respectively. The data obtained by asynchronous sampling include unwanted cross-point data in the eye-diagram, which reduces the measured value of the averaged Q-factor. Thus, it is necessary to remove the cross-point data. In this way, the two threshold levels were set at $\mu_{th1} = \mu_{1,avg} - \alpha\mu$ and $\mu_{th0} = \mu_{0,avg} + \alpha\mu$, and the coefficient α was defined as falling between 0 and 0.5.

In another approach, the peak levels of both mark and space level distribution (μ_1 and μ_0) are extracted, the data between μ_1 and μ_0 are eliminated and residual data at the mark level (larger than μ_1) and space level (smaller than μ_0) are symmetrically the reverse of the μ_1 and μ_0, respectively [12], and then the same evaluation is performed.

The essence of this method is that it does not use timing extraction or evaluate asynchronous eye diagrams. That is why this method provides signal format, modulation format, and bit rate flexibility. However, this technique is not timing jitter-sensitive despite the fact that jitter impairs the BER. This is the tradeoff with this method. Some analysis of bit rate flexibility and chromatic dispersion dependence has been provided [8].

3.2. Optical Power, Wavelength, and Optical SNR Monitor with Spectrum Measurement

Many methods using spectrum measurement have been published with a view to optical power, wavelength, and/or optical SNR (OSNR) monitoring. A simple approach for monitoring such kinds of analog parameter involves measuring the optical power spectrum of a tapped optical signal. However, this technique had two main problems. One is that the experimental equipment is large and expensive. The progress on DWDM networks makes it more difficult to monitor the optical power/ OSNR and wavelength of all channels. The second problem is that an optical spectrum monitor can measure the optical signal to out-of-band noise ratio, but it cannot monitor the optical SNR including in-band noise.

Recently, compact and stable equipment has been proposed by several groups to deal with the first problem. One approach employs an optical power and frequency monitor with a grating and a photo detector (PD) array [13], while another uses an arrayed waveguide grating (AWG) filter. With the latter technique, the AWG filtering wavelengths are controlled with the wavelength monitor and its feedback, using a reference light, thus realizing a precise wavelength and power monitoring. With yet another technique, a tunable Fabry-Perot etalon filter is used to separate the different spectral components in the spatial domain using temperature control [14]. An OSNR and optical wavelength monitor using an acousto-optic tunable filter have also been reported. The monolithic

integration of PD modules into an AWG filter is another approach for realizing an optical power and wavelength monitor in WDM networks. A point of interest as regards the abovementioned optical spectrum monitoring is its applicability to DWDM networks where the channel spacing is less than 50 GHz [15].

Further approaches have also been developed with a view to achieving precise OSNR monitoring. One technique monitors the OSNR by using the polarization-nulling technique, which employs the different polarization properties of optical signals and amplified spontaneous emission (ASE) noise [16]. The most recent approach to use this technique is reported in Ref. 16, where the polarization of an optical signal with ASE noise is controlled so that it is linear. The optical signal is split into a signal +ASE component and an ASE only component with polarization beam splitter (PBS). Then the ASE only component is divided into two with a 3 dB coupler. One of these ASE only components is optically filtered with a band-pass filter (BPF), and the powers of these three components are measured. As a result, OSNR is written as an equation of these three powers.

Another technique monitors OSNR by analyzing the low-frequency noise characteristics at the receiver [17]. With this technique, the total received power and received noise power are measured and compared. The noise power density is measured using an analog to digital converter and an FFT unit operating in the 40–50 kHz range. This technique is ineffective when the pattern length of the optical signal becomes longer than PRBS15. However, this limitation has been relaxed recently. In the latest result [18], the optical signal was split into orthogonally polarized lights by a polarization beam splitter and recombined after an optical delay $\Delta\tau$ in one of the paths. Then the measured electrical power P after the orthogonal delayed-homodyne module is written as

$$P = \{1 - 4\gamma(1-\gamma)\sin 2(\pi f \Delta\tau)\}S + N \qquad (5)$$

where γ is the power ratio at the polarization beam splitter, S and N are the electrical powers of the signal and noise, respectively, and f is the measured frequency. By setting $\Delta\tau$, f, and γ at adequate values, the electrical power component of the signal becomes zero, and the receiver noise component can be measured.

3.3. Pilot Tone Technique, Sub-Carrier Multiplexing

The pilot tone technique has been discussed for several years, and various approaches have been adopted. Sub-carrier multiplexing is used for the pilot tone and there are two main kinds of sub-carrier usage. One approach is to use the sub-carrier for monitoring the signal power, wavelength crosstalk, or OSNR. The other approach involves using the sub-carrier for an optical signal header. This means that the sub-carrier signal, which is modulated by header information data, is multiplexed into an optical signal (payload data) as a packet header or supervisory channel. Moreover, a variety of sub-carrier frequencies are used in these approaches (Fig. 3). The keys to these techniques relate to the methods used for combining and

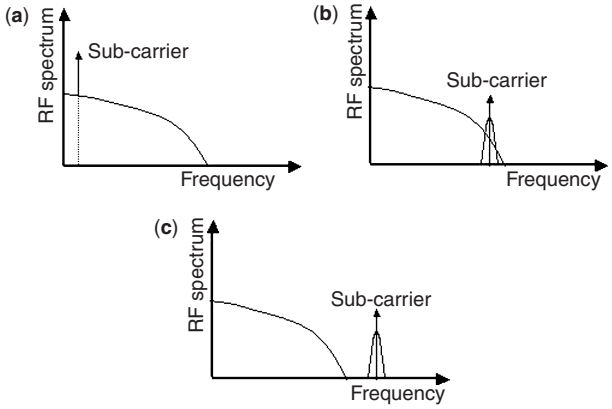

Figure 3. Typical RF spectrum of a data signal and a sub-carrier (pilot tone), when the sub-carrier frequency is (**a**) low (~ MHz), (**b**) near the signal bit rate (modulated by header information), and (**c**) higher than the signal bit rate (modulated by header information).

detecting the sub-carrier, the monitoring accuracy, and the influence of sub-carrier multiplexing on the signal.

The most effective approach for the pilot tone technique is to add a specific sinusoidal tone with a small amplitude to each optical WDM channel. In Ref. 19, the pilot tone is simply added to the laser bias current at the transmitter and is used to supervise individual wavelength channels along the optical path. At the transmitter an electrical pilot tone in the kHz regime is added to the signal, each wavelength channel being coded with a different tone frequency. The pilot tones are extracted at nodes between the transmitter and receiver by tapping a small portion of the signal power into a monitor module. The tapped optical power is detected, the pilot tones are filtered out electronically, and their levels are registered. The tones will provide signal identification and power level information for fault management. The tone amplitude is not more than 10% of the data level, and the tone frequency is below 100 kHz. This ensures that interference with the low-frequency components of the data results in negligible sensitivity degradation. Another approach uses a 10% peak-to-peak pilot tone modulation with a 50-kHz frequency and heterodyne detection with 20-Hz IF electrical filtering [20]. In Ref. 20, OSNR values measured by an optical spectrum analyzer and the pilot tone technique are compared, and good agreement in the OSNR region below 30 dB is reported. The OSNR sensitivity is limited to 30 dB with this technique because the electrical noise in the detector becomes nonnegligible.

Another approach designed simply for accurate frequency monitoring uses an AWG. With this approach, pilot tones with different RF frequencies are used for different wavelength channels. The pilot tones are split by the AWG where each center wavelength of each filter channel is set at the ITU grids using a temperature controller, so one AWG filter channel can split two pilot tones. The ratio of these two pilot tones with the same frequency split by adjacent AWG filters indicates the frequency of the optical channel [21].

Deciding on an adequate frequency range is also an important issue with respect to the accuracy of this

technique. Values ranging from several tens of kHz to the sub MHz level typically are used to minimize the penalty on a payload optical signal (Fig. 3a). However, a recent report states that when pilot tone–based monitoring techniques are used in amplified networks, their performance is deteriorated by the cross-gain modulation (XGM) of erbium-doped fiber amplifiers (EDFAs). The XGM problem is solved by using high-frequency tones in the 1-MHz range, but even when the pilot tone frequencies are in the few MHz range, the performance is limited by the Raman effect. As a result, tone frequencies higher than 100 MHz are recommended [22]. Another analysis suggests that, with regard to the pilot tone carrier to noise ratio, the tone detection sensitivity is limited by the power spectral density of the payload signal, and a pilot tone higher than 1 GHz is recommended for a 2.5-Gbit/s payload signal [23]. Some other approaches use pilot tone frequencies around the bit rate frequency, some of which is modulated by header information (Fig. 3b,c). The subject of pilot tone frequency remains an open issue.

In relation to the influence of the sub-carrier on the signal, the modulation intensity of a sub-carrier influences the payload signal, but detection sensitivity is reduced when the modulation intensity is low. This is a trade off problem and, for example, the number of payload signal wavelengths is limited because of this problem [23].

Wavelength conversion at intermediate nodes will become an important function in future DWDM networks. Some pilot tone–based approaches focusing on this function have already been reported [24]. These papers discuss the influence of the pilot tone in an interferometric wavelength converter using SOA, pilot tone frequency conversion with wavelength conversion using an semiconductor optical amplifier (SOA) + DFB laser, and the pilot tone technique when three SOA-interferometers are cascaded for wavelength conversion.

Some approaches use the sub-carrier technique for an optical signal header. Sub-carrier frequencies higher than the bit rate are sometimes used. The sub-carrier is encoded as a packet header using amplitude shift keying (ASK) or phase shift keying (PSK). The use of frequencies higher than the signal bit rate is advantageous in terms of the crosstalk between the sub-carrier and the payload signal. However, it is necessary to install high-speed, high-bandwidth electrical equipment at the transmitter and receiver. A sub-carrier frequency lower than the signal bit rate is used in [25] as a 50-Mbit/s NRZ channel overhead. A frequency of 9.73 GHz is used when the signal bit rate is 10 Gbit/s, using a differentially driven Mach-Zehnder (MZ) interferometer modulator. The sub-carrier is directly detected and filtered by an LPF. Another sub-carrier detection technique is proposed in Ref. 26. Here, the sub-carrier is encoded on the optical carrier by means of a dual-arm MZ $LiNbO_3$ (LN)-modulator, one arm is used for 10-Gbit/s data, the other is used for a 16.7-GHz RF tone modulated with a 100-Mbit/s ASK. A fiber loop mirror using polarization maintaining (PM) fiber birefringence is used to separate the baseband signal from the sub-carrier.

Other techniques focus on chromatic dispersion monitoring [27]. These techniques employ a chromatic dispersion monitor using the sub-carrier ratio method between higher and lower frequencies. The sub-carrier power measured at the receiver decreases due to the phase delay that the sub-carrier experiences in the dispersive fiber. A chromatic dispersion monitor using the optical side-band suppression method, which uses a sub-carrier frequency higher than the bit rate, measures the relative phase (time) delay between sub-carrier sidebands.

BIOGRAPHY

Ippei Shake was born in Kobe, Japan, in 1970. He received the B.S. and M.S. degrees in physics from Kyoto University, Kyoto, in 1994 and 1996, respectively. In 1996, he joined NTT Optical Network System Laboratories, NTT Corporation, Yokosuka, Japan. Since then he has been engaged in research and development of high-speed optical signal processing and high-speed optical transmission systems. He is now with NTT Network Innovation Laboratories, Yokosuka, Japan. His research interests also include optical networks, optical performance monitoring, and optical time-division multiplexing/demultiplexing circuits. He is a member of the Institute of Electrical and Electronics Engineers and the Institute of Electronics, Information and Communication Engineers (IEICE) of Japan.

1. INTRODUCTION

A multiple access method is a method for allowing several users to share a common physical channel, such as, a coaxial cable, an optical fiber, or a band of radio frequencies. Common multiple access methods are frequency-division multiple access (FDMA) and time-division multiple access (TDMA) [1–3]. Strictly speaking, the term "multiple access" is applicable for the case when the users are not at the same geographic location and the term "multiplexing" is applicable when they are; however, we use "multiple access" for both cases. In FDMA, the users' signals are selected such that they do not overlap in the frequency domain (an example is FM or AM broadcast radio), and in TDMA, the users' signals do not overlap in time (i.e., the users take turns using the channel). Ideally, this means that the users do not disturb each other, and the signals are said to be orthogonal. (In practice, there will be some interuser interference due to imperfections in the implementation and nonideal channels, but we will ignore these complications here.)

A third multiple access method that has become increasingly popular is code-division multiple access (CDMA) [4,5]. In CDMA, the users signals are overlapping in both time and frequency. This does not, however, imply that CDMA signals are necessarily nonorthogonal. As we will see shortly it is indeed possible, under certain strong restrictions, to find orthogonal signals that overlap in time and frequency.

Let us consider a simple example to illustrate the main idea behind the most common type of CDMA: direct-sequence CDMA (DS-CDMA). The name DS-CDMA stems from the fact that the users' signals are direct-sequence spread spectrum signals (DS-SS signals) [6–8]. Suppose that we have two users who each want to transmit data at a rate of $1/T$ bits/second. Let $b_1(t)$ and $b_2(t)$ be the data waveform of user 1 and 2, respectively, where bits are coded as ± 1 amplitudes of the waveforms. The kth user is assigned a signature waveform, $c_k(t)$, and the transmitted signal, $s_k(t)$, is formed as $s_k(t) = b_k(t)c_k(t)$, see Fig. 1. The data waveform is defined by the user's information bit sequence: in this case $b_1[n] = \{1, -1, \ldots\}$ for user 1 and $b_2[n] = \{-1, 1, \ldots\}$ for user 2. Similarly, the signature waveforms are defined by the users' signature sequences: $c_1[n] = \{1, -1, 1, 1, 1, -1, 1, 1, \ldots\}$ for user 1 and $c_2[n] = \{1, 1, -1, 1, 1, 1, -1, 1, \ldots\}$ for user 2. We note that the data waveforms can change polarity every T seconds and the signature waveforms can change polarity every T_c seconds. The ratio $N = T/T_c$ is called the spreading factor and also processing gain.

It is the signature waveform (also known as the code waveform or spreading waveform) that enables the

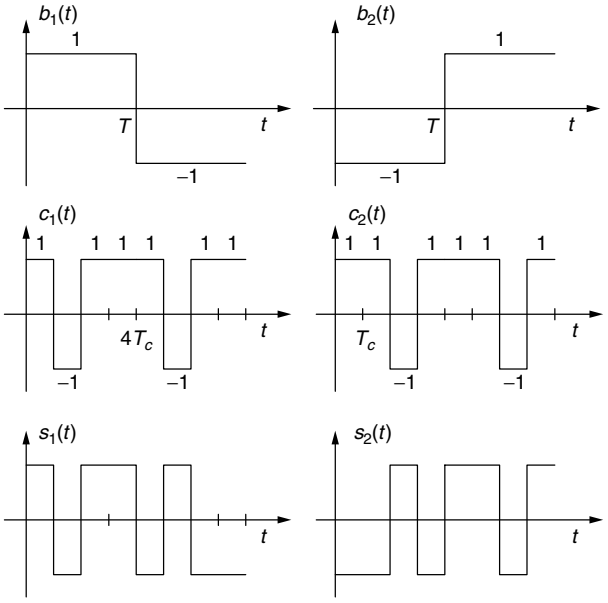

Figure 1. Data waveforms, signature waveforms, and transmitted waveforms for two users in a direct-sequence CDMA system.

receiver to separate users. Hence, the waveforms must be unique among the users. The process of multiplying the data waveform with the signature waveform is called spreading, since the bandwidth of the transmitted signal is significantly larger than the bandwidth of the data waveform. As a matter of fact, the bandwidth of the transmitted signal is approximately N times larger than the data waveform bandwidth (which justifies the terminology "spreading factor" for N).

The transmitted signals are added by the channel[1] and the received waveform is $r(t) = s_1(t) + s_2(t)$ (we ignore channel noise and other nonideal channel effects here). Now suppose that the receiver is interested in detecting the data from user 1. A block diagram of the system under consideration is found in Fig. 2. The receiver multiplies the received signal with the signature waveform of user 1, $c_1(t)$, and this results in the signal

$$\begin{aligned} z_1(t) &= r(t)c_1(t) \\ &= [b_1(t)c_1(t) + b_2(t)c_2(t)]c_1(t) \\ &= b_1(t)\underbrace{c_1^2(t)}_{=1} + b_2(t)c_2(t)c_1(t) \\ &= b_1(t) + b_2(t)c_2(t)c_1(t) \end{aligned}$$

We see that the signal $z_1(t)$ is the sum of two terms: the desired data waveform of user 1 and an interference term that is due to user 2. Since we have reduced the bandwidth of the desired part of the signal, the process of multiplying the received signal with the signature waveform is called despreading.

The standard method for recovering the data from a signal disturbed by additive noise or interference is to process the noisy signal with a matched filter. In this case, the filter should be matched to a rectangular pulse of length T seconds. Hence, the matched filter can be implemented as an integrator over T seconds. That is, the output of the matched filter is

$$y_1(t) = \int_{t-T}^{t} z_1(u)\,du$$

To decided on the nth bit, we sample the matched filter at time $(n+1)T$. Hence, to recover $b_1[0]$, we sample the filter at time T, which results in

$$\begin{aligned} y_1(T) &= \int_0^T z_1(t)\,dt \\ &= \int_0^T b_1(t)\,dt + \int_0^T b_2(t)c_1(t)c_2(t)\,dt \\ &= \int_0^T b_1[0]\,dt + b_2[0]\underbrace{\int_0^T c_1(t)c_2(t)\,dt}_{=0} \\ &= b_1[0]T \end{aligned}$$

where $b_1[0] = 1$ and $b_2[0] = -1$ are the transmitted bits. We see that the data bit from user 1 can be recovered as $\text{sgn}[y_1(T)]$, regardless of the value of $b_2[0]$. The condition

[1] There are situations when the transmitted signals are added already in the transmitter. This is the case when several users' signals are transmitted from the same geographical position. One example of this is a downlink in a cellular CDMA system, where all the users' signals in one cell are transmitted from the same base station [1–3].

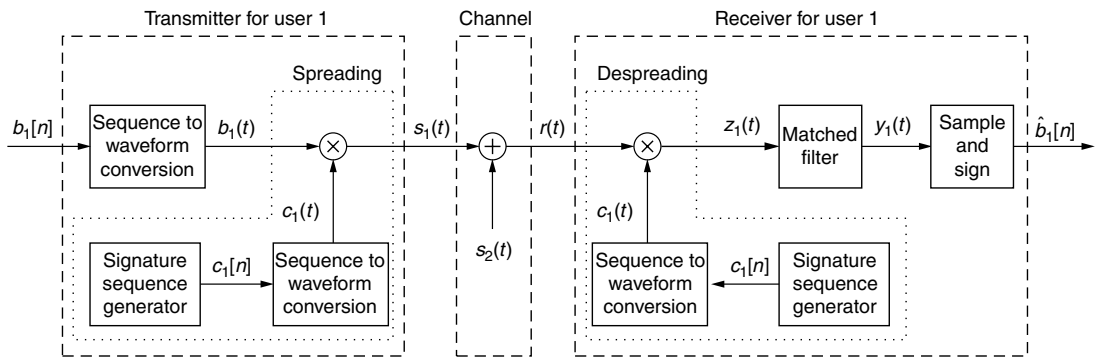

Figure 2. A block diagram for the transmitter and receiver for user 1. The channel is assumed to be noise-free and the only interference added is the signal from user 2.

that the cross-correlation between $c_1(t)$ and $c_2(t)$ is zero, that is,

$$\int_0^T c_1(t)c_2(t)\,dt = 0$$

proves that the signature waveforms $c_1(t)$ and $c_2(t)$ are orthogonal (over the interval $0 \le t \le T$). As long as the signature waveforms are orthogonal, users will not interfere with each other after despreading and matched filtering, and the data can be recovered without error (if we ignore channel noise). However, it is not necessary for the signature sequences to be completely orthogonal for a CDMA system to work. As a matter of fact, as long as the cross-correlation between the signature waveforms is small, the interference alone cannot cause errors (although the resistance against noise can be reduced).

It should now be clear that we need to choose signature sequences carefully to avoid excessive interference between users. In short, we want to select sequences that have low cross-correlations. As is discussed in more detail later, it is also important to select sequences that have good partial cross-correlation and autocorrelation properties. The autocorrelation of a sequence is the cross-correlation between the sequence and a time-shifted version of the same sequence. Ideally, we want the autocorrelation to be small for all nonzero time-shifts. The partial cross-correlation is the correlation between partial segments of the sequences. Ideally, the partial cross-correlation should be small for all choices of sequence segments.

This definition of "good correlation properties" is applicable for DS-CDMA, but not necessarily for other types of CDMA. Although many forms of CDMA exist, the most common type apart from DS-CDMA is frequency-hopping CDMA (FH-CDMA). FH-CDMA is similar to FDMA in that the users are assigned different frequency channels that are meant to be for exclusive use by the users. In FH-CDMA, the frequency channel allocation for a user is constantly changing. That is, the user hops among frequencies, and the hopping is done according to the user's signature sequence. Every now and then, two or more users will be assigned the same frequency. This is known as a collision and is a highly undesirable event, and FH-CDMA signature sequences are therefore primarily designed to avoid collisions. Hence, the signature sequences used for DS-CDMA and FH-CDMA are different. We will not cover FH-CDMA sequences further in this article; the interested reader is referred to Ref. [9] for an overview. More details on FH sequences (and DS sequences) can also be found in Refs. [6–8].

In addition to good cross-correlation properties (or good collision properties), it is desirable that the sequences are easily generated, that is, with as little hardware and software complexity as possible. Furthermore, in some applications, we also are interested in making the signature sequence a secret for all but the intended receiver. It is then important that it will be difficult for an unauthorized receiver to predict future values of the signature sequence by observing its past values. It should be noted that in most current CDMA systems, the signature sequences have not been designed with this last requirement in mind. Hence, security in these systems usually is obtained by other cryptographic methods.

We know that completely random sequences have, on average, good correlation properties and are impossible to predict. However, we cannot use true random sequences since both the transmitter and the receiver must be able to produce the same sequences. Instead, most sequences used in practice are derived from pseudorandom sequences (PN-sequences). The theory of PN sequences involves finite-field algebra; however, we will leave out all details here and rather give a brief description of how PN-sequences can be generated with digital hardware (or software). Most sequences in practical use are binary sequences (also known as bi-phase sequences) or 4-ary sequences (quadriphase sequences). The latter type is useful for quadrature modulated systems (e.g., phase-shift keying or quadrature amplitude modulation).

2. SPREAD SPECTRUM AND CDMA

In the introduction, it is noted by a simple example that, the signature sequences should be unique and have low partial cross-correlations for all time-shifts. To quantify these statements, let us go into more details.

As before, assume that a user k transmits the signal

$$s_k(t) = \sqrt{E_k/T}\,b_k(t)c_k(t) \tag{1}$$

where

$$b_k(t) = \sum_{i=0}^{\infty} b_k[i]h(t - iT) \tag{2}$$

is the data waveform

$$c_k(t) = \sum_{i=0}^{\infty} c_k[i]g(t - iT_c) \tag{3}$$

the signature waveform, and $h(t)$ a rectangular pulse shape given by

$$h(t) = \begin{cases} 1 & 0 \le t \le T \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

The chip-pulse-shape $g(t)$ can in general take any form. To simplify the presentation here, only the rectangular chip-pulse-shape is considered, such that

$$g(t) = \begin{cases} 1 & 0 \le t \le T_c \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

In practice, more spectrally efficient waveforms are used, but for the purpose of this article this only makes the mathematics untrackable. The properties and results that are discussed here hold with small changes for all pulse shapes used in practice. The data sequence and the chip sequence are denoted $b_k[i]$ and $c_k[i]$, respectively. In general, both of these sequences are complex-valued and take values from limited sets. Again for simplicity, we will concentrate here on real-valued data symbols and binary chips. The only difference in this model compared to the model presented in the introduction is that we have normalized the signal so its energy is

$$\int_0^T s_k^2(t)\,dt = \frac{E_k}{T}\int_0^T b_k^2(t)c_k^2(t)\,dt = \frac{E_k}{T}T = E_k \tag{6}$$

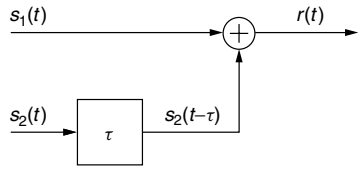

Figure 3. Block diagram of a two-user asynchronous noise-free channel with relative delay τ.

Let us consider a two-user case where the users are asynchronous (i.e., not time-aligned); see Fig. 3. This is the typical situation in a true multiple access scenario (such as the uplink in a cellular system). The received waveform can be expressed as

$$r(t) = s_1(t) + s_2(t-\tau) \tag{7}$$

where τ is the relative time-offset between the signals of users 1 and 2 depending on the propagation times of the user signals, and hence their distances to the receiver. Without loss of generality, we assume that $0 \le \tau < T$. Here we have, for simplicity, neglected the receiver noise that is always present, since it will not have any influence on the properties of the signature waveforms.

Assuming that we are interested in detecting user 1, we first despread the signal by multiplying with the waveform of user 1 as

$$\begin{aligned} z_1(t) &= r(t)c_1(t) \\ &= \left[\sqrt{E_1/T}b_1(t)c_1(t) + \sqrt{E_2/T}b_2(t-\tau)c_2(t-\tau)\right]c_1(t) \\ &= \sqrt{E_1/T}b_1(t) + \sqrt{E_2/T}b_2(t-\tau)c_2(t-\tau)c_1(t) \end{aligned} \tag{8}$$

The despread signal consists of the desired signal part and an interfering part from user 2. To recover $b_1[0]$ we calculate the output of the normalized filter matched to $h(t)$ at time T, which becomes

$$\begin{aligned} y_1(T) &= \frac{1}{\sqrt{T}}\int_0^T z_1(t)\,dt \\ &= \sqrt{E_1}\frac{1}{T}\int_0^T b_1(t)\,dt \\ &\quad + \sqrt{E_2}\frac{1}{T}\int_0^T b_2(t-\tau)c_2(t-\tau)c_1(t)\,dt \\ &= \sqrt{E_1}b_1[0]\frac{T}{T} + \sqrt{E_2}b_2[-1]\frac{1}{T}\int_0^\tau c_2(t-\tau)c_1(t)\,dt \\ &\quad + \sqrt{E_2}b_2[0]\frac{1}{T}\int_\tau^T c_2(t-\tau)c_1(t)\,dt \end{aligned} \tag{9}$$

The integrals in this expression are partial cross-correlations between the waveforms $c_1(t)$ and a time-shifted version of $c_2(t)$. Assuming that τ is a multiple of the chip time given as $\tau = pT_c$ $(0 \le p < N)$, we can calculate the individual partial cross-correlations as function of the discrete signature sequences as

$$\frac{1}{T}\int_0^\tau c_2(t-\tau)c_1(t)\,dt = \begin{cases} \dfrac{T_c}{T}\displaystyle\sum_{n=0}^{p-1} c_2[n-p]c_1[n] & 0 < p < N \\ 0 & p = 0 \end{cases} \tag{10}$$

$$\frac{1}{T}\int_\tau^T c_2(t-\tau)c_1(t)\,dt = \frac{T_c}{T}\sum_{n=p}^{N-1} c_2[n-p]c_1[n] \tag{11}$$

These derivations can easily be extended to more than two users with user i as the desired user. We now introduce the discrete partial cross-correlations as

$$X_{k,i}(p) = \sum_{n=p}^{N-1} c_k[n-p]c_i[n] \quad 0 \le p < N \tag{12}$$

and

$$\overline{X}_{k,i}(p) = \begin{cases} \displaystyle\sum_{n=0}^{p-1} c_k[n-p]c_i[n] & 0 < p < N \\ 0 & p = 0 \end{cases} \tag{13}$$

With these discrete partial cross-correlations the matched filter output in Eq. (9) can be rewritten as

$$\begin{aligned} y_1(T) &= \sqrt{E_1}b_1[0] + \sqrt{E_2}b_2[-1]\overline{X}_{2,1}(p)/N \\ &\quad + \sqrt{E_2}b_2[0]X_{2,1}(p)/N \end{aligned} \tag{14}$$

We clearly see that we get the desired signal $\sqrt{E_1}b_1[0]$ but also two multiple-access interference (MAI) terms that depend on the partial cross-correlations between the signature sequences of the two users. For ideal output (only the desired part), the sum of the two MAI terms should be zero for any combination of data symbols $b_2[-1]$ and $b_2[0]$, and for all values of the time-shift p, since p may vary. These equations can easily be extended to more users. The MAI term from user k on user i is obtained by replacing index 2 by index k and index 1 by index i in Eq. (14). Ideally, the sum of all these MAI terms should be zero for all time-shifts p. This is guaranteed when $\overline{X}_{k,i}(p) = 0$ and $X_{k,i}(p) = 0$ for all $p \in [0, N-1]$ and for all $k \ne i$, although in some cases this is an unnecessarily strong requirement.

For signature sequences with period N the cross-correlations can be expressed as

$$\begin{aligned} X_{k,i}(p) &= C_{k,i}(p) \\ \overline{X}_{k,i}(p) &= C_{k,i}(p-N) \end{aligned} \tag{15}$$

where we have introduced the aperiodic cross-correlation parameter $C_{k,i}(m)$ defined as

$$C_{k,i}(m) = \begin{cases} \displaystyle\sum_{n=0}^{N-1-m} c_k[n]c_i[n+m] & \text{if } 0 \le m \le N-1, \\ \displaystyle\sum_{n=0}^{N-1+m} c_k[n-m]c_i[n] & \text{if } 1-N \le m < 0, \\ 0 & \text{otherwise} \end{cases} \tag{16}$$

which is commonly used in the literature [10].

In many systems, the channel for the kth user can be modeled as a channel with L distinct propagation paths, where the lth path has complex gain $g_k(l)$ and delay $\tau_k(l)$.

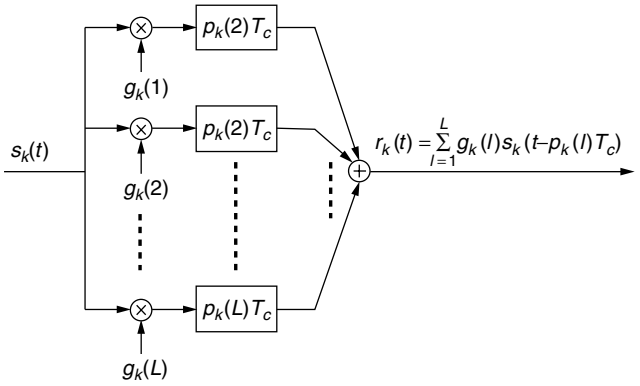

Figure 4. Noise-free L-path channel for the kth user. The lth path has complex gain $g_k(l)$ and delay $p_k(l)T_c$.

For simplicity, we assume that the delays can be written as $\tau_k(l) = p_k(l)T_c$, where $p_k(l)$ is an integer in $[0, N-1]$ and $p_1(1) = 0$. The multipath channel for the kth user is shown in Fig. 4.

Generalizing the given expressions for the case of a uplink CDMA system with K users experiencing delay spread, it can be shown that the matched filter output for user 1 at time T (path 1) can be written as

$$\begin{aligned} y_1(T) = {} & \sqrt{E_1}g_1(1)b_1[0] + \\ & \underbrace{\sum_{l=2}^{L}\sqrt{E_1}g_1(l)\Big(b_1[-1]\overline{X}_{1,1}(p_1(l))/N + b_1[0]X_{1,1}(p_1(l))/N\Big)}_{\text{ISI(+ICI)}} \\ & + \underbrace{\sum_{k=2}^{K}\sum_{l=1}^{L}\sqrt{E_k}g_k(l)\Big(b_k[-1]\overline{X}_{k,1}(p_k(l))/N + b_k[0]X_{k,1}(p_k(l))/N\Big)}_{\text{MAI}} \end{aligned} \tag{17}$$

The desired part is $\sqrt{E_1}g_1(1)b_1[0]$ in Eq. 17. The second part is the intersymbol interference (ISI), which is a weighted sum of aperiodic autocorrelations (partial cross-correlations between two equal sequences with different time-shifts) $\overline{X}_{1,1}(p_1(l))$ and $X_{1,1}(p_1(l))$. The part of the ISI that depends on $b_1[0]$ is sometimes referred to as interchip interference (ICI), but we prefer to refer to all of it as ISI. The third part is the MAI part, which is a weighted sum of the partial cross-correlations $\overline{X}_{k,1}(p_k(l))$ and $X_{k,1}(p_k(l))$. The ideal signature sequences should make the matched filter output as close as possible to the desired component. Again, this is obtained when all partial cross-correlations are zero for all time-shifts and the partial autocorrelation is zero for all time-shifts except zero. In practice, it may be enough to require that these partial correlations are close to zero.

From Eq. (17) it is seen that some information about the desired data symbol $b_1[0]$ is not used to form the desired part of the decision variable but instead becomes interference. The performance of a spread spectrum and CDMA receiver can be improved by using all the information about $b_1[0]$, which is available in the received signal (also that in the multipath components of the desired signal) [6–8]. Such a receiver is not matched to the transmitted waveform of the desired user only, but to that waveform convolved with the channel impulse response, and is commonly referred to as a RAKE receiver [6,8,11]. Now the decision variable becomes the weighted sum

$$y_{\text{rake}} = \sum_{l=1}^{L} g_1^*(l)y_1(T + p_1(l)T_c) \tag{18}$$

This expression can be worked out in the same way as Eq. (17). Again, it consists of three terms: the desired term, an ISI term, and a MAI term. The ISI and MAI terms are guaranteed to becomes zero under the same requirements as above, that is, the partial autocorrelation should be zero at all time-shifts except 0 and the partial cross-correlations should be zero at all time-shifts.

So far we have considered only the decision variable for data detection. The normalized matched filter output

$$y_1(t) = \frac{1}{\sqrt{T}}\int_{t-T}^{t} z_1(u)\,du \tag{19}$$

may also be used for acquisition and synchronization. Note that we have assumed that the sampling point T used to obtain a decision variable for $b_1[0]$ was known in the preceding derivation. In practice, this sampling point must be estimated. One common way of doing this is to find the maximum over a symbol interval of the matched filter output, since this maximum most likely corresponds to the time-shift where the timing of the received signal and the regenerated signal in the receiver are aligned. This normally is implemented as a two-stage procedure, where the matched filter output $y_1(t)$ is compared to a threshold in the first stage. The time where the threshold is exceeded is taken as a rough estimate of the timing (aquisition). In the next stage, the maximum of $y_1(t)$ in the vicinity of the point found in the first stage is found (synchronization) [6,8].

The contribution from the desired signal in $y_1(t)$ becomes very similar to the MAI term in Eq. (9), except that the user index is the same on both signature waveforms. After some derivations,

$$y_1(pT_c) = \sqrt{E_1}b_1[-1]\overline{X}_{1,1}(p)/N + \sqrt{E_1}b_1[0]X_{1,1}(p)/N \tag{20}$$

when $r(t) = s_1(t)$. On a multipath channel, there will be more terms of the type $\overline{X}_{1,1}(p + p_1(l))$ and $X_{1,1}(p + p_1(l))$. To have a distinct peak to use for timing estimation, it is clear that the requirements on the signature sequence used for synchronization is the same as the requirement to obtain low ISI in data detection.

3. COMMON SIGNATURE SEQUENCES

In this section, we describe some commonly used signature sequences and briefly discuss their properties.

The signature waveform of user k will, as before, be denoted as $c_k(t)$. This waveform is obtained as given in Eq. (3) where $c_k[i]$ takes values from $\{\pm 1\}$. The signature sequences are commonly defined by arithmetics in the binary field GF(2) where the elements are denoted as 0 and 1. In the following, we use uppercase letters to denote variables in GF(2) and lowercase letters to denote the corresponding antipodal variables. This means that the antipodal signature sequence is obtained from the corresponding signature sequence in GF(2) from

$$c_k[i] = 1 - 2\,C_k[i] \tag{21}$$

We do not use different symbols for addition and multiplication, because we believe it is clear from the expression whether it is operations in GF(2) or in the field of real numbers. The user index k will be suppressed when there is no reason to distinguish between several users.

Periodic sequences, like the ones discussed in this section, can be used in several ways to form signature waveforms for spread spectrum and CDMA. One way is to map the complete binary sequence to an antipodal sequence using Eq. (21), and then form the signature waveform as described in Eq. (3). When the spreading factor N is identical to the period P, this is referred to as short codes, while the case of $P > N$ corresponds to long codes.[2] With short codes, the signature waveform becomes identical for each transmitted symbol, while it changes over time for long codes. However, sometimes instead the signature waveform is obtained from a periodic repetition of part of the full period of the original sequence. Mathematically, this means that the signature sequence used to form the signature waveform is given by

$$\{C[0], C[1], \ldots, C[Q], C[0], C[1], \ldots, C[Q], \ldots\} \tag{22}$$

where $Q < P$. Different users may use different phase shifts of the same periodic sequence, or they may use different periodic sequences.

3.1. Maximal Length Sequences

Maximal length sequences (m-sequences) are generated by a shift register with feedback and have the maximum period that can be obtained with the given shift register [12]. The signature sequence $\{C[0], C[1], \ldots\}$ is generated by the recursive formula

$$\begin{aligned} C[i] &= G[1]C[i-1] + G[2]C[i-2] + \cdots + G[m]C[i-m] \\ &= \sum_{k=1}^{m} G[k]C[i-k] \end{aligned} \tag{23}$$

where $i \geq m$ and m is the length (memory) of the shift register and is commonly also referred to as the degree of the sequence. The coefficients $\{G[1], G[2], \ldots, G[m]\}$ and the initial state $\{C[0], C[1], \ldots, C[m-1]\}$ specify the sequence. The coefficient $G[m]$ is always 1 for binary m-sequences. The maximum period of this signature sequence is $P = 2^m - 1$ and is obtained when the characteristic polynomial $G(D) = G[m]D^m + G[m-1]D^{m-1} + \cdots + D + 1$ is an irreducible and primitive polynomial that divides $D^P + 1$ [7,8,12,13]. An irreducible polynomial cannot be factored and a primitive polynomial $G(D)$ of degree m is one for which the period of the coefficients of $1/G(D)$ is P.

M-sequences exist for all $m > 1$ and the number of characteristic polynomials is

$$N_p(m) = \frac{2^m - 1}{m} \prod_{i=1}^{k} \frac{P_i - 1}{P_i}$$

where $\{P_1, P_2, \ldots, P_k\}$ are prime numbers such that

$$2^m - 1 = \prod_{i=1}^{k} P_i^{m_i}$$

where $\{m_1, m_2, \ldots, m_k\}$ are integers.[3] It should be noted that a characteristic polynomial $G(D)$ can be reversed as $G'(D) = D^m + G[1]D^{m-1} + \cdots + G[m-1]D + G[m]$ to give a reversed m-sequence. These reversed polynomials are included in $N_p(m)$. For a given characteristic polynomial, different initial states give a different phase shift of the same sequence. In Table 1, the number of characteristic polynomials and the maximum period are given for degree m m-sequences. It is clear that the number of characteristic polynomials and thus sequences increases very fast when m increases. Characteristic polynomials for many periods can be found in Refs. [7,8,11,14,15] and we summarize some of them in Table 2 (the reversed polynomials are not included in this table).

In every period of length P of a m-sequence, the number of zeros is $2^{m-1} - 1$ and the number of ones is 2^{m-1}. Moreover, half of the number of runs of ones and zeros have length 1, 1/4 have length 2, 1/8 have length 3, and in general $1/2^k$ have length k with $k < m$.

With short codes using the full period of the m-sequences, that is, $Q = P = N$, it is well known that the periodic autocorrelation function is given by Refs. [7,8]

$$\phi(p) = \overline{X}_{k,k}(p) + X_{k,k}(p) = \begin{cases} N & \text{when } p = 0 \\ -1 & 1 \le p < N \end{cases} \tag{24}$$

For large N, $\phi(p)/\phi(0) = -1/N$, where $p \neq 0$, becomes insignificant, and the autocorrelation function approaches the autocorrelation function of an uncorrelated sequence. Therefore, m-sequences have excellent properties for synchronization in direct sequence spread spectrum when the data waveform is constant and the channel flat, since it contains well-defined autocorrelation peaks. They also lead to very small ISI under the same assumption. However, it is also well known that the periodic cross-correlation given by

$$\Phi_{k,i}(p) = \overline{X}_{k,i}(p) + X_{k,i}(p) \tag{25}$$

may have significant values [10,11]. The maximum periodic cross-correlation

$$\Phi_{\max} = \max_{p,k,i \neq k} |\Phi_{k,i}(p)| \tag{26}$$

between any pair of m-sequences is given in Table 3 for some short m-sequences. From table 3 it is clear that the maximum cross-correlation peak may be more than one-third of the length of the sequence. The maximum MAI is proportional to the maximum cross-correlation values when $b_k[-1] = b_k[0]$. Much less appears to be known about ISI and MAI in the general case when $b_k[-1] \neq b_k[0]$ and also about the synchronization properties when $b_i[-1] \neq b_i[0]$.

As an example of short codes based on m-sequences, we choose the length 31 sequence generated by using $G(D) = D^5 + D^4 + D^3 + D^2 + 1$ (75 in octal as seen in Table 2). When the initial values of the signature sequence are all ones, the first period becomes {1, 1, 1, 1, 1, 0, 0, 1, 0, 0, 1, 1, 0, 0, 0, 0, 1, 0, 1, 1, 1, 0, 1, 0, 1, 0, 0, 0, 1, 1, 0}. In Fig. 5 the aperiodic and periodic discrete autocorrelation sequences ($\phi(p)$) are shown as well as $X_{1,1}(p) - \overline{X}_{1,1}(p)$, which is proportional to the MAI when $b_k[-1] = -b_k[0]$. With binary antipodal modulation, the absolute value of the maximum MAI between two users using different shift of the same m-sequence is proportional to the maximum of $|X_{1,1}(p) - \overline{X}_{1,1}(p)|$ and

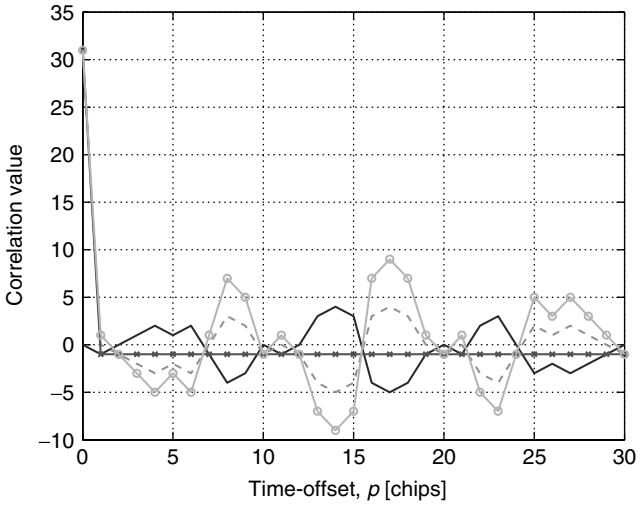

Figure 5. $\overline{X}_{1,1}(p)$ (solid line), $X_{1,1}(p)$ (dashed line), $\phi(p)$ (cross), and $X_{1,1}(p) - \overline{X}_{1,1}(p)$ (circle) for the m-sequence based on characteristic polynomial $G(D) = D^5 + D^4 + D^3 + D^2 + 1$.

$|\phi(p)|$ for $p \neq 0$. From Fig. 5 we see that this maximum MAI in this example is not larger than the maximum periodic cross-correlation $\Phi_{\max}$ as shown in Table 3. However, the maximum cross-correlation $|\Phi_{k,i}(p)|$ between the m-sequences generated by $G(D) = D^5 + D^4 + D^3 + D^2 + 1$ and $G(D) = D^5 + D^2 + 1$ (45 in octal) is 13, so the maximum correlation is not guaranteed to be at most the values given in Table 3. The conclusion is that $\Phi_{\max}$ should not be taken as a guarantee of the maximum MAI.

With long codes, much less is known about the autocorrelation and cross-correlation properties of signature sequences based on m-sequences. In this case, it is the partial correlations over $N < P$ chips that are important. The same is true for both long and short codes on multipath fading channels. In this case, the correlation properties also depend on whether a simple matched filter receiver is used or a RAKE receiver is used (or any other receiver). In the first case, it is the partial correlation between the transmitted signature waveform of user k convolved with the channel impulse response of user k and the signature waveform of the desired used that should have small values to reduce MAI. In the second case, it is the partial correlation between the transmitted signature waveform of user k convolved with the channel impulse response of user k and the signature waveform of the desired used convolved with the channel impulse response of the desired user that influence MAI. It seems that very little is known about these correlation properties on multipath channels in general for m-sequences.

M-sequences are used in the IS-95 CDMA system developed by Qualcomm [16]. In the uplink, a long m-sequence with period $2^{42} - 1$ is used to distinguish different channels (channelization). In both the uplink and the downlink, m-sequences with period $2^{15} - 1$ are used to separate mobiles (uplink) and base stations (downlink). Separate m-sequences are used on the I and Q channels in both directions. In the downlink, the data are also scrambled by a decimated long m-sequence.

3.2. Gold Sequences

M-sequences lead to the excessive amount of MAI in CDMA systems as seen previously. Another family of periodic signature sequences with somewhat better properties are Gold sequences [7,8,11,17,18]. A Gold sequence is obtained as the sum of two so-called preferred pairs of m-sequences, that is, $C[i] = C'[i] + C''[i]$, where $C'[i]$ and $C''[i]$ are the ith chips of two different m-sequences. In fact, each preferred pair of m-sequences generates a whole family of Gold sequences, namely, each of the two m-sequences alone and the sum of one of them with any shift of the other. Therefore, every preferred pair generates $P + 2$ Gold sequences, where P as before is the period of the m-sequence. A limited set of characteristic polynomials for preferred pairs of m-sequences is given in Table 4. A more complete table can be found in Ref. [7, page 502].

When $N = P$, the periodic autocorrelation $\phi(p)$ with $p \neq 0$ and the periodic cross-correlation $\Phi_{k,i}(p)$ can be shown to take at most three values, which are $\{-1, -t(m), t(m) - 2\}$, where

$$t(m) = \begin{cases} 2^{(m+1)/2} + 1 & m \text{ odd} \\ 2^{(m+2)/2} + 1 & m \text{ even} \end{cases} \tag{27}$$

Table 4. Characteristic Polynomial for Preferred Pairs of m-Sequences That Are Used to Form Gold Sequences. A More Complete Table can be found in Ref. [7, page 502]. The Octal Notation is Explained in Table 2

m	$P = 2^m - 1$	Preferred Pairs of Generator Polynomials in Octal Form
5	31	[45,75]
6	63	None
7	127	[211,217], [211,277]
8	255	[747,703]
9	511	[1021,1131], [1131,1423]

Table 5. The Maximum Periodic Autocorrelation and Cross-Correlation $\Phi_{\max}$ for Gold Sequences of Degree m

m	$t(m) = \Phi_{\max}$	$\Phi_{\max}/P$
5	9	0.29
6	17	0.27
7	17	0.13
8	33	0.13
9	33	0.06
10	65	0.06
11	65	0.03
12	129	0.03

These values are given in Table 5 together with the corresponding normalized values. Here it is clearly seen that these values are much improved compared with the corresponding values for m-sequences (see Table 3).

Thus, the MAI on a flat channel is reduced when $b_k[-1] = b_k[0]$. However, for other combinations of data, the MAI may be larger. The properties for synchronization on a flat channel have become poorer as compared with m-sequences, since the periodic autocorrelation function is larger for $0 < p < N$. This is illustrated in Figs. 6 and 7 for

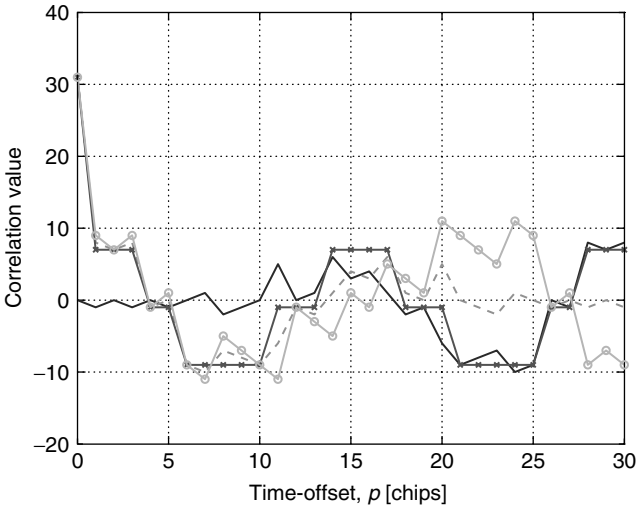

Figure 6. $\overline{X}_{1,1}(p)$ (solid line), $X_{1,1}(p)$ (dashed line), $\phi(p)$ (cross), and $X_{1,1}(p) - \overline{X}_{1,1}(p)$ (circle) for Gold sequence.

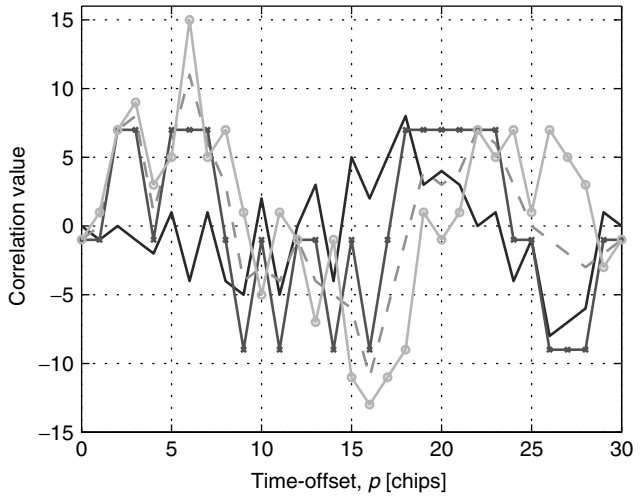

Figure 7. $\overline{X}_{2,1}(p)$ (solid line), $X_{2,1}(p)$ (dashed line), $\Phi_{2,1}(p)$ (cross), and $X_{2,1}(p) - \overline{X}_{2,1}(p)$ (circle) for two Gold sequences.

Gold sequences with period 31. The preferred pairs used are those given in Table 4 for $m = 5$. Both m-sequences have been generated starting from all ones. Figure 6 shows $\overline{X}_{1,1}(p)$ (solid line), $X_{1,1}(p)$ (dashed line), $\phi(p)$ (cross), and $X_{1,1}(p) - \overline{X}_{1,1}(p)$ (circle) for the Gold sequence obtained by adding the two sequences with a shift of 2 chips on the one generated from characteristic polynomial 45. Figure 7 shows $\overline{X}_{2,1}(p)$ (solid line), $X_{2,1}(p)$ (dashed line), $\Phi_{2,1}(p)$ (cross), and $X_{2,1}(p) - \overline{X}_{2,1}(p)$ (circle) where user two uses the sequence above and user 1 the sequence obtained by shifting 15 chips instead of 2. Both figures verify the three valued behavior of $\phi(p)$ and $\Phi_{k,i}(p)$ as discussed previously (curves shown with cross). However, in both cases, it is also clear that larger MAI may occur when $b_2[-1] = -b_2[0]$ (curves with circle).

Again, much less is known about the correlation properties when long codes based on Gold sequences are used and in general on multipath channels. In the Wideband CDMA (WCDMA) system used for third-generation mobile communications, Gold sequences are used to distinguish cells in the downlink and to distinguish mobiles in the uplink when simple receivers are used in the base station [4,5]. In both cases, long codes are used. The Gold sequence used in the downlink has period $2^{18} - 1$, while the Gold sequence used in the uplink has period $2^{41} - 1$. In both cases, only 38,400 chips are used to form a periodic sequence with period 38,400. The spreading factor is variable between 4 and 512.

3.3. Kasami Sequences

The *small set* of Kasami sequences can be obtained in a way similar to the Gold sequences [11,13,19]. Again, two m-sequences are added, but in this case, these two m-sequences have different periods. To obtain a period of $P = 2^m - 1$, with m even, of the Kasami sequence, one starts with an m-sequence with the same period. This m-sequence is then decimated by $2^{m/2} + 1$, which results in another m-sequence of period $2^{m/2} - 1$. By adding these two sequences, a Kasami sequence is obtained. Yet more Kasami sequences can be obtained by adding the original m-sequence with the other $2^{m/2} - 2$ shifts of the decimated sequence. By also including the original m-sequence in the set, $2^{m/2}$ Kasami sequences with period $2^m - 1$ have been obtained. It turns out that another way to generate all these sequences is by using the characteristic polynomial $G(D)G'(D)$ in (23), where $G(D)$ is the characteristic polynomial of the original m-sequence and $G'(D)$ is the characteristic polynomial of the decimated m-sequence.

The periodic discrete autocorrelation and cross-correlation is also three-valued for the *small set* of Kasami sequences. The values are from the set $\{-1, -(2^{m/2} + 1), 2^{m/2} - 1\}$. The *small set* of Kasami sequences therefore satisfies the Welch lower bound [11,20], which states that the maximum cross-correlation $\Phi_{\max}$ between any two sequences in a set of M sequences is bounded as

$$\Phi_{\max} \geq P\sqrt{\frac{M-1}{MP-1}} \approx \sqrt{P} \tag{28}$$

where the approximation is valid for large values of P and M. This set of sequences is therefore considered as optimal.

The *large set* of Kasami sequences with period $P = 2^m - 1$, with m even, contains both the Gold sequences and the *small set* of Kasami sequences and is obtained in the following way. Three different sequences are added. One is an m-sequence of period P. The other two are obtained by decimating the original m-sequence by $2^{m/2} + 1$ and $2^{(m+2)/2} + 1$. The two can be used in any possible shift. The number of sequences obtained are $2^{3m/2}$ when $m = 0 \bmod 2$ and $2^{3m/2} + 2^{m/2}$ when $m = 2 \bmod 2$. All the values of the periodic autocorrelation and cross-correlation are from the set $\{-1, -1 \pm 2^{m/2}, -1 \pm 2^{m/2+1}\}$. The Welch bound is not asymptotically approached with this larger set, but the packing of signal space is more efficient than for the Gold sequences. This set can be generated directly by using the characteristic polynomial $G(D)G'(D)G''(D)$, where $G(D)$ is the characteristic polynomial of the original m-sequence, $G'(D)$ is the characteristic polynomial of the first decimated m-sequence, and $G''(D)$ is the characteristic polynomial of the second decimated m-sequence.

However, still little is known about the performance of the sets of Kasami sequences when they are used as short or long signature sequences on multipath channels in CDMA. The reason, as before, is that it is not only the periodic autocorrelation and periodic cross-correlation between the full period of the signature sequences that matters.

3.4. Walsh–Hadamard Sequences

Two orthogonal signature sequences (on a flat channel) over the full period cannot be obtained by any of the sequence families discussed previously since $\Phi_{k,i}(p) \neq 0$. Complete orthogonality would make MAI to disappear and is therefore interesting. In the introduction, we indicated that under certain restrictions, it is in fact possible to obtain complete orthogonality. The family of orthogonal sequences is referred to as Walsh–Hadamard sequences

(sometimes Hadamard codes or Walsh functions). A Hadamard matrix of length $P = 2^m$ is defined as

$$\mathbf{H}_2 = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$$
$$\mathbf{H}_P = \begin{bmatrix} \mathbf{H}_{P/2} & \mathbf{H}_{P/2} \\ \mathbf{H}_{P/2} & \overline{\mathbf{H}}_{P/2} \end{bmatrix} \tag{29}$$

where $\overline{\boldsymbol{H}}_{P/2}$ denotes the complement of $\mathbf{H}_{P/2}$. The rows of such a matrix are orthogonal. Thus, a user can form its signature sequence as a periodic repetition of one row in the Hadamard matrix of length $P = N$. If another user forms its signature sequence in the same way, but based on another row in the same matrix, and these two users are synchronized such that the periods of the signature sequences completely overlap, the periodic cross-correlation $\Phi_{k,i}(0)$ becomes zero. These two users will therefore not interfere with each other on a channel without multipath propagation. However, $\Phi_{k,i}(p)$ and $\phi(p)$ for $0 < p < N$ are in general not zero and are in many cases quite large (can in fact be as large as $N - 1$). This means that the system must be synchronized and that Walsh-Hadamard sequences are not good for synchronization purposes. The orthogonality is also lost on multipath channels.

Signature sequences based on rows or parts of rows of a Hadamard matrix can also be used when different users have different spreading factors as in WCDMA [4,5]. From Eq. (29), it is seen that each Hadamard matrix can in fact be decomposed into four Hadamard matrices of half the size. Since the rows in Hadamard matrices of all sizes have orthogonal rows, it is possible to allow a user with spreading factor $P/2$ to form its signature sequence as a repetition of one of the rows in $\mathbf{H}_{P/2}$. To keep orthogonality between all signature sequences also over the period $P/2$, users with spreading factor P are now restricted to use one of the remaining rows not starting with the sequence of length $P/2$ already used. This can be generalized to any spreading factor between 2 and P, when the Hadamard matrix of length P is used.

In WCDMA, the Hadamard matrix of length 256 is used to allocate signature waveforms to different channels in a base station or in a mobile (referred to as channelization codes in WCDMA). This matrix can be used for spreading factors from 4 to 256 (only powers of two are used) and the orthogonality is always preserved as long as the channel is flat. A user with spreading factor 4, is allocated the first 4 bits on one row in the matrix. It forms its signature sequence by periodically repeating these four bits. Since 1/4 of the rows in the Hadamard matrix start with the same 4 bits, these cannot be used for other users, because this would not make them orthogonal over a 4 chip period. A user with spreading factor 8 can be allocated the 8 first bits on the one of the remaining (allowed) rows for its signature sequence. This means that another 1/8 of all the rows are not allowed for the rest of the users. This scheme can now be continued as long as there are rows available to allocate. These sequences are referred to as Orthogonal Variable Spreading Factor (OVSF) sequences in WCDMA.

Walsh–Hadamard sequences are also use in IS-95 CDMA [16]. In the downlink, different channels are separated by different Walsh–Hadamard sequences of length 64. Walsh–Hadamard sequences are also used in the uplink, not as signature sequences but to obtain orthogonal 64-level modulation.

4. SOME CONCLUDING REMARKS ON SIGNATURE SEQUENCES

Although we have not covered all known signature sequences, it is clear that families of signature sequences with $\overline{X}_{k,i}(p) = 0$ except for $p = 0$ and $k = i$ do not exist. This means that there will be interference (the sum of ISI, MAI, and receiver noise) in the decision variable of each user. The choice of signature waveforms can to a certain extent reduce the interference, but in practice channel coding is also used in the system to reduce the effects of the interference. Since most known channel codes are designed for independent errors, it is important that interference be white (or almost white), such that the interference in the decision variable is independent from one symbol interval to the next. Furthermore, the power of the total interference should be small. The average interference power (AIP) for user 1 in the output at time T of a filter matched to $h(t)$ is given by

$$\begin{aligned} \mathrm{AIP}_1(T) &= \mathrm{E}\,[y_1(T) - \sqrt{E_1}g_1(1)b_1[0]]^2 \\ &= \sum_{l=2}^{L} E_1 \mathrm{E}\,|g_1(l)|^2 \left(\overline{X}_{1,1}^2(p_1(l))/N^2 + X_{1,1}^2(p_1(l))/N^2\right) \\ &\quad + \sum_{k=2}^{K}\sum_{l=1}^{L} E_k\,\mathrm{E}\,|g_k(l)|^2 \left(\overline{X}_{k,1}^2(p_k(l))/N^2 \right. \\ &\quad \left. + X_{k,1}^2(p_k(l))/N^2\right) \end{aligned} \tag{30}$$

where the same assumptions as in Eq. (17) about the channels have been used. Here, we have used the fact that bits from different users and different times are independent and hence the expected value of the cross-terms are zero. This average depends on the channel (both the complex coefficients and the relative delays) so in order for signature sequences to be good, they must lead to low AIP for all reasonable channels. The average also depends on the received energy from the different users through E_k and $|g_k(l)|^2$. These can to a certain extent be reduced by power control, such that a nearby user is not received at much higher power than a distant user. Results exist that seem to show that all the different families of signature sequences discussed lead to approximately the same AIP with practical channels in asynchronous DS-CDMA [21]. There also is some evidence that Gold sequences lead to reasonably good performance on land mobile radio channels [22].

With short signature sequences, the correlation time of the interference only depends on the correlation time of the channel coefficients. Thus, a large interference value due to high cross-correlation between two users, may remain for a significant time, and this makes channel coding less efficient. Long signature sequences are a means to reduce the correlation between the interference in neighboring symbol intervals, since different segments of the signature

sequences are used in neighboring symbol intervals, leading to different cross-correlations. This significantly improves the performance of channel coding.

There also exist many different receivers that may be used with DS-CDMA [23–25]. Many of these attempt to remove some or all interference before the decision variable is formed. For such receivers, the actual choice of signature sequences may be somewhat less important. The processes of mapping data symbols $b_k(t)$ to a transmitted waveform in DS-CDMA can also be described as repetition coding followed by scrambling, where the scrambling sequences plays the role of the signature sequence above [26]. In such a system, the outer channel coding and the repetition coding can be combined into one encoding process and interleaving can be done either on symbols or on chips. For all these different kind of systems, signature sequences should be designed jointly with several other things like channel coding, interleaving scheme, detection algorithm, and so on. For such more elaborate schemes, it remains an open issue how to design signature sequences and what the actual performance of the system will be on different channels.

BIOGRAPHIES

Tony Ottosson received the M.Sc. in electrical engineering from Chalmers University of Technology, Göteborg, Sweden, in 1993, and the Lic. Eng. and Ph.D. degrees from the Department of Information Theory, Chalmers University of Technology, in 1995 and 1997, respectively. Currently, he is an associate professor at the Communication Systems Group, Department of Signals and Systems, Chalmers University of Technology. During 1999 he was also working as a Research Consultant at Ericsson Inc., Research Triangle Park, North Carolina.

Professor Ottosson's research interests are in communication systems and information theory and are targeted mainly to CDMA systems. Specific topics are modulation, coding, multirate schemes, multiuser detection, combined source-channel coding, joint decoding techniques, and synchronization.

Erik G. Ström received his M.Sc. in electrical engineering in 1990 from the Royal Institute of Technology (KTH), Stockholm, Sweden, and Ph.D. degree in electrical engineering from the University of Florida, Gainesville, in 1994. He joined the Department of Signals, Sensors, and Systems at KTH as a postdoc in 1995 and was appointed assistant professor (forskarassistent) in 1996. Later that year, Ström joined Chalmers University of Technology, Göteborg, Sweden, where he is now an associate professor (högskolelektor/docent). He received the Chalmers Teacher's Prize in 1998. Since 1990 Dr. Ström acted as a consultant for the Educational Group for Individual Development, Stockholm, Sweden. He is a contributing author and associate editor for the Royal Admiralty Publishers' FesGas-series. Ström is a member of the board of the IEEE VT/COM chapter of the Swedish section and was a coguest editor for the special issue IEEE *Journal on Selected Areas in Communications* on "Signal Synchronization in Digital Transmission Systems." His research interests include code-division multiple access, synchronization, and wireless communications. He has published approximately 40 journal and conference papers.

Arne Svensson received the M.Sc. degree in electrical engineering in 1979, and the Dr. Ing. (Tekniska Licentiat) and the Dr. Techn. (Ph.D.) in telecommunication theory in 1982 and 1984, respectively, from University of Lund, Lund, Sweden. He joined Ericsson in 1987 as a research engineer and became later a specialist in communications. At Ericsson he worked on the design and analysis of a communication systems for the Swedish air force and the personal digital cellular system for mobile communications in Japan. Since 1993, he has been professor in communication systems at Chalmers University of Technology, Göteborg, Sweden, where he has been working on design and analysis of air interfaces for mobile communications. Dr. Svensson has published more than 150 papers in international journals and conference proceedings, and he is a fellow of IEEE. In 1986, he received the paper of the year award from the IEEE Vehicular Technology Society. His areas of interest include channel coding/decoding, digital modulation methods, channel estimation, data detection, multiuser detection, digital satellite systems, wireless IP-based systems, CDMA and spread spectrum systems, personal communication networks, and ultra wideband systems.

SIMULATION OF COMMUNICATION SYSTEMS

K. SAM SHANMUGAN
University of Kansas
Lawrence, Kansas

1. INTRODUCTION

Modeling and simulation of communication systems can be viewed in a hierarchical manner starting at the network layer and progressing down to transmission systems level and then on to implementation details. The performance issues and tradeoffs addressed in each layer, and the modeling and simulation methods and the tools used at the various layers differ significantly. At the network layer, the simulation model will consist of processors, routers, traffic sources, buffers, transmission links, network topology, and protocols. The flow of packets and messages over the network will be simulated using an event-driven simulation framework, and system performance metrics such as network throughput, latency, resource utilization, and quality of service will be estimated from simulations. On the other hand, at the bottom level in the hierarchy dealing with implementation details, simulation of digital hardware, for example, will be done using hardware description language (HDL) simulators at the gate level. Performance metrics and design tradeoffs at this level may include power, speed, and chip area.

The focus of this article is on waveform level simulation of transmission systems or communication links, an example of which is shown in Fig. 1.

The primary simulation technique used at the link level is time-driven Monte Carlo simulation of the flow of waveforms or signals over the transmission link (Refs. 1–3 cover this topic in great detail). Waveform-level simulation of communication systems involves the following steps:

1. Modeling the communication system in a block diagram form in which each functional block performs a specific signal processing operation such as modulation, and filtering
2. Generating sampled values of the input signals, noise, and interference
3. Letting the functional blocks in the simulation model operate on the input samples
4. Gathering the samples generated during the simulation and estimating performance measures such as bit error rates as a function of E_b/N_0 and other design parameters

Details of these steps are presented in the following sections.

2. DISCRETE TIME REPRESENTATION OF SIGNALS AND SYSTEMS

In the simulation domain, all systems and signals are represented by their discrete-time equivalents. The simulation models and simulation algorithms draw heavily from DSP (digital signal processing) concepts [4,5]. The fundamental concept that permits us to go

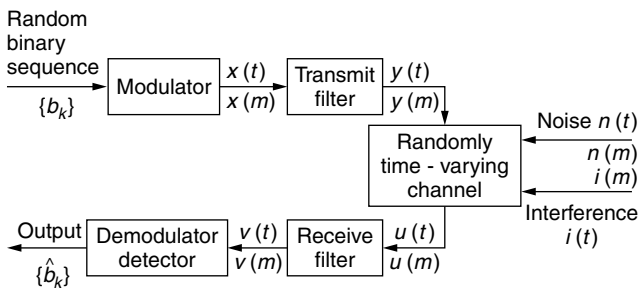

Figure 1. Waveform level simulation model of a communication system.

back and forth between discrete- and continuous-time representation of signals and systems is the sampling theorem. Implications of the sampling theorem as it applies to waveform-level simulation of communication systems are presented below.

2.1. Discrete-Time Representation of Lowpass Signals and Systems

The uniform sampling theorem in its simplest form states that a deterministic signal that is lowpass and band-limited to B Hz in the continuous-time domain can be represented exactly, *without loss of information*, in terms of its sampled values as long as the sampling rate f_s is greater than the *Nyquist rate* of $2B$ samples per second [4,5]. The relationship between the continuous time signal $x(t)$ and its sampled values $x(kT_s)$, where T_s is the time between samples, is given by the following equations:

$$x_s(t) = \sum_{k=-\infty}^{\infty} x(kT_s)\delta(t - kT_s) \tag{1}$$

$$X_s(f) = f_s \sum_{k=-\infty}^{\infty} X(f - kf_s) \tag{2}$$

$$x(t) = x_s(t)^* \frac{\sin(\pi f_s t)}{\pi f_s t} = \sum_{k=-\infty}^{\infty} x(kT_s) \frac{\sin(\pi f_s(t - kT_s))}{(\pi f_s(t - kT_s))} \tag{3}$$

Equation (3) represents an interpolation formula in the time domain that yields the values of $x(t)$ for *all* values of t in terms of the sampled values $x(kT_s)$. This interpolation operation in the time domain is equivalent to filtering of $x_s(t)$ in the frequency domain using an ideal lowpass filter with a bandwidth of $f_s/2$ Hz. If the signal is not strictly band-limited and/or the sampling rate is less than $2B$, then it will not be possible to reconstruct $x(t)$ exactly from $x_s(t)$ due to aliasing, which is a result of spectral overlap that occurs in the frequency domain [see Eq. (2)].

The lowpass sampling theorem applies to the discrete-time representation of both lowpass *signals* and lowpass *systems*. The impulse response $h(t)$ of a lowpass system in the continuous-time domain can also be represented in the discrete-time domain using the sampling theorem.

2.2. Sampling of Bandpass (Deterministic) Signals and Systems

Both lowpass and bandpass signals and components are usually present in communication systems. Information-bearing signals are usually lowpass in nature prior to modulation, after which they become bandpass in nature. Components such as filters can be lowpass or bandpass. Hence we need to represent both lowpass and bandpass signals and systems in the discrete time domain for simulation.

Bandpass signals and systems can be sampled directly using the bandpass version of the sampling theorem, or they can be sampled using the principle of the lowpass sampling theorem and the concept of the lowpass equivalent representation [1]. In the time domain, modulated signals can be expressed in the form

$$x(t) = x_c(t)\cos(2\pi f_c t) - x_s(t)\sin(2\pi f_c t) \tag{4}$$

$$= \text{Re } al\{\tilde{x}(t)\exp(j2\pi f_c t)\} \tag{5}$$

$$\tilde{x}(t) = x_c(t) + jx_s(t) \tag{6}$$

where $x_c(t)$ and $x_s(t)$ are the in-phase and quadrature phase modulating signals, which are usually lowpass; f_c is the carrier frequency; and $\tilde{x}(t)$ is the *complex envelope* of the bandpass signal. $\tilde{x}(t)$ will be lowpass since the modulating signals $x_c(t)$ and $x_s(t)$ are lowpass. Since the bandwidth of the modulating signals will be small compared to f_c, fewer samples will be needed to represent the lowpass complex envelope $\tilde{x}(t)$, which contains all the information in the modulated bandpass signal. Equation (5) clearly shows that the bandpass signal can be reconstructed from $\tilde{x}(t)$ by simply multiplying it with the complex carrier and taking the real part.

The lowpass equivalent representation of a deterministic bandpass signal can also be derived in the frequency domain using the Hilbert transform. When the bandwidth of the signal is small compared to the carrier frequency, the lowpass equivalent representation in the frequency domain is given by [1]

$$\begin{aligned} X_{\text{LP}}(f) &= \{2X_{\text{BP}}(f + f_c)\}_{\text{lowpass}} \\ &= 2X_{\text{BP}}(f + f_c)U(f + f_c) \end{aligned} \tag{7}$$

where $U(f)$ is the unit step function, $U(f) = 1$ for $f > 0$ and zero for $f < 0$.

Note that the lowpass equivalent can be asymmetric around $f = 0$ if the bandpass spectrum is not symmetric around the carrier frequency. This leads to a complex time-domain function as shown in Eq. (6). The minimum sampling rate for the lowpass equivalent representation is B *complex* samples per second or $2B$ real samples per second.

It should be noted that the complex envelope representation is with respect to a single-carrier frequency f_c. This representation can also be used for simulating multicarrier FDM (frequency-division multiplex) systems by using one of the mid-band carriers as the reference and representing the total composite complex envelope of the sum of the FDM carries with respect to the reference carrier according to

$$\sum_{i=1}^{n} A_i e^{j2\pi f_i t + j\phi_i} = e^{j2\pi f_c t} \sum_{i=1}^{n} A_i e^{j2\pi (f_i - f_c)t + j\phi_i} \tag{8}$$

where f_c is the carrier frequency chosen as the reference.

If multiple signals with widely differing bandwidths are present in a system, then a multirate sampling strategy will be useful for simulating such systems. Each signal is sampled at a rate consistent with its bandwidth, and interpolation and decimation techniques are used to upconvert or downconvert the sampling rates as necessary.

2.3. Sampling of Lowpass and Bandpass Random Processes

Signals, noise, and interference in communication systems are usually modeled as stationary random processes

characterized in the frequency domain by power spectral density functions. Frequency domain parameters such as bandwidth, and properties such as lowpass and bandpass are based on power spectral densities (PSDs). The sampling principle and the concept of lowpass equivalent representation also apply to random processes in terms of their PSDs [6].

A lowpass random process in the continuous-time domain can be represented in the discrete-time domain in terms of its sampled values, and it is possible to recover the continuous-time random signal (with a mean-squared error approaching zero) from its sampled values as long as the process being sampled is band-limited to B Hz and the sampling rate is greater than $2B$. The concept of lowpass equivalent representation applies for bandpass random processes also. For example, a bandpass Gaussian process $n(t)$ can be represented in terms of its lowpass equivalent as

$$\begin{aligned} n(t) &= n_c(t)\cos(2\pi f_c t) - n_s(t)\sin(2\pi f_c t) \\ &= \text{Real}\,\{\tilde{n}(t)\exp(j2\pi f_c t)\}, \tilde{n}(t) = n_c(t) + jn_s(t) \end{aligned} \tag{9}$$

where $n_c(t)$ and $n_s(t)$ are real-valued lowpass Gaussian random processes with the power spectral densities

$$\begin{aligned} S_{n_c n_c}(f) = S_{n_s n_s}(f) &= S_{NN}(f+f_c)U(f+f_c) \\ &\quad + S_{NN}(-f+f_c)U(-f+f_c) \\ jS_{n_s n_c}(f) &= S_{NN}(f+f_c)U(f+f_c) \\ &\quad - S_{NN}(-f+f_c)U(-f+f_c) \end{aligned} \tag{10}$$

If the bandpass process is nonsymmetric around the carrier frequency, then $n_c(t)$ and $n_s(t)$ will be correlated with the cross-PSD given above. For simulation purposes, bandpass random processes are sampled using their lowpass equivalent representations.

2.4. Simulation of Bandpass Systems with Bandpass Inputs

In order to minimize the computational burden, bandpass systems with bandpass inputs are simulated using sampled values of lowpass equivalent representations. It should be noted that while the lowpass equivalent representation of bandpass *signals* in the frequency domain contains a factor of 2 in Eq. (7), the lowpass equivalent representation of bandpass *systems* does not include the factor of 2.

The input–output relationship for the bandpass and lowpass equivalent representations are given by

$$\tilde{y}_{\text{LP}}(t) = \tilde{h}_{\text{LP}}(t)^* \tilde{x}_{\text{LP}}(t); \quad y_{\text{BP}}(t) = \text{Real}\,\{\tilde{y}_{\text{LP}}(t)e^{j2\pi f_c t}\} \tag{11}$$

2.5. Factors Influencing the Sampling Rate

The most important factor in determining an appropriate sampling rate for simulations is the amount of aliasing that can be tolerated. Other factors that have to be considered in setting the sampling rate for simulations include the effect of sampling on modeling functional blocks such as filters (frequency warping due to bilinear z transform), nonlinearities (bandwidth expansion), and feedback loops (delay in feedback loops). All the deleterious effects of sampling on simulation accuracy can be minimized by increasing the sampling rate. However, increasing the sampling rate will increase the computational burden.

This tradeoff between sampling rate and the accuracy of simulations is a very important one in simulations. A practical value for sampling rate that offers a good tradeoff between simulation accuracy and computational burden is 16–32 samples per hertz or symbol [1]. It is most convenient to use an integer number of samples per symbol for simulating digital transmission systems, and it is computationally most efficient to choose 16 or 32 samples per hertz so that the fastest version of the discrete Fourier transform (DFT) algorithm can be used during simulations.

3. MODELING AND SIMULATION OF FUNCTIONAL BLOCKS IN COMMUNICATION SYSTEMS

At the waveform level simulation of a communication system, each functional block in the simulation model performs a specific signal processing operation. If the signal processing operation performed by the functional block is discrete time, algorithmic, and at the symbol level (e.g., convolutional encoder/decoder), then there is very little modeling per se for such functional blocks: the simulation model of the functional block is the algorithm itself (e.g., a Viterbi decoder). On the other hand, there are a number of other functional blocks that perform (analog) waveform processing operations such as filtering and amplification. The signal processing operations performed by these blocks as well as the communication channel have to be *modeled* for simulation purposes. Examples of such *models*, which are described below, include infinite and finite impulse response filters and AM-to-AM and AM-to-PM models for memoryless nonlinearities.

3.1. Modeling and Simulation of Linear Time-Invariant (LTIV) Components

Many components in communication systems such as filters, optical fibers, cables, and other guided channels are linear and time-invariant. Such components are described in the time domain in terms of the impulse responses $h(t)$ or transfer functions $H(f)$. If these components are bandpass in nature, then for simulation purposes we will use the lowpass equivalent representations described in Section 2. The DSP literature contains a wide array of algorithms for implementing and virgule or simulating filters [4,5]. (We will use the generic term *filters* to represent LTIV components). The choice of simulation algorithm will depend on the nature of the filter specifications, the duration of the impulse response, and the context in which the filter is used in the overall simulation model.

3.1.1. Finite-Impulse Response (FIR) Model — Time-Domain Convolution. If the filter specification is given empirically in terms of the sampled values of the lowpass equivalent impulse response $\tilde{h}(kT_s)$, $k = 0, 1, 2, \ldots, M-1$, then the simplest simulation model is an FIR structure

that implements the input–output relationship as a finite convolution sum of the form

$$\tilde{y}(nT_s) = T_s \sum_{k=0}^{M-1} \tilde{h}(kT_s)\tilde{x}((n-k)T_s) \tag{12}$$

Simulation of this equation requires M complex multiplications and additions for each output sample. This may impose a considerable computational burden if the impulse response is very long. In order to reduce the processing load, impulses responses are truncated to the shortest possible duration without losing a significant amount of energy outside the truncation window and the truncated impulse response is used in Eq. (12). If the filter is specified in the frequency domain in terms of sampled values of the frequency response $H(kf_c)$, the inverse Fourier transform is used to compute the impulse response, which is then truncated and used in Equation (12) to perform time-domain convolutions.

3.1.2. FIR Model — DFT Implementation. The computational burden of time-domain convolution can be reduced by using DFT operators. In this implementation, the input samples and the impulse response are *padded* with enough zeroes and the padded input vector and the impulse response vectors are convolved using the DFTs operators according to

$$Y(kf_0) = \text{DFT}\ (\tilde{y}(kT_s)) = \text{DFT}\ (\tilde{h}(kT_s))\text{DFT}\ (\tilde{x}(kT_s)) \tag{13}$$

$$\tilde{y}(kT_s) = \text{Inv.DFT}\ (Y(kf_0)) \tag{14}$$

The minimum DFT size n is usually chosen to be a power of 2 nearest to the sum of the length of the unpadded impulse response and the input vectors. This will permit the use of fast FFT operators to perform the convolution [4,5].

DFT/FFT implementation will be computationally very efficient (several orders of magnitude faster) compared to direct-time-domain convolution when the length of the impulse response exceeds about 100 samples. One drawback of the DFT/FFT filters is that they introduce a processing delay of n samples (e.g., the output lags the input by n samples), which might cause a problem if the filter being simulated is part of a feedback loop, for example. The one block processing delay, which is strictly an artifact of the DFT/FFT filter, might render the feedback loop unstable and lead to totally incorrect simulation results. If all the blocks in the simulation model are serially cascaded, then this is not a problem.

If the input sequence is very long, then it can be broken up into smaller blocks and the response of the filter to each input block can be computed separately and the results can be added using the superposition principle. Either the input blocks or the output blocks have to be overlapped in order to produce the correct output [1,5,6].

3.1.3. Infinite Impulse Response (IIR) Models. If the filter specifications are given in the form of poles and zeroes or as a ratio of polynomial in the s domain, then the filter can be simulated using recursive computational structures that are very efficient. These recursive structures are derived using either *the impulse-invariant method or the bilinear z transform* [1,4,5]. In the first method the impulse response of the filter is obtained from the inverse transform of the transfer function and the z transform of the infinite-length impulse response (untruncated) is used to derive a recursive computational structure. In the second method, the transfer function in the Laplace transform domain is mapped into the z-transform domain directly using the bilinear z transform defined by

$$H_d(z) = H(s)@s = \frac{2}{T_s}\left[\frac{1-z^{-1}}{1+z^{-1}}\right] \tag{15}$$

The resulting transfer function in both cases can be factored into a product of quadratic factors:

$$H_d(z) = \alpha_0 \prod_{i=1}^{K} H_d^{(i)}(z); \qquad K = \frac{1}{2}(N+1);$$

$$H_d^{(i)}(z) = \frac{1+\alpha_{1i}z^{-1}+\alpha_{2i}z^{-2}}{1+\beta_{1i}z^{-1}+\beta_{2i}z^{-2}} \tag{16}$$

This leads to a simulation structure shown in Fig. 2.

The main source of error in the impulse-invariant IIR simulation model is aliasing, whereas the bilinear z transform suffers from frequency warping introduced by the transform. Both of these effects can be minimized by choosing a sufficiently high sampling rate. While the IIR structures are computationally faster compared to the FIR models, the IIR structures can be easily derived only for filters whose transfer functions are specified in analytical form by a transfer function in the Laplace or Fourier transform domains. The FIR filters can model and simulate filters with any arbitrary frequency or impulse responses specified empirically. Many important filters, such as the square-root raised-cosine filter, cannot be specified in the Laplace transform domain by poles and zeros and hence are not easy to simulate via the IIR methods.

3.2. Modeling and Simulation of Linear Time-Varying (LTV) Components

There are many components in a communication system that exhibit linear time-varying behavior. An important example of a LTV component is the mobile communication channel in which channel characteristics such as attenuation and delay change as a function of time due to relative motion between the transmit and receive antennas. The input–output relationship for LTV components can be expressed in the time domain by the convolution integral

$$\tilde{y}(t) = \int_{-\infty}^{\infty} \tilde{h}(\tau, t)\tilde{x}(t-\tau)d\tau \tag{17}$$

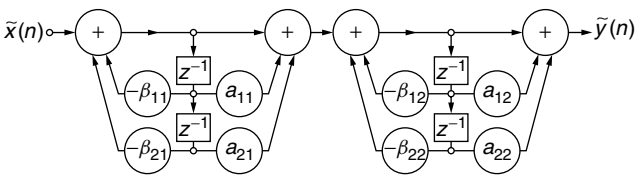

Figure 2. Recursive simulation structure for IIR models [1].

where $\tilde{h}(\tau, t)$ is the time-varying impulse response of the component measured at time t when the impulse is applied to the system input at $t - \tau$. If the input to the system is band-limited to W Hz, then we can derive an FIR model for the time-varying system via the sampling theorem as [7]

$$\begin{aligned}\tilde{y}(kT_s) &\approx \frac{1}{2W}\sum_{n=0}^{\infty}\tilde{h}\left(\frac{n}{2W}, kT_s\right)\tilde{x}\left(kT_s - \frac{n}{2W}\right)\\ &\approx \frac{1}{2W}\sum_{n=0}^{M}\tilde{h}\left(\frac{n}{2W}, kT_s\right)\tilde{x}\left(kT_s - \frac{n}{2W}\right)\\ &= \frac{1}{2W}\sum_{n=0}^{M}\tilde{g}_n(kT_s)\, x\left(kT_s - \frac{n}{2W}\right)\end{aligned} \tag{18}$$

where $\tilde{g}_n(kT_s)$ are called the *tap gain functions* that represent the time-varying impulse response of the system. For a time-*invariant* system, the tap gain functions will be constant and $\tilde{g}_n(kT_s) = \tilde{h}(nT_s)$. The FIR model given above can be implemented as a tapped delay line (TDL) model of the form shown in Fig. 3.

3.3. Modeling and Simulation of Nonlinear Components

Communication systems often contain nonlinear components. Sometimes a nonlinear component is placed in the system to improve performance. For example, a limiter is placed at the front end of a receiver that is subjected to impulsive noise. Also, devices such as high-power amplifiers exhibit an undesirable nonlinear behavior when the input power is high. This introduces nonlinear signal distortion, which might degrade the performance of the communication system significantly. The effects of nonlinearities on system performance are usually difficult to characterize by analytical means but are easy to simulate.

Nonlinearities in communication systems fall into two categories: (1) instantaneous nonlinearities such as limiters and (2) nonlinearities with memory, such as frequency-dependent wideband RF amplifiers. Nonlinearities are also sometimes classified according to whether the input/output signals are baseband or bandpass. Since bandpass nonlinearities are the most common type of nonlinear elements encountered in communication systems, we will concentrate on techniques for modeling and simulation of bandpass nonlinearities in this section.

3.3.1. Lowpass Equivalent Models for Memoryless Nonlinearities. Devices such as bandpass limiters and logarithmic amplifiers can be modeled using the complex envelope representation of the input and output signals. In the bandpass case the input–output relationship of a memoryless nonlinearity can be represented by

$$\begin{aligned}x(t) &= A(t)\cos(\omega_c t + \phi(t))\\ y(t) &= G[x(t)] = G[A\cos(\alpha)];\alpha = \omega_c t + \phi(t)\end{aligned} \tag{19}$$

where $G(\,)$ is a memoryless nonlinearity. If the bandwidth of the input signal is much smaller than f_c, then we can expand $y(t)$ as a Fourier series of the form

$$z = a_0 + \sum_{k=1}^{\infty}(a_k\cos k\alpha + b_k\sin k\alpha) \tag{20}$$

The output of the nonlinearity will contain spectral components in the vicinity of f_c as well as harmonic terms located in the vicinity of kf_c, $k > 1$. If $f_c \gg B$, then the harmonic terms will be far removed from the in-band terms and hence they can be ignored (these components can be easily removed by filtering in a real system). The in-band spectral components or the so-called *first-zone output components* correspond to $k = 1$ in the Fourier series expansion and the first-zone output of the nonlinearity can be expressed in the form

$$y(t) = a_1\cos[\omega_c t + \phi(t)] + b_1\sin[\omega_c t + \phi(t)] \tag{21}$$

where a_1 and b_1 are the Fourier series coefficients defined by

$$\begin{aligned}a_1 &= f_1(A) = \frac{1}{\pi}\int_0^{2\pi} G(A\cos\alpha)\cos\alpha\, d\alpha;\\ b_1 &= f_2(A) = \frac{1}{\pi}\int_0^{2\pi} G(A\cos\alpha)\sin\alpha\, d\alpha\end{aligned} \tag{22}$$

In terms $f_1(A)$ and $f_2(A)$ (which are called the first-order *Chebyshev transforms* of the nonlinearity), the complex lowpass equivalent simulation model for a memoryless nonlinearity is [1]

$$\tilde{y}(t) = f(A)\exp(j\phi + jg(A)) \tag{23}$$

$$f(A)e^{jg(A)} = f_1(A) - jf_2(A) \tag{24}$$

For nonlinearities such as soft and hard limiters, this model, in the form of $f(A)$ and $g(A)$ (which are also called the *AM-to-AM and AM-to-PM* transfer characteristics of

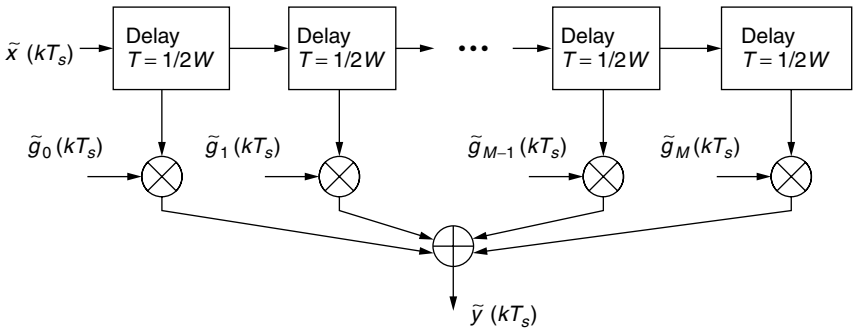

Figure 3. Tapped delay line model for a time-varying component.

the nonlinearity), can be derived in the closed form from the Fourier integrals given in Eq. (22) [1].

The AM–AM and AM–PM characteristics of devices such as high-power amplifiers are usually obtained from *swept-power measurements*, which are made with an input tone of the form $A\cos(\omega_c t + \phi(t))$. The input amplitude and hence the input power $A^2/2$ is varied in steps of 1 dB or so. The AM–AM characteristic is obtained from the input power–output power relationship and the AM–PM characteristic is obtained by measuring the phase offset between the input and output as a function of the input power level. Typical AM–AM and AM–PM characteristics are shown in Fig. 4. The AM–AM and AM–PM model can be simulated using either the empirical AM–AM and AM–PM data or the analytical approximation [8] such as the one shown in Fig. 4.

3.3.2. Lowpass Equivalent Models for Nonlinearities with Memory. When a nonlinear component operates over a wide bandwidth, it might exhibit a frequency selective nonlinear behavior. Models for nonlinearities with memory (or frequency-selective behavior) are difficult to derive analytically, but some useful models can be derived from swept-power/swept-frequency measurements. These measurements are made by probing the device with an unmodulated tone of the form $A\cos(2\pi(f_c t + f_i t))$ and changing both the input power levels and the frequency offset f_i and recording the AM–AM and AM–PM transfer characteristics at different frequencies. If these curves are significantly different at different frequencies, then a model of the form shown in Fig. 5 can be synthesized from the swept-frequency/swept-power measurements to account for the frequency selective behavior of the device. Details of the model synthesis may be found in papers by Saleh and Poza et al. [8,9]. Other simulation models for nonlinearities with memory in the form of Volterra series or nonlinear differential equations may be found in Ref. 1. (The best single source of reference for all the topics addressed in this article is Ref. 1.)

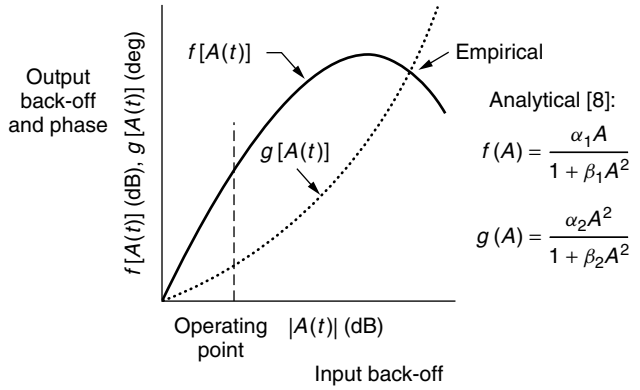

Figure 4. AM–AM and AM–PM characteristics.

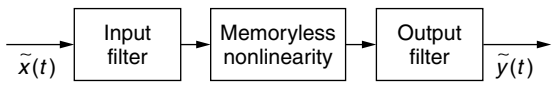

Figure 5. Simulation model for a frequency-selective nonlinearity.

3.4. Modeling and Simulation of Communication Channels

Communication channels introduce a variety of transmission impairments, including attenuation, linear distortion, noise, and interference. Simulation models for communication channels take one of two forms: (1) a transfer function model for time-invariant channels such as optical fibers and cables and (2) a TDL model for time-varying channels such as the mobile radio channel. The transfer function model of a time-invariant channel can be simulated using an FIR or IIR algorithm. Time-varying channels are more difficult to model and simulate. Some of the models and approaches that are used for simulating mobile radio communication channels and other time-varying channels are described below.

3.4.1. Simulation Models for Mobile Communication Channels. In a typical mobile communication environment there will be multiple propagation paths between the transmitter and the receiver due to reflection, refraction, and scattering [10,11]. Also, the path characteristics will be time-varying due to relative motion between the transmit and receive antennas (Fig. 6).

The input–output relationship for the two-ray multipath channel shown in Fig. 6 can be expressed as

$$\tilde{y}(t) = \tilde{a}_1(t)\tilde{x}(t - \tau_1(t)) + \tilde{a}_2(t)\tilde{x}(t - \tau_2(t)) \qquad (25)$$

where $\tau_1(t)$ and $\tau_2(t)$ are the path delays and $\tilde{a}_1(t)$ and $\tilde{a}_2(t)$ are the randomly time-varying complex attenuations of the two multipath components, which causes fluctuations in the received signal power. Changes in the received signal power as a function of time is called *fading*. The terms $\tilde{a}_1(t)$ and $\tilde{a}_2(t)$ are usually modeled as *uncorrelated and stationary* random processes.

Movement of the mobile unit over larger distances ($d \gg \lambda$, where λ is the wavelength), and changes in terrain features affect attenuation and received signal power slowly, and this phenomenon is called *large-scale (or slow) fading*. The received signal in each path in Fig. 6 is made up of a large number of scattered components, and hence the central-limit theorem leads to complex Gaussian process models for the complex attenuation and the complex envelope of the received signal for each path.

Movement over small distances on the order of $\lambda/2$ causes significant phase changes of the scattered components, resulting in rapid fluctuations in signal amplitude and power. This phenomenon is called *small-scale (fast) fading*. Large-scale fading impacts the link

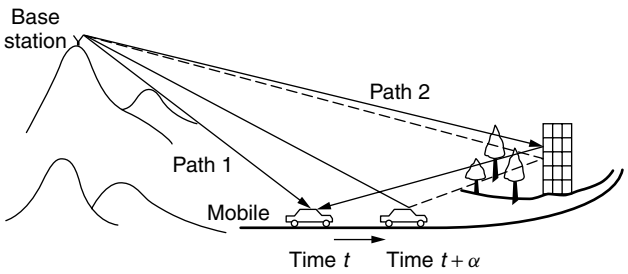

Figure 6. Mobile communication environment.

$S/N + I$ and coverage within a given area. Small-scale fading, on the other hand, impacts all the signal processing operations in the transmitter and receiver, and the effects of small-scale fading are simulated at the waveform level. The basic simulation model for small-scale fading is a TDL model of the form given in Fig. 3.

The tap gains are random processes representing the random variations in the channel characteristics such as the complex attenuation of each multipath component. These are usually modeled as complex Gaussian processes with zero mean and Rayleigh envelope distribution for dense urban environments, and nonzero mean and Rice envelope statistics for rural and suburban environments. The simulation model is specified in terms of the number of multipath components, relative delays, average power received in each path, and the power spectral density of the random process models that describe the random variations of the path characteristics (i.e., the tap gain functions). An example of the multipath model that is used for simulating the mobile radio environments for the design of the third-generation cellular systems is given in Table 1 [12].

In the simulation model, the tap gain functions are generated by filtering uncorrelated Gaussian random processes. The filter transfer function is carefully synthesized to produce the desired Doppler power spectral density. Details of the algorithms used for generating Gaussian sequences with a given power spectral density are discussed in Section 4.

3.4.2. Discrete-Channel Model. Whereas the TDL model is used to simulate the waveform-level distortions introduced by a multipath fading communication channel, a discrete Markov model is often used to characterize the burst errors introduced by fading channels [13–15]. These discrete channels models are computationally more efficient than the waveform-level simulation models for evaluating the performance of error control encoders/decoders, interleaves, and other devices. An example of a simple two-state Markov model for a fading channel is shown in Fig. 7.

Table 1. Example of a TDL Model for an Outdoor Mobile Radio Channel at 2 GHz

Tap Delay (ns)	Average Power (db)
0	0.0
244	−2.4
488	−6.5
732	−9.4
936	−12.7
1220	−13.3
1708	−15.4
1953	−25.4

In the Makov model, the channel is in one of the two states at the beginning of a symbol interval. If the channel is in good state, the transmitted symbol is error-free whereas the probability of transmission error is 0.5 when the channel is in the bad state. While the channel remains in the bad state, it produces bursts of transmission errors. The channel can transition from state i to state j at the end of a symbol interval with a probability of $p_{ij}, i, j = 1, 2$. The rate or the probability of transition between the good and bad states and the error generation probabilities can be derived analytically from the underlying fading channel model or estimated from error sequences obtained using waveform level simulations.

Markov models are also applicable to hard input and soft output channels. Details of the Baum–Welch algorithm used for estimating the structure and parameters of the Markov models and examples of discrete channel models may be found in the literature [16–18].

Simulation of the Markov model is carried out at the symbol rate. For simulating the flow of a symbol through the discrete-channel model, two uniform random numbers are drawn, one to determine the state of the channel (i.e., the transition) and a second random number to decide whether the transmitted symbol suffers a transmission error. Thus, the simulation of the discrete model is very efficient compared to having to generate sampled values of the transmitted waveform and process them through all the functional blocks in the waveform-level simulation model.

4. MONTE CARLO SIMULATION AND RANDOM-NUMBER GENERATION

With respect to the simulation model shown in Fig. 1, the inputs or stimuli that drive the simulation model are sampled values of the input signals, noise, and interference, which are modeled as random processes. Sampled values of random processes are random variables, and hence

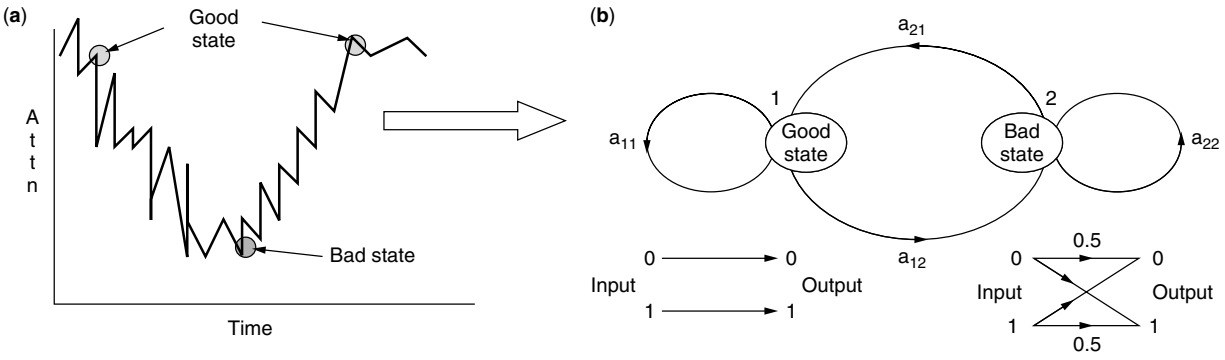

Figure 7. (**a**) Fading channel; (**b**) Markov model for a fading channel.

the input sequences that drive the simulation models are sequences of random numbers from arbitrary distributions and with arbitrary power spectral densities or autocorrelation functions. Hence Monte Carlo simulation involves the generation and processing of random numbers.

4.1. Uniform Random-Number Generator

A typical Monte Carlo simulation might entail the generation and processing of many thousand samples of random variables, and hence we need computationally efficient algorithms for generating random numbers. The starting point of random-number generation is the uniform random-number generator. An independent sequence of uniform random integers in the interval $[0, M-1]$ can be generated using the *linear congruential algorithm* [19–21]

$$X_{j+1} = (aX_j + c) \bmod M \quad \text{(integer arithmetic)} \tag{26}$$

This recursive algorithm is started using an initial random *seed* that is provided by the user and it produces a set of integers uniformly distributed in the interval $[0, M-1]$. A sequence of uniform random numbers in the interval [0,1) can be obtained according to $U_i = float(X_i/M)$.

The output sequence produced by the recursive algorithm given in Eq. (26) will be periodic with a maximum period of M. The values of a, c and M are carefully chosen such that the sequence is independent, is uniformly distributed, and has the maximum period. Two popular algorithms that produce uniform sequences with long periods are the Marsaglia–Zamann algorithm and the Wichmann–Hill algorithm [1].

Since the uniform random-number generators play such a central role in Monte Carlo simulation and random-number generation, they should be thoroughly tested for temporal and distributional properties. Statistical tests for these can be found in the literature [1,6].

4.2. Random-Number Generators for Arbitrary Distributions

An independent sequence of random numbers from arbitrary probability distributions can be generated by applying appropriate memoryless nonlinear transformations to an independent uniform sequence U_i [1]. It can be shown that U_i can be mapped to a sequence of random numbers X_i from an arbitrary distribution $F_X(x)$ according to

$$X_i = F_X^{-1}(U_i) \tag{27}$$

where F_X^{-1} is the inverse cumulative distribution function (CDF) of X. This method is called the *inverse transform method* of generating random numbers, and it can be easily applied to distributions that are analytically tractable. For example, if we want to produce a sequence of random numbers from an exponential probability density function (PDF), the inverse transform method yields the formula $X_i = (-1/\lambda)\ln(1-U_i)$.

If the CDF and/or the inverse of the CDF of X cannot be expressed in closed form, then the inverse transform method can be implemented in empirical form by quantizing the underlying PDF and creating a piecewise linear CDF and applying the inverse transform method empirically. The details of this approach are shown in Fig. 8.

4.3. Gaussian Random-Number Generators

Gaussian random processes are used to model signals, noise, and interference as well as fading in communication channels, and hence it is important to have computationally efficient algorithms for generating Gaussian random numbers. Two algorithms for generating Gaussian random numbers are [20,21]

1. The sum of a large number of uniform random numbers (usually 12), which leads to an approximately Gaussian distribution by virtue of the central-limit theorem
2. The Box–Mueller method, which uses the following algorithm

$$\begin{aligned} X_1 &= [-2\ln(U_1)]^{1/2}\cos 2\pi U_2 \\ X_2 &= [-2\ln(U_1)]^{1/2}\sin 2\pi U_2 \end{aligned} \tag{28}$$

where X_1, X_2 are two independent Gaussian samples derived from two independent uniform random numbers U_1, U_2.

The Box–Mueller method produces a better distribution than does the sum-of-12 method.

4.4. Correlated Gaussian Sequences

Correlated Gaussian sequences with a given power spectral density (PSD) or autocorrelation function can be generated by filtering an uncorrelated Gaussian sequence. The filter transfer function can be synthesized using a number of different approaches. For FIR implementation of the filter, the transfer function of the filter can be chosen according to

$$H(f) = \sqrt{(S_{YY}(f))} \tag{29}$$

where $S_{YY}(f)$ is the desired power spectral density. This method can be used for generating temporally correlated

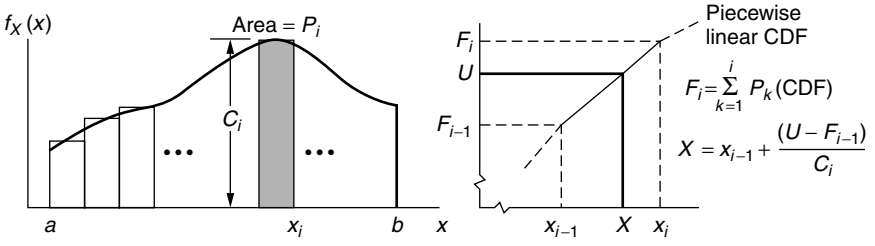

Figure 8. Empirical version of the inverse transform method.

Gaussian processes employed in modeling multipath fading communication channels. An IIR filter transfer function can be synthesized using auotregressive moving-average (ARMA) model. Details of this procedure may be found in the literature [1,6,22].

4.5. Binary and Nonbinary Sequences

The input symbol sequences used in the simulation of digital transmission systems can be generated by mapping the output of a uniform random-number generator into binary and M-ary sequences. Discrete-symbol sequences can also be generated using a linear feedback shift register arrangement in which the feedback tap weights are chosen to be the coefficients of primitive polynomials in Galois field (GF) (2^k), $2^k = M$. An example of this for the binary case is shown in Fig. 9.

These shift register sequences, which are also called *pseudonoise* (PN) *sequences*, have many desirable properties that are useful in the context of simulations. Two of the most important properties of the shift register sequences are that they have the maximum period ($2^m - 1$ in the binary case), and they produce all possible m symbol combinations within one period where m is the number of stages in the shift register structure. This property is very useful for simulating intersymbol interference (ISI) and other forms of linear distortion in digital transmission systems. Although it is possible to do this with random sequences derived from a uniform random-number sequence, the sequence length required to produce all possible m symbol combinations will be much longer than the PN sequences.

Details on PN sequence generation and a list of primitive polynomials can be found in Ref. 1.

5. PERFORMANCE ESTIMATION VIA MONTE CARLO SIMULATION

The primary use of simulation is performance evaluation and tradeoff studies. A number of performance metrics such as power spectral densities, S/N at the output of a receiver and bit error rates (BER) in digital systems can be estimated using Monte Carlo simulations. Just as in measurements, the estimated quantities are subjected to variations that are inherent in estimation of parameters from random observations (or simulation results). The metrics used to judge the quality of the estimators are the bias and variance. While it is easy to construct estimators that are unbiased, the variance of the estimator is not very easy to control since it depends on the type of estimator used as well as the number of observations used to obtain an estimated value. In general, the variance will be inversely proportional to the sample size, and this often leads to long simulation runs, especially in the case of low BER estimation. Since BER estimation is very important in the simulation of digital transmission systems, we present some of the approaches for estimating BERs in the following sections.

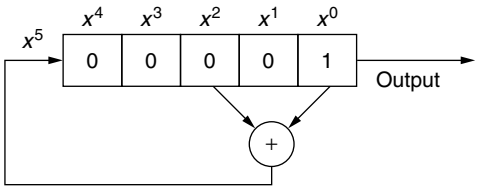

Figure 9. Feedback shift register for generating binary PN sequences; $m = 5$; $g(x) = 1 + x + x^5$.

5.1. MC Techniques for Estimating of BERs in Digital Communication Systems

The Monte Carlo technique is the most general method of estimating BERs and can be applied to any type of communication system with arbitrary distributions for noise and interference. The technique is simple to apply; perform a waveform-level simulation with a long input sequence of length N symbols, count the number of errors between the input symbol stream and the simulated output, and then form a counting estimate for the BER as the ratio of the number of errors counted and the number of symbols simulated (see Fig. 1). If the symbol errors in the system are occurring independently, then the normalized estimation error is given by [1]

$$\text{Normalized error} = \frac{\text{standard deviation of the estimator}}{\text{BER being estimated}} \approx \frac{1}{\sqrt{NP_e}} \tag{30}$$

For estimating a BER on the order of 10^{-6} with a normalized error of, say, 20%, the ordinary MC method requires a sample size on the order of $25(10^6)$ bits to be simulated. Hence the ordinary MC technique is not suitable for estimating very low BERs. A number of alternate methods have been developed in order to reduce sample size requirements for low-BER estimation. An overview of these methods and details may be found in the literature [1,23–25]. Two of these methods are described briefly here.

5.2. Semianalytical (SA) MC Techniques for Low-BER Estimation

This method is applicable to systems in which the effects of noise and interference can be assumed to be additive and Gaussian (of some other known distribution) at the output of the system [1]. In this case the BER in the system can be estimated by running a noiseless simulation to characterize the waveform distortion introduced by all the functional blocks in the system and analytically computing the probability of error due to noise superimposed on the distorted output. A simple example for the binary case with additive noise at the output is shown in Fig. 10. The basic form of the estimator becomes

$$\tilde{P}_e = \frac{1}{N}\sum_{k=1}^{N} P_k; \quad P_k = Q\left(\frac{d_k}{\sigma}\right) \tag{31}$$

where $Q(d_k/\sigma)$ is the analytically computed probability of error for the kth simulated value of the distorted output sample d_k at decision time, N is the number of symbols simulated, and σ is the standard deviation of

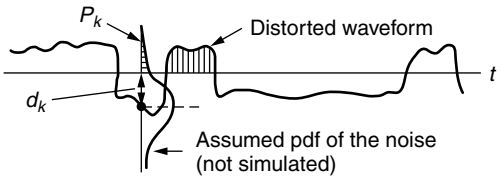

Figure 10. Semianalytical BER (bit error rate) estimator for a binary communication system.

the noise at the output of the system, which is assumed to be Gaussian in this example. With this approach, the simulation length is determined by the number of symbols N needed to simulate the distribution of the waveform distortion accurately. Typically this length will be much smaller than what would be necessary to simulate the effects of noise explicitly, particularly at low BERs. If the primary source of distortion in the system is linear (ISI) and lasts over m symbols, then a PN sequence of length 2^m is all that will be needed in a binary system to simulate all possible distortion values exactly. The variance of the estimator is zero in this case. The SA Monte Carlo methods lead to significant reduction in sample size for low-BER estimation. Indeed, with these methods the sample size requirements are independent of the BER being estimated. The SA methods are applicable to M-PSK and QAM (multiphase shift keying and quadrature amplitude modulation) schemes also [1].

5.3. An Important Sampling Method

This method, which is shown in Fig. 11, is based on biasing the input PDFs such that the important regions of the input PDFs are enhanced to produce a larger number of symbol errors during simulation. The higher error rates can be estimated with smaller sample sizes, and the bias in the estimator, which results from biasing the input PFDs, can be corrected easily at the output of the system where errors are counted. The important sampling method when applied properly has the potential to reduce sample size requirements significantly. Details of the important sampling method can be found in the literature [1,24,26].

6. SUMMARY

Simulation is a very useful tool for the design and analysis of communication systems. In this article we presented the basic principles behind waveform-level simulation of communication systems. The first step is developing a simulation model of the system under study in a block diagram form containing parameterized representations of all the functional blocks in the system that might have a bearing on the design and analysis issues being addressed. The second step is the selection of models for the signal processing operations performed by the functional blocks and representing them appropriately using the lowpass equivalent representation and the sampling theorem. After a simulation model is completely specified in terms of the topology, functional blocks, parameters, and input signals, the next step is to execute the simulations by generating sampled values of all the input signals using appropriate random-number generators and letting the functional blocks in the simulation model operate on the input sequences and produce output sequences. The final step is the estimation of performance metrics of interest such as BERs. This estimation can be done online while the simulation is being executed or at the end of the simulation as an offline postprocessing operation.

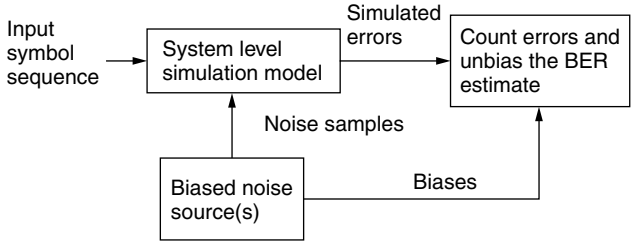

Figure 11. Important sampling method.

The overall simulation accuracy will depend on the modeling assumptions and approximations, accurate representation of signals, and accuracy of the algorithms used for random-number generation, estimation techniques used, and the length of the simulations. All of these issues were addressed in this article.

Simulation of communications is an interdisciplinary activity that requires skills in a broad range of areas, including communication systems, random signal theory, statistics, digital signal processing, and software engineering. A sound understanding of the fundamental principles in these areas as they apply to simulations is essential in order to produce valid and accurate answers to important design and analysis problems that face the communication engineers of today.

BIOGRAPHY

K. Sam Shanmugan received a Ph.D. degree from Oklahoma State University, Stillwater, Oklahoma, in electrical engineering in 1970. He is currently the SW Bell Distinguished Professor of Telecommunication in the Electrical Engineering and Computer Science Departments at the University of Kansas. He has also worked for AT&T Bell Laboratories, TRW, Hughes and Cadence Design Systems. Dr. Shanmugan is the author of over 100 publications in the above areas and is the author/coauthor of three books, *Digital and Analog Communication Systems* (Wiley, 1979), *Random Signals: Detection Estimation and Data Analysis* (Wiley, 1988), and *Simulation of Communication Systems* (Plenum Press, 1992). Dr. Shanmugan is a fellow of the IEEE and is the recipient of many teaching and research awards at the University of Kansas.

SOFT OUTPUT DECODING ALGORITHMS

LANCE C. PÉREZ
University of Nebraska
Lincoln, Nebraska

1. INTRODUCTION

The success of turbo codes and iterative decoding in the field of channel coding for the additive white Gaussian noise (AWGN) and other channels has led to the investigation of iterative techniques in a wide range of disciplines. Indeed, iterative processing is being considered for virtually every component in single and multiuser digital communication systems. Iterative processing typically involves iterative information exchange between system components, such as an equalizer and a channel decoder or an interference canceler and channel decoder, that traditionally operated independently.

The essential element of all iterative processing techniques is some form of a soft-input, soft-output (SISO) module. In this article, a detailed description is given of the most common SISO modules, namely, the soft-output Viterbi algorithm (SOVA) [1] and several versions of the Bahl, Cocke, Jelinek, and Raviv (BCJR) [2] or maximum a posteriori (MAP) algorithm. To make the descriptions concrete, these algorithms are described in the context of their application to the decoding of binary convolutional codes. The extension to other applications is generally straightforward and may be found in the appropriate literature.

The outline of this article is as follows. Section 2 provides a basic system description and introduces the basic concepts and notations of convolutional codes and their trellis representations necessary for the subsequent development of the SISO algorithms. A detailed description of the SOVA is given in Section 3. In Section 4, the MAP algorithm and its max-log variant are described. Section 5 contains some comparisons between these algorithms in the application of iterative decoding of turbo codes. Finally, some concluding remarks and pointers to areas for further reading are given in Section 6.

2. SYSTEM MODEL

For the purposes of this article, a digital communication system with forward error correction (FEC) channel coding can be represented by the block diagram shown in Fig. 1. A detailed derivation of this model and the required assumptions may be found in Ref. [3]. The source is a binary memoryless source that produces a sequence

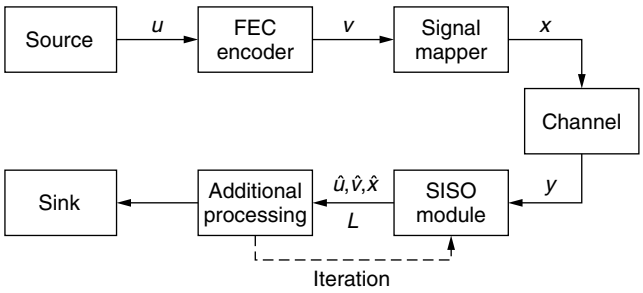

Figure 1. Block diagram of a digital communication system with forward error correction.

$\boldsymbol{u} = [u_0, \ldots, u_r, \ldots, u_{N-1}]$ of independent identically distributed 0's and 1's with equal a priori probabilities of $p_0 = p_1 = 1/2$. The FEC encoder maps the information sequence $\boldsymbol{u}$ to the code sequence $\boldsymbol{v} = [v_0, \ldots, v_r, \ldots, v_{N-1}]$ according to some encoding rule. The signal mapper maps each $n-$tuple v_r to one of 2^n symbols in the signal set. For convenience, the signal mapper is frequently chosen to be a binary phase shift keying (BPSK) or an antipodal modulator that maps each 0 and 1 of the code sequence $\boldsymbol{v}$ to a -1 or $+1$, respectively. The output sequence of the signal mapper, $\boldsymbol{x} = [x_0, \ldots, x_r, \ldots, x_{N-1}]$ is then transmitted across the memoryless AWGN channel, which adds to each transmitted symbol an independent Gaussian random variable with probability density function

$$p_N(n) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{n^2}{2\sigma^2}}$$

where $\sigma^2 = \dfrac{N_o}{2}$.

The FEC encoder explicitly considered here is a convolutional encoder of rate $R_c = k/n$ with total encoder memory ν. During each encoding epoch r, the convolutional encoder maps the current $k-$tuple of information bits $u_r = [u_r^{(1)}, \ldots, u_r^{(k)}]$ to an output $n-$tuple of coded bits $v_r = [v_r^{(1)}, \ldots, v_r^{(n)}]$ based on the current input and the current encoder state s_r. The $n-$tuple of coded bits v_r and its corresponding signal mapper output x_r are referred to as a symbol. Although not required, the subsequent decoder descriptions will assume finite length information sequences and thus $r = 0, \ldots, N-1$. The decoding algorithms considered in this article all require the notion of the trellis representation of a convolutional code, which is simply the time expansion of the state transition diagram. In this case, the trellis has a total of 2^ν distinct states $s_r = j$, $j = 0, \ldots, 2^\nu - 1$, at epoch r with 2^k state transitions, or branches, leaving and entering each state.

For example, Fig. 2 depicts a rate $R_c = 1/2$ convolutional encoder with total encoder memory $\nu = 2$ realized in nonsystematic feedforward form [4]. The code is specified by its two generator polynomials, $g_0 = 1 + D + D^2 = 111$ and $g_1 = 1 + D^2 = 101$, which are frequently represented in right justified octal format as $g_0 = 7$ and $g_1 = 5$. The equivalent recursive systematic encoder realization [5] is shown in Fig. 3. Assuming that the encoder is initialized to the all zero state, the trellis diagram with $N = 7$ sections for this encoder is shown in Fig. 4. Each full section of

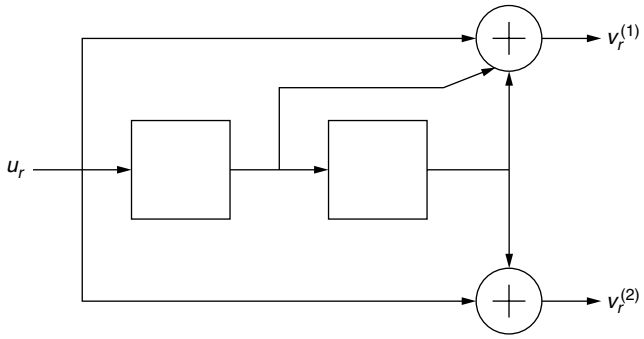

Figure 2. A rate $R_c = 1/2$ convolutional encoder with $\nu = 2$ realized in nonsystematic feedforward form with generator polynomials $g_0 = 1 + D + D^2$ and $g_1 = 1 + D^2$.

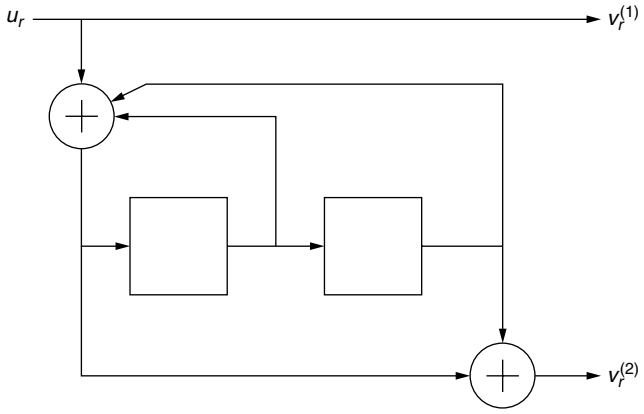

Figure 3. A rate $R_c = 1/2$ convolutional encoder with $\nu = 2$ realized in recursive systematic form with generator polynomials $g_0 = 1 + D + D^2$ and $g_1 = 1 + D^2$.

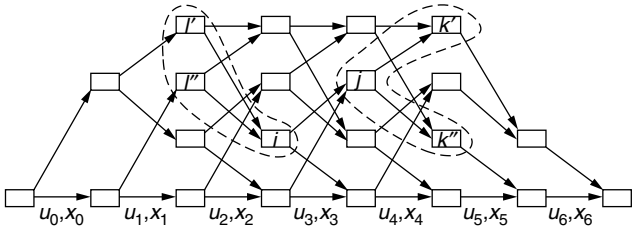

Figure 4. Trellis diagram corresponding to the encoders of Figs. 2 and 3 with information sequences of length 5 and two tail bits.

the trellis has $2^2 = 4$ states and there are $2^1 = 2$ branches leaving and entering each state. In this example, the trellis ends in the all zero state as well. This is referred to as *terminating* the trellis and is accomplished for rate one-half feedforward encoder realizations by appending a *tail* of ν zeroes to the end of the information sequence. Thus, this trellis represents information sequences of length 5 with a tail of 2 zeroes. For recursive systematic and systematic feedback encoder realizations, trellis termination is accomplished by a nonzero, state-dependent tail of ν bits [5]. Although not strictly required by the decoding algorithms described in this article, the subsequent development assumes that the code trellis is terminated.

The decoder operates on the noisy received sequence y. In traditional decoding algorithms for convolutional codes, such as the Viterbi algorithm [6] or sequential decoding, the primary goal of the decoder is to produce an estimate of the transmitted symbol sequence $\hat{\mathbf{x}}$, or equivalently an estimate of the information sequence $\hat{\mathbf{u}}$, consistent with minimizing, or nearly minimizing, an appropriate cost function, such as the probability of an information bit error P_b or the probability of a frame or sequence error P_f. The purpose of the SISO algorithms is to produce an estimate of the transmitted symbol sequence or information sequence along with a sequence $L = [L_0, \ldots, L_r, \ldots, L_{N-1}]$ of soft reliability information indicating the confidence of each component of the sequence estimate. In the context of this article, the reliability information is based on the calculation, or approximation, of the a posteriori probabilities of either the information bits $\Pr[u_r \mid \boldsymbol{y}]$, or the a posteriori probabilities of the transmitted symbols $\Pr[x_r \mid \boldsymbol{y}]$.

In traditional decoding, maximizing the a posteriori probabilities of the information bits, although optimum in terms of P_b, leads to only minor improvements compared to the Viterbi algorithm, which minimizes the sequence error rate $\Pr[\hat{\mathbf{v}} \neq \mathbf{v}] \mid \boldsymbol{y}]$. Thus, even though the MAP algorithm was originally formulated for convolutional codes by Bahl, Cocke, Jelinek, and Raviv [2] in 1972, it was not widely used because it provided no significant improvement over maximum-likelihood decoding and is significantly more complex. Interest in decoding algorithms with soft outputs was rekindled by the work of Hagenauer and Hoeher [1] on the soft output Viterbi algorithm (SOVA) in 1989 and pushed to its current ubiquity with the discovery of turbo codes and iterative decoding in 1993 [7]. For this reason, the discussion of the SISO algorithms begins with the SOVA and then progresses through the MAP algorithm and its variants.

The SISO algorithms described in this chapter all attempt to provide soft reliability information about each bit, either $u_r^{(i)}$ or $v_r^{(i)}$, or each symbol x_r. The basic approach to this is to partition the set of code sequences into two sets Ω_r, which contains sequences where the r^{th} bit or symbol takes on the desired value, and Ω_r^c, which contains sequences where the r^{th} bit or symbol differs from the desired value. The metrics associated with paths in each set may then be used to generate a reliability value for the current bit or symbol. The algorithms described here differ in two fundamental ways: (1) the number of paths used in each set Ω_r and Ω_r^c, and (2) the method for finding these paths.

3. SOFT OUTPUT VITERBI ALGORITHM (SOVA)

As its name suggests, the SOVA is a version of the classical hard output Viterbi algorithm modified to provide soft output reliability information. The Viterbi algorithm minimizes the probability of a sequence error by decoding that sequence $\boldsymbol{v}$ with the largest likelihood $\Pr[\boldsymbol{x} \mid \boldsymbol{y}]$ given the received sequence $\boldsymbol{y}$. For equally likely inputs, this is equivalent to maximizing $\Pr[\boldsymbol{y} \mid \boldsymbol{x}]$. (Thus, the Viterbi algorithm is a *sequence* MAP decoder.) The basic idea of the SOVA is to derive bit or symbol level reliability information from the sequence a posteriori probabilities. The SOVA described here is the algorithm discovered by Hagenauer and Hoeher [1] as modified by Fossorier et al. [8].

To see how this is done, we begin with a brief description of the Viterbi algorithm. For the AWGN channel with BPSK modulation, it is straightforward to show that

$$\Pr[\boldsymbol{y} \mid \boldsymbol{x}] = \prod_{r=0}^{N-1} \prod_{i=1}^{n} \frac{1}{\sqrt{\pi N_o}} \exp\left\{-\frac{(y_r^{(i)} - x_r^{(i)})^2}{N_o}\right\} \sim \prod_{r=0}^{N-1} \prod_{i=1}^{n} \exp\left\{-\frac{(y_r^{(i)} - x_r^{(i)})^2}{N_o}\right\}$$

Using logarithms, this becomes

$$\log \Pr[\boldsymbol{y} \mid \boldsymbol{x}] \sim -\sum_{r=0}^{N-1} \sum_{i=1}^{n} (y_r^{(i)} - x_r^{(i)})^2 \tag{1}$$

and maximizing $\Pr[\boldsymbol{y} \mid \boldsymbol{x}]$ is equivalent to finding the symbol sequence $\boldsymbol{x}$ that is closest to the received sequence in terms of squared Euclidean distance. The Viterbi algorithm is an efficient technique based on the code trellis for finding the closest sequence.

To formulate the Viterbi algorithm, notice that the inner summation in Eq. (1) corresponds to the squared Euclidean distance between the r^{th} symbol in the transmitted sequence $\boldsymbol{x}$ and the r^{th} received symbol in $\boldsymbol{y}$. Since each code sequence is represented by a path through the code trellis, the r^{th} transmitted symbol corresponds to a state transition or branch from a state $s_r = i$ to state $s_{r+1} = j$ and the inner summation in Eq. (1) is referred to as a branch metric. Formally, the branch metric associated with transmitted symbol x_r is defined to be

$$\beta_r(x_r = x) = \sum_{i=1}^{n} (y_r^{(i)} - x^{(i)})^2 \tag{2}$$

Finally, define the *partial path metric* for path l at epoch R and state j as

$$M_{R,l}(j) = \sum_{r=0}^{R-1} \beta_r(x_{r,l} = x) \tag{3}$$

where $j = 0, \ldots, 2^v - 1$ and $x_{r,l}$ is the r^{th} symbol on the l^{th} path.

With these definitions the Viterbi algorithm may now be stated as

Step 1: Initialize $M_0(0) = 0$ and $M_0(i) = \infty$ for $i \neq 0$. Set $R = 0$.

Step 2: Increment $R = R + 1$. For each state $s_R = j$, compute the branch metrics for the 2^k branches entering that state and compute the 2^k partial path metrics

$$M_{R,l}(j) = M_{R-1}(i) + \beta_{R-1}(x_{R-1,l} = x), \tag{4}$$

where $s_{R-1} = i$ is a state at epoch $R-1$ with a branch leading to state $s_R = j$ with branch label $x_{R-1,l}$.

Step 3: For each state $s_R = j$, compare the 2^k partial path metrics $M_{R,l}(j)$ and choose the minimum, that is,

$$M_R(j) = \min_l M_{R,l}(j).$$

Store the corresponding partial sequence $\tilde{\boldsymbol{u}}^j = [\hat{u}_0, \ldots, \hat{u}_{R-1}]$. This partial sequence is known as the survivor for state j at epoch R.

Step 4: If $R < N$, then return to Step 2. If $R = N$, then the survivor to state $s_N = 0$ with path metric $M_N(0)$ is the decoded sequence.

Note that this statement assumes that the encoder started in the all zero state and that the trellis is terminated and ends in the all zero state. Steps 2 and 3 are commonly referred to as the add-compare-select (ACS) operation of the Viterbi algorithm.

The output of the Viterbi algorithm is simply a decoded sequence with no explicit reliability information. The goal of a SISO algorithm is to provide some reliability information, usually in the form of an a posteriori probability, in addition to the decoded sequence. The basic observation behind the SOVA is that the real valued path metric, $M_N(0)$, of the decoded maximum likelihood sequence, $\hat{\mathbf{u}}$ or $\hat{\mathbf{x}}$, provides some reliability information about each decoded information bit $\hat{u}_r$. Assume for the moment that $\hat{u}_r = 1$. If the Viterbi algorithm could be modified to provide the path metric $M_N^c(0)$ of a path with $\hat{u}_r = 0$, then the path metric difference

$$\Delta = |M_N(0) - M_N^c(0)| \tag{5}$$

could be used as a reliability value for the r^{th} bit.

To provide the best reliability measure, the metric $M_N^c(0)$ should correspond to the *best* path with $\hat{u}_r = 0$. That is, $M_N^c(0)$ should correspond to the most likely path in the complementary set of sequences Ω_r^c. The question remains as to how this path can easily be found for each $\hat{u}_r$ of the decoded sequence. One solution is a modified Viterbi algorithm, called the SOVA, that computes reliability information for each bit via a traceback operation during the normal forward recursion of the Viterbi algorithm. These reliability values are stored for every bit in the partial sequence $\tilde{\mathbf{u}}^j$ for every state and the SOVA requires additional memory compared to the standard Viterbi algorithm.

For clarity of exposition and notation, the SOVA will be described for rate $R_c = 1/n$ codes realized in recursive systematic form. The latter assumption incurs no loss of generality, but simplifies the notation by ensuring that the information bit on the last branch of the two competing paths entering each state is different. That is, path 0 entering state $s_R = j$ has $\hat{u}_{R-1,0} = 0$ and path 1 entering $s_R = j$ has $\hat{u}_{R-1,1} = 1$. Consequently, each ACS operation at epoch R immediately generates a reliability value $L_{R-1}^j = \Delta = |M_{R,0} - M_{R,1}|$ for the current bit $\hat{u}_{R-1}$ at the current state $s_R = j$. Since this is the first time that the bit u_{R-1} is decoded, this is the best possible reliability value available at the moment. The situation for the remaining bits in the partial path is more complicated.

As the SOVA progresses through the trellis, it must update these reliability values such that when $R = N$ the reliability values for each bit $\hat{u}_r$ in the decoded sequence is generated from the best path with the complementary bit value in the r^{th} position. This is accomplished through careful updating of the reliability values L_r^j for $r = 0, \ldots, R-2$ following the ACS operation. To understand how this is done, two distinct cases must be considered for each ACS operation. A graphical representation of the ACS operation at state $s_R = 0$ is shown in Fig. 5. Without loss of generality, assume that path 0 is chosen as the survivor.

The first case occurs when the r^{th} bit, for some $0 \le r < R-1$, on path 0, denoted by $\hat{u}_{r,0}$, differs from the corresponding bit $\hat{u}_{r,1}$ on path 1. There are three reliability values to be considered when updating L_r^0:

1. $\Delta = |M_{R,0}(0) - M_{R,1}(0)|$, the difference in the partial path metrics of path 0 and path 1.
2. $L_r^0 = L_{r,0}$, the current reliability value of $u_r^0 = \hat{u}_{r,0}$ on path 0.
3. $L_{r,1}$, the current reliability value of $\hat{u}_{r,1}$ on path 1.

$L_{r,0}$ comes from an ACS operation prior to epoch R between path 0 and, say, path m in which $\hat{u}_{r,0} \neq \hat{u}_{r,m}$. That is, path m belongs to the complementary set Ω_r^c for $\hat{u}_{r,0}$. $L_{r,1}$ comes from an ACS operation prior to epoch R between path 1 and, say, path l in which $\hat{u}_{r,1} \neq \hat{u}_{r,l}$. It follows that $\hat{u}_{r,l} = \hat{u}_{r,0}$ and path l does not belong to the complementary set Ω_r^c for $\hat{u}_{r,0}$. Thus, the update equation for this first case is

$$L_r^j = \min\{\Delta, L_{r,0}\} \tag{6}$$

The second case occurs when the r^{th} bit, for some $0 \le r < R-1$, on path 0, denoted by $\hat{u}_{r,0}$, agrees with the corresponding bit $\hat{u}_{r,1}$ on path 1. Arguing as above, we find that in this case path l is now in the complementary set Ω_r^c with a reliability value of $\Delta + L_{r,1}$ and the update equation is

$$L_r^j = \min\{\Delta + L_{r,1}, L_{r,0}\} \tag{7}$$

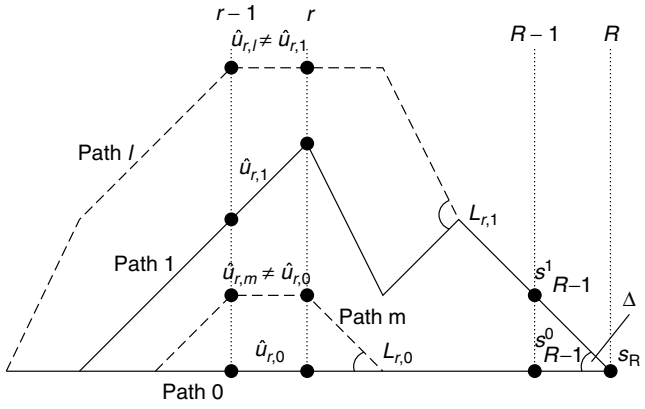

Figure 5. Figure illustrating the paths used in updating the reliability information at state 0 in the SOVA.

With these two update equations, the SOVA may now be stated as follows for rate $R_c = 1/n$ codes.

Step 1: Initialize $M_0(0) = 0$ and $M_0(i) = \infty$ for $i \neq 0$. Set $R = 0$.

Step 2: Increment $R = R + 1$. For each state $s_R = j$, compute the branch metrics for the 2^k branches entering that state and compute the 2^k partial path metrics

$$M_{R,l}(j) = M_{R-1}(i) + \beta_{R-1}(x_{R-1,l} = x) \tag{8}$$

where $s_{R-1} = i$ is a state at epoch $R-1$ with a branch leading to state $s_R = j$ with branch label $x_{R-1,l}$.

Step 3: For each state $s_R = j$, compare the 2^k partial path metrics $M_{R,l}(j)$ and choose the minimum, that is,

$$M_R(j) = \min_l M_{R,l}(j)$$

Store the corresponding partial sequence $\tilde{\boldsymbol{u}}^j = [\hat{u}_0, \ldots, \hat{u}_{R-1}]$. This partial sequence is known as the survivor for state j at epoch R.

Step 3a: For each state $s_R = j$, compute Δ, trace back the survivor and update the reliability values L_R^j of each bit according to Eqs. (6) and (7)

Step 4: If $R < N$, then return to Step 2. If $R = N$, then the survivor to state $s_N = 0$ with path metric $M_N(0)$ is the decoded sequence and the reliability values are L_N^0.

Note that this statement assumes that the encoder started in the all zero state and that the trellis is terminated and ends in the all zero state.

This version of the SOVA computes reliability values based on a single path from each of the sets Ω_r and Ω_r^c. The path used in each set is optimum in the maximum likelihood sequence sense of the Viterbi algorithm. The traceback operation required in this version of the SOVA for updating the reliability values introduces considerable complexity and may not be suitable for some applications. Several alternative algorithms may be found in the literature [9,10]. In the sequel, algorithms that attempt to compute or approximate the a posteriori probabilities directly are discussed.

4. A POSTERIORI PROBABILITY ALGORITHMS

4.1. BCJR or MAP Decoding

The ultimate purpose of this algorithm is the calculation of a posteriori probabilities, such as $\Pr[u_r \mid \boldsymbol{y}]$, or $\Pr[x_r \mid \boldsymbol{y}]$, where $\boldsymbol{y}$ is the received sequence observed at the output of a channel, whose input is the transmitted sequence $\boldsymbol{x}$. Following Ref. 2, it is convenient to calculate the probability that the encoder traversed a specific branch in the trellis, that is, $\Pr[s_r = i, s_{r+1} = j \mid \boldsymbol{y}]$, where s_r is the state at epoch r, and s_{r+1} is the state at epoch $r+1$. The BCJR or MAP algorithm computes this probability as

$$\begin{aligned}\Pr[s_r = i, s_{r+1} = j \mid \boldsymbol{y}] &= \frac{1}{\Pr(\boldsymbol{y})}\Pr[s_r = i, s_{r+1} = j, \boldsymbol{y}] \\ &= \frac{1}{\Pr(\boldsymbol{y})}\alpha_{r-1}(i)\gamma_r(j,i)\beta_r(j) \end{aligned} \tag{9}$$

The α-values are internal variables of the algorithm and are computed by the *forward recursion*

$$\alpha_{r-1}(i) = \sum_{\text{states } l} \alpha_{r-2}(l)\gamma_{r-1}(i,l) \tag{10}$$

This forward recursion evaluates α-values at time $r-1$ from previously calculated α-values at time $r-2$, and the sum is over all states l at time $r-2$ that connect with state i at time $r-1$. The forward recursion for the trellis of Fig. 4 is illustrated in Fig. 6. To enforce the boundary condition that the encoder begins in state 0, the α-values are initialized as $\alpha_0(0) = 1, \alpha_0(1) = \alpha_0(2) = \alpha_0(3) = 0$.

The β-values are calculated in a similar manner, called the *backward recursion*

$$\beta_r(j) = \sum_{\text{states } k} \beta_{r+1}(k)\gamma_{r+1}(k,j) \tag{11}$$

with initial values of $\beta_N(0) = 1, \beta_N(1) = \beta_N(2) = \beta_N(3) = 0$ to enforce the terminating condition of the trellis code. The sum is over all states k at time $r+1$ to which state j at time r connects. The backward recursion is illustrated in Fig. 7.

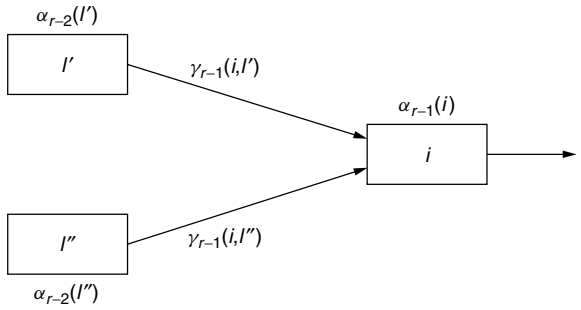

Figure 6. Illustration of the forward recursion of the MAP algorithm.

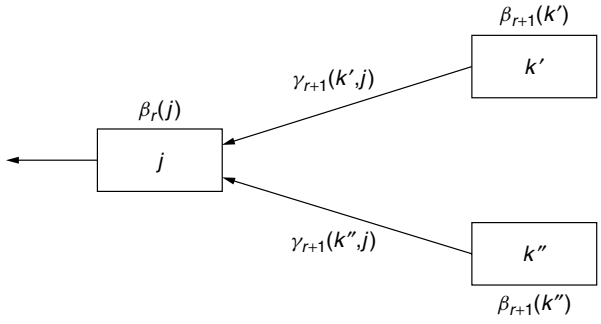

Figure 7. Illustration of the backward recursion of the MAP algorithm.

The γ-values are conditional transition probabilities and are the inputs to the algorithm based on the received sequence. Specifically, $\gamma_r(j,i)$ is the joint probability that the state at time $r+1$ is $s_{r+1}=j$ and that y_r is received, given $s_r=i$. It is calculated using the expression

$$\begin{aligned}\gamma_r(j,i) &= \Pr(s_{r+1}=j, y_r \mid s_r=i)\\ &= \Pr[s_{r+1}=j \mid s_r=i]\Pr(y_r \mid x_r)\end{aligned} \tag{12}$$

where $\Pr[s_{r+1}=j \mid s_r=i]$ is the a priori transition probability and is related to the probability of u_r. For feedforward encoders, the top transition in the trellis diagram of Fig. 4 is associated with $u_r=1$ and the bottom transition with $u_r=0$. This term is used to account for a priori probability information on the bits u_r. To simplify notation, this transition probability will be denoted as

$$p_{ij} = \Pr[s_{r+1}=j \mid s_r=i] = \Pr[u_r] \tag{13}$$

The second term, $\Pr(y_r \mid x_r)$, is simply the conditional channel transition probability, given that symbol x_r is transmitted. Note that x_r is the symbol associated with the transition from state $i \to j$.

The a posteriori symbol probabilities $\Pr[u_r \mid \boldsymbol{y}]$ can now be calculated from the a posteriori transition probabilities (9) by summing over all transitions corresponding to $u_r=1$, and, separately, by summing over all transitions corresponding to $u_r=0$, to obtain

$$p[u_r=1 \mid \boldsymbol{y}] = \frac{1}{\Pr(\boldsymbol{y})}\sum_{u_r=1}\Pr[s_r=i, s_{r+1}=j, \boldsymbol{y}] \tag{14}$$

$$p[u_r=0 \mid \boldsymbol{y}] = \frac{1}{\Pr(\boldsymbol{y})}\sum_{u_r=0}\Pr[s_r=i, s_{r+1}=j, \boldsymbol{y}] \tag{15}$$

From these equations it is clear that the MAP algorithm computes the a posteriori probabilities using all the sequences in the sets Ω_r and Ω_r^c.

The derivation of the MAP algorithm requires the probability

$$q_{ij}(x) = \Pr(\tau(u_r, s_r)=x \mid s_r=i, s_{r+1}=j) \tag{16}$$

that is, the a priori probability that the output x_r at time r assumes the value x on the transition from state i to state j. For convolutional codes, as opposed to coded modulation schemes, this probability is a deterministic function of i and j.

To begin, define the internal variables α and β by their probabilistic meaning. These are

$$\alpha_r(j) = \Pr(s_{r+1}=j, \tilde{\boldsymbol{y}}) \tag{17}$$

the joint probability of the partial sequence $\tilde{\boldsymbol{y}}=(y_{-l},\ldots,y_r)$ up to and including time epoch r and state $s_{r+1}=j$; and

$$\beta_r(j) = \Pr((y_{r+1},\ldots,y_l) \mid s_{r+1}=j) \tag{18}$$

the conditional probability of the remainder of the received sequence $\boldsymbol{y}$ given that the state at time $r+1$ is j.

It is now possible to calculate

$$\begin{aligned}\Pr(s_{r+1}=j, \boldsymbol{y}) &= \Pr(s_{r+1}=j, \tilde{\boldsymbol{y}}, (y_{r+1},\ldots,y_l))\\ &= \Pr(s_{r+1}=j, \tilde{\boldsymbol{y}})\Pr((y_{r+1},\ldots,y_l) \mid s_{r+1}=j, \tilde{\boldsymbol{y}})\\ &= \alpha_r(j)\beta_r(j)\end{aligned} \tag{19}$$

where we have used the fact that $\Pr((y_{r+1},\ldots,y_l) \mid s_{r+1}=j, \tilde{\boldsymbol{y}}) = \Pr((y_{r+1},\ldots,y_l) \mid s_{r+1}=j)$, that is, if $s_{r+1}=j$ is known, events after time r are independent of the history $\tilde{\boldsymbol{y}}$ up to s_{r+1}.

In the same way we calculate via Bayes' expansion

$$\begin{aligned}\Pr(s_r=i, s_{r+1}=j, \boldsymbol{y}) &= \Pr(s_r=i, s_{r+1}=j, (y_{-l},\ldots,y_{r-1}),\\ &\quad \times y_r, (y_{r+1},\ldots,y_l))\\ &= \Pr(s_r=i, (y_{-l},\ldots,y_{r-1}))\\ &\quad \times \Pr(s_{r+1}=j, y_r \mid s_r=i)\\ &\quad \times \Pr((y_{r+1},\ldots,y_l) \mid s_{r+1}=j)\\ &= \alpha_{r-1}(i)\gamma_r(j,i)\beta_r(j)\end{aligned} \tag{20}$$

Now, again applying Bayes' rule and $\sum_b p(a,b) = p(a)$, we obtain

$$\begin{aligned}\alpha_r(j) &= \sum_{\text{states } i}\Pr(s_r=i, s_{r+1}=j, \tilde{\boldsymbol{y}})\\ &= \sum_{\text{states } i}\Pr(s_r=i, (y_{-l},\ldots,y_{r-1}))\Pr(s_{r+1}=j, y_r \mid s_r=i)\\ &= \sum_{\text{states } i}\alpha_{r-1}(i)\gamma_r(j,i)\end{aligned} \tag{21}$$

For a trellis code started in the zero state at time $r=-l$ we have the starting conditions

$$\alpha_{-l-1}(0)=1, \alpha_{-l-1}(j)=0;\ j\neq 0 \tag{22}$$

As above, we similarly develop an expression for $\beta_r(j)$, that is,

$$\begin{aligned}\beta_r(j) &= \sum_{\text{states } i}\Pr(s_{r+2}=i, (y_{r+1},\ldots,y_l) \mid s_{r+1}=j)\\ &= \sum_{\text{states } i}\Pr(s_{r+2}=i, y_{r+1} \mid s_{r+1}=j)\\ &\quad \times \Pr((y_{r+2},\ldots,y_l) \mid s_{r+2}=i)\\ &= \sum_{\text{states } i}\beta_{r+1}(i)\gamma_{r+1}(i,j)\end{aligned} \tag{23}$$

The boundary condition for $\beta_r(j)$ is

$$\beta_l(0)=1, \beta_l(j)=0; \quad j\neq 0 \tag{24}$$

for a trellis code which is terminated in the zero state.

Furthermore, the general form of the γ values is given by

$$\begin{aligned}\gamma_r(j,i) &= \sum_{x_r} \Pr(s_{r+1}=j \mid s_r=i) \\ &\quad \times \Pr(x_r \mid s_r=i, s_{r+1}=j)\Pr(y_r \mid x_r) \\ &= \sum_{x_r} p_{ij} q_{ij}(x_r) p_N(y_r - x_r) \end{aligned} \tag{25}$$

Equations (21) and (23) are iterative and the a posteriori state and transition probabilities can now be calculated via the following algorithm.

Step 1: Initialize $\alpha_{-l-1}(0)=1, \alpha_{-l-1}(j)=0$ for all non-zero states ($j \neq 0$) of the encoder, and $\beta_l(0)=1, \beta_l(j)=0, j \neq 0$. Let $r=-l$.

Step 2: For all states j calculate $\gamma_r(j,i)$ and $\alpha_r(j)$ via Eqs. (25) and (21).

Step 3: If $r<l$, let $r=r+1$ and go to Step 2, else $r=l-1$ and go to Step 4.

Step 4: Calculate $\beta_r(j)$ using Eq. (23). Calculate $\Pr(s_{r+1}=j, \boldsymbol{y})$ from Eq. (19), and $\Pr(s_r=i, s_{r+1}=j; \boldsymbol{y})$ from Eq. (9).

Step 5: If $r>-l$, let $r=r-1$ and go to Step 4.

Step 6: Terminate the algorithm and output all the values $\Pr(s_{r+1}=j, \boldsymbol{y})$ and $\Pr(s_r=i, s_{r+1}=j, \boldsymbol{y})$.

The a posteriori state and transition probabilities produced by this algorithm can now be used to calculate a posteriori information bit probabilities, that is, the probability that the information k-tuple $u_r=u$, where u can vary over all possible binary k-tuples. Starting from the transition probabilities $\Pr(s_r=i, s_{r+1}=j \mid \boldsymbol{y})$, we simply sum over all transitions $i \to j$ that are caused by $u_r=u$. Denoting these transitions by $A(u)$, we obtain

$$\Pr(u_r=u) = \sum_{(i,j)\in A(u)} \Pr(s_r=i, s_{r+1}=j \mid \boldsymbol{y}) \tag{26}$$

As mentioned previously, another most interesting product of the APP decoder is the a posteriori probability of the transmitted output symbol x_r. Arguing analogously as above, and letting $B(x)$ be the set of transitions on which the output signal x can occur, we obtain

$$\begin{aligned}\Pr(x_r=x) &= \sum_{(i,j)\in B(x)} \Pr(x \mid y_r)\Pr(s_r=i, s_{r+1}=j \mid \boldsymbol{y}) \\ &= \sum_{(i,j)\in B(x)} \frac{p_N(y_r-x_r)}{p(y_r)} q_{ij}(x) \\ &\quad \times \Pr(s_r=i, s_{r+1}=j \mid \boldsymbol{y}) \end{aligned} \tag{27}$$

where the a priori probability of y_r can be calculated via

$$p(y_r) = \sum_{\substack{x' \\ ((i,j)\in B(x))}} p(y_r \mid x') q_{ij}(x') \tag{28}$$

and the sum extends over all transitions $i \to j$.

Equation (27) can be much simplified if there is only one output symbol on the transition $i \to j$. In this case, the transition automatically determines the output symbol, and

$$\Pr(x_r=x) = \sum_{(i,j)\in B(x)} \Pr(s_r=i, s_{r+1}=j \mid \boldsymbol{y}) \tag{29}$$

5. LOG-MAP AND THE MAX-LOG-MAP

5.1. The MAP Algorithm in the Logarithm Domain (Log-MAP)

Although the MAP algorithm is concise and consists only of multiplications and additions, current direct digital hardware implementations of the algorithm lead to complex circuits due to many real-number multiplications involved in the algorithm. To avoid these multiplications, we transform the algorithm into the logarithm-domain. This results in the so-called *log-MAP* algorithm.

First, we transform the forward recursion (10), (21) into the logarithm-domain using the definitions

$$A_r(i) = \log(\alpha_r(i)); \quad \Gamma_r(i,l) = \log(\gamma_r(i,l)) \tag{30}$$

to obtain the *log-domain* forward recursion

$$A_{r-1}(i) = \log\left(\sum_{\text{states } l} \exp\left(A_{r-2}(l) + \Gamma_{r-1}(i,l)\right)\right) \tag{31}$$

Likewise, the backward recursion can be transformed into the logarithm-domain using the analogous definition $B_r(j)=\log(\beta_r(j))$, and we obtain

$$B_r(j) = \log\left(\sum_{\text{states } k} \exp\left(B_{r+1}(k) + \Gamma_{r+1}(k,j)\right)\right) \tag{32}$$

The product in Eqs. (9) and (20) now turns into the simple sum

$$\alpha_{r-1}(i)\gamma_r(j,i)\beta_r(j) \to A_{r-1}(i) + \Gamma_r(j,i) + B_r(j) \tag{33}$$

Unfortunately, Eqs. (31) and (32) contain log() and exp() functions, which are more complex than the original multiplications. However, in most cases of current practical interest, the MAP algorithm is used to decode binary codes with $R_c=1/n$ where there are only two branches involved at each state, and therefore only sums of two terms in Eqs. (31) and (32). The logarithm of such a binary sum can be expanded as

$$\begin{aligned}\log(\exp(a)+\exp(b)) &= \log\left(\exp\left(\max(a,b)\right)\right. \\ &\quad \left. \times\ (1+\exp(-|a-b|))\right) \\ &= \max(a,b) + \log\left((1+\exp(-|a-b|))\right) \end{aligned}$$

The second term is now the only complex operation left and there are a number of methods to approach this including a look-up table.

Finally, for binary codes the algorithm computes the log-likelihood ratio (LLR) $\lambda(u_r)$ of the information bits u_r using the a posteriori probabilities (26) as

$$\begin{aligned}\lambda(u_r) &= \log\left(\frac{\Pr(u_r=1)}{\Pr(u_r=0)}\right)\\ &= \log\left(\frac{\displaystyle\sum_{(i,j)\in A(u=1)} \alpha_{r-1}(i)\gamma_r(j,i)\beta_r(j)}{\displaystyle\sum_{(i,j)\in A(u=0)} \alpha_{r-1}(i)\gamma_r(j,i)\beta_r(j)}\right)\end{aligned}$$

$$\lambda(u_r) = \log\left(\frac{\displaystyle\sum_{(i,j)\in A(u=1)} \exp(A_{r-1}(i)+\Gamma_r(j,i)+B_r(j))}{\displaystyle\sum_{(i,j)\in A(u=0)} \exp(A_{r-1}(i)+\Gamma_r(j,i)+B_r(j))}\right) \quad (34)$$

The range of the LLR is $[-\infty,\infty]$, where a large value signifies a high probability that $u_r = 1$.

5.2. Max-Log-MAP

The complexity of the log-MAP algorithm may be further reduced by approximating the forward and backward recursions by

$$\begin{aligned}A_{r-1}(i) &= \log\left(\sum_{\text{states } l} \exp\left(A_{r-2}(l)+\Gamma_{r-1}(i,l)\right)\right)\\ &\approx \max_{\text{states } l}\left(A_{r-2}(l)+\Gamma_{r-1}(i,l)\right)\end{aligned} \quad (35)$$

and

$$\begin{aligned}B_r(j) &= \log\left(\sum_{\text{states } k} \exp\left(B_{r+1}(l)+\Gamma_{r+1}(k,j)\right)\right)\\ &\approx \max_{\text{states } k}\left(B_{r+1}(l)+\Gamma_{r+1}(k,j)\right)\end{aligned} \quad (36)$$

which results in the max-log-MAP algorithm. The final LLR calculation in Eq. (34) is approximated by

$$\begin{aligned}\lambda(u_r) \approx &\max_{(i,j)\in A(u=1)}\left(A_{r-1}(i)+\Gamma_r(j,i)+B_r(j)\right)\\ &-\max_{(i,j)\in A(u=0)}\left(A_{r-1}(i)+\Gamma_r(j,i)+B_r(j)\right)\end{aligned} \quad (37)$$

The advantage of the max-log-MAP algorithm is that it uses only additions and maximization operations to approximate the LLR of u_r. It is very interesting to note that Eq. (35) is the Viterbi algorithm for maximum-likelihood sequence decoding. Furthermore, Eq. (36) is also a Viterbi algorithm, but it is operated in the reverse direction.

Further insight into the relationship between the log-MAP and its approximation can be gained by expressing the LLR of u_r in the form

$$\lambda(u_r) = \log\left(\frac{\displaystyle\sum_{\boldsymbol{x};(u_r=1)} \exp\left(-\frac{|\boldsymbol{y}-\boldsymbol{x}|^2}{N_0}\right)}{\displaystyle\sum_{\boldsymbol{x};(u_r=0)} \exp\left(-\frac{|\boldsymbol{y}-\boldsymbol{x}|^2}{N_0}\right)}\right) \quad (38)$$

where the sum in the numerator extends over all coded sequences $\boldsymbol{x}$ that correspond to information bit $u_r = 1$, and the denominator sum extends over all $\boldsymbol{x}$ corresponding to $u_r = 0$.

It is quite straightforward to see that the max-log-MAP retains only the path in each sum that has the best metrics, and therefore the max-log-MAP calculates an approximation to the true LLR, given by

$$\lambda(u_r) \approx \min_{\boldsymbol{x};(u_r=0)} \frac{|\boldsymbol{y}-\boldsymbol{x}|^2}{N_0} - \min_{\boldsymbol{x};(u_r=1)} \frac{|\boldsymbol{y}-\boldsymbol{x}|^2}{N_0} \quad (39)$$

that is, the metric difference between the nearest path to $\boldsymbol{y}$ with $u_r = 0$ and the nearest path with $u_r = 1$. That is, like the SOVA described earlier, the max-log-MAP approximates the LLR by using the best sequence in each set Ω_r and Ω_r^c. Fossorier et al. [8] have shown that the max-log-MAP and the SOVA presented earlier are identical.

6. PERFORMANCE IN ITERATIVE DECODING

The SOVA, MAP, and max-log-MAP algorithms offer a myriad of complexity and implementation tradeoffs that are application- and technology-dependent and will be left to the literature. The performance tradeoff is clearer, although still somewhat dependent on the application. From the development presented here, one would expect the MAP and log-MAP algorithms to perform identically (ignoring any issues of numerical stability) and that both would slightly outperform the SOVA and max-log-MAP. The latter two algorithms are again essentially identical. To illustrate this, we consider the use of these SISO algorithms in the iterative decoding of a turbo code. It is worth noting that some modifications are required to enable the SOVA to easily use the extrinsic information of the iterative turbo decoder. Details of these modifications may be found in Refs. 10 and 11.

The performance of a turbo code with iterative decoding is shown in Fig. 8. The turbo code is a rate $R_c = 1/3$ code with identical memory $\nu = 4$ constituent encoders and an interleaver of length 4096 bits. The constituent encoders have feedforward polynomial $g_1(D) = 1 + D^4$ and feedback polynomial $g_0(D) = 1 + D + D^2 + D^3 + D^4$. All of the performance curves shown are for 18 complete decoder iterations. As expected, the performance with the MAP and log-MAP component decoders are identical, as is performance with the SOVA and max-log-MAP component decoders. There is a gap of approximately 0.5 dB between the two curves. This loss is attributable to the poorer quality soft information provided by the SOVA and max-log-MAP algorithms due to the use of only a single sequence in complementary set Ω_r^c.

7. CONCLUSION

This article discussed several SISO algorithms suitable, with minor adaptation, to the majority of applications considering soft-information exchange or iterative processing. They were presented in the context of the decoding of binary convolutional codes with finite block lengths. The extensions to sliding windows, block codes, equalization,

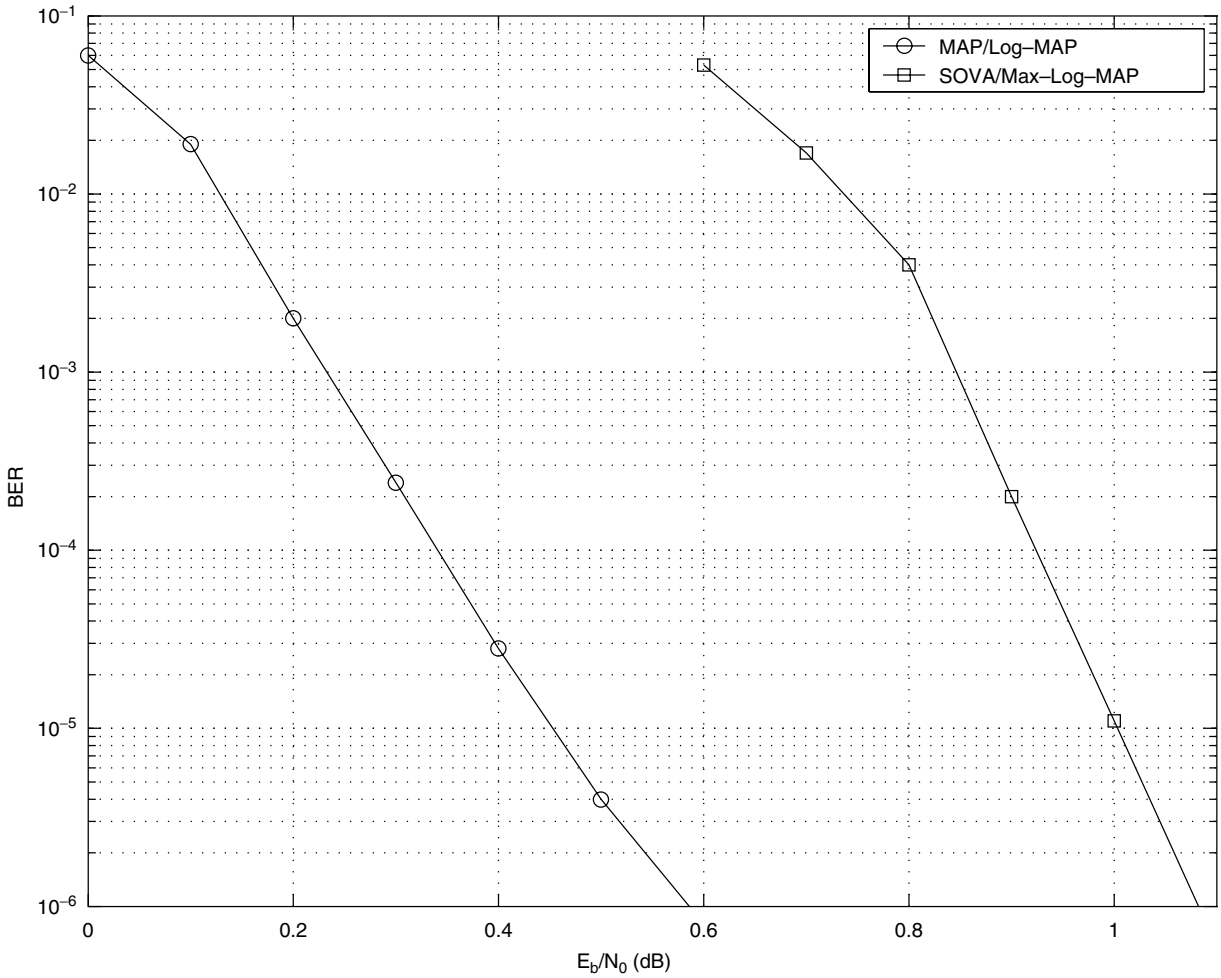

Figure 8. Performance comparison of rate 1/3 turbo code, with interleaver size 4096, and 18 iterations of decoding.

and other applications are relatively straightforward and may be found in the literature.

The virtually universal adoption of SISO algorithms has led to renewed interest in the general theory of decoding algorithms. This has led to several interesting results that unify ideas in fields as diverse as decoding algorithms, graph theory and belief propagation. These results require a degree of mathematical sophistication, but they provide a more general framework in which to understand a broad class of SISO algorithms. The interested reader may find some of these results in Refs. 12–14 and the references therein.

SOFTWARE RADIO

JOSEPH MITOLA III
Consulting Scientist
Tampa, Florida

1. INTRODUCTION

Software radio (SWR), briefly, is about increasingly wider-bandwidth radiofrequency (RF)-capable digital hardware that is given much or all of its function–personality by software. This chapter provides an overview of the mathematical, engineering, and economics principles of SWR from the theory to practice of radio systems engineering. In the space available, there is little opportunity to address either the larger network architectures, or the software-defined radio (SDR) implementation details. However, the treatment differentiates SWR from SDR. It describes the end-to-end partitioning of SDR requirements. Further, it describes the allocation of critical parameters including dynamic range and processing capacity. Allocation tradeoffs among hardware platforms, firmware and software depend on cost–benefit in the marketplace. In addition, as implementations migrate to software, one must assure that the software is structured well and performs robustly — even when many tasks are competing for processing resources. There are also pointers to relevant industry forums [1] and standards bodies [2].

Some try to "sell" the software radio, but that is not the purpose here. On the contrary, an ideal SWR approach sometimes yields an ineffective product. Pagers, for example, maximize display area and battery life, while minimizing the size and weight of a fixed-function product. Hardware-intensive application-specific integrated circuits (ASICs) are best for that market niche at present. On the other hand, nearly ideal SWR base stations have been deployed since early 2000 because of lower cost of ownership than the baseband–digital signal processor (DSP) base stations that they replace. One therefore must appreciate how analog, digital, and software-intensive approaches complement each other and drive alternative cost–benefit profiles. One may then select the right mix of hardware-intensive and software-defined implementation aspects of a design. This introduction should help the reader appreciate the potential contributions and pitfalls of SWR technology.

SWR is an interdisciplinary technology. It is helpful for software people to understand the RF hardware and air interface standards concepts of an interdisciplinary team. The software-oriented discussion is for people with strong background in RF, analog radio, or DSP but little background in large-scale software. SDRs typically have over one million lines of code (LoC), which is a complex, large-scale software systems. Thus large-scale software tools such as the Unified Modeling Language (UML), the Common Object Request Broker Architecture (CORBA), and the eXtensible Markup Language (XML), typically unfamiliar to RF engineers, loom large in software radio architecture.

The appropriate host platforms for SDR functions change over time. Commercial digital filter ASICs become obsolete as DSP capacity increases, changing the systems level tradeoffs from ASIC to DSP. As needs, technology, and team expertise evolve, the effective choice will also change. Platforms also change with the top–down design constraints, such as market economics, consumer values, and network architecture. For quick time to market, one may procure functions in off-the-shelf code or intellectual property. A sound systems-level architecture facilitates this process, while an inferior architecture inhibits it. The in-depth understanding of SDR therefore includes markets and economics.

One revolutionary aspect of software radio is that knowing how to code a radio algorithm in the programming language C on a DSP chip no longer gives a software engineer the core skills needed to contribute effectively to software radio systems development. In fact, that experience becomes a liability if it causes one to minimize the importance of the new large-scale software engineering methods such as UML, XML, and CORBA.

In addition, European readers will recognize SDL, the ITU-standard Specification and Description Language. In teaching the software radio course on which this article is based, the author finds that Asian and U.S. engineers are less practiced in formal methods for specifying radio functions then their European counterparts. The European Telecommunications Standards Institute (ETSI) emphasis on formal methods and the widespread use of SDL in support of the European standards-setting

process has not permeated U.S. practice, particularly in military, civil, and other non-ITU marketplaces. As a result, U.S. practitioners of radio engineering are doing with generic computer-aided software engineering (CASE) tools what their European counterparts are doing with communications-oriented SDL — defining new radio air interface standards and implementations. This article introduces the formal techniques and software tools needed to effectively develop radios of the next-generation level of complexity.

In addition, software radio has become an industry focus area. Several texts now provide further background reading [3], industry perspectives [4], and in-depth treatment of architecture [5]. This article therefore highlights the numerous approaches with references for the interested reader.

This section introduced SWR and SDR. The next section summarizes the expanding role of SWR in contemporary telecommunications. The subsequent section reviews the fundamental precepts of the ideal SWR: the placement of the analog-to-digital converter (ADC) near the antenna, and the use of software to replace formerly analog or digital hardware. Section 4 introduces implementation-dependent SDR architecture, based on defining functions, components, and design rules that guide SDR product migration. Section 5 examines practical SDR designs, emphasizing implementation constraints. Isochronous performance of the real-time software, for example, is a critical design constraint in the signal processing streams. Section 6 reviews the development parameters and risks associated with choosing designs from the conservative baseband DSP through a variety of SDR alternatives to the ideal SWR. Many SDR projects of the 1990s failed or fell substantially short of requirements because of unanticipated software complexity. Section 7 surveys the broader implications of SWR. Importantly, SWR brings the substantial mitigation of the so-called shortage of radio spectrum, which is an issue more of the economics of spectrum reuse infrastructure than of the laws of physics. Section 8 underscores a few conclusions. A list of acronyms is provided for the reader's convenience, while references are appended in the Bibliography.

2. THE TRANSFORMATION OF RADIO ENGINEERING

We are in the midst of a transformation of radio systems engineering. Throughout the 1970s and 1980s, radio systems migrated from analog to digital in system control, source and channel coding, and baseband signal processing. In the early 1990s, the SWR transformation began to extend these horizons by soft-coding traditionally hardware-defined characteristics of wireless devices, including

- Radiofrequency (RF) band
- RF channel broadband channel coding and bandwidth
- Diversity, intermediate-frequency (IF) combining, beamforming, and antenna characteristics [6]

Today the evolution toward practical SDR is accelerating through a combination of techniques. These include multiband antennas and wideband RF devices. Wideband ADCs and digital-to-analog converters (DACs) now affordably access GHz of spectrum instantaneously. Multiband radios for military, commercial, teleinformatic, intelligent transportation, aircraft, and other applications are increasingly affordable. Processing of IF, baseband, and bit streams is implemented using increasingly general-purpose programmable processors. The complexity of the physical and link-layer protocol software for the many diverse RF bands and physical-layer modes of third- and fourth-generation wireless (3G/4G) now extends to millions of lines of code.

The ideal SWR consists of wideband antenna, wideband ADC/DAC, and general-purpose processor(s). Although SWR configurations are of research interest, they do not meet market constraints. The SDR therefore embraces the evolution of programmable hardware, increasing flexibility via increased programmability within market constraints. The ideal SWR represents and end state of maximum flexibility in this evolution. SDR "futureproofs" practical infrastructure against continually evolving standards and hardware. Strong SWR architecture permits one to insert SDR technology gracefully and affordably. For a clear path for product evolution, one must adapt SWR to specific applications or market niches. The attempts of researchers to build the ideal SWR yield lessons learned from technology pathfinders such as SPEAK*easy* [7,8], FIRST [9,10], and TRUST [11]. Continuing transformation is evident in the creation of the Wireless World Radio Foundation (WWRF) and SDR Forum work in SDR, with global emphasis on SDR as a critical enabler of 3G and 4G wireless. Related work continues to expand in DARPA, the Americas, the ITU, the EC (e.g., GSM MoU and ETSI), and Asia (e.g., ARIB and IEICE).

3. THE IDEAL SOFTWARE RADIO

The top-level components of an ideal SWR handset consist of a power supply, an antenna, a multiband RF converter, a power amplifier, and a single-chip ADC and DAC. These components plus on-chip general-purpose processor and memory perform the radio functions, as illustrated in Fig. 1.

The ideal SWR mobile wireless terminal interfaces directly to the user (e.g., via voice, data, fax, and/or multimedia) and to multiple RF "air" interfaces. Driven by user demands, the mobile unit minimizes dissipated power for long battery life and minimizes manufacturing parts count by maximizing hardware integration for lower unit cost. The generic wireless base station accesses multiple radio air interfaces and the Public Switched Telephone Network (PSTN). With access to the power grid, base stations may employ computationally intensive software designs using modular, open-architecture processing hardware that facilitates technology insertion. Technology insertion futureproofs base-station infrastructure against the continuing evolution of air interfaces. Military base stations ("nodes") need to support multiple networks on

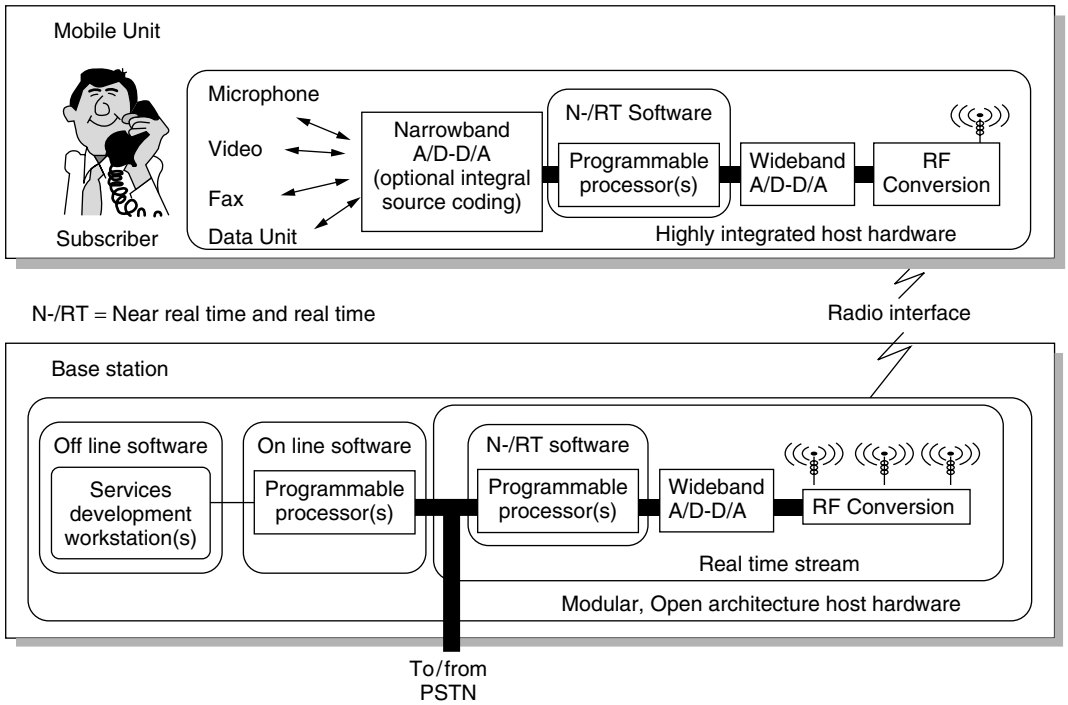

Figure 1. The ideal software radio handset and base station.

multiple RF bands with multiple air interfaces ("modes"). Command-and-control communications (C3) nodes may be formed by the collocation of several radios on mobile vehicles. These configurations often interfere with each other. The military calls this "cosite interference." The SWR basestation attempting to support push-to-talk (PTT) traffic on multiple channels in the same band can also generate self-interference. With software downloads to evolve radio personalities, the management of self-generated interference that was a design issue for the radio engineering laboratory of the 1980s is a deployment-time configuration management issue for SWR.

The placement of the ADC and DAC as close to the antenna as possible and the definition of radio functions in software are the hallmarks of the SWR. Although SWRs use digital techniques, software-controlled digital radios are not ideal SWRs. The essential difference is the total programmability of the SWR, including software-defined RF bands, channel access filters, beamforming, and physical-layer channel modulation. SDR designs, on the other hand, liberally mix analog hardware, digital hardware, and software technologies. SDR has become practical as DSP costs per millions of instructions per second (Mips) have dropped below $10 and continue to plummet. The economics of software radios become increasingly compelling as demands for flexibility increase while these costs continue to drop by a factor of 2 every 1.5–3 years.

By April 2002, SDR technology cost-effectively implemented commercial 1G analog and 2G digital mobile cellular radio air interfaces. 3G SDR base stations were being developed. Over time, wideband 4G air interfaces will also yield to software techniques on wideband RF platforms. In parallel, multiband multimode military radios were being deployed, such as the digital modular radio (DMR) [12], and the Joint Tactical Radio System (JTRS) [13] "clusters."[1] Such SDR implementations require a mix of increasingly sophisticated software technology along with hardware-intensive techniques such as ASICs.[2]

3.1. The Ideal Functional Components

Technology advances have ushered in new radio capabilities that require an expansion of the canonical communications functional model: source coding, the channel, and channel coding. The new aspects are captured in the software radio functional model. First, multiband technology [14], accesses more than one RF band of communications channels at once. The RF channel, then, is generalized to the channel set of Fig. 2. This set includes RF channels, but radio nodes such as personal communications system (PCS) base stations and portable military radios also interconnect to fiber and cable; therefore these are also included in the channel set. The channel encoder

[1] In this article, the conventional notion of cellular radio is extended to embrace the idea that the propagation of RF from any SDR transmitter defines an implicit RF cell. Its size and shape is determined by the physical placement of antenna(s) and the environment. Antenna height, directivity, path loss, diffraction, and multipath loss shape the cell. A multiband, multimode SDR is uniquely suited to turn such implicit cells into explicitly managed ad hoc cellular networks.

[2] In fact, the continuing interplay among military and commercial software radios plays an important role in the evolution of SDR technology. The merger of these market segments around common interest in open architecture SDR platforms is an on-going process, complete with the common interests and discontinuities.

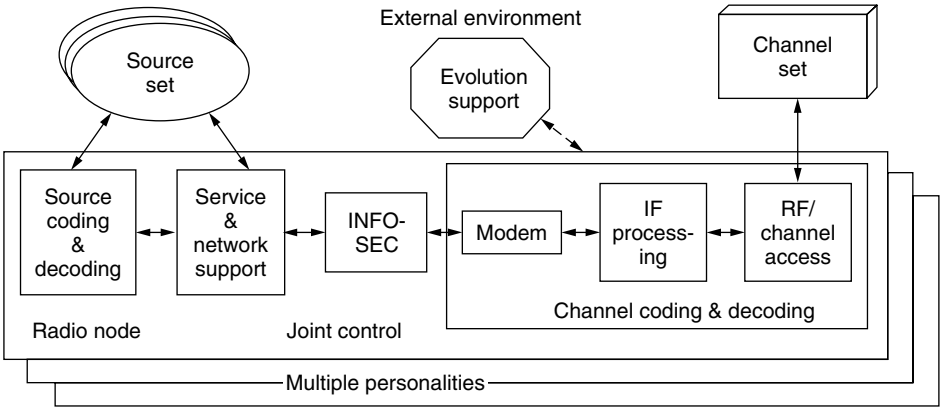

Figure 2. Functional model of a software radiocommunications system.

of a multiband radio includes RF/channel access, IF processing, and modem. The RF/channel access includes wideband antennas, and the multielement arrays of smart antennas [15]. This segment also provides multiple signal paths and RF conversion that span multiple RF bands. IF Processing may include filtering, further frequency translation, space/time diversity processing, beamforming, and related functions. Multimode radios [7] generate multiple air interfaces (also called "waveforms") defined principally in the modem, which is the RF channel modulator–demodulator. These waveforms may operate only in specific RF bands or may span multiple bands. A software-defined personality includes RF band, channel set (e.g., control and traffic channels), air interface waveforms, INFOSEC, network interfaces, and related user interface functions. In this abstraction of information source, the user is just another source (/sink) set.

Although few applications require Information Security (INFOSEC), there are incentives for its use. Authentication reduces fraud. Stream encipherment ensures privacy. Both help assure data integrity. Transmission security (TRANSEC) hides the fact of a communications event (e.g., by spread-spectrum techniques [16]). INFOSEC is therefore included in the functional model, although this function may be null for some applications.

In addition, the source coding/decoding pair of the expanded model includes the data, facsimile, video, and multimedia sources essential for new services. Some sources will be physically remote from the radio node, connected via the synchronous digital hierarchy (SDH), a local-area network (LAN) [17], and other systems, through the Service & Network Support shown in Fig. 2.

These functions may be implemented in multithreaded multiprocessor software orchestrated by a joint control function. Joint control assures system stability, error recovery, timely dataflow, and isochronous streaming of voice and video. As radios become more advanced, joint control becomes more complex, evolving toward autonomous selection of band, mode, and data format in response to implicit user needs. An autonomous software radio capable of machine learning is called a "cognitive radio." Cognitive radio requires a knowledge processing architecture in the joint control function, overlaid on the SWR architecture discussed in this article [18].

Any of the radio node functions may be singleton (e.g., single band vs. multiple bands) or null, further complicating joint control. Agile beamforming supports additional users and enhances quality of service (QoS) [19]. Beamforming today requires dedicated processors, but in the future, these algorithms may timeshare a DSP pool along with, for instance, a rake receiver [20] and other modem functions. Joint source and channel coding [21] also yields computationally intensive waveforms. Dynamic selection of band, mode, and diversity as a function of QoS [22] introduces large variations into demand, potentially causing conflicts for processing resources. These resources may include ASICs, field-programmable gate arrays (FPGAs), DSPs, and general-purpose computers. Channel strapping, adaptive waveform selection, and other forms of data-rate agility [23] further complicate the statistical structure of the computational demand. In addition, processing resources may be unavailable because of equipment failure [24]. Joint control therefore integrates fault modes, personalities, and support functions, mapping the highest priority radio functions onto the available processing resources. to yield a reliable telecommunications object [25].

In a software radio, the user can upload a variety of new air interface personalities [26]. These may modify any aspect of the air interface, including how the carrier is hopped, the spectrum is spread, and beams are formed. The required radio resources are RF access, digitized bandwidth, dynamic range, memory, and processing capacity. Resources used must not exceed those available on the radio platform. Some mechanism for evolution support is therefore needed to define the waveform personalities, to download them (e.g., over the air) and to ensure that each personality is safe before being activated. Evolution support therefore must include a software factory. In addition, the evolution of the radio platform — the analog and digital hardware of the radio node — must also be supported. This may be accomplished via the development of customized hardware/firmware modules, or by the acquisition of commercial off-the-shelf (COTS) modules, or both.

The block diagram of the radio functional model is a partitioning of the blackbox functions of the ideal SWR node into the functional components shown in Fig. 2, characterized further in Table 1.

Table 1. Function Allocation of the Software Radio Functional Model

Functional Component	Allocated Functions	Remarks
Source coding and decoding	Audio, data, video, and fax interfaces	Ubiquitous algorithms (e.g., ITU [27], ETSI [28])
Service and network support	Multiplexing; setup and control; data services; internetworking	Wireline and Internet standards, including mobility [29]
Information security[a]	Transmission security, authentication, nonrepudiation, privacy, data integrity	May be null, but is increasingly essential in wireless applications [30]
Channel coding/decoding: modem[a]	Baseband modem, timing recovery, equalization, channel waveforms, predistortion, black data processing	INFOSEC, modem, and IF interfaces are not yet well standardized
IF processing[a]	Beamforming, diversity combining, characterization of all IF channels	Innovative channel decoding for signal and QoS enhancement
RF access	Antenna, diversity, RF conversion	IF interfaces are not standardized
Channel set(s)	Simultaneity, multiband propagation, wireline interoperability	Automatically employ multiple channels or modes for managed QoS
Multiple personalities[a]	Multiband, multimode, agile services, interoperable with legacy[b] modes	Multiple *simultaneous* personalities may cause considerable RFI[c]
Evolution support[a]	Define & manage personalities	Local or network support
Joint control[a]	Joint source/channel coding, dynamic QoS vs. load control, processing resource management	Integrates user and network interfaces; multiuser; multiband; and multimode capabilities

[a]Interfaces to these functions have historically been internal to the radio, not plug-and-play.
[b]"Legacy" refers to modes that are deployed but may be deprecated.
[c]Radiofrequency interference.

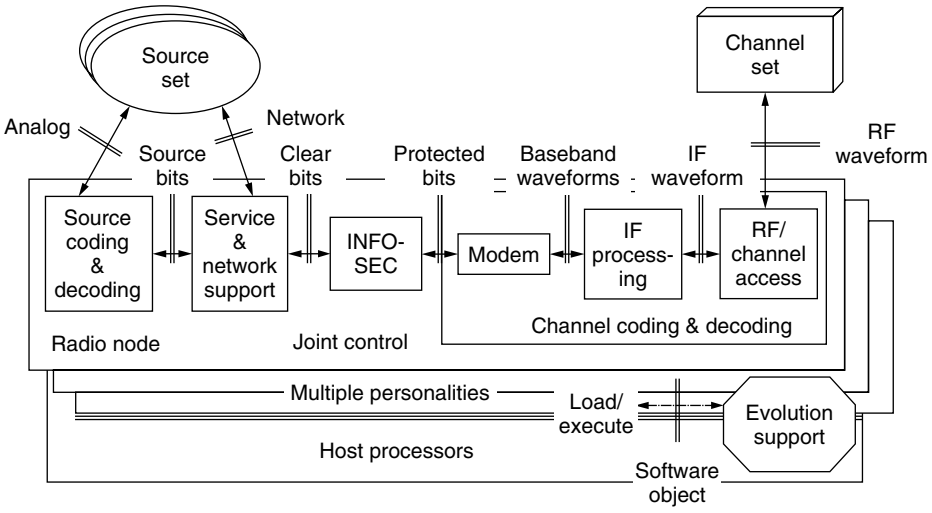

Figure 3. Standard interface points facilitate development, deployment, and evolution.

Not every implementation needs all sub-functions of this functional model. Thus, one may consider the functional model to be a point of departure for the tailoring of SDR implementations.

3.2. The Ideal Functional Interfaces

After identifying the functions to be accomplished in a software radio, one must define the interface points among the functional components. Figure 3 identifies these interfaces. The notation "RF waveform" includes spatial beamforming and the air interface. The IF waveform consists of signals filtered and converted to an intermediate carrier frequency that facilitates analog filtering, signal conditioning, and related analog processing.

In addition, IF processing may include A/D and D/A conversion. If so, some IF processing may be implemented digitally. Baseband waveforms are usually digital streams (e.g., of message packets or coded voice). These digital streams may also be sampled replicas of analog signals, such as digitized FM broadcast waveforms. The modem delivers what may be called *decoded channel bits* that may be encrypted ("black" bits in INFOSEC jargon) to the INFOSEC function if one is present. The modem transforms IF signals to channel bits. INFOSEC then transforms these protected bits into unencrypted ("clear")

bits (also called "red" bits). These bits may be manipulated through a protocol stack in order to yield source or network bit streams. Network bit streams conform to a network protocol, while source bits are appropriate for a source decoder. The interface to local sources of voice, music, video, and other media includes an analog transducer. Access to remote sources is accomplished via the network interface. In addition to these signal processing interfaces, there are control interfaces mediated by the user or network (both of which are source sets).

Personalities are downloaded to the radio via the software object interface. The simplest mechanism for maintaining radio software after deployment is the downloading of a complete binary image of the radio. A more flexible approach allows one to download a specific new function such as a specialized voice coder (vocoder). Such incremental downloads conserve network bandwidth at the expense of increased risk of configuration errors in the download process.

The interfaces thus defined may be thought of as the "horizontal" interfaces of the software radio, since they are concatenated to create the signal and control flows through functional components between sources and channels. These interfaces are further characterized in Table 2. Design-level interfaces ("design to") specify the data to be exchanged, while code-to interfaces directly or indirectly specify the exact format and meaning of each hardware signal, bit, word, byte, and message sequence of the interface.

In traditional radio engineering, these interfaces were addressed primarily in the design and development of the radio. For plug-and-play in software radio, they must be open architecture standards that facilitate the insertion of third-party components in deployment and operations. This is the business model that made the IBM PC a commercial success. How can such interfaces be standardized for industrywide third-party plug-and-play business to grow?

4. SOFTWARE-DEFINED RADIO (SDR) ARCHITECTURE

The *Random House Unabridged Dictionary* defines architecture as "a fundamental underlying design of computer hardware, software, or both" [38]. While this is an agreeable definition, it provides no prescription of what "underlying design" entails. The IEEE prescribes that architecture consists of components and interfaces. This leaves undefined what the components and interfaces are supposed to accomplish. The ideal software radio functional model and interfaces of the previous section begin to specify the functions of the architecture. The Defense Information Systems Agency (DISA) is the U.S. Department of Defense (DoD) agency charged with

Table 2. Top Level Component Interfaces

Interface	Characteristics	Properties
Analog stream	Audio, video, facsimile streams	Continuous, infinite dimensional; filtering constraints are imposed here
Source bit stream	Coded bit streams and packets; ADC, vocoder, text data compression [31]	Includes framing and data structures; finite arithmetic precision defines a coded, Nyquist [32] or oversampled dynamic range[a]
Clear bit stream	Framed, multiplexed, forward-error-controlled (FEC) bit streams and packets	FEC imparts algebraic properties over the Galois fields defined by these bit streams [33]
Protected bit stream	Random challenge, authentication responses; public key; enciphered bit streams [34] and packets	Finite-dimensional; randomized streams, complex message passing for downloads; if null, this interface reverts to clear bits
Baseband waveform	Discrete-time synchronous quantized sample streams (one per carrier)	Digital waveform properties determine fidelity of analytic representation of the signal
IF waveform	Composite, digitally preemphasized waveform ready for upconversion	Analog IF is continuous with infinite dimensions; digital IF may be oversampled
RF waveform	Power level, shape, adjacent channel interference, etc. are controlled	Analog RF: channel impulse response, spatial distributions via beams and smart antennas [35]
Network interface	Packaged bit streams may require asynchronous transfer mode (ATM), SS7, or ISO protocol stack processing	Synchronous digital hierarchy (SDH), ATM, and/or signaling system 7 (SS7)
Joint control	Control interfaces to all hardware and software; initialization; fault recovery	Loads binary images, instantiates waveforms, manipulates control parameters; cognitive joint control learns user needs [36]
Software objects	Download from evolution support systems	Represents binary images, applets; includes self-description of system capabilities [e.g., 37]
Load/execute	Software object encapsulation	Downloads require authentication and integrity

[a]A coded dynamic range is defined by the vocoder. Nyquist dynamic range results when an analog signal is sampled so as to meet the Nyquist criteria for bandwidth recovery of the sampled signal and has been quantized with sufficient bits of sufficient accuracy to represent the two-tone spurious-signal-free dynamic range of the application. Oversampling above the Nyquist rate can yield additional dynamic range through processing gain.

defining architecture. DISA defines architecture in terms of profiles for communications standards [39], defining architecture by analogy to "zoning laws and building codes" that constrain the construction of residential and industrial buildings [40].

4.1. Functions, Components, and Design Rules

None of the many possible definitions of architecture completely suits the architecture needs of the SDR community. One is needed that relates services, systems, technology, and economics. "Architecture" for SDR is therefore defined as a comprehensive, consistent set of *functions, components* and *design rules* according to which radio (and/or "wireless") communications systems may be cost-effectively organized, designed, constructed, deployed, operated, and *evolved over time*. This definition of architecture is consistent with the other definitions, but addresses more clearly the needs for plug-and-play and component reuse. By including functions and design rules, architecture supports component reuse, spanning component migration among hardware and software implementations.

The *design rules* must assure that when SDR hardware and software components are mated, the resulting composite entity accomplishes the intended functions within the performance bounds established by regulatory bodies, service providers, and users. The abstract functions and interfaces of the ideal SWR above constitute a horizontal architecture for software radio, an abstract functional flow from user to antenna and back. The ideal SWR does not specify the physical arrangement of physical components of an actual radio, of an SDR. Vertical levels are also needed to manage SDR hardware platforms and to achieve platform-independence of increasingly complex SDR software.

4.2. Plug-and-Play

In order for SDR architecture to support plug-and-play, design rules must be published that permit hardware and software from different suppliers to work together when plugged into an existing system. Hardware modules will plug-and-play if the physical interfaces and logical structure of the functions supplied by that module are compatible with the physical interfaces, allocation of functions, and related design rules of the host hardware platform. Software modules will plug-and-play if the individual modules and the SDR configuration of modules are computationally stable. For this, there must be a comprehensive interface to the host environment, and the module must describe itself to the host environment so the component can be managed as a radio resource. SDR architecture, then, defines the partitioning of functions at appropriate levels of abstraction so that software functions may be allocated to software components at appropriate levels of abstraction. SDR architecture defines the design rules, including design patterns [41,42] and interface standards. Rules defining logical levels of abstraction hide irrelevant details in the lower layers. These rules comprise a vertical architecture for SDR.

4.3. Vertical Architecture Design Rules

While horizontal architecture applies to any software radio, vertical architecture applies to radio implementations, SDRs. SDR components do not all share the same logical level of abstraction. A DSP module, for example, is part of the SDR platform. CORBA facilities are part of the software infrastructure on which ideal SWR functions are built using practical SDR software modules. In an advanced SDR, a modem may be a software module, a radio application. Bridging from one air interface to another is a service built on air interface radio applications. For example, in a military disaster-relief scenario, a SDR may bridge the Global System for Mobile communications (GSM) [43] to a military air interface like SINCGARS or HAVE QUICK [13]. One must therefore identify the SDR levels of abstraction that naturally partition the hardware and software into radio platforms, middleware,[3] radio applications, and communications services, as illustrated in Fig. 4.

In digital radios of the 1980s, the radio hardware platform ("radio platform") accomplished most of the RF and IF radio functions in hardware. The RF and IF parameters could be set through a microprocessor from a simple

[3] *Middleware* is software that insulates applications from the details of the operating environment (e.g., the hardware).

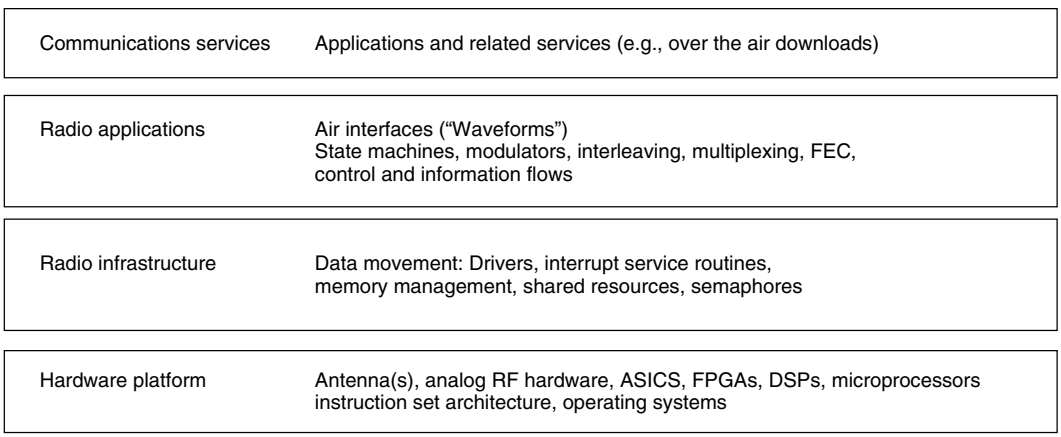

Figure 4. Logical levels of abstraction of the SDR implementations.

user interface or a low-speed data bus. Today's SDR platforms embody GFLOPS of processing capacity that host hundreds of thousands of LoC. This software performs the three top-layer functions of Fig. 4. At the infrastructure level, the code moves data among the distributed multiprocessors of the radio platform. At the applications level, software processes thus distributed cooperate to form radio applications, such as a 3G cellphone (cellular telephone) standard or a military waveform like HAVE QUICK. At the highest level of abstraction, applications software delivers communications services to users. Radio applications may incorporate specialized air interface protocols, and also may employ standard wireline data exchange protocols like TCP/IP.

One must define interfaces among these levels of abstraction, such as using an applications programming interface (API). APIs may map from one horizontal layer to the next. The API calls may be thought of as the vertical interfaces among horizontal layers. This approach has been used with reported success on SWR technology pathfinders [8]. The four layers of abstraction defined above are useful for defining software–software and software–hardware interfaces. Not all API's conform to these four layers. However, they are architecture anchors that help organize the process of evolving SDR implementations.

4.4. Mathematical Structure

Some mathematical principles illuminate the path toward SDR architecture. Some key principles are based on computability and point-set topology [44]. Consider transceiver state, consisting of a set of labels such as "Idle," "Synchronizing," "Receive," "Transmit," and "CarrierFault," asserted by other algorithms such as SquelchDetection (e.g., no squelch means the channel is Idle). SquelchDetection has possible wait states that have topological structure [45]. There is a set (e.g., of state labels, process names) with a family of subsets (e.g., the ones over which the software operations are valid), which has [or fails to have] topological properties. In addition, SDR architecture regarded as a collection of SDR implementations ("instances") has topological structure [46]. Maps over topological spaces define critical mathematical properties such as SDR module composability per the gluing lemma [47]. If the SDR has strong topological structure, then the insertion of plug-and-play components preserves the composability of software modules, including isochronism and controllability [48]. If not, then those critical properties cannot be guaranteed. In the absence of mathematical properties, one must test all possible configurations of SDR modules, a computationally intractable task for merely a few dozen downloadable SDR modules. Industry standards facilitate the application of such mathematical principles to broad classes of SDR.

4.5. Industry-Standard SDR Architectures

An important evolutionary step in the definition of vertical SDR interfaces is use of middleware (e.g., CORBA [49]) in SDR architecture. The Object Management Group (OMG) has defined an Interface Definition Language (IDL) in their Common Object Request Broker Architecture (CORBA). CORBA was developed primarily to define interfaces among software modules that were not originally designed to work together. IDL provides facilities for defining interfaces among software components through the mediation of an Object Request Broker (ORB). Since each new component implements only one interface to the ORB rather than N interfaces to the existing components, the process of integrating a new software component is greatly simplified.

The JTRS JPO began the development of its CORBA-based Software Communications Architecture (SCA) [50] in 1997. Version 2.2 (Fig. 5) includes the architecture specification with supplements on military security,

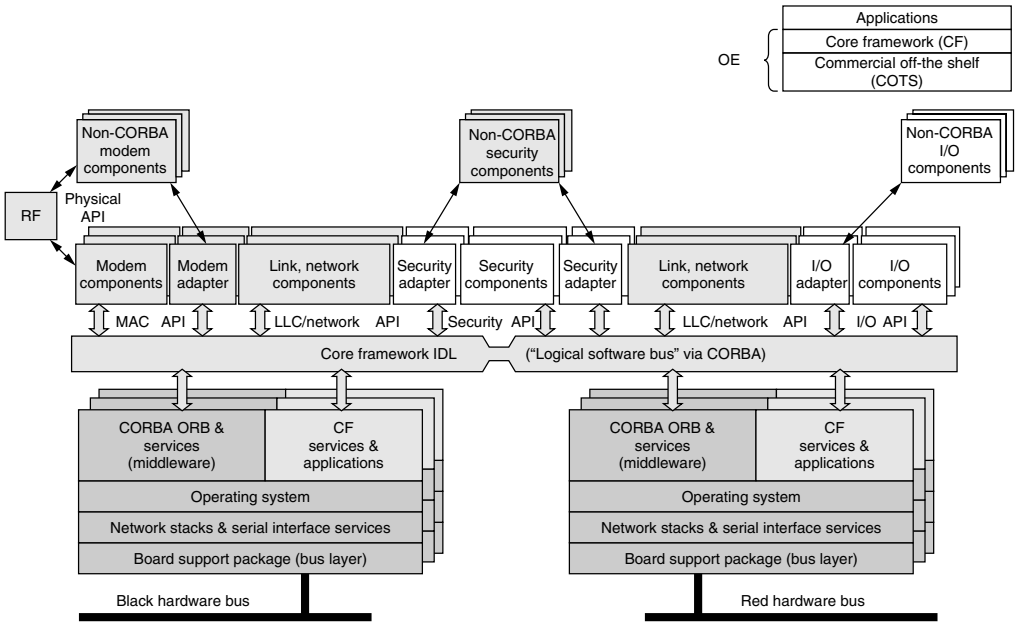

Figure 5. SCA Version 2.2.

APIs, and rationale. The framework applies UML to define hardware devices, software objects, and related interface rules. Its operating environment includes a core framework (CF) consisting of

1. *Base application interfaces* used by all software applications (Port, LifeCycle, TestableObject, PropertySet, PortSupplier, ResourceFactory, and Resource)
2. *Framework control interfaces*, used to control the system (Application, ApplicationFactory, Domain Manager, Device, LoadableDevice, ExecutableDevice, AggregateDevice and DeviceManager)
3. *Framework services interfaces* that support both core-compatible and non-core-compatible (vendor-unique and hardware-defined) applications (File, FileSystem, FileManager, and Timer)
4. A *domain profile* that describes the properties of hardware devices (DeviceProfile) and software components (SoftwareProfile) of the radio system using XML

Since this architecture does not yet map radio communications functions (e.g., 3G or military standards like HAVE QUICK) to its functional model, it provides a framework, an important first step toward plug-and-play architecture. In addition, its code-to level of specification is limited to the XML descriptions of interfaces. Therefore, different "fully compliant" implementations of a given air interface from two different vendors do not necessarily interoperate. For example, one implementation might specify RF in kilohertz while the other specifies it in Hz. With no units-consistency checking or remapping, the different software components would not use the facilities of the RF platform consistently. The government, academic, and industry bodies developing this standard plan to continue to evolve it towards an open-architecture plug-and-play standard.

5. SDR DESIGNS

Design-to and code-to architecture design rules assure that the critical properties of software radios are met as plug-and-play components are configured. Among these is the computational stability of the integrated software, a mathematical property emphasized above. Next is isochronism, the sufficiently precise timing of the real-time signal processing streams. Consider first the signal streams of an ideal SDR, illustrated in Fig. 6. These include a real-time isochronous channel-processing stream, a near-real-time environment management stream, an online control stream to manage the radio's configuration and modes of operation, and radio personalities from offline evolutionary development.

5.1. Real-Time Channel Processing Streams

In practical SDR designs, the real-time channel processing stream is a signal structure within the channel coding/decoding function. In an aggressive SDR design, each broadband channel (e.g., a cellular band) is accessed via a wideband ADC and DAC. This aspect of SDR design merits particular attention. The real-time stream generates subscriber channels in the transmit-path and isolates them in the receive path, such as by

1. Filtering of frequency-division multiple-access (FDMA) [51] waveforms
2. Timing recovery of time-division multiple-access (TDMA) [52] waveforms
3. Despreading military spread-spectrum [53] or commercial code-division multiple-access (CDMA) [54] waveforms

Historically, subscriber channel isolation was allocated to analog IF processing (e.g., in first-generation FDMA cellphones) or ASIC hardware (e.g., a CDMA cellphone).

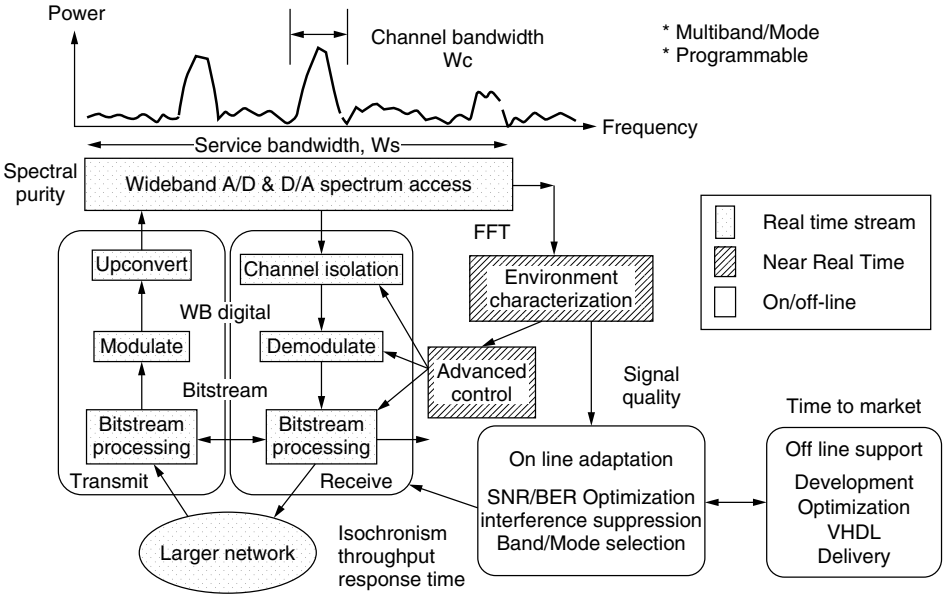

Figure 6. Signal processing streams of software radio.

When implemented in software, the isochronous processing windows for these functions are on the order of the time between DAC/ADC samples: microseconds to tens of nanoseconds. Modulation and demodulation of the channel waveform are also accomplished in the real-time channel-processing stream. Isochronous windows for these functions are on the order of tens to hundreds of microseconds. Once the narrowband subscriber bit streams are recovered, the timing of the isochronous windows increases to milliseconds. INFOSEC encryption and decryption, if applicable, are performed on the subscriber bit streams, with appropriately long isochronous windows — tens to hundreds of milliseconds. For baseband DSP, the time between digital samples (e.g., for baseband voice) is on the order of milliseconds to hundreds of microseconds. This allows plenty of time for processing between samples. In the software radio's IF stream, however, the time between samples is from tens of microseconds to hundreds of nanoseconds. Such point operations require Mflops to Gflops for isochronous performance. For isochronous performance, sampled data values must be computationally produced and consumed within short-buffer timing windows in order to maintain the integrity of the digital signal representation. Subscriber channels may be organized in parallel, resulting in a multiple-instruction multiple-datastream (MIMD) multiprocessing architecture [55]. Input/output (I/O) data rates of this stream approach 200 MB/s (megabytes per second) per IF ADC or DAC. Although these data rates are decimated through processing, to sustain isochronism blocks and events must be timed through I/O interfaces, FPGAS/ASICS and hard real-time embedded software in these streams.

To implement the approaches described above in a practical SDR design requires the integration of the real-time channel processing streams with related radio functions such as local oscillator (LO) signal generation. Figure 7 shows these radio signal flows structured into RF, IF, baseband, bit stream, and source segments, each with order-of-magnitude differences in isochronous windows. This view clarifies the sharing of the power management and low-noise amplifier (LNA) elements with RF conversion and with the RF frequency standard. These RF elements typically need physical proximity to the antenna. The LNA is placed near the antenna in order to set the system sensitivity. The power amplifier is near the antenna for power efficiency. The RF section may be remote from IF processing, such as in diversity architectures.

Digital IF processing in an SDR filters the wideband signal structure from the RF segment to yield the narrower baseband bandwidth. SDR ADCs appear at the IF–RF or RF–antenna interface. The baseband segment performs the modem functions, converting information between channel code and source code. The bit stream segment performs operations on bit streams, including multiplexing, demultiplexing, interleaving, framing, bit stuffing, protocol stack operations, and FEC. SDR system control is included in the bit stream segment because of the digital nature of control messages. The source segment includes the user, the local source and sink of information, and control. Source coding is the transformation of communications signals into bit streams if the design conforms to the ideal SWR functional partitioning described above. The organization of the design of SDR nodes into RF, IF, baseband, bit stream, and source segments promotes the application of a given talent pool and isochronous design discipline within a segment and minimizes the interdependencies between segments.

5.2. The Environment Management Stream

The other shaded boxes in Fig. 6 constitute the near-real-time environment management stream. In an ideal SWR, this stream continuously manages radio environment usage in frequency, time, and space. In a practical SDR design, the message exchanges with the host network are typically defined in specific signaling and multiple-access protocols. These traditionally include the assignment of traffic to clear channels, and the handoff of a mobile subscriber from one cell to the next. This may further include channel identification, equalization, and the estimation of parameters such as multipath time delays and cochannel interference levels. For example, the HF Automatic Link Establishment (ALE) protocol

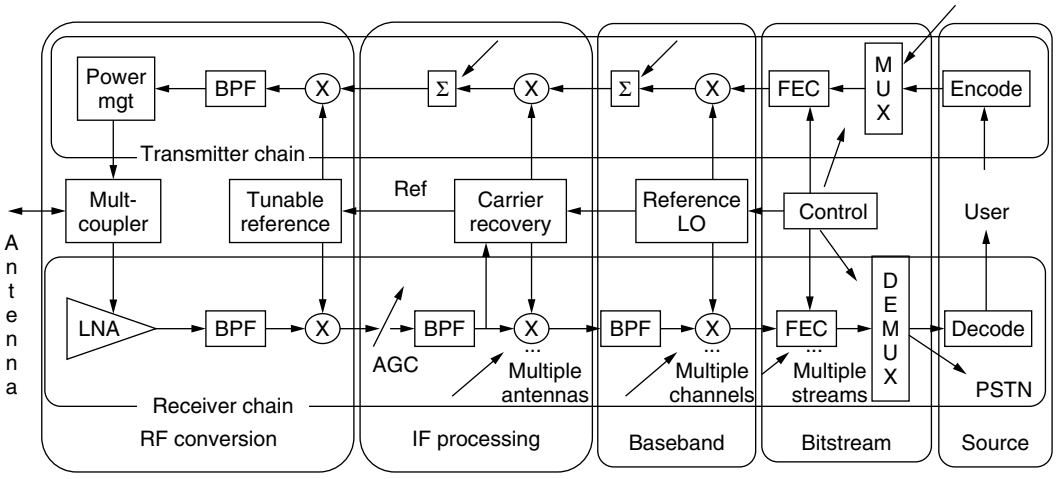

Figure 7. SDR isochronous and interdependent signal flows.

includes probes and responses that characterize several assigned channels [56]. The ALE data are then sent on the channel that is best for the specific subscriber location. In orthogonal FDM (OFDM), narrowband channels with excessive interference may be dynamically deallocated from use [57]. The environment management stream may employ block operations such as matrix multiplications for smart-antenna beamforming. Real-time adaptation by smart antennas may respond to signal parameters computed on every TDMA burst or CDMA symbol. GSM, for example, requires channel identification within 540 μs–2 ms. This establishes top-down limits on the execution time of environment management software. Forgiving operations, such as power-level updates may be refreshed every few frames. Location-aware services (e.g., emergency 911 cellphone location) typically define timing requirements for subscriber emitter location.

5.3. Online Adaptation: Mode Selection and Download Management

Online adaptation includes mode selection, as suggested in Fig. 6, as well as download management. A practical SDR is a multiband/multimode radio. The graceful transition from one RF band or air interface mode to another is called "mode handover." Military radios may change modes as a function of information priority, RF propagation, and other military criteria. An air interface mode typically defines the QoS provided by that mode. 3G air interfaces offer a wide range of data rates. Generally, high data rates require high signal-to-noise ratio (SNR[4]) for a required bit error rate (BER). Online adaptation selects the appropriate air interface mode to satisfy the competing goals of the user and/or of the network. Because of the number and complexity of 3G modes, ITU standards define mode handover in detail.

As modes become more elaborate, users are confronted with an increasing array of choices of QoS versus price. The burden of choosing RF band and mode in the future will be shared among the user, the network, and intelligent wireless appliances [e.g., personal digital assistant (PDA)], SDRs that employ natural-language processing and machine learning to assist the user with mode selection are called "cognitive radios" [18]. Because of Moore's law, cognitive wirelesses PDAs are likely to emerge soon, along with cognitive networks [58]. Cognitive PDAs and networks provide interesting cross-discipline research opportunities, fostering collaboration across natural-language processing, cognitive science, and radio engineering. In the past, mode control was primarily up to the network. As wireless LANs, home wireless networks, and intelligent transportation systems converge with cellular technology, cognitive PDAs will shape offered demand, for example, by delaying a large email attachment until the connection is free.

SDR personality management by over-the-network download also adapts the behavior of practical SDRs. Prior to SDR, the flexibility of RF access of a handheld wireless device was limited to merely choosing one of several predefined air interface modes. With SDR, parameters of the predefined modes may be modified along with higher-level software functions such as the user interface, network applications and air interface protocols.

[4] The SNR may be expressed in terms of unmodulated carrier and interference (CIR), or signal to interference plus noise (SINR).

5.4. Offline Adaptation: The Software Factory

Offline SDR development environments define SWR personalities. Offline functions include radio systems analysis, enhanced algorithms, hardware platform creation, and the rehosting of existing software to new hardware/software platforms. These functions assist in defining incremental service enhancements. For example, an enhanced beamformer, equalizer, and trellis decoder may be developed to increase subscriber density. These enhancements may be prototyped and linked into the channel processing stream in a research, testbed, or evaluation facility [59]. Such an arrangement allows one to debug the algorithm(s) and to experiment with parameter settings prior to deploying new personalities. One may determine the value of the new feature (e.g., in terms of improved subscriber density), as well as its cost. Network traffic to download such features constitutes overhead. Offline adaptation thus includes the definition of personalities [60], download protocols [61], and download traffic [62].

5.5. Software Tools

An advanced SDR does not just transmit a waveform. It characterizes the available transmission channels, probes the available propagation paths, and constructs an appropriate channel waveform. It may also electronically steer its transmit beam in the right direction, select the appropriate power level and pick an appropriate data rate before transmitting. Again, an advanced SDR does not just receive an incoming signal. It characterizes the energy distribution in the channel and in adjacent channels, it recognizes the mode of the incoming transmission, and it creates an appropriate processing stream. With a smart antenna, it also adaptively nulls interfering signals, estimates the dynamics of the multipath, coherently combines desired-signal multipath, and adaptively equalizes this ensemble. It may also trellis decode the channel modulation and then correct residual errors via FEC decoding to receive the signal with the lowest possible bit error rate (BER). Such operations require a family of software components and related tools, including those illustrated in Fig. 8.

Figure 8 organizes software tools according to the time-criticality of the supported software functions. In an SDR, hard real-time software may be delivered as the personality of an ASIC or FPGA. Reduced time-criticality means the function is more compatible with software implementation. The tradeoff among ASIC, FPGA, and software changes with each 18-month Moore's law cycle. The columns labeled C (criticality) and A (availability) identify SDR challenge areas. Bit interleaving, for example, is not challenging in terms of either its criticality to SDR architecture or its availability as a software component. Interference suppression, on the other hand,

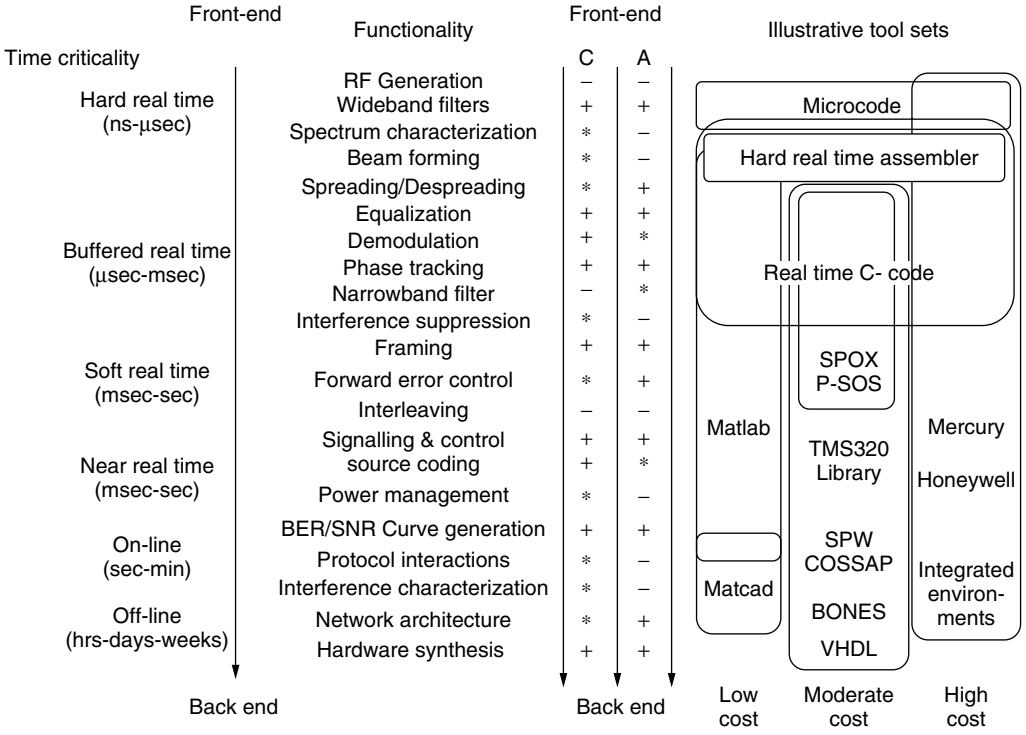

Figure 8. Toolsets of a software factory. (C = criticality; A = availability; $*$ = key performance driver; $+$ = important issue).

is a critical issue differentiating SDR from conventional radios; it also can be a performance driver. To the right are three columns of toolsets that represent the sophistication of the software factory. One may develop software radio products of limited scope [e.g., <40 kloc 40,000 lines of code] using the low-cost tools in the first column. As team size grows, or the mix of ASICs, FPGAs, and DSP hardware in the delivery environment becomes more complex, the investment of tens of thousands of dollars (per design seat) pays off. The largest, most complex systems benefit from the high-cost tool suites costing millions of dollars per system.

5.6. SDR Technology Alternatives

Technology alternatives for digital radios, SDR, and software radios are characterized in the software radio parameter space of Fig. 9. The parameter space compares two critical SDR technology parameters: digital access bandwidth and the flexibility of the processing platform. Digital access bandwidth is approximately half of the sampling rate of the widest bandwidth ADC in the isochronous signal-processing path. Thus, for example, an ideal SDR with 5 GHz conversion rate supports nominally a 2.5-GHz analog bandwidth, based on the Nyquist criterion [32]. Similarly, wideband digital-signal synthesis, digital upconversion, and wideband DAC yield an ideal software radio transmitter.

ADCs with continuous conversion bandwidths of >6 GHz have been built [63], although they are expensive. If all the processing after the ADC were accomplished on a single general-purpose computer, one would have an ideal software radio receiver (the point marked X in the figure). Using a rule of thumb of 100 operations per sample, the digital filtering of a 5-GS/s (gigasamples per second) stream to access a 25-MHz band of RF spectrum requires 500 gigamultiplications (5×10^{11}) per second. This processing capacity is about two orders of magnitude beyond 2002-generation DSPs [64,65] and three or four beyond general-purpose computers. This translates to about 6–10 Moore's law cycles or only 10–15 years of continued exponential development of DSP technology and an additional 5 years beyond that of general purpose computing technology.

Another limitation of the ideal SWR is that no single antenna nor RF stage can sustain the analog bandwidth from 2 MHz to 2.5 GHz RF with reasonable losses or power efficiency. The single wideband RF required for the 5 GHz ADC (and for the transmitter/DAC) is therefore not feasible. Antenna and RF stages depend on properties of materials that have stubbornly resisted pushing bandwidths beyond one RF decade, a 10 : 1 ratio of high to low RF. Thus, the ideal SWR is not possible with today's technology. The ideal properties of such a radio are a useful reference point for measuring progress towards generality and flexibility.

Practical SDR implementations limit RF coverage to medium or narrowband antennas, RF conversion, and IF processing technology. They also use a mix of digital technologies including ASICs, FPGAs, DSP, and general-purpose processors. Examples are illustrated in the figure. The STR-2000 (point *A* in Fig. 9) was an early baseband HF DSP radio developed by Standard Marine AB. This radio digitized its HF IF signal at a 24 kHz sampling

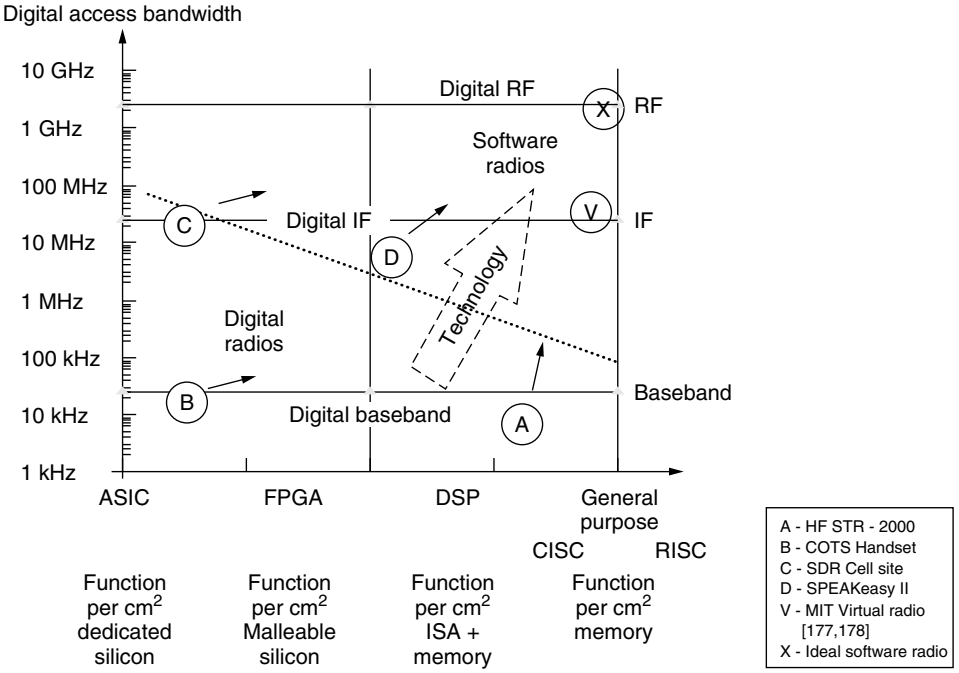

Figure 9. Software radio parameter space.

rate. It used twin Texas Instruments (TI) TMS320C30 DSPs to provide a half-dozen standard HF signal formats digitally. This is readily accomplished by amateur radio operators using general-purpose processors today [66,67]. Second-generation (e.g., GSM) COTS SDR handsets (point *B* in Fig. 9) minimize size, weight, and power using a direct-conversion receiver [68] RF-ASIC [69], and baseband DSP. Combining such ASICs in a handset enclosure for a dual-mode cellphone creates a "Velcro radio" [70]. Aggressive implementations incorporate high-density FPGAs to provide software-driven configurability in a delivery platform that maximizes throughput for a given technology clock rate [71]. 3G CDMA researchers employ FPGAs to replace despreader ASICs [72]. These FPGAs have greater speed and power efficiency for a given clock rate than do DSPs. In addition, the personality of an FPGA can be upgraded in the field by software download. On the other hand, FPGAs lack the silicon area and computational flexibility of the DSP instruction set architecture (ISA). With increasing chip density and area, system-on-chip (SoC) architectures of the near future are likely to include both fixed ISA and variable-personality FPGA coprocessors.

Contemporary software radio cell-site designs (point *C* in Fig. 9) access the allocated unlink[5] RF using a single ADC, such as with 25 MHz of analog bandwidth (viz., 70 MHz conversion rate). These designs employ a bank of digital filter ASICs [73] or parallel digital filters [74] to access a hundred or more subscriber channels in parallel. Research radios like the European ACTS Flexible Interoperable Radio System Technology (FIRST) used Pentek boards [75] with Harris parallel digital filter ASICs. The larger commercial cellular infrastructure suppliers include Alcatel, Ericsson, Fujitsu, Lucent, Motorola, Nippon Electric Corp (NEC), Nokia, NorTel, Siemens, and Toshiba. Although all contribute to open research, few publish the details of their commercial SDR handset or infrastructure products. Research supported by one or more of these industry leaders, explores ASIC [76], DSP [77], and FPGA [78] cell sites [79,80], some with smart antennas [81–82,83]. In addition, emerging products now include ADCs with 200 MHz of bandwidth with >80 dB dynamic range with integrated digital IF processing [84].

Technologically aggressive designs include SPEAK*easy*, the military technology pathfinder. SPEAK*easy* II (point *D* in Fig. 9), which became the baseline for Motorola's WITS 6000 software radio product line [85], incorporated over a Gflops of processing capacity for enhanced flexibility, substantial DSP in 1996–1998. The virtual radio (point *V* in Fig. 9) is the most flexible software radio research implementation reported in the literature [86]. A general purpose DEC Alpha processor running UNIX accesses a wideband IF digitally. Narrowband AM and FM broadcast receivers and an RF LAN were implemented purely in software on this platform. The related SpectrumWare software technology is being commercialized for military and commercial applications [87].

None of the designs *A*–*X* in Fig. 9 is a panacea: the architecture question is the degree of digital RF access and programmability required for the intended market. Contemporary radio designs therefore vary across the dotted line in the phase space. Advancing microelectronics technology moves all implementations inexorably upward and to the right over time. The three fundamental waveform limitations of any SDR implementation, then, are RF access, digital access bandwidth, and digital processing flexibility and capacity.

[5] The *uplink* is the link from mobile to base station. The *downlink* is the reverse link.

5.7. SDR Radio Reference Platform

The definition and use of a radio platform facilitates the evolution of SDR implementations through generations of hardware and software releases. It also enhances the use of UML, CASE tools, and middleware. A radio reference platform is a high-level characterization of the capabilities of the hardware environment of the software radio. Table 3 identifies the critical radio platform parameters that determine the performance of a software radio.

The parameters of Table 3 should be specified with precision. If the platforms in the family are tested for conformance to a well-specified reference platform, then software developed for one member of the family should port readily to another member of the family. The software will not port well (and may not port at all) if special features of the platform beyond the reference set are used. The specification of a minimum level of capability for each parameter defines a reference platform for a family of software radio implementations. Illustrative platforms are suggested in Table 4. The PDAs will have replaced conventional cell phones in this vision of the future. Given the reference platforms, they will have broadband RF, multiple parallel data channels, and wide digital processing bandwidth (BMW).

Devices now in development, mostly in proprietary settings promise to bring such platforms to market in the 2002–2007 timeframe. Such reference platforms closer to the ideal software radio are beginning to make economic and technical sense in infrastructure applications. A reference platform need not have an associated block diagram, but it is often convenient to use such a diagram in the analysis of the feasibility of a reference model.

The reference design of Fig. 10, illustrates the value of a reference platform, but has the following drawbacks. First, it implies that ADCs and DACs are the interface between the digital processing and analog RF sections of the radio. That is often the case, but an ultrawideband (UWB) [88] communications system, for example, uses subnanosecond pulses to spread the communications over 2 GHz or more of bandwidth. These pulses are both transmitted and received with analog circuits, not with DACs and ADCs. The primary value is to associate critical parameters with physical devices in such a way that one may outline an evolutionary path for software radio architecture.

6. DEVELOPMENT PARAMETERS AND RISKS

In 1992 when Mitola [89] introduced the term, almost nobody knew what a "software radio" was. By 1996, 6 months after the publication of the special issue of the *IEEE Communications Magazine* on the software radio, almost every radio vendor claimed to have one. The term had become an industry "buzzword." By 1999, it had become widely understood that nobody even *wanted* to offer an ideal software radio product because one would be unaffordable or inefficient or both. Thus, in 1996, the acronym SDR was introduced as the family affordable, practical implementations of software radio [90]. Today,

Table 3. Software Radio Reference Platform Parameters

Critical Parameter	Remarks
Number of channels	Number of parallel RF, IF, and/or baseband channels
RF access	Continuous coverage from a minimum to a maximum RF
Digital bandwidth	Bandwidth of the maximum ADC for each RF/IF channel
Dynamic range	End to end, including RF, IF, ADC, and processing gain
Interconnect bandwidth	Bandwidth of critical buses, serial ports, backplanes, etc.
Timing accuracy	The precision and stability of system clock(s)
Frequency performance	RF, IF, and local oscillator (LO) accuracy and stability
Processing capacity	Mips, Mflops using standard benchmarks, arithmetic precision (per processor class if appropriate)
Memory capacity	RAM, ROM per processor; mass storage capacity
Hardware acceleration	Parameterize capabilities encapsulated in hardware such as despreader ASICS, FPGAs, and related hybrids.
Operating environment	Operating system and related facilities (including CORBA middleware), interfaces (e.g., APIs), and measured determinism

Table 4. Illustrative Mobile SDR Reference Platforms

Notional Platform	RF Access (MHz)	Channels	Digital Bandwidth (MHz)
Lowband PDA	450–1200	3 (traffic, control, rental)	5
Midband PDA	850–2500	3 (traffic, control, rental)	20
Lowband military	30–500	4 (voice, 2 data, 1 scan)	10
Midband military	88–1200	4 (voice, 2 data, 1 scan)	20
Wideband military	800–4000	6 (4 JTIDS, 1 voice, 1 scan)	250

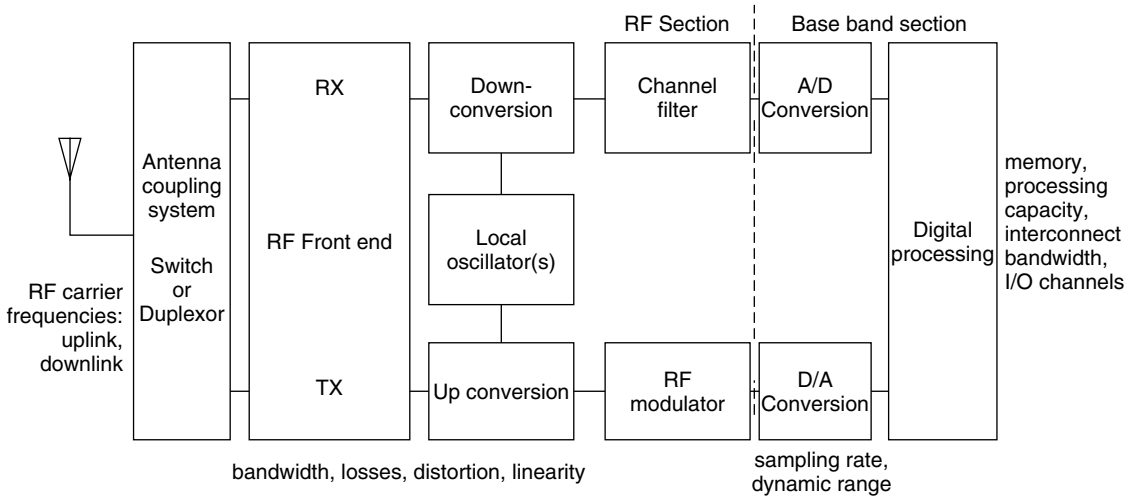

Figure 10. Reference design for an SDR implementation.

SDR is regarded as a ubiquitous technology that is key to the affordable evolution of military and commercial wireless markets. The four key characteristics of SDR from a development or acquisition perspective are

1. The number of air interface channels simultaneously supported (N)
2. The level of programmable digital access (PDA)
3. The degree of hardware modularity (HM)
4. The scope of software flexibility and affordability (SFA)

The number N defines hardware risk. There is low risk with single channel SDRs. With multiple channel (i.e., $N<6$), and full channel access (i.e., N is the full number of subscribers in an allocated RF band), risks increase. Two to four channel nodes are typical of military, civil aviation, and law enforcement hub applications. The full access class is typical of cellular base-station infrastructure. Single-channel SDR provides a baseline of minimum development risk and complexity. Multiple channel nodes require distributed multiprocessing. With small numbers of channels, hardware efficiency per channel is not a major challenge. It becomes a market-discriminator for the full access class, however. This class also carries maximum risk of mismatch between the processing demand offered by the software and the processing capacity deliverable by the hardware. Matching demand to capacity is therefore an essential design issue for practical SDR implementations.

The level of PDA is the point in the software radio functional model at which the conversion to digital occurs. This defines the scope over which the radio's functions are programmable with substantial flexibility. The types of PDA include baseband programmability, IF programmability, and RF programmability.

HM identifies the economic impact of the differences in hardware upgrade paths. Architecture may be based on capability-oriented coarse-grain (possibly programmable) modules such as receivers and exciters that are specific to an air interface. Alternatively, architecture may be based on technology-oriented coarse-grain modules such as COTS ADC and DSP boards. Finer grain modules such as FPGA, ADC and DSP chips are also candidate modules. Finally, the system-on-a-chip approach defines module as a chunk of intellectual property (IP). The granularity of hardware modularity is not prejudicial, but should be determined by the needs of the market segment.

SFA characterizes the service provider's ability to acquire plug-and-play software modules that are driven by a vital, multisupplier marketplace. Software that runs on just one radio platform and is available from only the original manufacturer tends to box the service provider into single-source (sometimes very expensive) maintenance and upgrade paths. If the functionality of the unit will not change over its lifecycle, then this may be a perfectly acceptable path. This would be a rare occurrence in today's fast-moving marketplaces, however. Software that runs on many platforms (e.g., Java) and is available from multiple vendors generally gives the service provider a better software product with more flexibility and at a lower cost over the lifecycle than the alternatives.

7. BROADER IMPLICATIONS

The prospect of a new technology of multiband, multimode software radios — handsets and infrastructure — has social and political implications. Type certification authorities, for example, are charged with administering the equitable use of radio spectrum. Among other things, they certify that radio equipment meets legally imposed constraints. In addition, software radios may operate on any RF band that is within the capabilities of the underlying radio platform, and with any mode for which a software load-image is available. This raises the possibility of truly novel approaches to spectrum management. One of the more interesting is the possibility that software radios could use a spectrum rental protocol to autonomously share spectrum. Another is that by incorporating advanced agent technology, they could evolve their own protocols. As mentioned previously, radios capable of such behavior are called "cognitive radios" [18].

7.1. Type Certification

The prospect of an evolving radio platform raises substantial questions among regulatory bodies about type certification. In remarks before the SDR Forum, the U.S. FCC [91] described type certification of software radios as presenting "regulatory issues." These include the following:

1. To which service(s) is an SDR approved?
2. Is a new approval needed for each "change" to an approved SDR unit?
3. How does the FCC enforce the equipment authorization rules for SDRs?
4. How can an unauthorized use of an SDR be prevented?

Regulators rely on a mix of tactics to achieve their goals. Industry is required to obtain licenses for some uses of spectrum, while others are available without a license, provided the manufacturer complies with the regulations. The FCC relies on legal remedies to motivate manufacturers to comply with the rules. They generally specify license requirements in terms of RF power output, modulation, occupied bandwidth, spurious emissions, and frequency stability (over temperature and voltage supply variations). Analog radios embody these parameters in hardware, so the type certification process has historically focused on the certification of devices. Digital radios, similarly, embody these parameters in a mix of analog and digital hardware, so the process remains valid. Current-generation SDRs with baseband programmable digital access embody these parameters in relatively fixed core images that are tightly coupled to the hardware, and this is compatible with the current process as well.

However, SDRs with at IF programmability embody these parameters in software that is loosely coupled to the hardware. Each combination of band and mode has to be certified separately, according to today's process. Over the air downloads to the SDR complicate the certification process substantially. At present, regulators in the United States are in the process of obtaining the advice of industry through an expected request for comments on proposed rule-making. Industry has the challenge of assisting regulators in defining a certification process that is responsive to the broader social and legal issues, but that does not seriously impede the benefits of SDR technology. Open architecture in some ways exacerbates the certification challenges. A proliferation of software packages enabled by open architecture drives the combinatorial complexity of type certification. Must a service provider certify every possible combination of software modules from every possible vendor? A helpful architecture might have properties that simplify and expedite type certification.

7.2. Incremental Download Stability and Type Certification

In addition to defining a partitioning, an architecture may define principles that assure that plug-and-play with desired properties of controllability and reliability. For example, to type-certify an open-architecture SDR, one must guarantee that the properties specified by the regulatory bodies will be preserved *in spite of the software radio's high degree of flexibility*. The need for such guarantees motivates the study of the mathematical properties of the software radio [92]. For example, one may model the statistical demand for computational resources versus processing capacity using queuing theory [93,94]. Real-time performance can be assured in a fixed architecture using this approach.

The plug-and-play SDR, however, has a *variable architecture* as modules are introduced into the environment and removed. This raises the complexity of the statistics, particularly in complex nodes. In a future 3G cell site, for example, hundreds of users can invoke dozens of variable-bandwidth services via a pool of shared DSP resources. To make this tractable, there should be a predictable relationship of computational demand between plug-and-play software modules and the host processor environment. This calls for a theory of plug-and-play resource bounds for the software radio within which such predictable relationships will exist. The fact that radio software must run to complete in a short, finite time period that can be specified in advance leads to a proof that radio software need not be Turing-computable [92]. The theory translates into a prohibition on unconstrained "while" and "until" loops. These have to be replaced by bounded-while and bounded-until loops that are allowed to run at most n times before generating a protection fault. The related theory of bounded recursion shows how a compiler can calculate n for the programmer so there is no additional programming burden to obtain this protection. Without such protection, while loops may run forever, consuming unacceptable amounts of time and processing power.

This theoretical advance makes it possible for one to provide a software engineering environment that can place tight upper bounds on the computational resources of an arbitrary radio software module. One may therefore prove by induction that a bounded recursive downloaded module will consume resources that are within tightly specified a-priori limits when loaded into a bounded recursive system. This can reduce the combinatorial complexity of the type certification of incremental software downloads. Given, for example, M vocoders and N air interfaces, a bounded recursive software system need test only $M + N$ software configurations, proving the other $MN - (M + N)$ configurations by induction. This supports the incremental download of the M vocoders, reducing download bandwidth on the network. Conventional software has to test all MN integrated load images. Furthermore, a change of vocoder requires the download of a complete load image, with increased network overhead. This article therefore sets forth the technical issues that underlie this tradeoff between network overhead and download complexity.

7.3. Spectrum Management Implications

Given that SDRs will continue to become more capable, one can ask whether they might have some fundamental impact on our approach to the use of the radio spectrum. A new research area, cognitive radio, suggests that this might indeed be the case [18]. Wireless multimedia applications require significant bandwidth, some of which

will be provided by third-generation 3G services. Even with substantial investment in 3G infrastructure, the radio spectrum allocated to 3G will be limited. Cognitive radio is a particular extension of software radio that employs model-based reasoning about users, multimedia content, and communications context. Cognitive radio offers a mechanism for the flexible pooling of radio spectrum using a new class of protocols called "formal radio etiquette." This approach could expand the bandwidth available for conventional uses (e.g., police, fire, and rescue) and extend the spatial coverage of 3G in a novel way. This section characterizes the potential contributions of cognitive radio to spectrum pooling and outlines an initial framework for formal radio etiquette protocols.

Figure 11 illustrates important aspects of spectrum allocation.

Bandwidth that could be made available for the sharing of spectrum, based on current allocations to mobile users, is summarized in Table 5.

The literature describes a protocol for spectrum rental among cognitive radios and infrastructure [95]. The effective use of this new protocol requires software radios that always know where they are (e.g., in latitude, longitude, and altitude above mean sea level), and which embed propagation models that include terrain and buildings. In addition, they must know what their users are doing (e.g., shopping, which is a low precedence use, or in need of emergency assistance, which is a high precedence use). Cognitive radios accomplish this by parsing all incoming and outgoing messages and voice traffic, and analyzing this information to establish the user's priority for use of spectrum. In addition, cognitive infrastructure can offer unused radio spectrum for rent for as little as one second in a microcell. Alternatively, rentals may allow use for minutes to hours in macrocells. The cognitive protocol includes listening for legacy radios to attempt to use the spectrum so that the cognitive radios may politely defer to legacy users. Police, for example, may require the renters to immediately yield the spectrum back to the renting authority. The protocol supports the return of spectrum within 30 ms. Throughput is enhanced if the legacy users can wait for $\geq$0.5 s before being guaranteed clear spectrum.

Table 5. Mobile Spectrum Pools

Band	RF_{min}	RF_{max}	W_c	Remarks
Very low	26.9	399.9	315.21	Long-range vehicular traffic
Low	404	960	533.5	Cellular
Mid	1390	2483	930	PCS
High	2483	5900	1068.5	Indoor and RF LANs

Although cognitive radios may not be practical for years to come, the research points in an interesting direction for spectrum managers. Instead of hard-allocations with primary and secondary users, the spectrum managers at some point in the not-too-distant future should be able to delegate the details of spectrum management to the radios themselves. The spectrum managers would then assume the higher-level task of specifying the rules the radios have to follow to ensure equitable access that conforms to social, political, and legal norms.

This article has provided an overview of software radios. It began top-down by introducing the functional model of the software radio. Next, it introduced the important aspects of software, especially the need for isochronism in multiband multimode radios that share a pool of processing resources among multiple users. A range of hardware implementations were introduced, to differentiated among digital radios, PDRs, SDRs, and ideal software radios. This led to the characterization of acquisition parameters that divide software radios into broad classes. Finally, broader implications were

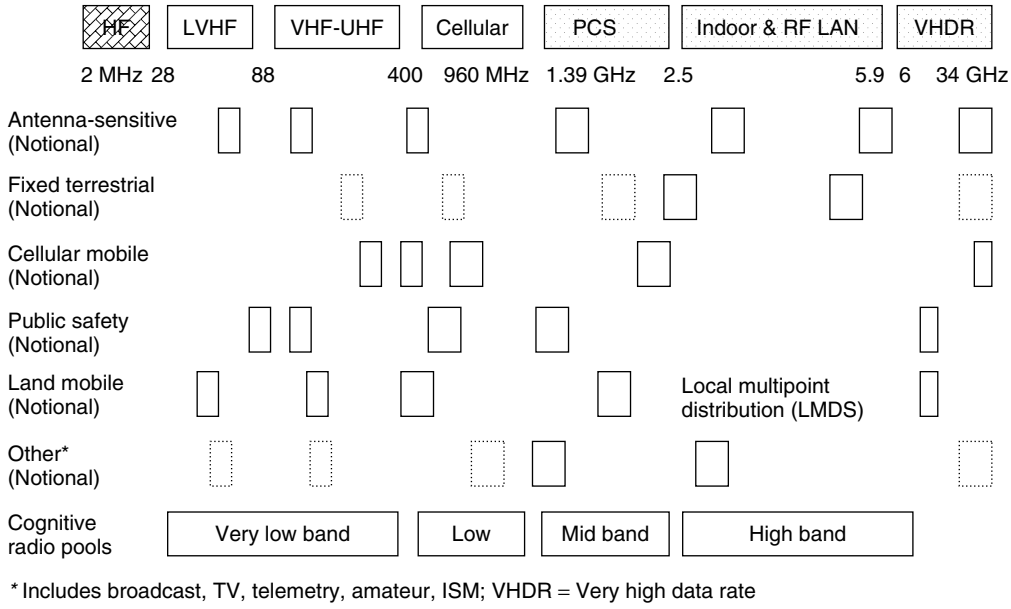

Figure 11. Potential spectrum pools.

presented, including the apparent challenge of type-certifying software radios. The chapter concluded with a view towards the future of the software radio — the evolution toward the cognitive radio.

8. CONCLUSION

Software radio has proved to be a valuable abstraction for the radio science, engineering, and user communities. During 2001, over 65 technical papers published in refereed journals of the IEEE and ACM included software radio or SDR as a theme. Although not a perfect metric, it indicates the degree to which the SWR/SDR abstraction is shaping research and technology development on a global scale. Practical SDR implementations continue to emerge with increasingly wider bandwidths and more tailored air interface capabilities. The challenges to the ideal software radio pose important research challenges, notably in the physics of antennas and RF conversion. The opportunities for innovative SDR implementations continue to attract substantial investments as the potential of this technology to reshape the physical layer of RF communications remains fertile ground.

ACRONYMS

3G/4G	Third- and fourth-generation wireless
ADC	Analog-to-digital-converter
ALE	Automatic Link Establishment, an HF air interface protocol
API	Applications programmer interface
ASICs	Application-specific integrated circuits
BER	Bit error rate
C3	Command-and-control communications
CASE	Computer-aided software engineering
CDMA	Code-division multiple access
CF	Core framework (of the JTRS/SDRF/OMG SCA)
CORBA	The Common Object Request Broker Architecture
DAC	Digital-to-analog converters
DARPA	The Defense Advanced Research Projects Agency
DISA	Defense Information Systems Agency
DMR	Digital modular radio
DoD	Department of Defense (U.S.)
DSP	Digital signal processor (or processing)
EC	The European Community, Brussels, Netherlands
ETSI	European Telecommunications Standards Institute
FDMA	Frequency-division multiple access
FEC	Forward error control
FPGA	Field programmable gate arrays
Gflops	Giga-floating-point operations per second
GHz	Gigahertz, 10^9 Hz
HF	High frequency, nominally 3–30 MHz
Hz	Hertz, cycles per second (e.g., of RF carrier frequency)
I/O	Input/output
IDL	Interface Definition Language
IEEE	Institute of Electrical and Electronics Engineers
IF	Intermediate frequency
INFOSEC	Information Security
IP	Internet Protocol, as in TCP/IP
ISA	Instruction set architecture
ITU	International Telecommunications Union
JTRS	Joint Tactical Radio System
kHz	Kilohertz, 10^3 Hz
LNA	Low-noise amplifier
LO	Local oscillator
loc	Lines of code
LVHF	Low VHF, typically 28–88 MHz
MHz	Megahertz, 10^6 Hz
Mips	Millions of instructions per second
OMG	Object Management Group
ORB	Object Request Broker
PCS	Personal communications system
PDA	Personal digital assistant
PSTN	Public Switched Telephone Network
PTT	Push to talk
QoS	Quality of service
RF	Radiofrequency
SCA	Software Communications Architecture
SDL	Specification and Description Language (ITU Standard Z.100)
SDR	Software-defined radio
SDRF	SDR Forum
SDR Forum	See *www.sdrforum.org*
SNR	Signal-to-noise ratio
SWR	Software radio
TCP	Transmission Control Protocol, usually used with IP, as in TCP/IP
TDMA	Time-division multiple access
UHF	Ultrahigh frequency, typically 300–3000 MHz
UML	The Unified Modeling Language
VHF	Very high frequency, typically 30–300 MHz
XML	The eXtensible Markup Language

BIOGRAPHY

Dr. Joseph Mitola III is an internationally recognized expert on software radio systems and technologies. In addition to having published the first paper on software radio architecture in 1992, he teaches in the United States, Asia, and Europe. He was Founding Chair of the SDR Forum in 1996 and co-chairs the Forum's Technical Symposium, November 2002. He published the first interdisciplinary graduate text on SWR, *Software Radio Architecture* [Wiley Interscience]. His doctoral dissertation, *Cognitive Radio* (KTH, June 2000), created the first teleinformatics framework for autonomous software radios, integrating machine learning and language processing into software radio. He edited the IEEE text *Software Radio Technologies*. With The MITRE Corporation, Dr. Mitola applies his expertise in telecommunications and information processing to the national and tactical needs of DoD. More recently he served as Senior Program Manager at the Defense Advanced Research Projects Agency and General Systems Engineer of the Defense Airborne Reconnaissance Office

(DARO). Prior to MITRE, Dr. Mitola was the Chief Scientist of Electronic Systems, E-Systems Melpar Division, culminating a career at E-Systems that began in 1976. He has also held positions of technical leadership with Harris Corporation, Advanced Decision Systems, and ITT Corporation. He began his career with the U.S. DoD in 1967. Dr. Mitola holds the B.S. in EE (Northeastern University '72); M.S.E. (The Johns Hopkins University, 1974); Licentiate in Engineering (May 1999), and Doctorate in Teleinformatics (The Royal Institute of Technology, KTH, Stockholm, June 2000).

SPACE–TIME CODES FOR WIRELESS COMMUNICATIONS

A. R. CALDERBANK
AT&T Shannon Laboratory
Florham Park, New Jersey

AYMAN F. NAGUIB
Morphics Technology Inc.
Campbell, California

Space–time coding is a communications technique for wireless systems that employ multiple transmit antennas and single or multiple receive antennas. Information theory has been used to demonstrate that multiple antennas have the potential to dramatically increase achievable data rates. Space–time codes realize these gains by introducing temporal and spatial correlation into the signals transmitted from different antennas. There is, in fact, a diversity gain that results from multiple paths between base station and mobile terminal, and a coding gain that results from how symbols are correlated across transmit antennas. Significant increases in throughput are possible with only two antennas at the base station and one or two antennas at the mobile, and with simple receiver structures. The second antenna at the mobile terminal can be used to further increase system capacity through interference suppression. This article provides an overview of space–time coding techniques and the associated signal processing framework for narrowband and broadband wireless communications.

Current cellular standards such as IS136 support circuit data and fax (facsimile) services at a rate of 9.6 kbps (kilobits per second), and a packet data mode is now being standardized. Rapid growth in mobile computing and other wireless data services is inspiring many proposals for high-speed data services in the range of 64–384 kbps for microcellular wide-area and high-mobility applications, and up to 2 Mbps for indoor applications [1].

However, data rates on band–limited wireless channels are limited by multipath fading and interference from other users [2–8]. Deploying multiple antennas at the both the transmitter and the receiver increases the capacity of wireless channels, and information theory provides measures of this increase [9–11]. The standard approach to increasing capacity is to use linear processing at the receiver with optimum linear combining to combat multipath fading and suppress interference [3,4]. Here, the received signals are weighted and combined to maximize the signal-to-interference-plus-noise ratio (SINR) at the receiver. By contrast, transmit diversity schemes use processing at the transmitter to spread the information across multiple transmit antennas. The earliest forms of transmit diversity were proposed by Uddenfeldt and Raith [12] and Wittneben [13]. The latter is a delay diversity scheme where a signal is transmitted from one antenna, then delayed one symbol, and transmitted from a second antenna. Wittneben's work includes the delay diversity scheme of Seshadri and Winters [14] as a special case (see also Refs. 15 and 16). Winters [17] showed that delay diversity is optimal in the sense that the diversity order experienced by an optimal receiver is equal to the number of transmit antennas. Diversity is the link-level advantage (over a single path) obtained from spreading information over multiple independent paths from base station to mobile unit. Note that superposition of fading statistics at the receiver also reduces variation in signal strength, and allows smoother and more efficient power control. This means that the base station can support significantly more users for a given constraint on radiated signal power. Space–time coding [18–25] combines correlation techniques designed for multiple transmit antennas with the appropriate signal processing at the receiver to provide significant gain over the delay diversity schemes in Refs. 13 and 14.

This article is organized as follows. Section 1 describes fundamentals of space–time coding for flat-fading channels. Equalization schemes necessary for implementation of space–time codes over frequency-selective channels are discussed in Section 2, and channel estimation issues are discussed in Section 3. An extensive reference list is provided to help the reader undertake a more detailed study of any of the topics discussed.

1. SPACE–TIME CODING

This section presents a mathematical model of a *narrowband* communications system with N_t transmit antennas and N_r receive antennas and it assumes a flat-fading channel (see Section 2 for frequency-selective channels). As shown in Fig. 1, the space–time encoder transforms the input data at time l into N_t code symbols

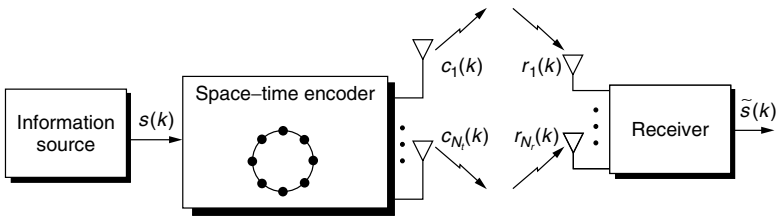

Figure 1. Space–time coding.

$c_1(l), c_2(l), \ldots, c_{N_t}(l)$ that are transmitted *simultaneously* from the different transmit antennas.

Signals arriving at different receive antennas undergo independent fading. The signal at each receive antenna is a noisy superposition of the faded versions of the N_t transmitted signals. Let E_s be the average energy of the signal constellation. The constellation points are scaled by a factor $\sqrt{E_s}$ so that the average energy of the constellation points is 1. Let $r_j(l), j = 1 \cdots N_r$ be the received signal at antenna j after matched filtering. Assuming ideal timing and frequency information, we have

$$r_j(l) = \sqrt{E_s} \cdot \sum_{i=1}^{N_t} \alpha_{ij}(l) c_i(l) + \eta_j(l), \qquad j = 1, \ldots, N_r \tag{1}$$

where $\eta_j(l)$ are independent samples of a zero-mean complex white Gaussian process with two-sided power spectral density $N_0/2$ per dimension. It is also assumed that $\eta_j(l)$ and $\eta_k(l)$ are independent for $j \neq k$, $1 \leq j, k \leq N_r$. The gain $\alpha_{ij}(l)$ models the complex fading channel gain from transmit antenna i to receive antenna j. The channel gain α_{ij} is modeled as a lowpass-filtered complex Gaussian random process with zero mean, variance 1, and autocorrelation function $R_\alpha(\tau) = J_0(2\pi f_d \tau)$, where $J_0(\cdot)$ is the zeroth-order Bessel function of the first kind and f_d is the maximum Doppler frequency [26]. It is assumed that signals transmitted from different antennas are subject to independent fades. This can be achieved by separating transmit antennas by more than half the underlying wavelength or by using antennas with different polarizations.

Let $\mathbf{c}_l = [c_1(l), \ldots, c_{N_t}(l)]^T$ be the $N_t \times 1$ *codeword* transmitted from the N_t antennas at time l, $\alpha_j(l) = [\alpha_{1j}(l), \ldots, \alpha_{N_t j}(l)]^T$ be the corresponding $N_t \times 1$ channel vector from the N_t transmit antennas to the jth receive antenna, and $\mathbf{r}(l) = [r_1(l), \ldots, r_{N_r}(l)]^T$ be the $N_r \times 1$ received signal vector. Also, let $\eta(l) = [\eta_1(l), \ldots, \eta_{N_r}(l)]^T$ be the $N_r \times 1$ noise vector at the receive antennas. Furthermore, let us define the $N_r \times N_t$ channel matrix $\mathcal{H}_l$ from the N_t transmit to the N_r receive antennas as $\mathcal{H}(l) = [\alpha_1(l), \ldots, \alpha_{N_r}(l)]^T$. Equation (1) can be rewritten in a matrix form as

$$\mathbf{r}(l) = \sqrt{E_s} \cdot \mathcal{H}(l) \cdot \mathbf{c}_l + \eta(l) \tag{2}$$

We can easily see that the *signal-to-noise ratio* (SNR) *per receive antenna* is given by

$$\text{SNR} = \frac{N_t \cdot E_s}{N_0} \tag{3}$$

1.1. Space–Time Trellis Codes (STTCs)

Suppose that the *codeword* sequence

$$\mathcal{C} = \mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_L$$

were transmitted and consider the probability that the decoder decides erroneously in favor of another legitimate codeword sequence

$$\tilde{\mathcal{C}} = \tilde{\mathbf{c}}_1, \tilde{\mathbf{c}}_2, \ldots, \tilde{\mathbf{c}}_L$$

Assume a data frame of length L and define the $N_t \times N_t$ error matrix $\mathcal{A}$ as

$$\mathcal{A}(\mathcal{C}, \tilde{\mathcal{C}}) = \sum_{l=1}^{L} (\mathbf{c}_l - \tilde{\mathbf{c}}_l)(\mathbf{c}_l - \tilde{\mathbf{c}}_l)^* \tag{4}$$

The squared distance between $\mathcal{C}$ and $\tilde{\mathcal{C}}$ at the output of the wireless channel turns out to be proportional to $\sum_{j=1}^{N_r} \mathcal{H}_j^* \mathcal{A}(\mathcal{C}, \tilde{\mathcal{C}}) \mathcal{H}_j$, where $\mathcal{H}_j$ is the column vector of path gains from the different transmit antennas to the jth receive antenna. The vector $\mathcal{H}_j$ varies with time, and when it finds the null space of $\mathcal{A}(\mathcal{C}, \tilde{\mathcal{C}})$, the jth receive antenna experiences a deep fade. Diversity gain is just the minimum rank of $\mathcal{A}(\mathcal{C}, \tilde{\mathcal{C}})$, where the minimization is over all pairs of codewords. Coding gain depends on the product of the nonzero eigenvalues, and again there is a minimization over all pairs of codewords.

If ideal channel state information (CSI) $\mathcal{H}(l), l = 1, \ldots, L$ is available at the receiver, it is straightforward to show that the probability of transmitting $\mathcal{C}$ and deciding in favor of $\tilde{\mathcal{C}}$ is upper-bounded by

$$P(\mathcal{C} \to \tilde{\mathcal{C}}) \leq \left(\prod_{i=1}^{p} \lambda_i \right)^{-N_r} \cdot \left(\frac{E_s}{4N_0} \right)^{-pN_r} \tag{5}$$

where p is the rank of the error matrix $\mathcal{A}$ and $\lambda_i, i = 1, \ldots, p$ are the nonzero eigenvalues of the error matrix $\mathcal{A}$ (see Ref. 27 for details). The bound on probability of error given in Eq. (5) is similar to the probability of error bound for trellis-coded modulation for flat-fading channels. The first term $g_p = (\lambda_1 \lambda_2 \cdots \lambda_p)$ represents the coding gain achieved by the space–time code, and the second term $(E_s/4N_0)^{-pN_r}$ represents a diversity gain of pN_r. This analysis leads to two design criteria for space–time codes. The first is to maximize the rank p of $\mathcal{A}(\mathcal{C}, \tilde{\mathcal{C}})$, thereby maximizing diversity gain. The second, for a given diversity gain p, is to maximize the coding gain g_p.

Now consider the problem of decoding space–time codes. Under the assumption that ideal CSI $\mathcal{H}(l), l = 1, \ldots, L$ is available at the receiver, we can derive the maximum-likelihood (ML) decoding rule for the space–time code as follows. Suppose that all codewords are equiprobable, a codeword

$$\mathcal{C} = \mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_L$$

has been transmitted, and

$$\mathcal{R} = \mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_L$$

has been received, where $\mathbf{r}_l$ is given by Eq. (2). At the receiver, optimum decoding amounts to choosing a codeword sequence

$$\tilde{\mathcal{C}} = \tilde{\mathbf{c}}_1, \tilde{\mathbf{c}}_2, \ldots, \tilde{\mathbf{c}}_L$$

for which the a posteriori probability

$$\Pr(\tilde{\mathcal{C}} | \mathcal{R}, \mathcal{H}(l), l = 1, \ldots, L)$$

is maximized. Since the noise vector is assumed to be a multivariate AWGN (additive white Gaussian noise), it can be easily shown [27] that the optimum decoder is

$$\tilde{\mathcal{C}} = \arg \min_{\tilde{\mathcal{C}} = \tilde{\mathbf{c}}_1, \cdots, \tilde{\mathbf{c}}_L} \sum_{l=1}^{L} \| \mathbf{r}(l) - \sqrt{E_s} \cdot \mathcal{H}(l) \cdot \tilde{\mathbf{c}}_l \|^2 \tag{6}$$

It is obvious that the optimum decoder in (6) can be implemented using the Viterbi algorithm (VA) when the space–time code has a trellis representation.

Figure 2 shows an 8-PSK 8-state space–time code designed for two transmit antennas, where the edge label xy means that symbol x is transmitted from the first antenna and symbol y, from the second antenna. The different symbol pairs in a given row label the transitions (edges) out of a given state, in order, from top to bottom. Observe that labels on edges leaving a given state disagree in the first position. It follows that the rank of the matrix $\mathcal{A}(\mathcal{C}, \tilde{\mathcal{C}})$ corresponding to codewords $\mathcal{C}$ and $\tilde{\mathcal{C}}$ (that diverge and then remerge) is equal to 2. The reader may verify that, for odd-numbered states, if the symbol transmitted from the first antenna is negated, the result is the delay diversity scheme proposed by Wittneben. Both schemes provide a diversity gain of 2, but with the space–time code there is an additional coding gain of 2.5 dB.

1.2. Space–Time Block Codes (STBCs)

When the number of antennas is fixed, the decoding complexity of space–time trellis coding (measured by the number of trellis states at the decoder) increases exponentially as a function of the diversity level and transmission rate [22]. In addressing the issue of decoding complexity, Alamouti [18] discovered a remarkable space–time block coding scheme for transmission with two antennas. This scheme supports maximum-likelihood detection based only on linear processing at the receiver. It was later generalized [19] to an arbitrary number of antennas and is able to achieve the full diversity promised by the number of transmit and receive antennas. Here, we will briefly review the basics of space–time block codes [18]. Figure 3 shows the baseband representation for transmit diversity employing space–time block coding with two transmit antennas. The input symbols to the space–time block encoder are divided into pairs. At a given symbol period, the two symbols in each group $\{c_1, c_2\}$ are transmitted simultaneously from the two antennas. The signal transmitted from antenna 1 is c_1, and the signal transmitted from antenna 2 is c_2. In the next symbol period, the signal $-c_2^*$ is transmitted from antenna 1 and the signal c_1^* is transmitted from antenna 2. Let h_1 and h_2 be the channel gains from the first and second transmit antennas to the receive antenna, respectively. The major assumption here is that h_1 and h_2 are constant over two consecutive symbol periods:[1]

$$h_i(nT) = h_i((n+1)T), \qquad i = 1, 2$$

Let r_1 and r_2 be the received signals over two consecutive symbol periods. Then

$$r_1 = h_1 c_1 + h_2 c_2 + \eta_1 \tag{7}$$

$$r_2 = -h_1 c_2^* + h_2 c_1^* + \eta_2 \tag{8}$$

where η_1 and η_2 represent the AWGN and are modeled as i.i.d. complex Gaussian random variables with zero mean and power spectral density $N_0/2$ per dimension. Define the received signal vector $\mathbf{r} = [r_1\ r_2^*]^T$, the codeword vector $\mathbf{c} = [c_1\ c_2]^T$, and the noise vector $\eta = [\eta_1\ \eta_2^*]^{\mathbf{T}}$. Equations (7) and (8) can be rewritten in a matrix form as

$$\mathbf{r} = \mathbf{H} \cdot \mathbf{c} + \eta \tag{9}$$

where the channel matrix $\mathbf{H}$ is defined as

$$H = \begin{bmatrix} h_1 & h_2 \\ h_2^* & -h_1^* \end{bmatrix} \tag{10}$$

The vector η is a complex Gaussian random vector with zero mean and covariance $N_0 \cdot \mathbf{I}$. Define $\mathcal{C}$ as the set of

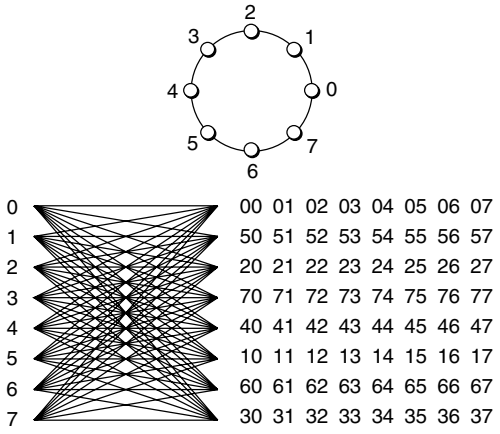

Figure 2. 8-PSK 8-state space–time code with two transmit antennas and a bandwidth efficiency of 3 bits/channel use.

[1] For GSM (Global System for Mobile Communication) mobiles traveling at 60 mph (mi/h) and a carrier frequency of 1 GHz, the channel coherence time is around 11 ms, which is about 3000 GSM symbol durations. Hence, the channel can be safely assumed constant over several hundred symbol durations even at highway speeds. For IS136 mobiles, the symbol duration is around 41 μs; hence, the channel can be assumed constant over few tens of consecutive symbols. Therefore, the assumption of a fixed channel over two consecutive symbols is satisfied for both systems.

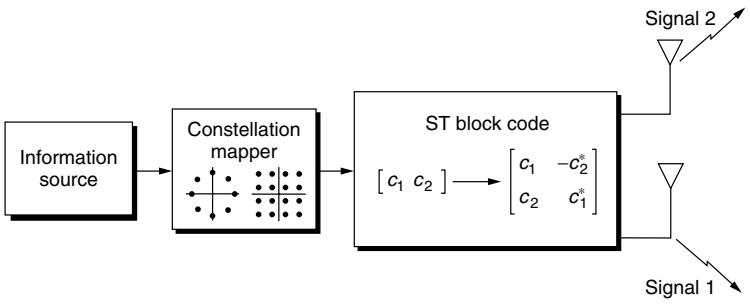

Figure 3. Transmit diversity with space–time block coding.

all possible symbol pairs $\mathbf{c} = \{c_1, c_2\}$ and assume that all symbol pairs are equiprobable. Since the noise vector η is assumed to be a multivariate AWGN, it follows that the optimum ML decoder is

$$\hat{\mathbf{c}} = \arg\min_{\hat{\mathbf{c}} \in \mathcal{C}} \|\mathbf{r} - \mathbf{H} \cdot \hat{\mathbf{c}}\|^2 \tag{11}$$

The ML decoding rule in this equation can be further simplified by realizing that the channel matrix $\mathbf{H}$ is orthogonal ($\mathbf{H}^*\mathbf{H} = (|h_1|^2 + |h_2|^2) \cdot \mathbf{I}$). Consider the modified received signal vector $\tilde{\mathbf{r}}$ given by

$$\tilde{\mathbf{r}} = \mathbf{H}^* \cdot \mathbf{r} = (|h_1|^2 + |h_2|^2) \cdot \mathbf{c} + \tilde{\eta} \tag{12}$$

where $\tilde{\eta} = \mathbf{H}^* \cdot \eta$. In this case the ML decoding rule becomes

$$\hat{\mathbf{c}} = \arg\min_{\hat{\mathbf{c}} \in \mathcal{C}} \|\tilde{\mathbf{r}} - (|h_1|^2 + |h_2|^2) \cdot \hat{\mathbf{c}}\|^2 \tag{13}$$

Since $\mathbf{H}$ is orthogonal, it follows that the noise vector $\tilde{\eta}$ will have a zero mean and covariance $(|h_1|^2 + |h_2|^2) \cdot \mathbf{I}$, that is, the elements of $\tilde{\eta}$ are independent and identically distributed. Hence, it follows immediately that simple linear combining reduces the ML decoding rule in Eq. (13) to two separate, and much simpler, ML decoding rules for c_1 and c_2, as established elsewhere [18]. Assuming that we are using a signaling constellation with 2^b constellation points, this linear combining reduces the number of decoding metrics that have to be computed for ML decoding from 2^{2b} to 2×2^b. It is also straightforward to verify that the SNR for c_1 and c_2 will be

$$\text{SNR} = \frac{(|h_1|^2 + |h_2|^2) \cdot E_s}{N_0} \tag{14}$$

and hence a two-branch diversity performance is obtained at the receiver. When the receiver uses N_r receive antennas, we can write the received signal vector $\mathbf{r}_m$ at receive antenna m and 2, respectively as

$$\mathbf{r}_m = \mathbf{H}_m \cdot \mathbf{c} + \eta_{\mathbf{m}} \tag{15}$$

where $\eta_{\mathbf{m}}$ is the noise vector and $\mathbf{H}_m$ is the channel matrix from the two transmit antennas to the mth receive antenna. In this case the optimum ML decoding rule is

$$\hat{\mathbf{c}} = \arg\min_{\hat{\mathbf{c}} \in \mathcal{C}} \sum_{m=1}^{N_r} \|\mathbf{r}_m - \mathbf{H}_m \cdot \hat{\mathbf{c}}\|^2 \tag{16}$$

As before, in the case of N_r receive antennas, the decoding rule can be further simplified by premultiplying the received signal vector $\mathbf{r}_m$ by $\mathbf{H}_m^*$. In this case, the diversity order provided by this scheme is $2N_r$. Figure 4 shows a simplified block diagram for the receiver with two receive antennas. The properties of the space–time block coding scheme in Fig. 4 and its extension in Ref. 19 can be further exploited to improve wireless capacity and/or throughput. The reader is referred to Ref. 28 for further discussion on this point.

2. EQUALIZATION OF SPACE–TIME CODES ON FREQUENCY-SELECTIVE CHANNELS

As the transmission bandwidth increases beyond the *coherence bandwidth* [29] of the channel, equalization becomes indispensable. Equalization complexity increases with the channel memory (also referred to as the *channel delay spread*), signal constellation size, and the use of multiple transmit and/or receive antennas. The objective of this section is to give an overview of candidate equalization schemes for space–time-coded transmission over broadband wireless channels. In this article, we use the terms *frequency-selective channel*, *broadband channel*, and *intersymbol interference* (ISI) *channel* interchangeably.

We start in Section 2.1 by describing the frequency-selective channel model and assumptions. Effective equalization schemes for STTC and STBC are discussed in Sections 2.2 and 2.3, respectively.

2.1. Channel Model and Assumption

The channel impulse response (CIR) from transmit antenna i to receive antenna j is denoted by the vector $\mathbf{h}_{ij}$. The multiple-input/multiple-output (MIMO) channel memory, denoted by ν, is the maximum memory of all constituent single-input/single-output (SISO) channels. For simplicity, we focus on the case $N_t = 2$ and $N_r = 1$, hence, $\mathbf{h}_{ij}$ will be simply denoted by the vector $\mathbf{h}_i$ or its corresponding D-transform $h_i(D) \stackrel{def}{=} \sum_{k=0}^{\nu} \mathbf{h}_i(k) D^k$. Extension to the general case is straightforward. The CIRs are assumed constant over the transmission block (quasistatic fading) and vary independently from block

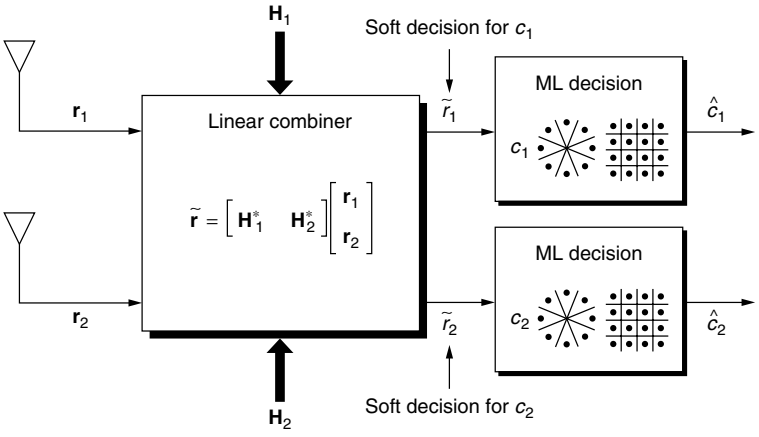

Figure 4. Receiver for space–time block coding.

to block. The input symbols are assumed complex zero-mean and belong to a 2^b signal constellation. The noise is additive white Gaussian and independent of the input.

2.2. Equalization Schemes for Space–Time Trellis Codes

Our focus will be on the 8-state 8-PSK STTC shown in Fig. 2. This code has a rich and transparent structure that can be exploited to simplify equalization.

1. *Turbo Equalization*. While it is possible in theory to model the STTC and the ISI channel, separated by an interleaver,[2] by a single trellis and perform maximum a posteriori (MAP) decoding on this trellis using, for instance, the BCJR (Bahl–Cocke–Jelinek–Raviv) algorithm [30], the complexity would be prohibitive. An alternative lower-complexity decoding scheme views the space–time encoder and the ISI channel, separated by an interleaver, as a serial concatenation of two finite-state machines that can be decoded iteratively using the *Turbo principle* [31]. Using this Turbo equalization scheme, joint space–time equalization and decoding is performed by iteratively exchanging *soft* extrinsic information between the separate BCJR-MAP equalizer and decoder modules. Hard decisions are generated only after the last iteration. The BCJR algorithm consists of a forward and a backward recursion and is usually implemented in the log domain to reduce computational complexity and improve numerical accuracy. Turbo equalization achieves remarkable performance very close to theoretical performance limits [32]. The number of states in the BCJR equalizer module is *exponential* in the channel memory, the number of transmit antennas, and the spectral efficiency (in bps/Hz). The use of MIMO FIR shortening prefilters [33] to reduce the complexity of the BJRC equalizer module and its application to STTC have been studied in [34]. However, for spectrally efficient modulation schemes (such as 8-PSK modulation used in EDGE[3]), the complexity of turbo equalization is still too high [36]. In addition, the long decoding delay might not be acceptable for speech and real-time data applications. An attractive alternative in this case is the M-BCJR equalizer described next.

2. *Prefiltered M-BCJR Equalizer*. The M-BCJR algorithm [37], is a reduced-complexity version of the BCJR algorithm [30] where at each trellis step, only the M active states associated with the highest metrics are retained. An improved version of the M-BCJR algorithm was proposed [38] and applied to the equalization of STTC. Moreover, it was shown [38] that preceding the M–BCJR equalizer with a channel-shortening prefilter improves its performance, especially for small values of M. Even better performance is achieved when a different prefilter is used for the forward and backward recursions of the M-BCJR algorithm. The value of M and the number of prefilter taps can be jointly optimized to achieve the best performance–complexity tradeoffs.

3. *Prefiltered MLSE/DDFSE Equalizer*. Unlike the BJCR-MAP equalizer, which minimizes the *symbol* error probability, maximum-likelihood sequence estimation (MLSE) minimizes the *sequence* error probability assuming equally likely inputs and can be implemented efficiently using the VA. A major advantage of the BCJR-MAP algorithm over the conventional VA[4] is the generation of *soft* information on the decisions. Generalization of the MLSE equalizer to the MIMO case was first reported by Van Etten [40]. For a 2^b signal constellation, N_t transmit antennas, and MIMO channel memory of ν, the MIMO MLSE equalizer has $2^{b \cdot N_t \cdot \nu}$ states in general. The number of equalizer states can be reduced to $2^{b \cdot \nu}$ by using the STTC trellis structure as shown in Ref. 41. However, this complexity is still too high for large signal constellations and long MIMO channel memory. Delayed decision feedback sequence estimation (DDFSE) was introduced [42] as a hybrid scheme between MLSE and decision feedback equalization (DFE) [43] for channels with long memory. Basically, the CIR is divided into a leading part and a tail. Then, an MLSE equalizer is constructed on the basis of the leading part, and the interfering effect of the CIR tail is canceled by feedback using previous (hard) decisions (assumed correct). Like all feedback schemes, DDFSE suffers from error propagation effects. These effects are minimized if most of the channel energy is concentrated in its leading part (as in minimum-phase channels). This is the task of the FIR prefilter designed [44] to improve DDFSE performance in equalizing the 8-state 8-PSK STTC [41].

4. *Orthogonal Frequency Division Multiplexing* (*OFDM*). In OFDM, the high-rate input stream is demultiplexed and transmitted over N low-rate independent frequency subcarriers. This multicarrier transmission scheme is implemented digitally using the efficient fast Fourier transform (FFT) method [45]. OFDM is a block transmission scheme; therefore, a guard sequence (of length at least equal to channel memory) is needed to eliminate interblock interference (IBI). The most popular choice for guard sequence is a *cyclic prefix*, which makes the channel matrix *circulant*; hence, diagonalizable by the FFT. If the FFT size is made large enough such that the width of each frequency bin is less than the *coherence bandwidth* of the channel, then no equalization is needed.[5] A large FFT size (compared to channel memory) also reduces the guard sequence overhead at the expense of increased storage and processing requirements and increased delay which might not be acceptable for delay-sensitive applications.

The OFDM scheme has been extended to the MIMO case [46]. OFDM was successfully applied to equalization of STTC [47].

[2] The randomizing effect of the interleaver is critical to the remarkable performance exhibited by Turbo schemes.

[3] EDGE stands for *enhanced data rates for GSM evolution* and is the proposed third-generation TDMA cellular standard [35].

[4] A modified soft-output Viterbi algorithm (SOVA) was presented by Hagenauer and Hoeher [39]. However, its performance is suboptimal compared to that of BCJR-MAP.

[5] Except for a simple gain and phase adjustment using a single complex tap for each subchannel, assuming negligible intercarrier interference due to Doppler effects or frequency offset errors.

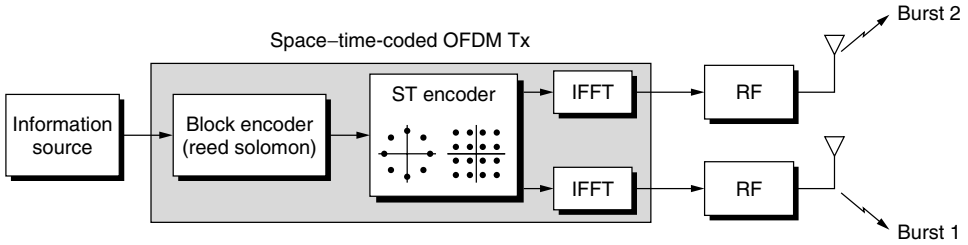

Figure 5. Transmitter for space–time-coded OFDM for broadband applications.

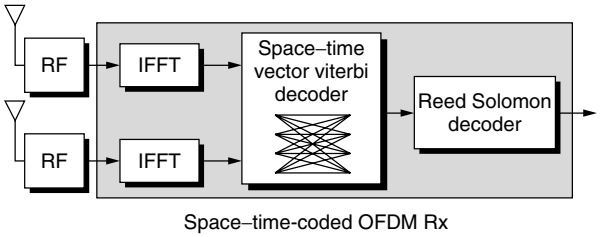

Figure 6. Receiver for space–time-coded OFDM for broadband applications.

Figures 5 and 6 show simplified block diagrams for the transmitter and receiver, respectively, for an OFDM modem with a concatenated space–time coding scheme. The input information symbols are first encoded by an outer conventional channel code. The output of the outer code is then space–time-encoded. Each of the space–time code output streams is then OFDM-modulated and sent over the corresponding antenna. At the receiver, the signal at each receive antenna is OFDM-demodulated. The demodulated signals from the antennas are then fed into the space–time decoder followed by the outer decoder. Figure 7 shows the simulation results for the abovementioned OFDM space–time-coded modem. In this simulation, the available bandwidth is 1 MHz, and the maximum Doppler frequency is 200 Hz. The number of OFDM tones used for modulation is 256. These correspond to a subcarrier separation of 3.9 kHz and OFDM frame duration of 256 μs. To each frame, a cyclic prefix of 40 μs duration is added. Each tone modulates a 4-PSK constellation, although higher-order constellations may be used. We used 16-state 4-PSK space–time code with two transmit and two receive antennas. In addition, an outer (72,64,9) RS code over Galois Field GF(2^7) is used. We plot the frame error probability as function of SNR for different channel delay spreads. From this plot, we can see that an E_b/N_0 between 2.7-4 dB (depending on the delay spread) is needed to achieve a data rate of 1.5 Mbps.

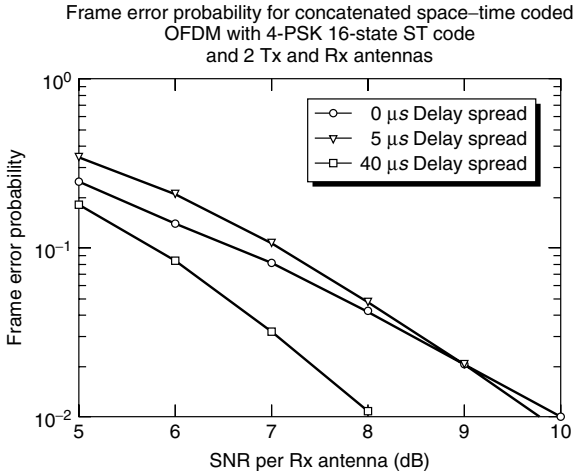

Figure 7. FER of concatenated space–time-coded OFDM with 4-PSK 16-state STC with 2Tx and 2Rx antennas.

2.3. Equalization Schemes for Space–Time Block Codes

Our focus will be on the case of two transmit antennas described in Section 1.2, where a full-rate STBC can be constructed for any signal constellation.

1. *Time-Reversal Space–Time Block Coding* (*TRSTBC*). TRSTBC was introduced [48] as an extension of the Alamouti STBC scheme [18] to frequency-selective channels by imposing the Alamouti orthogonal structure at a *block*, *not symbol*, level as in the flat-fading channel case. At the receiver, TRSTBC employs clever time-domain processing to eliminate the mutual interference effects between the two inputs *while still achieving the maximum diversity gain* of $|\mathbf{h}_1|^2 + |\mathbf{h}_2|^2$. Effectively, TRSTBC converts the two-input/single-output channel to two SISO channels, each with equivalent impulse response $h_{\text{eqv}}(D) = h_1(D)h_1^*(D^{-1}) + h_2(D)h_2^*(D^{-1})$ to which standard SISO equalization schemes such as MLSE [49] or DFE [50] can be applied. TRSTBC assumes that the two channels $h_1(D)$ and $h_2(D)$ are fixed over two consecutive transmission blocks and perfectly known at the receiver and that guard symbols (of length at least equal to channel memory) are inserted between data blocks to eliminate IBI.

2. *Orthogonal Frequency-Division Multiplexing* (*OFDM*). An elegant scheme for combining OFDM and STBC by implementing the Alamouti orthogonal structure at a block level was first reported by Liu et al. [51]. This OFDM–STBC scheme achieves the *full* diversity gain of $|\mathbf{h}_1|^2 + |\mathbf{h}_2|^2$ without bandwidth expansion for two transmit antennas, assuming that the channel is fixed over two consecutive OFDM blocks and known at the receiver and a cyclic prefix is used to eliminate IBI.

3. *Single-Carrier Frequency-Domain Equalization* (*SCFDE*). OFDM has two main drawbacks with respect to single-carrier transmission, namely, a higher peak : average ratio (PAR), which results in larger back-off with nonlinear amplifiers and increased sensitivity to frequency errors and phase noise [52]. An alternative equalization scheme that overcomes these two drawbacks

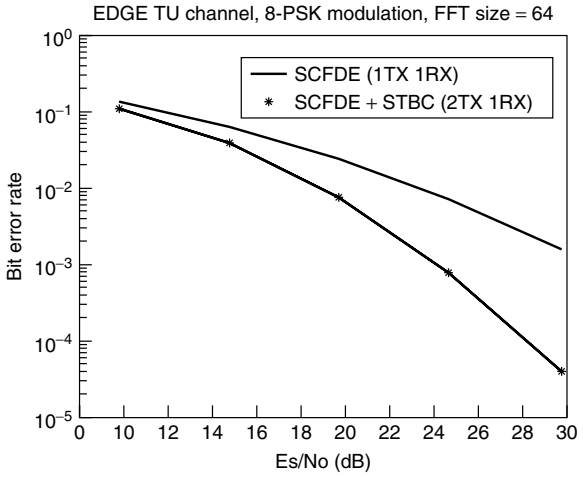

Figure 8. Bit error rate of SCFDE with 1TX and 2TX (STBC) for EDGE TU environment, 8-PSK modulation, and size 64 FFT (1 RX is assumed).

of OFDM while retaining its reduced implementation complexity advantage (due to use of FFT) is single-carrier frequency-domain equalization (SCFDE) [53]. An effective transmit diversity scheme for combining STBC and SCFDE over frequency-selective channels is described in Ref. 54. Figure 8 shows the significant transmit diversity gain achieved as exhibited by the increased slope of the BER curve at high SNR. This simulation assumes a typical urban (TU) EDGE channel with a linearized GMSK transmit pulseshape, 8-PSK modulation, and an FFT size of 64.

3. CHANNEL ESTIMATION ISSUES

Channel estimation for space–time-coded transmissions over flat-fading channels can be performed effectively using orthogonal pilot tones and interpolation as discussed in detail in Ref. 25. Here, we discuss the more challenging frequency-selective channel case.

In single-carrier block transmission systems, a *training sequence* is typically inserted in each block and used to estimate the CIR at the receiver (e.g., using a least-squares algorithm [55]). If the CIR varies within the block, this initial CIR estimate can be tracked using one of various adaptive algorithms.

For single-transmit-antenna scenarios, the training sequence is only required to have a "good" (i.e., impulselike) autocorrelation sequence. However, for the N_t transmit antenna scenarios, the N_t training sequences should, in addition, have "low" (ideally zero) cross-correlation, at least over time lags less than or equal to those of the MIMO channel memory. It can be shown that *perfect root of unity sequences* (PRUS) [56] have these ideal correlation properties. However, PRUS do not belong to standard signal constellations such as PSK. Additional challenges in channel estimation for multiple-transmit-antenna systems over the single-transmit-antenna case are the increased number of channel parameters to be estimated and the reduced transmit power (by a factor of N_t) for each transmit antenna. An obvious transmission scheme that forces the cross-correlation between the N_t training sequences to zero consists of dividing the training interval into N_t subintervals where only one antenna is allowed to transmit its training sequence in each subinterval. This scheme has two major drawbacks: (1) the peak : average ratio (PAR) is increased, which in turn increases amplifier nonlinear distortion; and (2) the effective training period for each transmit antenna is reduced by a factor of N_t.

The rich structure of space–time codes can be used to reduce the number of channel parameters to be estimated. For example, for TRSTBC, decoupling of the two inputs due to the Alamouti orthogonal structure removes the requirement of low cross-correlation between the two training sequences. Similarly, for the 8-state 8-PSK STTC, the special code structure can be exploited to simplify the training sequence design problem while restricting the training symbols to belong to standard signal constellation and incurring negligible performance loss from PRUS [57].

4. CONCLUSION

Space–time coding is a new coding/signal processing framework for wireless communications systems with multiple transmit/receive antennas. This new framework offers the best tradeoff between spectral efficiency and power consumption by optimum combination of modulation, coding, and diversity gains over flat-fading channels.

Space–time trellis codes offer the maximum possible diversity and coding gains without any sacrifice in transmission bandwidth. Their decoding requires a vector Viterbi algorithm. Alamouti-type space–time block codes offer maximum diversity gain, much lower decoding complexity, and full rate transmission but sacrifice coding gain.

For frequency-selective fading channels, we described several competitive equalization schemes for space–time codes that further exploit the temporal diversity of the channel. For space–time trellis codes, prefiltered M-BCJR and OFDM achieve the best performance-complexity tradeoff. For Alamouti's space–time block code, TRSTBC, OFDM–STBC, and FDE–STBC are the most promising candidates. OFDM-based schemes are less attractive when issues of high PAR, frequency errors, and delay become critical. Exploiting the rich structure of space–time codes is critical in simplifying the channel estimation and equalization schemes.

Acknowledgments

We would like to thank the following colleagues (in alphabetical order) for many technical discussions and contributions to this work: G. Bauch, S. N. Diggavi, C. Fragouli, N. Seshadri, A. Stamoulis, V. Tarokh, and W. Younis.

BIOGRAPHIES.

Naofal Al-Dhahir received his M.S. and Ph.D. degrees from Standford University in 1990 and 1994, respectively, in electrical engineering. He was as instructor at Stanford University during Winter 1993. From August 1994 to 1999, he was a member of the technical staff at the Communications Program at GE Corporate R&D Center

in Schenectady, New York, where he worked on various aspects of satellite communication systems design and anti-jam GPS receivers. Since August 1999, he has been a principal member of technical staff at AT&T Shannon Laboratory in Florham Park, New Jersey. His current research intersts include equalization schemes, space-time coding and signal processing, OFDM, and digital subscriber line technology. He has authored more than 40 journal papers and holds 7 U.S. patents in the areas of satellite communications, digital television, and space-time processing. He is a senior member of the IEEE and a member of the IEEE SP4COM technical committee. He is editor for *IEEE Transaction on Signal Processing*, *IEEE Communications Letters*, and *IEEE Transactions on Communications*. He is co-author of the book *Dopler Applications for LEO Satellite System* (Kluwer 2001).

Robert Calderbank is vice president for research at AT&T. He also is responsible for directing the research program in Internet and network systems. This program provides AT&T with technical and industry leadership in all areas of networking technology. These areas include network security, content distribution, operations support, network measurement and management, and end-to-end optical systems.

Dr. Calderbank is an IEEE and AT&T Fellow, and a recipient of the IEEE Third Millennium Medal for his contributions to digital communications. These include the design of high-speed voiceband modems, the development of advanced read channels for magnetic disk storage, and the invention of space-time codes, a breakthrough wireless technology that uses a small number of antennas to significantly improve throughput and reliability.

Ayman Naguib received the B.Sc. Degree (with honors) and the M.S. degree in electrical engineering from Cairo University, Cario, Egypt, in 1987 abd 1990, respectively, and the M.S. degreee in statistics and the Ph.D. degree in electrical engieering from Stanford University, Stanford, California, in 1993 and 1996, respectively.

From 1987 to 1989, he spent his military service at the Signal Processing Laboratory, The Military Technical College, Cairo, Egypt. From 1989 to 1990, he was employed at Cairo University as a research and teaching assistant in the Communication Theory Group, Department of Electrical Engineering. From 1990 to 1995, he was a research and teaching assistant in the Information Systems Laboratories, Stanford University, Stanford California. In 1996, he joined AT&T Labs, Florham Park, New Jersey, as a principal member of technical staff. In September 2000, he joined Morphics Technology Inc. as a technical leader. His current research interests include in general space-time signal processing and coding for high data rate wireless communications (W-CDMA, OFDM, etc.).

SPATIOTEMPORAL SIGNAL PROCESSING IN WIRELESS COMMUNICATIONS

DIMITRIOS HATZINAKOS
RYAN A. PACHECO
University of Toronto
Toronto, Ontario, Canada

1. INTRODUCTION

Wireless channels are severely limited by fading due to multipath propagation. When fading is "flat," the receiver experiences fast or slow variations of the received signal amplitude, which makes detection of the information symbols difficult. Fading can also be frequency-selective, in which case in addition to signal variations we experience intersymbol interference. An effective strategy to deal with multipath propagation and fading has been the utilization of multiple antennas at the receiver and or at the transmitter. Beamforming with multiple antennas closely spaced together has been traditionally used for directive transmission and rejection of multipath components. However, this approach requires line-of-sight communications and the formation of steerable multiple beams in the case of mobile multiuser communications. Another approach is diversity, which is based on the weighted combination of multiple signal copies that are subject to independent fading. Therefore, two adjacent receive or transmit antennas must be apart by several wavelengths so that signals transmitted or received from different antennas are sufficiently uncorrelated. The latter approach is considered in this article.

The information-theoretic capacity of multiple antenna systems and data communication techniques that exploit the potential of spatial diversity have been studied [3,4], and dramatic increases in supportable data rates are expected. In such systems, the capacity can theoretically increase by a factor up to the number of transmit and receive antennas in the array. Spacetime diversity and coding techniques, such as trellis spacetime codes, block spacetime codes, and variations of the very popular BLAST (Bell Laboratories layered spacetime) architecture, among others [5,7–9] are currently under investigation. However, there is a need for more thorough investigation of the potential and limits of such technologies and the development of efficient low complexity systems. In the first half of this article, we provide a general treatment of the spacetime signal processing scenario and spacetime diversity and coding frameworks based on block spacetime codes and discuss potential benefits, requirements, and limitations.

A common assumption in existing spacetime coding literature is the knowledge or availability of a good estimate for the multipath channel [3,7]. In the absence of channel knowledge, the capacity gains to be achieved depend on the particular characteristics (e.g., coherence time) of the channel. Various schemes, consisting of an antenna array and a spatio-temporal processor at the base station (or at the mobile unit), have been proposed to mitigate the effects of intersymbol interference (ISI), and to reject cochannel interference (CCI) or multiple-access interference (MAI) induced by simultaneous intra- or intercell users [5,17]. To cope with the time-varying and fading nature of wireless channels, data are transmitted in bursts, and attached to each burst is a training sequence of short duration that is used to help the receiver recover the unknown parameters of the communication channel [10]. In many cases unsupervised (i.e., blind) techniques [12,21], which require no training data, as well as semiblind approaches, which provide a synergistic treatment of training and blind principles, are employed to address the channel estimation and/or the direct channel equalization problems [1,11,14]. In the second half of the article, a semiblind channel equalization approach will be presented and integrated with spacetime diversity and coding to form a realistic scenario for detection and estimation.

The aim of the article is by no means to provide an exhaustive coverage but rather to illustrate the principle and potential and to suggest a realistic approach for implementation of spacetime wireless transceivers, and also to provide a motivation for exploring the fast-growing literature and technological developments in the area.

2. THE DISCRETE-CHANNEL MODEL

The basic structure of a wireless transceiver employing spacetime diversity and coding (multiple-input multiple-output system) is depicted in Fig. 1.

The received equivalent discrete-time signal at the receiver antenna a, $a = 1, \ldots, A$, after demodulation, filtering, and oversampling (i.e., taking N samples per symbol period) can be written as [1]

$$r_a[n] = \sum_{m=1}^{M} \sum_{k=0}^{N_b-1} b_m[k] \cdot g_{ma}[n - kN] + v_a[n] \qquad (1)$$

where N_b is the length of the transmitted burst of data and the $\{b_m[k]\}_{k=0}^{N_b-1}$ denote the data symbols transmitted from the antenna $m, m = 1, \ldots, M$. When spacetime coding is employed in the transmitter, we may assume that M

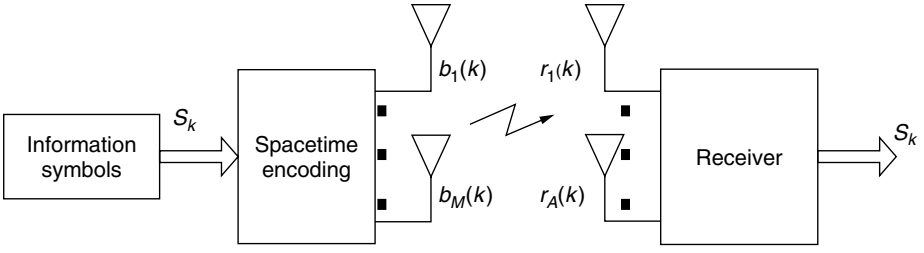

Figure 1. Single-user communication using multiple transmit and receive antennas.

complex symbols are transmitted simultaneously from the M transmit antennas. In this case, we may write [3]

$$\mathbf{b}[k] = \sum_{l=1}^{M} \mathbf{q}_l^r[k] \cdot s_l^r + \sum_{l=1}^{M} j\mathbf{q}_l^j[k] \cdot s_l^j \tag{2}$$

where $\mathbf{b}(k) = [b_1(k), \ldots, b_M(k)]^T$ is the transmitted data vector at time instant k, $s_l = s_l^r + js_l^j, l = 1, \ldots, M$ are the transmitted symbols and $\mathbf{q}_l^r(k)$ and $\mathbf{q}_l^j(k)$ are the $M \times 1$ transmit antenna weight vectors for the real and imaginary part of the symbol l, respectively, at time instant k. The $g_{ma}[n], n = 0, \ldots, LN-1$ accounts for the transmit and receive filters and the multipath channel between transmit antenna m and receive antenna a. Without loss of generality we will assume that all the channels between transmit and receive antennas are of the same length $LN-1$ samples and are time-invariant during the transmission of a burst of N_b data symbols. Finally $v_a[n]$ is circular complex white Gaussian noise, uncorrelated with $b_m[n] \forall m$, with zero mean and variance σ^2.

Assume that we are interested in recovering the mth transmitted symbol at time instant k. To do this we first collect N samples from all antenna elements to form the vector $\mathbf{r}(k)$, which takes the following form:

$$\mathbf{r}(k) = [\mathbf{G}(L-1), \ldots, \mathbf{G}(0)] \cdot [\mathbf{b}(k-L+1)^T, \ldots, \mathbf{b}(k)^T]^T + \mathbf{v}(k) \tag{3}$$

where

$$\mathbf{r}(k) = \begin{bmatrix} r_1[kN] \\ \vdots \\ r_1[(k+1)N-1] \\ \vdots \\ r_A[kN] \\ \vdots \\ r_A[(k+1)N-1] \end{bmatrix}_{AN\times 1}$$

$$\mathbf{G}(l) = \begin{bmatrix} g_{11}[lN] & \cdots & g_{M1}[lN] \\ \vdots & & \vdots \\ g_{11}[(l+1)N-1] & \cdots & g_{M1}[(l+1)N-1] \\ \vdots & & \vdots \\ g_{1A}[lN] & \cdots & g_{MA}[lN] \\ \vdots & & \vdots \\ g_{1A}[(l+1)N-1] & \cdots & g_{MA}[(l+1)N-1] \end{bmatrix}_{AN\times M}$$

$$\mathbf{b}(k) = \begin{bmatrix} b_1[k] \\ \vdots \\ b_M[k] \end{bmatrix}_{M\times 1} \qquad \mathbf{v}(k) = \begin{bmatrix} v_1[kN] \\ \vdots \\ v_1[(k+1)N-1] \\ \vdots \\ v_A[kN] \\ \vdots \\ v_A[(k+1)N-1] \end{bmatrix}_{AN\times 1}$$

In general, the simultaneous transmission of M symbols will span μ received vectors. Thus, it may be necessary to process more than one received vector at a time in order to estimate the mth symbol. Then, assuming a linear receiver structure and in the absence of noise, the recovery of the real information symbol s_m^q, where $q = r$ or $q = j$, at time instant k, requires that the $A \times 1$ weight vectors $\mathbf{W}_{i,m}^q$ of the spacetime equalizer at $i = k, \ldots, k+\mu-1$ satisfy the relation

$$\sum_{i=k}^{k+\mu-1} \mathbf{W}_{i,m}^{qH} \cdot \mathbf{r}(i) = s_m^q[k-d] \tag{4}$$

where d is an arbitrary delay. Throughout the article the symbols $*$, T, and H denote conjugate, transpose, and conjugate transpose operations, respectively.

3. SPACETIME DIVERSITY AND FLAT-FADING CHANNELS

Here we are going to examine the benefits that can be expected by employing both transmit and receive diversities. We follow a procedure based on an excellent analysis [3] of this problem. To simplify the mathematical formulas, we assume a flat-fading channel described by the constant matrix $\mathbf{G}$ and that $N = 1$, with no oversampling. Then, by placing $L = 1, N = 1$, and $\mathbf{G}(0) = \mathbf{G}$ into the relation of Section 2, we obtain the following simplified relation between the $A \times 1$ receive signal vector $\mathbf{r}(k)$ and the $M \times 1$ transmit data symbol vector $\mathbf{b}(k)$:

$$\mathbf{r}(k) = \mathbf{G} \cdot \mathbf{b}(k) + \mathbf{v}(k) \tag{5}$$

where

$$\mathbf{r}(k) = \begin{bmatrix} r_1[k] \\ \vdots \\ r_A[k] \end{bmatrix}_{A\times 1} \qquad \mathbf{G} = \begin{bmatrix} g_{11} & \cdots & g_{M1} \\ \vdots & & \vdots \\ g_{1A} & \cdots & g_{MA} \end{bmatrix}_{A\times M}$$

$$\mathbf{b}(k) = \begin{bmatrix} b_1[k] \\ \vdots \\ b_M[k] \end{bmatrix}_{M\times 1} \qquad \mathbf{v}(k) = \begin{bmatrix} v_1[k] \\ \vdots \\ v_A[k] \end{bmatrix}_{AN\times 1}$$

The transmitted data vector at time instant k is given by Eq. (2). Then, according to Eq. (4), the output of the linear spatiotemporal receiver filter (detector) for the real symbol $s_m^q, q = r$ or $q = j, m = 1, \ldots, M$ is

$$\begin{aligned} \hat{s}_m^q &= Real\left\{ \sum_{i=k}^{k+\mu-1} \mathbf{W}_{i,m}^{qH} \cdot \mathbf{r}(i) \right\} \\ &= Real\left\{ \sum_{i=k}^{\mu+k-1} \mathbf{W}_{i,m}^{qH} \mathbf{G} \sum_{l=1}^{M} \mathbf{q}_l^r(i) s_l^r \right. \\ &\quad \left. + \sum_{i=k}^{\mu+k-1} \mathbf{W}_{i,m}^{qH} \mathbf{G} \sum_{l=1}^{M} j\mathbf{q}_l^j(i) s_l^j + \sum_{i=k}^{\mu+k-1} \mathbf{W}_{i,m}^{qH} \mathbf{v}(i) \right\} \end{aligned} \tag{6}$$

It can be shown [3,6] that the maximum signal to noise ratio (SNR) for this linear spatiotemporal receiver is achieved when (within a scale term)

$$\mathbf{W}_{i,m} = \mathbf{G}\mathbf{q}_m^r(i) \qquad \text{or} \qquad \mathbf{W}_{i,m} = \mathbf{G}_j\mathbf{q}_m^j(i) \tag{7}$$

for s_m^r and s_m^j, respectively. By substituting these values in Eq. (6), we determine the detector output $\hat{s}_m^r$ for s_m^r, where $m = 1, \ldots, M$:

$$\begin{aligned}\hat{s}_m^r &= Real\left\{\sum_{i=k}^{\mu+k-1} \mathbf{q}_m^{rH}(i)\mathbf{G}^H\mathbf{G}\sum_{l=1}^{M}\mathbf{q}_l^r(i)s_l^r\right\} \\ &\quad + Real\left\{\sum_{i=k}^{\mu+k-1} \mathbf{q}_m^{rH}(i)\mathbf{G}^H\mathbf{G}\sum_{l=1}^{M}j\mathbf{q}_l^j(i)s_l^j\right\} \\ &\quad + Real\left\{\sum_{i=k}^{\mu+k-1} \mathbf{q}_m^{rH}(i)\mathbf{G}^H\mathbf{v}(i)\right\} \\ &= Real\left\{\sum_{l=1}^{M} trace(\mathbf{G}\mathbf{Q}_l^r\mathbf{Q}_m^{rH}\mathbf{G}^H)s_l^r\right\} \\ &\quad + Real\left\{\sum_{l=1}^{M} j\,trace(\mathbf{G}\mathbf{Q}_l^j\mathbf{Q}_m^{rH}\mathbf{G}^H)s_l^j\right\} \\ &\quad + Real\left\{\sum_{i=k}^{\mu+k-1} \mathbf{q}_m^{rH}(i)\mathbf{G}^H\mathbf{v}(i)\right\} \qquad (8)\end{aligned}$$

where $\mathbf{Q}_m^r = [\mathbf{q}_m^r(k), \ldots, \mathbf{q}_m^r(k+\mu-1)]_{M\times\mu}$ and $\mathbf{Q}_m^j = [\mathbf{q}_m^j(k), \ldots, \mathbf{q}_m^j(k+\mu-1)]_{M\times\mu}$ are the transmitter weight matrices for symbols s_m^r and s_m^j, respectively. Similarly, we find the detector output $\hat{s}_m^j$ for s_m^j, where $m = 1, \ldots, M$:

$$\begin{aligned}\hat{s}_m^j &= -Real\left\{\sum_{l=1}^{M} trace(\mathbf{G}\mathbf{Q}_l^j\mathbf{Q}_m^{jH}\mathbf{G}^H)s_l^j\right\} \\ &\quad + Real\left\{\sum_{l=1}^{M} j\,trace(\mathbf{G}\mathbf{Q}_l^r\mathbf{Q}_m^{jH}\mathbf{G}^H)s_l^r\right\} \\ &\quad + Real\left\{\sum_{i=k}^{\mu+k-1} \mathbf{q}_m^{jH}(i)\mathbf{G}^H\mathbf{v}(i)\right\} \qquad (9)\end{aligned}$$

By properly choosing the weight matrices $\mathbf{Q}_m^r, \mathbf{Q}_m^j, m = 1, \ldots, M$, the interference from other symbols can be significantly reduced or completely eliminated and the output SNR maximized. In this case, a transmit diversity gain up to the order M and a transmit–receive diversity gain of order up to AM is possible. Another way of looking at the above procedure is that of mapping the set of symbols $\{s_l\}$ to the set of vectors $\{\mathbf{b}(k)\}$, that is

$$[s_1 s_2 \cdots s_M]_{1\times M} \rightarrow [\mathbf{b}(k)\mathbf{b}(k+1)\cdots\mathbf{b}(k+\mu-1)]_{M\times\mu} \quad (10)$$

which is a form of spacetime block code. Thus, the objective is to design efficient such codes. It can be shown that in general this is possible only if $\mu \geq M$ [3–5]. Next we provide a few examples to demonstrate some important points.

Example 1. Let us consider the transmission of two complex symbols s_1, s_2 from a transmitter with two antennas by using the above mentioned process ($M = 2$) and let $\mu = 2$. First let us consider the following choice of weight matrices

$$\mathbf{Q}_1^r = [\mathbf{q}\ \mathbf{0}]\mathbf{Q}_2^r = [\mathbf{0}\ \mathbf{q}]\mathbf{Q}_1^j = [\mathbf{q}\ \mathbf{0}]\mathbf{Q}_2^j = [\mathbf{0}\ \mathbf{q}]$$

where $\mathbf{q}$ is a 2×1 weight vector. The transmitted complex vectors are

$$\mathbf{b}(k) = [\mathbf{q}s_1], \quad \mathbf{b}(k+1) = [\mathbf{q}s_2]$$

This is clearly the situation of *Space-only* transmission. Then, since

$$\mathbf{Q}_l^x\mathbf{Q}_m^{xH} = \mathbf{0}, \quad x = r, j, \quad m \neq l$$

interference from different symbols is eliminated. Furthermore since

$$\mathbf{Q}_m^x\mathbf{Q}_m^{yH}, \quad m = 1, 2$$

are Hermitian, the terms

$$Trace(\mathbf{G}\mathbf{Q}_m^x\mathbf{Q}_m^{yH}\mathbf{G}^H), \quad m = 1, 2$$

are real. Thus, equations (8) and (9) are reduced to

$$\begin{aligned}D_m^x &= \pm trace(\mathbf{G}\mathbf{q}\mathbf{q}_m^H\mathbf{G}^H)s_m^x + \mathbf{q}^H\mathbf{G}^H\mathbf{v} \\ &\quad x = r, j \quad m = 1, 2 \qquad (11)\end{aligned}$$

and the corresponding SNR per real symbol is easily found to be

$$\text{SNR} = \frac{E_s}{\sigma^2} trace(\mathbf{G}\mathbf{q}\mathbf{q}^H\mathbf{G}^H)$$

where E_s is the energy of the real symbol and σ^2 the variance of the white noise.

Example 2. Let again $M = 2$ and $\mu = 2$ but this time choose the weight matrices as follows [3–5]:

$$\mathbf{Q}_1^r = \begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}, \quad \mathbf{Q}_2^r = \begin{bmatrix}0 & 1\\ -1 & 0\end{bmatrix}, \quad \mathbf{Q}_1^j = \begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix},$$
$$\mathbf{Q}_2^j = \begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}$$

and the transmitted complex vectors are

$$\mathbf{b}(k) = \begin{bmatrix}s_1\\ -s_2^*\end{bmatrix}, \quad \mathbf{b}(k+1) = \begin{bmatrix}s_2\\ s_1^*\end{bmatrix}$$

In this case of *spacetime* processing it is easy to show by following arguments similar to those in example 1 that all interference is eliminated and since

$$\mathbf{Q}_m^x\mathbf{Q}_m^{xH} = \mathbf{I}_{2\times 2}, \quad m = 1, 2$$

are identity matrices

$$\begin{aligned}D_m^x &= \pm trace(\mathbf{G}\mathbf{G}^H)s_m^x + \sum_{i=k}^{k+1}\mathbf{q}_m^{xH}(i)\mathbf{G}^H(0)\mathbf{v}(i) \\ &\quad x = r, j \quad m = 1, 2 \qquad (12)\end{aligned}$$

and the corresponding SNR per real symbol is found to be

$$\text{SNR} = \frac{E_s}{\sigma^2} trace(\mathbf{G}\mathbf{G}^H) = \frac{E_s}{\sigma^2}\sum_{i=1}^{2}\sum_{j=1}^{2}|g_j^i|^2$$

Example 3. Consider now the case of $M = 1, A > 1$ corresponding to pure receive diversity. In this case the matrix G reduces to a vector $A \times 1$. Similarly, the transmit weight matrices reduce to scalars and after some calculations we find that the corresponding maximum SNR per real symbol is

$$\text{SNR} = \frac{E_s}{\sigma^2} \sum_{i=1}^{A} |g_1^i|^2$$

which corresponds to the case of *Maximal Ratio Combining*.

From these examples, we conclude the following:

1. In the case of space-only processing (Example 1), it is important that both the transmitter and the receiver know the channel, that is, the matrix **G**, to maximize the output SNR. This is achieved when the transmit weight vector **q** is equal to the eigenvector of **G** corresponding to the largest eigenvalue.
2. On the other hand, in the case of spacetime processing of Example 2, the transmitter does not need to know the channel. Obviously the receiver still requires knowledge of the channel for decoding.
3. Examples 2 and 3 indicate that the spacetime diversity gain with M transmit and A receive antennas is of the order $M \cdot A$. Thus, in Example 3, in order to achieve similar gains as in Example 2, we must choose $A = 4$. Similar arguments can be made for the case of transmit only diversity where $M > 1, A = 1$.
4. Spacetime diversity exploits the propagation environment itself to improve the performance. The *richer* the multipath channel (matrix **G**), the higher the diversity gain is.

4. SPACETIME DIVERSITY AND SEMIBLIND CHANNEL EQUALIZATION

In multiaccess communications, channel resources are allocated in ways that require either strict cooperation among users, such as in time- or frequency-division multiple access (TDMA or FDMA), or not, as in code- or space-division multiple access (DS-CDMA or SDMA). DS-CDMA and SDMA systems generally require more complex receivers than do TDMA or FDMA since the received data may contain interference from other users (multiuser interference, also called *multiple-access interference* (MAI)). The amount of interference that one user contributes to another is dependent on the orthogonality between their received signals. In DS-CDMA systems, orthogonality may exist on the transmitting end by assigning orthogonal spreading codes to users but will not exist on the receiver end because of propagation effects (multipath propagation in the case of wireless channels). The end result is that correlation-type receivers are no longer viable and some method of multiuser detection is needed in order to deal effectively with MAI. Many different multiuser detection strategies have been proposed over the past decade from prohibitively complex [20] to extremely simple [13].

In addition to MAI there is also intersymbol interference (ISI), or *self-interference*, that is also caused by multipath propagation. ISI is negligible in low-rate DS-CDMA applications but is becoming more of an issue in third-generation systems (where the symbol duration is on the order of the multipath delay spread [10]). Consequently, high-rate DS-CDMA systems suffer from MAI and ISI. Thus, receivers for such systems need to perform equalization and multiuser detection.

When MAI and ISI are present, an analytic treatment of the spacetime diversity and coding scenario is not as straightforward as with flat-fading single-user channels. In any case, the unknown wireless channel must be estimated at the receiver or directly equalized for cancellation of the interference and detection of the desired data symbols. In this section, we complement the spacetime diversity and coding principles described in the previous section with a spacetime semiblind channel equalization technique and propose a realistic and effective wireless communications transceiver.

4.1. Revised Signal Model

A K-user DS-CDMA system is considered. Each user is assigned a unique spreading code with a processing gain of N. In addition, each user transmits from an M-element antenna array to an antenna array with A elements. The block diagram of such a transceiver is depicted in Fig. 2. Let $b_m^k[n]$ be the nth symbol for the kth user from the mth transmit antenna. We assume a 4-QAM modulation scheme $b_m^k[n] \in \{e^{\pm j(\pi/4)}, e^{\pm j(3\pi/4)}\}$. Summing over all transmit antennas for all users, we can rewrite the received signal at the ath receive antenna

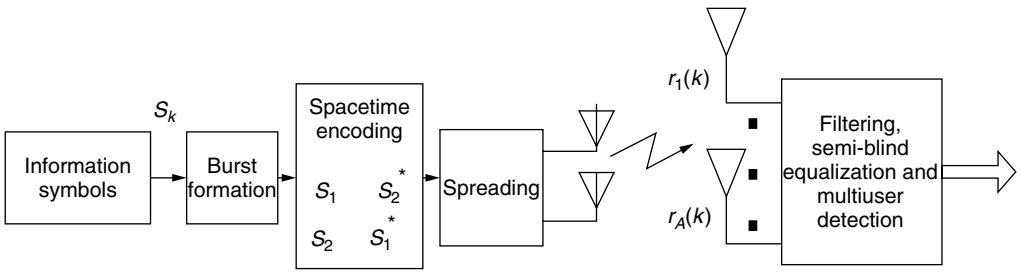

Figure 2. kth-user transceiver using 2 transmit and A receive antennas including spacetime coding and channel equalization.

is as

$$r_a[n] = \sum_{k=1}^{K} \sum_{m1}^{M} \sum_{k=0}^{N_b-1} b_m^k[n_b] g_{ma}^k[n - Nn_b] + v_a[n] \tag{13}$$

where now $g_{ma}^k[n]$ represents the combined impulse response of channel plus spreading code for the kth user from the mth transmit antenna to the ath receive antenna:

$$g_{ma}^k[n] = \sum_{l=0}^{L_k-1} \beta_{ma} k[l] c_k[n-l] \tag{14}$$

In this equation $\{\beta_{ma}^k[l]\}_{l=0}^{L_k-1}$ represents the frequency-selective multipath channel for the given user. The $c_k[n]$ is the normalized spreading code for the kth user: $c_k[n] \in \{\pm 1\}/\sqrt{N}$. Once again, it is assumed that the fading coefficients do not change during the transmission of N_b data symbols and that $\max(L_k - 1) \le (L-1)N$ for some integer L.

Collecting the N chips corresponding to the n_bth transmitted symbol, the received vector is written as

$$\mathbf{r}_a(n_b) = \mathbf{G}_a \cdot \mathbf{b}_{n_b} + \mathbf{v}_a(n_b) \tag{15}$$

where

$$\begin{aligned}
\mathbf{r}_a(l) &= [r_a[lN], \ldots, r_a[(l+1)N-1]]^T \\
\mathbf{G}_a &= [\mathbf{G}_a(L-1), \ldots, \mathbf{G}_a(0)] \\
\mathbf{G}_a(l) &= [\mathbf{g}_{1a}^1(l), \mathbf{g}_{2a}^1(l), \ldots, \mathbf{g}_{Ma}^K(l)] \\
\mathbf{g}_{ia}^k(l) &= [g_{ia}^k[lN], \ldots, g_{ia}^k[(l+1)N-1]]^T \\
\mathbf{b}_{n_b} &= [\mathbf{b}(n_b - L + 1)^T, \ldots, \mathbf{b}(n_b)^T]^T \\
\mathbf{b}(l) &= [b_1^1[l], b_2^1[l], \ldots, b_M^K[l]]^T \\
\mathbf{v}_a(l) &= [v_a[lN], \ldots, v_a[(l+1)N-1]]^T
\end{aligned}$$

4.2. Interference Suppression Strategies

We now fix the number of transmit antennas per user (M) at two and apply the block code of Example 2 (this is similar to the Alamouti scheme [7]). In this case, symbols for the kth user, $\{b_k[n]\}_{n=0}^{N_b-1}$, are mapped as follows for each pair of symbols $(\{b_k[0], b_k[1]\}, \{b_k[2], b_k[3]\}, \ldots)$:

$$\begin{aligned}
b_1^k[0] &= \frac{b_k[0]}{\sqrt{2}}, \quad b_2^k[0] = \frac{-b_k^*[1]}{\sqrt{2}} \\
b_1^k[1] &= \frac{b_k[1]}{\sqrt{2}}, \quad b_2^k[1] = \frac{b_k^*[0]}{\sqrt{2}}
\end{aligned}$$

The additional normalization by $\sqrt{2}$ has been introduced so that the total transmitted energy remains constant and independent of M. In the receiver we employ two linear filters. The first, $\mathbf{W}_1$, is trained to extract the even-numbered symbols $(b_1[0], b_1[2], \ldots)$ and the other, $\mathbf{W}_2$, is trained to extract the odd-numbered symbols (in this case user number one is the desired user).

4.2.1. Least-Squares Optimization.

Using least squares, the solution then becomes

$$\mathbf{W}_1^{\mathrm{LS}} = \arg\min_{\mathbf{W}} \frac{2}{N_t} \sum_{i=0}^{N_t/2-1} |\mathbf{W}^H \mathbf{r}(i) - b_1[2i]|^2 \tag{16}$$

$$\mathbf{W}_2^{\mathrm{LS}} = \arg\min_{\mathbf{W}} \frac{2}{N_t} \sum_{i=0}^{N_t/2-1} |\mathbf{W}^H \mathbf{r}(i) - b_1^*[2i+1]|^2 \tag{17}$$

where N_t is the number of training symbols per burst (see Fig. 3) and

$$\mathbf{r}(i) = [\mathbf{r}_1(2i)^T, \mathbf{r}_1^*(2i+1)^T, \ldots, r_A(2i)^T, r_A^*(2i+1)^T]^T$$

The second vector for each antenna element is conjugated to account for the conjugate introduced by the space-time code.

If $N_t/2 \ge 2AN$, then the solution to Eqs. (16) and (17) is well known:

$$\mathbf{W}_1^{\mathrm{LS}} = \overbrace{\left(\frac{2}{N_t} \sum_{i=0}^{N_t/2-1} \mathbf{r}(i)\mathbf{r}(i)^H\right)^{-1}}^{\mathbf{R}_{N_t}} \overbrace{\left(\frac{2}{N_t} \sum_{i=0}^{N_t/2-1} \mathbf{r}(i) b_1^*[2i]\right)}^{\mathbf{P}_{N_t^1}} \tag{18}$$

$$\mathbf{W}_2^{\mathrm{LS}} = \left(\frac{2}{N_t} \sum_{i=0}^{N_t/2-1} \mathbf{r}(i)\mathbf{r}(i)^H\right)^{-1} \underbrace{\left(\frac{2}{N_t} \sum_{i=0}^{N_t/2-1} \mathbf{r}(i) b_1[2i+1]\right)}_{\mathbf{P}_{N_t^2}} \tag{19}$$

In cases where this is not true, the time-averaged autocorrelation matrix, $\mathbf{R}_{N_t}$, becomes singular, so we use diagonal loading for regularization

$$\mathbf{W}_{1,2}^{\mathrm{LS}} = (\mathbf{R}_{N_t} + \delta \mathbf{I}_{2AN})^{-1} \mathbf{P}_{N_t}^{1,2} \tag{20}$$

where δ is some small positive constant (σ^2 ideally). As $N_t \to \infty$, $\mathbf{R}_{N_t} \to \mathbf{R}$, where $\mathbf{R}$ is the autocorrelation matrix

$$\mathbf{R} = \mathbf{G}\mathbf{B}\mathbf{G}^H + \sigma^2 \mathbf{I}_{2AN} \tag{21}$$

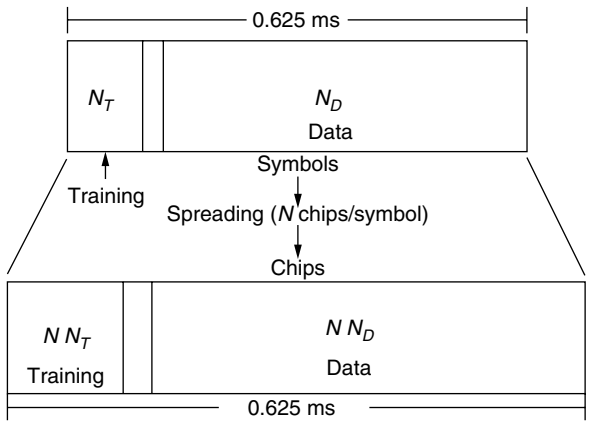

Figure 3. Burst structure.

and

$$\mathbf{G} = \begin{bmatrix} \mathbf{G}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{G}_1^* \\ \vdots & \vdots \\ \mathbf{G}_A & \mathbf{0} \\ \mathbf{0} & \mathbf{G}_A^* \end{bmatrix}, \quad \mathbf{B} = E\left(\begin{bmatrix} \mathbf{b}_{2i} \\ \mathbf{b}_{2i+1}^* \end{bmatrix} [\mathbf{b}_{2i}^H \quad \mathbf{b}_{2i+1}^T] \right)$$

Assuming that $2AN \geq 4KL$, and that $\mathbf{G}$ has full rank, it can be shown that the dimensionality of the signal space, k, (rank($\mathbf{GBG}^H$)) is given by

$$\kappa = \begin{cases} 2 \cdot K & \text{if } L = 1 \text{ (flat-fading)} \\ 2 \cdot K \cdot (L+1) & \text{if } L > 1 \end{cases} \tag{22}$$

Thus, in the noiseless case ($\sigma^2 = 0$) the minimum number of training symbols required to completely suppress the interference (multiple access and intersymbol) is simply $2 \cdot \kappa$. However, in the presence of noise and in a time-varying propagation environment, longer training sequences are needed. For a given length of training, the performance degrades with decreasing SNR and is highly dependent on the time-varying channel characteristics. This has serious implications on both user detectability and system spectral efficiency, which is measured as a percentage of training data in a burst. To alleviate this problem semiblind algorithms that utilize *blind* signal estimation principles to effectively increase the equivalent length of the training sequence have been proposed [1,14,16]. The semiblind algorithm described next can be effectively incorporated in a spatiotemporal framework and provide significant performance gains as it will be demonstrated by means of computer simulations.

4.2.2. Semiblind Processing. The objective is to find the weight vectors that minimize the cost functions

$$\mathbf{W}_1 = \arg\min_{\mathbf{W}} \frac{2}{N_b} \sum_{i=0}^{N_b/2-1} |\mathbf{W}^H \mathbf{r}(i) - b_1[2i]|^2 \tag{23}$$

$$\mathbf{W}_2 = \arg\min_{\mathbf{W}} \frac{2}{N_b} \sum_{i=0}^{N_b/2-1} |\mathbf{W}^H \mathbf{r}(i) - b_1^*[2i+1]|^2 \tag{24}$$

given the following information about the source symbols:

- $b_1[i]$ is known for $i = 0, \ldots, N_t - 1$ (training symbols),
- $|b_1[i]| = 1, i = 0, \ldots, N_b - 1$.

Our strategy is to use an alternating projection approach such as that discussed by van der Veen [2]. For the ith iteration of the weight vector, let

$$\tilde{b}_1^{1(i)} \triangleq \left\{ \mathbf{b}_{N_t}^1, \frac{\mathbf{W}_1^{H(i)} \mathbf{r}(N_t/2)}{|\mathbf{W}_1^{H(i)} \mathbf{r}(N_t/2)|}, \ldots, \frac{\mathbf{W}_1^{H(i)} \mathbf{r}(N_b/2-1)}{|\mathbf{W}_1^{H(i)} \mathbf{r}(N_b/2-1)|} \right\}$$

$$\tilde{b}_1^{2(i)} \triangleq \left\{ \mathbf{b}_{N_t}^2, \frac{\mathbf{W}_2^{H(i)} \mathbf{r}(N_t/2)}{|\mathbf{W}_2^{H(i)} \mathbf{r}(N_t/2)|}, \ldots, \frac{\mathbf{W}_2^{H(i)} \mathbf{r}(N_b/2-1)}{|\mathbf{W}_2^{H(i)} \mathbf{r}(N_b/2-1)|} \right\}$$

where $\mathbf{b}_{N_t}^1 = [b_1[0], b_1[2], \ldots, b_1[N_t - 2]]$ and $\mathbf{b}_{N_t}^2 = [b_1[1], b_1[3], \ldots, b_1[N_t - 1]]$) are a sequence that contains the known N_t source symbols, and $(N_b - N_t)/2$ estimated source symbols (via the Godard-type nonlinearity $\frac{\mathbf{W}_1^H \mathbf{r}(k)}{|\mathbf{W}_1^H \mathbf{r}(k)|}$). The function $\frac{\mathbf{W}_1^H \mathbf{r}(k)}{|\mathbf{W}_1^H \mathbf{r}(k)|}$ is chosen based on a priori knowledge of the source constellation (it returns a complex number with unit magnitude). If the initialization is accurate, then it will return the correct phase of the source symbol. We refer to the corresponding $(N_b - N_t)/2$ symbols in $\tilde{b}_1^{1(i)}(\tilde{b}_1^{2(i)})$ as *pseudotraining symbols*.

The sequence $\tilde{b}_1^{1(i)}(\tilde{b}_1^{2(i)})$ is then used to estimate a new cross-correlation vector, $\tilde{\mathbf{P}}_{N_b}^{1(i)}(\tilde{\mathbf{P}}_{N_b}^{2(i)})$, and $\mathbf{W}_1^{(i)}(\mathbf{W}_2^{(i)})$ is updated using this new vector and signal space parameters computed from eigen-decomposition of the time-averaged autocorrelation matrix $\mathbf{R}_{N_b}$:

$$\tilde{\mathbf{P}}_{N_b}^{1(i)} = \frac{2}{N_b} \sum_{k=0}^{N_b/2-1} \tilde{b}_1^{*1(i)}(k) \mathbf{r}(k) \tag{25}$$

$$\tilde{\mathbf{P}}_{N_b}^{2(i)} = \frac{2}{N_b} \sum_{k=0}^{N_b/2-1} \tilde{b}_1^{2(i)}(k) \mathbf{r}(k) \tag{26}$$

$$\mathbf{W}_1^{(i+1)} = \hat{\mathbf{U}}_S \hat{\mathbf{\Lambda}}_S^{-1} \hat{\mathbf{U}}_S^H \tilde{\mathbf{P}}_{N_b}^{1(i)} \tag{27}$$

$$\mathbf{W}_2^{(i+1)} = \hat{\mathbf{U}}_S \hat{\mathbf{\Lambda}}_S^{-1} \hat{\mathbf{U}}_S^H \tilde{\mathbf{P}}_{N_b}^{2(i)} \tag{28}$$

where $\mathbf{U}_S$ are the signal space eigenvectors and $\mathbf{\Lambda}_S$ are the signal space eigenvalues. The complete algorithm is given in Table 1. The algorithm is called the (*semiblind constant-modulus algorithm*) (SBCMA).

5. SIMULATION EXAMPLES

This section compares the MSE and probability of error performance of the SBCMA algorithm against LS. Channel coefficients, $\{\beta_{ia}^k[l]\}_{l=0}^{L_k-1}$, are randomly generated for each user $(k = 1, \ldots, K)$ and for each transmitter/receiver pair $(i = 1, 2, a = 1, \ldots, A)$ from a complex Gaussian distribution of unit variance and zero mean. The channel coefficients do not change during the transmission of N_b data symbols. SNR is defined as $10 \log_{10}(1/\sigma^2)$. In all cases

Table 1. SBCMA

In: $\hat{\mathbf{U}}_s$, $\hat{\mathbf{\Lambda}}_s$, $\{\mathbf{r}(k)\}_{k=0}^{N_b/2-1}$, $\{b_1[k]\}_{k=0}^{N_t-1}$, ζ *Out*: $\mathbf{W}_{1,2}$

$\mathbf{H} \triangleq \hat{\mathbf{U}}_s \hat{\mathbf{\Lambda}}_s^{-1} \hat{\mathbf{U}}_s^H$

$\mathbf{X} \triangleq [\mathbf{r}(0), \ldots, \mathbf{r}(N_b/2-1)]$

Choose $\mathbf{W}_1^{(0)} = \mathbf{W}_1^{LS}, \mathbf{W}_2^{(0)} = \mathbf{W}_2^{LS}$

for $i = 0, 1, \ldots$

a. $Y_1 = (\mathbf{W}_1^{(i)H} \mathbf{X}) / |\mathbf{W}_1^{(i)H} \mathbf{X}|$
$Y_2 = (\mathbf{W}_2^{(i)H} \mathbf{X}) / |\mathbf{W}_2^{(i)H} \mathbf{X}|$
$\tilde{\mathbf{b}}_1 = [\mathbf{b}_{Nt}^1, Y_1[N_t/2], \ldots, Y_1[N_b/2-1]]$
$\tilde{\mathbf{b}}_2 = [\mathbf{b}_{Nt}^2, Y_2[N_t/2], \ldots, Y_2[N_b/2-1]]$

b. $\tilde{\mathbf{P}}_{N_b}^{1(i)} = (\mathbf{X} \cdot \tilde{\mathbf{b}}_1^H)/(N_b/2)$
$\tilde{\mathbf{P}}_{N_b}^{2(i)} = (\mathbf{X} \cdot \tilde{\mathbf{b}}_2^T)/(N_b/2)$

c. $\mathbf{W}_1^{(i+1)} = \mathbf{H} \cdot \tilde{\mathbf{P}}_{N_b}^{1(i)}, \mathbf{W}_2^{(i+1)} = \mathbf{H} \cdot \tilde{\mathbf{P}}_{N_b}^{2(i)}$

until $\|\mathbf{W}_1^{(i+1)} - \mathbf{W}_1^{(i)}\|^2 / \|\mathbf{W}_1^{(i)}\|^2 < \zeta$

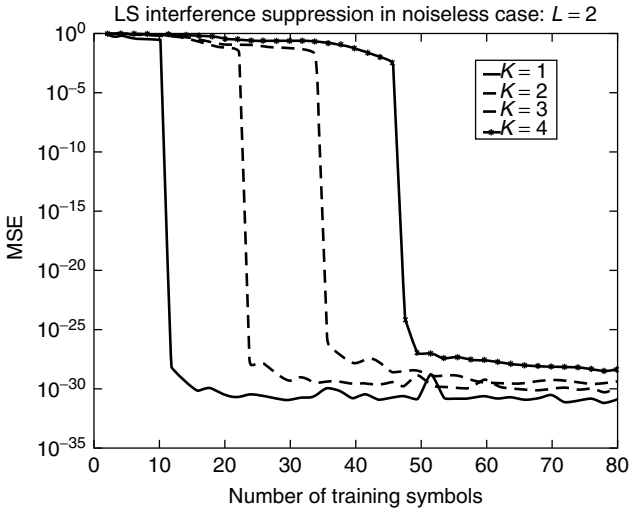

Figure 4. MSE comparison for noiseless case ($\sigma^2 = 0$): $L = 2$; $K = 1, 2, 3, 4$; $A = 2$; $N = 7$.

$\zeta = 10^{-5}$, and $N = 7$. The signal space rank was estimated using the MDL criterion.

Figure 4 demonstrates the zero-forcing ability of the LS filter when the number of training symbols is greater than the signal space dimensionality [as predicted by Eq. (22)]. In this case $L = 2$ and K is increased from 1 to 4. It is seen that once $N_t \geq 2 \cdot \kappa$ there is complete suppression of multiple access and intersymbol interference.

Figure 5 compares the MSE performance of the SBCMA with LS under the conditions that $K = 3, L = 2$ and $A = 2$ or $A = 4$. It is observed that the SBCMA uses significantly fewer training symbols than the LS and that the SBCMA is able to converge using fewer training symbols than required by LS in the noiseless case (36 in this case). When $A = 4$, the MSE is significantly lower but the required number of training symbols for convergence is roughly the same. This can be understood from the fact that increasing A does not increase the column space of $\mathbf{G}$.

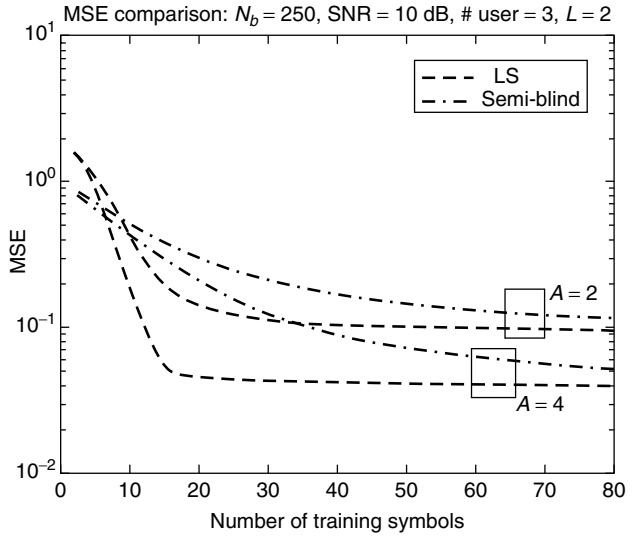

Figure 5. MSE comparison for $A = 2$ and $A = 4$: SNR = 10 dB, $L = 2, K = 3, N = 7$.

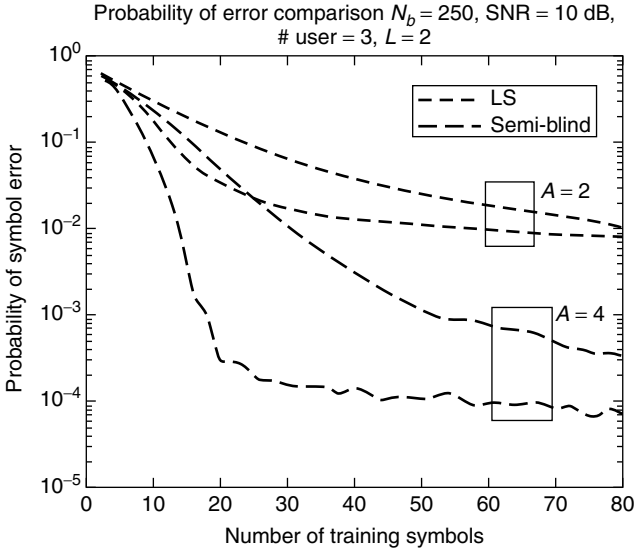

Figure 6. Probability of error comparison for $A = 2$ and $A = 4$: SNR = 10 dB, $L = 2, K = 3, N = 7$.

Finally, Fig. 6 compares the probability of error performance of the SBCMA with LS under the same conditions as above. Again, we observe the superior convergence speed of the SBCMA over LS.

6. CONCLUSION

Some theoretical results and a practical approach on spatio-temporal signal processing for wireless communications have been presented. The investigation for efficient utilization of multiple antennas at both ends of a wireless transceiver combined has raised the expectations for significant increases of the system capacity but at the same time created new challenges in developing the required signal processing technologies. The research and developments in this area are ongoing, and the corresponding literature is rapidly increasing as we now try to define the systems that will succeed the third generation of wireless mobile systems.

BIOGRAPHIES

Dimitrios Hatzinakos, Ph.D., is a Professor at the Department of Electrical and Computer Engineering, University of Toronto. He has also served as Chair of the Communications Group of the Department since July 1, 1999. His research interests are in the area of digital signal processing with applications to wireless communications, image processing, and multimedia. He is author or co-author of more than 120 papers in technical journals and conference proceedings, and he has contributed to five books in his areas of interest.

He served as an Associate Editor for the *IEEE Transactions on Signal Processing* from July 1998 until 2001; Guest Editor for the special issue of *Signal Processing*, Elsevier, on *Signal Processing Technologies*

for Short Burst Wireless Communications, which appeared in October 2000. He was a member of the Conference board of the IEEE Statistical Signal and Array Processing Technical Committee (SSAP) from 1992 to 1995 and was Technical Program co-Chair of the 5th Workshop on Higher-Order Statistics in July 1997. He is a senior member of the IEEE and member of EURASIP, the Professional Engineers of Ontario (PEO), and the Technical Chamber of Greece.

Ryan A. Pacheco is currently working towards a Ph.D. in Electrical Engineering at the University of Toronto. His research is concerned with blind/semiblind interference suppression, tracking, and signal acquisition for wireless communications.

SPEECH CODING: FUNDAMENTALS AND APPLICATIONS

MARK HASEGAWA-JOHNSON

1. INTRODUCTION

Speech coding is the process of obtaining a compact representation of voice signals for efficient transmission over band-limited wired and wireless channels and/or storage. Today, speech coders have become essential components in telecommunications and in the multimedia infrastructure. Commercial systems that rely on efficient speech coding include cellular communication, voice over internet protocol (VOIP), videoconferencing, electronic toys, archiving, and digital simultaneous voice and data (DSVD), as well as numerous PC-based games and multimedia applications.

Speech coding is the art of creating a minimally redundant representation of the speech signal that can be efficiently transmitted or stored in digital media, and decoding the signal with the best possible perceptual quality. Like any other continuous-time signal, speech may be represented digitally through the processes of sampling and quantization; speech is typically quantized using either 16-bit uniform or 8-bit companded quantization. Like many other signals, however, a sampled speech

signal contains a great deal of information that is either redundant (nonzero mutual information between successive samples in the signal) or perceptually irrelevant (information that is not perceived by human listeners). Most telecommunications coders are *lossy*, meaning that the synthesized speech is perceptually similar to the original but may be physically dissimilar.

A speech coder converts a digitized speech signal into a coded representation, which is usually transmitted in frames. A speech decoder receives coded frames and synthesizes reconstructed speech. Standards typically dictate the input–output relationships of both coder and decoder. The input–output relationship is specified using a reference implementation, but novel implementations are allowed, provided that input–output equivalence is maintained. Speech coders differ primarily in bit rate (measured in bits per sample or bits per second), complexity (measured in operations per second), delay (measured in milliseconds between recording and playback), and perceptual quality of the synthesized speech. *Narrowband* (NB) coding refers to coding of speech signals whose bandwidth is less than 4 kHz (8 kHz sampling rate), while *wideband* (WB) coding refers to coding of 7-kHz-bandwidth signals (14–16 kHz sampling rate). NB coding is more common than WB coding mainly because of the narrowband nature of the wireline telephone channel (300–3600 Hz). More recently, however, there has been an increased effort in wideband speech coding because of several applications such as videoconferencing.

There are different types of speech coders. Table 1 summarizes the bit rates, algorithmic complexity, and standardized applications of the four general classes of coders described in this article; Table 2 lists a selection of specific speech coding standards. Waveform coders attempt to code the exact shape of the speech signal waveform, without considering the nature of human speech production and speech perception. These coders are high-bit-rate coders (typically above 16 kbps). Linear prediction coders (LPCs), on the other hand, assume that the speech signal is the output of a linear time-invariant (LTI) model of speech production. The transfer function of that model is assumed to be all-pole (autoregressive model). The excitation function is a quasiperiodic signal constructed from discrete pulses (1–8 per pitch period), pseudorandom noise, or some combination of the two. If the excitation is generated only at the receiver, based on a transmitted pitch period and voicing information, then the system is designated as an LPC vocoder. LPC vocoders that provide extra information about the spectral shape of the excitation have been adopted as coder standards between 2.0 and 4.8 kbps. LPC-based analysis-by-synthesis coders (LPC-AS), on the other hand, choose an excitation function by explicitly testing a large set of candidate excitations and choosing the best. LPC-AS coders are used in most standards between 4.8 and 16 kbps. Subband coders are frequency-domain coders that attempt to parameterize the speech signal in terms of spectral properties in different frequency bands. These coders are less widely used than LPC-based coders but have the advantage of being scalable and do not model the incoming signal as speech. Subband coders are widely used for high-quality audio coding.

This article is organized as follows. Sections 2, 3, 4 and 5 present the basic principles behind waveform coders, subband coders, LPC-based analysis-by-synthesis coders, and LPC-based vocoders, respectively. Section 6 describes the different quality metrics that are used to evaluate speech coders, while Section 7 discusses a variety of issues that arise when a coder is implemented in a communications network, including voice over IP, multirate coding, and channel coding. Section 8 presents an overview of standardization activities involving speech coding, and we conclude in Section 9 with some final remarks.

2. WAVEFORM CODING

Waveform coders attempt to code the exact shape of the speech signal waveform, without considering in detail the nature of human speech production and speech perception. Waveform coders are most useful in applications that require the successful coding of both speech and nonspeech signals. In the public switched telephone network (PSTN), for example, successful transmission of modem and fax signaling tones, and switching signals is nearly as important as the successful transmission of speech. The most commonly used waveform coding algorithms are uniform 16-bit PCM, companded 8-bit PCM [48], and ADPCM [46].

2.1. Pulse Code Modulation (PCM)

Pulse code modulation (PCM) is the name given to memoryless coding algorithms that quantize each sample of $s(n)$ using the same reconstruction levels $\hat{s}_k$, $k = 0, \ldots, m, \ldots, K$, regardless of the values of previous samples. The reconstructed signal $\hat{s}(n)$ is given by

$$\hat{s}(n) = \hat{s}_m \quad \text{for} \quad s(n) \text{ s.t. } (s(n) - \hat{s}_m)^2 = \min_{k=0,\ldots,K} (s(n) - \hat{s}_k)^2 \tag{1}$$

Many speech and audio applications use an odd number of reconstruction levels, so that background noise signals with a very low level can be quantized exactly to

Table 1. Characteristics of Standardized Speech Coding Algorithms in Each of Four Broad Categories

Speech Coder Class	Rates (kbps)	Complexity	Standardized Applications	Section
Waveform coders	16–64	Low	Landline telephone	2
Subband coders	12–256	Medium	Teleconferencing, audio	3
LPC-AS	4.8–16	High	Digital cellular	4
LPC vocoder	2.0–4.8	High	Satellite telephony, military	5

	2.4	3.4	DDVPC	MELP	MELP	1996
	4.8	3.4	DDVPC	FS1016	CELP	1989
	16–32	3.4	DDVPC	CVSD	CVSD	

$\hat{s}_{K/2} = 0$. One important exception is the A-law companded PCM standard [48], which uses an even number of reconstruction levels.

2.1.1. Uniform PCM. Uniform PCM is the name given to quantization algorithms in which the reconstruction levels are uniformly distributed between $S_{\max}$ and $S_{\min}$. The advantage of uniform PCM is that the quantization error power is independent of signal power; high-power signals are quantized with the same resolution as low-power signals. Invariant error power is considered desirable in many digital audio applications, so 16-bit uniform PCM is a standard coding scheme in digital audio.

The error power and SNR of a uniform PCM coder vary with bit rate in a simple fashion. Suppose that a signal is quantized using B bits per sample. If zero is a reconstruction level, then the quantization step size Δ is

$$\Delta = \frac{S_{\max} - S_{\min}}{2^B - 1} \tag{2}$$

Assuming that quantization errors are uniformly distributed between $\Delta/2$ and $-\Delta/2$, the quantization error power is

$$\begin{aligned} 10\log_{10} E[e^2(n)] &= 10\log_{10}\frac{\Delta^2}{12} \\ &\approx \text{constant} + 20\log_{10}(S_{\max} - S_{\min}) - 6B \end{aligned} \tag{3}$$

2.1.2. Companded PCM. Companded PCM is the name given to coders in which the reconstruction levels $\hat{s}_k$ are not uniformly distributed. Such coders may be modeled using a compressive nonlinearity, followed by uniform PCM, followed by an expansive nonlinearity:

$$\begin{aligned} s(n) \rightarrow \boxed{\text{compress}} \rightarrow t(n) \rightarrow \boxed{\text{uniform PCM}} \\ \rightarrow \hat{t}(n) \rightarrow \boxed{\text{expand}} \rightarrow \hat{s}(n) \end{aligned} \tag{4}$$

It can be shown that, if small values of $s(n)$ are more likely than large values, expected error power is minimized by a companding function that results in a higher density of reconstruction levels $\hat{x}_k$ at low signal levels than at high signal levels [78]. A typical example is the μ-law companding function [48] (Fig. 1), which is given by

$$t(n) = S_{\max}\frac{\log(1 + \mu|s(n)/S_{\max}|)}{\log(1+\mu)}\text{sign}(s(n)) \tag{5}$$

where μ is typically between 0 and 256 and determines the amount of nonlinear compression applied.

2.2. Differential PCM (DPCM)

Successive speech samples are highly correlated. The long-term average spectrum of voiced speech is reasonably

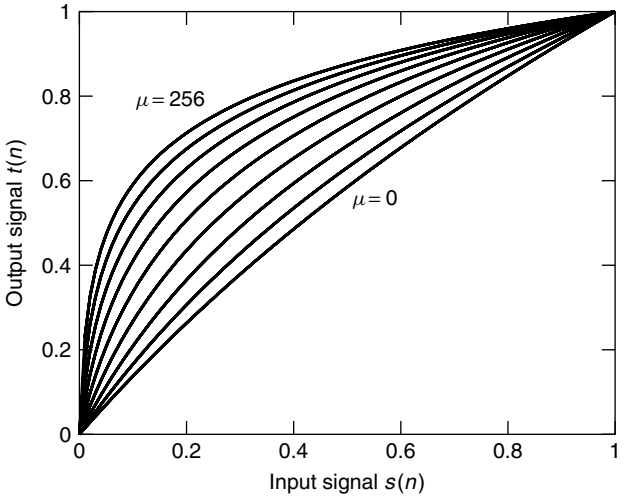

Figure 1. μ-law companding function, $\mu = 0, 1, 2, 4, 8, \ldots, 256$.

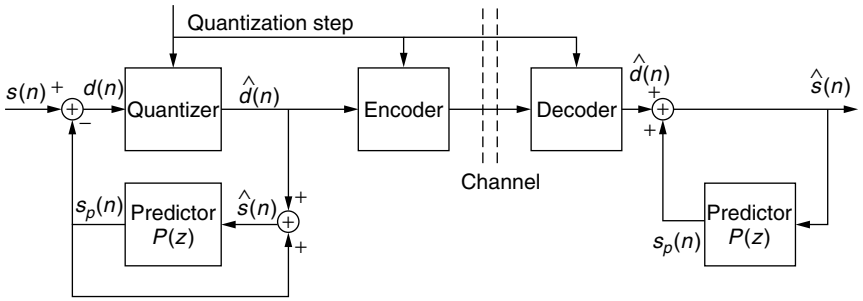

Figure 2. Schematic of a DPCM coder.

well approximated by the function $S(f) = 1/f$ above about 500 Hz; the first-order intersample correlation coefficient is approximately 0.9. In differential PCM, each sample $s(n)$ is compared to a prediction $s_p(n)$, and the difference is called the prediction residual $d(n)$ (Fig. 2). $d(n)$ has a smaller dynamic range than $s(n)$, so for a given error power, fewer bits are required to quantize $d(n)$.

Accurate quantization of $d(n)$ is useless unless it leads to accurate quantization of $s(n)$. In order to avoid amplifying the error, DPCM coders use a technique copied by many later speech coders; the encoder includes an embedded decoder, so that the reconstructed signal $\hat{s}(n)$ is known at the encoder. By using $\hat{s}(n)$ to create $s_p(n)$, DPCM coders avoid amplifying the quantization error:

$$d(n) = s(n) - s_p(n) \tag{6}$$

$$\hat{s}(n) = \hat{d}(n) + s_p(n) \tag{7}$$

$$e(n) = s(n) - \hat{s}(n) = d(n) - \hat{d}(n) \tag{8}$$

Two existing standards are based on DPCM. In the first type of coder, continuously varying slope delta modulation (CVSD), the input speech signal is upsampled to either 16 or 32 kHz. Values of the upsampled signal are predicted using a one-tap predictor, and the difference signal is quantized at one bit per sample, with an adaptively varying Δ. CVSD performs badly in quiet environments, but in extremely noisy environments (e.g., helicopter cockpit), CVSD performs better than any LPC-based algorithm, and for this reason it remains the U.S. Department of Defense recommendation for extremely noisy environments [64,96].

DPCM systems with adaptive prediction and quantization are referred to as adaptive differential PCM systems (ADPCM). A commonly used ADPCM standard is G.726, which can operate at 16, 24, 32, or 40 kbps (2–5 bits/sample) [45]. G.726 ADPCM is frequently used at 32 kbps in landline telephony. The predictor in G.726 consists of an adaptive second-order IIR predictor in series with an adaptive sixth-order FIR predictor. Filter coefficients are adapted using a computationally simplified gradient descent algorithm. The prediction residual is quantized using a semilogarithmic companded PCM quantizer at a rate of 2–5 bits per sample. The quantization step size adapts to the amplitude of previous samples of the quantized prediction error signal; the speed of adaptation is controlled by an estimate of the type of signal, with adaptation to speech signals being faster than adaptation to signaling tones.

3. SUBBAND CODING

In subband coding, an analysis filterbank is first used to filter the signal into a number of frequency bands and then bits are allocated to each band by a certain criterion. Because of the difficulty in obtaining high-quality speech at low bit rates using subband coding schemes, these techniques have been used mostly for wideband medium to high bit rate speech coders and for audio coding.

For example, G.722 is a standard in which ADPCM speech coding occurs within two subbands, and bit allocation is set to achieve 7-kHz audio coding at rates of 64 kbps or less.

In Refs. 12,13, and 30 subband coding is proposed as a flexible scheme for robust speech coding. A speech production model is not used, ensuring robustness to speech in the presence of background noise, and to nonspeech sources. High-quality compression can be achieved by incorporating masking properties of the human auditory system [54,93]. In particular, Tang et al. [93] present a scheme for robust, high-quality, scalable, and embedded speech coding. Figure 3 illustrates the basic structure of the coder. Dynamic bit allocation and prioritization and embedded quantization are used to optimize the perceptual quality of the embedded bitstream, resulting in little performance degradation relative to a nonembedded implementation. A subband spectral analysis technique was developed that substantially reduces the complexity of computing the perceptual model.

The encoded bitstream is embedded, allowing the coder output to be scalable from high quality at higher

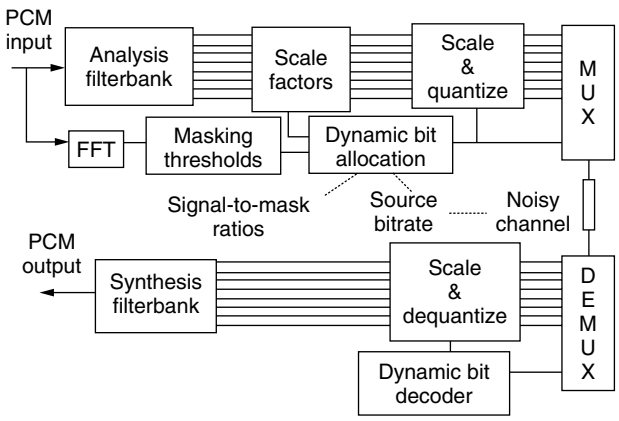

Figure 3. Structure of a perceptual subband speech coder [93].

bit rates, to lower quality at lower rates, supporting a wide range of service and resource utilization. The lower bit rate representation is obtained simply through truncation of the higher bit rate representation. Since source rate adaptation is performed through truncation of the encoded stream, interaction with the source coder is not required, making the coder ideally suited for rate adaptive communication systems.

Even though subband coding is not widely used for speech coding today, it is expected that new standards for wideband coding and rate-adaptive schemes will be based on subband coding or a hybrid technique that includes subband coding. This is because subband coders are more easily scalable in bit rate than standard CELP techniques, an issue which will become more critical for high-quality speech and audio transmission over wireless communication channels and the Internet, allowing the system to seamlessly adapt to changes in both the transmission environment and network congestion.

4. LPC-BASED ANALYSIS BY SYNTHESIS

An analysis-by-synthesis speech coder consists of the following components:

- A model of speech production that depends on certain parameters θ:
$$\hat{s}(n) = f(\theta) \tag{9}$$
- A list of K possible parameter sets for the model
$$\theta_1, \ldots, \theta_k, \ldots, \theta_K \tag{10}$$
- An error metric $|E_k|^2$ that compares the original speech signal $s(n)$ and the coded speech signal $\hat{s}(n)$. In LPC-AS coders, $|E_k|^2$ is typically a perceptually weighted mean-squared error measure.

A general analysis-by-synthesis coder finds the optimum set of parameters by synthesizing all of the K different speech waveforms $\hat{s}_k(n)$ corresponding to the K possible parameter sets θ_k, computing $|E_k|^2$ for each synthesized waveform, and then transmitting the index of the parameter set which minimizes $|E_k|^2$. Choosing a set of transmitted parameters by explicitly computing $\hat{s}_k(n)$ is called "closed loop" optimization, and may be contrasted with "open-loop" optimization, in which coder parameters are chosen on the basis of an analytical formula without explicit computation of $\hat{s}_k(n)$. Closed-loop optimization of all parameters is prohibitively expensive, so LPC-based analysis-by-synthesis coders typically adopt the following compromise. The gross spectral shape is modeled using an all-pole filter $1/A(z)$ whose parameters are estimated in open-loop fashion, while spectral fine structure is modeled using an excitation function $U(z)$ whose parameters are optimized in closed-loop fashion (Fig. 4).

4.1. The Basic LPC Model

In LPC-based coders, the speech signal $S(z)$ is viewed as the output of a linear time-invariant (LTI) system whose input is the excitation signal $U(z)$, and whose transfer function is represented by the following:

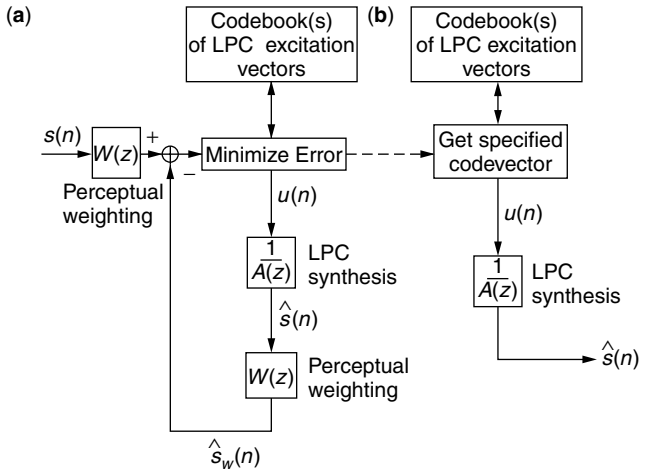

Figure 4. General structure of an LPC-AS coder (**a**) and decoder (**b**). LPC filter $A(z)$ and perceptual weighting filter $W(z)$ are chosen open-loop, then the excitation vector $u(n)$ is chosen in a closed-loop fashion in order to minimize the error metric $|E|^2$.

$$S(z) = \frac{U(z)}{A(z)} = \frac{U(z)}{1 - \sum_{i=1}^{p} a_i z^{-i}} \tag{11}$$

Most of the zeros of $A(z)$ correspond to resonant frequencies of the vocal tract or *formant frequencies*. Formant frequencies depend on the geometry of the vocal tract; this is why men and women, who have different vocal-tract shapes and lengths, have different formant frequencies for the same sounds.

The number of LPC coefficients (p) depends on the signal bandwidth. Since each pair of complex-conjugate poles represents one formant frequency and since there is, on average, one formant frequency per 1 kHz, p is typically equal to $2BW$ (in kHz) + (2 to 4). Thus, for a 4 kHz speech signal, a 10th–12th-order LPC model would be used.

This system is excited by a signal $u(n)$ that is uncorrelated with itself over lags of less than $p + 1$. If the underlying speech sound is unvoiced (the vocal folds do not vibrate), then $u(n)$ is uncorrelated with itself even at larger time lags, and may be modeled using a pseudo-random-noise signal. If the underlying speech is voiced (the vocal folds vibrate), then $u(n)$ is quasiperiodic with a fundamental period called the "pitch period."

4.2. Pitch Prediction Filtering

In an LPC-AS coder, the LPC excitation is allowed to vary smoothly between fully voiced conditions (as in a vowel) and fully unvoiced conditions (as in /s/). Intermediate levels of voicing are often useful to model partially voiced phonemes such as /z/.

The partially voiced excitation in an LPC-AS coder is constructed by passing an uncorrelated noise signal $c(n)$ through a pitch prediction filter [2,79]. A typical pitch prediction filter is

$$u(n) = gc(n) + bu(n - T_0) \tag{12}$$

where T_0 is the pitch period. If $c(n)$ is unit variance white noise, then according to Eq. (12) the spectrum of $u(n)$ is

$$|U(e^{j\omega})|^2 = \frac{g^2}{1 + b^2 - 2b\cos\omega T_0} \tag{13}$$

Figure 5 shows the normalized magnitude spectrum $(1-b)|U(e^{j\omega})|$ for several values of b between 0.25 and 1. As shown, the spectrum varies smoothly from a uniform spectrum, which is heard as unvoiced, to a harmonic spectrum that is heard as voiced, without the need for a binary voiced/unvoiced decision.

In LPC-AS coders, the noise signal $c(n)$ is chosen from a "stochastic codebook" of candidate noise signals. The stochastic codebook index, the pitch period, and the gains b and g are chosen in a closed-loop fashion in order to minimize a perceptually weighted error metric. The search for an optimum T_0 typically uses the same algorithm as the search for an optimum $c(n)$. For this reason, the list of excitation samples delayed by different candidate values of T_0 is typically called an "adaptive codebook" [87].

4.3. Perceptual Error Weighting

Not all types of distortion are equally audible. Many types of speech coders, including LPC-AS coders, use simple models of human perception in order to minimize the audibility of different types of distortion. In LPC-AS coding, two types of perceptual weighting are commonly used. The first type, perceptual weighting of the residual quantization error, is used during the LPC excitation search in order to choose the excitation vector with the least audible quantization error. The second type, adaptive postfiltering, is used to reduce the perceptual importance of any remaining quantization error.

4.3.1. Perceptual Weighting of the Residual Quantization Error. The excitation in an LPC-AS coder is chosen to minimize a perceptually weighted error metric. Usually, the error metric is a function of the time domain waveform error signal

$$e(n) = s(n) - \hat{s}(n) \tag{14}$$

Early LPC-AS coders minimized the mean-squared error

$$\sum_n e^2(n) = \frac{1}{2\pi}\int_{-\pi}^{\pi} |E(e^{j\omega})|^2\, d\omega \tag{15}$$

It turns out that the MSE is minimized if the error spectrum, $E(e^{j\omega})$, is white — that is, if the error signal $e(n)$ is an uncorrelated random noise signal, as shown in Fig. 6.

Not all noises are equally audible. In particular, noise components near peaks of the speech spectrum are hidden by a "masking spectrum" $M(e^{j\omega})$, so that a shaped noise spectrum at lower SNR may be less audible than a white-noise spectrum at higher SNR (Fig. 7). The audibility of noise may be estimated using a noise-to-masker ratio $|E_w|^2$:

$$|E_w|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{|E(e^{j\omega})|^2}{|M(e^{j\omega})|^2}\, d\omega \tag{16}$$

The masking spectrum $M(e^{j\omega})$ has peaks and valleys at the same frequencies as the speech spectrum, but the difference in amplitude between peaks and valleys is somewhat smaller than that of the speech spectrum. A variety of algorithms exist for estimating the masking spectrum, ranging from extremely simple to extremely complex [51]. One of the simplest model masking spectra that has the properties just described is as follows [2]:

$$M(z) = \frac{|A(z/\gamma_2)|}{|A(z/\gamma_1)|}, \quad 0 < \gamma_2 < \gamma_1 \le 1 \tag{17}$$

where $1/A(z)$ is an LPC model of the speech spectrum. The poles and zeros of $M(z)$ are at the same frequencies as the poles of $1/A(z)$, but have broader bandwidths. Since the zeros of $M(z)$ have broader bandwidth than its poles, $M(z)$ has peaks where $1/A(z)$ has peaks, but the difference between peak and valley amplitudes is somewhat reduced.

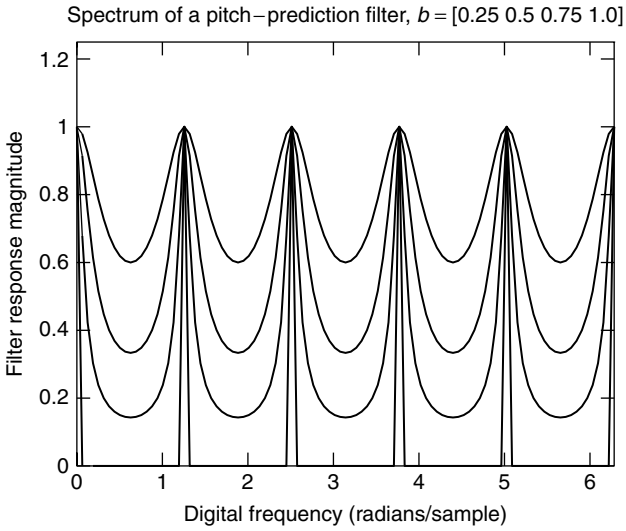

Figure 5. Normalized magnitude spectrum of the pitch prediction filter for several values of the prediction coefficient.

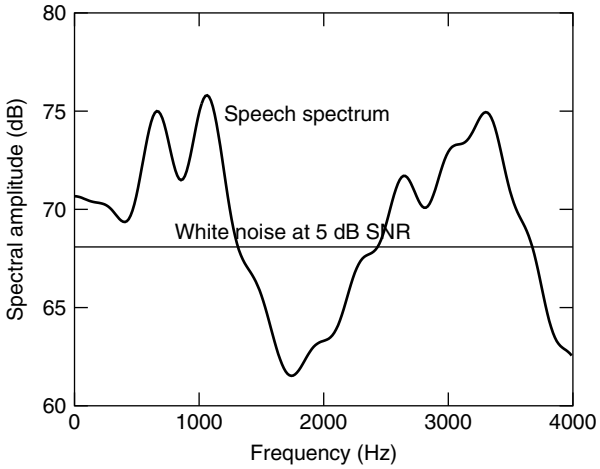

Figure 6. The minimum-energy quantization noise is usually characterized as white noise.

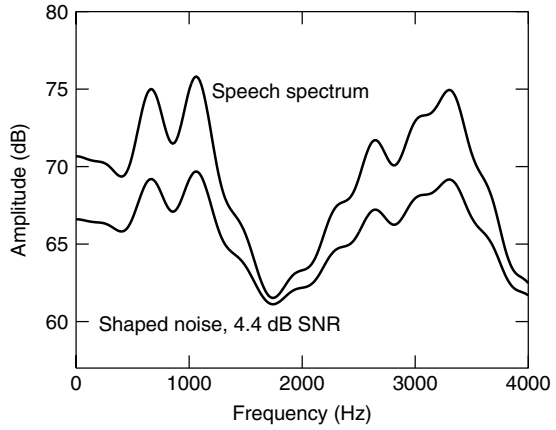

Figure 7. Shaped quantization noise may be less audible than white quantization noise, even at slightly lower SNR.

The noise-to-masker ratio may be efficiently computed by filtering the speech signal using a perceptual weighting filter $W(z) = 1/M(z)$. The perceptually weighted input speech signal is

$$S_w(z) = W(z)S(z) \tag{18}$$

Likewise, for any particular candidate excitation signal, the perceptually weighted output speech signal is

$$\hat{S}_w(z) = W(z)\hat{S}(z) \tag{19}$$

Given $s_w(n)$ and $\hat{s}_w(n)$, the noise-to-masker ratio may be computed as follows:

$$|E_w|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi} |S_w(e^{j\omega}) - \hat{S}_w(e^{j\omega})|^2\, d\omega = \sum_n (s_w(n) - \hat{s}_w(n))^2 \tag{20}$$

4.3.2. Adaptive Postfiltering. Despite the use of perceptually weighted error minimization, the synthesized speech coming from an LPC-AS coder may contain audible quantization noise. In order to minimize the perceptual effects of this noise, the last step in the decoding process is often a set of adaptive postfilters [11,80]. Adaptive postfiltering improves the perceptual quality of noisy speech by giving a small extra emphasis to features of the spectrum that are important for human-to-human communication, including the pitch periodicity (if any) and the peaks in the spectral envelope.

A pitch postfilter (or long-term predictive postfilter) enhances the periodicity of voiced speech by applying either an FIR or IIR comb filter to the output. The time delay and gain of the comb filter may be set equal to the transmitted pitch lag and gain, or they may be recalculated at the decoder using the reconstructed signal $\hat{s}(n)$. The pitch postfilter is applied only if the proposed comb filter gain is above a threshold; if the comb filter gain is below threshold, the speech is considered unvoiced, and no pitch postfilter is used. For improved perceptual quality, the LPC excitation signal may be interpolated to a higher sampling rate in order to allow the use of fractional pitch periods; for example, the postfilter in the ITU G.729 coder uses pitch periods quantized to $\frac{1}{8}$ sample.

A short-term predictive postfilter enhances peaks in the spectral envelope. The form of the short-term postfilter is similar to that of the masking function $M(z)$ introduced in the previous section; the filter has peaks at the same frequencies as $1/A(z)$, but the peak-to-valley ratio is less than that of $A(z)$.

Postfiltering may change the gain and the average spectral tilt of $\hat{s}(n)$. In order to correct these problems, systems that employ postfiltering may pass the final signal through a one-tap FIR preemphasis filter, and then modify its gain, prior to sending the reconstructed signal to a D/A converter.

4.4. Frame-Based Analysis

The characteristics of the LPC excitation signal $u(n)$ change quite rapidly. The energy of the signal may change from zero to nearly full amplitude within one millisecond at the release of a plosive sound, and a mistake of more than about 5 ms in the placement of such a sound is clearly audible. The LPC coefficients, on the other hand, change relatively slowly. In order to take advantage of the slow rate of change of LPC coefficients without sacrificing the quality of the coded residual, most LPC-AS coders encode speech using a frame–subframe structure, as depicted in Fig. 8. A frame of speech is approximately 20 ms in length, and is composed of typically three to four subframes. The LPC excitation is transmitted only once per subframe, while the LPC coefficients are transmitted only once per frame. The LPC coefficients are computed by analyzing a window of speech that is usually longer than the speech frame (typically 30–60 ms). In order to minimize the number of future samples required to compute LPC coefficients, many LPC-AS coders use an asymmetric window that may include several hundred milliseconds of past context, but that emphasizes the samples of the current frame [21,84].

The perceptually weighted original signal $s_w(n)$ and weighted reconstructed signal $\hat{s}_w(n)$ in a given subframe

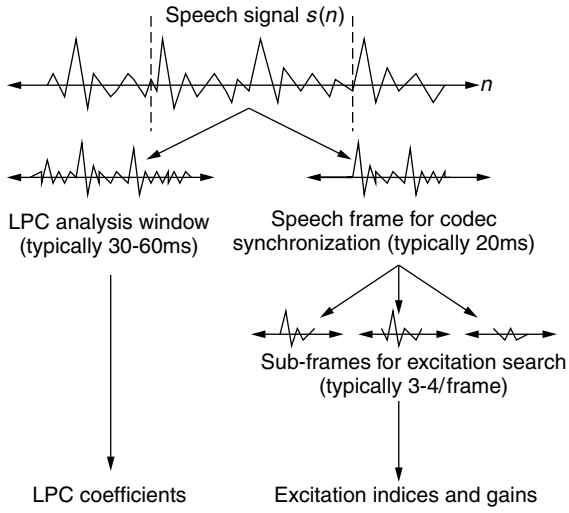

Figure 8. The frame/subframe structure of most LPC analysis by synthesis coders.

are often written as L-dimensional row vectors S and $\hat{S}$, where the dimension L is the length of a subframe:

$$S_w = [s_w(0), \ldots, s_w(L-1)], \quad \hat{S}_w = [\hat{s}_w(0), \ldots, \hat{s}_w(L-1)] \tag{21}$$

The core of an LPC-AS coder is the closed-loop search for an optimum coded excitation vector U, where U is typically composed of an "adaptive codebook" component representing the periodicity, and a "stochastic codebook" component representing the noiselike part of the excitation. In general, U may be represented as the weighted sum of several "shape vectors" X_m, $m = 1, \ldots, M$, which may be drawn from several codebooks, including possibly multiple adaptive codebooks and multiple stochastic codebooks:

$$U = GX, \quad G = [g_1, g_2, \ldots], \quad X = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \end{bmatrix} \tag{22}$$

The choice of shape vectors and the values of the gains g_m are jointly optimized in a closed-loop search, in order to minimize the perceptually weighted error metric $|S_w - \hat{S}_w|^2$.

The value of S_w may be computed prior to any codebook search by perceptually weighting the input speech vector. The value of $\hat{S}_w$ must be computed separately for each candidate excitation, by synthesizing the speech signal $\hat{s}(n)$, and then perceptually weighting to obtain $\hat{s}_w(n)$. These operations may be efficiently computed, as described below.

4.4.1. Zero State Response and Zero Input Response. Let the filter $H(z)$ be defined as the composition of the LPC synthesis filter and the perceptual weighting filter, thus $H(z) = W(z)/A(z)$. The computational complexity of the excitation parameter search may be greatly simplified if $\hat{S}_w$ is decomposed into the zero input response (ZIR) and zero state response (ZSR) of $H(z)$ [97]. Note that the weighted reconstructed speech signal is

$$\hat{S}_w = [\hat{s}_w(0), \ldots, \hat{s}_w(L-1)], \quad \hat{s}_w(n) = \sum_{i=0}^{\infty} h(i)u(n-i) \tag{23}$$

where $h(n)$ is the infinite-length impulse response of $H(z)$. Suppose that $\hat{s}_w(n)$ has already been computed for $n < 0$, and the coder is now in the process of choosing the optimal $u(n)$ for the subframe $0 \le n \le L-1$. The sum above can be divided into two parts: a part that depends on the current subframe input, and a part that does not:

$$\hat{S}_w = \hat{S}_{\text{ZIR}} + UH \tag{24}$$

where $\hat{S}_{\text{ZIR}}$ contains samples of the zero input response of $H(z)$, and the vector UH contains the zero state response. The zero input response is usually computed by implementing the recursive filter $H(z) = W(z)/A(z)$ as the sequence of two IIR filters, and allowing the two filters to run for L samples with zero input. The zero state response is usually computed as the matrix product UH, where

$$H = \begin{bmatrix} h(0) & h(1) & \ldots & h(L-1) \\ 0 & h(0) & \ldots & h(L-2) \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \ldots & h(0) \end{bmatrix},$$
$$U = [u(0), \ldots, u(L-1)] \tag{25}$$

Given a candidate excitation vector U, the perceptually weighted error vector E may be defined as

$$E_w = S_w - \hat{S}_w = \tilde{S} - UH \tag{26}$$

where the target vector $\tilde{S}$ is

$$\tilde{S} = S_w - \hat{S}_{\text{ZIR}} \tag{27}$$

The target vector needs to be computed only once per subframe, prior to the codebook search. The objective of the codebook search, therefore, is to find an excitation vector U that minimizes $|\tilde{S} - UH|^2$.

4.4.2. Optimum Gain and Optimum Excitation. Recall that the excitation vector U is modeled as the weighted sum of a number of codevectors X_m, $m = 1, \ldots, M$. The perceptually weighted error is therefore:

$$|E|^2 = |\tilde{S} - GXH|^2 = \tilde{S}\tilde{S}' - 2GXH\tilde{S}' + GXH(GXH)' \tag{28}$$

where prime denotes transpose. Minimizing $|E|^2$ requires optimum choice of the shape vectors X and of the gains G. It turns out that the optimum gain for each excitation vector can be computed in closed form. Since the optimum gain can be computed in closed form, it need not be computed during the closed-loop search; instead, one can simply assume that each candidate excitation, if selected, would be scaled by its optimum gain. Assuming an optimum gain results in an extremely efficient criterion for choosing the optimum excitation vector [3].

Suppose we define the following additional bits of notation:

$$R_X = XH\tilde{S}', \quad \Sigma = XH(XH)' \tag{29}$$

Then the mean-squared error is

$$|E|^2 = \tilde{S}\tilde{S}' - 2GR_X + G\Sigma G' \tag{30}$$

For any given set of shape vectors X, G is chosen so that $|E|^2$ is minimized, which yields

$$G = R_X'\Sigma^{-1} \tag{31}$$

If we substitute the minimum MSE value of G into Eq. (30), we get

$$|E|^2 = \tilde{S}\tilde{S}' - R_X'\Sigma^{-1}R_X \tag{32}$$

Hence, in order to minimize the perceptually weighted MSE, we choose the shape vectors X in order to maximize the covariance-weighted sum of correlations:

$$X_{\text{opt}} = \arg\max(R'_X \Sigma^{-1} R_X) \tag{33}$$

When the shape matrix X contains more than one row, the matrix inversion in Eq. (33) is often computed using approximate algorithms [4]. In the VSELP coder [25], X is transformed using a modified Gram–Schmidt orthogonalization so that Σ has a diagonal structure, thus simplifying the computation of Eq. (33).

4.5. Types of LPC-AS Coder

4.5.1. Multipulse LPC (MPLPC). In the multipulse LPC algorithm [4,50], the shape vectors are impulses. U is typically formed as the weighted sum of 4–8 impulses per subframe.

The number of possible combinations of impulses grows exponentially in the number of impulses, so joint optimization of the positions of all impulses is usually impossible. Instead, most MPLPC coders optimize the pulse positions one at a time, using something like the following strategy. First, the weighted zero state response of $H(z)$ corresponding to each impulse location is computed. If C_k is an impulse located at $n = k$, the corresponding weighted zero state response is

$$C_k H = [0, \ldots, 0, h(0), h(1), \ldots, h(L-k-1)] \tag{34}$$

The location of the first impulse is chosen in order to optimally approximate the target vector $\tilde{S}_1 = \tilde{S}$, using the methods described in the previous section. After selecting the first impulse location k_1, the target vector is updated according to

$$\tilde{S}_m = \tilde{S}_{m-1} - C_{k_{m-1}} H \tag{35}$$

Additional impulses are chosen until the desired number of impulses is reached. The gains of all pulses may be reoptimized after the selection of each new pulse [87].

Variations are possible. The multipulse coder described in ITU standard G.723.1 transmits a single gain for all the impulses, plus sign bits for each individual impulse. The G.723.1 coder restricts all impulse locations to be either odd or even; the choice of odd or even locations is coded using one bit per subframe [50]. The regular pulse excited LPC algorithm, which was the first GSM full-rate speech coder, synthesized speech using a train of impulses spaced one per 4 samples, all scaled by a single gain term [65]. The alignment of the pulse train was restricted to one of four possible locations, chosen in a closed-loop fashion together with a gain, an adaptive codebook delay, and an adaptive codebook gain.

Singhal and Atal demonstrated that the quality of MPLPC may be improved at low bit rates by modeling the periodic component of an LPC excitation vector using a pitch prediction filter [87]. Using a pitch prediction filter, the LPC excitation signal becomes

$$u(n) = bu(n-D) + \sum_{m=1}^{M} c_{k_m}(n) \tag{36}$$

where the signal $c_k(n)$ is an impulse located at $n = k$ and b is the pitch prediction filter gain. Singhal and Atal proposed choosing D before the locations of any impulses are known, by minimizing the following perceptually weighted error:

$$|E_D|^2 = |\tilde{S} - bX_D H|^2, X_D = [u(-D), \ldots, u((L-1)-D)] \tag{37}$$

The G.723.1 multipulse LPC coder and the GSM (Global System for Mobile Communication) full-rate RPE-LTP (regular-pulse excitation with long-term prediction) coder both use a closed-loop pitch predictor, as do all standardized variations of the CELP coder (see Sections 4.5.2 and 4.5.3). Typically, the pitch delay and gain are optimized first, and then the gains of any additional excitation vectors (e.g., impulses in an MPLPC algorithm) are selected to minimize the remaining error.

4.5.2. Code-Excited LPC (CELP). LPC analysis finds a filter $1/A(z)$ whose excitation is uncorrelated for correlation distances smaller than the order of the filter. Pitch prediction, especially closed-loop pitch prediction, removes much of the remaining intersample correlation. The spectrum of the pitch prediction residual looks like the spectrum of uncorrelated Gaussian noise, but replacing the residual with real noise (noise that is independent of the original signal) yields poor speech quality. Apparently, some of the temporal details of the pitch prediction residual are perceptually important. Schroeder and Atal proposed modeling the pitch prediction residual using a stochastic excitation vector $c_k(n)$ chosen from a list of stochastic excitation vectors, $k = 1, \ldots, K$, known to both the transmitter and receiver [85]:

$$u(n) = bu(n-D) + gc_k(n) \tag{38}$$

The list of stochastic excitation vectors is called a *stochastic codebook*, and the index of the stochastic codevector is chosen in order to minimize the perceptually weighted error metric $|E_k|^2$. Rose and Barnwell discussed the similarity between the search for an optimum stochastic codevector index k and the search for an optimum predictor delay D [82], and Kleijn et al. coined the term "adaptive codebook" to refer to the list of delayed excitation signals $u(n-D)$ which the coder considers during closed-loop pitch delay optimization (Fig. 9).

The CELP algorithm was originally not considered efficient enough to be used in real-time speech coding, but a number of computational simplifications were proposed that resulted in real-time CELP-like algorithms. Trancoso and Atal proposed efficient search methods based on the truncated impulse response of the filter $W(z)/A(z)$, as discussed in Section 4.4 [3,97]. Davidson and Lin separately proposed center clipping the stochastic codevectors, so that most of the samples in each codevector are zero [15,67]. Lin also proposed structuring the stochastic codebook so that each codevector is a slightly-shifted version of the previous codevector; such a codebook is called an *overlapped codebook* [67]. Overlapped stochastic codebooks are rarely used in practice today, but overlapped-codebook search methods are often used to reduce the computational complexity of an adaptive codebook search. In the search of

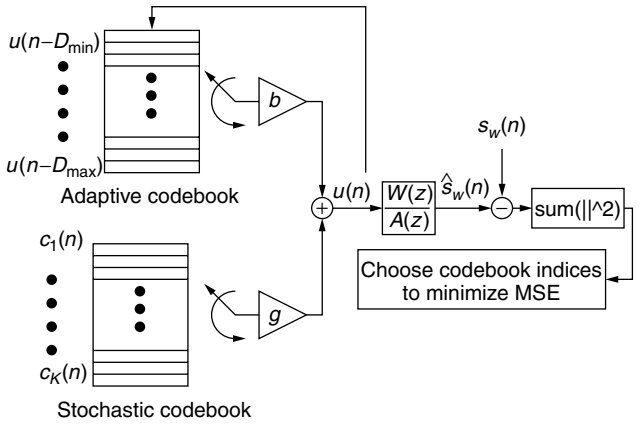

Figure 9. The code-excited LPC algorithm (CELP) constructs an LPC excitation signal by optimally choosing input vectors from two codebooks: an "adaptive" codebook, which represents the pitch periodicity; and a "stochastic" codebook, which represents the unpredictable innovations in each speech frame.

an overlapped codebook, the correlation R_X and autocorrelation Σ introduced in Section 4.4 may be recursively computed, thus greatly reducing the complexity of the codebook search [63].

Most CELP coders optimize the adaptive codebook index and gain first, and then choose a stochastic codevector and gain in order to minimize the remaining perceptually weighted error. If all the possible pitch periods are longer than one subframe, then the entire content of the adaptive codebook is known before the beginning of the codebook search, and the efficient overlapped codebook search methods proposed by Lin may be applied [67]. In practice, the pitch period of a female speaker is often shorter than one subframe. In order to guarantee that the entire adaptive codebook is known before beginning a codebook search, two methods are commonly used: (1) the adaptive codebook search may simply be constrained to only consider pitch periods longer than L samples — in this case, the adaptive codebook will lock onto values of D that are an integer multiple of the actual pitch period (if the same integer multiple is not chosen for each subframe, the reconstructed speech quality is usually good); and (2) adaptive codevectors with delays of $D < L$ may be constructed by simply repeating the most recent D samples as necessary to fill the subframe.

4.5.3. SELP, VSELP, ACELP, and LD-CELP. Rose and Barnwell demonstrated that reasonable speech quality is achieved if the LPC excitation vector is computed completely recursively, using two closed-loop pitch predictors in series, with no additional information [82]. In their "self-excited LPC" algorithm (SELP), the LPC excitation is initialized during the first subframe using a vector of samples known at both the transmitter and receiver. For all frames after the first, the excitation is the sum of an arbitrary number of adaptive codevectors:

$$u(n) = \sum_{m=1}^{M} b_m u(n - D_m) \tag{39}$$

Kleijn et al. developed efficient recursive algorithms for searching the adaptive codebook in SELP coder and other LPC-AS coders [63].

Just as there may be more than one adaptive codebook, it is also possible to use more than one stochastic codebook. The vector-sum excited LPC algorithm (VSELP) models the LPC excitation vector as the sum of one adaptive and two stochastic codevectors [25]:

$$u(n) = bu(n - D) + \sum_{m=1}^{2} g_m c_{k_m}(n) \tag{40}$$

The two stochastic codebooks are each relatively small (typically 32 vectors), so that each of the codebooks may be searched efficiently. The adaptive codevector and the two stochastic codevectors are chosen sequentially. After selection of the adaptive codevector, the stochastic codebooks are transformed using a modified Gram–Schmidt orthogonalization, so that the perceptually weighted speech vectors generated during the first stochastic codebook search are all orthogonal to the perceptually weighted adaptive codevector. Because of this orthogonalization, the stochastic codebook search results in the choice of a stochastic codevector that is jointly optimal with the adaptive codevector, rather than merely sequentially optimal. VSELP is the basis of the Telecommunications Industry Associations digital cellular standard IS-54.

The algebraic CELP (ACELP) algorithm creates an LPC excitation by choosing just one vector from an adaptive codebook and one vector from a fixed codebook. In the ACELP algorithm, however, the fixed codebook is composed of binary-valued or trinary-valued algebraic codes, rather than the usual samples of a Gaussian noise process [1]. Because of the simplicity of the codevectors, it is possible to search a very large fixed codebook very quickly using methods that are a hybrid of standard CELP and MPLPC search algorithms. ACELP is the basis of the ITU standard G.729 coder at 8 kbps. ACELP codebooks may be somewhat larger than the codebooks in a standard CELP coder; the codebook in G.729, for example, contains 8096 codevectors per subframe.

Most LPC-AS coders operate at very low bit rates, but require relatively large buffering delays. The low-delay CELP coder (LD-CELP) operates at 16 kbps [10,47] and is designed to obtain the best possible speech quality, with the constraint that the total algorithmic delay of a tandem coder and decoder must be no more than 2 ms. LPC analysis and codevector search are computed once per 2 ms (16 samples). Transmission of LPC coefficients once per two milliseconds would require too many bits, so LPC coefficients are computed in a recursive backward-adaptive fashion. Before coding or decoding each frame, samples of $\hat{s}(n)$ from the previous frame are windowed, and used to update a recursive estimate of the autocorrelation function. The resulting autocorrelation coefficients are similar to those that would be obtained using a relatively long asymmetric analysis window. LPC coefficients are then computed from the autocorrelation function using the Levinson–Durbin algorithm.

4.6. Line Spectral Frequencies (LSFs) or Line Spectral Pairs (LSPs)

Linear prediction can be viewed as an inverse filtering procedure in which the speech signal is passed through an all-zero filter $A(z)$. The filter coefficients of $A(z)$ are chosen such that the energy in the output, that is, the residual or error signal, is minimized. Alternatively, the inverse filter $A(z)$ can be transformed into two other filters $P(z)$ and $Q(z)$. These new filters turn out to have some interesting properties, and the representation based on them, called the *line spectrum pairs* [89,91], has been used in speech coding and synthesis applications.

Let $A(z)$ be the frequency response of an LPC inverse filter of order p:

$$A(z) = -\sum_{i=0}^{p} a_i z^{-i}$$

with $a_0 = -1$. The a_i values are real, and all the zeros of $A(z)$ are inside the unit circle.

If we use the lattice formulation of LPC, we arrive at a recursive relation between the mth stage $[A_m(z)]$ and the one before it $[A_{m-1}(z)]$ For the pth-order inverse filter, we have

$$A_p(z) = A_{p-1}(z) - k_p z^{-p} A_{p-1}(z^{-1})$$

By allowing the recursion to go one more iteration, we obtain

$$A_{p+1}(z) = A_p(z) - k_{p+1} z^{-(p+1)} A_p(z^{-1}) \tag{41}$$

If we choose $k_{p+1} = \pm 1$ in Eq. (41), we can define two new polynomials as follows:

$$P(z) = A(z) - z^{-(p+1)} A(z^{-1}) \tag{42}$$

$$Q(z) = A(z) + z^{-(p+1)} A(z^{-1}) \tag{43}$$

Physically, $P(z)$ and $Q(z)$ can be interpreted as the inverse transfer function of the vocal tract for the *open-glottis* and *closed-glottis* boundary conditions, respectively [22], and $P(z)/Q(z)$ is the driving-point impedance of the vocal tract as seen from the glottis [36].

If p is odd, the formulae for p_n and q_n are as follows:

$$\begin{aligned} P(z) &= A(z) + z^{-(p+1)} A(z^{-1}) \\ &= \prod_{n=1}^{(p+1)/2} (1 - e^{jp_n} z^{-1})(1 - e^{-jp_n} z^{-1}) \end{aligned} \tag{44}$$

$$\begin{aligned} Q(z) &= A(z) - z^{-(p+1)} A(z^{-1}) \\ &= (1 - z^{-2}) \prod_{n=1}^{(p-1)/2} (1 - e^{jq_n} z^{-1})(1 - e^{-jq_n} z^{-1}) \end{aligned} \tag{45}$$

The LSFs have some interesting characteristics: the frequencies $\{p_n\}$ and $\{q_n\}$ are related to the formant frequencies; the dynamic range of $\{p_n\}$ and $\{q_n\}$ is limited and the two alternate around the unit circle $(0 \le p_1 \le q_1 \le p_2 \ldots)$; $\{p_n\}$ and $\{q_n\}$ are correlated so that intraframe prediction is possible; and they change slowly from one frame to another, hence, interframe prediction is also possible. The interleaving nature of the $\{p_n\}$ and $\{q_n\}$ allow for efficient iterative solutions [58].

Almost all LPC-based coders today use the LSFs to represent the LP parameters. Considerable recent research has been devoted to methods for efficiently quantizing the LSFs, especially using vector quantization (VQ) techniques. Typical algorithms include predictive VQ, split VQ [76], and multistage VQ [66,74]. All of these methods are used in the ITU standard ACELP coder G.729: the moving-average vector prediction residual is quantized using a 7-bit first-stage codebook, followed by second-stage quantization of two subvectors using independent 5-bit codebooks, for a total of 17 bits per frame [49,84].

5. LPC VOCODERS

5.1. The LPC-10e Vocoder

The 2.4-kbps LPC-10e vocoder (Fig. 10) is one of the earliest and one of the longest-lasting standards for low-bit-rate digital speech coding [8,16]. This standard was originally proposed in the 1970s, and was not officially replaced until the selection of the MELP 2.4-kbps coding standard in 1996 [64]. Speech coded using LPC-10e sounds metallic and synthetic, but it is intelligible.

In the LPC-10e algorithm, speech is first windowed using a Hamming window of length 22.5ms. The gain (G) and coefficients (a_i) of a linear prediction filter are calculated for the entire frame using the Levinson–Durbin recursion. Once G and a_i have been computed, the LPC residual signal $d(n)$ is computed:

$$d(n) = \frac{1}{G}\left(s(n) - \sum_{i=1}^{p} a_i s(n-i)\right) \tag{46}$$

The residual signal $d(n)$ is modeled using either a periodic train of impulses (if the speech frame is voiced) or an uncorrelated Gaussian random noise signal (if the frame is unvoiced). The voiced/unvoiced decision is based on the average magnitude difference function (AMDF),

$$\Phi_d(m) = \frac{1}{N - |m|} \sum_{n=|m|}^{N-1} |d(n) - d(n - |m|)| \tag{47}$$

The frame is labeled as voiced if there is a trough in $\Phi_d(m)$ that is large enough to be caused by voiced excitation. Only values of m between 20 and 160 are examined, corresponding to pitch frequencies between 50 and 400 Hz. If the minimum value of $\Phi_d(m)$ in this range is less than

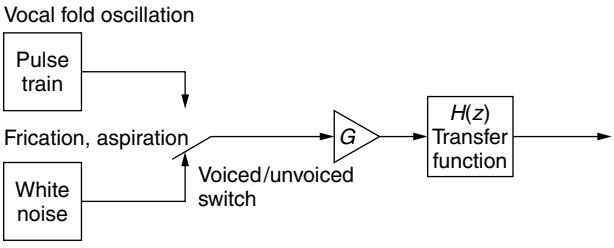

Figure 10. A simplified model of speech production whose parameters can be transmitted efficiently across a digital channel.

a threshold, the frame is declared voiced, and otherwise it is declared unvoiced [8].

If the frame is voiced, then the LPC residual is represented using an impulse train of period T_0, where

$$T_0 = \arg \min_{m=20}^{160} \Phi_d(m) \tag{48}$$

If the frame is unvoiced, a pitch period of $T_0 = 0$ is transmitted, indicating that an uncorrelated Gaussian random noise signal should be used as the excitation of the LPC synthesis filter.

5.2. Mixed-Excitation Linear Prediction (MELP)

The mixed-excitation linear prediction (MELP) coder [69] was selected in 1996 by the United States Department of Defense Voice Processing Consortium (DDVPC) to be the U.S. Federal Standard at 2.4 kbps, replacing LPC-10e. The MELP coder is based on the LPC model with additional features that include mixed excitation, aperiodic pulses, adaptive spectral enhancement, pulse dispersion filtering, and Fourier magnitude modeling [70]. The synthesis model for the MELP coder is illustrated in Fig. 11. LP coefficients are converted to LSFs and a multistage vector quantizer (MSVQ) is used to quantize the LSF vectors. For voiced segments a total of 54 bits that represent: LSF parameters (25), Fourier magnitudes of the prediction residual signal (8), gain (8), pitch (7), bandpass voicing (4), aperiodic flag (1), and a sync bit are sent. The Fourier magnitudes are coded with an 8-bit VQ and the associated codebook is searched with a perceptually-weighted Euclidean distance. For unvoiced segments, the Fourier magnitudes, bandpass voicing, and the aperiodic flag bit are not sent. Instead, 13 bits that implement forward error correction (FEC) are sent. The performance of MELP at 2.4 kbps is similar to or better than that of the federal standard at 4.8 kbps (FS 1016) [92]. Versions of MELP coders operating at 1.7 kbps [68] and 4.0 kbps [90] have been reported.

5.3. Multiband Excitation (MBE)

In multiband excitation (MBE) coding the voiced/unvoiced decision is not a binary one; instead, a series of voicing decisions are made for independent harmonic intervals [31]. Since voicing decisions can be made in different frequency bands individually, synthesized speech may be partially voiced and partially unvoiced. An improved version of the MBE was introduced in the late 1980s [7,35] and referred to as the IMBE coder. The IMBE

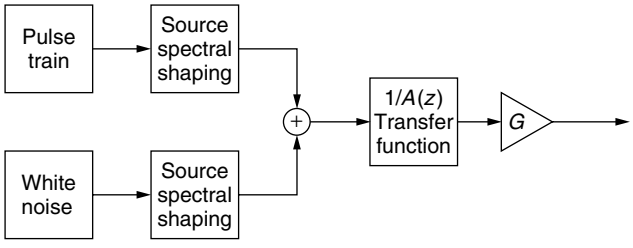

Figure 11. The MELP speech synthesis model.

at 2.4 kbps produces better sound quality than does the LPC-10e. The IMBE was adopted as the Inmarsat-M coding standard for satellite voice communication at a total rate of 6.4 kbps, including 4.15 kbps of source coding and 2.25 kbps of channel coding [104]. The Advanced MBE (AMBE) coder was adopted as the Inmarsat Mini-M standard at a 4.8 kbps total data rate, including 3.6 kbps of speech and 1.2 kbps of channel coding [18,27]. In [14] an enhanced multiband excitation (EMBE) coder was presented. The distinguishing features of the EMBE coder include signal-adaptive multimode spectral modeling and parameter quantization, a two-band signal-adaptive frequency-domain voicing decision, a novel VQ scheme for the efficient encoding of the variable-dimension spectral magnitude vectors at low rates, and multiclass selective protection of spectral parameters from channel errors. The 4-kbps EMBE coder accounts for both source (2.9 kbps) and channel (1.1 kbps) coding and was designed for satellite-based communication systems.

5.4. Prototype Waveform Interpolative (PWI) Coding

A different kind of coding technique that has properties of both waveform and LPC-based coders has been proposed [59,60] and is called *prototype waveform interpolation* (PWI). PWI uses both interpolation in the frequency domain and forward–backward prediction in the time domain. The technique is based on the assumption that, for voiced speech, a perceptually accurate speech signal can be reconstructed from a description of the waveform of a single, representative pitch cycle per interval of 20–30 ms. The assumption exploits the fact that voiced speech can be interpreted as a concentration of slowly evolving pitch cycle waveforms. The prototype waveform is described by a set of linear prediction (LP) filter coefficients describing the formant structure and a prototype excitation waveform, quantized with analysis-by-synthesis procedures. The speech signal is reconstructed by filtering an excitation signal consisting of the concatenation of (infinitesimal) sections of the instantaneous excitation waveforms. By coding the voiced and unvoiced components separately, a 2.4-kbps version of the coder performed similarly to the 4.8-kbps FS1016 standard [61].

Recent work has aimed at reducing the computational complexity of the coder for rates between 1.2 and 2.4 kbps by including a time-varying waveform sampling rate and a cubic B-spline waveform representation [62,86].

6. MEASURES OF SPEECH QUALITY

Deciding on an appropriate measurement of quality is one of the most difficult aspects of speech coder design, and is an area of current research and standardization. Early military speech coders were judged according to only one criterion: intelligibility. With the advent of consumer-grade speech coders, intelligibility is no longer a sufficient condition for speech coder acceptability. Consumers want speech that sounds "natural." A large number of subjective and objective measures have been developed to quantify "naturalness," but it must be stressed that any scalar measurement of "naturalness" is an oversimplification.

"Naturalness" is a multivariate quantity, including such factors as the metallic versus breathy quality of speech, the presence of noise, the color of the noise (narrowband noise tends to be more annoying than wideband noise, but the parameters that predict "annoyance" are not well understood), the presence of unnatural spectral envelope modulations (e.g., flutter noise), and the absence of natural spectral envelope modulations.

6.1. Psychophysical Measures of Speech Quality (Subjective Tests)

The final judgment of speech coder quality is the judgment made by human listeners. If consumers (and reviewers) like the way the product sounds, then the speech coder is a success. The reaction of consumers can often be predicted to a certain extent by evaluating the reactions of experimental listeners in a controlled psychophysical testing paradigm. Psychophysical tests (often called "subjective tests") vary depending on the quantity being evaluated, and the structure of the test.

6.1.1. Intelligibility. Speech coder intelligibility is evaluated by coding a number of prepared words, asking listeners to write down the words they hear, and calculating the percentage of correct transcriptions (an adjustment for guessing may be subtracted from the score). The diagnostic rhyme test (DRT) and diagnostic alliteration test (DALT) are intelligibility tests which use a controlled vocabulary to test for specific types of intelligibility loss [101,102]. Each test consists of 96 pairs of confusable words spoken in isolation. The words in a pair differ in only one distinctive feature, where the distinctive feature dimensions proposed by Voiers are voicing, nasality, sustention, sibilation, graveness, and compactness. In the DRT, the words in a pair differ in only one distinctive feature of the initial consonant; for instance, "jest" and "guest" differ in the sibilation of the initial consonant. In the DALT, words differ in the final consonant; for instance, "oaf" and "oath" differ in the graveness of the final consonant. Listeners hear one of the words in each pair, and are asked to select the word from two written alternatives. Professional testing firms employ trained listeners who are familiar with the speakers and speech tokens in the database, in order to minimize test-retest variability.

Intelligibility scores quoted in the speech coding literature often refer to the composite results of a DRT. In a comparison of two federal standard coders, the LPC 10e algorithm resulted in 90% intelligibility, while the FS-1016 CELP algorithm had 91% intelligibility [64]. An evaluation of waveform interpolative (WI) coding published DRT scores of 87.2% for the WI algorithm, and 87.7% for FS-1016 [61].

6.1.2. Numerical Measures of Perceptual Quality. Perhaps the most commonly used speech quality measure is the mean opinion score (MOS). A mean opinion score is computed by coding a set of spoken phrases using a variety of coders, presenting all of the coded speech together with undegraded speech in random order, asking listeners to rate the quality of each phrase on a numerical scale, and then averaging the numerical ratings of all phrases coded by a particular coder. The five-point numerical scale is associated with a standard set of descriptive terms: 5 = excellent, 4 = good, 3 = fair, 2 = poor, and 1 = bad. A rating of 4 is supposed to correspond to standard toll-quality speech, quantized at 64 kbps using ITU standard G.711 [48].

Mean opinion scores vary considerably depending on background noise conditions; for example, CVSD performs significantly worse than LPC-based methods in quiet recording conditions, but significantly better under extreme noise conditions [96]. Gender of the speaker may also affect the relative ranking of coders [96]. Expert listeners tend to give higher rankings to speech coders with which they are familiar, even when they are not consciously aware of the order in which coders are presented [96]. Factors such as language and location of the testing laboratory may shift the scores of all coders up or down, but tend not to change the rank order of individual coders [39]. For all of these reasons, a serious MOS test must evaluate several reference coders in parallel with the coder of interest, and under identical test conditions. If an MOS test is performed carefully, intercoder differences of approximately 0.15 opinion points may be considered significant. Figure 12 is a plot of MOS as a function of bit rate for coders evaluated under quiet listening conditions in five published studies (one study included separately tabulated data from two different testing sites [96]).

The diagnostic acceptability measure (DAM) is an attempt to control some of the factors that lead to variability in published MOS scores [100]. The DAM employs trained listeners, who rate the quality of standardized test phrases on 10 independent perceptual scales, including six scales that rate the speech itself (fluttering, thin, rasping, muffled, interrupted, nasal), and four scales that rate the background noise (hissing, buzzing, babbling, rumbling). Each of these is a 100-point scale, with a range of approximately 30 points between the LPC-10e algorithm (50 points) and clean speech (80 points) [96]. Scores on the various perceptual scales are combined into a composite quality rating. DAM scores are useful for pointing out specific defects in a speech coding algorithm. If the only desired test outcome is a relative quality ranking of multiple coders, a carefully controlled MOS test in which all coders of interest are tested under the same conditions may be as reliable as DAM testing [96].

6.1.3. Comparative Measures of Perceptual Quality. It is sometimes difficult to evaluate the statistical significance of a reported MOS difference between two coders. A more powerful statistical test can be applied if coders are evaluated in explicit A/B comparisons. In a comparative test, a listener hears the same phrase coded by two different coders, and chooses the one that sounds better. The result of a comparative test is an apparent preference score, and an estimate of the significance of the observed preference; for example, in a 1999 study, WI coding at 4.0 kbps was preferred to 4 kbps HVXC 63.7% of the time, to 5.3 kbps G.723.1 57.5% of the time (statistically significant differences), and to 6.3 kbps G.723.1 53.9% of the time (not statistically significant) [29]. It should be

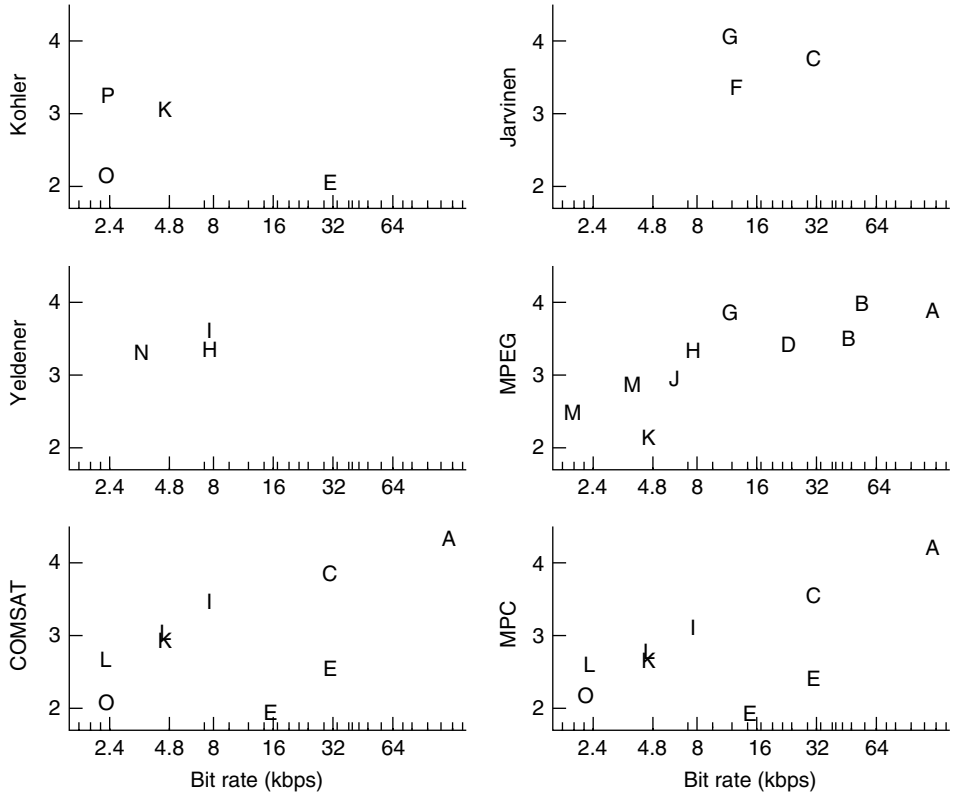

Figure 12. Mean opinion scores from five published studies in quiet recording conditions — Jarvinen [53], Kohler [64], MPEG [39], Yeldener [107], and the COMSAT and MPC sites from Tardelli et al. [96]: (A) unmodified speech, (B) ITU G.722 subband ADPCM, (C) ITU G.726 ADPCM, (D) ISO MPEG-II layer 3 subband audio coder, (E) DDVPC CVSD, (F) GSM full-rate RPE-LTP, (G) GSM EFR ACELP, (H) ITU G.729 ACELP, (I) TIA IS54 VSELP, (J) ITU G.723.1 MPLPC, (K) DDVPC FS-1016 CELP, (L) sinusoidal transform coding, (M) ISO MPEG-IV HVXC, (N) Inmarsat mini-M AMBE, (O) DDVPC FS-1015 LPC-10e, (P) DDVPC MELP.

noted that "statistical significance" in such a test refers only to the probability that the same listeners listening to the same waveforms will show the same preference in a future test.

6.2. Algorithmic Measures of Speech Quality (Objective Measures)

Psychophysical testing is often inconvenient; it is not possible to run psychophysical tests to evaluate every proposed adjustment to a speech coder. For this reason, a number of algorithms have been proposed that approximate, to a greater or lesser extent, the results of psychophysical testing.

The signal-to-noise ratio of a frame of N speech samples starting at sample number n may be defined as

$$\mathrm{SNR}(n) = \frac{\sum_{m=n}^{n+N-1} s^2(m)}{\sum_{m=n}^{n+N-1} e^2(m)} \tag{49}$$

High-energy signal components can mask quantization error, which is synchronous with the signal component, or separated by at most a few tens of milliseconds. Over longer periods of time, listeners accumulate a general perception of quantization noise, which can be modeled as the average log segmental SNR:

$$\mathrm{SEGSNR} = \frac{1}{K}\sum_{k=0}^{K-1} 10\log_{10}\mathrm{SNR}(kN) \tag{50}$$

High-amplitude signal components tend to mask quantization error components at nearby frequencies and times. A high-amplitude spectral peak in the speech signal is able to mask quantization error components at the same frequency, at higher frequencies, and to a much lesser extent, at lower frequencies. Given a short-time speech spectrum $S(e^{j\omega})$, it is possible to compute a short-time "masking spectrum" $M(e^{j\omega})$ which describes the threshold energy at frequency ω below which noise components are inaudible. The perceptual salience of a noise signal $e(n)$ may be estimated by filtering the noise signal into K different subband signals $e_k(n)$, and computing the ratio between the noise energy and the masking threshold in each subband:

$$\mathrm{NMR}(n,k) = \frac{\sum_{m=n}^{n+N-1} e_k^2(m)}{\int_{\omega_k}^{\omega_{k+1}} |M(e^{j\omega})|^2\, d\omega} \tag{51}$$

where ω_k is the lower edge of band k, and ω_{k+1} is the upper band edge. The band edges must be close enough together that all of the signal components in band k are effective in masking the signal $e_k(n)$. The requirement of effective masking is met if each band is exactly one Bark in width, where the Bark frequency scale is described in many references [71,77].

Fletcher has shown that the perceived loudness of a signal may be approximated by adding the cube roots of the signal power in each one-bark subband, after properly accounting for masking effects [20]. The total

loudness of a quantization noise signal may therefore be approximated as

$$\mathrm{NMR}(n) = \sum_{k=0}^{K-1} \left(\frac{\sum_{m=n}^{n+N-1} e_k^2[m]}{\int_{\omega_k}^{\omega_{k+1}} |M(e^{j\omega})|^2 \, d\omega} \right)^{1/3} \tag{52}$$

The ITU perceptual speech quality measure (PSQM) computes the perceptual quality of a speech signal by filtering the input and quantized signals using a Bark-scale filterbank, nonlinearly compressing the amplitudes in each band, and then computing an average subband signal to noise ratio [51]. The development of algorithms that accurately predict the results of MOS or comparative testing is an area of active current research, and a number of improvements, alternatives, and/or extensions to the PSQM measure have been proposed. An algorithm that has been the focus of considerable research activity is the Bark spectral distortion measure [73,103,105,106]. The ITU has also proposed an extension of the PSQM standard called perceptual evaluation of speech quality (PESQ) [81], which will be released as ITU standard P.862.

7. NETWORK ISSUES

7.1. Voice over IP

Speech coding for the voice over Internet Protocol (VOIP) application is becoming important with the increasing dependency on the Internet. The first VoIP standard was published in 1998 as recommendation H.323 [52] by the International Telecommunications Union (ITU-T). It is a protocol for multimedia communications over local area networks using packet switching, and the voice-only subset of it provides a platform for IP-based telephony. At high bit rates, H.323 recommends the coders G.711 (3.4 kHz at 48, 56, and 64 kbps) and G.722 (wideband speech and music at 7 kHz operating at 48, 56, and 64 kbps) while at the lower bit rates G.728 (3.4 kHz at 16 kbps), G.723 (5.3 and 6.5 kbps), and G.729 (8 kbps) are recommended [52].

In 1999, a competing and simpler protocol named the Session Initiation Protocol (SIP) was developed by the Internet Engineering Task Force (IETF) Multiparty Multimedia Session Control working group and published as RFC 2543 [19]. SIP is a signaling protocol for Internet conferencing and telephony, is independent of the packet layer, and runs over UDP or TCP although it supports more protocols and handles the associations between Internet end systems. For now, both systems will coexist but it is predicted that the H.323 and SIP architectures will evolve such that two systems will become more similar.

Speech transmission over the Internet relies on sending "packets" of the speech signal. Because of network congestion, packet loss can occur, resulting in audible artifacts. High-quality VOIP, hence, would benefit from variable-rate source and channel coding, packet loss concealment, and jitter buffer/delay management. These are challenging issues and research efforts continue to generate high-quality speech for VOIP applications [38].

7.2. Embedded and Multimode Coding

When channel quality varies, it is often desirable to adjust the bit rate of a speech coder in order to match the channel capacity. Varying bit rates are achieved in one of two ways. In multimode speech coding, the transmitter and the receiver must agree on a bit rate prior to transmission of the coded bits. In embedded source coding, on the other hand, the bitstream of the coder operating at low bit rates is embedded in the bitstream of the coder operating at higher rates. Each increment in bit rate provides marginal improvement in speech quality. Lower bit rate coding is obtained by puncturing bits from the higher rate coder and typically exhibits graceful degradation in quality with decreasing bit rates.

ITU Standard G.727 describes an embedded ADPCM coder, which may be run at rates of 40, 32, 24, or 16 kbps (5, 4, 3, or 2 bits per sample) [46]. Embedded ADPCM algorithms are a family of variable bit rate coding algorithms operating on a sample per sample basis (as opposed to, e.g., a subband coder that operates on a frame-by-frame basis) that allows for bit dropping after encoding. The decision levels of the lower-rate quantizers are subsets of those of the quantizers at higher rates. This allows for bit reduction at any point in the network without the need of coordination between the transmitter and the receiver.

The prediction in the encoder is computed using a more coarse quantization of $\hat{d}(n)$ than the quantization actually transmitted. For example, 5 bits per sample may be transmitted, but as few as 2 bits may be used to reconstruct $\hat{d}(n)$ in the prediction loop. Any bits not used in the prediction loop are marked as "optional" by the signaling channel mode flag. If network congestion disrupts traffic at a router between sender and receiver, the router is allowed to drop optional bits from the coded speech packets.

Embedded ADPCM algorithms produce codewords that contain enhancement and core bits. The feedforward (FF) path of the codec utilizes both enhancement bits and core bits, while the feedback (FB) path uses core bits only. With this structure, enhancement bits can be discarded or dropped during network congestion.

An important example of a multimode coder is QCELP, the speech coder standard that was adopted by the TIA North American digital cellular standard based on code-division multiple access (CDMA) technology [9]. The coder selects one of four data rates every 20 ms depending on the speech activity; for example, background noise is coded at a lower rate than speech. The four rates are approximately 1 kbps (eighth rate), 2 kbps (quarter rate), 4 kbps (half rate), and 8 kbps (full rate). QCELP is based on the CELP structure but integrates implementation of the different rates, thus reducing the average bit rate. For example, at the higher rates, the LSP parameters are more finely quantized and the pitch and codebook parameters are updated more frequently [23]. The coder provides good quality speech at average rates of 4 kbps.

Another example of a multimode coder is ITU standard G.723.1, which is an LPC-AS coder that can operate at

2 rates: 5.3 or 6.3 kbps [50]. At 6.3 kbps, the coder is a multipulse LPC (MPLPC) coder while the 5.3-kbps coder is an algebraic CELP (ACELP) coder. The frame size is 30 ms with an additional lookahead of 7.5 ms, resulting in a total algorithmic delay of 67.5 ms. The ACELP and MPLPC coders share the same LPC analysis algorithm and frame/subframe structure, so that most of the program code is used by both coders. As mentioned earlier, in ACELP, an algebraic transformation of the transmitted index produces the excitation signal for the synthesizer. In MPLPC, on the other hand, minimizing the perceptual-error weighting is achieved by choosing the amplitude and position of a number of pulses in the excitation signal. Voice activity detection (VAD) is used to reduce the bit rate during silent periods, and switching from one bit rate to another is done on a frame-by-frame basis.

Multimode coders have been proposed over a wide variety of bandwidths. Taniguchi et al. proposed a multimode ADPCM coder at bit rates between 10 and 35 kbps [94]. Johnson and Taniguchi proposed a multimode CELP algorithm at data rates of 4.0–5.3 kbps in which additional stochastic codevectors are added to the LPC excitation vector when channel conditions are sufficiently good to allow high-quality transmission [55]. The European Telecommunications Standards Institute (ETSI) has recently proposed a standard for adaptive multirate coding at rates between 4.75 and 12.2 kbps.

7.3. Joint Source-Channel Coding

In speech communication systems, a major challenge is to design a system that provides the best possible speech quality throughout a wide range of channel conditions. One solution consists of allowing the transceivers to monitor the state of the communication channel and to dynamically allocate the bitstream between source and channel coding accordingly. For low-SNR channels, the source coder operates at low bit rates, thus allowing powerful forward error control. For high-SNR channels, the source coder uses its highest rate, resulting in high speech quality, but with little error control. An adaptive algorithm selects a source coder and channel coder based on estimates of channel quality in order to maintain a constant total data rate [95]. This technique is called *adaptive multirate* (AMR) coding, and requires the simultaneous implementation of an AMR source coder [24], an AMR channel coder [26,28], and a channel quality estimation algorithm capable of acquiring information about channel conditions with a relatively small tracking delay.

The notion of determining the relative importance of bits for further unequal error protection (UEP) was pioneered by Rydbeck and Sundberg [83]. Rate-compatible channel codes, such as Hagenauer's rate compatible punctured convolutional codes (RCPC) [34], are a collection of codes providing a family of channel coding rates. By puncturing bits in the bitstream, the channel coding rate of RCPC codes can be varied instantaneously, providing UEP by imparting on different segments different degrees of protection. Cox et al. [13] address the issue of channel coding and illustrate how RCPC codes can be used to build a speech transmission scheme for mobile radio channels. Their approach is based on a subband coder with dynamic bit allocation proportional to the average energy of the bands. RCPC codes are then used to provide UEP.

Relatively few AMR systems describing source and channel coding have been presented. The AMR systems [99,98,75,44] combine different types of variable rate CELP coders for source coding with RCPC and cyclic redundancy check (CRC) codes for channel coding and were presented as candidates for the European Telecommunications Standards Institute (ETSI) GSM AMR codec standard. In [88], UEP is applied to perceptually based audio coders (PAC). The bitstream of the PAC is divided into two classes and punctured convolutional codes are used to provide different levels of protection, assuming a BPSK constellation.

In [5,6], a novel UEP channel encoding scheme is introduced by analyzing how symbol-wise puncturing of symbols in a trellis code and the rate-compatibility constraint (progressive puncturing pattern) can be used to derive rate-compatible punctured trellis codes (RCPT). While conceptually similar to RCPC codes, RCPT codes are specifically designed to operate efficiently on large constellations (for which Euclidean and Hamming distances are no longer equivalent) by maximizing the residual Euclidean distance after symbol puncturing. Large constellation sizes, in turn, lead to higher throughput and spectral efficiency on high SNR channels. An AMR system is then designed based on a perceptually-based embedded subband encoder. Since perceptually based dynamic bit allocations lead to a wide range of bit error sensitivities (the perceptually least important bits being almost insensitive to channel transmission errors), the channel protection requirements are determined accordingly. The AMR systems utilize the new rate-compatible channel coding technique (RCPT) for UEP and operate on an 8-PSK constellation. The AMR-UEP system is bandwidth efficient, operates over a wide range of channel conditions and degrades gracefully with decreasing channel quality.

Systems using AMR source and channel coding are likely to be integrated in future communication systems since they have the capability for providing graceful speech degradation over a wide range of channel conditions.

8. STANDARDS

Standards for landline public switched telephone service (PSTN) networks are established by the International Telecommunication Union (ITU) (*http://www.itu.int*). The ITU has promulgated a number of important speech and waveform coding standards at high bit rates and with very low delay, including G.711 (PCM), G.727 and G.726 (ADPCM), and G.728 (LDCELP). The ITU is also involved in the development of internetworking standards, including the voice over IP standard H.323. The ITU has developed one widely used low-bit-rate coding standard (G.729), and a number of embedded and multimode speech coding standards operating at rates between 5.3 kbps (G.723.1) and 40 kbps (G.727). Standard G.729 is a speech coder operating at 8 kbps, based on algebraic code-excited LPC (ACELP) [49,84]. G.723.1 is a multimode coder, capable of operating at either 5.3 or 6.3 kbps [50]. G.722

is a standard for wideband speech coding, and the ITU will announce an additional wideband standard within the near future. The ITU has also published standards for the objective estimation of perceptual speech quality (P.861 and P.862).

The ITU is a branch of the International Standards Organization (ISO) (*http://www.iso.ch*). In addition to ITU activities, the ISO develops standards for the Moving Picture Experts Group (MPEG). The MPEG-2 standard included digital audiocoding at three levels of complexity, including the layer 3 codec commonly known as MP3 [72]. The MPEG-4 motion picture standard includes a structured audio standard [40], in which speech and audio "objects" are encoded with header information specifying the coding algorithm. Low-bit-rate speech coding is performed using harmonic vector excited coding (HVXC) [43] or code-excited LPC (CELP) [41], and audiocoding is performed using time–frequency coding [42]. The MPEG homepage is at *drogo.cselt.stet.it/mpeg*.

Standards for cellular telephony in Europe are established by the European Telecommunications Standards Institute (ETSI) (*http://www.etsi.org*). ETSI speech coding standards are published by the Global System for Mobile Telecommunications (GSM) subcommittee. All speech coding standards for digital cellular telephone use are based on LPC-AS algorithms. The first GSM standard coder was based on a precursor of CELP called *regular-pulse excitation with long-term prediction* (RPE-LTP) [37,65]. Current GSM standards include the enhanced full-rate codec GSM 06.60 [32,53] and the adaptive multirate codec [33]; both standards use algebraic code-excited LPC (ACELP). At the time of writing, both ITU and ETSI are expected to announce new standards for wideband speech coding in the near future. ETSI's standard will be based on GSM AMR.

The Telecommunications Industry Association (*http://www.tiaonline.org*) published some of the first U.S. digital cellular standards, including the vector-sum-excited LPC (VSELP) standard IS54 [25]. In fact, both the initial U.S. and Japanese digital cellular standards were based on the VSELP algorithm. The TIA has been active in the development of standard TR41 for voice over IP.

The U.S. Department of Defense Voice Processing Consortium (DDVPC) publishes speech coding standards for U.S. government applications. As mentioned earlier, the original FS-1015 LPC-10e standard at 2.4 kbps [8,16], originally developed in the 1970s, was replaced in 1996 by the newer MELP standard at 2.4 kbps [92]. Transmission at slightly higher bit rates uses the FS-1016 CELP (CELP) standard at 4.8 kbps [17,56,57]. Waveform applications use the continuously variable slope delta modulator (CVSD) at 16 kbps. Descriptions of all DDVPC standards and code for most are available at *http://www.plh.af.mil/ddvpc/index.html*.

9. FINAL REMARKS

In this article, we presented an overview of coders that compress speech by attempting to match the time waveform as closely as possible (waveform coders), and coders that attempt to preserve perceptually relevant spectral properties of the speech signal (LPC-based and subband coders). LPC-based coders use a speech production model to parameterize the speech signal, while subband coders filter the signal into frequency bands and assign bits by either an energy or perceptual criterion. Issues pertaining to networking, such as voice over IP and joint source–channel coding, were also touched on. There are several other coding techniques that we have not discussed in this article because of space limitations. We hope to have provided the reader with an overview of the fundamental techniques of speech compression.

Acknowledgments

This research was supported in part by the NSF and HRL. We thank Alexis Bernard and Tomohiko Taniguchi for their suggestions on earlier drafts of the article.

BIOGRAPHIES

Mark A. Hasegawa-Johnson received his S.B., S.M., and Ph.D. degrees in electrical engineering and computer science from MIT in 1989, 1989, and 1996, respectively. From 1989 to 1990 he worked as a research engineer at Fujitsu Laboratories Ltd., Kawasaki, Japan, where he developed and patented a multimodal CELP speech coder with an efficient algebraic fixed codebook. From 1996–1999 he was a postdoctoral fellow in the Electrical Engineering Department at UCLA. Since 1999, he has been on the faculty of the University of Illinois at Urbana-Champaign. Dr. Hasegawa-Johnson holds four U.S. patents and is the author of four journal articles and twenty conference papers. His areas of interest include speech coding, automatic speech understanding, acoustics, and the physiology of speech production.

Abeer Alwan received her Ph.D. in electrical engineering from MIT in 1992. Since then, she has been with the Electrical Engineering Department at UCLA, California, as an assistant professor (1992–1996), associate professor (1996–2000), and professor (2000–present). Professor Alwan established and directs the Speech Processing and Auditory Perception Laboratory at UCLA (http://www.icsl.ucla.edu/~spapl). Her research interests include modeling human speech production and perception mechanisms and applying these models to speech-processing applications such as automatic recognition, compression, and synthesis. She is the recipient of the NSF Research Initiation Award (1993), the NIH FIRST Career Development Award (1994), the UCLA-TRW Excellence in Teaching Award (1994), the NSF Career Development Award (1995), and the Okawa Foundation Award in Telecommunications (1997). Dr. Alwan is an elected member of Eta Kappa Nu, Sigma Xi, Tau Beta Pi, and the New York Academy of Sciences. She served as an elected member on the Acoustical Society of America Technical Committee on Speech Communication (1993–1999), on the IEEE Signal Processing Technical Committees on Audio and Electroacoustics (1996–2000) and Speech Processing (1996–2001). She is an editor in chief of the journal *Speech Communication*.

Speech is probably one of the oldest methods of communication. It is produced by an articulatory system constituting the respiratory tract, the vocal cords, the mouth, nasal passages, tongue, and lips. Precisely coordinated actions of all these parts produce a highly complex signal that encodes messages in a very robust manner, which enables the receiver to understand the message even if it is severely degraded by noise or distortion. What exactly makes speech intelligible? A definite answer to this question has yet to come, but a large amount of research has revealed a multitude of factors that are important for speech intelligibility. This article seeks to elucidate some of these factors, especially those that are important for the design of communication systems. A brief description of the speech signal is followed by a brief discussion of some basic properties of speech perception and an overview of some theories that have been proposed to account for them. These theories may be thought to provide a microscopic account of speech perception in

that they typically seek to explain how listeners map the acoustic properties of the speech signal onto an internal linguistic representation of the message. Other theories take a macroscopic approach. They are not concerned with the specific errors that a listener may make. Rather, they attempt to predict the overall percentage of the speech that will be understood when the speech signal is degraded by noise, distortion, reverberation, and other artifacts that typically are introduced by communication systems and room acoustics. Although these theories reveal relatively little about the processes involved in speech perception, a large portion of this article is devoted to them because they are useful for predicting how the intelligibility of speech is affected by the properties of a communication system.

1. THE SPEECH SIGNAL

Speech is usually considered to consist of a string of individual speech sounds — phonemes — that combine into words, phrases, and sentences. The phonemes correspond to the individual consonants and vowels in a word. At a finer level of analysis, the phonemes are composed of a combination of phonetic features, each of which corresponds to specifics of its production and/or the acoustic properties that signal it. The phonetic features fall into three classes: voicing, place of articulation, and manner of articulation. *Voicing* refers to whether the vocal cords vibrate when the phoneme is produced. Voiced phonemes include all vowels and consonants such as /b/ (as in bat), /z/ (as in zip); in contrast, consonants such as /p/ (as in pat) and /s/ (as in sat) are voiceless. *Place of articulation* refers to the position of the primary constriction of the vocal tract. Examples are *bilabial* (e.g., /m/ as in mat), *alveolar* (e.g., /n/ as in net), and *velar* (e.g., /g/ as in get). *Manner of articulation* includes features such as *nasal* (e.g., /m/ and /n/, which are produced by lowering the soft palate to open the passage to the nasal cavity), *stop* (e.g., /b/, /p/, and /d/, which are produced by momentarily blocking the vocal tract such that pressure builds up to produce a brief burst of noise when the closure is released), and *fricative* (e.g., /s/ and /f/, which are produced by turbulent air flow through a constriction of the vocal tract). Whether phonemes, phonetic features, or other units of speech constitute basic units in speech perception remains an open question.

1.1. Temporal Representation

Figure 1 shows the acoustic waveform of a male talker saying the phrase "the happy prince." On the timescale of Fig. 1a, the envelope of the signal is the most prominent feature. Bursts of acoustic energy can be seen clearly. These bursts typically are 100–200 ms apart and often coincide with the syllables of the speech. Note that word boundaries are not clearly marked. There is no pause between "the" and "happy," yet there is a pause-like gap within "happy." The complex envelope of the speech signal encodes considerable information about the message.

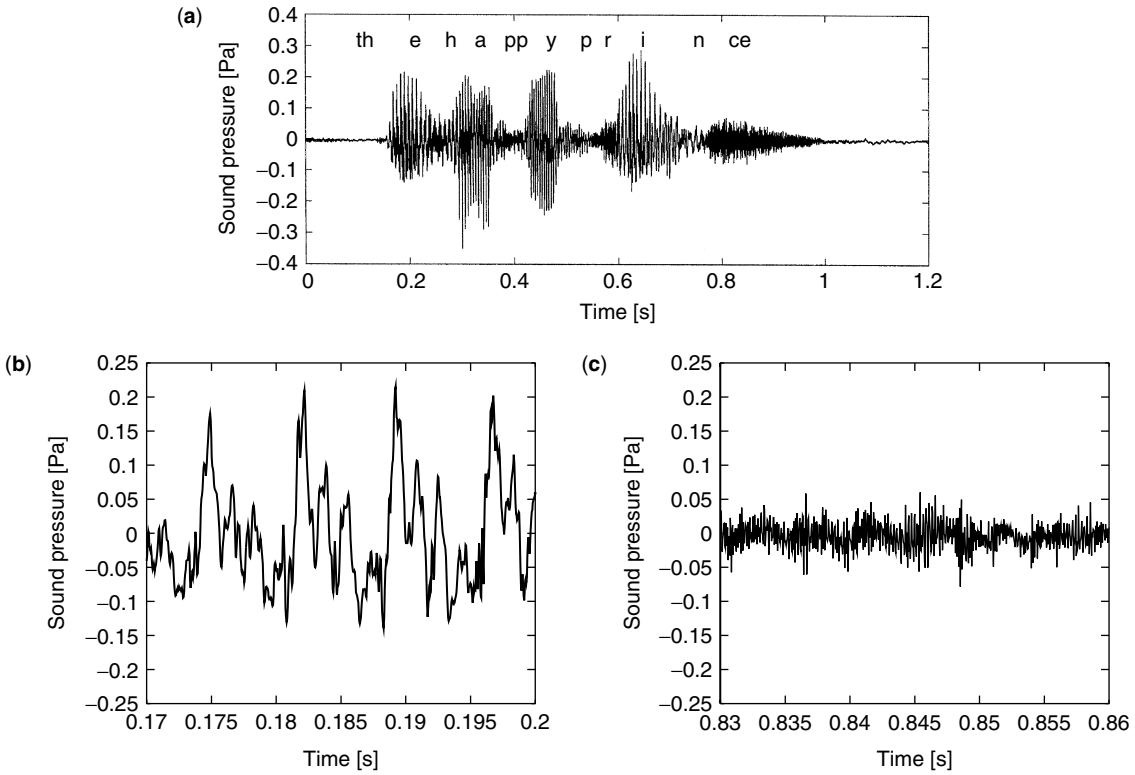

Figure 1. Sound pressure–time function of the phrase "the happy prince," spoken by a male talker. The average speech level is 65 dB SPL. (**a**) The envelope fluctuations are the most prominent feature. (**b**) Fine structure of the vowel /ə/ in "the." (**c**) Fine structure of the fricative /s/ in "prince."

Enlarging part of the graph reveals the fine structure of the acoustic wave. The fine structure also contains much information about the message. The panel in Fig. 1b shows the trace of the sound pressure during the vowel /ə/ in "the." The sound is not strictly periodic, but there is a high degree of regularity in the signal, which gives rise to a well-defined pitch. The repetition rate of the pattern is called the *pitch period*. The pitch helps convey meaning by prosody (e.g., the pitch rises at the end of a question) and specifying the identity of the speaker, but it is not important for the identity of the vowel.

In contrast, the hissing sound /s/ at the end of "prince" has a noise-like fine structure. Because it is a voiceless consonant, the vocal cords do not vibrate during its production. Rather, the sound is generated by the turbulence that results when air is pressed through a constriction in the vocal tract. The acoustic energy of voiceless consonants typically is much lower than that of vowels.

The speech envelope, which is so obvious in Fig. 1, is obliterated when a masking noise is added to the speech. At negative signal-to-noise ratios (SNRs), the envelope of the speech-and-noise composite is almost flat and the time course of the signal looks almost like that of a noise. Nevertheless, most people have no problems communicating at SNRs somewhat below 0 dB. (As will become evident later, the SNR necessary to just understand speech depends on the spectral shape and temporal characteristics of the noise.)

1.2. Spectral Representation

Many aspects of the speech signal are best described in the frequency domain. Spectra of vowels, for example, have prominent peaks, which represent the resonances of the acoustic filter formed by the vocal tract. They are called *formants*, and their interrelationships are important in defining the identity of vowels and some features of consonants. Thus, short-term spectra yield a highly useful characterization of speech. They, too, encode much information about the message contained in the speech and are used as a foundation for most automatic speech-recognition schemes. The changing spectral content of the speech signal is often displayed in a *spectrogram*, which is a power spectrum–time plot. Figure 2 shows the spectrogram of the utterance whose time trace is shown in Fig. 1. The timescale on the abscissa is the same in both figures. Frequency is shown on the ordinate. The signal power at any frequency and point in time is represented by the darkness of the plot. Dark areas correspond to high power and light areas correspond to low power.

The energy fluctuations that were seen in Fig. 1 are also apparent in this presentation. The high-energy periods produced by vocal-cord vibration are easily seen as dark patches, which are separated by light low-energy periods that occur during periods of consonantal noise and during speech pauses. For most speech sounds, the energy is concentrated in the frequency region below 5000 Hz. An exception is the /s/ at the end of "prince," which has most of its energy at high frequencies.

The formants are identified by the dark traces below 3000 Hz. They are visible primarily during the voiced

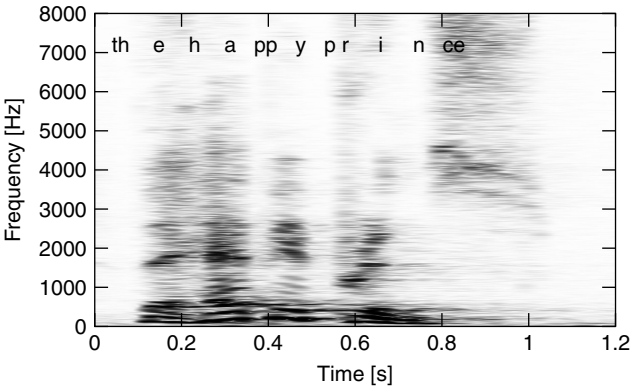

Figure 2. Spectrogram of the signal shown in Fig. 1. Time is plotted along the abscissa and frequency along the ordinate. The instantaneous signal power is shown by the darkness of the plot. Dark areas represent high power and light areas represent low power.

excitation of the vowels. The formants of a steady-state vowel have constant frequencies, which produce horizontal formant trajectories. The formant frequencies reflect the shape of the vocal tract, which the talker adjusts to produce the desired vowel. Ideally, it should attain a specific shape to produce a given vowel. During natural speech, however, the articulators must move quite rapidly to produce the desired sequence of phonemes and they never reach the ideal positions. Rather, they constantly move from one (unreached) target to the next. As a result, the formants of natural speech show a pattern of rising and falling trajectories that reflect the articulator movement. Because they reflect the movement from one vocal tract shape to the next, the formant trajectories encode not only the vowel identity but also the identity of the preceding and succeeding consonant — at least to some degree. This interaction is called *coarticulation*. When a masking noise masks the low-energy consonants but not the high-energy vowels, a large number of the consonants can still be identified correctly. This is possible because a part of the consonant is encoded in the format transitions that result from coarticulation. Coarticulation also is at the heart of one of the most vexing problems in speech recognition by humans or machines: the lack of a one-to-one correspondence between the acoustic properties of the speech signal and the speech units [1]; (see, however, Ref. 2). For example, the acoustic properties of a speech segment that encodes the phoneme /b/ vary greatly depending on the context (i.e., other phonemes) that surrounds it, as well as on the speaker and speaking rate.

2. SPEECH WITH REDUCED ACOUSTIC INFORMATION

The speech signal encodes the message in the envelope, in the fine structure, and in the short-term spectrum to varying degrees. This produces a redundancy that allows speech to retain a high degree of intelligibility, even if some of these aspects are altered or removed by noise, distortion, or signal processing. For example, Shannon et al. [3] modulated bands of noise with the envelope of the speech signal in these bands. As a result of this

operation, the temporal fine structure of the signal was lost completely and the spectral resolution was greatly reduced, but intelligibility remained high. Even when all spectral information was removed — that is, when the broadband envelope of speech was imprinted on a broadband noise — the speech was still recognizable. In this latter condition, the temporal envelope was the only cue available to the listener.

The fact that speech remains intelligible after the entire fine structure has been removed does not mean that only a small fraction of the message is encoded in the fine structure. On the contrary, speech can be highly intelligible when the listeners' only cue is the fine structure. To demonstrate this, Licklider and Pollack [4] passed speech through an infinite peak clipper, so that the processed signal had a fixed positive value whenever the input signal was positive and a fixed negative value whenever the input was negative. This binary code flattens the envelope completely and broadens the spectrum. The processed signal contains information only about the zero crossings of the original signal. Nevertheless, speech processed in this way is intelligible enough to let conversation take place with little difficulty. Even if it sounds very distorted, its quality is high enough to reveal readily the identity of the speaker.

Yet another minimalist representation of speech is sine-wave speech. In this modification, the speech is synthesized by tracing the dominant formants with variable-frequency tone generators. The speech thus synthesized is also highly intelligible, even when only a small number of generators are used [5].

These examples make it clear that speech is very robust. Both spectral and temporal cues carry the message. Speech cannot be defined completely in the spectral domain, nor can it be described only in the temporal domain. The large redundancy allows communication in very unfavorable listening conditions. At the same time, it makes speech a difficult subject to study.

3. SOME BASICS OF SPEECH PERCEPTION

One hallmark of speech perception is that it is categorical. If one constructs a set of speech sounds that gradually changes the acoustic properties from those corresponding to one phoneme (e.g., /d/) to those corresponding to another (e.g., /g/), listeners will report hearing /d/ until the stimuli reach a boundary at which point the perception changes rapidly to become /g/. Discrimination between two members of the same phonemic category usually is difficult, whereas discrimination between members of different phonemic categories is easy [6]. However, listeners can discriminate among stimuli within a single category under ideal conditions [7] and some members of a stimulus set may be shown to be better exemplars than others [8]. Thus, the categorization of speech does not eliminate information about differences between tokens of the same categories. In fact, more recent research indicates that the phonetic categories have a complex internal structure [9], and much current research aims to discover the internal organization of phonetic categories [10,11].

Another hallmark of speech perception is its sensitivity to context. As discussed above, coarticulation makes the acoustic representation of a particular phoneme depend on the context in which it occurs. However, contextual effects are not limited to coarticulation. Variables such as speaking rate and lexical context also may change the perception produced by a given set of acoustical properties. For example, a particular speech sound may be heard as /ba/ if it occurs in a context of slow speech, but as /wa/ if it occurs in a context of rapid speech [12]. Complete theories of speech perception ultimately must explain such context effects, as well as how listeners deal with the lack of invariance between phonemes (or features) and their acoustic representations.

4. THEORIES OF SPEECH PERCEPTION

Various theories have been proposed to account for speech perception at differing levels of detail. Some take a macroscopic approach and seek to predict how the overall percentage of recognition depends on the long-term average properties of speech, distortion, and background noise. This class of theories encompasses the classic articulation index (AI) and derivative theories such as the speech intelligibility index (SII) and speech transmission index (STI). These theories do not attempt to predict how recognition errors depend on the details of the speech signal, but aim to provide a tool that can predict the intelligibility of speech transmitted through a communication system. Because these theories have proved to be very useful engineering tools, they are discussed at some length below. Other theories take a microscopic approach and seek to explain how the detailed properties of the speech signal determine its mapping into linguistic units. This class of theories encompasses a number of very different approaches to various parts of this difficult problem. Some seek to explain speech perception as a result of the general properties of signal processing by the auditory system, sometimes combined with cognitive processing. Others hold that speech recognition is mediated by mapping the acoustic properties of the speech to the processes necessary to produce it. They imply that the recognition of speech is specific to humans. Whether extraction of the phonetic units occurs directly by auditory processes or through reference to articulatory processes, subsequent processing also is important. Thus, other models seek to incorporate the interplay between lexical processes and lower-level phonetic processes.

Auditory theories of speech recognition hold that the auditory processes responsible for perception of any sound generally define the relation between acoustic properties and the categorical perception of phonemes [13], although subsequent lexical, syntactical, and grammatical processing may modify the perception. Specific theories within this class range from auditory processes being responsible for mapping the acoustic properties into features that feed into linguistic processes [14] to ones that claim that a detailed analysis of auditory processing can explain how the categorical boundaries between phonemes depend on context and provide the invariance that appears to be lacking in the acoustical properties of the speech [2]. Holt and

co-workers have suggested that many context effects can be explained as a spectral contrast enhancement mediated, in part, by neural adaptation that occurs throughout the auditory pathway [15,16].

Theories that rely on listeners' knowledge of speech production to explain speech perception hold that listeners achieve a mapping between the context-dependent acoustic properties of speech and the corresponding phonemes because they infer how the speech was produced. The most prominent of these theories is the motor theory of speech perception [17]. This theory holds that speech perception is accomplished, at least in part, by a specialized phonetic processor that maps the acoustic signal into the articulatory gestures that underlie the production of it.

Theories on the processing that occurs subsequent to the extraction of phonetic units often hold that speech perception reflects an intimate interaction between low-level auditory and phonetic processes and higher-level lexical processes (for a review, see the article by Protopapas [18]). Some employ *top–down processing*, in which excitatory and inhibitory connections let nodes corresponding to words modify the response properties of nodes corresponding to individual phonemes [19]. Others employ *bottom–up processing*, in which lower-level nodes of a network activate higher-level nodes in a manner that allows sequences of short-term spectra to map into words [20].

5. THE ARTICULATION INDEX

Although speech intelligibility is determined by many factors, two parameters appear to be of paramount importance: the *bandwidth* and the *audibility* of the signal. Both parameters are affected by the transfer function of a transmission system, and it is important for the communication engineer to understand how they affect intelligibility. A group of models, collectively known as *articulation index* (AI) *models*, attempt to predict intelligibility from the transfer function of a transmission system. A team led by Harvey Fletcher at Bell Labs laid the groundwork for the development of the Articulation Index in the early 1900s (see Allen [21] for a historical perspective). The complete model was published in 1950 by Fletcher and Galt [22], but is rarely used because it is very complex [23]. A simpler version was published earlier [24]. On the basis of French and Steinberg's model, Kryter [25] devised a model that was easy to use. With minor modifications, Kryter's model was later accepted as ANSI standard S3.5 [26]. The newest member of the group of Articulation-Index models is the *speech intelligibility index* (SII) [27].

Articulation index models are macroscopic models of speech recognition. They predict the *average* intelligibility achievable with a linear or nearly linear transmission system, where the average is taken across many talkers and speech materials. The model predictions are based on the statistics of the speech signal. Therefore, AI models do not predict the intelligibility of a short speech segment, nor do they account for the intelligibility of particular phonemes and the patterns of confusions among phonemes that occur in the perception of partly intelligible speech [28].

The basic assumption underlying AI theory is that speech intelligibility is determined by the audibility of the speech signal and that different frequency ranges make unequal contributions to the intelligibility. The AI model provides a method to calculate an articulation index. The AI is highly correlated with speech intelligibility and is a descriptor of the intelligibility that can be achieved with the transmission system for which it was calculated. If two people, one meter apart and facing each other, converse in a quiet room that is free of reverberation, intelligibility can reasonably be expected to be optimal. For such a condition, the AI is unity. In this optimal listening condition, all relevant speech cues are completely audible. If, on the other hand, the listener cannot hear the talker at all, there will be no intelligibility. For such a condition, the AI is zero. In general, the AI is a scalar between zero and unity.

Every listening condition has associated with it a single value of AI. Different speech materials yield the same AI — as long as they are equally audible. The AI does not reflect the fact that the intelligibility differs among syllables, words, and various types of sentences presented through a given transmission system. Such differences occur mainly because these materials differ in terms of how much information they provide by context. To account for the effects of context on the speech test score, AI models use different transformation functions between the AI and the predicted test score. These transformations are independent of the speech transmission system and specific to the test material and the scoring procedure. Typical transformations are shown in Fig. 8 (later in this article). Although equivalent to the AI in many respects, the SII (the result of the speech intelligibility index model [27]) differs from the AI by assuming that the SII is not exclusively determined by audibility but to a small degree also by the type of the speech material used [29].

The AI is calculated as an importance-weighted sum of a quantity W_i that is related to the audibility of the speech signal in a set of spectral bands that span the range of audiofrequencies:

$$\mathrm{AI} = \sum_i I_i W_i \tag{1a}$$

where I_i is the importance weight of the ith band. The product of I_i and W_i is the AI in the ith band, AI_i. Accordingly, Eq. (1a) can be rewritten as

$$\mathrm{AI} = \sum_i \mathrm{AI}_i \tag{1b}$$

5.1. Audibility

The quantity W_i is a fraction less than or equal to unity that indicates how many of the cues carried in the ith band are actually available to the listener. It is related to the audibility of the speech signal. Audibility is expressed in terms of the *sensation level*, which is the number of decibels that a sound is above its threshold. The sensation level of a band of speech can be calculated as the difference between the critical-band level of the speech and the level of a just-audible tone centered in that band. The critical band is a measure of the bandwidth of frequency

analysis in the auditory system. It can be defined as "that bandwidth at which subjective responses [to sound] rather abruptly change" [30] and represents a frequency range across which the acoustic energy is integrated by the auditory system. The critical band is about 100 Hz wide for center frequencies below 500 Hz and 15–20% of the center frequency at higher frequencies [30–32]. [It should be noted that modern measurements of auditory filter characteristics yield an *effective rectangular bandwidth* that is somewhat narrower than the critical bandwidth, especially at low frequencies [33].]

In quiet, the level of a just-audible tone depends only on the listener's sensitivity to sound. The lowest level at which the tone can be heard is called the *absolute threshold*. Threshold levels vary with frequency and among listeners, but established norms exist for normal threshold levels [34,35]. In individuals with hearing loss, thresholds are elevated — that is, the tone levels at threshold are higher than in normal-hearing persons. Therefore, audibility is decreased in listeners with hearing loss. In agreement with the reduced intelligibility of unamplified speech for listeners with hearing loss, the elevated thresholds produce lower AI values.

Interfering sounds (i.e., maskers) also can reduce the audibility of speech. If the masker is above threshold, it may produce masking and make a tone at absolute threshold inaudible. The level of the test tone that can just be detected in the presence of the masker is called the *masked threshold*. The *amount of masking*, which is the difference between the masked threshold and the absolute threshold, depends on the level and spectral shape of the masker and the frequency of the tone (for review, see Buus' article [33]). For typical maskers with spectra that change relatively slowly with frequency, the amount of masking is determined primarily by the sound level of the masker measured within a critical band centered on the tone. For such maskers, masking is linear. Whenever the masker level is increased by, for example, 10 dB, the masked threshold increases by 10 dB. For listening situations with masking sounds, the sensation level of the speech is determined as the difference between the critical-band level of the speech and the masked or absolute threshold for tones at the center of the band, whichever is higher.

The relation between band sensation level and W_i differs somewhat across AI models [36]. In their simplest form, AI models assume a linear relation between sensation level and W_i [25–27] over a 30-dB range of sensation levels (see Fig. 3). Within this range W_i increases as the sensation level increases. In the models of French and Steinberg [24] and Fletcher and Galt [22], the relation is nonlinear and the range of sensation levels over which W_i changes is larger than 30 dB.

Because W_i and band AI_i are proportional [see Eq. (1)], the AI_i also increases with sensation level. The level dependence of the AI can be understood by noting that speech is an amplitude-modulated signal. French and Steinberg [24] analyzed data of Dunn and White [37], who measured the level distribution of 125-ms speech segments in a number of frequency bands. The duration of these segments corresponds roughly to the average duration of syllables. When plotting the percentage of

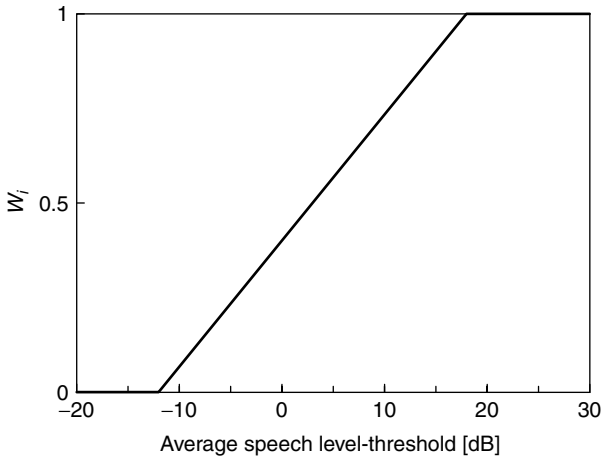

Figure 3. Relation between the audibility-related quantity W_i and the number of decibels that the average speech level is above threshold [25,26]. This function reflects the distribution of the short-term speech level in 125-ms intervals. If the long-term average speech level is 12 dB below the listener's threshold, speech peaks will exceed the listener's threshold and W_i becomes larger than zero.

intervals that exceed a certain level as a function of the difference between that level and the long-term average speech level, French and Steinberg found a relationship that is well described by a linear function. This relationship, together with the masked or absolute threshold, allows one to derive the percentage of syllables that are intense enough to be heard by the listener at any given speech level. The difference between speech level and threshold level is a measure of the proportion of syllables that the listener hears. When this proportion increases, W_i — and the AI — in the band also increase. According to Kryter [25], approximately 1% of the 125-ms intervals of speech is audible when the long-term average speech level is 12 dB below detection threshold. At this point W_i is just above zero. From there, W_i increases linearly with level as a larger proportion of the syllables becomes audible. Once the long-term average speech level is 18 dB above threshold, even the weakest percentile of 125-ms intervals exceeds threshold. At this point, W_i is unity and does not increase further with additional level increases.

5.2. Independence Assumption

As already stated, the AI and the intelligibility score are related by a nonlinear transformation function that is different for different test materials. With one exception, these transformations are derived empirically. Only the transformation between AI and the proportion of phonemes correctly identified in a nonsense-syllable recognition task, also known as the *articulation*, s, is determined by the structure of the AI model. Articulation and AI are related by

$$\mathrm{AI} = -k \cdot \log_{10}(1 - s) \tag{2}$$

where k is a scale factor that is chosen such that AI is unity in the most favorable listening condition. Equation (2) results from the fundamental assumption that speech

bands contribute independently to articulation. This assumption underlies most AI models (see, however, Ref. 38). Combining Eqs. (1) and (2) yields

$$\log_{10}(1-s) = \sum_i \log_{10}(1-s_i) \tag{3}$$

which is equivalent to

$$(1-s) = \prod_i (1-s_i) \tag{4}$$

where s is the articulation in the broadband condition and s_i is the articulation achieved when listening to the individual bands. The terms $(1-s)$ and $(1-s_i)$ are the associated error probabilities. Equation (4) states that the probability of identifying a phoneme in a nonsense syllable incorrectly is equal to the product of the error probabilities when decisions are based on the information available in the individual bands. Whenever a joint probability equals the product of the conditional probabilities, the events are said to be independent. Therefore, Eqs. (3) and (4) reflect the AI model assumption that speech bands contribute independently to the intelligibility of phonemes in nonsense syllables.

5.3. Band Importance

The importance of various frequency bands for speech understanding varies with frequency. This can be seen in Fig. 4, which shows the proportion of correctly understood phonemes in highpass- and lowpass-filtered nonsense syllables as a function of the filters' cutoff frequencies. The speech is at a level that ensures that audibility in the passband is always unity. For the purpose of speech intelligibility predictions, a lowpass filter with a cutoff frequency of 8000 Hz is equivalent to an allpass, because the speech signal carries very little energy in the bands above 8000 Hz. By definition, the AI of a system with a flat transfer function that provides optimal gain is unity. The data in Fig. 4 show that articulation is almost perfect ($s = 0.985$) for this ideal transmission system. Likewise, when the cutoff frequency of a highpass filter is 100 Hz, the same high performance is observed because the acoustic information in bands below 100 Hz is irrelevant for speech intelligibility.

Performance decreases when the low-frequency components of the speech are gradually removed by increasing the cutoff frequency of the highpass filter. Initially, the performance decrease is only slight. Raising the cutoff frequency from 100 to 1000 Hz affects articulation only marginally. This suggests that the speech bands between 100 and 1000 Hz make only small contributions to intelligibility. When the cutoff frequency is raised further, articulation decreases sharply. Removing the frequency range between 1000 and 4000 Hz causes articulation to drop from almost perfect to just above 0.5. Apparently, this frequency band carries a significant portion of the speech cues.

Similarly, performance decreases when the high-frequency speech components are removed by decreasing the cutoff frequency of the lowpass filter. Again, performance declines very gradually at first, but the decrease becomes quite rapid once the cutoff frequency is below 5000 Hz. The frequency at which the two curves intersect divides the speech spectrum into two equally important bands. This frequency, called the *crossover frequency*, is approximately 1700 Hz. Because the AI is unity for a broadband condition in which the speech is clearly audible across the entire frequency range, it follows that the AI for each of the two equally important bands must be 0.5.

Equation (1a) states that the AI is an importance-weighted sum of W_i, which is related to the audibility in the bands. The *importance density function* describes how the inherent potential for intelligibility is distributed across frequency. It can be derived from the relation between the filter cutoff frequency and the associated

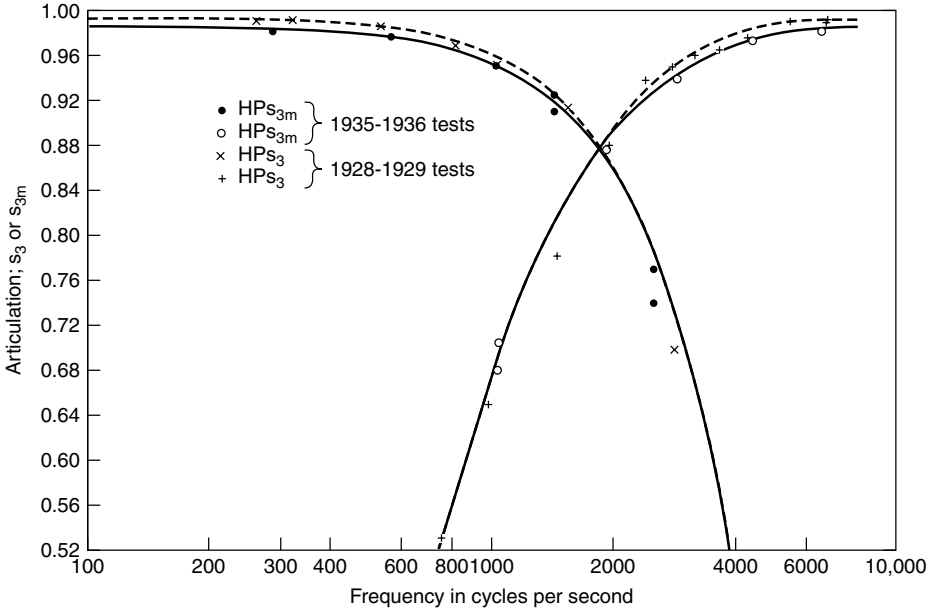

Figure 4. Crossover functions. The proportion of correctly identified phonemes in a nonsense-syllable context is plotted as a function of the cutoff frequencies of ideal highpass and lowpass filters. Filled dots and crosses represent highpass filters; open dots and plusses, lowpass filters. (Reprinted from Fletcher and Galt [22], with permission of the publisher.)

articulation. Using Eq. (2), the articulation scores are transformed into the corresponding AI values. This results in a relation between filter cutoff frequency and AI. Thus with the help of Eq. (2), the data in Fig. 4 can be transformed into a cumulative importance function. Simple differentiation yields the importance-density function. The band-importance weights, I_i, are derived from the importance-density function by integrating over the width of the band. Figure 5 shows the importance weights for critical-band wide bands of nonsense syllables [27].

The various AI models differ in the details of the calculation [39]. For example, different models use different importance functions. The exact shape of the importance function seems to depend on the speech material used [29,40]. Accordingly, the SII specifies several speech-material-specific importance functions. Differences also exist in the degree of sophistication with which the sensation level of the speech is predicted from parameters of the transmission system and the spectrum of the masking noise. The representation of the speech spectrum and the masker spectrum in the inner ear is "smeared" in both the spectral and temporal domains. Not only can the masker mask the speech, but the speech signal also acts as a masker upon itself. The amounts of noise-masking and self-masking depend on the speech level and on the transfer function of the transmission system and can be predicted quite accurately. The model by Fletcher and Galt [22] and the SII [27] exhibit the most sophistication in modeling both forms of masking. The simple AI of ANSI [26] does not model self-masking of speech and its prediction accuracy is compromised if the transmission system filters speech so that high-level portions of the spectrum are adjacent to low-level portions.

The AI model discussed so far predicts that when speech exceeds an optimal level, further level increases do not result in increased intelligibility. However, intelligibility may decrease at excessive sound levels [22,41]. This effect is known as *rollover*. The AI by Fletcher and Galt [22] and the SII [27] model this effect.

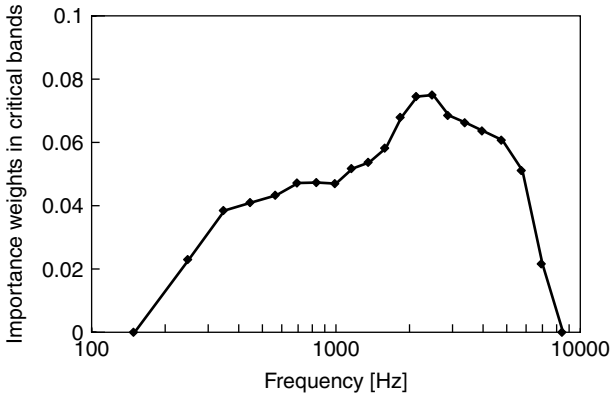

Figure 5. The importance function for nonsense syllables as defined by the speech intelligibility index (SII). Every data point represents the integral of the importance density function over a frequency range equal to one critical bandwidth centered at the frequency of the symbol. This importance function is in good agreement with the data in Fig. 4.

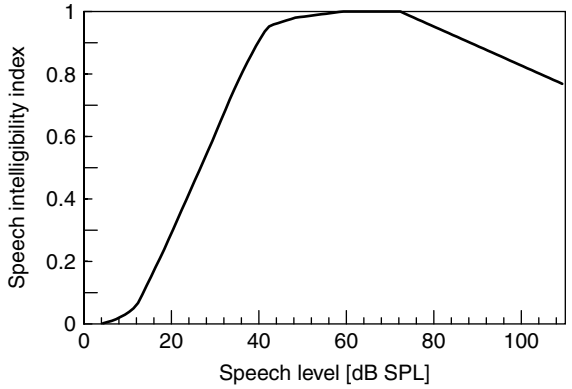

Figure 6. Speech intelligibility index (SII) of undistorted speech as a function of speech level. The predictions are for speech reception in quiet by normal-hearing listeners.

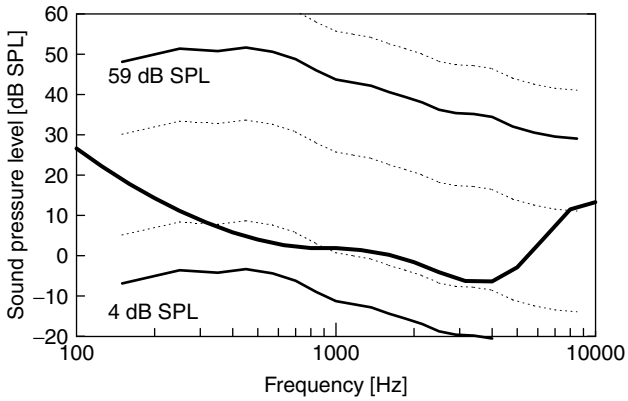

Figure 7. The sound pressure level (SPL) at the detection threshold (bold line, ISO 226) is plotted together with the long-term average level of speech in critical bands (solid lines labeled with the overall speech level). The dashed lines indicate the dynamic range of the speech (from 12 dB above to 18 dB below the long-term average).

Figure 6 shows the SII of unfiltered speech as a function of the overall speech level. At very low speech levels, the signal is inaudible and the SII is zero. As the speech level increases, spectral components in the critical band centered at 500 Hz are the first to exceed threshold. This can be seen from Fig. 7, which shows the long-term average critical-band level of speech with an overall level of 4 dB SPL (lower solid line) in relation to the threshold of normally hearing listeners (bold line [35]). The dashed line 12 dB above the long-term average speech level marks Kryter's [25] estimate of the top of the dynamic range of the speech signal.

The rate at which the SII increases with speech level depends on the sum of the importance weights in the bands whose audibility is affected by the level change. At low levels, the SII increases only slowly with level because only the bands near 500 Hz contribute. At higher levels, all bands are audible and a 3-dB change in speech level changes the SII by 0.1. This rate is equal to the rate at which W_i increases with sensation level (see Fig. 3) and is the steepest slope possible.

Once the speech level reaches 59 dB SPL, all speech bands are completely audible. Figure 6 shows that at this level the SII is unity, indicating that intelligibility is optimal. This is also seen in Fig. 7, where the critical-band level of 59-dB-SPL speech is shown by the upper solid line. The dashed line 18 dB below represents Kryter's [25] estimate of the lower bound of the dynamic range. In frequency bands that carry speech cues, this lower bound is above threshold, indicating that all speech cues are available to the listener. Further increasing the speech level does not result in increased intelligibility. On the contrary, when the speech level increases above 68 dB SPL, the SII decreases.

5.4. Transformation Between Articulation Index and Intelligibility

The articulation index describes the extent to which the sensation generated by the stimulus itself affects intelligibility. However, speech recognition depends not only on the sensory input but also on the context in which it occurs. Semantic and syntactic context, lexical constraints, and the size of the test set strongly affect intelligibility. None of these factors are reflected in the AI (some are reflected in the SII, however). Instead, they are accounted for by a set of transformation functions between AI and the predicted intelligibility score. Because these transformations depend strongly on the contextual constraints in the speech material and on the scoring procedure, their form varies significantly. One set of transformation functions that can serve as a reference is reproduced in Fig. 8. However, many users of AI models prefer to derive transformation functions specifically for their particular speech materials. In fact, the SII [27] states that users must define the appropriate transformations for the particular speech material and scoring method being used. Whatever transformation is used, those shown in Fig. 8 are reasonably representative. They indicate that for highly redundant materials, such as everyday speech, an AI of about 0.2 is needed to obtain a marginal intelligibility of 75%.

It has been shown that words in meaningful sentences are more easily understood than words in isolation or words preceded by a carrier phrase. Lexical constraints cause the intelligibility of phonemes in meaningful words to be higher than the intelligibility of phonemes in nonsense syllables. In general, intelligibility increases as the predictability of the speech sounds increases.

By applying optimal decision theory to speech recognition, Pollack [42] has shown that the increased recognition performance for items with high *a priori* probability of occurrence cannot be explained by more successful guessing. When he calculated the receiver operating characteristics (ROCs) that describe the speech-recognition performance for speech tokens with different *a priori* probabilities of occurrence, he found that the observers were more sensitive to speech tokens with a high *a priori* probability of occurrence than to those with a low *a priori* probability. The better performance for items with high priori probability was not the result of a response

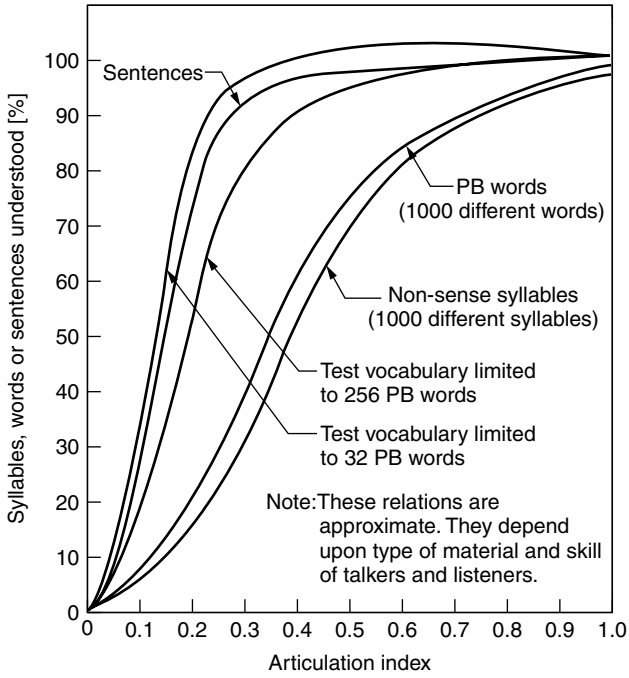

Figure 8. Transformation functions between the AI and the predicted intelligibility of various speech materials. The more contextual constraints are placed on the signal, the higher the intelligibility. (Reprinted from Kryter [25], with permission of the publisher.)

bias. Rather, it appears as if context provides an additional source of information that increases the listener's sensitivity to speech recognition. It has been shown that a signal-detection model may account for such effects by changing the amount of variance contributed to the decision variable by a single, central noise source [43].

An entirely different method of accounting for context effects assumes that contextual information is statistically independent from the sensory information used to recognize the target without context [44]. Expanding on the idea of multiplicative error probabilities and assuming that the context is extracted from speech presented in the same listening condition as the sensory input, this model derives a simple relation between the probability, p_c, of correctly recognizing items in the presence of context and the probability, p_i, of recognizing the same items without context:

$$p_c = 1 - (1 - p_i)^a \tag{7}$$

When this equation was applied to several sets of data, a was nearly constant over a wide range of values of p_i, lending support to the assumption of an independent contribution of the context [44].

5.5. The Speech Transmission Index

The AI model definition of audibility implicitly assumes that the temporal structure of the speech signal is undisturbed and that the short-term level of the masking noise is unrelated to the short-term level of the speech signal. AI models break down when these requirements are not met. To circumvent this

problem, the speech transmission index (STI) [45] converts temporal distortions of the speech signal into an equivalent reduction in the audibility of the speech. This approach extends the AI concept to include temporal distortions such as reverberation and nonlinearities (e.g., a level-compression circuit), which can reduce the modulation depth of an amplitude-modulated signal such as speech. The reduction of modulation depth caused by temporal distortion usually varies across modulation frequencies. For example, reverberation tends to reduce fast modulations more than slow modulations. Therefore, the STI model determines the effective SNR in every frequency band for a set of modulation frequencies ranging from 0.63 to 12.5 Hz, which are typical for speech. Any reduction in modulation depth is transformed into an equivalent noise level, which yields a transmission index for each modulation frequency. The average of the transmission indices at a given spectral frequency band yields an overall modulation transmission index for the band, which is largely equivalent to the AI contribution by the band. Thus, the STI is very similar to the AI models, but its reliance on modulation transfer allows it to account for situations that the AI models do not handle readily.

6. SUMMARY

Speech is a signal in which a message is encoded. The coding is not yet fully understood, but it is known that it is very robust, because speech remains intelligible even after severe signal distortion. Speech perception is categorical. Theories of speech perception attempt to explain the speech-perception process. Examples of such theories are *auditory theories* [e.g., 2] and the *motor theory of speech perception* [17]. Although the process of speech recognition and comprehension is not yet fully understood, models exist that predict human speech-recognition performance without attempting to explain the speech perception process. These models are statistical in nature and predict only the average intelligibility. Examples of such models are the speech intelligibility index (SII), the speech transmission index (STI), and the articulation index (AI).

BIOGRAPHIES

Hannes Müsch received the Diplom Ingenieur degree in acoustics and electrical engineering in 1993 from the Technische Universität Dresden, Germany, and the MSEE and Ph.D. degrees in electrical engineering from Northeastern University, Boston, Massachusetts, in 1997 and 2000, respectively. Dr. Müsch was a consultant in industrial and building acoustics at Müller-BBM, Germany, and a research scientist at GN ReSound's Core Technology Center in Redwood City, California, where he worked on the development of signal processing algorithms for hearing aids. In 2001, he joined Sound ID, Palo Alto, California, where he is the director of signal processing. Dr. Müsch's research interests are psychoacoustics, models for the prediction of speech recognition performance, and the effects of hearing loss on audition. His work is focused on developing signal processing algorithms to improve the listening experience for the hearing impaired.

Søren Buus is the director of the Communications and Digital Signal Processing Center and professor of electrical and computer engineering at Northeastern University Boston, Massachusetts. He graduated with an M.S. degree in electrical engineering and acoustics from the Technical University of Denmark in 1976 and a Ph.D. in experimental psychology from Northeastern University in 1980. His primary research interests are in basic psychoacoustics. In particular, he has published extensively on intensity coding, detection, loudness, and temporal processes in the auditory system. Before joining the faculty at Northeastern University in 1986, Professor. Buus held research appointments at Northeastern University and Harvard University, Massachusetts. He also has been a guest researcher at the Acoustics and Mechanics Laboratory, CNRS, Marseille, France; Institute of Electroacoustics at the Technical University of Munich, Germany; Department of Environmental Psychology, Faculty of Human Sciences, Osaka University, Japan; and the Acoustics Laboratory, Technical University of Denmark. He is a fellow of the Acoustical Society of America.

SPEECH PROCESSING

DOUGLAS O'SHAUGHNESSY
INRS-Telecommunications
Montreal, Quebec, Canada

1. INTRODUCTION

When a computer is used to handle the acoustic signal we call speech, sound is captured by a microphone, digitized for storage in the computer, and then manipulated or transformed to serve some useful purpose, such as efficient coding for transmission or analysis for automatic

conversion to text. Such processing of speech signals by computer converts the speech pressure wave variations (which actually constitute speech) to other forms of information that are more useful for practical computer applications.

Speech is normally produced by a human speaker, whose brain does the processing needed to generate the speech signal. Similarly, human listeners receive speech through their ears and process it with their brains to understand the spoken message. In this chapter, we examine ways that computers use to analyze speech and to simulate production or perception of speech signals. There are many applications for this speech processing: text-to-speech synthesis (e.g., a machine capable of reading aloud to the visually handicapped; a system able to respond vocally from a textual database), speech recognition (e.g., controlling machines via voice; fast entry into databases), speaker verification (e.g., using one's voice as an identifier instead of fingerprints or passwords), and speech coding (i.e., compressing speech into a compact form for storage or transmission, and subsequent reconstruction of the speech when and where needed). All these uses require converting the original speech into a compact digital form, or vice versa, and related digital signal processing.

Such processing usually involves either analysis or synthesis of speech. Recognition of speech (where the desired result is the text that one usually associates with the speech) or of speakers (where the output is the identity of the source of the speech, or a verification of a claimed identity) requires analysis of the speech, to extract relevant (and usually compact) features that characterize how the speech was produced (e.g., features related to the shape of the vocal tract used to utter the speech). Text-to-speech synthesis, on the other hand, tries to convert normal text into an understandable synthetic voice. For speech coding, both the input and output of the process are in the form of speech; thus text is not directly involved, and the objectives are a compression of the data rate (for efficient and secure transmission) and a retention of the naturalness and intelligibility of the original speech, during the analysis and synthesis stages.

2. SPEECH ANALYSIS

For speech analysis, we first convert the speech waves (which, like all analog signals in nature, vary continuously in both time and intensity) into a bitstream, that is, analog-to-digital (A/D) conversion, so that a computer can process the speech signal. The resulting information or "bit rate" (which is of prime interest for efficient operations) is controlled by two factors: the sampling rate (number of evaluations or samples per second) and the sampling precision (number of bits per sample). The sampling rate is directly proportional to the allowed bandwidth of the speech; the Nyquist theorem specifies that the rate be at least twice the highest frequency in the processed signal (otherwise, inevitable "aliasing" distortion appears in the later D/A conversion) [1]. The minimum rate used in practical speech applications is usually 8000 samples/s, thus retaining a range from very low frequencies (theoretically, 0 Hz, although no useful audio data occur below 50 Hz) up to 4 kHz (in practice, an analog lowpass filter usually precedes the A/D converter, and there is a gradual cutoff of frequencies below 4 kHz). Such a low rate is standard for telephone applications, because the switched network only preserves approximately the 300–3200-Hz range. The maximal rate typically employed is 44,100/second (used for audio on compact disks [2–5]), which preserves frequencies beyond the normal hearing range.

Unlike the sampling rate, which follows immediately from the selection of bandwidth range, the choice of bits/sample corresponds to how much distortion is tolerable in a given speech application. To minimize distortion to inaudible levels after A/D conversion, we typically need 12 bits/sample. This gives about 60 dB (decibels) in signal-to-noise ratio, which allows for a typical 30-dB range between strong vowels and weak fricatives in speech. Hence, 12-bit A/D converters are acceptable, although 16-bit systems are more common. In the telephone network, where bandwidth is at a high premium, 8-bit logarithmic (nonuniform) quantization is used on most digital links.

The objective of speech analysis is to transform speech samples into a more useful information representation, for specific objectives other than simply furnishing speech to human ears. The bit rate of basic digital speech (via simple or logarithmic A/D conversion) is typically 64 kbit/s or higher. If we compare that rate to the amount of fundamental information in the signal, we can see a large discrepancy. An average speaking rate is about 12 sounds or phonemes/s, and most languages have an inventory of about 32 phonemes. Thus the phonemic sequence of speech can be sent in approximately 60 bps (bits per second) ($12 \log_2 32$). This does not include intonational or speaker-specific aspects of the speech, but ignores the fact that phoneme sequences are not random (e.g., Huffman coding can reduce the rate). The overall information rate in speech is perhaps 100 bps. Current speech coders are far from providing transparent coding at such rates, but some complex systems can reduce the rate to about 8 kpbs (at 8000 samples/s) without losing quality (other than limiting bandwidth to 4 kHz).

Typical analysis methods try to extract features that correspond to some well-known aspects of speech production or perception. For example, experiments have shown that speakers can easily control the intensity of speech sounds (and that listeners can easily detect small changes in intensity) [6]. Thus intensity (or a related parameter, energy) is often determined in speech analysis, by simply summing a sequence of (squared) speech samples. Similarly, the positions of resonance peaks in the amplitude spectrum of speech (known as formants, abbreviated F1, F2, ..., in order of increasing frequency) have been correlated with shapes of the vocal tract in speech production; they are also well discerned perceptually (peaks are much more salient than spectral valleys). Analysis techniques typically try to extract compact parameterizations of these spectral peaks, either modeling the underlying resonances of the vocal tract (including resonance bandwidths) or some form of the detail (both coarse and fine) in the amplitude spectrum.

Another feature that is often examined in speech analysis is that of the fundamental frequency of the vocal cords, which vibrate during "voiced" (periodic) sounds such as vowels. The rate (abbreviated F0) is directly controlled in speech production, and the resulting periodicity is easily discriminated by listeners. It is used in tone languages directly for semantic concepts, and cues aspects of stress and syntactic structure in many languages. While F0 (or its inverse, the pitch period — the time between successive closures of the vocal cords) is rarely extracted for speech recognizers, it is often used in low-bit-rate speech coders and must be properly modeled for speech synthesis.

3. SPEECH CODING

The objective of speech coding is to represent speech as compactly as possible (i.e., few bps), while retaining high intelligibility and naturalness, with minimal time delay in inexpensive hardware. There are many practical compromises possible here, ranging from zero-delay, cheap, transparent, high-rate PCM (pulse-code modulation) to systems that trade off naturalness for decreased bit rates and increased complexity [5]. We distinguish higher-rate waveform-based coders (usually yielding high-quality speech) from lower-rate parametric coders. Coders in the first class reconstruct speech signals sample-by-sample, representing each speech sample directly with at least a few bits, while the latter class typically discards spectral phase information and processes blocks ("frames") of many samples at a time, which allows the average number of bits/sample to be one or below (e.g., speech coding at 8 kbps).

3.1. Structure in Speech That Coders Exploit

Coders typically try to identify structure in signals, extract it for efficient representation, and leave the remaining (less predictable) signal components either to be ignored (in low-rate systems) or coded using simple techniques (in high-rate systems). There are many sources of structure in speech signals (which, indeed, account for the large difference between typical rates of 64 kbps and an approximately 100-bps theoretical limit). Phonemes typically last 80 ms (e.g., approximately 10 pitch periods), largely due to the increasing difficulty of articulating speech more rapidly (but also to avoid losses in human perception at higher speaking rates). However, identification of each sound is possible from a fraction of each pitch period (at least for speech in noise-free environments). The effective repetition of information in multiple periods helps increase redundancy in human speech communication, which allows reliable communication even in difficult conditions.

The spectra of most speech show a regular structure, which is the product of a periodic excitation (at a rate of F0) and the set of resonances of the vocal tract (which appears as a series of peaks and valleys, averaging about one peak every 1 kHz). Rather than code the speech waveform sample by sample or the spectrum point by point, efficient coders extract from the speech some parameters directly related to the overall amplitude, F0, and the spectral peaks, and use these for transmission.

A simple spectral measure for speech analysis is the zero-crossing rate (ZCR), which provides a basic frequency estimate for the major energy concentration. The ZCR is just the number of times the speech signal crosses the time axis (i.e., changes algebraic sign) in a given time period (e.g., taking an overly simple nonspeech case, a sinusoid of 100 Hz has a ZCR of 200/s). Background acoustic noise often has a steady, broad lowpass spectrum and thus has a ZCR corresponding roughly to a stable frequency in the low range of the signal bandwidth. On the other hand, for weak speech obstruents that are difficult to detect against background noise, the ZCR is either high (corresponding to a high-frequency concentration of energy in fricatives and stop bursts) or very low (if a "voicebar," corresponding to radiation of F0 through the throat, dominates). The ZCR is easy to compute, and can be used for speech endpoint detection (see below).

3.2. Exploiting Simple Structure

Advanced coders examine blocks of data, consisting of sequences of speech samples (which necessarily increases the response time, but facilitates temporal exploitation). The simplest coders (PCM) represent each sample independently. Using a uniform quantifier, however, is inefficient because most speech samples tend to be small (i.e., speech is more often weak than strong), and thus the quantifier levels assigned to large samples are rarely used. Optimal encoding occurs when, on average, all levels are equally used. Since the distribution of speech samples typically resembles a Gamma probability density function (their likelihood decaying roughly exponentially as amplitude increases), a logarithmic compression prior to uniform quantization is useful (e.g., the μ-law or A-law log PCM, common in telephone networks).

Many coders adapt in time, exploiting slowly changing characteristics of the speech and/or transmission channel, such as following the shape or movements of the vocal tract. For example, the step size of the quantifier can be adjusted to follow excursions of the speech signal, integrated over time periods ranging from 1 to 100 ms. When the signal has large energy, using larger step sizes can avoid clipping (which causes nonlinear and severe distortion). When the step size is reduced for low-energy samples, the quantization noise is proportionally reduced without clipping.

3.3. Exploiting Detailed Spectral Structure

Many speech coders use linear prediction methods to estimate a current speech sample based on a linear combination of previous samples [8]. This is useful when the speech spectrum is nonuniform (pure white noise, with independent samples and a flat spectrum, would allow no gain through such prediction). The simplest prediction occurs in delta modulation, where one previous speech sample directly provides the estimate of each current sample; the assumption is that a typical sample changes little from its immediately prior neighbor. This becomes truer if we sample well above the Nyquist rate, as is done in delta modulation, which in turn allows the use of a one-bit quantifier (trading off sampling rate for bit precision) [7].

The power of linear prediction becomes more apparent when the order of the predictor (i.e., the window or number of prior samples examined) is about 10 or so, and when the predictor adapts to movements of the vocal tract (e.g., is updated every 10–30 ms). This occurs in two very popular speech coders, ADPCM (adaptive differential PCM) and LPC (linear predictive coding). They exploit the fact that the major excitation of the vocal tract for voiced speech occurs at the time that the vocal cords close (once per pitch period), which causes a sudden increase in speech amplitude, after which the signal decays exponentially (with a rate inversely proportional to the bandwidth of the strongest resonance — usually F1). Each pitch period approximately corresponds to the impulse response of the vocal tract, and is directly related to its resonances. Since there are about four such formants (in a typical 0–4-kHz bandwidth) and since each formant can be directly characterized by a center frequency and a bandwidth, a predictor order of ten or so is adequate (higher orders give more precision, but offer diminishing returns as computation and bit rate increase).

The 10–16 LPC parameters derived from such an analysis form the basis of many coders, as well as for speech recognizers. These parameters are the multiplier coefficients of a direct-form digital filter, which, when used in a feedforward fashion, converts a speech signal being modeled into a "residual" or "error" signal, which is then suitable for either simple coding (with fewer bits, typically 3–4/sample, in ADPCM) or further parameterization (as in LPC systems).

Using the coefficients in a feedback filter, the system acts as a speech synthesizer, when excited by an impulse train (impulses spaced every 1/F0 samples) or a noise signal (simulating the frication noise generated at a narrow constriction in the vocal tract). This latter, dual excitation is a very simple, but powerful, model of the LPC residual signal, which allows very low bit rates in basic LPC systems [9]. The result is intelligible but synthetic-quality speech (less natural than the "toll-quality" speech of the telephone network with log PCM, or with other medium-rate, waveform-coding methods). The LPC model, with its dozen spectral coefficients parameterizing the vocal tract shape (filter) and its three excitation parameters (F0, amplitude, and a single "voicing" bit noting a decision whether the speech is periodic) modeling the residual, often operates around 2.4 kbps (using updates every 20 ms). The LPC coefficients are usually transformed into a more efficient set for coding, such as the reflection coefficients (which are the multipliers in a lattice-form vocal tract filter, and can actually correspond to reflected energy in simple three-dimensional vocal tract models, modeling the two traveling waves of pressure, one going up the vocal tract, the other down). Another popular set is the line spectral frequencies (LSF), which displace the resonance poles in the digital spectral z plane onto the unit circle, which allows more efficient differential coding in one dimension around the circle, rather than the implicit two-dimensional coding of the resonances inherent in other LPC forms.

3.4. Exploiting Structure Across Parameters

More efficient coders go beyond simple temporal and spectral structure in speech, to exploit correlations across parameters, both within and across successive frames of speech. Even relatively efficient spectral representations such as the LSFs do not produce orthogonal parameter sets; that is, there remain significant correlations among sets of parameters describing adjacent frames of speech. Shannon's theorem states that it is always more efficient to code a signal in vector form, rather than code the samples or parameters as a succession of independent numbers. Thus, we can group related parameters as a block and represent the set with a single index. For example, to code a speech frame every 20 ms, a set of 10 reflection coefficients might need 50 bits as scalar parameters (about 5 bits each), but need only 10 bits in vector quantization (VQ). In the latter, we chose 1024 ($= 2^{10}$) representative points in 10-dimensional space (where each dimension corresponds to a parameter). The points are usually chosen in a training phase (i.e., coder development) by examining many minutes of typical speech (ranging over a wide variety of different speakers and phonemes). Each frame provides one point in this space, and the chosen points for the VQ are the centroids of the most densely populated clusters. Since there are only about 1000 different spectral patterns easily discriminable in speech perception (ignoring the effects of F0 and overall amplitude), a 10-bit system is often adequate. Ten-bit VQ represents effectively a practical limit computationally as well, since a search for the optimal point among much more than 1024 possibilities every 20 ms may exceed hardware capacity. VQ basically trades off increased computation during the analysis stage for lower bit rates in later transmission or storage. The most common use today for speech VQ is in CELP (code-excited linear prediction) speech, where short sequences of LPC residual signals are stored in a codebook, to excite an LPC filter (whose vocal tract spectra are themselves represented by another codebook). CELP provides toll-quality speech at low rates, and has become very popular in recent years.

4. FUNDAMENTAL FREQUENCY (F0) ESTIMATION (PITCH DETECTORS)

Both low-rate speech coders and text-to-speech synthesizers require estimation of the F0 of speech signals, as well as the related (and simpler) estimation of the presence or absence of periodicity (i.e., voicing). For many speech signals, it is a relatively simple task to detect periodicity and measure the period. However, despite hundreds of algorithms in the literature [10], no one pitch detector (so called because of the close correlation of F0 and perceived pitch) is fully accurate. Environmental noise often obscures speech periodicity, and the interaction of phase, harmonics, and spectral peaks often creates ambiguous cases where pitch detectors can make small or even large mistakes (especially in weaker sections of speech).

The basic approach to F0 estimation simply looks for peaks in the speech waveform, spaced at intervals roughly corresponding to typical pitch periods. Periods can range

from 2 ms (sounds from small infants) to 20 ms (for large men), but each individual speaker usually employs about an octave range (e.g., 6–12 ms for a typical adult male). Many estimators use heuristics, such as the fact that F0 rarely changes abruptly (except when voicing starts or ceases). Since F0 is roughly independent of which phoneme is being uttered, and since the structure of formants (and related phase effects) in a voiced spectrum can obscure F0 estimation, we often eliminate from analysis the frequencies above 900 Hz (via a lowpass filter), thus retaining one strong formant containing several harmonics to supply the periodicity information. (This also simplifies processing by use of a decimated signal, which allows a lower sampling rate after lowpass filtering.) At extra cost, spectral flattening can be provided by autocorrelation methods or by LPC inverse filtering, to further reduce F0 estimation errors. Other pitch detectors do peak-picking directly on the harmonics after a Fourier transform of the speech.

5. AUTOMATIC SPEECH RECOGNITION (ASR)

Translating a speech signal into its underlying message (i.e., ASR) is a pattern recognition problem. In principle, one could store all possible speech signals, each transcribed with its corresponding text. Given today's faster computers and the decreasing cost of computer memory, one might wonder if this radically simple approach could eventually solve the ASR problem. To see that this is not true, consider the immense number of possible utterances. Typical utterances last a few seconds; at 10,000 samples/s, we potentially have, say, $2^{30,000}$ signals. Even with very efficient coding (e.g., 100 bps), we would still have an immense 2^{300} signals. Most of these would not be recognizable as speech, but it is impossible *a priori* to just consider ones that might eventually occur as an input to an ASR system (even enlisting millions of speakers talking for days would be quite insufficient).

Thus speech signals to be recognized must be processed to reduce the amount of information from perhaps 64 kbps to a much lower figure. Obvious candidates are low-rate coders, since they preserve enough information to reconstruct intelligible speech. (Higher-rate waveform coders retain too much information, which is useful for naturalness but is not needed for intelligibility; only the latter is important for ASR.)

Unlike speech coding, where the objective of speech analysis is to reproduce speech from a compact representation, ASR instead transforms speech into its corresponding textual equivalent. The direct relationship between the spectral envelope of speech and vocal tract shape (and hence to the phoneme being uttered) has led to intense use of efficient representations of spectral envelope for ASR. (The lack of a simple, direct correlation between F0 and phonemes, on the other hand, has led to F0 being largely ignored in ASR, despite its use to cue semantic and syntactic information in human speech recognition.) One difficulty has been how to extract compact yet relevant information about the envelope. Simple energy is useful, but is often subject to variations (e.g., automatic gain control, variable mouth-to-microphone distance, varying channel gain) irrelevant for phonemic distinctions; as a result, a simple energy measure is often not used for ASR, but change in energy between frames is.

LPC parameters were once popular for ASR, but they have been largely replaced by the mel-scale frequency cepstral coefficients (MFCCs) [11,12]. The term *mel-scale* refers to a frequency-axis deformation, to weight the lower frequencies more than higher ones (which is quite difficult to do in LPC analysis). This follows critical-band spacing in audition, where perceptual resolution is fairly linear below 1 kHz, but becomes logarithmic above that. The cepstrum is the inverse transform of the log amplitude of the Fourier transform of speech. The amplitude spectrum of speech in decibels is weighted via triangular filters spaced at critical bands, and then coefficients are produced via weightings from increasingly higher-frequency sinusoids (in the inverse Fourier transform step). The first 10 or so MFCCs provide a good spectral envelope representation for ASR. C0 (the first MFCC) is actually just the overall speech energy (and is often omitted from use); C1 provides a simple measure of the balance between low- and high-frequency energy (the one-period sinusoid weights low frequencies positively and high ones negatively). Higher coefficients provide the increasingly finer spectral details needed to distinguish, say, the vowels /i/ and /e/.

5.1. Timing Problems in ASR

The major difficulty for ASR is the large amount of variability in speech production. In text-to-speech synthesis, one synthetic voice may suffice, and all listeners must adjust to its accent. ASR systems, however, must accommodate different speaking styles, by storing many different speakers' patterns or by integrating knowledge about different styles. Variations occur at several levels: timing, spectral envelope, and intonation. There is much freedom in how a speaker times articulations and how exactly the vocal tract moves. In 1986, ASR commonly stored templates consisting of successive frames of spectral parameters (e.g., LPC coefficients), and compared them with those of an unknown utterance. Since utterances of the same text could easily have different numbers of frames, the alignment of frames could not simply be one-to-one. Nonlinear "dynamic time warping" (DTW) was popular because it compensated for small speaking rate variations. However, it was still computationally expensive and extended awkwardly to longer utterances; it was also difficult to improve models with additional training speech.

5.2. General Stochastic Approach

During the 1980s, the hidden Markov model (HMM) approach became the dominant method for ASR. It accepted large amounts of computation during an initial training phase in order to get a more flexible and faster model at recognition time. Furthermore, HMMs provided a mathematically elegant and computationally practical solution to some of the serious problems of variability in speech production. DTW had partially accommodated the timing problem, via its allowance of nonlinear temporal paths in the recognition search space,

but was unsatisfactory for variations in pronunciation (e.g., spectral differences due to perturbations in vocal tract shape, different speakers, phonetic contexts). DTW was essentially a deterministic approach to a stochastic problem.

With HMMs, speech variability is treated in terms of probabilities. The likelihood of a speaker uttering a certain sound in a certain context is modeled via probability distributions, which are estimated from large amounts of "training data" speech. Given sufficient computer power and memory, ASR systems tend to have improved recognition accuracy as more data are implicated in the stochastic models, to make them more reliable. While computer resources are never infinite, this approach is feasible to improve systems for "speaker-independent ASR," where training speech is obtained from hundreds of different speakers, and the system then accepts input speech from all users.

For alternative "speaker-dependent" recognizers, which need training from individual users and only employ models trained on each speaker's voice at recognition time, the large amounts of training data are less feasible, given most users' reluctance to provide more than a few minutes of speech. The latter systems have better accuracy, since the HMM models are directly relevant for each user's speech, whereas speaker-independent HMMs must model much more broadly across the diversity of many speakers (such models, as a result, are less discriminative).

Most ASR is done using the ML (maximum-likelihood) approach, in which statistical models for both speech and language are estimated based on prior training data (of speech and texts, respectively). After training establishes the models, at recognition time an input speech signal is analyzed and the text with the corresponding highest likelihood is chosen as the recognition output. Thus, given a signal S, we choose text T, which maximizes the a posteriori probability $P(T|S) = P(S|T)P(T)/P(S)$, using Bayes' rule. It is impossible to directly get good estimates for $P(T|S)$ because of the extremely large number of possible speech signals S. Instead, we develop estimates for $P(S|T)$ (the acoustic model) and for $P(T)$ (the language or text model). When maximizing across possible texts T, we ignore the denominator $P(S)$ term as irrelevant for the best choice of T. Even for large vocabularies, the number of text possibilities is much smaller than the number of speech signals; thus it is more practical to estimate $P(S|T)$ than $P(T|S)$. For each possible text, the acoustical statistics are obtained from speakers repeatedly uttering that text (in practice, such estimates can be obtained for small text units, such as words and phonemes, while still using speech conveniently consisting of sentences). The a priori likelihood of a text T being spoken is $P(T)$, which is obtained by examining computerized textual databases.

There are efficient methods to develop such statistics and to evaluate the large number of possibilities when searching for the maximum likelihood (the search space for a vocabulary with thousands of words and for an utterance of several seconds, at typically 100 frames/s, is quite large). The "forward–backward" method examines all possible paths, summing many small joint likelihoods, while the more efficient Viterbi method looks for the single best path [11]. The latter is much faster, and is commonly used because in practice it tends to sacrifice little in recognition accuracy. When trying to discriminate among similar words, however, the ML approach sometimes fails, because it does not examine how close alternative possible texts are. In addition, HMMs treat all speech frames as equally important, which is not the case in human speech perception. Alternative methods such as maximum mutual information estimation or linear discriminant analysis are considerably more expensive and complex, but are more selective in examining the data, focusing on the differences between competing similar texts, when examining a speech input.

5.3. Details of the Hidden Markov Model (HMM) Approach

The purpose of this method is to model random dynamic behavior via a mathematical method where different "states" represent some aspects of the behavior. The basic, first-order Markov chain has several states, connected by transitions among states. The likelihood of leaving each state is modeled by a probability distribution (usually a PDF — probability density function), and each state itself is also so modeled. For speech, these two sets of PDFs attempt to model the variable timing and articulation of utterances, respectively. Each state roughly corresponds to a vocal tract shape (or more precisely to a speech spectral envelope with formants resulting from the vocal tract shape). Each transition models the likelihood that the vocal tract moves from one position to another.

The PDF for transitions from a given state usually has a simple form: a relatively high likelihood of remaining in that state (e.g., 0.8), a smaller chance of moving to the next state in the time chain (e.g., 0.15), and a yet smaller chance of skipping to the state after the next one. Since time always moves forward, we do not allow backward transitions (e.g., we go through an HMM modeling a word, starting with its first sound and proceeding to its last sound). Since each state models roughly a vocal tract shape (or more often an average of shapes), we stay in each state for several 10-ms frames (hence the high self-loop likelihood). Allowing an occasional state to be skipped accounts for some variability in speech production, especially for rapid, unstressed speech. For example, the training speech may be clear and slow, thus creating states that need not always be visited in later (perhaps fast) test speech.

The transition PDF thus described leads to an exponential PDF for the duration of state visits, which is an inaccurate model for actual phoneme durations. There is too much bias toward short sounds. For instance, very few phonemes last only 1–2 frames. Some more complicated HMM approaches allow direct durational modeling, but at the cost of increased complexity.

In practice, every incoming speech signal is divided into successive 10-ms frames of data for analysis (as in speech coding). During the training phase, many frames are assigned to each given HMM state, and the state's PDF is simply the average across all such frames. Similarly, the PDF describing which state B follows any given state A in modeling the dynamics of the speech simply follows the likelihood of moving to a nearby vocal tract shape (B)

in one frame, given that the previous speech frame was assigned to state A. This simple approach in which the model takes no direct account of the history of the speech (beyond one state in the past) is called a *first-order Markov model*. It is clear, when dealing with typical 10-ms frames, that there is certainly significant correlation across many successive frames (due to coarticulation in vocal tract movements). Thus the first-order assumption is an approximation, to simplify the model and minimize computer memory. Attempts to use higher-order models have not been successful because of the immense increase in complexity needed to accommodate reasonable amounts of coarticulation. The HMM is called "hidden" because the vocal tract behavior being modeled is not directly observable from the speech signal (if the input to an ASR system were X rays of the actual moving vocal tract during speech, we could use direct Markov models, but this is totally impractical).

Gaussian PDFs are normally used to specify each state in an HMM. Such a PDF for an N-dimensional feature vector $\mathbf{x}$ for a spoken word assigned index i is

$$P_i(x) = (2\pi)^{-N/2}|\mathbf{W}_i|^{-1/2}\exp\left[\frac{-(\mathbf{x}-\mu_i)^{\mathrm{T}}\mathbf{W}_i^{-1}(\mathbf{x}-\mu_i)}{2}\right] \quad (1)$$

where $\mathbf{W}_i$ is the covariance matrix (noting the individual correlations between parameters), $|\mathbf{W}_i|$ is the determinant of $\mathbf{W}_i$, and μ_i is the mean vector for word i. Most systems use a fixed $\mathbf{W}$ matrix (instead of individual $\mathbf{W}_i$ for each word) because (1) it is difficult to obtain accurate estimates for $\mathbf{W}_i$ from limited training data, (2) using one $\mathbf{W}$ matrix saves memory and computation, and (3) $\mathbf{W}_i$ matrices are often similar for different words. If one chooses parameters that are independent (i.e., no relationship among the numbers in the vector $\mathbf{x}$), the $\mathbf{W}$ matrix simplifies to a diagonal matrix, which greatly simplifies calculation of the PDF (which must be repeatedly done for each speech frame and for each HMM). Thus many ASR systems assume (often without adequate justification, other than reducing cost) such a diagonal $\mathbf{W}$. Unless an orthogonalization procedure is performed (e.g., a Karhunen–Loeve transformation—itself quite costly), most commonly used feature sets (LPC coefficients, MFCCs) have significant correlation.

The elements along the main diagonal of $\mathbf{W}$ indicate the individual variances of the speech analysis parameters. The use of $\mathbf{W}_i^{-1}$ in the Gaussian PDF notes that those features with the smallest variances are the most useful for discriminating sounds in ASR. Parameter sets that lead to small variances and widely spaced means $\boldsymbol{\mu}_i$ are best, so that similar sounds can be consistently discriminated.

The Gaussian form for the state PDF is often appropriate for modeling many physical phenomena; the idea follows from basic stochastic theory: the sum of a large number of independent, identically distributed random variables resembles a Gaussian. Natural speech, coming from human vocal tracts, can be so treated, but only for individual sounds. If we try to model too many different vocal tract shapes with one HMM state (as occurs in multispeaker, or context-independent ASR), the Gaussian assumption is much less reasonable (see text below for the discussion of mixtures of Gaussian PDFs).

We create HMMs to model different units of speech. The most popular approaches are to model either phonemes or words. Phonemic HMMs require fewer states than word-based HMMs, simply because phonemes are shorter and less phonetically varied than words. If we ignore coarticulation with adjacent sounds, many phonemes could be modeled with just one state each. Inherently dynamic phonemes, such as stops and diphthongs, would require more states (e.g., a stop such as /t/ would at least need a state for the silence portion, a state for the explosive release, and probably another state to model ensuing aspiration). There is a very practical issue of how many states are appropriate for each HMM. There is no simple answer; too few states lead to diffuse PDFs and poor discriminability (especially for similar sounds such as /t/ and /k/), due to averaging over diverse spectral patterns. Too many states lead to excessive memory and computation, as well as to "undertraining," where there are not enough speech data in the available training set to provide reliable model parameters.

Consider the (very practical) task of simply distinguishing "yes" versus "no" (or perhaps just the 10 digits: 0, 1, 2,...9); it is efficient to create an HMM for every word in the allowed vocabulary. There will be several states in each HMM to model the sequence of phonemes in each word. HMMs work best when there is a rough correspondence between the number of states and the number of distinguishable sounds in the speech unit being modeled. If the model creation during the training phase is done well, this allows each state to have a PDF with minimal variance. At recognition time, such tight PDFs will more easily discriminate words with different phoneme sequences.

As the size of the allowed vocabulary increases, however, it becomes much less practical to have one or more models for every word. Even in speaker-independent ASR, where we could ask thousands of different people to furnish speech data to model the many tens of thousands of words in any given language such as English, the memory and search time needed for word-based HMMs goes beyond current computer resources. Thus, for vocabularies larger than 1000 words, most systems employ HMMs that model phonemes (or sometimes "diphones," which are truncated sequences of phoneme pairs, used to model coarticulation during transitions between two phonemes). Diphones are obtained by dividing a speech waveform into phoneme-sized units, with the cuts in the middle of each phone (thus preserving in each diphone the transition between adjacent phonemes). In text-to-speech applications, concatenating diphones in a proper sequence (so that spectra on either side of a boundary match) usually yields smooth speech because the adjacent sounds at the boundaries are spectrally similar; e.g., to synthesize *straight*, the six-diphone sequence /#s-st-tr-re-et-t#/ would be used (# denoting silence).

Using phonemic HMMs reduces memory and search time, as well as allowing a fixed set of models, which does not have to be updated every time a word is

added to the vocabulary. If the models are "context-independent," however, their discriminability is small. When averaging over a wide range of phonetic contexts, the states modeling the initial and final parts of each phoneme have varying spectral patterns and thus broad PDFs of poorer discriminability.

Nowadays, more advanced ASR systems employ "context-dependent" phonemic HMMs (e.g., diphone models), where each phoneme is assigned many HMMs, depending on its immediate neighbors. A simple and common (but expensive) technique uses triphone models, where for a language with N phonemes we have N^3 models; each phoneme has N^2 models, one for each context (looking before and after by one phoneme). There is much evidence from the speech production literature about the effects of coarticulation, which are significant even beyond a triphone window. (A diphone approach is a compromise between a simple context-independent scheme and a complex triphone method; it has N^2 models.) For English, with about 32 phonemes, the triphone method leads to tens of thousands of HMMs (which need to be adequately analyzed and stored in the training phase, and all must be examined at recognition time). Many systems adopt a compromise by grouping or clustering similar models according to some set of phonetic rules (e.g., the decision-tree approach). If the clustering is done well, one could even expand the analysis window beyond triphones, to accommodate further coarticulation (e.g., in the word "strew," lip rounding for the vowel /u/ affects the spectrum of the initial /s/; thus a triphone model for /u/ looking leftward only at the neighbor /r/ is inadequate).

5.4. Language Models for ASR

Going back only a decade or so, we find much less successful ASR methods that concentrated only on the acoustic input to make decisions. It was thought that all the required information to translate speech to text could be found in the speech signal itself; thus no cognitive modeling of the listener seemed necessary. Some surprisingly simple experiments that modeled some aspects of language changed that naive approach, with positive results in recognition accuracy. Indeed, it can be easily observed that words in speech (as in text) rarely occur in random order. Both syntactically and semantically, there is much redundancy in word order. For example, when talking about a dog, one may well find the semantically related words "small" or "black" immediately prior to "dog." As for syntax, there are many restrictions on word sequences, such as the common structure of article+adjective+noun for English noun phrases, and strict order in verb phrases such as "may not have been eaten."

Thus researchers developed models for language, in which the likelihood of a given word occurring after a prior word sequence is evaluated and used in the decision process of speech recognition. The most common approach is that of a trigram language model, where we estimate the probability that any given word in text (or speech) will follow its preceding two words (written or spoken). Textual redundancy in English (and indeed many languages) goes well beyond a trigram window of analysis, but practical issues of computer memory and the availability of training data have so far limited most models to a three-word range. Training for language models has been almost exclusively done using written texts (and rarely transcriptions of speech), despite the inappropriateness for ASR of written compositions (i.e., most speech is spontaneous, rarely from written texts), owing to the cost (and often limited accuracy) of transcribing large amounts of speech. Researchers find it much easier to use the many databases of text available today, despite their shortcomings.

The major advantage of models such as trigrams is that they incorporate diverse aspects of practical text redundancies automatically (no complex semantic or syntactic analysis is needed). This reflects the current premature state of natural language processing (e.g., the continuing difficulties in automatic language translation). This lack of intelligent analysis in trigram models, however, leads to serious inefficiencies. As the allowed vocabulary increases in size, for applications not limited to specific topics of conversation, the availability of sufficient text to obtain reliable statistics is a major problem. Depending on what is counted as a word (e.g., do "eat, eats, eating, eaten" count as four individual words?), there are easily hundreds of thousands of words in English; taking a very conservative estimate of 10^5 words, there are 10^{15} trigrams, which strains current computer capacities, or at least significantly increases costs. As a result, many acceptable trigrams (and even many bigrams and unigrams) are not observed in any given training text (even large ones containing millions of words). The usual estimation of probabilities simply divides the number of occurrences of each specific trigram (or bigram) by the total number of occurrences of each word being modeled in the training text. For sequences occurring frequently in training texts, the estimates are reasonable, at least for the purposes of modeling (and recognizing speech from) additional text from the same source. One may readily create different language models for different types of text, such as those for physicians, lawyers, and other professionals, corresponding to specific applications.

A serious problem with the approach above is how to handle unobserved sequences (e.g., the very large number of three-word sequences not found in a given training text, but nonetheless permitted in the language). Assigning them all a probability of zero is quite inappropriate, since such word sequences would then never appear in a speech recognizer's output, even if they were actually spoken. One solution simply assigns all unseen sequences the same tiny probability, and reduces the probabilities of all observed sequences by a compensatory amount (to ensure that the total probability remains equal to one). This is somewhat better than arbitrarily assigning zero likelihoods, but treats all unseen sequences as equally likely, which is a very rough and poor estimate. A more popular way is the "backoff" approach, in which the overall assigned likelihood for a word is a weighted combination of trigram, bigram, and unigram probabilities. The weightings are appropriately adjusted for unseen sequences. If no trigram (or bigram) estimate is available, one simply assigns its corresponding weighting a value of zero, and uses existing

(bigram and) unigram statistics. Of course, words that never appear at all in a training set have no statistics to which to back off; their likelihoods must be estimated another way.

While the trigram method has considerable power as a language model for ASR, there is also considerable waste. The memory for trigram statistics for large-vocabulary applications is very large, and many of the probabilities are poorly estimated due to insufficient training data. It is more efficient if one clusters similar words together, thus reducing memory and making the fewer statistics more reliable. One extreme case is the tri-PoS approach, where all words are classified by their syntactic category (e.g., part of speech, such as noun, verb, or preposition). Depending on how many categories are used, the statistics can be very reduced in size, while still retaining some powerful syntactic information to predict common word-class sequences. Unfortunately, the semantic links among adjacent words are largely lost with this purely syntactic language model. Owing to the reduced model size, one can easily extend the tri-PoS method to windows of more than three words, or one can extend the word categories to include semantic labels as well. Word-class language models using perhaps hundreds of hybrid syntactic-semantic classes may eventually be a good compromise approach between the too simple tri-PoS method and the huge trigram approach.

5.5. Practical Issues in ASR — Segmentation

In addition to the serious ASR issues of computer resources and of speech variability, there is another aspect of recognizing speech that makes the task more difficult than synthesizing speech: segmentation. In the case of automatic speech synthesis, the computer's task is easier for two reasons: (1) the input text is clearly divided into separate words, which simplifies processing; and (2) the burden is placed on the human listener to adapt to the weaknesses of the computer's synthetic speech. In ASR, on the other hand, the machine must adapt to each user's different style of speech, and there are few clear indications to boundaries in a speech signal. In particular, acoustic cues to word boundaries in speech are very few. Automatic segmentation of a long utterance into smaller units (ideally into words) is very difficult, but is effectively necessary to reduce computation and lower error rates. One is tempted to exploit periods of silence for segmentation, but they are unreliable cues to linguistic boundaries. Long pauses are usually associated with sentence boundaries, but they often occur within a sentence and even within words (e.g., in hesitations). Short pauses are easily confused with phonemic silences (i.e., the vocal tract closures during unvoiced stops).

Segmenting speech into syllabic units is easier, because of the typical rise and fall of speech energy between vowels and consonants. However, many languages (e.g., English) allow many different types of syllables (ranging from ones with only a vowel to ones with several preceding and ensuing consonants). Many languages (e.g., Japanese) are much easier to segment because of their consistent alternation of consonants and vowels. Segmenting speech into phonemes is also difficult if the language allows sequences of similar phonemes, such as vowels, or large variations in phonemic durations (e.g., English allows severe reduction of unstressed phonemes, such that recognizers often completely miss brief sounds; at the other extreme, long vowels or diphthongs can often be misinterpreted as containing multiple phonemes).

To facilitate segmentation, many commercial recognizers still require speakers to adopt an artificial style of talking, pausing briefly (at least a significant fraction of a second) after each word. Silences of more than, say, 100 ms should not normally be confused with (briefer) stop closures, and such sufficiently long pauses allow simple and reliable segmentation of speech into words.

In order of increasing recognition difficulty, four styles of speech are often distinguished: *isolated-word* or *discrete-utterance* speech, *connected-word* speech, *continuous*-read speech, and normal conversational speech. The last two categories concern continuous-speech recognition (CSR), which requires little or no adaptation of speaking style by system users. CSR allows the most rapid input (e.g., 150–250 words/min), but is the most difficult to recognize. For isolated-word recognition, requiring the speaker to pause after each word is very unnatural for speakers and significantly slows the rate at which speech can be processed (e.g., to about 20–100 words/min), but it clearly alleviates the problem of isolating words in the input speech signal.

Using word units, the search space (in both memory and computation) is much smaller than for longer utterances, and this leads to faster and more accurate recognition. However, few speakers like to talk in "isolated word" style. There remains also the serious issue of "endpoint detection," where the beginning and end times for speech must be determined; against a background of noise, it is often difficult to discriminate weak sounds from the noise. Endpoint detection is more difficult in noise: speaker-produced (lip smacks, heavy breaths, mouth clicks), environmental (stationary: fans, machines, traffic, wind, rain; nonstationary: music, shuffling paper, door slams), and transmission (channel noise, crosstalk). The large variability of durations and amplitudes for different sounds makes reliable speech versus silence detection difficult; strong vowels are easy to locate, but the boundaries between weak obstruents and background noise are often poorly estimated. Typically, endpoint location uses energy as the primary measure to cue the presence of speech, but also employs some spectral parameters. Clear endpoint decisions are required very often in isolated-word speech. For these various reasons, most current research focuses on more normal "continuous" speech.

Stochastic modeling has an important place in speech processing, given the large amount of variability in speech production. Humans are indeed incapable of producing exactly the same utterance twice. With effort, they can likely make utterances sound virtually the same to listeners, but at the sampling and precision levels of automatic speech analyzers, there are always differences, which result in parameter variations. If one selects ASR parameters well and such variation is minimal, system performance can be high with proper stochastic models.

However, all too often, variability is large and goes beyond the modeling capability of current ASR systems. Future ASR must find a way to combine deterministic knowledge modeling (e.g., the "expert system" approach to artificial intelligence tasks) with well-controlled stochastic models to accommodate the inevitable variability. Currently, the research pendulum has swung far away from the expert-system approach common in the mid-1970s.

5.6. Practical Issues in ASR: Noise

In many applications, the speech signal is subject to various distortions before it is received by a recognizer [13]. Noise may occur at the microphone (e.g., in a telephone booth on the street) or in transmission (e.g., fading over a portable telephone). Noise leads to decreased accuracy in the parameters during speech analysis, and hence to poorer recognition, especially (as is often the case) if there is a mismatch in conditions between the training and testing speech. It is very difficult (and/or expensive) to anticipate all distortion possibilities during training, and thus ASR accuracy certainly decreases in such cases.

As an attempt to normalize across varying conditions, ASR systems often calculate an average parameter vector over several seconds (e.g., over the entire utterance), and then subtract this from each frame's parameters, applying the net results to the recognizer. This approach takes account of slow changes in average energy as well as the filtering effects of the transmission microphone and channel, which usually change slowly over time. Such "mean subtraction" is simple and useful in noisy conditions, but can delay recognition results if we must determine the mean for several seconds of speech and only then start to recognize the speech. A similar method called RASTA (RelAtive SpecTrAl) uses a highpass filter (with a very low-frequency cutoff) to eliminate very slowly varying aspects of a noisy speech signal, as being specific to the transmission channel and irrelevant to the speech message.

More traditional speech enhancement techniques can also be used in ASR [14]. These include spectral subtraction (or related Wiener filtering), where the average amplitude spectrum observed during signal periods that are estimated to be devoid of actual speech is subtracted from the spectrum of each speech frame. In this way, stationary noise can be somewhat suppressed. Frequency ranges dominated by noise are thus largely eliminated from consideration in the analysis to determine relevant parameters. The output of speech enhancers sounds more pleasant, but intelligibility is not enhanced by this removal of noise.

Sometimes used for speech enhancement, another approach called "comb filtering" estimates F0 in each frame and suppresses portions of the speech spectrum between the estimated harmonics. Again, the enhanced output speech sounds more pleasant, but this method requires a reliable F0 detector, and the resulting comb filter must adapt dynamically to the many changes in pitch found in normal speech.

Much more powerful speech enhancement is possible if several microphones are allowed to record in a noisy environment. For example, in a noisy plane cockpit, one microphone close to the pilot's lips would capture a signal containing speech plus some noise, while another microphone outside the helmet would capture a version of the noise corrupting the initial signal. Using adaptive filtering techniques very similar to those for echo cancellation at 2/4-wire junctions in the switched telephone network, one can improve very significantly both the quality and the intelligibility of such speech.

5.7. Artificial Neural Networks (ANNs)

Since 1990, in another attempt to solve many problems of pattern recognition, significant research has been done in the field of artificial neural networks. These ANNs simulate very roughly the behavior of neurons in the human central nervous system. Given a signal (e.g., speech) to recognize, each node of an ANN accepts a set of signal-based inputs, computes a linear combination of the these values, compares the result against a threshold, and provides a binary output (1 if the linear combination exceeds the threshold, 0 otherwise). By combining such nodes in a network, quite complicated decision spaces can be constructed, which have proven useful in numerous pattern recognition applications, including speech recognition [15]. For ASR, the ANN typically accepts a long vector of L parameters (e.g., for 10 MFCCs per frame and a 100-frame utterance, one has a vector of $L = 1000$ dimensions), as emitted by the usual speech analysis methods discussed above, and these L numbers provide the input to a set of M nodes (each individual input value may be input to several nodes). Each node thus makes a linear combination of a selected set of values from the input vector. The conceptually simplest ANN would assign one output node to each possible output of the recognition process (e.g., if the utterance must be one of the 10 spoken digits, $M = 10$, and one tries to specify the weights in the ANN such that, on any given trial, only one of the M outputs will be 1; the label on that output node provides the textual output. Thus, with proper training of the ANN to choose the appropriate weights, when one says "six" and the L resulting analysis parameters are fed through the ANN, ideally only one of the 10 output nodes (i.e., that corresponding to "six") will show a 1 (the others showing 0). This assumes, however, that each of the allowed vocabulary words corresponds to a simple distribution in L-dimensional acoustic space, such that basic hyperplanes can partition the space into 10 separable clusters (and furthermore that a training algorithm looking at many utterances of the 10 digits can determine the correct weights). It is very rare that these assumptions are exactly true, however. To adapt to practical speech cases, a partial solution has been to add extra layers of nodes to the ANN. We allow the number M_2 of nodes in the second layer to be larger than M, and allow the binary outputs of those M_2 nodes to pass through another layer of weights and N nodes. Such a double-layer ANN can partition the speech space into the much more complex shapes that correspond to practical systems. For speech, in general, it appears that a three-tier system is needed; the original input speech-parameter vector provides the numbers for the lowest layer, the information propagates through three levels of weightings

(two "hidden" layers of nodes) to finally appear at the output layer (with one node for each textual label).

For static patterns (e.g., simple steady vowels), ANNs have provided excellent classification when properly trained. However, general ASR must handle dynamic speech, and thus the practical success of ANNs has been more limited. So-called time-delay ANNs allow complicated feedback within ANN layers to try to account for the fact that small delays (variability in timing) in speech signals occur often in human speech communication and do not hinder perception. In a basic ANN, however, shifting the set of inputs can cause large changes in the ANN outputs. As a result, for ASR, ANNs have typically found application, not as a replacement for HMMs, but as an additional aid to the basic HMM scheme (e.g., ANNs can be used in the training phase for better estimation of HMM parameters).

6. SPEAKER VERIFICATION

We have shown speech analysis to be useful in coding, where speech is regenerated after efficient compression, and in ASR, where speech is converted to text. Another application for speech analysis is speaker verification, where one determines whether speakers are who they claim to be. Fingerprints or retinal scans are often more accurate in identifying people than speech-based methods, but speech is much less intrusive and is feasible over the telephone. Many financial institutions, as well as companies furnishing access to computer databases, would like to provide automatic customer service by telephone. Since personal number codes (keyed on a telephone pad) can easily be lost, stolen, or forgotten, speaker verification may provide a viable alternative. The required decision process can be much simpler than for ASR, since a given speech signal is converted into a simple binary digit ("yes," to accept the claim, or "no," to refuse it). However, the accuracy of such verification has only relatively recently reached the point of commercialization.

In ASR, for speech signals corresponding to the same spoken text, any variation due to different speakers is viewed as "noise" to be either (1) (ideally) eliminated by speaker normalization or (2) (more commonly) accommodated through models based on a large number of speakers. When the task is to verify the person talking, rather than what that person is saying, the speech signal must be processed to extract measures of speaker variability instead of segmental acoustic features. What to look for in a speech signal for the purpose of distinguishing speakers is much more complex than for ASR. In ASR we look for spectral features to distinguish different fundamental vocal tract positions, and we can exploit language models to raise accuracy.

One common speaker verification approach indeed employs ASR techniques, with the exception of labeling models with speaker names instead of word or phoneme labels. When two speakers utter the same word or phoneme, spectral patterns are compared to see which speaker provides the more precise match. In ASR, competing phoneme or word candidates can often be distant in spectral space, making the choice relatively easy. In speaker verification, however, many people have quite similar vocal tract shapes and speaking styles; using analysis over many frames, however, renders the task feasible.

For speech recognition, much is known about the human speech production process, which links a text and its phonemes to the spectra and prosodics of a corresponding speech signal. Each phoneme has specific articulatory targets, and the corresponding acoustic events have been well studied (but still are not fully understood). For speaker verification, on the other hand, the acoustic aspects of what characterizes the principal differences between voices are difficult to separate from signal aspects that reflect ASR. There are three major sources of variation among speakers: differences in vocal cords and vocal tract shape, differences in speaking style (including variations in both target positions for phonemes and dynamic aspects of coarticulation such as speaking rate), and differences in what speakers choose to say. Automatic speaker verification exploits only the first two of the variation sources, examining low-level acoustic features of speech, since a speaker's tendency to use certain words and syntactic structures (the third source) is difficult to exploit (e.g., impostors could easily mimic a speaker's choice of words, but would find simulating a specific vocal tract shape or speaking style much more difficult).

Unlike the relatively clear correlation between phonemes and spectral resonances, there are no evident acoustic cues specifically or exclusively dealing with speaker identity. Most of the parameters and features used in speech analysis contain information useful for the identification of both the speaker and the spoken message. The two types of information, however, are coded quite differently in the speech signal. Unlike ASR, where decisions are made for every phoneme or word, speaker verification requires only one decision, based on parts or all of a test utterance, and there is no clear set of acoustic cues that reliably distinguishes speakers. Speaker verification typically utilizes long-term statistics averaged over whole utterances or exploits analysis of specific sounds. The latter approach is common in "text-dependent" applications where utterances of the same text are used for both training and testing.

There are two classes of errors in speaker verification: *false rejections* and *false acceptances*. A false rejection occurs when the system incorrectly rejects a true speaker. A false acceptance occurs when the system incorrectly accepts an impostor. The decision to accept or reject usually depends on a threshold: if the distance between a test speech pattern and a reference pattern exceeds the threshold (or equivalently, using a PDF for the claimed speaker, the evaluated probability value is too low), the system rejects a match. Depending on the costs of each type of error, verification systems can be designed to minimize an overall penalty by biasing the decisions in favor of less costly errors. Low thresholds are generally preferred because false acceptances are usually more expensive (e.g., admitting an impostor to a secure facility might be disastrous, while excluding some authorized customers is often merely annoying). System parameters are often

adjusted so that the two types of error occur equally often (*equal error rate condition*).

One popular method is the *Gaussian mixture model* [16], which follows the popular modeling approach for ASR, but eliminates separate HMMs for each phoneme as unnecessary. It is essentially a one-state HMM, but allows the PDF to be complicated. In ASR, we can often justify that each state's PDF may be approximated as approaching a Gaussian distribution (especially for triphone HMMs, where context is well controlled). When merging all speech from a speaker into one PDF, however, that PDF is far from Gaussian. To retain the simple statistics of Gaussians (complete specification with only the mean and variance), however, both ASR and speaker verification often allow a state's PDF to be a weighted combination of many Gaussian PDFs. Using the same set of Gaussians for all speakers, each speaker is characterized simply by the corresponding set of weights. Evaluation is thus quite rapid, even when all the frames of an utterance contribute to the overall speaker decision.

Such an approach ignores dynamic speech behavior (as well as ignoring intonation, as do most ASR systems), and further assumes that both training and testing utterances will be roughly similar in phonetic composition. This latter assumption is ensured when doing "text-dependent" verification, where the speaker is asked to utter words already made known to the system during the training phase; for instance, a commercial system may train on two-digit numbers (e.g., "74") and then ask each candidate speaker to utter a few such numbers at test time. False rejections are much lower for these systems than for "text-independent" verifiers, although the latter are sometimes needed for forensic work (e.g., there is no text control in wiretapped conversations). The former, however, run the risk of an impostor playing a recording of the desired speaker (over the telephone, or if there is no camera surveillance at a secure facility). Such impostors, of course, elevate false-acceptance rates with "text-independent" verifiers (which have lower accuracy) as well, but impostors would have difficulty anticipating the requested text that customers are asked to speak, in the case of the much larger vocabulary in the latter systems.

In any pattern recognition task (ASR included), training and test data must be kept separate (i.e., testing on data already used for training artificially raises performance to levels that will usually not be replicated in practical testing situations), but this is even more important in the case of speaker verification. Speakers tend to vary their style of speech over time (e.g., morning versus evening, Monday–Saturday, healthy–ill). Training a speaker verifier in only one session, and then testing a few months later will usually not give good results. Ideally, speaker verification needs months of training (or at least an adaptive system, which allows for periodic updates while being used). If the same utterances are used to train and test a system, a high degree of accuracy is due to the model parameters often being heavily tuned toward the training data. For good results, the training data must be sufficiently diverse to represent many different possible future input speech signals. With shared training and test data, it is difficult to know whether the system has been designed to take advantage of specific speech or speaker characteristics that may not be repeated in new data. Given K utterances per speaker as data, one common procedure trains its system using $K-1$ as data and one as test, but repeats the process K times treating each utterance as test once. Technically, this "leave one out" method designs K different systems, but this method verifies whether the system design is good using a limited amount of data, while avoiding the problems of common train and test data.

7. TEXT-TO-SPEECH SYNTHESIS (TTS)

Our final speech processing application concerns the automatic generation of speech from text [17–19]. Here, speech processing occurs both in the development stage of the system, when spoken units from one or more speakers are recorded, and again at synthesis time, when selected stored units are concatenated to produce the synthetic output voice. The units involved can range from full sentences (e.g., as in talking cars and ovens) to shorter phrases and words (e.g., telephone directory assistance) to phonemes (e.g., for unlimited text applications).

We distinguish true TTS systems, which accept any input text in a chosen language (this could include new words and typographical errors), from "voice response systems," which accept a very limited vocabulary and are essentially voice coders of much simpler complexity (but suffer from inflexibility). Commercial synthesizers have now become much more widespread owing to both advances in computer technology and improvements in the methodology of speech synthesis.

The simplest applications requiring only small vocabularies are speech coders that merely play back the speech when needed. This is impossible for general TTS applications, because no one training speaker can provide all possible utterances. For TTS, small units (typically, phonemes or diphones) are concatenated to form the synthetic speech, and significant adjustments must be done at unit boundaries to avoid unacceptable disjointed (jumpy) speech. The quantity and complexity of such adjustments vary in indirect proportion to the unit size, which in turn also varies inversely with quality (e.g., general text-to-speech using smaller units sounds less natural).

The critical issues for synthesizers concern tradeoffs among the conflicting demands of simultaneously maximizing speech quality, while minimizing memory space, algorithmic complexity, and computation speed. While simple TTS is possible in real time with low-cost hardware, there is a trend toward using more complex programs (tens of thousands of lines of code, and megabytes of storage). Real-time TTS systems produce speech that is generally intelligible, but lacks naturalness.

Most synthesizers reproduce speech of bandwidth ranging from 300–3000 Hz (e.g., for telephone applications) to 100–5000 Hz (for higher quality). A spectral range up to 3 kHz is sufficient for vowel perception because vowels are adequately specified by the lowest three formants. The perception of some consonants, however, is slightly impaired when energy in the 3–5-kHz range is omitted. Frequencies above 5 kHz help improve speech naturalness but seldom aid speech intelligibility. If we assume

that a synthesizer reproduces speech up to 4 kHz, a rate of 8000 samples/s is needed. Since linear PCM requires 12 bits/sample for toll-quality speech, storage rates near 100 kbps result, which are acceptable only for synthesizers with very small vocabularies.

The memory requirement for a simple synthesizer is often proportional to its vocabulary size. Continued decreases in memory costs have allowed the use of very simple TTS systems. Nonetheless, storing all possible speech waveforms for synthesis purposes (even with efficient coding) is impractical for TTS. The sacrifices usually made for large-vocabulary synthesizers involve simplistic modeling of spectral dynamics, vocal tract excitation, and intonation. Such modeling usually causes quality limitations that are the primary problems for current TTS research.

7.1. The Steps in Producing Speech from Text

TTS requires several steps to convert the linguistic textual message into an acoustic signal. The linguistic processing is, in a sense, an inverse of the procedures for ASR. First, a "preprocessing" stage "normalizes" the input text so that it is a series of spelled-out words (retaining any punctuation marks as well). All abbreviations and digits are converted to words, typically via a lookup table or simple programs (sophisticated systems however might distinguish ways of saying "$19.99" and "1999"); word context may be necessary to handle cases such as "St. Peter St." The words are then converted into a string of phonemes (and basic intonation parameters), usually via a combination of a dictionary and pronunciation rules. Reduced memory costs have led to use of large dictionaries containing all the words in a given language and their phonemic pronunciations. With a dictionary, additional relevant information can be readily available, including lexical stress (which syllable in each word is stressed), part of speech, and even semantics.

The alternative approach of letter-to-phoneme rules is useful to handle new, foreign, and mistyped words (cases where simple dictionaries fail). Complex languages such as English (derived from both Romance and Germanic languages) require many hundreds of these rules to pronounce letter sequences correctly (e.g., consider "-ough-:" rough, cough, though, through, thought, drought). Languages are often much simpler phonetically; for instance, Spanish employs just one rule per letter. In all cases, developing TTS capability for a language requires establishing a dictionary and/or pronunciation rules. Hence commercial TTS exists only for about 20 of the world's languages, whereas many commercial ASR systems (those based on word units and without a language model) can handle virtually all languages, since most languages employ similar versions of stops, fricatives, vowels, and nasals.

The next TTS step is intonation specification, determining a duration and amplitude for each phoneme, as well as a complete F0 pattern for the utterance. This is much more difficult than the prior two TTS steps, and requires a syntactic and semantic analysis of the input text. Most languages use intonation in complex ways to cue many aspects of speech communication. Many languages (including English) stress only a small number of syllables in any utterance. This involves not just simple lexical stress from a dictionary but also a judgment about the semantic importance of the words in a sentential context; for synthetic speech comparable to that of humans, this would require a natural-language processor typically beyond current capabilities. People often cue syntactic structure via intonation; for example, in English, long word phrases often start with an F0 rise and end with a fall. Questions in many languages are cued with a large final F0 rise if they request a yes/no answer (but not questions with the "wh-words": what, when, why, who, how). Tone languages (e.g., Chinese, Thai) employ four or five different F0 patterns on syllables to distinguish different words with the same phoneme sequence. Finally, speech uttered with emotion often changes intonation significantly.

In the last TTS step, speech units are concatenated using the specified intonation, and adjustments are made to the model parameters at unit boundaries. Few such manipulations are needed for phrasal concatenation, but smaller units require at least smoothing of all parameters across the boundary for several frames. This is relatively straightforward when the units contain spectral parameters (e.g., LPC coefficients or formants), although improved quality occurs with more complicated smoothing rules. Storing small units with waveform coding (e.g., log PCM or ADPCM) is often not suitable (despite the higher general quality of such speech) here because smoothing the available parameters does not approximate well the actual coarticulation and F0 manipulation found in human speech production.

Smoothing of parameters at the boundaries between concatenated units is most important for short units (e.g., phones) and decreases in importance for larger units owing to fewer boundaries. Smoothing is much simpler when the joined units approximately correspond at the boundaries. Since diphone boundaries link spectra from similar sections of two realizations of the same phoneme, smoothing rules for their concatenation are simple. Systems that link phones, however, must use complex smoothing rules to represent coarticulation in the vocal tract. Not enough is understood about coarticulation to establish a complete set of rules to describe how the spectral parameters for each phone are modified by its neighbors. Diphone synthesizers circumvent this problem by storing parameter transitions from one phone to the next, since coarticulation influences primarily the immediately adjacent phones. However, since coarticulation often extends over several phones, using only average diphones or those from a neutral context leads to lower-quality synthetic speech. Improved quality is possible by using multiple diphones dependent on context, effectively storing "triphones" of longer duration (which may substantially increase memory requirements). Some coarticulation effects can be approximated by simple rules, such as lowering all resonant frequencies during lip rounding, but others such as the undershoot of phoneme target positions (which occurs in virtually all speech) are much harder to model accurately.

It is in this last TTS step that the system yields poorer quality than many speech coders, because TTS is often

forced to employ synthetic-quality coding techniques. The traditional excitation for vocal tract filters in TTS (either LPC or formant-based approaches, which constitute most commercial methods) is a simple train of periodic pulses (for voiced speech) or white noise (a random-number generator) for unvoiced speech. The combination of oversimplified excitation and the limited modeling accuracy of the LPC or simple formant models leads to intelligible, but slightly unnatural, synthetic speech.

Since the late 1980s, some commercial systems have been successful in concatenating waveform-coded small units, with limited amounts of perceptually annoying spectral jumps at unit boundaries; for instance, the PSOLA (pitch-synchronous overlap and add) method outputs successive smoothed pitch periods [20]. While such speech can sound more natural, it is inflexible in producing alternative voices. It is typically based on one speaker uttering a large inventory of diphones; for a language such as English with about 32 phonemes, about 1000 diphones must be uttered and in a uniform fashion. One cannot simply adjust some synthesizer parameters here to get other synthetic voices (as is possible with formant synthesizers).

8. CURRENT TECHNOLOGY

Today's speech coders deliver toll quality (i.e., equivalent to the analog telephone network) at 8 kbps with minimal amounts of delay (and even at 4 kbps, if delay is less of an issue). The favored approach is CELP, for which there are several standards accepted internationally (e.g., in digital cellular telephony). The digital links in most telephone networks still employ simpler 64 kbps log PCM coding; 24–32 kbps ADPCM and delta modulation are also still popular because of their relative simplicity. We are still far from an ultimate limit of perhaps 100 bps to code speech. Despite the reducing cost of computer memory and speed, further research in coding is needed because of the increasing use of wireless telephony, where limited bandwidth is very much an issue.

The lack of formal standards for human–machine applications of speech (i.e., synthesis and recognition) hinders comparison of commercial systems. Several companies offer unlimited text-to-speech for several languages (typically the major European languages, plus Japanese and Chinese). Such synthetic speech is largely intelligible, but is easily discerned as synthetic and lacking naturalness. All synthesizers suffer from our lack of understanding of the complex relationships between text and intonation. Synthesizers are clearly increasing in use, but wider public acceptance awaits further improvements in quality.

Speech recognizers are also increasing in use, but their severe limitations (compared to human speech perception) have also hindered wider acceptance. The need to pause between words, restrict the choice of words, and/or do prior training, as well as frequent recognition errors, have significantly limited the use of ASR. Systems eliminating all these restrictions (i.e., continuous, speaker-independent, large-vocabulary ASR) still suffer from high cost and frequent errors, especially if they are used in noisy or telephone environments, and such conditions occur often in practical applications. Progress in ASR has been attributed more to general improvements in computers and to the wider availability of training data, than to algorithmic breakthroughs. The basic HMM approach using MFCCs was developed largely before 1985. Even more recent additions, such as delta coefficients, mean subtraction, Gaussian mixtures, and language models, have been in wide use since 1990.

Future systems will likely integrate more structure into the stochastic approach. It is clear that the expert-system approach to ASR common in the early 1970s will never replace stochastic methods, for the simple reason that individual human phoneticians can never assimilate enough information from hundreds of hours of speech, in ways that probabilistic computer models can improve with larger amounts of training data. The extremely simple stochastic models in current widespread ASR use, however, are too unstructured and allow too much freedom (similar complaints hold for recent neural network approaches to ASR). For example, the MFCCs, while appropriately scaling the frequency axis to account for perceptual resolution, do not take account of the wide perceptual difference between resonances and spectral valleys. First-order HMMs ignore the high degree of correlation across many frames of speech data (compensating by using delta coefficients is only a very rough use of speech dynamics). Intonation is widely ignored (e.g., F0) or treated as noise (e.g., durational factors), despite evidence of its use in human speech perception. Of course, in a practical world, you use whatever works, and current systems, despite their flaws, provide sufficiently high accuracy for small vocabularies (e.g., recognizing the digits in spoken telephone or credit card numbers, or controlling computer menu selections via voice). More widespread use of speech in telephone dialogs will await advances in both the quality of synthetic speech and the recognition accuracy of spontaneous conversations.

BIOGRAPHY

Douglas O'Shaughnessy has been a professor at INRS-Telecommunications at the University of Quebec and adjunct professor at McGill University in Montreal, Québec, Canada, since 1977. His interests include automatic speech synthesis, analysis, coding, and recognition. He has been an associate editor for the Journal of the Acoustical Society of America since 1998, and will be the general chair of the 2004 International Conference on Acoustics, Speech, and Signal Processing (ICASSP) in Montreal, Canada. Dr. O'Shaughnessy received all his degrees from the Massachusetts Institute of Technology (MIT), and is a fellow of the Acoustical Society of America.

He is the author of the textbook *Speech Communications: Human and Machine* (IEEE Press, 2000).

SPEECH RECOGNITION

JAYADEV BILLA
BBN Technologies
Cambridge, Massachusetts

1. INTRODUCTION

Speech is a natural and preferred form of communication among humans. Automatic speech recognition attempts to extend this mode of communication to human–machine interaction. As a field of study, automatic speech recognition has a history extending back to the late 1960s. Over these years our understanding of the process of speech communication has increased substantially. This greater understanding, coupled with an even more developed ability to harness powerful computational models to encapsulate our knowledge of speech communication, has allowed for the development of increasingly capable speech recognition systems. Today, in some specialized applications, state-of-the-art speech recognition systems are capable of recognition and transcription of speech at performance levels that rival human ability.

In this article, we introduce the problem of automatic speech recognition and describe the reasons that make speech recognition by machine difficult. We also describe the science behind automatic speech recognition and discuss the principles and architecture of a typical large vocabulary speech recognition system. We then provide an overview of current state-of-the-art speech recognition research and applications, and conclude with a description of current trends in speech recognition system research and development.

2. WHY SPEECH RECOGNITION IS DIFFICULT

The ease with which humans use speech understates the complexity of this task for machines. The fundamental difficulty with speech recognition is the overwhelming variability in the production of speech. Indeed, if everyone always spoke in exactly the same way so that each word, whether spoken by the same person or different people, always sounded exactly the same, then we could simply store all the words and recognize speech by a simple comparison with the words we had heard and stored earlier. However, this is not the case; there is a considerable amount of variation in spoken speech even when the same speaker repeats the same sentence. Some forms of variability include those arising in the speaker due to mood, stress, and state of health, and those arising from the environment such as background noise or room acoustics. Other causes of variability in spoken speech include those due to gender, age, accent, or speaking rate among speakers and due to language differences, such as regional dialects, or formal versus conversational speaking style.

Figure 1 shows the speech signal and spectrogram for the utterance "gray whales". Spectrograms are pictures of the distribution of energy in frequency over time. The dark horizontal bars correspond to resonances of the vocal tract, and change their vertical frequency positions over time, depending on the sound being produced as well as on neighboring sounds. The dependency of each sound on its neighboring sounds further increases the number of ways in which a particular word can be pronounced. If this were not enough, normal human speech is a continuous stream of words without any interword separation, unlike the clearly separated words of written text. As an example of the difficulty in word boundary identification, consider spoken instances of the phrases "recognize speech" and "wreck a nice beach."

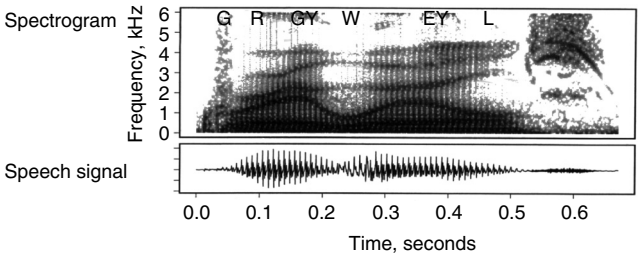

Figure 1. A spoken instance of the utterance "gray whales." The speech signal (bottom) is displayed as a simple amplitude plot over time. The spectrogram (top) shows the energy distribution of the utterance over frequency and time. The horizontal dark areas correspond to the resonances of the vocal tract.

An automatic speech recognition system must successfully address these variabilities in speech before any useful output can be provided to the user. Current understanding of the speech production process and the semantic and grammatic structure of language provides a means to model some of the variability. We are, however, limited by an incomplete knowledge of the process of speech communication. We do not really know how humans organize acoustic information and store knowledge of language; not do we know how cognitive processes are formed and used to perform recognition tasks. Current automatic speech recognition systems reflect these shortcomings and attempt to fit mathematical models to account for our incomplete understanding of the speech recognition problem. Tremendous advances in speech recognition technology have come from our ability to build sophisticated models that compensate for this lack of knowledge. Nevertheless, the lack of complete understanding of the speech communication process is an additional obstacle for automatic speech recognition systems to overcome, in addition to the inherent difficulty of the speech recognition task.

Moreover, automatic speech recognition systems must work effectively over the majority of acoustic environments that the systems may encounter. The difficulty in producing robust speech recognition systems that can work effectively over different acoustic environments is the primary reason for the limited use of such systems. Advances since 1980 have enabled us to build and deploy speech recognition systems for tasks ranging from responses to interactive voice response (IVR) systems with prompts of the type, "please say or press one to select choice one for ..., say or press two" to highly accurate transcription of dictation in certain specialized areas. The corresponding research recognition systems are close to achieving real-time transcription of general English such as in news broadcasts. Figure 2 charts commercial speech recognition system complexity, measured by speaking mode and vocabulary size, and its corresponding application area over time, against a projection for the near future. Early commercial speech recognition systems possessed vocabularies of several words that were spoken in isolation. More recently deployed speech recognition systems have had vocabularies in the tens of thousands of words and are capable of recognizing fluent speech. In the future, commercial systems are likely to recognize normal conversational speech with vocabulary sizes approaching that of humans.

3. THE SCIENCE BEHIND AUTOMATIC SPEECH RECOGNITION

The term *recognition* in the context of speech recognition is typically framed as a classification problem. Classification is when one has a finite set of possible outcomes, such as in a multiple-choice question, and attempts to classify an object or event of interest as one of these possibilities based on some observations. In automatic speech recognition systems, classification is usually considered a statistical pattern recognition problem. In the context of speech recognition, this involves building mathematical models of spoken speech and using them to identify the most likely sequence of words in the vocabulary as the recognized sentence or phrase.

A typical speech recognition system, illustrated in Fig. 3, consists of three main components: a *feature extraction stage*, where one extracts a set of speech features that can minimize some of the variability in speech without loss of information; a *training stage*, where one builds a set of mathematical models of speech; and a *recognition stage*, where one uses the trained models to make the classification of the spoken speech into a word or sentence.

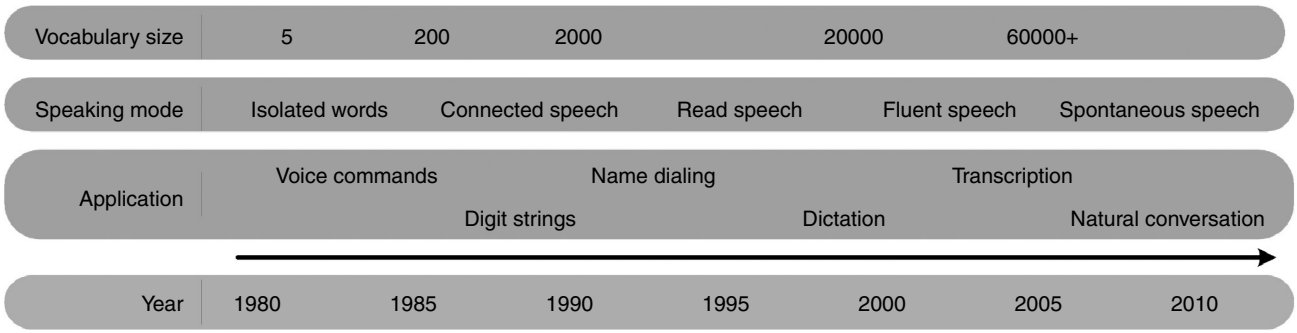

Figure 2. Timeline of the increase in speech recognition system complexity and its corresponding area of application. Early systems were capable of recognition of a few words spoken in isolation. Future systems are likely to have vocabularies sizes similar to human vocabularies and capable of recognition of natural spoken language.

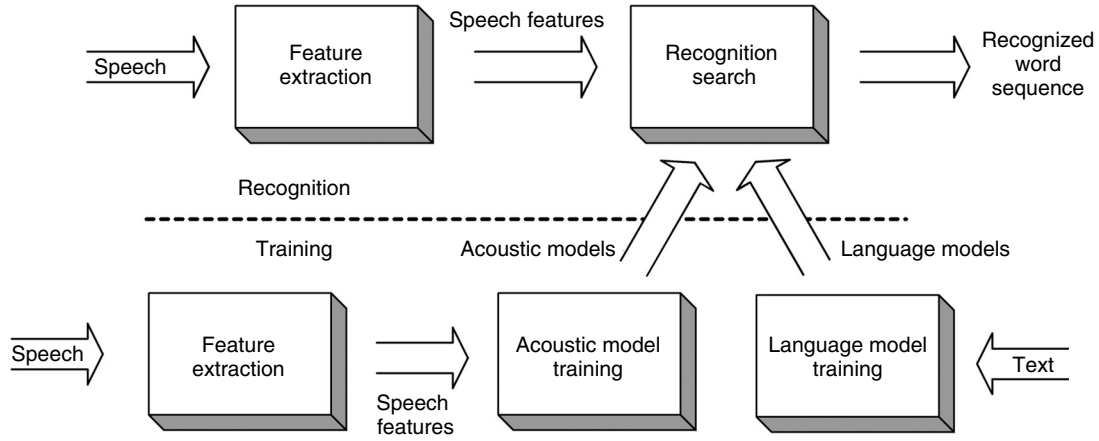

Figure 3. Components of a typical speech recognition system. A speech recognition system must first be trained (bottom) to generate models of speech. Recognition proceeds by comparing the input speech to the speech models to determine which speech model is closest to the input speech.

The catalog of mathematical models with which we compare features of a spoken word or sentence must be created beforehand, and often involves *levels of knowledge* akin to the many ways in which humans use prior knowledge to recognize speech. Typically, automatic speech recognition systems use at least two levels of knowledge: an *acoustic model* describing the actual acoustics of the speech signal, and a *language model* describing what word follows or is most likely to follow the current word or set of words.

The acoustics of a spoken sentence can be decomposed into a sequence of progressively finer acoustic events such as words, syllables, allophones, and phonemes. Fig. 4 shows the decomposition of the utterance "gray whales" into allophones and phonemes. The term *phoneme* has its origins in linguistics and is defined as the smallest unit of speech that can distinguish one word from another, such as *bit* versus *pit*. An allophone, on the other hand, is one of two or more variants of the same phoneme such as the phoneme \p\ in *pin* and *spin*. Each of these acoustic events can be modeled individually, and recognition can be achieved by identifying the appropriate sequence of acoustic events. The fundamental acoustic event is often determined by the application and by the amount of training data. For example, if we intend to build a recognizer that recognizes the 10 digits, 0–9, we can simply build a model for each of these digits. It is likely, in this case, that we will have many instances of each digit spoken by many people with which to build a representative model. On the other hand, if we intend to build a speech recognition system for general dictation with a vocabulary of 60,000 words, it is unlikely that we will have many spoken instances for most of the words in the vocabulary. In these cases, it is advisable to build phonetic models as the number of phonemes is much smaller than the number of words and therefore far more likely to have sufficient training instances. These models of acoustic events encapsulate the characteristics of the actual spoken speech signal and form the acoustic model.

Words	Gray			Whales			
Phonemes	-g	r	ey	w	ey	l	z-
Allophones	- [g] r	g [r] ey	r [ey] w	ey [w] ey	w [ey] l	ey [l] z	l [z] -

Figure 4. Decomposition of the utterance "gray whales" into words, phonemes, and allophones. Depending on the application and availability of training data, any of these acoustic events can be modeled individually. Recognition is then achieved by identifying the appropriate sequence of acoustic events.

Acoustic models are created by organizing labeled samples of speech, specifically, spoken speech and its corresponding text, using a training paradigm. Most often, acoustic modeling is attempted via statistical models that are capable of automatically modeling the key distinguishing features of their training data. This ability to "learn" the key features from highly variable input is crucial to the application of statistical models to the speech recognition problem. Of these statistical models, hidden Markov models (HMMs) are the most widely used methodology for acoustic modeling. HMMs possess many interesting properties and are supported by elegant algorithms that allow for their application to the speech recognition problem.

A language model, in contrast, determines valid linguistic constructs and encapsulates the ways in which words are connected to form phrases and sentences. An alternate description of the language model is that it specifies the grammar that the speech recognizer must adhere to when producing a recognition result. Depending on the intended area of application of the speech recognition system, language modeling can be one of two types: rule-based or statistical. Rule-based language models are used when there is a rigid structure to the spoken sentence, such as a credit card number spoken by a person, and are created by writing explicit rules that specify allowable sentences. Statistical language models are used when there is no rigid structure to the spoken utterances, such as in normal conversational speech. Unlike rule-based language models, statistical language models do not explicitly specify all allowable sentences, but assign scores to each sequence or group of words,

proportional to the frequency that a particular sequence or group of words occurs in the training data.

3.1. Feature Extraction

The goal of feature extraction is to translate the raw speech waveform into a set of features that effectively capture the salient aspects of the speech signal and at the same time reduce the effect of variability due to speaker or environment in the final representation. There is a considerable amount of information in the speech signal. Some information, such as the resonances of the vocal tract that correspond to vowel-like sounds in spoken words, is crucial to speech recognition. Other information, such as gender and mood of the speaker or the acoustic environment, provides no useful information for speech recognition.

Information in a speech signal is encapsulated mostly in the energy and in the frequency distribution of that energy. The spectral characteristics of speech change rapidly over time as different words are spoken. To capture these rapid changes in speech over the course of a word or sentence, features must be generated sequentially over the duration of the utterance. Furthermore, features must be generated on sufficiently short time segments so that the spectral characteristics are relatively invariant. Typically, small Fourier analysis algorithms such as the fast Fourier transform (FFT) are used to perform the spectral analysis of the speech segment. Since the analysis is performed on relatively short segments of speech, this mode of analyzing speech is often referred to as *short-time Fourier analysis*.

The source-filter model of speech production provides a convenient parametric model for feature extraction. Parametric modeling reduces the representation of a signal to the estimation of model parameters that, in turn, are likely to form a much more compact representation of the signal. Figure 5 provides a graphical view of a model of human speech production and its source-filter model equivalent. The idea behind the source-filter model is that speech is a result of airflow (source) being shaped by the vocal tract (filter). The type of source excitation controls the realization of different types of speech. For example, voiced speech, which includes sounds with strong periodic structure such as vowels, can be generated with periodic source excitation. Unvoiced speech, which encompasses sounds with little or no periodic structure such as the \s\ in *set*, is generated with white-noise excitation. Further, it is assumed that information is carried primarily by the shape of the vocal tract rather than in the airflow, and that variability in airflow is the primary source of variability among speakers. These simplifying assumptions render the feature extraction problem mathematically tractable and allow the immediate applicability of many techniques from signal processing theory.

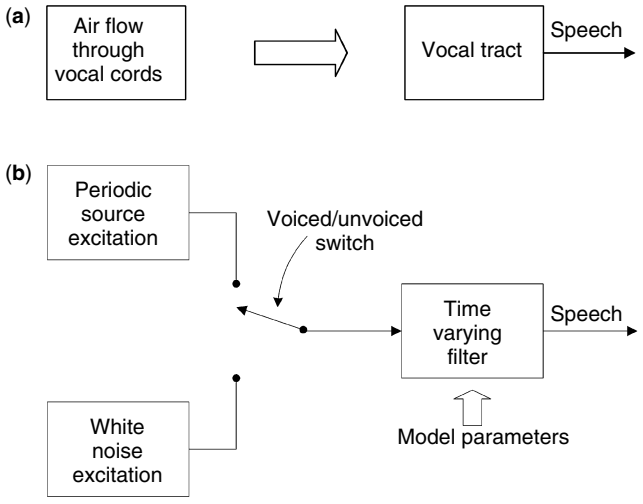

Figure 5. A model of human speech production and its corresponding source-filter model equivalent: (**a**) human speech production; (**b**) speech production model.

Figure 6 illustrates a typical speech feature extraction paradigm. From basic Fourier analysis, given a source-filter model, one can consider the speech spectrum to be the product of the excitation spectrum and the filter spectrum. Furthermore, if one takes the logarithm of the speech spectrum and transforms it back to the time domain (by way of the inverse Fourier transform) one can represent the excitation and vocal tract separately. The result of this inverse transform of the log spectrum is the *cepstrum*. The term *cepstrum* is actually derived from "spectrum" spelled with the first four letters in reverse order as *c-e-p-s*-trum to signify the inversion of the spectrum. Excitation and vocal tract have very different spectral characteristics; excitation is usually located in the higher order terms and the vocal tract in the lower-order terms of the cepstrum. The noninformative excitation can be easily discarded by considering only the lower-order cepstral terms.

This basic paradigm can be further enhanced by incorporating information from psychoacoustic studies. For example, the human auditory system is more sensitive to lower-frequency components than higher-frequency components. The differential emphasis of frequency content can be incorporated into the feature extraction paradigm by warping the frequency scale to compress the higher frequencies relative to the lower frequencies. This allows us to place more emphasis on low-frequency components over high-frequency components. Common

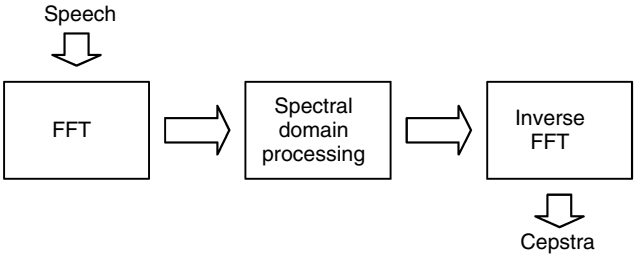

Figure 6. Block diagram of a typical speech feature extraction paradigm. Speech is first transformed into the spectral domain with an FFT algorithm. Various techniques, such as log compression and frequency warping, are used to emphasize or deemphasize characteristics of the speech signal depending on their importance for speech recognition. Finally, the modified spectrum is inverted using an inverse FFT algorithm to yield cepstra. The lower order ceptral terms typically form the speech features used during speech recognition.

warping strategies include mel-scale warping and bark-scale warping, both of which are approximately linear to about 1000 Hz and logarithmic thereafter.

Excellent overviews of the various techniques for speech feature extraction can be found in the literature [1,2].

3.2. Model Training

Speech model training allows us to encapsulate the acoustics of the speech signal and the manner in which words are connected to form phrases and sentences. As mentioned earlier, the acoustics of the speech signal are captured in the acoustic model, and the language and word structure in the language model.

3.2.1. Acoustic Modeling. Acoustic modeling in current speech recognition systems is most commonly based on *hidden Markov models* (HMMs), statistical models that are capable of automatically extracting statistically significant information from available speech data. In HMM theory, the distance or closeness to incoming speech is measured in terms of the probability that the input speech could be generated by that model. This probabilistic approach allows us to absorb the variation in speech features and provides a powerful paradigm for speech recognition.

Often in physical processes, the current state of the process has a significant influence on subsequent events. This concept is embodied in the Markov property, which states that given the current state of the process or system, the future evolution of the system is independent of its past. Models based on the Markov property are called *Markov models*. Figure 7a shows a simple four-state Markov model of weekly weather. Each state in this Markov model is associated with an output symbol indicative of a possible weather observation: hot, cold, windy, or cloudy. These weather observations are called *output symbols* because the Markov model can be regarded as a generative model; it outputs symbols as a transition is made from one state to the other. The arrows connecting the states indicate allowable transitions, and each number on the arcs corresponds to the *transition probability*: the probability of an arc being taken. For example, the self-arc on the "cloudy" state has a probability of 0.6, indicating that if one makes the observation that it was "cloudy" this week, then there will be a 60% chance of making the observation that the weather is still "cloudy" the following week. Note that in the Markov model, the transition from one state to another is probabilistic, but the production of the output symbol is deterministic and known. Also note that at any given instance the current state completely determines the set of all possible states to transition to without regard to how one transitioned into the current state. For example, in the Markov model of Fig. 7a, if the current weekly weather corresponds to the state "hot," next week's weather can only be hot, windy, or cold and this holds true irrespective of whether last week was observed as cloudy, hot, or cold.

As it turns out, this definition of Markov models is too restrictive to be useful in many interesting problems. In this example, it is too restraining to confine the output symbols from any state to correspond to a particular weather observation. Indeed, it is far more meaningful to describe the weekly weather as some combination of the four weather patterns: hot, cloudy, cold, or windy. In *hidden* Markov models (HMMs) the output of each state is associated with an output probability distribution rather than a deterministic and known outcome. In an HMM all output symbols are possible at each state, albeit with differing probabilities. The probabilities associated with each state are known as output probabilities.

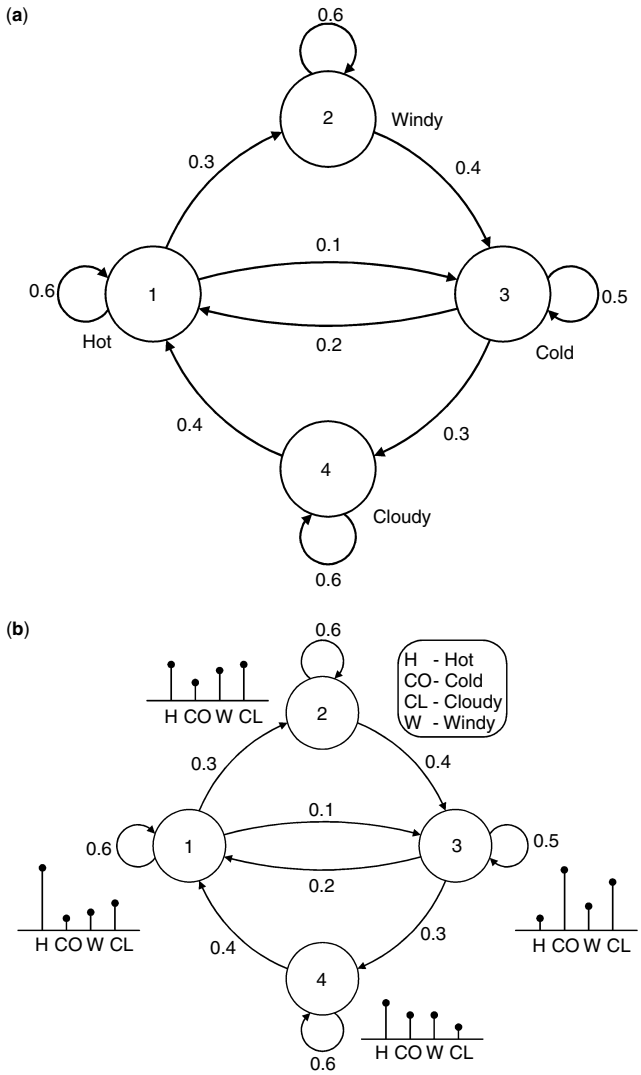

Figure 7. A model of weekly weather patterns. A Markov model of weather is presented in (**a**). A corresponding hidden Markov model (HMM) is presented in (**b**). Note the output probability distributions in the HMM compared to the deterministic single output in the Markov model.

Figure 7b shows the Markov model of Fig. 7a extended to the HMM formulation. The difference is that we now have a probability distribution associated with each state, and when a transition is made into a state, the output symbol is chosen according this probability distribution. Since weather of any type is possible with varying likelihoods in every state, given a sequence of weekly weather readings, the state sequence is unobservable and *hidden*.

The HMM methodology is very well suited for speech recognition and provides a natural and highly reliable way of modeling and recognizing speech. In the case of speech, we can visualize the states as corresponding to functional (or largely unchanging) portions of the word or subword, such as the beginning or end, and the speech features as corresponding to the outputs of the state. HMMs simultaneously model time and feature variability. Time variability is modeled by state-transition probabilities, and feature variability by state output probability distributions. Training the HMM involves estimation of the output state probability distributions and the state-transition probabilities. Figure 8 shows the structure of a typical three-state speech HMM. The structure of a speech HMM has a natural flow of transitions from left to right to indicate the forward time flow of speech. In a typical speech recognition system there is one HMM per phonetic context, to reflect the differing pronunciation of phonemes in different contexts. Although different phonetic contexts could have different structures, the HMM structure is usually kept the same, with HMMs being distinguished from each other by their transition and output probabilities.

Thus far we have referred to neither the language or type of acoustic event that the HMM is modeling. This brings out an important quality of statistical modeling in general, and HMMs in particular: that the HMM is independent of language and type of acoustic event. An HMM does not require any specific changes for language or type of acoustic event.

An HMM can be regarded as a generative model. For example, in Fig. 8, as we enter into state 1, a speech feature is emitted. Based on the transition probabilities out of state 1, a transition can be made back to state 1, 2, or 3, and another speech feature emitted based on the probability distribution corresponding to the state to which the transition was made. This continues until a transition is made out of state 3. At that point, the sequence of emitted speech features corresponds to the phoneme or phonetic context for which the HMM had been constructed.

In a recognition paradigm, the same HMM can be used to solve the reverse problem — given a sequence of speech features, what is the probability that the HMM could have generated this speech feature sequence? In this mode, given a starting speech feature, one can estimate the probability of the feature being generated by the probability distribution of state 1. One can now assume that a transition is made from state 1 to state 2 and estimate the probability that the next speech feature was generated by the probability distribution of state 2. This is continued until the last state is exited. The product of all the encountered output probabilities and transition probabilities gives the probability that this specific state sequence generated the speech feature sequence. For every possible sequence of states, one obtains a different probability value. During recognition, the probability computation is performed for all speech HMMs and all possible state sequences. The state sequence and speech HMM that gives the highest probability is declared to be the recognized phoneme or phonetic context.

Mathematically tractable techniques such as the Baum–Welch reestimation and Viterbi algorithms provide elegant automatic solutions to these problems and have allowed HMMs to be successful in a wide variety of difficult speech recognition applications. In-depth presentations of HMMs and their application to speech recognition can be found in Rabiner and Juang [2] and Huang et al. [3].

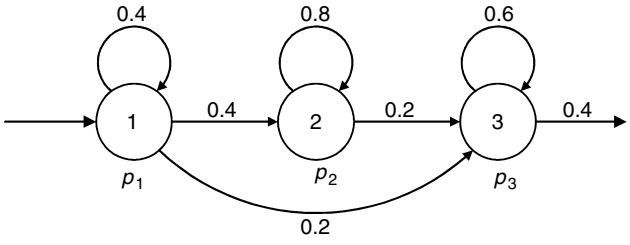

Figure 8. Typical structure of a three-state speech HMM. Numbers on the arcs indicate transition probabilities and p_1, p_2, and p_3 refer to state output probability distributions. HMM training involves the estimation of both the transition and state output probabilities.

3.2.2. Language Modeling. A language model acts as a grammar dictating which word can or cannot follow another word or group of words. Without a language model, every word in the vocabulary of the speech recognition system is equally likely and must be considered at the end of every other word. Language modeling provides a means to limit the vocabulary at each decision point either by eliminating unlikely words or by increasing the probability of more likely words.

There are two approaches to language modeling for speech recognition: rule-based and statistical. *Rule-based language modeling* involves the construction of a set of rules that encompass all allowable sentences. Since the set of rules is explicit and must specify *all* allowable sentences, rule-based language models are primarily used in very restrictive tasks such as IVR systems. A sample rule-based language model for a speech recognition system, used to recognize names for automatic telephone dialing by name, is shown in Fig. 9. Allowable names are John Doe, Jane Smith, Simon Smith, and Mike Phillips with an additional *garbage* name. Since a rule-based grammar completely specifies all the allowable output of the speech recognizer, a valid name is always recognized even when invalid names are spoken. The catchall *garbage* word is often included to prevent the recognition of one of the allowable names when an invalid input is presented to

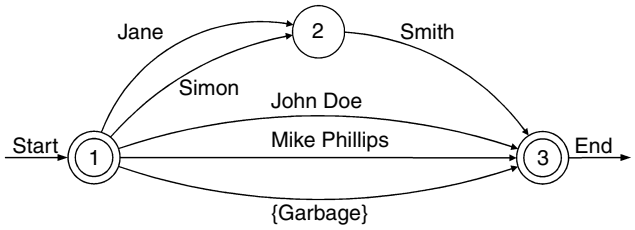

Figure 9. A rule-based language model for recognizing names for an automatic dialing task. The "garbage" name is used to prevent incorrect results with invalid input.

the system. Since rule-based language modeling imposes a rigid structure on the recognized utterance, it provides an excellent means for task automation. In the name-dialer example, the person using the system would be required to say the first and last name in that order. Any valid name can be dialed out simply by looking up the name in the directory. The advantage of rigid structure is also the greatest shortcoming of rule-based language modeling. To describe a speech recognition task of any complexity, it becomes increasingly harder to describe all valid sentences. Consider, for example, designing a rule-based grammar to recognize an interview on television. It would be virtually impossible to describe the myriad ways in which the conversation can even start, let alone proceed.

Statistical language models, on the other hand, are based on probability estimates of the likelihood that one word will follow one or more other words. Because they are estimated directly from training data, statistical models have the advantage of be able to encapsulate the colloquial characteristics of speech in addition to its semantic and syntactic elements. However, statistical language modeling requires a large pool of training data. Without a large training data set, many word sequences are either not observed or are observed far too infrequently to reliably estimate probabilities. Despite this constraint, statistical language models have contributed significantly to improvement in speech recognition system performance, especially in large vocabulary speech recognition tasks, where it is far too complex and virtually impossible to build rule-based language models. A detailed discourse on statistical language modeling can be found Jelinek's treatise [4].

4. CURRENT STATE OF SPEECH RECOGNITION AND FUTURE DIRECTIONS

Automatic speech recognition technology has now advanced to the point where speech recognition systems with vocabularies of a hundred to several thousand words can be robustly deployed in a variety of tasks, ranging from service automation to general consumer applications to the management of spoken information. Table 1 shows the error rates of current high-performance speech recognition systems on various tasks. Observe the increase in error rates as the vocabulary of the speech recognition system and the complexity of the speech increases.

A logical area of deployment has been in the telephony market, where speech is the primary modality for information exchange. Telephony applications include service automation, an early example of which is the automation of operator services with *yes*/*no* responses in the collect call prompt: "You have a collect call from . . ., to accept this call press one or say yes". A telephony application rapidly now gaining popularity is voice dialing. Today, many vendors offer the ability to dial numbers via simple voice commands such as "call home."

Consumer applications of speech recognition have been primarily in the dictation and computer command and control arenas, allowing users to dictate for a variety of word processing tasks or to perform basic computer commands such as "open file" or "close file." Some popular products aimed for the general consumer include Dragon Systems' Dragon NaturallySpeaking, IBM's ViaVoice, and L&H's Voice Xpress.

A relatively new area of application of speech recognition technology has been in the management of spoken information. The conversion of spoken information into textual form allows rapid access to information which would otherwise require the arduous task of listening to large archives of spoken material. An example of an application providing this ability is BBN's Rough 'n' Ready (RnR) audio indexer system [5]. The RnR system is capable of real-time speech recognition of broadcast news, and provides information extraction and indexing coupled with a Web-enabled interface allowing for rapid retrieval of spoken information in a computer accessible form.

Although speech recognition by machine is increasingly used in popular applications, significant issues remain. The translation of speech recognition technology from the laboratory into the "real world" is still fraught with problems. Fielded systems typically show higher error rates than systems evaluated in the laboratory, due mostly to the lack of control over the working environment. To address this vulnerability, current speech recognition systems are normally trained on large amounts of real-world training data. This ensures that, when fielded outside the laboratory, the speech recognition system can handle the unconstrained environment of the real world. Typical real-world training data include recordings of broadcast news such as from CNN or NPR (National Public Radio), and recordings, taken with participants' consent, of telephone conversations between friends and family. Broadcast news recordings include the accompanying commercials, background music, and noise. On the other hand, telephone conversation between family and friends is typical of normal conversational speech with the attendant disfluencies. State-of-the-art speech recognition systems have an average word error rate of close to 10% on broadcast speech, and close to 30% on conversational speech, with vocabularies of up to 65,000 words [6,7].

Table 1. Error Rates of High-Performance Speech Recognition Systems in 2001

Task	Type of Speech (complexity)	Vocabulary Size (Words)	Word Error Rate (%)
Connected digits	Read	10	< 0.3
Automated travel agent	Spontaneous	2,500	< 2
Broadcast news	Read and spontaneous (mixed)	64,000	15
Telephone conversations	Spontaneous and conversational	45,000	35

While the use of real-world training data has enhanced the usefulness of speech technology in everyday applications, significant barriers remain to the seamless integration of speech technology in day-to-day environments. Some issues currently being addressed in speech recognition research laboratories to improve the practical use of speech technology are presented below.

4.1. Speaker and Environmental Adaptation and Robustness

Current speech recognition is often handicapped by the fact that it typically does not run "out of the box." Noise in the environment is a common reason for the failure of speech recognition systems. In some cases, even using a different microphone to capture the speech signal can significantly change the properties of the resultant speech features, with consequent loss in system performance [8]. Speaker and environment adaptation allow an existing speech recognition system to handle new speakers and environment without substantial change in performance. Adaptation can be performed in two different paradigms: supervised, where the system is adapted based on enrollment data, or unsupervised, where the system adapts automatically without any specific input to the system beyond that spoken for the purpose of recognition.

4.2. Conversational Speech

In normal spontaneous spoken conversation, there is a significant amount of disfluency such as hesitations and false starts. In addition, conversational speech commonly suffers from the lack of clear articulation as well as other speaker maladies such as highly variable speaking rate or increased emotional emphasis. These factors combine to cause significant problems for accurate speech recognition. It would not be unusual to see a doubling in error rates by moving from broadcast news to conversational speech recognition task with all other factors remaining the same.

4.3. Speed Versus Accuracy

Another issue with state-of-art speech recognition systems is the large amount of time needed to provide the most accurate recognition result or transcript. Speech recognition systems often need to be tuned to run in real time by sacrificing performance. This is slowly changing due to the ever-increasing speed of computers as well as due to algorithmic improvements. Nevertheless, significant work still needs to be done to allow for real-time speech recognition without losing accuracy.

4.4. Language and Task Independence

Most speech recognition systems are built for specific languages and, more often than not, specific tasks within those languages. This artifact of the specificity of the training that goes into the system invariably requires retraining the system if the language or task changes. The idea behind language and task independence is to lessen the effect of specificity by either generalization of the system or by developing the system's capability to automatically acquire new language or task skills.

4.5. Understanding

After speech recognition, understanding speech is the next frontier in human–machine interaction. Give a system capable of consistently accurate speech recognition, the next logical step would be to use this ability to extract the meaning of the spoken words and provide the appropriate response.

5. CONCLUSION

Speech recognition is perhaps one of a handful of technologies that have the potential to fundamentally change the way we interact with machines. The science of speech recognition continues to develop, and as it does, so will its impact on our lives. Even now, simple applications such as voice dialing for mobile phones or voice controllable car radios are making everyday tasks both safe and convenient. In the future, these and other emerging applications will surely change the nature of human–machine interaction and be responsible for many new and exciting changes to the ways we work and live.

BIOGRAPHY

Jayadev Billa received the B.E. degree in electronics and communication engineering in 1991 from Osmania University, Hyderabad, India, and M.S. and Ph.D. degrees in electrical engineering from the University of Pittsburgh, Pennsylvania, in 1993 and 1997, respectively. He joined the BBN Technologies, Cambridge, Massachusetts, in 1996 where he is now a senior scientist. At BBN he works on the design and development of large vocabulary speech recognition system in a variety of languages. His areas of interest are speech feature extraction and acoustic modeling for speech recognition.

SPREAD SPECTRUM SIGNALS FOR DIGITAL COMMUNICATIONS

JOHN G. PROAKIS
Northeastern University
Boston, Massachusetts

1. INTRODUCTION

Spread spectrum signals is a class of signals that were designed primarily for use in digital communication systems to overcome either intentional or unintentional interference. Such signals were originally used in military communication systems either to provide resistance to jamming or to hide the signal by transmitting it at low power and, thus, making it difficult for an unintended listener to detect its presence in noise (low probability of intercept). However, today, spread spectrum signals are used to provide reliable communications in a variety of commercial applications. For example, spread spectrum signals are used in the so-called unlicensed frequency bands, such as the Industry, Scientific, and Medical (ISM) band at 2.4 GHz. Typical applications in the ISM band are cordless telephones, wireless LANs, and cable replacement systems such as Bluetooth. Since the band is unlicensed, there is no central control over the radio resources, and the systems have to function even in the presence of severe interference from other communication systems and other electrical and electronic equipment (e.g., microwave ovens, radars, etc.). Here the interference is not intentional, but the interference may nevertheless be enough to disrupt the communication for non–spread spectrum systems.

Code-division multiple access systems (CDMA systems) use spread spectrum techniques to provide communication to several concurrent users. CDMA is used in one second generation (IS-95) and several third generation wireless cellular systems (e.g., cdma2000 and WCDMA). One advantage of using interference-resistant signals in these applications is that the radio resource management (primarily the channel allocation to the active users) is significantly reduced.

The name spread spectrum stems from the fact that the transmitted signals occupy a much wider frequency band than is required to transmit the information. There are many different ways to spread the bandwidth of the information-bearing signal. The most common ones are called direct-sequence (DS) and frequency-hopping (FH) spread spectrum (SS). In DS-SS, the information-bearing signal is spread over the entire channel bandwidth in a manner that appears random. In a FH-SS, the transmitter changes the carrier frequency of the relatively narrowband information-bearing signal in a fashion that appears random. At any given time, only a small fraction of the available channel bandwidth is used and exactly which fraction used is known only to the intended receiver. A hybrid of DS and FH spread spectrum is also possible. Several other methods are available for spreading the bandwidth of the information-bearing signals; however, the clear majority of the implemented systems are either DS or FH or a hybrid of DS/FH.

The literature in the field of spread spectrum communications is quite voluminous and ranges from text books to specialized conference and journal papers. For an interesting review of the history of the development of spread spectrum, we recommend the papers [1–3]. Among the available books, we would like to especially mention the text by Simon, Omura, Scholtz, and Levitt [4] which covers quite a lot of the classical spread spectrum techniques. The books by Ziemer, Peterson, and Borth [5] and by Dixon [6], which cover more of the current commercial applications, are also recommended. The reference lists of the above mentioned books contain several thousand entries. Among the tutorial-style papers that are available in the literature, we would like to especially mention the 1982 paper by Pickholtz, Schilling, and Milstein [7].

2. MODEL OF A SPREAD SPECTRUM DIGITAL COMMUNICATION SYSTEM

The basic elements of a spread spectrum digital communication system are illustrated in Fig. 1. We observe that the channel encoder and decoder and the modulator and demodulator are the basic elements of a conventional digital communication system. In addition to these elements, a spread-spectrum system employs two identical pseudorandom sequence generators, one which interfaces with the modulator at the transmitting end and the second which interfaces with the demodulator at the receiving end. These two generators produce a pseudorandom or pseudonoise (PN) binary-valued sequence, which is used to spread the transmitted signal at the modulator and to despread the received signal at the demodulator.

Time synchronization of the PN sequence generated at the receiver with the PN sequence contained in the received signal is required to properly despread the received spread-spectrum signal. In a practical system, synchronization is established prior to the transmission

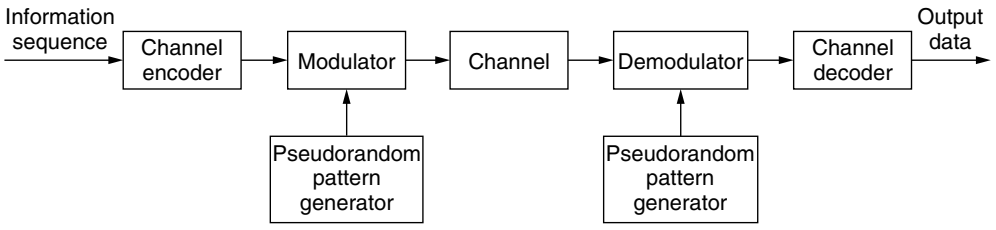

Figure 1. Model of spread-spectrum digital communications system.

of information by transmitting a fixed PN bit pattern which is designed so that the receiver will detect it with high probability in the presence of interference. After time synchronization of the PN sequence generators is established, the transmission of information commences. In the data mode, the communication system usually tracks the timing of the incoming received signal and keeps the PN sequence generator in synchronism. The synchronization of spread spectrum signals is treated in Refs. 4 and 7 and in the article by Luise et al. [8] in this encyclopedia.

Interference is introduced in the transmission of the spread-spectrum signal through the channel. The characteristics of the interference depend to a large extend on its origin. The interference may be generally categorized as being either broadband or narrowband (partial band) relative to the bandwidth of the information-bearing signal, and either continuous in time or pulsed (discontinuous) in time. For example, an interfering signal may consist of a high-power sinusoid in the bandwidth occupied by the information-bearing signal. Such a signal is narrowband. As a second example, the interference generated by other users in a multiple-access channel depends on the type of spread-spectrum signals that are employed by the various users to transmit their information. If all users employ broadband signals, the interference may be characterized as an equivalent broadband noise. If the users employ frequency hopping to generate spread-spectrum signals, the interference from other users may be characterized as narrowband or partial band.

Our discussion will focus on the performance of spread-spectrum signals for digital communication in the presence of narrowband and broadband interference. Two types of digital modulation are considered, namely, PSK and FSK. PSK modulation is appropriate for applications where phase coherence between the transmitted signal and the received signal can be maintained over a time interval that spans several symbol (or bit) intervals. This is usually the case in DS-SS, where a single carrier frequency is modulated by the spread spectrum signal that covers the entire channel bandwidth. On the other hand, FSK modulation with noncoherent detection is appropriate in applications where phase coherence of the carrier cannot be accurately estimated. This is usually the case in FH-SS, where the carrier frequency is hopped rapidly, typically at the transmitted symbol (or bit) rate. In such a case, the relatively short time interval spanned by a single symbol (or bit) is not sufficient to obtain an accurate estimate of the carrier phase.

The PN sequence generated at the modulator is used in conjunction with the PSK modulation to shift the phase of the PSK signal pseudorandomly, as described below at a rate that is an integer multiple of the bit rate. The resulting modulated signal is called a *direct-sequence* (*DS*) *spread-spectrum signal*. When used in conjunction with binary or M-ary ($M > 2$) FSK, the PN sequence is used to select the carrier frequency of the transmitted signal pseudorandomly. The resulting signal is called a *frequency-hopped* (*FH*) *spread-spectrum signal*.

3. DIRECT-SEQUENCE SPREAD-SPECTRUM SYSTEMS

Let us consider the transmission of a binary information sequence by means of binary PSK. The information rate is R bits/sec and the bit interval is $T_b = 1/R$ sec. The available channel bandwidth is W Hz, where $W \gg R$. At the modulator, the bandwidth of the information signal is expanded to W Hz by shifting the phase of the carrier pseudorandomly at a rate of W times/sec according to the pattern of the PN generator. The basic method for accomplishing the spreading is shown in Fig. 2.

The information-bearing baseband signal is denoted as $v(t)$ and is expressed as

$$v(t) = \sum_{n=-\infty}^{\infty} a_n g_T(t - nT_b) \tag{1}$$

where $\{a_n = \pm 1, -\infty < n < \infty\}$ and $g_T(t)$ is a rectangular pulse of duration T_b. This signal is multiplied by the signal from the PN sequence generator, which may be expressed as

$$c(t) = \sum_{n=-\infty}^{\infty} c_n p(t - nT_c) \tag{2}$$

where $\{c_n\}$ represents the binary PN code sequence of ± 1's and $p(t)$ is a rectangular pulse of duration T_c, as illustrated in Fig. 2. This multiplication operation serves to spread the bandwidth of the information-bearing signal (whose bandwidth is R hz, approximately) into the wider bandwidth occupied by PN generator signal $c(t)$

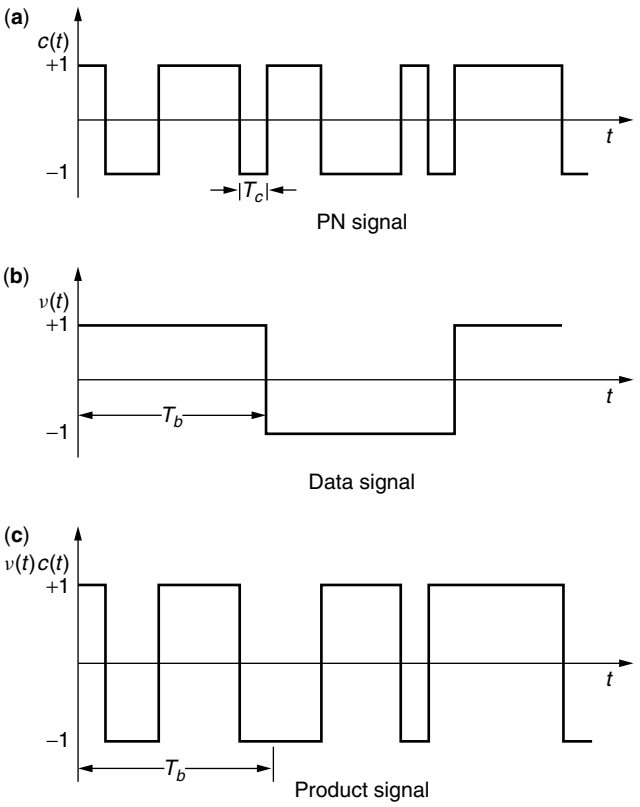

Figure 2. Generation of a DS spread-spectrum signal.

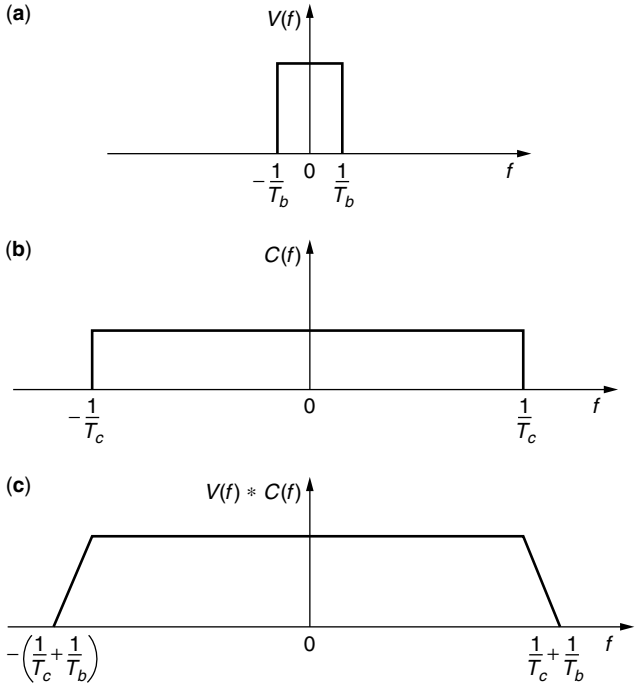

Figure 3. Convolution of spectra of the (**a**) data signal with the (**b**) PN code signal.

(whose bandwidth is $1/T_c$, approximately). The spectrum spreading is illustrated in Fig. 3, which shows, in simple terms, using rectangular spectra, the convolution of the two spectra, the narrow spectrum corresponding to the information-bearing signal and the wide spectrum corresponding to the signal from the PN generator.

The product signal $\upsilon(t)c(t)$, also illustrated in Fig. 2, is used to amplitude modulate the carrier $A_c \cos 2\pi f_c t$ and, thus, to generate the double-sideband, suppressed carrier (DSB-SC) signal

$$u(t) = A_c \upsilon(t) c(t) \cos 2\pi f_c t \tag{3}$$

Since $\upsilon(t)c(t) = \pm 1$ for any t, it follows that the carrier-modulated transmitted signal may also be expressed as

$$u(t) = A_c \cos[2\pi f_c t + \theta(t)] \tag{4}$$

where $\theta(t) = 0$ when $\upsilon(t)c(t) = 1$ and $\theta(t) = \pi$ when $\upsilon(t)c(t) = -1$. Therefore, the transmitted signal is a binary PSK signal.

The rectangular pulse $p(t)$ is usually called a *chip* and its time duration T_c is called the *chip interval*. The reciprocal $1/T_c$ is called the *chip rate* and corresponds (approximately) to the bandwidth W of the transmitted signal. The ratio of the bit interval T_b to the chip interval T_c usually is selected to be an integer in practical spread spectrum systems. We denote this ratio as

$$L_c = \frac{T_b}{T_c} \tag{5}$$

Hence, L_c is the number of chips of the PN code sequence/information bit. Another interpretation is that L_c represents the number of possible 180° phase transitions in the transmitted signal during the bit interval T_b.

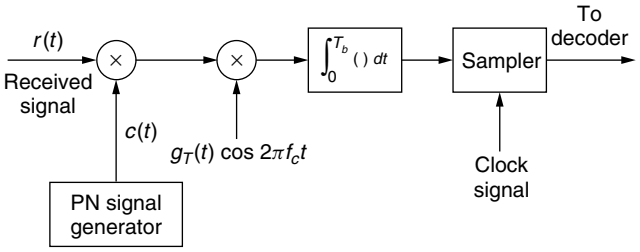

Figure 4. Demodulation of DS spread spectrum signal.

The demodulation of the signal is performed as illustrated in Fig. 4. The received signal is first multiplied by a replica of the waveform $c(t)$ generated by the PN code sequence generator at the receiver, which is synchronized to the PN code in the received signal. This operation is called (spectrum) despreading, since the effect of multiplication by $c(t)$ at the receiver is to undo the spreading operation at the transmitter. Thus, we have

$$A_c \upsilon(t) c^2(t) \cos 2\pi f_c t = A_c \upsilon(t) \cos 2\pi f_c t \tag{6}$$

since $c^2(t) = 1$ for all t. The resulting signal $A_c \upsilon(t) \cos 2\pi f_c t$ occupies a bandwidth (approximately) of R hz, which is the bandwidth of the information-bearing signal. Therefore, the demodulator for the despread signal is simply the conventional cross correlator or matched filter. Since the demodulator has a bandwidth that is identical to the bandwidth of the despread signal, the only additive noise that corrupts the signal at the demodulator is the noise that falls within the information-bandwidth of the received signal.

3.1. Effect of Despreading on a Narrowband Interference

It is interesting to investigate the effect of an interfering signal on the demodulation of the desired information-bearing signal. Suppose that the received signal is

$$r(t) = A_c \upsilon(t) c(t) \cos 2\pi f_c t + i(t) \tag{7}$$

where $i(t)$ denotes the interference. The despreading operation at the receiver yields

$$r(t)c(t) = A_c \upsilon(t) \cos 2\pi f_c t + i(t)c(t) \tag{8}$$

The effect of multiplying the interference $i(t)$ with $c(t)$, is to spread the bandwidth of $i(t)$ to W HZ.

As an example, let us consider a sinusoidal interfering signal of the form

$$i(t) = A_I \cos 2\pi f_I t \tag{9}$$

where f_I is a frequency within the bandwidth of the transmitted signal. Its multiplication with $c(t)$ results in a wideband interference with power-spectral density $I_0 = P_I/W$, where $P_I = A_I^2/2$ is the average power of the interference. Since the desired signal is demodulated by a matched filter (or correlator) that has a bandwidth R,

the total power in the interference at the output of the demodulator is

$$I_0 R_b = P_I R_b / W = \frac{P_I}{W/R_b} = \frac{P_I}{T_b/T_c} = \frac{P_I}{L_c} \tag{10}$$

Therefore, the power in the interfering signal is reduced by an amount equal to the bandwidth expansion factor W/R. The factor $W/R = T_b/T_c = L_c$ is called the *processing gain* of the spread-spectrum system. The reduction in interference power is the basic reason for using spread-spectrum signals to transmit digital information over channels with interference.

In summary, the PN code sequence is used at the transmitter to spread the information-bearing signal into a wide bandwidth for transmission over the channel. By multiplying the received signal with a synchronized replica of the PN code signal, the desired signal is despread back to a narrow bandwidth while any interference signals are spread over a wide bandwidth. The net effect is a reduction in the interference power by the factor W/R, which is the processing gain of the spread-spectrum system.

The PN code sequence $\{c_n\}$ is assumed to be known only to the intended receiver. Any other receiver that does not have knowledge of the PN code sequence cannot demodulate the signal. Consequently, the use of a PN code sequence provides a degree of privacy (or security) that is not possible to achieve with conventional modulation. The primary cost for this security and performance gain against interference is an increase in channel bandwidth utilization and in the complexity of the communication system.

3.2. Probability of Error

In this section we derive the probability of error for a DS spread spectrum system assuming that the information is transmitted via binary PSK. Within the bit interval $0 \le t \le T_b$, the transmitted signal is

$$s(t) = a_0 g_T(t) c(t) \cos 2\pi f_c t, \quad 0 \le t \le T_b \tag{11}$$

where $a_0 = \pm 1$ is the information symbol, the pulse $g_T(t)$ is defined as

$$g_T(t) = \begin{cases} \sqrt{\dfrac{2\mathcal{E}_b}{T_b}}, & 0 \le 1 \le T_b \\ 0, & \text{otherwise} \end{cases} \tag{12}$$

and $c(t)$ is the output of the PN code generator which, over a bit interval, is expressed as

$$c(t) = \sum_{n=0}^{L_c - 1} c_n p(t - nT_c) \tag{13}$$

where L_c is the number of chips per bit, T_c is the chip interval, and $\{c_n\}$ denotes the PN code sequence. The PN code chip sequence $\{c_n\}$ is designed to be uncorrelated (white); that is,

$$E(c_n c_m) = E(c_n) E(c_m) \text{ for } n \ne m \tag{14}$$

and each chip is $+1$ or -1 with equal probability. These conditions imply that $E(c_n) = 0$ and $E\left(c_n^2\right) = 1$.

The received signal is assumed to be corrupted by an additive interfering signal $i(t)$. Hence,

$$r(t) = a_0 g_T(t) c(t) \cos(2\pi f_c t + \phi) + i(t) \tag{15}$$

where ϕ represents the carrier phase shift. Since the received signal $r(t)$ is typically the output of an ideal bandpass filter in the front end of the receiver, the interference $i(t)$ is also a bandpass signal, and may be represented as

$$i(t) = i_c(t) \cos 2\pi f_c t - i_s(t) \sin 2\pi f_c t \tag{16}$$

where $i_c(t)$ and $i_s(t)$ are the two quadrature components of $i(t)$.

We assume that the receiver is perfectly synchronized to the received signal and the carrier phase is perfectly estimated by a PLL. Then, the signal $r(t)$ is demodulated by first despreading through multiplication by $c(t)$ and then crosscorrelation with $g_T(t) \cos(2\pi f_c t + \phi)$, as shown in Fig. 5. At the sampling instant $t = T_b$, the output of the correlator is

$$y(T_b) = \mathcal{E}_b + y_i(T_b) \tag{17}$$

where $y_i(T_b)$ represents the interference component, which has the form

$$\begin{aligned} y_i(T_b) &= \int_0^{Tb} c(t) i(t) g_T(t) \cos(2\pi f_c t + \phi)\, dt \\ &= \sum_{n=0}^{L_c - 1} c_n \int_0^{Tb} p(t - nT_c) i(t) g_T(t) \cos(2\pi f_c t + \phi)\, dt \\ &= \sqrt{\frac{2\mathcal{E}_b}{T_b}} \sum_{n=0}^{L_c - 1} c_n v_n \end{aligned} \tag{18}$$

where, by definition,

$$v_n = \int_{nT_c}^{(n+1)T_c} i(t) \cos(2\pi f_c t + \phi)\, dt \tag{19}$$

The probability of error depends on the statistical characteristics of the interference component. Its mean value is

$$E[y_i(T_b)] = 0 \tag{20}$$

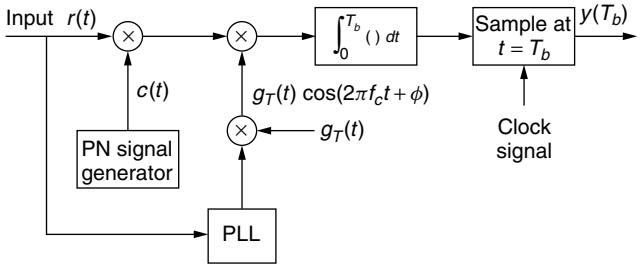

Figure 5. DS spread-spectrum signal demodulator.

Its variance is

$$E[y_i^2(T_b)] = \frac{2\mathcal{E}_b}{T_b} \sum_{n=0}^{Lc-1} \sum_{m=0}^{Lc-1} E(c_n c_m) E(v_n v_m)$$

But $E(c_n c_m) = \delta_{mn}$. Therefore,

$$E[y_i^2(Tb)] = \frac{2\mathcal{E}_b}{T_b} \sum_{n=0}^{L_c-1} E\left(v_n^2\right) = \frac{2\mathcal{E}_b}{T_b} L_c E\left(v^2\right) \tag{21}$$

where $v = v_n$, as given by Eq. (9).

Consider for sinusoidal interfering signal at the carrier frequency, that is,

$$i(t) = \sqrt{2P_I}\cos(2\pi f_c t + \Theta_I) \tag{22}$$

where P_I is the average power and Θ_I is the phase of the interference, which is random and uniformly distributed over the interval $(0, 2\pi)$. If we substitute for $i(t)$ in Eq. (19), it is easy to show that

$$E(v^2) = \frac{T_c^2 P_I}{4} \tag{23}$$

and, therefore,

$$E[y_i^2(T_b)] = \frac{\mathcal{E}_b P_I T_c}{2} \tag{24}$$

The ratio of $\{E[y(T_b)]\}^2$ to $E[y_i^2(T_b)]$ is the SNR at the detector. In this case we have

$$(\text{SNR})_D = \frac{\mathcal{E}_b^2}{\mathcal{E}_b P_I T_c/2} = \frac{2\mathcal{E}_b}{P_I T_c} \tag{25}$$

To see the effect of the spread-spectrum signal, we express the transmitted energy $\mathcal{E}_b$ as

$$\mathcal{E}_b = P_S T_b \tag{26}$$

where P_S is the average signal power. Then, if we substitute for $\mathcal{E}_b$ in Eq. (25) we obtain

$$(\text{SNR})_D = \frac{2P_S T_b}{P_I T_c} = \frac{2P_S}{P_I/L_c} \tag{27}$$

where $L_c = T_b/T_c$ is the processing gain. Therefore, the spread-spectrum signal has reduced the power of the interference by the factor L_c.

Another interpretation of the effect of the spread-spectrum signal on the sinusoidal interference is obtained if we express $P_I T_c$ in Eq. (27) as follows. Since $T_c \simeq 1/W$, we have

$$P_I T_c = P_I/W = I_0 \tag{28}$$

where I_0 is the power-spectral density of an equivalent interference in a bandwidth W. Therefore, in effect, the spread-spectrum signal has spread the sinusoidal interference over the wide bandwidth W, creating an equivalent spectrally flat noise with power-spectral density I_0. Hence,

$$(\text{SNR})_D = \frac{2\mathcal{E}_b}{I_0} \tag{29}$$

The probability of error for a DS spread-spectrum system with binary PSK modulation is easily obtained from the SNR at the detector, if we make an assumption on the probability distribution of the sample $y_i(T_b)$. From Eq. (18) we note that $y_i(T_b)$ consists of a sum of L_c uncorrelated random variables $\{c_n v_n, 0 \le n \le L_c - 1\}$, all of which are identically distributed. Since the processing gain L_c is usually large in any practical system, we may use the Central Limit Theorem to justify a Gaussian probability distribution for $y_i(T)$. Under this assumption, the probability of error is

$$P_b = Q\left(\sqrt{\frac{2\mathcal{E}_b}{I_0}}\right) \tag{30}$$

where I_0 is the power-spectral density of an equivalent broadband interference and $Q(x)$ is defined as

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-t^2/2}\, dt \tag{31}$$

Hence, the effect of the interference on the error probability is equivalent to that of broadband white Gaussian noise with spectral density I_0.

3.3. The Interference Margin

We may express $\dfrac{\mathcal{E}_b}{I_0}$ in the Q-function in Eq. (30) as

$$\frac{\mathcal{E}_b}{I_0} = \frac{P_S T_b}{P_I/W} = \frac{P_S/R}{P_I/W} = \frac{W/R}{P_I/P_S} \tag{32}$$

Also, suppose we specify a required E_b/I_0 to achieve a desired level of performance. Then, using a logarithmic scale, we may express Eq. (32) as

$$10\log\frac{P_I}{P_S} = 10\log\frac{W}{R} - 10\log\frac{\mathcal{E}_b}{I_0}$$
$$\left(\frac{P_I}{P_S}\right)_{\text{dB}} = \left(\frac{W}{R}\right)_{\text{dB}} - \left(\frac{\mathcal{E}_b}{I_0}\right)_{\text{dB}} \tag{33}$$

The ratio $(P_I/P_S)_{\text{dB}}$ is called the *interference margin*. This is the relative power advantage than an interference may have without disrupting the communication system.

For example, suppose we require an $(\mathcal{E}_b/I_0))_{\text{dB}} = 10$ dB to achieve reliable communication. What is the processing gain that is necessary to provide an interference margin of 20 dB? Clearly, if $W/R = 1000$, then $(W/R)_{\text{dB}} = 30$ dB and the interference margin is $(P_I/P_S)_{\text{dB}} = 20$ dB. This means that the average interference power at the receiver may be 100 times the power P_S of the desired signal and we can still maintain reliable communication.

3.4. Performance of Coded Spread-Spectrum Signals

It is shown in many textbooks on digital communications (for reference, see [9], Chapter 8), that when the transmitted information is coded by a binary linear (block or convolutional) code, the SNR at the output of a soft-decision decoder in the presence of spectrally flat Gaussian interference is increased by the coding gain, defined as

$$\text{coding gain} = R_c d_{\min}^H \tag{34}$$

where R_c is the code rate and $d_{\min}^H$ is the minimum Hamming distance of the code. Therefore, the effect of coding is to increase the interference margin by the coding gain. Thus, Eq. (33) may be modified as

$$\left(\frac{P_I}{P_S}\right)_{\text{dB}} = \left(\frac{W}{R}\right)_{\text{dB}} + (CG)_{\text{dB}} - \left(\frac{\mathcal{E}_b}{I_0}\right)_{\text{dB}} \tag{35}$$

where $(CG)_{\text{dB}}$ denotes the coding gain. Typical coding gains obtained by use of binary block or convolutional codes are in the range of 4 to 7 dB.

3.5. Pulsed Interference

A very damaging type of interference for DS-SS is broadband pulsed noise, whose power is spread over the entire system bandwidth W. The pulsed interference is transmitted for a fraction ρ of the time, that is, ρ is the duty cycle of the transmitted interference, where $0 < \rho \leq 1$. If this signal is being transmitted by a jammer, this allows the jammer to transmit pulses with a power level P_I/ρ for ρ percent of the time, with an equivalent spectral density of $I_0 = P_I/W$, where P_I is the average transmitted power. For simplicity, let us assume that the interference pulse spans an integer number of symbols (or bits) and that the pulsed noise is Gaussian distributed. When the interferer is not transmitting, the received information bits are assumed to be error-free, and when the interferer is transmitting, the probability of error for an uncoded DS-SS system is

$$P(\rho) = \rho Q\left(\sqrt{\frac{2\mathcal{E}_b}{I_0}\rho}\right) \tag{36}$$

The worst case duty cycle that maximizes the probability of error for the communication system can be found by differentiating $P(\rho)$ with respect to ρ. Thus, we find that the worst-case pulsed noise occurs when

$$\rho^* = \begin{cases} \dfrac{0.71}{\mathcal{E}_b/I_0}, & \dfrac{\mathcal{E}_b}{I_0} \geq 0.71 \\ 1, & \dfrac{\mathcal{E}_b}{I_0} < 0.71 \end{cases} \tag{37}$$

and the corresponding probability of error is

$$P(\rho^*) = \begin{cases} \dfrac{0.082}{\mathcal{E}_b/I_0} = \dfrac{0.082 P_I/P_S}{W/R}, & \dfrac{\mathcal{E}_b}{I_0} \geq 0.71 \\ Q\left(\sqrt{\dfrac{2\mathcal{E}_b}{I_0}}\right) = Q\left(\sqrt{\dfrac{2W/R}{P_I/P_S}}\right), & \dfrac{\mathcal{E}_b}{I_0} < 0.71 \end{cases} \tag{38}$$

The error rate performance given by Eq. (38) for $\rho = 1.0, 0.1$, 0.01, and 0.001 along with the worst-case performance based on ρ^* is plotted in Fig. 6. When we compare the error rate for continuous wideband Gaussian noise interference ($\rho = 1$) with worst-case pulse interference, we find a large difference in performance; for example, approximately 40 dB at an error rate of 10^{-6}. This is, indeed, a large penalty.

If we simply add coding to the DS spread-spectrum system, the performance in SNR is improved by an amount equal to the coding gain, which in most cases is limited to less than 10 dB. The reason that the addition of coding does not improve the performance significantly is that the interfering signal pulse duration (duty cycle) may be selected to affect many consecutive coded bits. Consequently, the code word error probability is high due to the burst characteristics of the interference.

In order to improve the performance of the coded DS spread-spectrum system, we should interleave the coded bits prior to transmission over the channel. The effect of interleaving is to make the coded bits that are affected by the interferer statistically independent. Figure 7 illustrates a block diagram of a DS spread-spectrum system that employs coding and interleaving. By selecting a sufficiently long interleaver so that the burst characteristics of the interference are eliminated, the penalty in performance due to pulse interference is significantly reduced; for example, to the range of 3–5 dB for conventional binary block or convolutional codes (for reference, see [9], Chapter 13).

4. FREQUENCY-HOPPED SPREAD SPECTRUM

In frequency-hopped (FH) spread spectrum, the available channel bandwidth W is subdivided into a large number of nonoverlapping frequency slots. In any signaling interval the transmitted signal occupies one or more of the available frequency slots. The selection of the frequency slot (s) in each signal interval is made pseudorandomly according to the output from a PN generator.

A block diagram of the transmitter and receiver for an FH spread-spectrum system is shown in Fig. 8. The modulation is either binary or M-ary FSK (MFSK). For example, if binary FSK is employed, the modulator selects one of two frequencies say f_0 or f_1, corresponding to the transmission of a 0 for a 1. The resulting binary FSK signal is translated in frequency by an amount that is determined by the output sequence from a PN generator, which is used to select a frequency f_c that is synthesized by the frequency synthesizer. This frequency is mixed with the output of the FSK modulator and the resultant frequency-translated signal is transmitted over the channel. For example, by taking m bits from the PN generator, we may specify $2^m - 1$ possible carrier frequencies. Figure 9 illustrates an FH signal pattern.

At the receiver, there is an identical PN sequences generator synchronized with the received signal, which is used to control the output of the frequency synthesizer. Thus, the pseudorandom frequency translation introduced at the transmitter is removed at the demodulator by mixing the synthesizer output with the received signal.

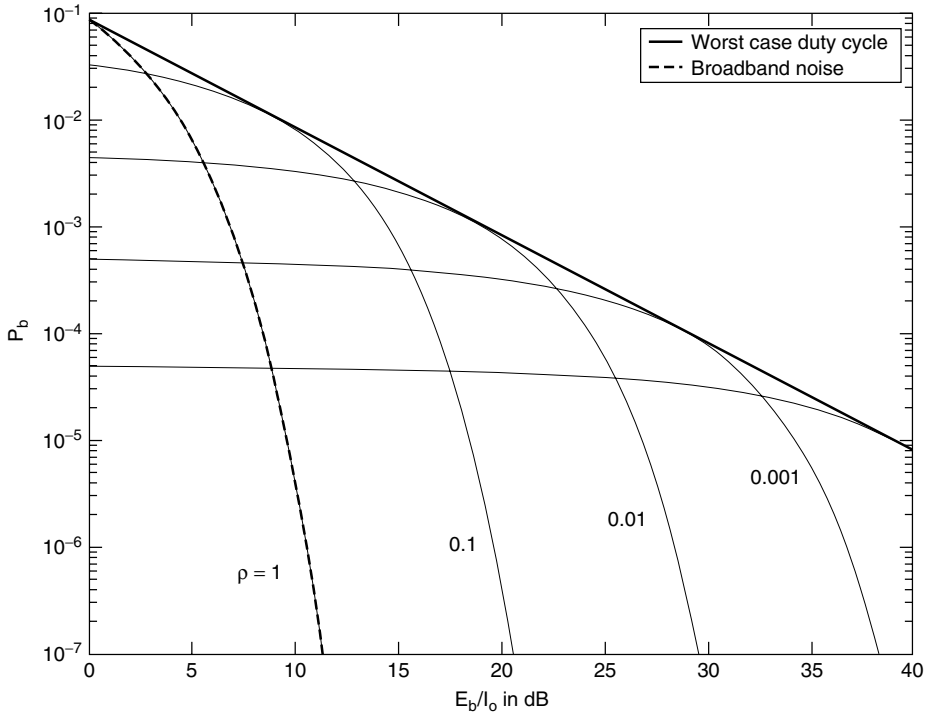

Figure 6. Bit error probability for BPSK modulated DS spread spectrum with pulsed interference having a duty cycle P.

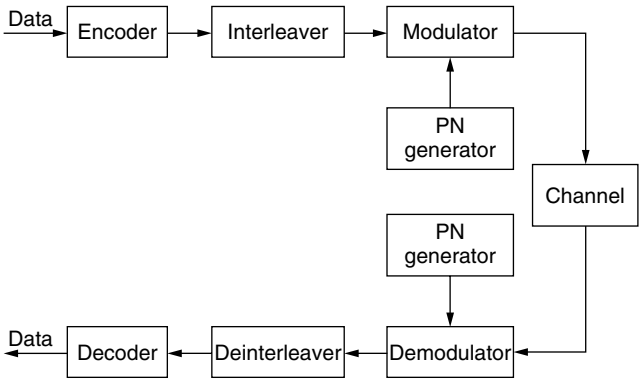

Figure 7. Black diagram of communication system with coding and interleaving.

The resultant signal is then demodulated by means of an FSK demodulator. A signal for maintaining synchronism of the PN sequence generator with the FH received signal is usually extracted from the received signal.

Although binary PSK modulation generally yields better performance than binary FSK, it is difficult to maintain phase coherence in the synthesis of the frequencies used in the hopping pattern and, also, in the propagation of the signal over the channel as the signal is hopped from one frequency to the another over a wide bandwidth. Consequently, FSK modulation with noncoherent demodulation is usually employed in FH spread-spectrum systems.

The frequency-hopping rate, denoted as R_h, may be selected to be either equal to the symbol rate, or lower than the symbol rate, or higher than the symbol rate. If R_h is equal to or lower than the symbol rate, the FH system is called a slow-hopping system. If R_h is higher than the symbol rate; that is, there are multiple hops/symbols, the FH system is called a fast-hopping system. However, there is a penalty incurred in subdividing an information symbol into several frequency-hopped elements, because the energy from these separate elements is combined noncoherently (for reference, see [9], Chapter 12).

FH spread-spectrum signals may be used in CDMA where many users share a common bandwidth. In some cases, an FH signal is preferred over a DS spread-spectrum signal because of the stringent synchronization requirements inherent in DS spread-spectrum signals. Specifically, in a DS system, timing and synchronization must be established to within a fraction of a chip interval $T_c = 1/W$. Conversely, in an FH system, the chip interval T_c is the time spend in transmitting a signal in a particular frequency slot of bandwidth $B \ll W$. But this interval is approximately $1/B$, which is much larger than $1/W$. Hence, the timing requirements in an FH system are not as stringent as in a DS system.

4.1. Slow Frequency-Hopping Systems

Let us consider a slow frequency-hopping system in which the hop rate $R_h = 1$ hop/bit. If the interference on the channel is broadband and is characterized as AWGN with power-spectral density I_0, the probability of error for the detection of noncoherently demodulated binary FSK is

$$P_b = \tfrac{1}{2} e^{-\mathcal{E}_b/2I_0} \tag{39}$$

where $\mathcal{E}_b/I_0$ is the SNR/bit.

As in the case of a DS spread-spectrum system, we observe that $\mathcal{E}_b$, the energy/bit, can be expressed as $\mathcal{E}_b = P_S T_b = P_S/R$, where P_S is the average transmitted power and R is the bit rate. Similarly, $I_0 = P_I/W$, where

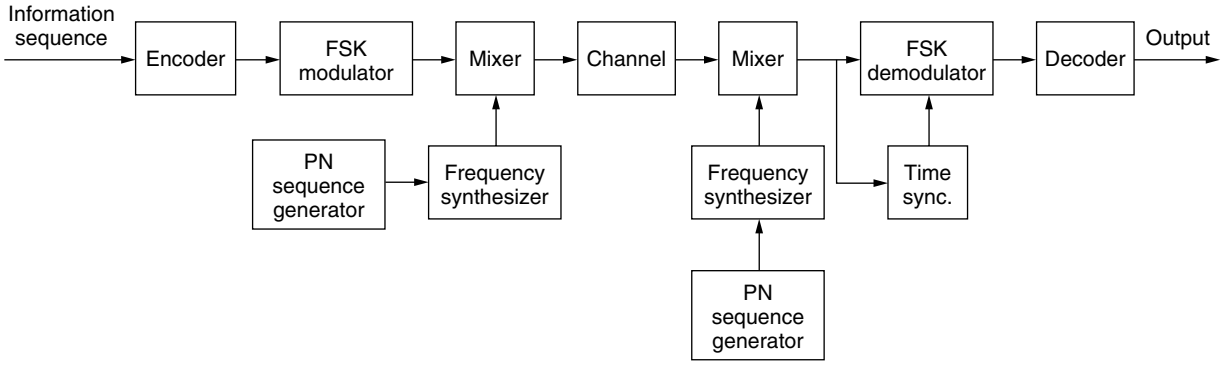

Figure 8. Black diagram of an FH spread-spectrum system.

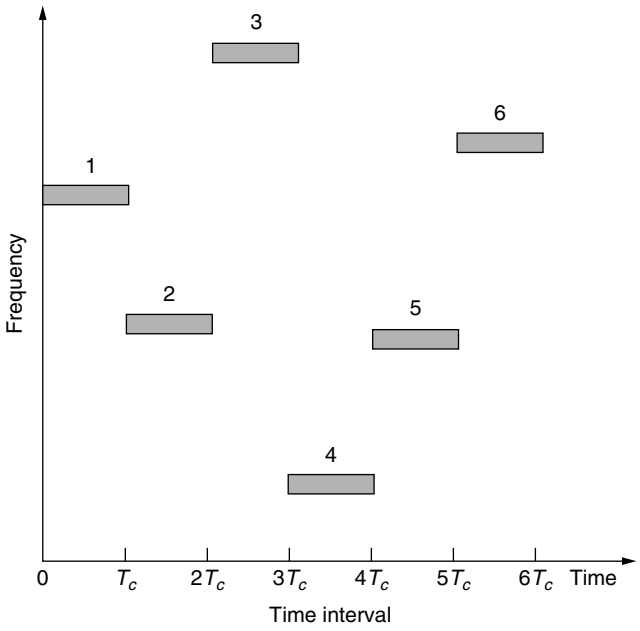

Figure 9. An example of an FH pattern.

P_I is the average power of the broadband interference and W is the available channel bandwidth. Therefore, the SNR/bit can be expressed as

$$\frac{\mathcal{E}_b}{I_0} = \frac{W/R}{P_I/P_S} \tag{40}$$

where W/R is the processing gain and P_I/P_S is the interference margin for the FH spread-spectrum signal.

Slow FH spread-spectrum systems are particularly vulnerable to partial-band interference that may result in FH CDMA systems. To be specific, suppose that the partial-band interference is modeled as a zero-mean Gaussian random process with a flat power-spectral density over a fraction of the total bandwidth W and zero in the remainder of the frequency band. In the region or regions where the power-spectral density is nonzero, its value is I_0/ρ, where $0 < \rho < 1$. In other words, the interference average power P_I is assumed to be constant.

Let us consider the worst-case partial-band interference by selecting the value of ρ that maximizes the error probability. In an uncoded slow-hopping system with binary FSK modulation and noncoherent detection, the transmitted frequencies are selected with uniform probability in the frequency band W. Consequently, the received signal will be corrupted by interference with probability ρ. When the interference is present, the probability of error is $\frac{1}{2}\exp(-\rho\mathcal{E}_b/2I_0)$ and when it is not, the detection of the signal is assumed to be error free. Therefore, the average probability of error is

$$\begin{aligned} P_b(\rho) &= \frac{\rho}{2} e^{-\rho\mathcal{E}_b/2I_0} \\ &= \frac{\rho}{2}\exp\left(\frac{\rho W/R}{2P_I/P_S}\right) \end{aligned} \tag{41}$$

Figure 10 illustrates the error rate as a function of $\mathcal{E}_b/I_0$ for several values of ρ. By differentiating $P_b(\rho)$, and solving for the value of ρ that maximizes $P_b(\rho)$, we find

$$\rho^* = \begin{cases} 2I_0/\mathcal{E}_b, & \rho \geq 2 \\ 1, & \mathcal{E}_b/I_0 < 2 \end{cases} \tag{42}$$

The corresponding error probability for the worst case partial-band interference is

$$P_b = \begin{cases} e^{-1}/\mathcal{E}_b/I_0, & \mathcal{E}_b/I_0 \geq 2 \\ \frac{1}{2}e^{-\mathcal{E}_b/2I_0}, & \mathcal{E}_b/I_0 < 2 \end{cases} \tag{43}$$

which is also shown in Fig. 10. Whereas the error probability decreases exponentially for full-band interference as given by Eq. (39), the error probability for worst-case partial band interference decreases only inversely with $\mathcal{E}_b/I_0$. This result is similar to the error probability for DS spread-spectrum signals in the presence of pulse interference. It is also similar to the error probability for binary PSK in a Rayleigh fading channel.

An effective method for combatting partial band interference in a FH system is signal diversity, which can be obtained by simple repetition of the transmitted information bit on different frequencies (or by means of block or convolutional coding). Signal diversity obtained through coding provides a significant improvement in performance relative to uncoded signal transmission. In fact, it has been shown by Viterbi and Jacobs [10] that by optimizing the code design for the partial-band

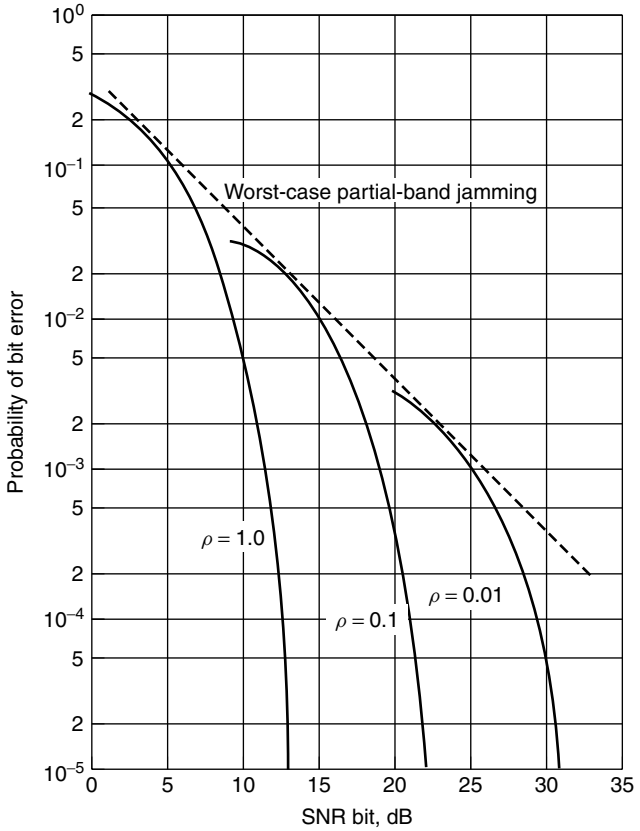

Figure 10. Performance of binary FSK with Partial-band interference.

interference, the communication system can achieve an average bit-error probability of

$$P_b = e^{-\mathcal{E}_b/4I_0} \tag{44}$$

Therefore, the probability of error achieved with the optimum code design decreases exponentially with an increase in SNR and is within 3 dB of the performance obtained in an AWGN channel. Thus, the penalty due to partial-band interference is reduced significantly.

4.2. Fast Frequency-Hopping Systems

In fast FH systems, the frequency-hop rate R_h is some multiple of the symbol rate. Basically, each (M-ary) symbol interval is subdivided into N subintervals, which are called *chips* and one of M frequencies is transmitted in each subinterval. Fast frequency-hopping systems are particularly attractive for military communications. In such systems, the hop rate R_h may be selected sufficiently high so that a potential intentional interferer does not have sufficient time to detect the presence of the transmitted frequency and to synthesize a jamming signal that occupies the same bandwidth.

To recover the information at the receiver, the received signal is first dehopped by mixing it with the hopped carrier frequency. This operation removes the hopping pattern and brings the received signal in all subintervals (chips) to a common frequency band that encompasses the M possible transmitted frequencies. The signal in each subinterval is then passed through the M matched filters (or correlators) tuned to the M possible transmitted frequencies which are sampled at the end of each subinterval and passed to the detector. The detection of the FSK signals is noncoherent. Hence, decisions are based on the magnitude of the matched filter (or correlator) outputs.

Since each symbol is transmitted over N chips, the decoding may be performed simply on the basis of hard decisions for the chips on each hop.

To determine the probability of error for the detector, we recall that the probability of error for noncoherent detection of binary FSK for each hop is

$$p = \tfrac{1}{2}e^{-\mathcal{E}_b/2NI_0} \tag{45}$$

where N is the number of frequency hops (chips) per bit, and $\mathcal{E}_b/N$ is the energy of the signal per hop. Assuming that N is odd, the decoder decides in favor of the transmitted binary FSK bit that is larger in at least $(N+1)/2$ chips. Thus, the decision is made on the basis of a majority vote given the decisions on the N chips. Consequently, the probability of a bit error is

$$P_b = \sum_{m=(N+1)/2}^{N} \binom{N}{m} p^m (1-p)^{N-m} \tag{46}$$

where p is given by Eq. (45). We should note that the error probability P_b for hard-decision decoding of the N chips will be higher than the error probability for a single hop/bit PSK system, which is given by Eq. (39), when the SNR/bit $\mathcal{E}_b/I_0$ is the same in the two systems.

5. COMMERCIAL SPREAD SPECTRUM SYSTEMS

As mentioned earlier, the number of nonmilitary spread spectrum systems have increased rapidly the last decades. The applications are quite diverse: underwater communications [11], wireless local loop systems [12], wireless local area networks, cellular systems, satellite communications [13], and ultra wideband systems [14]. Spread spectrum is also used in wired application in, for example, power-line communication [15] and have been proposed for communication over cable-TV networks [12] and optical fiber systems [16,17]. Finally, spread spectrum techniques have been found to be useful in ranging, such as, radar and navigation and the Global Positioning System (GPS) [18]. Other applications are watermarking of multimedia [19] and (mentioned here as a curiosity) in clocking of high-speed electronics [20,21]. Due to space constraint, we will only briefly mention some of the hot wireless applications here.

The wireless local area network (WLAN) standard IEEE 802.11 was originally designed to operate in the ISM band at approximately 2.4 GHz. The standard supports several different coding and modulation formats and several data rates. The first version of the standard was released in 1997 and supports both FH and DS spread spectrum formats with data rates of 1 or 2 Mbit/s [22]. The FH modes are slow hopping and use so-called Gaussian

FSK (GFSK) modulation (binary for 1 Mbit/s and 4-ary for 2Mbit/s). The system hops over 79 subcarriers with 1-MHz spacing. The DS-SS modes use a 11-chip long Barker sequence which is periodically repeated for each symbol. The chip rate is 11 Mchips/s, and the symbol rate is 1 Msymbols/s. The modulation is differentially encoded BPSK or QPSK (for 1 and 2 Mbit/s, respectively). We note that the processing gain is rather low, especially for the DS-SS modes.

The 802.11 standard has since 1997 been extended in several directions (new bands, higher data rates, etc). In 1999, the standard was updated to IEEE 802.11b (also known as Wi-Fi, if the equipment, also passes an interoperability test). In addition to the original 1 and 2 Mbit/s modes, IEEE 802.11b also supports 5.5 and 11 Mbit/s DS-SS modes [23] and several other optional modes with varying rates. The higher rate DS-SS modes uses so-called complementary code keying (CCK). The chip rate is still 11 Mchips/s and each symbol is represented by 8 complex chips. Hence, for the 5.5-Mbit/s mode, each symbol carries 4 bits, and for the 11-Mbit/s mode, each symbol carries 8 bits. Hence, the processing gains is reduced compared to the 1- and 2-Mbit/s modes. As a matter of fact, the 11 Mbit/s is perhaps not even a spread-spectrum system. The CCK modulation is a little bit complicated to describe, but in essence it forms the complex chips by combining a block code and differential QPSK [22], Section 18.4.6.5].

Bluetooth is primarily a cable replacement system, that is, a system for short range communication with relatively low-data rate. It is designed for the ISM band and uses slow hopping FH-SS with GFSK modulation ($BT = 0.5$ and modulation index between 0.28 and 0.35). The system hops over 79 subcarriers with a rate of 1600 hop/s. The subcarrier spacing is 1 MHz, and in most countries the subcarriers are placed at $f_k = 2402 + k$ MHz for $k = 0, 1, \ldots, 78$. Bluetooth supports both synchronous and asynchronous links and several different coding and packet schemes. The user data rates varies from 64 kbits/s (symmetrical and synchronous) to 723 kbits/s (asymmetrical and asynchronous). The maximum symmetrical rate is 434 kbits/s. The range of the system is quite short, probably less than 10 m in most environments. It is likely that future versions of Bluetooth will support higher data rates and longer ranges.

The first cellular system with a distinct spread spectrum component was IS-95 (also known as cdmaOne or somewhat pretentiously as CDMA). Although the Global System for Mobile Communications (GSM), has a provision for frequency hopping, it is not usually considered to be a spread spectrum system. Often, spread spectrum and code-division multiple access (CDMA) are used as synonyms, although they really are not. A multiple access method is a method for allowing several links (that are not at the same geographical location) to share a common communication resource. CDMA is a multiple access method where the links are spread spectrum links. A receiver that is tuned to a certain user relies on the anti-jamming properties of the spread spectrum format to suppress the other users' signals.

IS-95 uses DS-SS links with a chip rate of 1.2288 Mchips/s and a bandwidth of (approximately) 1.25 MHz. In the downlink (forward link or base-station-to-terminal link) the chips are formed by a combination of convolutional encoding, repetition encoding, and scrambling. The chips are transmitted both in inphase and quadrature (but scrambled by different PN sequences). In the uplink (reverse link), the transmitted chips are formed by a combination of convolutional coding, orthogonal block coding, repetition coding, and scrambling. In the original IS-95 (IS-95A), the uplink was designed such that the detection could be done noncoherently. In the third generation evolution of IS-95, known as cdma2000, the modulation and coding has changed and the transmitted bandwidth tripled to allow for peak data rates exceeding 2 Mbit/s [24,–26].

Another third generation system is Wideband CDMA (WCDMA) [27]. WCDMA is a rather complex system with many options and modes. We will here only briefly describe the frequency-division duplex (FDD) mode. The FDD mode uses direct-sequence spreading with a chip rate of 3.84 Mchips/s. The chip waveform is a root-raised cosine pulse with roll-off factor 0.22, and the bandwidth of the transmitted signal is approximately 5 MHz. WCDMA supports many different information bit rates by changing the spreading factor (from 4 to 256 in the uplink and from 4 to 512 in the downlink) and the error control scheme (no coding, convolutional coding, or turbo coding); however, the modulation is QPSK with coherent detection in all cases. Today, the maximum information data rate is roughly 2 Mbits/s, but it is likely that future revisions of the standard will support higher rates through new combinations of spreading, coding, and modulation.

BIOGRAPHY

Dr. John G. Proakis received the B.S.E.E. from the University of Cincinnati in 1959, the M.S.E.E. from MIT in 1961, and the Ph.D. from Harvard University in 1967. He is an Adjunct Professor at the University of California at San Diego and a Professor Emeritus at Northeastern University. He was a faculty member at Northeastern University from 1969 through 1998 and held the following academic positions: Associate Professor of Electrical Engineering, 1969–1976; Professor of Electrical Engineering, 1976–1998; Associate Dean of the College of Engineering and Director of the Graduate School of Engineering, 1982–1984; Interim Dean of the College of Engineering, 1992–1993; Chairman of the Department of Electrical and Computer Engineering, 1984–1997. Prior to joining Northeastern University, he worked at GTE Laboratories and the MIT Lincoln Laboratory.

His professional experience and interests are in the general areas of digital communications and digital signal processing and more specifically, in adaptive filtering,

adaptive communication systems and adaptive equalization techniques, communication through fading multipath channels, radar detection, signal parameter estimation, communication systems modeling and simulation, optimization techniques, and statistical analysis. He is active in research in the areas of digital communications and digital signal processing and has taught undergraduate and graduate courses in communications, circuit analysis, control systems, probability, stochastic processes, discrete systems, and digital signal processing. He is the author of the book *Digital Communications* (McGraw-Hill, New York: 1983, first edition; 1989, second edition; 1995, third edition; 2001, fourth edition), and co-author of the books *Introduction to Digital Signal Processing* (Macmillan, New York: 1988, first edition; 1992, second edition; 1996, third edition), *Digital Signal Processing Laboratory* (Prentice-Hall, Englewood Cliffs, NJ, 1991); *Advanced Digital Signal Processing* (Macmillan, New York, 1992), *Algorithms for Statistical Signal Processing* (Prentice-Hall, Englewood Cliffs, NJ, 2002), *Discrete-Time Processing of Speech Signals* (Macmillan, New York, 1992, IEEE Press, New York, 2000), *Communication Systems Engineering* (Prentice-Hall, Englewood Cliffs, NJ: 1994, first edition; 2002, second edition), *Digital Signal Processing Using MATLAB V.4* (Brooks/Cole-Thomson Learning, Boston, 1997, 2000), and *Contemporary Communication Systems Using MATLAB* (Brooks/Cole-Thomson Learning, Boston, 1998, 2000). Dr. Proakis is a Fellow of the IEEE. He holds five patents and has published over 150 papers.

STATISTICAL CHARACTERIZATION OF IMPULSIVE NOISE*

ARTHUR A. GIORDANO

1. INTRODUCTION

A statistical characterization of impulsive noise is a multifaceted task. For the characterization to be meaningful and useful in predicting communications performance, knowledge of the underlying physical mechanisms is required. In order to develop a statistical noise model that accurately represents the communications channel under investigation, physical measurements of the impulsive noise characteristics are generally needed. With this understanding, a statistical noise model can be developed and used to construct optimum or near-optimum detectors, estimate physical system and noise parameters, and determine communications performance. As a consequence, there is no single noise model that can be used as a representation of all impulsive noise channels. This article describes a number of important noise models where the reader is cautioned to first confirm that the appropriate noise model is selected for the communications channel under investigation.

Gaussian noise, which is the predominant noise source associated with thermal noise in receiver front-ends and numerous communications channels such as microwave and satellite channels, is analytically tractable and used to predict communications performance for a broad class of communications systems. Noise statistics are characterized by a Gaussian probability density function (pdf) where only knowledge of the mean and variance of the noise is needed to completely characterize the noise statistics. The spectral characteristics of the noise may be white or nonwhite, with both cases having been extensively investigated [23]. Perhaps the most common and simple case is associated with additive white Gaussian noise (AWGN) where a number of analytical performance results have been obtained [33]. In fact, Gaussian noise is so prevalent that all other cases are categorized as non-Gaussian. This categorization is perhaps unfortunate in that it leads to the assumption that non-Gaussian noise has a single representation.

Impulse noise is typically associated with noise pulses that have large peak amplitudes and bandwidths that generally exceed the receiver bandwidth. The tails of the pdf of impulse noise are greater in extent than that of Gaussian noise and often lead to moments of the distribution that are ill defined. In contradistinction to the Gaussian case where only the pdf is needed, statistical characterization of an impulsive noise process requires multiple statistics for a complete characterization. The most extensively studied statistic is acknowledged to be the amplitude probability distribution (APD) and is defined as the probability that the noise envelope exceeds a specified value. This statistic is referred to as a first-order statistic. A complete characterization of the noise process requires higher-order statistics generally associated with the time statistics of the noise. Examples of these statistics include the autocorrelation, the pulse spacing distribution (also termed pulse interarrival times), the pulse duration distribution, and the average envelope crossing rate.

When a Gaussian noise model is accepted as a meaningful model for the communications channel under investigation, it is well known [48] that the optimum detector is linear and is implemented as either a matched filter or a correlation receiver.[1] A consequence of this result is that bit error rate (BER) computations are often analytically tractable for a large class of modulations. In contrast, for an impulsive noise process the optimum detector is nonlinear with a structure that is dependent on the noise model utilized. Thus, many different receiver structures can be derived where each structure is optimized for the specified noise model.

To determine the detector structure for an impulsive noise model, two approaches, referred to as analytical and ad hoc, are followed. The analytical approach is based on an accurate model of the noise statistics developed from the physical processes that generate the noise. The ad hoc approach is based on suboptimal detector structures that utilize nonlinearities that are easily implemented and reduce the tails in the noise distribution resulting in improved performance over linear detectors operating in the same impulsive noise environment. This latter approach has the advantage that the receiver performance is likely to be less sensitive to the noise model and therefore may offer more robust performance in time-varying or unknown noise statistics.

2. CHARACTERIZATION OF IMPULSIVE NOISE

Common examples of communication channels with impulsive noise include atmospheric radio noise, man-made noise, telephone communications, underwater acoustic noise, and magnetic recording noise. Atmospheric radio noise, arising from lightning discharges in the atmosphere, is an electromagnetic interference that can seriously degrade receiver performance [43,44]. Man-made noise occurs in automotive ignitions [22], electrical machinery such as welders, power transmission and distribution lines [32], medical and scientific apparatus, and so on. In telephone communications impulsive noise is generated

* This article is adapted, with permission, from a chapter in a textbook to be published by Prentice-Hall.

[1] In the non–white noise case, the detector uses a whitening filter prior to detection.

from telephone switches and is particularly important in characterizing the performance of high-speed digital subscriber loops [20,21,34,46]. These examples represent a diverse subset of impulsive noise environments where knowledge of the physical characteristics dictates the noise model selection.

To maintain generality but provide a basis for relating the noise model to a physical case, the important case of atmospheric radio noise will be emphasized. Although much of the treatment that follows is specific to this channel, the process is likely to be extendable to other physical channels.

A summary of several principal noise models is provided.

2.1. Statistical-Physical Model

The noise $\mathbf{n}(t)$ is represented over an interval T by a summation of impulses filtered by the channel and expressed as

$$\mathbf{n}(t) = \sum_{i=1}^{\mathbf{N}} \mathbf{a}_i \delta(t - \mathbf{t}_i) \tag{1}$$

where $\mathbf{N}$ is the number of impulses occurring in the interval T, $\mathbf{a}_i$ is a random variable (rv) representing the strength of the ith impulse and $\mathbf{t}_i$ is the occurrence time of the ith impulse.

$\mathbf{N}$ is typically assumed to be Poisson distributed with parameter μT where μ is the average rate of arrival of the impulses. Other investigators postulate a Poisson-Poisson distribution [8] or a Pareto [24] distribution leading to different pulse clustering behavior than that of a Poisson. For example, in the Poisson-Poisson case clusters of noise pulses occur where the pulses within a cluster occur at a Poisson rate μ_p and the clusters themselves are Poisson at a slower rate than μ_p.

The rv $\mathbf{a}_i$ can be often assumed to be Gaussian [34]. However, for the atmospheric radio noise case, the statistical physical model is well founded based on measurements and analytical modeling of the physical behavior of the communications environment. Giordano has shown that the rv $\mathbf{a}_i$ is proportional to the received field strength which depends on the source to receiver distance $\mathbf{r}_i$ in accordance with a generalized propagation law g, where $\mathbf{a}_i = g(\mathbf{r}_i)$ [9]. By assuming a spatial distribution of noise sources and a specific propagation law, the pdf of the rv $\mathbf{a}_i$ can be determined.

Middleton has extended the statistical-physical model developed in Giordano by introducing more general assumptions on the noise spatial conditions and propagation assumptions [25,26,28]. These models are termed "canonical" in that their form is invariant of the physical source mechanisms. Two important cases, referred to as Class A and Class B, were developed. Class A models are used for the narrowband case where the noise bandwidth is comparable or less than the receiver front-end bandwidth and Class B models are used in the wideband case.[2]

[2] That is, the noise bandwidth is wider than the receiver front-end bandwidth.

A Class C model has also been defined consisting of a combination of Class A and B models.

2.2. Generalized-t or Hall Model

This model, developed by Hall [13], has the form represented by a the product of a zero mean, narrowband Gaussian process $\mathbf{n}_g(t)$ with variance σ_1^2 and a slowly varying modulating stationary process $\mathbf{a}(t)$ that is independent of $\mathbf{n}_g(t)$, that is

$$\mathbf{n}(t) = \mathbf{a}(t)\mathbf{n}_g(t) \tag{2}$$

This model is premised on the fact that the noise sources vary with time over a large dynamic range and that, unlike a Gaussian noise source where energy is delivered at a constant rate, the impulses tend to occur in bursts. To model atmospheric radio noise, the slowly varying modulating process $\mathbf{a}(t)$ is selected to behave in a way that is similar to that of an empirical model obtained from measurements.

A variant of this model referred to as a truncated Hall model [35] removes some of the undesirable attributes of the Hall model where moments associated with the APD are undefined. This model is obtained by truncating the pdf of the noise envelope thereby producing finite moments and a noise process that is physically realizable. It has a further advantage in that the impulsiveness of the noise can be specified by means of the parameter Vd, which is the rms to average envelope ratio.

2.3. Mixture Model

The mixture model [29] is obtained by judiciously selecting two noise models which can be added together to produce the desired noise statistics. Thus, the term mixture model actually represents a collection of models since the two subsidiary noise processes can be chosen from many possibilities. One form of the mixture model is represented as a zero mean noise process $\mathbf{n}_0(t)$ that is,

$$\mathbf{n}_0(t) = (1 - \varepsilon_r)\mathbf{n}_g(t) + \varepsilon_r \mathbf{n}_i(t) \tag{3}$$

where $\mathbf{n}_g(t)$ is a Gaussian noise process, $\mathbf{n}_i(t)$ is an impulsive noise process and ε_r is a constant with $0 < \varepsilon_r < 1$. (An alternate formulation can be obtained by adding a combination of noise envelopes.) This model is appealing in that for small amplitudes approaching zero, $\mathbf{n}_0(t)$ approaches a Gaussian distribution ($\varepsilon_r \to 0$); for large noise amplitudes which create "spikes" of noise, the heavy tails of the impulsive noise distribution predominate ($\varepsilon_r \to 1$).

2.4. Empirical Model

The empirical model is based on graphical fits of the APD [7]. This model assumes that the small amplitude part of the APD is represented by a Rayleigh distribution and that the large amplitude region can be represented by a log-normal or power Rayleigh distribution. The parameters for the distributions are based on measurements of three statistical moments which are the average noise envelope, the rms noise

envelope, and the average logarithm of the noise envelope. Denoting the noise envelope as $v(t)$, the average noise envelope V_{ave} over an interval T is given by

$$V_{\text{ave}} = 1/T \int_0^T v(t)\,dt \tag{4}$$

Similarly, the rms noise envelope V_{rms} and average logarithm of the noise envelope $V_{\log}$ are given respectively by

$$V_{\text{rms}} = \left[1/T \int_0^T v^2(t)\,dt\right]^{1/2} \tag{5}$$

and

$$V_{\log} = \text{antilog}\left(1/T \int_0^T \log v(t)\,dt\right) \tag{6}$$

These moments are ordinarily measured in one bandwidth and are converted to other bandwidths as needed [39].

3. APD COMPUTATION USING HANKEL TRANSFORMS

When the statistical-physical model given in Eq. (1) is adopted, a very powerful method based on Hankel transforms is available to compute the APD and relate it to the underlying physical environment [9]. This method has been utilized in the atmospheric noise channel but is not restricted to that case. The method in fact applies to any narrowband receiver output representation when the input is a time sequence of independent impulses. An outline of the approach is presented here with a more complete derivation provided in Ref. 9.

Let us assume that a narrowband receiver with a carrier frequency f_c has an impulse response given by

$$h(t) = \beta(t)\cos(\omega_c t - \psi)u(t) \tag{7}$$

where $\beta(t)$ is the amplitude of $h(t)$, ψ is the phase, $\omega_c = 2\pi f_c$, and $u(t)$ is the unit step function. If the noise process given by Eq. (1) is applied to the input of a receiver with an impulse response given by Eq. (7), the output noise process $\mathbf{n}_0(t)$ can be expressed as

$$\mathbf{n}_0(t) = \sum_{i=1}^{\mathbf{N}} \mathbf{v}_i(t)\cos(\omega_c t - \omega_c \mathbf{t}_i - \psi)u(t - \mathbf{t}_i) \tag{8}$$

where $\mathbf{v}_i(t) = \mathbf{a}_i\beta(t - \mathbf{t}_i)$. The output noise can also be expressed in terms of its envelope $\mathbf{v}(t)$ and phase $\psi_s(t)$ as

$$\mathbf{n}_0(t) = \mathbf{v}(t)\cos(\omega_c t + \psi_s(t)) \tag{9}$$

The $\mathbf{N}$ terms in Eq. (8) can now be viewed as $\mathbf{N}$ vectors (or phasors) where the ith vector amplitude is $\mathbf{v}_i(t) = \mathbf{a}_i\beta(t - \mathbf{t}_i)$ with a phase $\psi_i = -\omega_c \mathbf{t}_i - \psi$ as shown in Fig. 1. The vectors then sum to the total vector with amplitude $\mathbf{v}(t)$ and phase $\psi_s(t)$.

The Hankel transform is the tool required to relate $\mathbf{v}(t)$ to $\mathbf{v}_i(t)$ for a fixed value of $\mathbf{N} = k$. The method is based on the characteristics function (cf) theorem for determining the pdf of a sum of independent random vectors where the cf of the sum vector is the product of the cf's of the individual vectors. It is now assumed

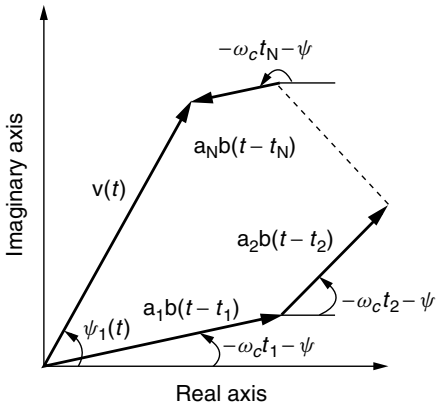

Figure 1. Phasor representation of output noise process.

that the phase of each vector ψ_i is uniformly distributed. Then for a sum of independent random vectors with uniformly distributed phase, the Hankel transform of the magnitude of the sum vector can be found by forming the product of the Hankel transforms of the magnitudes of the individual vectors.

Let $H_{\mathbf{v}_i}(z)$ denote the Hankel transform of the ith vector and $H_{\mathbf{v}_{N=k}}(z)$ denote the Hankel transform of the sum of $\mathbf{N} = k$ vectors. Then, the above description leads to

$$H_{\mathbf{v}_{N=k}}(z) = \prod_{i=1}^{k} H_{\mathbf{v}_i}(z) \tag{10}$$

Reference 9 shows that the Hankel transform of the ith vector can be defined as the expected value of the $rvJ_0(z\mathbf{v}_i)$ that is,

$$H_{\mathbf{v}_i}(z) = E[J_0(z\mathbf{v}_i)] \tag{11}$$

or equivalently

$$H_{\mathbf{v}_i}(z) = E[J_0(z\mathbf{a}_i\beta(t - \mathbf{t}_i))] \tag{12}$$

Because the individual vectors are identically distributed and the number of vectors $\mathbf{N}$ is a Poisson distributed rv, it can be shown that $H_{\mathbf{v}}(z)$, the Hankel transform of the envelope has a convenient representation in terms of the envelope of the receiver impulse response $\beta(t)$, the rate of arrival of the impulses μ, and the pdf of $\mathbf{a}_i$ given by $f_{\mathbf{a}}(a_i)$. The actual form derived in Ref. 9 is

$$H_{\mathbf{v}}(z) = \exp\left\{-\mu \int_0^\infty f_{\mathbf{a}}(a_i) \int_0^T [1 - J_0(za_i\beta(s))]\,ds\,da_i\right\} \tag{13}$$

Because $\mathbf{a}_i = g(\mathbf{r}_i)$, an alternative form of Eq. (13) can be obtained in terms of the pdf of the source to receiver distance $f_{\mathbf{r}}(r_i)$ that is,

$$H_{\mathbf{v}}(z) = \exp\left\{-\mu \int_0^\infty f_{\mathbf{r}}(r_i) \int_0^T [1 - J_0(zg(r_i)\beta(s))]\,ds\,dr_i\right\} \tag{14}$$

The pdf of the envelope can now be obtained by computing the inverse Hankel transform, that is,

$$p_{\mathbf{v}}(v) = v \int_0^\infty z H_{\mathbf{v}}(z) J_0(zv)\, dz \tag{15}$$

for $v \geq 0$ and 0 otherwise.

Reference 9 also shows that the cumulative distribution function (cdf) of the envelope can be expressed as

$$F_{\mathbf{v}}(v) = v \int_0^\infty H_{\mathbf{v}}(z) J_1(zv)\, dz \tag{16}$$

for $v \geq 0$ and 0 otherwise.

The APD is defined as the probability that the envelope $\mathbf{v}$ exceeds a value v_0 and is represented as $P[\mathbf{v} > v_0]$. It is given in terms of the cdf

$$P[\mathbf{v} > v_0] = 1 - F_{\mathbf{v}}(v_0) \tag{17}$$

or equivalently for $v_0 > 0$

$$P[\mathbf{v} > v_0] = 1 - v_0 \int_0^\infty H_{\mathbf{v}}(z) J_1(zv_0)\, dz \tag{18}$$

for $v_0 > 0$.

Example. In the case of atmospheric noise we now assume that lightning discharge occur in a uniform spatial distribution about the receiver out to a specified maximum range r_m resulting in a pdf given by

$$f_{\mathbf{r}}(r_i) = 1/r_m \tag{19}$$

where $0 < r_i < r_m$.

It is further assumed that the individual impulses arrive at the receiver in accordance with an inverse propagation law $\mathbf{a}_i = k_0/\mathbf{r}_i$, where k_0 is a constant. Then, it can be shown using Eqs. (14) and (18) that the APD for $v > 0$ can be expressed as [9]

$$P[\mathbf{v} > v_0] = K_u/[K_u^2 + {v_0}^2]^{1/2} \tag{20}$$

where

$$K_u = \mu k_0/r_m \int_0^T \beta(s)\, ds \tag{21}$$

This APD form has been shown to be a reasonable fit to measured atmospheric noise APDs [9,13]. Note that other assumptions on spatial distributions and propagation laws will produce other APD forms.

4. ATMOSPHERIC NOISE CHANNEL MODELS

One of the most extensively investigated impulsive noise channels is the atmospheric radio noise channel. Communications systems with center frequencies below 100 MHz must operate in the presence of atmospheric noise that arise from lightning discharges as a result of storms occurring throughout the world. Experimental data on some statistical properties of atmospheric noise can be found in several publications [5,14,15].

Receivers operating in atmospheric noise may experience two types of noise behavior, that is, 1) highly impulsive noise from local storms associated with distances that are within 1000 Km and 2) continuous noise from distant storms. With local storms radiated energy travels along the ground with low attenuation so that the receiver is subjected to strong electrical fields over a short duration. Storms that occur at ranges greater than 1000 Km propagate in modes within the earth-ionosphere cavity and arrive at the receiver with only a small portion of their original energy. In this latter case large numbers of lightning discharges occur simultaneously at various locations throughout the world causing bursts from distant storms to be numerous and overlap in time thereby producing the continuous background noise. As a result, APDs tend to have two dominant regions where the low-amplitude region is Rayleigh and arises via the central limit theorem from many independent, weak components whereas the high-amplitude region is dominated by strong distinguishable impulses that follow another distribution such as a power Rayleigh, log-normal, and so on.

The receiver bandwidth and operating frequency are also significant in characterizing impulsive noise. Very low frequency (VLF) (3–30 KHz) receivers experience significant interference as a result of the large radiated energy from the short (100 μsec) main strokes (also referred to as the return stroke) of lightning discharges which tend to be centered around 10 KHz [45]. Inan [16] provides recent progress and results in this band. The radiated spectrum from a lightning discharge decays with frequency with the result that the predischarge consisting of several stepped discrete leaders prior to the stronger main stroke produces interference in higher frequency bands. With regard to the receiver bandwidth a receiver that uses a wide bandwidth will be subjected to individual pulses from lightning discharges that are more easily distinguished so that the noise appears impulsive. Narrow bandwidths produce overlapping pulses resulting in noise that appears more continuous.

Another mechanism that strongly impacts the time statistics of atmospheric noise is due to multiple stroking. Multiple stroking from "long" (200 μsec) discharges usually consists of three or four return strokes spaced at about 40 msec apart. This phenomenon accounts for the departure from a random distribution in time and introduces the dependencies evident in the pulse spacing distributions.

Researchers have expended considerably less effort in modeling higher-order statistics that are important in characterizing receiver performance. One study that has investigated the effects of time dependencies in the noise pulses, involves noise measurements in the medium frequency band (300KHz–3MHz) [11]. In this case BER performance for linear and nonlinear receivers was obtained and compared by simulation using channels that included either a truncated Hall model or measured noise having pulse dependencies. The results show that when the bursty nature of the noise is neglected by assuming independent noises samples, the performance of nonlinear receivers over linear receivers is significantly greater than if pulse dependencies are incorporated in

the analysis. Typically, in measured noise it is noted that nonlinearities can improve the performance of a linear receiver by an amount that is on the order of the V_d value.

With the above limited explanation of the underlying physical mechanisms, we now return to more detailed descriptions of atmospheric noise models. The models introduced in Section 2 will be extensively described and subsequently used to estimate bit error rate performance in selected cases. Other performance results on coherent and noncoherent signaling in impulsive noise can be found in Refs. 1,4,6,30,40,41.

4.1. Hall Model

The Hall model presented above is repeated here and used to compute the envelope, that is

$$\mathbf{n}(t) = \mathbf{a}(t)\mathbf{n}_g(t) \tag{22}$$

The envelope $\mathbf{v}(t)$ can now be expressed as

$$\mathbf{v}(t) = |\mathbf{a}(t)\mathbf{n}_g(t)| \tag{23}$$

By selecting a "two-sided" Chi distribution for $\mathbf{b}(t) = 1/\mathbf{a}(t)$, the envelope distribution fits empirical data for large values of the envelope. The pdf of $\mathbf{b}(t)$ with parameters m and σ^2 is then given by

$$p(b) = \frac{(\frac{m}{2})^{m/2}}{\sigma^m \Gamma(\frac{m}{2})} |b|^{m-1} \exp\left(-\frac{m}{2\sigma^2} b^2\right) \tag{24}$$

Note that for $m = 1$ the pdf of $\mathbf{b}(t)$ is Gaussian so that the pdf of $\mathbf{n}_0(t)$ is the ratio of two Gaussian processes. Hall then shows that the pdf of $\mathbf{n}_0(t)$ is given by

$$p(n_0) = \frac{\Gamma(\frac{\theta}{2})}{\Gamma(\frac{\theta-1}{2})} \frac{\gamma^{\theta-1}}{\sqrt{\pi}(n_0^2 + \gamma^2)^{\theta/2}} \tag{25}$$

where $\gamma = \sqrt{m}\frac{\sigma_1}{\sigma}$ and $\theta = m + 1 > 1$. For $\sigma_1 = \sigma$ the above equation is a Student t distribution with parameter m so that in the general case Hall named Eq. (25) as a generalized t distribution with parameters θ and γ. Letting $\mathbf{x}(t)$ and $\mathbf{y}(t)$ denote the inphase and quadrature components of $\mathbf{n}_0(t)$ respectively, Hall derives the joint pdf $p_{\mathbf{xy}}(x, y)$ from a transformation of the product of random variables in Eq. (2) resulting in

$$p_{\mathbf{xy}}(x, y) = \frac{(\theta - 1)\gamma^{\theta-1}}{2\pi} \frac{1}{[x^2 + y^2 + \gamma^2]^{(\theta+1)/2}} \tag{26}$$

If we let $\mathbf{x} = \mathbf{v}\cos\psi_s$ and $\mathbf{y} = \mathbf{v}\sin\psi_s$ where $\mathbf{v}$ and ψ_s denote the envelope and phase respectively of the noise, we can write the joint pdf of the envelope and phase as

$$p_{\mathbf{v}\psi_s}(v, \psi_s) = \frac{v(\theta - 1)\gamma^{\theta-1}}{2\pi[v^2 + \gamma^2]^{(\theta+1)/2}} \tag{27}$$

From this equation, it is seen that ψ_s is independent of $\mathbf{v}$ and has a uniform pdf in the interval $(0, 2\pi)$ so that

$$\begin{aligned} p(v) &= \frac{1}{2\pi} \int_0^{2\pi} p_{\mathbf{v}\psi_s}(v, \psi_s) d\psi_s \\ &= \frac{(\theta - 1)\gamma^{\theta-1} v}{[v^2 + \gamma^2]^{(\theta+1)/2}}, \quad 0 \le v \le \infty \end{aligned} \tag{28}$$

Asymptotic forms of the pdf are

$$p(v) \approx \begin{cases} (\theta - 1)\gamma^{\theta-1}/v^\theta, & \text{for } v \text{ large} \\ (\theta - 1)v/\gamma^2, & \text{for } v \text{ small} \end{cases} \tag{29}$$

The form of the pdf for large v is consistent with empirical data and for small v follows a limiting form of a Rayleigh distributed envelope.

The APD or exceedance distribution can be shown to be

$$P(\mathbf{v} > v_0) = \int_{v_0}^{\infty} p(v)\, dv = \frac{\gamma^{\theta-1}}{(v_0^2 + \gamma^2)^{(\theta-1)/2}} \tag{30}$$

To fit measured data θ is typically taken to be an integer between 2 and 5 and γ is related to the average or rms value of v for the specified value of θ. Note that if $\theta = 2$ the above equation takes the same form as Eq. (20).

The APD $P(\mathbf{v} > v_0)$ is plotted as a function of v_0/γ for $\theta = 2, 3, 4$, and 5. The Rayleigh exceedance distribution is

$$P(\mathbf{v} > v_0) = \exp\left(-\frac{v_0^2}{2\gamma^2}\right)$$

and is shown in Fig. 2 for reference purposes.[3]

Examination of Fig. 2 shows that longer tails are exhibited with $\theta = 2$ rather than with $\theta = 3, 4$, or 5. This behavior is consistent with impulsive noise that has a large dynamic range. A measure of the impulsiveness of the noise is V_d, the ratio of the rms to average envelope value defined as

$$V_d = 20 \log\left(\frac{\sqrt{\mu_2}}{\mu_1}\right) \tag{31}$$

where

$$\mu_j = \int_0^{\infty} v^j p(v)\, dv \quad j = 1, 2 \tag{32}$$

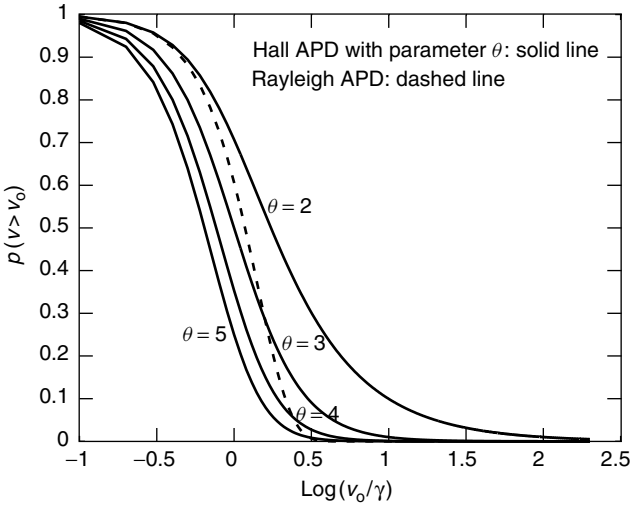

Figure 2. APD for Hall model and Rayleigh random variables.

[3] These results are obtained with MATLAB.

For $\theta = 4$ and 5 $V_d = 3$ dB and 2 dB respectively and the noise is considered to be moderately impulsive. For $\theta = 3$ the second moment does not exist and for $\theta = 2$ neither the first or second moments exist. One explanation of the infinite moments can be attributed to the propagation model where the received field strength follows an inverse distance relation. Near the origin the field strength is arbitrarily large which does not correspond to a physical condition. The actual noise moments must be finite and can be forced to this condition by truncating and normalizing the envelope distribution. Thus, a Hall model envelope pdf can be developed for the truncated case and is

$$p_E(v) = \begin{cases} \dfrac{c(\theta-1)\gamma^{\theta-1}v}{[v^2+\gamma^2]^{(\theta+1)/2)}} & 0 \le v \le v_m \\ 0, & v > v_m \end{cases} \tag{33}$$

where v_m is the maximum allowed envelope level and c is selected to ensure that

$$\int_0^\infty p_E(v)\,dv = 1 \tag{34}$$

Applying the above equation, we can show that

$$c = \frac{D^{\theta-1}}{D^{\theta-1}-1} \tag{35}$$

where $D = \sqrt{1+(v_m/\gamma)^2}$. For $\theta = 2$ the envelope pdf of the truncated Hall model is

$$p_E(v) = \begin{cases} \dfrac{D\gamma}{D-1}\dfrac{v}{[v^2+\gamma^2]^{3/2}}, & 0 \le v \le \gamma\sqrt{D^2-1} \\ 0, & v > \gamma\sqrt{D^2-1} \end{cases} \tag{36}$$

and

$$V_d = 20\log\left(\frac{(D-1)^{3/2}}{-\sqrt{D^2-1}+D\ln(D+\sqrt{D^2-1})}\right) \tag{37}$$

The truncated Hall model APD is given by

$$P(\mathbf{v} > v_0) = \frac{D}{D-1}\left[\frac{1}{\left(1+\dfrac{v_0^2}{\gamma^2}\right)^{1/2}} - \frac{1}{D}\right] \tag{38}$$

With this formulation more impulsive noise conditions can be realized and larger values of V_d can be obtained.

An advantage of the truncated Hall model is that computations can be performed for a specified V_d. For example, a highly impulsive case with $V_d = 10$ dB can be obtained by use of a normalized truncation point $v_m/\gamma = 290$. Other values for the normalized truncation point can be obtained from the plot given in Fig. 3.

4.2. Mixture Model

As described previously, mixture models are obtained by a "mixing" two simpler noise models. (See, for example, [35], [31], or [29]), that is

$$\mathbf{n}_0(t) = (1-\varepsilon_r)\mathbf{n}_g(t) + \varepsilon_r\mathbf{n}_i(t) \tag{39}$$

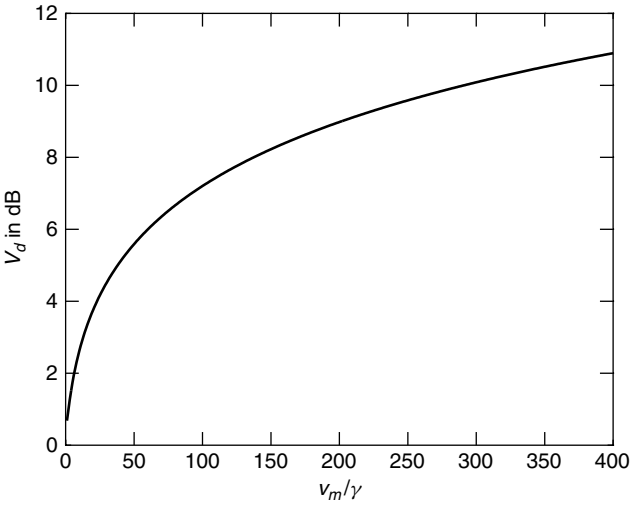

Figure 3. V_d as a function of truncation level for Hall model.

An alternate formulation of the mixture model can be obtained in terms of the noise envelope

$$\mathbf{v}(t) = \left(\frac{\mathbf{v}_i(t)+\mathbf{v}_R(t)}{2}\right) + \left(\frac{\mathbf{v}_i(t)-\mathbf{v}_R(t)}{2}\right)\mathbf{u}(t) \tag{40}$$

where $\mathbf{v}_R(t)$ is a Rayleigh envelope corresponding to the Gaussian noise component, $\mathbf{v}_i(t)$ is the envelope of the impulsive noise component, and $\mathbf{u}(t)$ is $+1$ with probability ε and -1 with probability $1-\varepsilon$. Thus, when $\mathbf{u}(t) = 1$, the envelope is Rayleigh distributed and given by

$$p(v_R) = \begin{cases} \dfrac{v_R}{\sigma^2}\exp\left(-\dfrac{v_R^2}{2\sigma^2}\right), & v_R \ge 0 \\ 0, & \text{otherwise} \end{cases} \tag{41}$$

and when $\mathbf{u}(t) = -1$, the envelope is distributed in accordance with an assumed distribution. One specific impulsive envelope pdf which has been used is referred to as a generalized Laplacian [35] and is given by

$$p(v_i) = \frac{v_i^v}{2^{v-1}(P_r\sigma)^{v+1}\Gamma(v)}K_{1-v}\left(\frac{v_i}{P_r\sigma}\right), \quad v_i \ge 0 \tag{42}$$

and zero when $v_i < 0$ where $K_{1-v}()$ is a modified Bessel function of order $1-v$ with $v > 0$ and P_r controls the ratio of the power between the impulsive and Rayleigh portions of the noise. The pdfs of the inphase and quadrature components can be determined from the joint pdf of the envelope v and phase ψ_s similar to that of Eq. (27) resulting in

$$p_{xy}(x,y) = \frac{(x^2+y^2)^{(v-1)/2}}{2\pi(P_r\sigma)^{v+1}\Gamma(v)2^{v-1}}K_{1-v}\left(\frac{\sqrt{x^2+y^2}}{P_r\sigma}\right) \tag{43}$$

The pdf of the inphase (or quadrature) components is then, from item 6.596-3 in [12],

$$p(x) = \frac{|x|^{v-1/2}}{\sqrt{\pi}(P_r\sigma)^{v+1/2}\Gamma(v)2^{v-1/2}}K_{1/2-v}\left(\frac{|x|}{P_r\sigma}\right) \tag{44}$$

This equation becomes a Laplace pdf when $v = 1$ and $P_r = 1/\sqrt{2}$ by using the relationships on page 444 in Ref. 2, that is,

$$K_{1/2}(z) = \left(\frac{\pi}{2z}\right)^{1/2} e^{-z}$$

and

$$K_{1/2-v}(z) = K_{v-1/2}(z)$$

The Laplace pdf then becomes, from Ref. 18

$$p(x) = \frac{1}{\sqrt{2\sigma^2}} \exp\left(-|x|\sqrt{\frac{2}{\sigma^2}}\right), -\infty < x < \infty \tag{45}$$

Note that the Laplace pdf has zero mean and variance σ^2 so that the Gaussian and Laplacian random variables have the same mean and variance.

By computing the first and second moments of the envelope of the mixture model, the V_d ratio for the mixture model can then be determined, that is,

$$V_d = 20 \log \left[\frac{\sqrt{4vP_r^2\varepsilon + 2(1-\varepsilon)}}{\dfrac{\varepsilon P_r \sqrt{\pi}\,\Gamma(v+1/2)}{\Gamma(v)} + (1-\varepsilon)\sqrt{\dfrac{\pi}{2}}} \right] \tag{46}$$

For $v = 1$ this reduces to

$$V_d\,|_{v=1} = 20 \log \left[\frac{\sqrt{4P_r^2\varepsilon + 2(1-\varepsilon)}}{\varepsilon P_r \dfrac{\pi}{2} + (1-\varepsilon)\sqrt{\dfrac{\pi}{2}}} \right] \tag{47}$$

With $P_r = 1$ and $\varepsilon = 0$, corresponding to the Gaussian only case, the V_d ratio is 1.05 dB. For $\varepsilon = 1$ and $v = 1$ the noise is impulsive according to a Laplacian distribution and $V_d = 20 \log 4/\pi = 2.1$ dB so that the noise is only mildly impulsive. More impulsive noise cases can be obtained by allowing $v < 1$ to be small in Eq. (46) Plots of V_d for several values of P_r and v are computed and shown in Figs. 4, 5, and 6 as a function of ε.

The APD for the mixture model can be obtained from

$$\begin{aligned} P\{\mathbf{v} > v_0\} &= P\{\mathbf{v} > v_0 \mid \mathbf{u} = 1\}P\{\mathbf{u} = 1\} \\ &\quad + P\{\mathbf{v} > v_0 \mid \mathbf{u} = -1\}P\{\mathbf{u} = -1\} \end{aligned} \tag{48}$$

Using item 6.561–12 in Ref. 12, this can be shown to be

$$\begin{aligned} P\{\mathbf{v} > v_0\} &= P\{\mathbf{v_i} > v_0\}\varepsilon + P\{\mathbf{v}_R > v_0\}(1-\varepsilon) \\ &= \varepsilon \int_{v_0}^{\infty} \frac{v_i^v}{2^{v-1}(P_r\sigma)^{v+1}\Gamma(v)} K_{1-v}\left(\frac{v_i}{P_r\sigma}\right) dv_i \\ &\quad + (1-\varepsilon)\int_{v_0}^{\infty} \frac{v_R}{\sigma^2} \exp\left(-\frac{v_R^2}{2\sigma^2}\right) dv_R = \varepsilon \left(\frac{v_0}{P_r\sigma}\right)^v \\ &\quad \times \frac{K_v\left(\dfrac{v_0}{P_r\sigma}\right)}{2^{v-1}\Gamma(v)} + (1-\varepsilon)\exp\left(-\frac{v_0^2}{2\sigma^2}\right) \end{aligned} \tag{49}$$

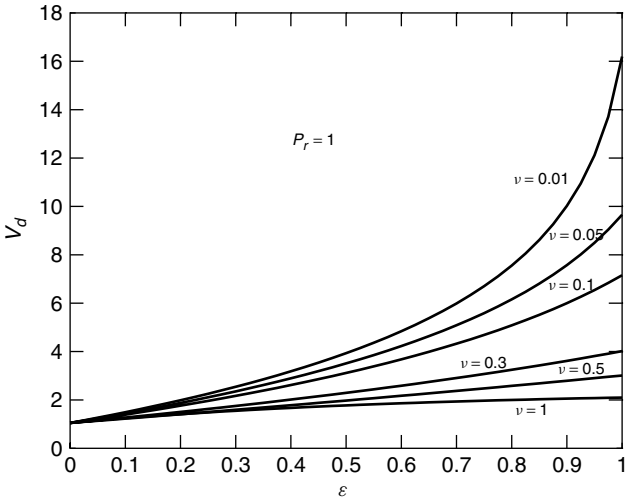

Figure 4. V_d as a function of v and ε with $P_r = 1$.

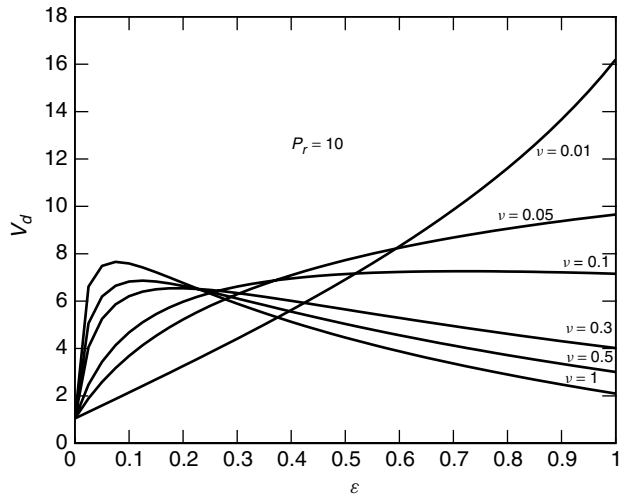

Figure 5. V_d as a function of v and ε with $P_r = 10$.

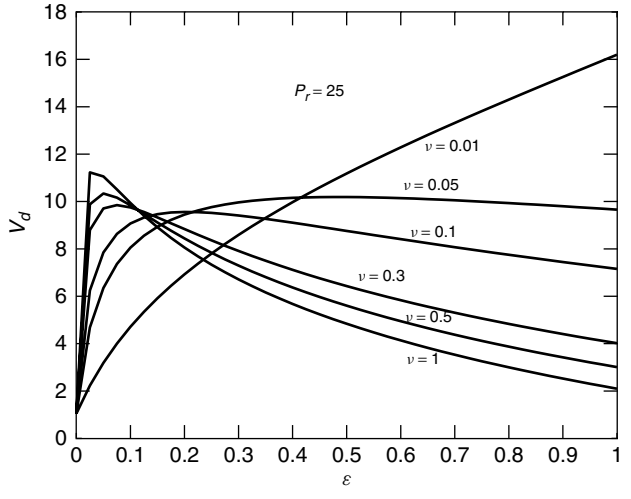

Figure 6. V_d as a function of v and ε with $P_r = 25$.

4.3. Middleton Class A and B Models

Middleton's models are statistical physical models like that given in Eq. (1) but with more general assumptions regarding noise source spatial distributions and propagation conditions. See Refs. 25–27,38. Thus, these models are regarded as canonical because noise source spatial distributions and propagation formulas need not be explicitly specified. Both Class A and B models assume that the noise sources are Poisson distributed in space with received waveforms produced by interfering sources that are independent and Poisson distributed in time. The broadband Class B models are useful in representing atmospheric noise statistics.

For Class A noise the instantaneous amplitude has a pdf described in terms of a parameter A referred to as the impulsive index and a parameter $P_r = \sigma_g^2/\sigma_i^2$ representing the ratio of the Gaussian noise power σ_g^2 to the impulsive noise power σ_i^2. The Class A instantaneous amplitude pdf is given by Ref. 49 as

$$p(w) = e^{-A} \sum_{m=0}^{\infty} \frac{A^m e^{-w^2/2\sigma^2\sigma_m^2}}{m!\sqrt{2\pi\sigma_m^2\sigma^2}} \tag{50}$$

where $\sigma^2 = \sigma_g^2 + \sigma_i^2$ and

$$\sigma_m^2 = \frac{\dfrac{m}{A} + P_r}{1 + P_r} \tag{51}$$

Middleton uses normalized instantaneous amplitudes defined as $x = w/\sigma$ so that

$$p(x) = e^{-A} \sum_{m=0}^{\infty} \frac{A^m}{m!\sqrt{2\pi\sigma_m^2}} \exp\left(-\frac{x^2}{2\sigma_m^2}\right) \tag{52}$$

Small values of the parameter A produce large impulsive tails whereas large values of $A >\approx 10$ yield the limiting case of Gaussian interference. Thus, the reciprocal of A behaves as V_d in the truncated Hall and mixture models. Middleton also derives the pdf of the normalized envelope defined as $\mathrm{v}_N = \mathrm{v}/\sqrt{2\sigma^2}$ resulting in

$$p(v_N) = 2e^{-A} \sum_{m=0}^{\infty} \frac{A^m}{m!\sigma_m^2} v_N \exp\left(-\frac{v_N^2}{\sigma_m^2}\right), \quad v_N \geq 0 \tag{53}$$

and zero for $v_N < 0$.

A special case of a mixture model can be obtained by splitting the above expression into two terms as

$$p(v_N) = \frac{2e^{-A}}{\sigma_0^2} v_N e^{-v_N^2/\sigma_0^2} + 2e^{-A} \sum_{m=1}^{\infty} \frac{A^m}{m!\sigma_m^2} v_N \times \exp\left(-\frac{v_N^2}{\sigma_m^2}\right), \quad v_N \geq 0 \tag{54}$$

where

$$\sigma_0^2 = \frac{P_r}{1+P_r} = \frac{\sigma_g^2}{\sigma_g^2 + \sigma_i^2} \tag{55}$$

The first term in Eq. (54) can be seen to be Rayleigh distributed whereas the second term represents an impulsive distribution. The normalized form of the APD is obtained from

$$P\{\mathbf{v}_N > v_{N_0}\} = \int_{v_{N_0}}^{\infty} p(v_N)\, dv_N \tag{56}$$

where $v_{N_0} = N_0/\sqrt{2\sigma^2}$ resulting in

$$P\{\mathbf{v}_N > v_{N_0}\} = e^{-A} \sum_{m=0}^{\infty} \frac{A^m}{m!} \exp\left(-\frac{v_{N_0}^2}{\sigma_m^2}\right) \tag{57}$$

For Class B noise the instantaneous noise amplitude can be written in normalized form as

$$p(x) = \frac{e^{-x^2/W}}{\pi\sqrt{W}} \sum_{m=0}^{\infty} \frac{(-1)^m}{m!} A_\alpha^m \Gamma\left(\frac{m+1}{2}\right) {}_1F_1\left(-\frac{m\alpha}{2}; \frac{1}{2}; \frac{x^2}{W}\right) \tag{58}$$

where ${}_1F_1$ is the confluent hypergeometric function, A_α is a parameter that includes the impulsive index A and other parameters that depend on the physical mechanism, α is a constant between 0 and 2 related to the noise source density and propagation law, and W is a parameter that normalizes the noise process to the energy contained in the Gaussian portion of the noise. As indicated in Ref. 42, the normalization cannot be associated with the total energy because the moments of Eq. (58) are not finite.

The pdf of the normalized envelope for Class B noise is

$$p(v_N) = \frac{2v_N}{W} \exp\left(-\frac{v_N^2}{W}\right) \sum_{m=0}^{\infty} \frac{(-1)^m}{m!} \times A_\alpha^m \Gamma\left(1 + \frac{m\alpha}{2}\right) {}_1F_1\left(-\frac{m\alpha}{2}; 1; \frac{v_N^2}{W}\right), \quad v_N \geq 0 \tag{59}$$

and zero for $v_N < 0$. The normalized APD for Class B noise is

$$P\{\mathbf{v}_N > v_{N_0}\} = \exp\left(-\frac{v_{N_0}^2}{W}\right) \left[1 - \frac{v_{N_0}^2}{W} \sum_{m=1}^{\infty} \frac{(-1)^m}{m!} \times A_\alpha^m \Gamma\left(1 + \frac{m\alpha}{2}\right) {}_1F_1\left(1 - \frac{m\alpha}{2}; 2; \frac{v_{N_0}^2}{W}\right)\right] \tag{60}$$

An alternate form for the APD of Class B noise is given by Ref. 26 as

$$P\{\mathbf{v}_N > v_{N_0}\} = 1 - \exp\left(-\frac{v_{N_0}^2}{W}\right) \frac{v_{N_0}^2}{W} \sum_{m=0}^{\infty} \frac{(-1)^m}{m!} \times A_\alpha^m \Gamma\left(1 + \frac{m\alpha}{2}\right) {}_1F_1\left(1 - \frac{m\alpha}{2}; 2; \frac{v_{N_0}^2}{W}\right) \tag{61}$$

To see that Eqs. (60) and (61) are equivalent, we can rewrite the last equation as

$$P\{\mathbf{v}_N > v_{N_0}\} = 1 - \exp\left(-\frac{v_{N_0}^2}{W}\right) {}_1F_1\left(1; 2; \frac{v_{N_0}^2}{W}\right) - e^{-v_{N_0}^2/W} \frac{v_{N_0}^2}{W} \times \sum_{m=1}^{\infty} \frac{(-1)^m}{m!} A_\alpha^m \Gamma\left(1 + \frac{m\alpha}{2}\right) {}_1F_1\left(1 - \frac{m\alpha}{2}; 2; \frac{v_{N_0}^2}{W}\right) \tag{62}$$

However, from Ref. 2,

$$ {}_1F_1(1;2;z) = \frac{e^z - 1}{z} \tag{63} $$

which allows the above equation to be written as

$$ P\{\mathbf{v}_N > v_{N_0}\} = \exp\left(-\frac{v_{N_0}^2}{W}\right) - \exp\left(-\frac{v_{N_0}^2}{W}\right)\frac{v_{N_0}^2}{W} \times \sum_{m=1}^{\infty} \frac{(-1)^m}{m!} A_\alpha^m \Gamma\left(1 + \frac{m\alpha}{2}\right) {}_1F_1\left(1 - \frac{m\alpha}{2}; 2; \frac{v_{N_0}^2}{W}\right) \tag{64} $$

For large values of the argument $z = v_{N_0}^2/W$ an approximate form of the APD, which is useful for numerical evaluation, can be obtained by replacing the confluent hypergeometric function with the expression, using Ref. 2,

$$ {}_1F_1(a;b;z) = \frac{\Gamma(b)}{\Gamma(a)} z^{a-b} e^z, \quad \text{large } z \tag{65} $$

Using Eq. (65) in Eq. (61) leads to

$$ \begin{aligned} P\{\mathbf{v}_N > v_{N_0}\} &= 1 - ze^{-z} \sum_{m=0}^{\infty} \frac{(-1)^m A_\alpha^m}{m!} \\ &\quad \times \Gamma\left(1 + \frac{m\alpha}{2}\right) \frac{\Gamma(2)}{\Gamma(1 - \frac{m\alpha}{2})} z^{-\frac{m\alpha}{2}-1} e^z \\ &= -\sum_{m=1}^{\infty} (-1)^m \frac{A_\alpha^m}{m!} \frac{\Gamma(1 + \frac{m\alpha}{2})}{\Gamma(1 - \frac{m\alpha}{2})} z^{-m\alpha/2}, \quad \text{large } z \end{aligned} \tag{66} $$

From Ref. 2, we can use the identities

$$ \Gamma\left(1 + \frac{m\alpha}{2}\right) = \frac{m\alpha}{2} \Gamma\left(\frac{m\alpha}{2}\right) \tag{67} $$

and

$$ \Gamma\left(\frac{m\alpha}{2}\right) \Gamma\left(1 - \frac{m\alpha}{2}\right) = \frac{\pi}{\sin \pi\alpha \frac{m}{2}} \tag{68} $$

in Eq. (66) resulting in

$$ P\{\mathbf{v}_N > v_{N_0}\} = \sum_{m=1}^{\infty} (-1)^{m+1} \frac{A_\alpha^m}{(m-1)!} \frac{\alpha}{2\pi} \times \Gamma^2\left(\frac{m\alpha}{2}\right) \sin\left(\pi\alpha\frac{m}{2}\right) z^{-m\alpha/2}, \quad \text{large } z \tag{69} $$

An example of the APD of Middleton's Class B noise for $V_d = 10$ dB is given below in Section 4.5.

4.4. Empirical First-Order Model

The empirical first-order (simulation) noise model is based upon the Crichlow graphical model for the APD of the noise envelope [7]. This model uses a special type of probability graph paper; one on which the power Rayleigh functions plot as straight lines.[4] The coordinate transformations for the probability paper is found by considering the APD of a normalized Rayleigh function

$$ \frac{n}{\sqrt{\mu_2}} = \text{APD}(w) = e^{-w^2} \tag{70} $$

We use the transformation

$$ x' = -20 \log(-\ln w) \tag{71} $$

$$ y' = 20 \log \frac{n}{\sqrt{\mu_2}} \tag{72} $$

On this probability paper, the APD of atmospheric noise can be represented by a three-section curve as shown in Fig. 7. The lower region of the curve, representing random low-amplitude envelopes of high probability, approaches a Rayleigh distribution. Hence, it can be approximated by a straight line (R). The higher region of the curve, representing high-impulsive envelopes of low probability, approaches a power Rayleigh distribution. It can also be approximated by a straight line (PR). The center region of the curve corresponds to a circular arc tangent to the two straight lines. The circular arc is also tangent to the line (T) which is parallel to line (BI), which bisects the acute angle formed by the intersection of the Rayleigh and power Rayleigh lines. Four parameters are necessary to specify a unique pair of lines and an arc. They are:

1. Slope of the power Rayleigh line;
2. Point through which the power Rayleigh line passes;
3. Point through which the Rayleigh line passes (the slope is known to be $\frac{-1}{2}$);
4. Parameter determining the radius of the circular arc.

Crichlow defined the four parameters as follows:

1. $X = -2s$, where s is the slope of the power Rayleigh line;
2. C (dB) = the dB difference between the power Rayleigh line and the Rayleigh line at $p = 0.01$;
3. A (dB) = the dB value of the Rayleigh line at $p = 0.5$;
4. B (dB) = the dB difference between the y' -axis intercepts of lines (BI) and (T).

Experimentally measured APDs indicate that the parameter B is linearly related to first order to the parameter X by

$$ B = 1.5(X - 1) \tag{73} $$

Thus, once the values of parameters X, C, and A are known, a unique APD can be constructed. The X, C, and A parameters vary according to the V_d value of the APD. Wilson [47] has calculated the values of these parameters for V_d values of 4.0 through 30.0. Parameter values for $V_d = 2.0$ and 3.0 were determined by extrapolating upon Wilson's values along with experimental curve fitting. The above transformations were thoroughly tested with a total of 20,000 samples, for each of ten different V_d values. The APDs were then determined by experimental

[4] A Rayleigh function plots as a straight line with slope = −.5.

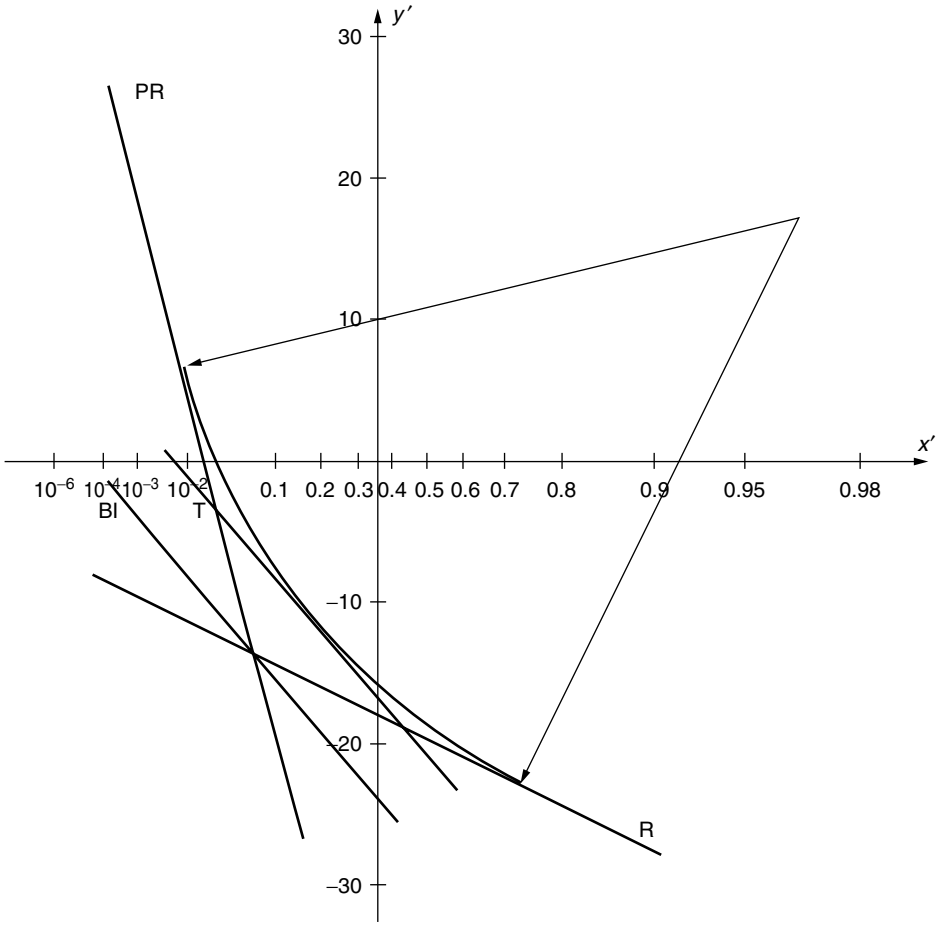

Figure 7. Crichlow APD model.

measurements. This can be seen in Fig. 8 for V_d ratios of 6, 10, and 14 dB. It is clear from the figure that more than 20,000 samples should be used to test the APD curves for values of Δ greater than 20.

4.5. Comparison of Selected APD Results for Different Models

In this section the Middleton Class B model, the truncated Hall model, and the empirical model are compared with CCIR 322 data [5]. The main point of this section is to show that numerous models can be used to obtain good fits to measured APD data and that no matter what model is selected, error rate performance estimates will be the same as long as the noise samples are independent.[5]

Figure 9 shows a comparison of the APD curves for the truncated Hall model with $V_d = 10$ dB, the Middleton Class B model with $A_\alpha = 1, \alpha = 1$, and $W = 0.007$, and CCIR 322 data with $V_d = 10$ dB. For reference purposes, the Rayleigh APD is also shown; it is known that the Rayleigh distribution corresponds to $V_d = 1.05$ dB. The

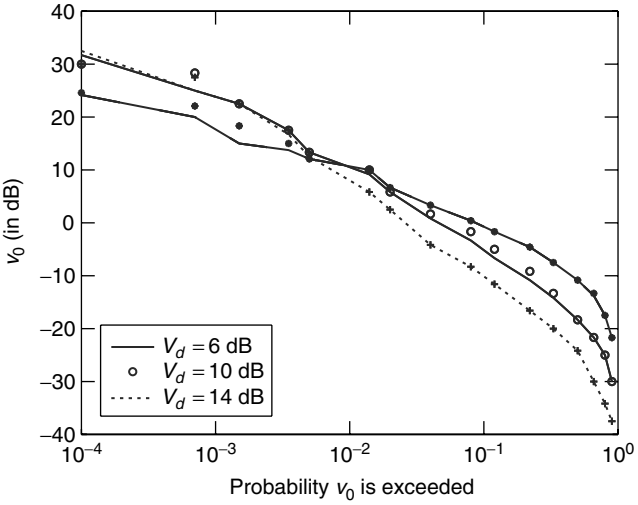

Figure 8. Verification of Crichlow APD using Wilson's parameters.

curves are plotted on semilog paper where the vertical scale is in dB above the rms level. For the trancated Hall case, the rms level is $\gamma\sqrt{D-1}$ and for the Rayleigh case the rms level is $\sqrt{2}\gamma$. The parameter W provides the normalization for the Class B Middleton model. A comparison of the empirical model for $V_d = 10$ dB

[5] Atmospheric noise measured data reveals that noise samples are correlated because of multiple lightning discharges. Nevertheless, it can be shown that the APD is essentially the same; higher order statistics will, however, be affected, although this behavior is rarely modeled. See Ref. 9.

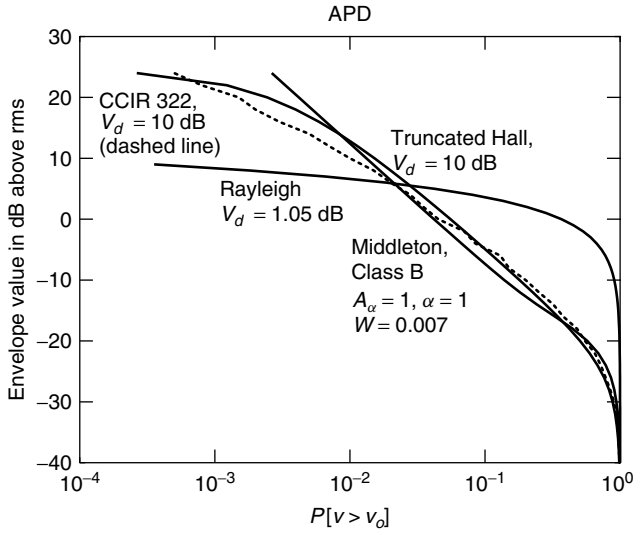

Figure 9. Comparison of some atmospheric noise models.

is presented in Fig. 8. Good fits with CCIR 322 data are obtained in these particular examples, especially for envelope values in dB above rms that are below about 20 dB. Computational problems arise with both the truncated Hall model and the Class B model for large envelope values. In the trancated Hall case the curve stops when the truncation point is exceeded. In the Class B case the exact formulation in Eq. (61) converges poorly so that the approximation of Eq. (66) is involved for $z > 100$. The Class B parameters were selected to provide good but not necessarily an optimum fit to the CCIR 322 data.

5. DETECTOR STRUCTURES IN NON-GAUSSIAN NOISE

At this point it is apparent that numerous models exist to represent non-Gaussian noise. The development of optimal structures would, in principle, require computation of the likelihood ratio or log-likelihood ratio. Because of the non-Gaussian noise, however, each model can in general lead to a unique optimum detector structure. This section describes a few of the common cases which have been derived and built. As indicated below in Section 5.1, an optimal detector structure under the conditions of small snr leads to the general form of a nonlinearity followed by a linear correlator or matched filter demodulation for making a decision. Figure 10 shows the general structure. A wide variety of nonlinearities have been used, including hard limiters, soft clippers, hole punchers, and logarithmic devices [10].

Section 5.2 shows one detector structure that has been developed based upon Hall's model. Finally, in Section 5.3, some commonly-used *ad-hoc* structures are presented.

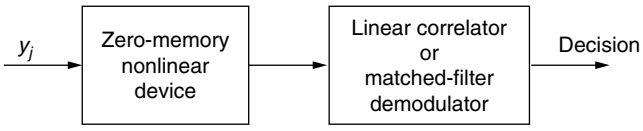

Figure 10. Common detector structure for impulsive noise.

5.1. Weak Signal Detection

A commonly derived receiver structure for the case of a weak signal is referred to as the locally optimum Bayes' detector (LOBD).(The LOBD is also called a low snr detector or a threshold receiver.) References 17, 19, and 40 give up-to-date derivations of this detector, although Ref. 3 gives one of the earliest presentations. Following the presentations in Refs. 3 and 40, we define two hypotheses as

$$\vec{\mathbf{y}} = \vec{\mathbf{u}}_i + \vec{\mathbf{n}}, \quad i = 0, 1 \tag{74}$$

where each vector contains k samples. The likelihood ratio is given by

$$L(\vec{y}) = \frac{p_1(\vec{y})}{p_0(\vec{y})} = \frac{p_{\mathbf{n}}(\vec{y} - \vec{u}_1)}{p_{\mathbf{n}}(\vec{y} - \vec{u}_0)} \tag{75}$$

We now expand the pdf $p_{\mathbf{n}}(\vec{y} - \vec{u})$ in a vector Taylor series and ignore, for small signals, terms of degree two and higher. This results in

$$p_{\mathbf{n}}(\vec{y} - \vec{u}_i) \simeq p_{\mathbf{n}}(\vec{y}) - \sum_{j=1}^{k} \frac{\partial p_{\mathbf{n}}(\vec{y})}{\partial y_i} u_{ij} \tag{76}$$

Substituting this expression into the likelihood ratio above yields

$$L(\vec{y}) = \frac{p_{\mathbf{n}}(\vec{y}) - \sum_{j=1}^{k} \frac{\partial p_{\mathbf{n}}(\vec{y})}{\partial y_i} u_{1j}}{p_{\mathbf{n}}(\vec{y}) - \sum_{j=1}^{k} \frac{\partial p_{\mathbf{n}}(\vec{y})}{\partial y_i} u_{0j}} \tag{77}$$

Dividing the numerator and denominator by $p_{\mathbf{n}}(\vec{y})$ results in

$$\begin{aligned} L(\vec{y}) &= \frac{1 - \sum_{j=1}^{k} \frac{1}{p_{\mathbf{n}}(\vec{y})} \frac{\partial p_{\mathbf{n}}(\vec{y})}{\partial y_i} u_{1j}}{1 - \sum_{j=1}^{k} \frac{1}{p_{\mathbf{n}}(\vec{y})} \frac{\partial p_{\mathbf{n}}(\vec{y})}{\partial y_i} u_{0j}} \\ &= \frac{1 - \sum_{j=1}^{k} \frac{d}{dy_j} \ln p_{\mathbf{n}}(y_j) u_{1j}}{1 - \sum_{j=1}^{k} \frac{d}{dy_j} \ln p_{\mathbf{n}}(y_j) u_{0j}} \end{aligned} \tag{78}$$

The unity constant does not affect the decision and can be ignored leading to the decision to choose H_1 if[6]

$$-\sum_{j=1}^{k} \frac{d}{dy_j} \ln p_{\mathbf{n}}(y_j) u_{1j} > -\sum_{j=1}^{k} \frac{d}{dy_j} \ln p_{\mathbf{n}}(y_j) u_{0j} \tag{79}$$

The receiver structure for this case is depicted in Fig. 11 and is often referred to as a threshold receiver, that is,

[6] These results assumes equal a priori probabilities and uniform costs.

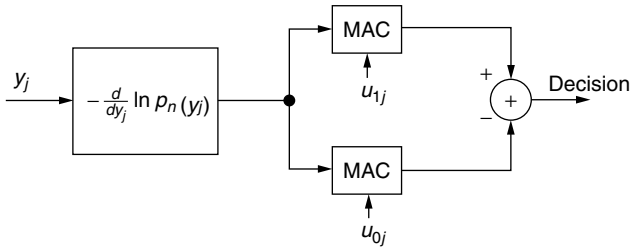

Figure 11. LOBD detector.

LOBD, because the signal is assumed to be small. It is apparent that the structure of Fig. 11 is an example of that of Fig. 10.

It is instructive to examine the form of Fig. 11 when the noise is white and Gaussian. In this case, the density is

$$p_{\mathbf{n}}(\vec{y}) = \frac{1}{(2\pi\sigma^2)^{k/2}} \exp\left(-\frac{1}{2\sigma^2}\sum_{j=1}^{k} y_j^2\right), \tag{80}$$

$$\ln p_{\mathbf{n}}(\vec{y}) = -\frac{k}{2}\ln(2\pi\sigma^2) - \frac{1}{2\sigma^2}\sum_{j=1}^{k} y_j^2, \tag{81}$$

and

$$-\frac{d}{dy_j}\ln p_{\mathbf{n}}(\vec{y}) = \frac{y_j}{\sigma^2} \tag{82}$$

In other words, the nonlinearity, in this case, is linear. This is comforting for we know that the optimum detector in white Gaussian noise is linear.

An example of a non-Gaussian noise distribution for which the detector can be solved in its entirety is the Laplace distributed noise. In this case, k independent noise samples comprise the vector $\vec{\mathbf{n}}$ so that the received signal vector can be represented by

$$\vec{\mathbf{y}} = \vec{\mathbf{u}}_i + \vec{\mathbf{n}} \tag{83}$$

where $\vec{\mathbf{u}}_i,\ i = 0, 1$ is the transmitted signal vector. The pdf of $\vec{\mathbf{n}}$ is given by

$$p(\vec{n}) = \frac{1}{\sqrt{2\sigma^2}} \exp\left(-\sqrt{\frac{2}{\sigma^2}}\sum_{j=1}^{k}|n_j|\right) \tag{84}$$

Under hypothese $H_i, i = 0, 1$ the pdf of $\vec{y}$ becomes

$$p(\vec{y}_j) = \frac{1}{\sqrt{2\sigma^2}} \exp\left(-\sqrt{\frac{2}{\sigma^2}}\sum_{j=1}^{k}|y_j - u_{ij}|\right) \tag{85}$$

The log-likelihood ratio can now be computed as

$$\ell(\vec{y}) = \ln\frac{p_1(\vec{y})}{p_0(\vec{y})} = \sqrt{\frac{2}{\sigma^2}}\sum_{j=1}^{k}[|y_j - u_{0j}| - |y_j - u_{1j}|] \tag{86}$$

and the decision rule is to choose H_1 when[7]

$$\sum_{j=1}^{k}|y_j - u_{0j}| > \sum_{j=1}^{k}|y_j - u_{1j}| \tag{87}$$

Continuing with the example, if we let $u_{1j} = c$ and $u_{0j} = -c$ for all j and define the function $g(y_j)$ as

$$g(y_j) = |y_j + c| - |y_j - c|, \tag{88}$$

then the receiver structure can be obtained and is shown in Fig. 12 where the Laplace noise nonlinearity is shown in Fig. 13. This detector structure is of the general form of Fig. 11 but in this example it is not necessary to impose the weak signal restriction.

5.2. Hall's Log-Correlator

Hall derived the optimum receiver for Hall model noise by forming a likelihood ratio computed from the pdf of the complex envelope of the noise as shown in [13]. A few definitions are required before the pdf of the complex noise envelope can be obtained. Assume samples of the received noise are taken at a spacing Δt and let $\mathbf{v}_g(t)$ be the complex envelope of the noise $\mathbf{n}_g(t)$ in Eq. (2). We further assume that $\mathbf{v}_g(t)$ has the covariance

$$E\{\mathbf{v}_g(t_i)\mathbf{v}_g^*(t_j)\} = N_0\delta_{ij}, \quad i, j = 1, \ldots, k \tag{89}$$

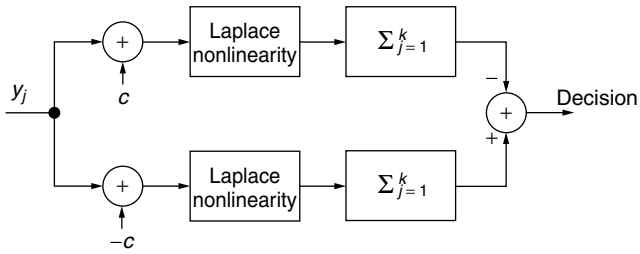

Figure 12. Detector structure for laplace noise.

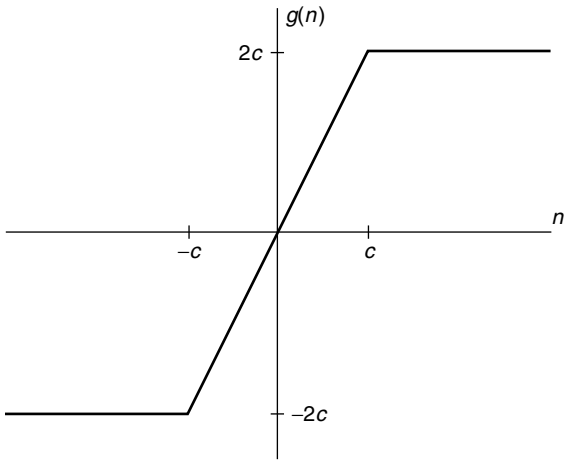

Figure 13. Laplace noise nonlinearity.

[7] This decision rule assumes equal a priori probabilities and uniform costs.

where k represents the number of received complex samples. If the noise signal has a duration T and $2B$ is the RF bandwidth of the receiver front-end, $k \approx 2BT$, and a good approximation of the complex noise envelope results.

The process $\mathbf{b}(t)$, which is the reciprocal of the slowly varying modulating process $\mathbf{a}(t)$ in Eq. (2) has a zero mean with a pdf given by Eq. (24) and a covariance that is assumed to be

$$E\{\mathbf{b}(t_i)\mathbf{b}(t_j)\} = \frac{B_0}{2}\delta_{ij}, \quad i,j = 1, \cdots, k \tag{90}$$

Let $\vec{\mathbf{z}}$ be a vector of k complex envelope samples for the Hall model in Eq. (2) for the special case $\theta = 2$. Hall then shows that the pdf of the noise in the independent sample case can be expressed as

$$p(\vec{z}) = \left(\frac{\gamma_2}{2\pi}\right)^k \prod_{j=1}^{k} \frac{1}{[|z_j|^2 + \gamma_2^2]^{3/2}} \tag{91}$$

where $\gamma_2^2 = (N_0\Delta t)/B_0$. Under hypothesis H_i, $i = 0, 1$, the received signal vector $\vec{\mathbf{y}}$ can be written as a sum of the complex signal vector $\vec{u}_i$ and the noise vector $\vec{\mathbf{z}}$ as

$$\vec{\mathbf{y}} = \vec{u}_i + \vec{\mathbf{z}}, \quad i = 0, 1 \tag{92}$$

and from Eq. (91) the pdf of $\vec{\mathbf{y}}$ is given by

$$p(\vec{y}) = \left(\frac{\gamma_2}{2\pi}\right)^k \prod_{j=1}^{k} \frac{1}{[|y_j - u_{ij}|^2 + \gamma_2^2]^{3/2}} \tag{93}$$

The log-likelihood ratio can then be written as

$$\ell(\vec{y}) = \ln \frac{p_1(\vec{y})}{p_0(\vec{y})} = \sum_{j=1}^{k} \ln[|y_j - u_{0j}|^2 + \gamma_2^2]^{3/2} - \sum_{j=1}^{k} \ln[|y_j - u_{1j}|^2 + \gamma_2^2]^{3/2} \tag{94}$$

Note that the power 3/2 has no effect on the decision so that an equivalent rule is to choose H_1 when

$$\sum_{j=1}^{k} \ln[= |y_j - u_{0j}|^2 + \gamma_2^2] > \sum_{j=1}^{k} \ln[|y_j - u_{1j}|^2 + \gamma_2^2] \tag{95}$$

Hall's log-correlator is depicted at baseband in Fig. 14. Note that the term γ_2^2 is referred to as the bias and must in general be estimated. Although the log-correlator receiver was developed for $\theta = 2$, Hall shows that the decision rule of Eq. (95) is the same when γ_2^2 is replaced by $\gamma^2 = m\gamma_2^2$.

Exact error rate computations for this receiver are intractable even with a central limit theorem argument which requires only the first and second moments of the log of the decision variable. Instead Hall computes bounds on the probability of error. Below, in Section 6.2, we present error rate results for the log-correlator and other receiver structures obtained by simulation.

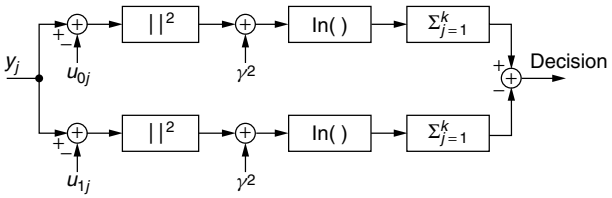

Figure 14. Log-correlator receiver.

5.3. Ad Hoc Receiver Structures

Optimal Zero Memory Nonlinear (ZMNL) devices are often difficult to implement in practice. Thus, more practical, yet suboptimal, nonlinearities are used. Figure 15 shows the three most common ad hoc nonlinearities. In Fig. 15a the transfer characteristics of a hole puncher are shown. In this case, the input signal is passed undistorted as long as its envelope is smaller than a threshold t_h. If any samples of the envelope are larger than t_h, these samples are totally suppressed.

In Fig. 15b, the transfer characteristics for a clipper ZMNL device is shown. Its characteristics are similar to a hole puncher except that if the envelope exceeds t_h, a constant output proportional to t_h is available rather than a total suppression of the signal. By allowing t_h to get very small relative to the signal plus noise envelope, the clipper approximates a hard limiter, whose characteristics are shown in Fig. 15c.

6. SELECTED EXAMPLES OF NOISE MODELS, RECEIVER STRUCTURES, AND ERROR RATE PERFORMANCE

Sample results are presented in this section for several noise models and corresponding receiver structures. No attempt is made to be exhaustive because in general, every noise model yields a different receiver structure and its associated error rate performance. Conversely, as mentioned previously, if the APD of the noise models is essentially the same, then the resulting error rate performance for any *specific* receiver structure will be similar for all the noise models, assuming independence of the noise samples.

The results provided here illustrate the available improvement in error rate performance when a nonlinear receiver is utilized in the presence of impulsive noise. Sample cases presented below include:

- Bandpass limiter and linear correlator in Gaussian noise, outlined in Section 6.1.

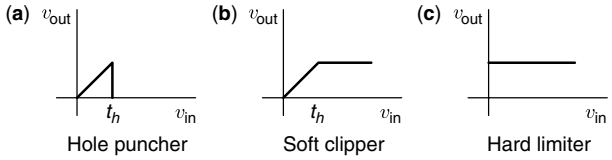

Figure 15. Ad Hoc zero memory nonlinearities used on atmospheric noise channel receivers.

- Bandpass limiter, linear correlator, and log-correlator performance in truncated Hall noise with a V_d of 10 dB, presented in Section 6.2.
- Weak signal receiver with Middleton noise, presented in Section 6.3, and
- Hole puncher and soft clipper in empirically generated noise with a V_d of 6 dB, detailed in Section 6.4.

In the impulsive noise cases multiple samples per symbol are assumed to allow the matched filter or linear correlator to average the residual noise following the nonlinearity. It can be shown that the case of a single sample per symbol provides no advantage from use a nonlinearity. Error rate performance is obtained by simulation for coherent antipodal signaling with the number of samples per symbol denoted by NSAM and the number of symbols used denoted by NSYM. For an RF receiver filter bandwidth denoted by $2B$ and a symbol duration of T, then NSAM $= 2BT$ so that the signal to noise ratio SNR is related to the energy contrast ratio E_b/N_0 by SNR*NSAM $= E_b/N_0$.

6.1. Bandpass Limiter and Linear Correlator in Gaussian Noise

Because the optimum receiver in independent Gaussian noise is a linear receiver, use of a bandpass limiter (or any other nonlinearity) in this case prior to the linear correlator will therefore degrade the error rate performance. Figures 16 and 17 show the BPL/linear correlator and linear correlator receivers respectively. These receivers structures were used in a simulation to estimate error rate performance. The simulated transmitted sequence was assumed to be symbols with values that are ± 1. White Gaussian noise was added to the transmitted sequence and then input to each receiver. Using MATLAB, error rate performance shown in Fig. 18 was obtained for NSAM $= 10$ and NSYM $= 5000$. The theoretical error rate is expressed as

$$P_e = \tfrac{1}{2}\text{erfc}\left(\sqrt{\frac{E_b/N_0}{\text{NSAM}}}\right) \tag{96}$$

The simulation shows good agreement between the linear correlator simulation and the theoretical performance and

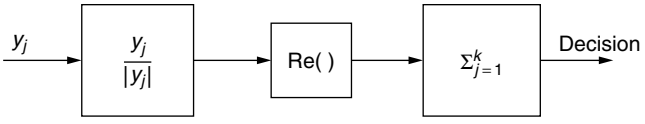

Figure 16. Bandpass limiter/linear correlator receiver.

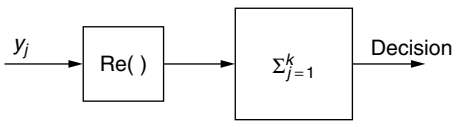

Figure 17. Linear correlator receiver.

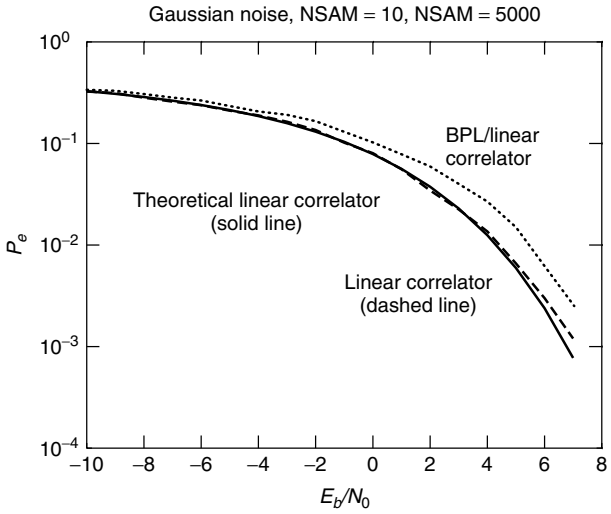

Figure 18. Error rate performance for a linear and BPL/linear receiver in Gaussian noise.

that the BPL performance is approximately 1-dB poorer than the linear receiver for larger values of E_b/N_0.

6.2. Bandpass Limiter, Linear Correlator, and Log-Correlator in Truncated Hall Noise

To generate the noise samples, in-phase and quadrature samples of the Hall model noise are computed from

$$\mathbf{n}_{0r} = |\mathcal{T}| \cos \mathbf{u} \tag{97}$$

and

$$\mathbf{n}_{0i} = |\mathcal{T}| \sin \mathbf{u} \tag{98}$$

where $\mathcal{T}$ is a random variable from a generalized t distribution and $\mathbf{u}$ is uniformly distributed in the interval $(-\pi, \pi)$. The random variable $\mathcal{T}$ is defined by

$$\mathcal{T} = \frac{\mathcal{G}}{\sqrt{\frac{1}{m}\sum_{i=1}^{m} \mathbf{x}_i^2}} \tag{99}$$

where $\mathcal{G}$ is a zero mean Gaussian random variable with variance σ_1^2 and the $\mathbf{x}_i$ are independent zero mean Gaussian distributed random variables with variance σ^2. Note that $\sum_{i=1}^{m} \mathbf{x}_i^2$ is chi-squared with m degrees of freedom and is independent of $\mathcal{G}$. Therefore $|\mathcal{T}|$, can be generated from the ratio of a Rayleigh distributed random variable $\mathbf{r}$ to the square root of a chi-squared random variable with m degrees of freedom. $\mathbf{r}$ in turn can be obtained from a transformation of a uniformly distributed random variable $\mathbf{u}$ on the interval (0, 1) by

$$\mathbf{r} = [-2\sigma_1^2 \ln \mathbf{u}]^{1/2} \tag{100}$$

The Hall bias term γ is computed from $\gamma^2 = m\sigma_1^2/\sigma^2$. The above procedure can also be used to compute noise samples from a truncated Hall distribution. In such a case, the samples obtained from the Hall model noise with $\theta = 2$

are generated and samples whose amplitude exceed the truncation value v_m are discarded.

Before presenting the simulation results for the truncated Hall model, a result for one sample per symbol in a linear receiver is derived. For symbols $\mathbf{u}$ that assume the values of $\pm a$ with equal probability, the error rate can be expressed as

$$P_e = P\{\mathbf{u} > 0 \mid \mathbf{u} = -a + \mathbf{n}\} \tag{101}$$

where $\mathbf{n}$ is the additive truncated Hall model noise with parameter γ, v_m, and $\theta = 2$. Because the pdf of $\mathbf{n}$ is

$$p(n) = \frac{1}{\pi\gamma[(\frac{n}{\gamma})^2 + 1]} \tag{102}$$

it follows that

$$P_e = \int_0^{n_m} \frac{du}{\pi\gamma[(\frac{u+a}{\gamma})^2 + 1]} \tag{103}$$

where n_m is the maximum value of the noise corresponding to the truncation point. For high V_d, the truncation point can be approximated as infinite so that the resulting error probability becomes

$$P_e \approx \frac{1}{2} - \frac{1}{\pi}\tan^{-1}\left(\frac{a}{\gamma}\right) \tag{104}$$

For $a = 1$, the average transmitted power is unity and the noise power is $\gamma^2(D-1)$ so that the parameter γ can be replaced by

$$\gamma = \sqrt{\frac{1}{(D-1)E_b/N_0}} \tag{105}$$

Figure 19 shows[8] the error rate results for the linear correlator, BPL/linear correlator, and log-correlator receivers for NSAM = 10 and NSYM = 10000; for reference the theoretical error rate for one sample per symbol and $a = 1$ is also shown. The curves are obtained by simulation using MATLAB. It can be seen that the log-correlator receiver is the best and the BPL/linear correlator is slightly degraded. Conversely, both nonlinear receivers are significantly better than the linear correlator. These results neglect pulse dependencies from multiple stroking where the bursty nature of measured atmospheric noise tends to limit the performance improvement of nonlinear receivers to an amount that is on the order of the V_d value [15,11].

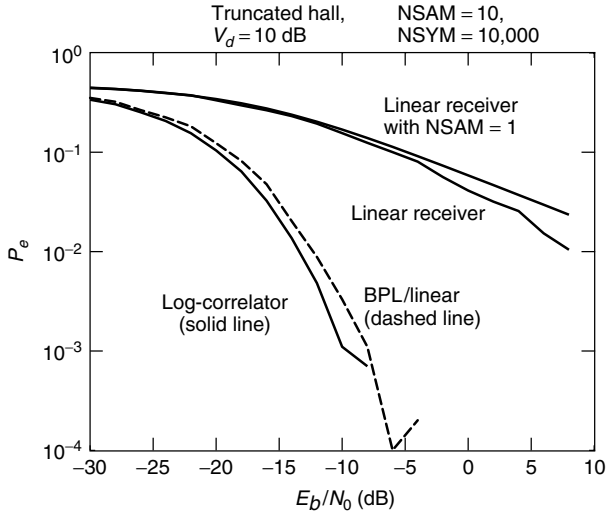

Figure 19. Error rate performance for various receivers in truncated hall noise.

[8] Note that some scatter occurs at low estimated error probabilities as a result of an insufficient number of samples for the estimate.

6.3. WEAK SIGNAL DETECTOR IN MIDDLETON NOISE

Returning to the result of Fig. 11, Spaulding and Middleton, in Refs. 37 and 40, provide a general result for the error rate performance of antipodal signals in Middleton's Class A noise as

$$P_e = \tfrac{1}{2}\text{erfc}\,(\sqrt{k\Gamma_o f/2}),\ \Gamma_o f \ll 1 \tag{106}$$

where Γ_o is the signal to noise ratio and f is defined as

$$f = \int_{-\infty}^{\infty}\left[\frac{d}{dy}\ln p_n(y)\right]^2 p_n(y)\,dy \tag{107}$$

Performance results for noncoherent signaling in Middleton's Class A noise and weak signals are provided by Spaulding and Middleton in Refs. 37 and 41, leading to an approximate error rate for the LOBD as

$$P_e = \tfrac{1}{2}\ \text{erp}\left(-\frac{k\Gamma_o f}{4}\right),\ \Gamma_o f \ll 1 \tag{108}$$

6.4. Hole Puncher and Clipper in Empirically Generated Noise

In this section the noise is generated using the empirical method described in Section 4.4 using $V_d = 6$ dB. The error rate performance, displayed in Figs. 20 and 21, for the soft clipper and hole puncher receivers respectively, are obtained parametric in the threshold t_h in dB above the average envelope. Although these figures are displayed using MATLAB, the original data is derived from a simulation reported on in Ref. 36. The simulated transmitted signal is Minimum Shift Keying (MSK) with a two-sided bandwidth of 900 Hz and a signaling rate of 100 bps. The best threshold for the soft clipper is 0 dB with little degradation for a setting of 3 dB. The best threshold for the hole puncher is 3 dB for high signal to noise ratios. It should be noted that the performance for both nonlinearities obtained with their optimum thresholds is about the same, as evident in Fig. 22. For reference, a Gaussian error rate curve for coherent detection of MSK is displayed in all three figures.

7. CONCLUSIONS

This article has provided a brief introduction on impulsive noise physical phenomena, impulsive noise statistics,

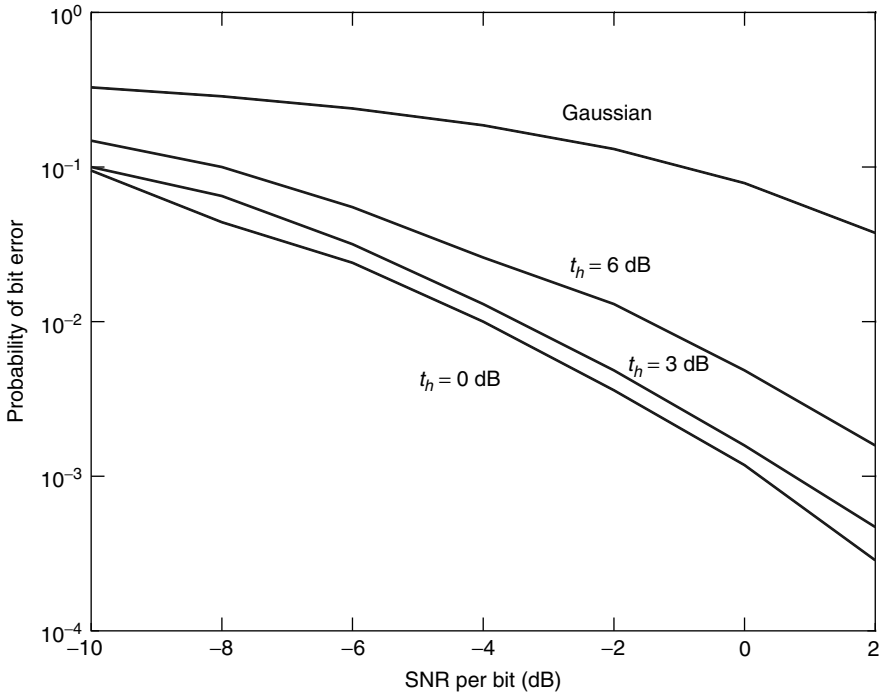

Figure 20. Probability of error as a function of SNR per bit with clipper threshold as a parameter.

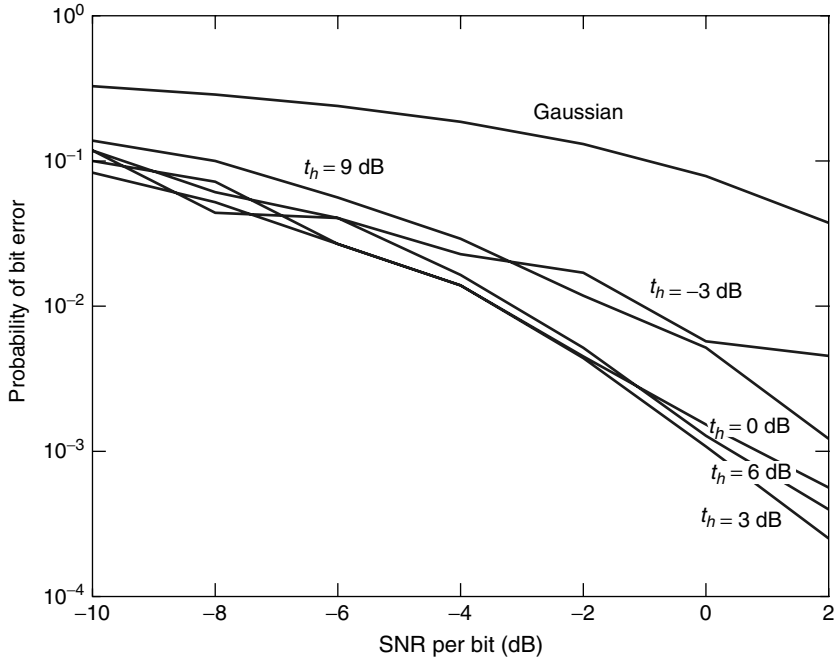

Figure 21. Probability of error as a function of SNR per bit with hole-puncher threshold as a parameter.

appropriate utilized receiver structures and some selected BER performance results. A few significant points that have been presented are now emphasized:

1. There is no single noise model that can be used as a representation of all impulsive noise channels.
2. Physical measurements of the impulsive noise characteristics are generally needed to understand the behavior of the noise allowing noise models, receiver structures, and performance estimates to be obtained.
3. Optimum receiver structures are nonlinear but are "optimum" only in terms of the noise model assumed.
4. Specific channels require knowledge of higher order statistics to completely characterize the noise process and produce reliable performance estimates.

It is anticipated that future work on the statistical characterization of impulsive noise for various communications channels will involve new measurements and continued emphasis on first order statistical models that

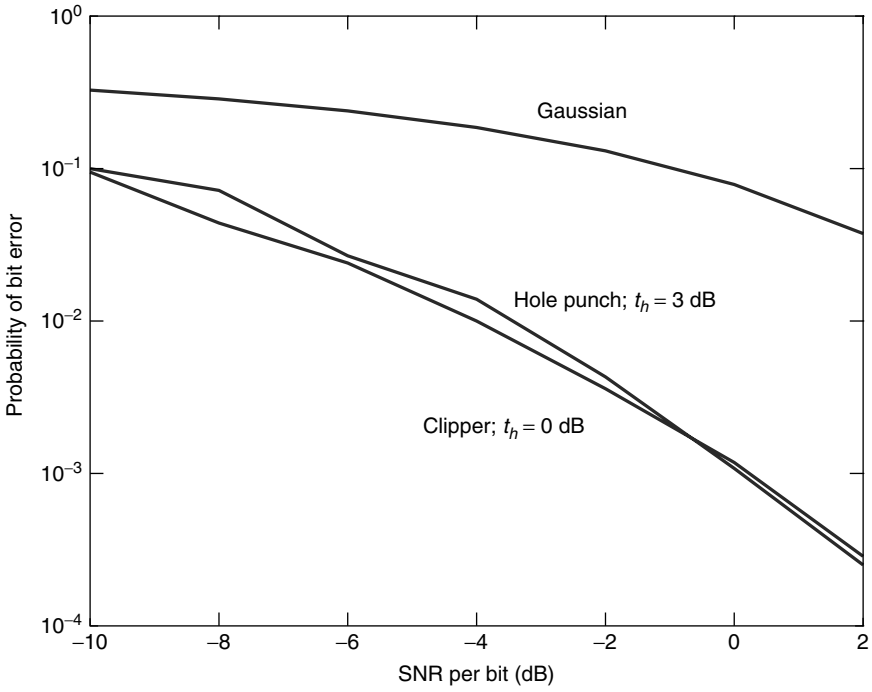

Figure 22. Comparison of bit error rates for two nonlinearities.

are analytically tractable. It is also expected that significant research will focus on the time statistics of the noise for the channel under investigation. Gratifying results may very well be attained by continued emphasis on the underlying physical process such as that developed for statistical physical models.

BIOGRAPHIES

Arthur A. Giordano formed AG Consulting, LLC in June 2001 to consult in the field of military and commercial communications. Specific consulting activities have included: 1) investigation of secure net broadcast for voice and data to evaluate the potential interoperability of commercial cellular systems including CDMA, GSM, TDMA, and next generation (3G) cellular systems with planned military systems; 2) investigation and documentation on a comparison of SMR, CDMA, 1xRTT, and GPRS 3) expert witness on cases involving RF coverage and next generation CDMA; and 4) development of a satellite channel simulator. From 1993 to June 2001, he worked as a wireless manager for GTE and later Verizon Laboratories and was primarily involved in the analysis, design, and deployment of cellular and fixed wireless networks. From 1985 to 1993, he was a vice president at CNR responsible for a critical government program to provide secure, formatted message traffic for a user network employing multimedia communications assets consisting of landlines, satellites, and HF radios. Prior to 1985, he held several engineering positions encompassing communications network architecture development, spread spectrum communications, modulation and coding designs, adaptive signal processing, and measurement and modeling of atmospheric noise. He has a Doctorate from the University of Pennsylvania in EE and MS and BS degrees in EE from Northeastern University. He has published numerous technical articles, holds two patents, has coauthored a book entitled Least Square Estimation with Applications to Digital Signal Processing and is currently coauthoring a text on Detection and Estimation Theory.

Thomas A. Schonhoff received his Bachelor's degree from M.I.T., his Master's degree from Johns Hopkins University, Baltimore, Maryland, and his Ph.D. from Northeastern University, Boston, Massachusetts. He has worked at six different corporations, although he has been with LinCom Corporation (now Titan System Corporation, Communication and Software Solutions Division) since 1985. For the last 21 years, Dr. Schonhoff has also taught graduate courses as an adjunct at Worcester Polytechnic Institute, Massachusetts.
