Fitting these conditions assumes that different forensic operators rely on consistent methodologies and efficient tools at all the steps of the evidence management process. A basic consideration is to ensure that all the operations on digital evidence should be made by authorized persons and should be fully documented. Moreover, to identify, collect, and analyze pieces of evidence, several tools providing reliability and quality should be used. Disk editors and disk imaging tools may be used for disk forensics, whereas the use of log analysis tools and sniffers may be of interest to handle network evidence.

Several attempts to propose standard methodologies respecting the requirements discussed above have been made by governmental and international organizations. In its *Good Practice Guide for Computer Based Evidence*, the Association of Chief Police Officers (ACPO, 2003) defines four principles that have to be followed during an investigation process. These principles are given below (Association of Chief Police Officers, 2003):

- First Principle: No action taken by Police or their agents should change data held on a computer or other media, which may subsequently be relied on in Court.
- Second Principle: In exceptional circumstances where a person finds it necessary to access original data held on a target computer, that person must be competent to do so and to give evidence explaining the relevance and the implications of their actions.
- Third Principle: An audit trail or other record of all processes applied to computer-based evidence should be created and preserved. An independent third party should be able to examine those processes and achieve the same result.
- Fourth Principle: The Officer in charge of the case is responsible for ensuring that the law and these principles are adhered to. This applies to the possession of, and access to, information contained in a computer. They must be satisfied that anyone accessing the computer, or any use of a copying device, complies with these laws and principles.

It appears that the ACPO guideline relies on the fact that digital evidence has the same nature as traditional evidence. Therefore, it should be subject to the same rules and laws. Despite their popularity, the ACPO principles, in their current version have two major shortcuts. First, they do not guarantee some of the fundamental properties

of digital evidence. For example, they are not sufficient to produce integrity because data in electronic format are intrinsically volatile and, thus, can disappear without user intervention. In other terms, the four principles are necessary, but not sufficient, to provide integrity. Another limit is that the ACPO guide is limited to the investigation of stand-alone computers. It does not address cases where a suspect performs a network attack.

Other standards have also been developed for the exchange of digital evidence between nations or to recommend preservation principles. Nonetheless, they have the same limitations as the ACPO guide because they have a too low technical detail level. Recently, the Internet Engineering Task Force (IETF) published a Request for Comments (RFC) dealing with digital evidence collection and archival (RFC 3227). In addition, Yasinsac and Manzano (2001) proposed a set of practical policies showing how to handle the digital evidence in such a way that the efficiency of the forensic process is improved.

## DISK FORENSICS

When trying to retrieve data from a computer to search for pieces of evidence, the forensic examiner should possess the necessary knowledge to avoid losing inadvertently the evidence. Particularly, he or she should know exactly how data are managed inside a computer. In the following, a brief explanatory overview of the storage possibilities provided by computers is given. Then various techniques that are commonly used to hide and recover information are described. Finally, several problems that might be faced by the investigator are discussed.

### Storing Data in Computers

Putting aside forensic-related issues, electronic data storage mechanisms follow two types: short-term memory and long-term memory. The former, which consists typically of the random access memory (RAM), has the virtue of being able to convey helpful information to the investigator such as logged users, the running processes, or files in use. The main factor of interest of this kind of memory is that most of its content is tightly related to the operating system (OS). However, it is unfortunately rarely advisable to explore the RAM during investigation as it is cleared out when the computer is switched off. Thus, for convenience of making use of this volatile memory, the elapsed time between the last doubtful activities and the instant where the investigator seizes and accesses the computer should be minimal. This constraint is emphasized by the fact that some critical information expires after 1 or 2 min. This makes recourse to this option very rare as it is conditioned by many events that are not easy to combine.

Long-term memories, which can take many forms (e.g., hard disks, floppies, tapes, and CDs), are commonly used to store personal information that has no direct relation with the machine state. Therefore, analyzing the hard disk of a machine under examination may reveal valuable information about attacker. Nevertheless, criminals are aware of this opportunity and they often try to obfuscate the situation by making their secret information inaccessible or by making it unreadable. Another possible use of long-term memory is to partially recover the

data included in the short-term memory to prevent it from being lost. This can be achieved, for example, by monitoring and logging particular actions on the system.

## Hiding and Recovering Information from Hard Disks

As it has been pointed out in the foregoing discussion, hard disks constitute a primary source of digital evidence for the forensic analyst. Therefore, they should be handled carefully to gather as much information as possible. Primarily, the investigator should perform an image, or exact copy, of the hard disk using free disk controllers (on the same computer) or network connections (from other machines). Then, all the forensic operations will be carried out on this image to preserve the original data. Obviously, disk imaging differs from copying the content of a hard disk on another media using standard functionalities implemented in OSs. Practically, an image is a file from which an exact duplicate of a bit stream can be constructed. In other terms, an image is a bit-for-bit copy of a hard disk content. Therefore, disk imaging tools should follow several principles to guarantee this property (National Institute of Standards and Technologies, 2001). Nonetheless, there are no standard guidelines for building hard disk images because this operation is often affected by hazardous events, which are essentially related to the system attacker behavior. For example, prior to any other operation, a cryptographic hash function of the content should be computed to check whether the imaging has resulted in an exact duplicate. In addition, a virus scan must be applied to annihilate the effect of potential malicious codes that might have been left deliberately on the disk. This sequence might, in several cases, be inconsistent from a security point of view. If imaging is done before proceeding to virus detection, potential pieces of malicious code can propagate from the original hard disk (subjected to the digital forensic process) to the disk that will support the duplicate, which belongs to the investigation platform. The investigator's experience counts for most in similar cases. In fact, he or she should be aware of the different means the criminals may use to hide their data or actions.

A possible approach here is to act at the partitioning stage by marking several partitions as hidden or leaving unused spaces that can be filled through the use of specific disk editors. Another category of free sectors that can be exploited for illegal purposes consists in the unassigned sectors that are left between partitions. File systems, conversely, present other possibilities to the suspect as he or she may delete some files to recover them later. Effectively, several OSs do not thoroughly erase the sectors containing a deleted file but they mark them as possible to reallocate instead. Of course, the examiner may be asked to perform some more skillful tasks depending on the technical capabilities of the suspect (that could be estimated from his or her profile). In the following, two from the myriad of the hiding techniques that require a relatively high technical level are described.

When being manufactured, hard disks are checked for bad sectors. When a defective sector is found, one possibility is to mark it by setting the bit 0 of the sector flag to

1. Once performed, this operation denies access from the controller to the concerned sector. To avoid affecting the disk capacity, several controllers are able to format substitutive free sectors to replace the damaged ones. Then, the address value of a bad sector is substituted by the address of the newly affected sector. Attackers can use this process, called bad sector mapping, by making access requests to sectors containing incriminating information to other normal sectors. Thus, the content of the hidden sectors cannot be explored through the OS.

The second method for hiding data inside a hard disk stems from the incompatibility between the addressing structures of IDE/ATA hard disks and several BIOS programs. In fact, this makes an important number of physical sectors inaccessible by the execution of BIOS interruption operation. The solution that has been adopted by most of the computer manufacturers to attenuate this space loss is called translated disk geometry. It consists of finding the biggest integer  $n$  such that

$$\left\lfloor \frac{N_{IDE/ATA}^C}{2^n} \right\rfloor \leq 1024, \quad (1)$$

where  $N_{IDE/ATA}^C$  is the number of cylinders of the IDE/ATA geometry and  $\lfloor \cdot \rfloor$  rounds a decimal to the nearest integer to less than or equal to it (also called the floor).

Thus, the number of cylinders considered by the BIOS, denoted  $N_{BIOS}^C$  is expressed as follows:

$$N_{BIOS}^C = \left\lfloor \frac{N_{IDE/ATA}^C}{2^n} \right\rfloor, \quad (2)$$

$$N_{BIOS}^H = N_{IDE/ATA}^H \times 2^n, \quad (3)$$

where  $N_{IDE/ATA}^H$  refers to the number of headers of the IDE/ATA geometry.

A glance at this process shows that a number of sectors are still impossible to access by the BIOS because of the use of the rounding operator  $\lfloor \cdot \rfloor$ . This fact can be exploited by attackers because the disk space that is presumed to be unusable for a BIOS may be recognized by other BIOS programs.

The fundamental limitation of the above techniques is that they are not general. For instance, even though the latter scheme, which is related to BIOS programs, gives a good location for searching for evidence, it cannot be applied to SCSI hard disks. Likewise, the analysis of a laptop may turn out to be somewhat unfeasible because of size constraints. The absence of free disk controllers or network interfaces worsens the situation further.

## Cryptanalysis: Breaking Attackers' Ciphers and Codes

Ciphers and codes have been in use by attackers for centuries as such use has been reported by many historians and novelists. Cryptanalysis, which deals with unraveling encrypted secrets, has also arisen in parallel. It has become a key component of the digital forensic field as

cryptography use by criminals is getting more and more extensive. Old forms of cryptography include the following:

- *Concealment cipher*. This means that the plaintext itself is transmitted after being hidden. Null cipher consists of making most of the letters of the message insignificant. One example would be to put the interesting letters at the end of each word of the transmitted sentence that makes no sense to its reader. Cryptanalysis of concealment writing relies on the examiner experience; no algorithm or mathematical framework has been proposed to this end.
- *Transposition cipher*. This is done by rearranging the letters making up the message according to a given pattern. The major weakness of this form is that it keeps letters' distribution unchangeable. As a result, most of the related cryptanalysis techniques involve frequency analysis.
- *Substitution cipher*. This replaces the original letters by others, which might have been taken from another alphabet. For this category, decryption is used by various methods suitable to their type. The telephone keypad cipher, for example, that is done by replacing digits by the letters corresponding to the telephone buttons can be broken through a combinatorial analysis of the letters. However, it often confuses the investigators, especially if all letters in the alphabet are used on the telephone keypad.

The techniques mentioned above are commonly used by attackers to exchange messages. Thus, the corresponding cryptanalysis methods (Gaines, 1956; Olson, 2000) are particularly applied to investigate e-mail box contents. To protect files on a computer, other techniques that rely mainly on number theory are rather used. They break into two categories: symmetric and asymmetric. They have strong mathematical foundations such as the discrete logarithm problem or elliptic curves. Possible ways to break these ciphers include the brute force attack, which is based on trying all possible key combinations. This is not always advisable to do because such operations may last too long if the key is sufficiently long. Consequently, other techniques should work better in most cases. In view of the fact that a basic assumption of many cryptographic algorithms is to choose large prime numbers, and knowing that designers must always fix a greater upper bound for these prime numbers to ensure an accepted execution time, the cryptanalyst can exploit subsequent weaknesses in the algorithms' implementations. For instance, he or she might try to factor large numbers (for systems like RSA or Rabin-Williams) or solve the discrete logarithm problem (to solve El Gamal ciphers or to break the Diffie-Hellman key exchange algorithm). Moreover, the examiner might exploit potential errors that the encryption party (i.e., the attacker) would have made at the key management level. For example, if the entropy associated to random number generators used at the key generation step is too low, then the keys can be regenerated based on certain knowledge about the original generation circumstances. In addition, having known a portion of a secret

key may lead the investigator to recover the remaining part by using differential cryptanalysis.

## Steganography and Digital Watermarking

Steganography, as opposed to cryptography, deals with concealing the existence of pieces of information instead of protecting them. Most of steganography schemes share the same principle consisting of embedding a secret message  $M$  in a harmless message  $C$  using a key  $K$ . In the steganography jargon,  $C$  and  $K$  are called cover object and stego key, respectively. It is worth mentioning that the structure of the message  $M$  is not modified, although the resulting message  $S$  will be transmitted over an insecure channel. The receiver can reconstruct the relevant message  $M$  knowing the embedding method used by the sender to combine  $M$  and  $Z$ . Next, several widely used steganography applications are briefly discussed:

1. Covert channels: Possible weaknesses in OSs or network and security protocols can be exploited to convey information. For instance, some protocols of the open system interconnect (OSI) layered network model can allow finding excellent cover objects. The transmission control protocol (TCP) considers six reserved bits that can be used to transfer an important quantity of data with regard to the huge number of packets transmitted over normal communication channels. More related subtle methods can be found in Ahsan and Kundur (2002) and Hansel and Stanford (1996).
2. Subliminal channels in cryptographic algorithms: Cryptographic protocols, especially digital signature algorithms, can be used by cyberattackers to exchange hidden information. In Simmons (1993), it has been demonstrated that any digital signature scheme where  $b_0$  bits are used to represent a digital signature that contains  $b_1$  bits of protection (i.e., that will effectively be used by the verification algorithm) can contain subliminal channels if  $b_0 > b_1$ . When all of the  $b_0 - b_1$  bits are used to convey hidden data, the subliminal channel is said to be broadband; otherwise, it is called narrowband.
3. Noise in digital communication infrastructures: Digital signals are often affected by noise and distortion that can be viewed as stochastic processes. Knowing the model of the statistical distribution of this noise, an attacker can code information to make it have the same distribution. In other terms, the hidden data would not be distinguished from noise. The simplest encoding method consists of substituting the redundant parts of a cover signal with portions of a secret message. Bitplane substitution is perhaps the most popular application in this context. It relies on replacing the least significant bit of each octet of data by a bit belonging to the hidden information. However, substitution schemes remain highly vulnerable to signal manipulations. For example, the application of a denoising algorithm would result in a definitive loss of the secret information. Thus, to improve its robustness, steganography can be applied in a transform domain rather than in the spatial domain. The discrete cosine transform (DCT), Laplace filtering, and the wavelet

transform (WT) are examples of transforms that map a signal from a domain to another (e.g., from the time domain to the frequency domain), where the secret data is effectively combined with the cover signal. More sophisticated approaches such as spread spectrum techniques or distortion techniques can also be used to enhance the robustness of the steganographic process.

Different types of attacks against steganography applications can be considered, the most known are given below:

- Stego-only attack: Only the stego object resulting from the combination of the cover object and the secret message is known by the steganalyst.
- Known cover attack: Both of the cover object and the stego object are available.
- Known message attack: The secret message is known by the steganalyst who wants to analyze the embedding method.
- Chosen stego attack: The embedding method and the stego object are known.

The main concern of the forensic examiner is to detect and extract information embedded into cover objects. When a hard disk is seized, its content should be accurately scanned to look for hidden data. Steganalysis is the act of performing attacks against steganographic applications. Practically, many ways to defeat a steganalysis scheme exist. Choosing the convenient technique is never easy. In fact, investigators can perform steganalysis activities at different stages of the forensic process such as evidence identification and evidence analysis. In the sequel, steganalysis aspects related to both of these steps are detailed.

Identifying the sources of evidence is particularly important when the suspect is supposed to have used steganographic techniques. Unlike the other types of evidence, where the amount of data is the main problem faced at the identification level, stego objects are intrinsically hard to detect, making the related evidence difficult to access. Of course, this difficulty depends on the steganographic embedding scheme. Given a heterogeneous collection of digital information having belonged to a suspect (e.g., log files, documents, images, and e-mail messages), it is obvious that applying all steganalysis techniques to all of these data would be unfeasible. Hence, the security specialist should first know which pieces of information convey secret data. For example, to detect potential covert channels that rely on network protocols, filters can be built to check whether a packet flow conforms with TCP and Internet protocol (IP) specifications. In addition, when multimedia files are used as cover objects, selecting the steganalysis method is done according to the available information. One approach to detect hidden objects in hidden noisy images is to look for redundancies by applying a noise detection algorithm. This task is not as easy as it may seem as many cases have to be treated by the investigator. If the initial covermessage is available, the analysis should be based on a comparison between this cover image and the potential stego images. Conversely, if

only the noise distribution model is known (chosen stego attack), the identification process should just highlight the images that contain such noisy components.

The second key issue when examining a piece of evidence from steganography angle is information extraction. Knowing that the relevant data reside in the least significant bit of each byte of an image (excepting the header bytes) does not necessarily lead to the evidence. The embedded message may be encrypted in addition to being hidden. Therefore, processing a stego object often involves activities related to other fields (e.g., cryptanalysis and intrusion detection). This shows the complexity of the evidence processing steps when steganalysis intervenes in the forensic process. Effectively, this requires a significant experience and a good technical knowledge from the forensic analyst.

## IDENTIFYING THE SOURCE OF NETWORK ATTACKS

Up to this point, the problem of computer forensics has been addressed only for stand-alone machines. However, as networked systems are continuing to proliferate and given that attacks against these systems are becoming more and more frequent and sophisticated, the use of specific forensic techniques is necessary. These techniques should be specific so that the intrinsic features of computer network attacks can be taken into consideration.

### Computer Network Attack Features

Introducing network protocols and applications in the computing environment opens many breaches that malicious entities are able to exploit. For instance, attackers can easily hide their identities because of the stateless nature of the existing routing protocols. Furthermore, the effect of an attack can propagate rapidly from a physical location to another through the use of means provided by communication infrastructure itself. Therefore, intrusion detection systems (IDSs) are not sufficient to solve the fundamental problems of network forensics. Basically, IDSs detect events that are correlated with attacks and can react in different ways (i.e., generating alarms, blocking connections). This is not sufficient when conducting an investigation process as the identity of the attacker has to be determined. This is often a complex task because intruders use stepping-stones and zombies when carrying out their attacks. More clever attackers may send their packets across encrypted links to make their identification more difficult.

Tracing anonymous attack flows is not the only issue the investigator should consider, but it is, by far, the most critical one. Besides, an important research effort should be directed toward identifying the source of attacks. Other activities such as evaluating the impact of an attack or studying its modus operandi have also to be performed within the frame of the forensic process. Assessing the damage resulting from an intrusion is particularly helpful to determine whether the investigation should be pursued or not on the basis of a cost-benefit balance. Of course, this assumes that an efficient cost model for computer

network forensics has been applied. In addition, a deep analysis of the attack technique may reveal useful information about the attacker as it will be demonstrated in the next section. In the remainder of this section, we focus on the trace-back problem as we believe it is a challenging issue.

Several solutions have been developed as an attempt to locate particular hosts in a specific network that are initiating network attacks. They are called source tracing systems. At this stage, it may seem to the reader that trace-back methods are not related to digital forensics. In fact, these methods have been seldom presented as forensic tools and they have been rather viewed as IDS components. Particularly, they confer reactivity to intrusion detection. Nevertheless, they remain efficient for postmortem analysis (i.e., after the occurrence of the attack).

Tracing methods can be divided into two classes: host-based methods and network-based methods. The former techniques consist of installing agents on each network host, whereas the latter use the network infrastructure to identify attack sources. A trivial shortcoming of host-based tracing is that it is no longer applicable if the attacker uses a host where the trace-back system is not installed. In other terms, such component has to be installed on each host, which is obviously an unrealistic assumption in an open environment such as the Internet. In the sequel, the study is restricted to network-based tracing approaches because they are more appropriate for modern networks that are, by nature, open. Several improvements and theoretical discussions of these methods have been proposed in the literature. However, because of space limitations, they are not presented here. The interested readers can refer to Yaar, Perrig, and Song (2003) and Adler (2002).

### IP Marking Approaches

The first task is to build a map of routes originating from the victim using a traditional mapping technique (Cheswick, Burch, & Branigan, 2000; Govindan & Tangmunarunkit, 2000; Claffy, 2000). Typically, this map consists of a directed acyclic graph as shown on Figure 1, where  $V$  is the victim host,  $\{R_i\}$  are the routers and leaves, and  $\{A_i\}$  represents the potential attack sources.

The attack path from a leaf node  $A_i$  is the ordered list of routers between  $A_i$  and  $V$ . Savage, Wetherall, Karlin, and Andreson (2001) defined the exact trace-back problem as determining the attack path and the associated attack origin for each attacker.

In essence, IP marking consists of the fact that routers add path information into the packets during forwarding to allow the victim to reconstruct the attack path. Of course, this approach extends the flow transmitted across the network and would be likely unfeasible without considering several probabilistic and encoding issues.

### Edge Sampling Algorithm and Fragment Marking Scheme

Savage et al. (2001) stated that it is more efficient to mark edges in the attack path rather than nodes. The edge sampling algorithm consists of introducing three fields:

**Figure 1:** Figure 1. A map of routes network (the dashed line corresponds to a valid attack path).

*start*, *end*, and *distance* that have to be added to marked packets. When a router marks a packet, it puts its IP address into the start field and zero into the distance field. However, if the distance field is already set to zero, meaning that the previous router has marked the packet, the router writes its IP address into the end field. Clearly, this mechanism allows the representation of the edge between the current router and the previous router that marked the packet. Moreover, even if the router does not mark the packet, it always to increment the distance field to guarantee a more efficient characterization of spoofed packets. The distance fields corresponding to those packets would be greater than the length of the attack path. Assuming that each router marks packets with a probability  $p$ , it can be shown that the number  $X$  of the packets needed from the victim to reconstruct an attack path of length  $d$  respects the following inequality:

$$E(X) \leq \frac{\ln(d)}{p(1-p)^{d-1}}, \quad (4)$$

where  $E(X)$  and  $\ln(d)$  denote the expectancy and the Neperian logarithm, respectively.

To write the marking information in a given packet, Savage et al. (2001) suggested the overload of the IP identification field of the IP header that is normally used for fragmentation. This choice relies on measurements that have shown that less than 0.25% of packets are actually fragmented. However, IP identification is a 16-bit field, whereas 72 bits are needed to encode edge information (32 bits for start and end IP addresses and 8 bits for distance). Thus, an encoding technique called the fragmentation sampling scheme (FSS) has been developed in Savage et al. (2001). FSS is based on two mechanisms. First, the usage of exclusive-OR (XOR) of the IP addresses constituting the edge permits to reduce the required storage space by a factor of 2. The resulting value from this operation is called the edge id. Therefore, the victim will receive the edge ids of two adjacent routers except for packets arriving from routers that are at one hop from those routers. For example, if we consider the attack path represented

by a dashed line on Figure 1, the victim will receive the following edge ids:

$$IP_{R_1}, IP_{R_1} \oplus IP_{R_2}, IP_{R_2} \oplus IP_{R_3}, IP_{R_3} \oplus IP_{R_6}, \quad (5)$$

where  $IP_x$  is the IP address of node  $x$  and  $\oplus$  denotes the XOR operator.

Then, the investigator can recover  $R_2$ 's IP address by benefiting from the idem potency of the XOR operation. By repeating this process iteratively for all the upstream routers, the whole attack path can be reconstructed.

The second encoding mechanism consists of splitting each packet into eight nonoverlapping fragments. When a packet is marked, the router selects a random fragment and adds it up to the packet. This solves the problem as the 16 bits of the IP identification field can be filled by assigning 8 bits to the edge-id fragment, 3 bits to the position of the fragment, and 5 bits to the distance.

Nonetheless, because the use of edge ids instead of traditional logical addresses, another problem called collision (or birthday paradox) arises. Effectively, edge ids are not unique and the probability that the victim host receives two identical edge fragments is not zero. To overcome this limitation, a redundancy check mechanism can be added to the algorithm.

## Advanced and Authenticated Marking Schemes

To overcome the computational shortcuts of the basic IP marking approach, a set of improvements have been proposed in Song and Perrig (2001). Assuming that the route map has been predetermined by the victim host, the full IP addresses are not needed for the tracing purpose. In this way, 11-bit hash values of edge ids can be used instead of fragments. Supposing that  $R_i$  and  $R_j$  marked a given packet, the victim would receive the result of the XOR of  $IP_{R_i}$  and  $IP_{R_j}$  hashes conforming to the following equation:

$$edge\_id = h_1(IP_{R_i}) \oplus h_2(IP_{R_j}), \quad (6)$$

where  $h_1$  and  $h_2$  are two distinct 11-bit hash functions.

Two one-way functions are used to recover the order of the routers at the victim stage; using a single function would not allow path reconstruction as the XOR operator is commutative.

The robustness of this technique toward collision can be enhanced through the use of two sets of independent hash functions. Approaches to construct these sets are given in Song and Perrig (2001). Although the advanced marking scheme presents an acceptable computational overhead, it can be thwarted if an upstream router is compromised. In fact, all routers are supposed to be trustful. A potential method to address this issue is to authenticate packet marking. An alternative based on cryptographic checksums has been presented by Song and Perrig.

Assuming that each router  $R_i$  holds a symmetric key  $K_i$ , it can compute the message authentication codes (MAC) of edge ids and append them to marked packets to prevent other routers from forging its marking information. As for every symmetric encryption technique, key

management is the fundamental problem arising in the authenticated marking scheme. Time-released keys authentication mechanisms can be used if the size of the route map is important (yielding an impractical number of keys). Examples of such mechanisms can be found in Song and Perrig (2001).

The alert reader would have noticed that the aforementioned marking methods, referred to as probabilistic packet marking (PPM) schemes, have three principal shortcomings. First, they require important processing and memory capabilities at the victim level. Furthermore, their application is restricted to denial of service (DoS) and distributed denial of service (DDoS) attacks. However, the main limitation of these techniques is that they may not converge because a large number of packets of the order of thousands must be available at the victim host to reconstruct the attacked paths.

### Deterministic Packet Marking

To overcome PPM disadvantages, a new marking technique, called deterministic packet marking (DPM) was introduced in Belenky and Ansari (2003). The rationale behind this scheme is to perform the marking at the ingress interface of the closest router to the attacker because multiple attack paths can correspond to the same attack (this is the essence of routing algorithms). In other words, the attack flow is uniquely identified by its source and destination. In addition, this marking scheme is deterministic in the sense that every packet is marked by the nearest router to the station that emitted it.

To encode the marking information (the source IP address) in IP datagrams, DPM uses the IP identification field and the 1-bit reserved flag of the IP header. The IP address is divided into two equal segments, and the marking process consists of putting randomly, with probability of 0.5, one of those parts into the IP identification field. Clearly, the 1-bit flag is used to state whether the marking information consists of the first or the second half of the source IP address.

This method outperforms PPM because it does not have an important computational complexity. The number of packets that are needed by the victim to identify the attacker is by far less than in the PPM case. In fact, two packets originating from the same source and having two different marks are sufficient. Yet, it assumes the existence of a strong intervention from Internet service providers (ISPs), which cannot be usually provided for obvious reasons. In addition, DPM cannot be used if network address translation (NAT) is used in the network that includes the attacker's machine. Indeed, the victim would recover the private address of the attacker that does not contain any interesting information.

### Hash-Based IP Trace-Back

The hash-based IP trace-back approach, also referred to as source path isolation engine (SPIE) (Snoern, 2002), introduces a three-level hierarchy consisting of data generation agents (DGAs), SPIE collection and reduction agents (SCARs), and a SPIE traceback manager (STM). DGAs, which are at the lowest level of the hierarchy, consist typically of routers that offer the possibility of capturing a

compressed piece of information. They uniquely identify each packet they forward. To achieve this goal, hash functions are applied to the constant fields of the IP header (that do not change during the transmission) and to the first 8 bytes of the packet payload. A backup functionality has also been considered to overcome routers' memory limitations.

At the upper level, SCARs receive notifications of attack occurrence from the STM, which is the communicating component with various IDSs existing in the network. SCARs send queries to the appropriate DGAs to get the digests of the packets that were forwarded at the time interval including the instant where the attack took place. Having analyzed packet hashes, every SCAR reports to the STM the results concerning the attack paths in its region. Finally, the STM combines the elementary attack paths and thus performs the packet tracing.

Although SPIE is efficient and robust against various packet transformations (e.g., NAT and encryption), some important factors might obstruct its application in real contexts. The most important issue is related to the industry because SPIE relies on routers, which include sophisticated functionalities. Each router must be equipped with specific functions to extract packet hashes and an implemented backup strategy. Similarly, ISPs are closely involved in this marking scheme. For instance, the synchronization of the time intervals is a particularly tricky task. An additional limitation results from the fact that a centralized STM controls the whole system, which makes the framework more vulnerable as everything would collapse in the case of an STM failure.

### Connection Chain Identification

The goal of connection chain identification is to find the set of hosts that the intruder used to carry out an attack. A common technique to hide source's attack is to log on to a set of sources before breaking into the target. The attacker identification task becomes harder if the intrusion traces are deleted or if encrypted networks segments are used. Thus, finding connection chain should not rely on the study of traditional intrusion traces (essentially log files), but on the study of other characteristics that represent uniquely a connection and that are difficult to forge.

If  $H_0, H_1, \dots, H_{n-1}$  are the potential intermediate hosts the attacker used to perform an intrusion, a connection  $c_i$  is defined as a log-on operation between hosts  $H_{i-1}$  and  $H_i$ . When the attacker establishes connection  $c_i$ , the data flow sent between  $H_{i-1}$  and  $H_i$  is called a packet stream. The goal of the connection chain identification process is, given a packet stream of a connection  $c_i$ , to determine the entire connection steps denoted  $c_1, c_2, \dots, c_m$  from the attacker to the victim.

### Thumb Printing

The idea behind thumb printing is that several features of the transmitted data are constant at all points on a connection chain. Thumbprints can be thought of as signatures that uniquely identify a connection chain.

This method relies on the observation that the evolution of sequence numbers during the transmission of a

packet stream is a good criterion to measure the correlation between connections. In Yoda and Etoh (2000), a metric based on the evolution of sequence numbers during a connection was introduced to measure the deviation between connections. This metric should be kept small when computed for two connections that belong to the same connection chain. Basically, the correlation metric represents the slope of the graph that maps sequence numbers to time. Thus, the main assumption is that this metric is nearly invariant (or constant) for connections occurring in the same chain.

Given two connections  $c_i$  and  $c_j$ , the sequence numbers of the corresponding packet streams are denoted by  $(s_i^j)_{0 \leq l \leq n_i}$  and  $(s_j^j)_{0 \leq l \leq n_j}$ . Similarly, the packet arrival time is represented by two series  $(t_i^j)_{0 \leq l \leq n_i}$  and  $(t_j^j)_{0 \leq l \leq n_j}$ . The deviation between the packet streams is computed using the following expression:

$$D_{ij} = \frac{1}{d} \min_{0 \leq k \leq m'} \left\{ \left| \sum_{h=1}^{h=d} \left( T(h, k) - \min_h (T(h, k)) \right) \right|, \left| \sum_{h=1}^{h=d} \left( T(h, k) - \max_h (T(h, k)) \right) \right| \right\}, \quad (7)$$

where  $T(h, k) = t_{k+h}^i - t_h^j$ ,  $d = s_{n_i}^i - s_1^j$  and  $m' = \max\{l | s_l^j + d \leq n_j\}$ .

More informally, a deviation is a measure of similarity of the evolution of sequence numbers according to time for two packet streams. In fact,  $T(h, k)$  can be seen as a distance, in terms of time, between the  $k + h^{\text{th}}$  packet of the connection  $j$  and the  $h^{\text{th}}$  of the connection  $i$ . Equation (7) means that the graphs representing this evolution have to be adjusted horizontally and vertically so that the average distance between them is minimal. Thus, an advantage of deviation-based connection chain identification is that it does not require clock synchronization as only the shapes of the aforementioned graphs are compared.

Meanwhile, sequence numbers are generally managed by OSs kernels and this makes the invariance assumption inconsistent if multiple OSs are used along the connection chain. Moreover, because the packet content is not used in the deviation-based approach, it is still accurate when the attacker uses application-level encryption (e.g., SSH and SSL) to hide the transmitted data. However, this reasoning no longer holds if encryption occurs at the network level (e.g., ESP) as deviation-based tracing is vulnerable against payload padding. Even worse, the system may not be able to analyze properly packet headers.

## Interpacket Delay-Based Tracing

To address the problem of characterizing partially (or totally) encrypted connection chains, Wang, Reeves, and Wu (2002) proposed a method, which is very similar to the previous one except that it relies only on packet timestamps to evaluate the correlation between the two packet streams. More precisely, it introduces the notion of interpacket delay (IPD) correlation window as a feature that characterizes a portion of a packet stream. Using the same notations as for deviation-based tracing, this window can

be expressed as follows:

$$W_{l,s}((d_1^i, \dots, d_{n_i}^i)) = (d_1^i, \dots, d_{l+s-1}^i), \quad (8)$$

where

$l \in \{1, \dots, n_i\}$  is the starting point of the window,

$s \in \{1, \dots, n_i - l + 1\}$  is the size of the window, and

$d_k^i = t_{k+1}^i - t_k^i$  for every  $k \in \{1, \dots, n_i\}$ .

To compare the connections  $c_i$  and  $c_j$ , a correlation point function (CPF) is used and defined as below:

$$CPF(c_i, c_j, l, k, s) = \phi(W_{l,s}(c_i), W_{l+k,s}(c_j)), \quad (9)$$

where  $\phi(., .)$  is a similarity evaluation criterion (e.g., mini/max sum ratio and the correlation coefficient).

The first step is to find, for a given value of  $j$ , the offset  $k$  that corresponds to a maximum of  $CPF(., ., .)$ . The alert reader would have noticed that this procedure is equivalent to the graph adjustment used in deviation-based tracing. By varying  $j$ , a set of optimal offsets are determined. Therefore, according to the basic hypothesis, these offsets should be equal for all the correlation points if  $c_i$  and  $c_j$  belong to the same connection chain.

The main advantage of IPD-based tracing is that it can be used in real time, which may not be very important from the computer forensics point of view. Another interesting feature is that it needs relatively a few packets when compared to other methods to perform the correlation process.

## DISCOVERING ATTACK STEPS

The main goal of the investigator is to reconstruct as much information as possible about digital crimes. Revealing the identity of the suspect, by discovering hidden data in a hard disk or tracing an attack flow, is often insufficient to achieve such objective. Determining the technique of the attack as well as its steps is a crucial step for at least two reasons.

- **Primo:** Understanding the details of a crime and identifying the vulnerabilities that the attacker exploited can serve to improve the incident response process. The victim would have more data to thwart this attack by making proactive countermeasures.
- **Secundo:** Proving the responsibility of a suspect just by identifying him or her as legally inadequate. To pass a sentence, the law court must know what the suspect has exactly done.

So far, computer forensic techniques have been considered from an angle that narrows several key issues. One of the most basic questions about digital investigation is *Does basic human reasoning allow the conduction of a forensic process at an acceptable time?* Regarding the numerous practical problems that the investigator could face, the answer to this question would be negative. The wide use of computers and networks results in a huge amount of data being stored and transmitted. Collecting and analyzing evidence in such environment cannot be achieved by only humans without the assistance of advanced techniques. In this section, the application of

statistics and artificial intelligence to digital forensics is discussed.

### Statistical Computer Forensics

Neither of the foregoing investigation approaches allows us to absolutely state any determination about an event. Even if a source identification method shows that host  $X$  performed a network attack, this cannot be considered as an undeniable proof against its owner  $Y$ . This can be expressed in general in terms of probabilities: “The probability that  $Y$  is innocent, conditional on the identification of  $X$  as an attack source” is less than “the probability that  $Y$  is innocent.”

Practically, probabilities can be computed in two ways: using frequencies, under the assumptions of the central limit theorem, or degree of belief, which is rather subjective. The fundamental interest in using probabilities in computer forensics stems from Bayes’ rule that can be expressed, for two events  $A$  and  $B$ , as follows:

$$p(A|B) = p(B|A) \times \frac{p(A)}{p(B)}. \quad (10)$$

This formula shows how to update a probability to take account of new elements. When applied to digital forensics,  $A$  and  $B$  can stand for “Suspect is innocent” and “Evidence is presented,” respectively. As a consequence of Eq. (10), we have the following:

$$\frac{p(A|B)}{p(\neg A|B)} = \frac{p(B|A)}{p(B|\neg A)} \times \frac{p(A)}{p(\neg A)}, \quad (11)$$

where  $\neg$  denotes the negation symbol. Clearly,  $\frac{p(B|A)}{p(B|\neg A)}$  represents the prior knowledge relative to the evidence that can be deduced from statistics.

Different probabilistic reasoning applications can be used in computer investigation. For example, by showing that  $p(B|A)$  (i.e., probability of the evidence, conditional to the innocence of the suspect) is too low, the investigator can argue that the suspect is likely to be guilty.

### Computer Forensics and Artificial Intelligence

It appears from the description of investigation techniques that the forensic process relies largely on the available data constituting potential sources of evidence. Consequently, several features should be properly monitored to provide information that might be used if needed. Of the infinity of candidate metrics, only a few are substantially important. Determining these metrics is extremely relevant to ensure an acceptable error rate. The introduction of inappropriate features results in distorting the accuracy of the corresponding digital evidence.

The problem that arises at this level is that metric selection is impossible to be done manually. The Computer Emergency Response Team (CERT) defined a set of parameters that should be controlled to detect the occurrence of network attacks (Computer Emergency Response Team, 2000). Nevertheless, this is not exactly what is required for computer forensics. What misses is a link that

should exist between each feature and computer crime. The stronger is this link, the bigger is the appropriation of the metric to analyze corresponding computer attacks.

Mukammala and Sung (2003) proposed a feature selection technique based on artificial intelligence. Basically, it consists of allocating a significance factor to each potential parameter. This factor will then serve to rank the features to choose the most convenient ones.

Significance, which is the kernel of this approach, is quantified by evaluating the performance of the detection method on a training set and a testing set. The algorithm consists of removing one feature from those sets (meaning that the corresponding data is deleted). The detector is trained again with respect to the remaining data and its performance is assessed in terms of some predefined criteria. Ordering features can be performed through the use of support vector machines (SVMs) or artificial neural networks (ANNs). Experiments that were carried out on the 1999 DARPA intrusion showed that SVMs provide better results.

Two difficulties might be faced when applying this method. These are as follows:

1. **Building the testing and training data.** In fact, if these sets do not reflect the environment of the monitored network, the efficiency of the approach would be perceptibly affected.
2. **Complexity.** Besides, as automated significance ranking is performed on a per detector basis, it becomes considerably complex when many detection mechanisms are set to protect a network.

Conversely, many works have been done in the field of intelligent intrusion analysis. Flexibility is becoming a key issue in modern intrusion detection techniques, which have to automatically update their signature databases. Neural networks have often been proposed in this context, see Obaidat and Sadoun (1997). However, their use requires important cautions because attackers can use this learning functionality to forge the behavior of IDSs. Training, which is the basis of ANNs, consists basically of executing the IDS on a network flow where attack occurrences are known in advance. This process can allow criminals to let their traffic be seen as normal by injecting a sample of attack flows in the IDS during the training period.

Alternatively, decision trees (Stallard & Levitt, 2003), which can be viewed as the application of a well-known data fusion method, has been used to detect the occurrence of security violations that are expressed in terms of invariants. The interest of adapting this method to computer forensics is that multiple sources of information can be considered. This results in a better accuracy of the detection results. Stallard introduces a data aggregation scheme that permits the examination of the digital evidence at different levels of abstraction (e.g., raw data, aggregated data, and metadata). To build deductions from these data, two possibilities exist: forward chaining and backward chaining. The former uses inference rules to derive “facts whose premises match several known facts.” The latter begins with a goal to prove. It first checks the

working memory to see if the goal has been previously added. The system then checks to see if the goal rule's premises are listed in the working memory. Results given by the software prototype developed within the frame of this work show that the use of expert systems in digital forensics is very promising.

## LEGAL ISSUES

In Lee and Schields (2001), laws were presented as constraints for the packet trace-back problem. More generally, the regulatory framework can be a serious obstacle for every computer forensic activity. Particularly, privacy is a crucial issue that may cause problems to the investigator. As an illustrative example, consider an attacker that took the control of multiple stepping-stones before reaching the victim. To perform a posteriori analysis of this incident, the forensic analyst should study several log files concerning the stepping-stones or the victim host. These files can be found on the computers themselves or in the ISP network. In both cases, giving access to the required data may lead to the disclosure of confidential private information, which may be stored on the same machines as the log files. In fact, computers contain data having different levels of confidentiality. Conversely, it would be inappropriate to restrict the investigator's access to a machine to a few number of log files because this approach would affect seriously the efficiency of the evidence collection process. In the case of traditional forensic science, investigators can avoid similar problems if they possess official search warrants that confer a legal aspect to their activities. Unfortunately, such permissions to seize physical facilities are not applicable for digital investigation, especially when communication networks are considered. Taking the control of a network link implies the access to information belonging not only to the attacker, but also to the other users as the communication infrastructure is in essence public.

Other problems can result from conflicts between national regulations. Often, network attacks involve computers that are situated at different geographical locations. For this reason, nations are focusing seriously on international legal aspects such as evidence exchange or attacker extradition (CoE, 2001). Nonetheless, the existence of a sound regulatory environment is necessary as the notion of evidence admissibility cannot be considered without it. Defining and enforcing legal proofs helps the investigator to direct his or her search toward the most relevant features and improves the chance of discovering accurate pieces of evidence.

## ENHANCING THE EXISTING INFRASTRUCTURE

Because the existing security infrastructure does not allow the application of the techniques mentioned below, standards, research activities, applications, and human skills should be improved to help forensic success. Issues related to these modifications are addressed in this section.

## Improving Standards, Protocols, and Regulation

It is noteworthy from the previous sections that most of the existing forensic standards are limited to disk forensics. Although many procedures and guidelines treated various facets of disk examination, network investigation activities have not been standardized yet. A potential topic to consider would be the relation between signs and the nature of intrusions. Such link would permit a rapid deduction of the attack mechanism before deeper investigation takes place. In fact, because meticulous network forensic tasks are very time consuming, a preliminary coarse analysis should be done prior to them.

Conversely, network protocol standards need to be secured. The numerous techniques that have been proposed in the literature to fit with traceability requirements, and that have been resumed in this chapter, are insufficient and the research activity in this branch is still immature. Disk standards as well, especially those related to sector addressing and controller-disk communication, should be considered since most of the problems that have been discussed above derive from incongruities in those standards. Another key aspect concerns regulation is that most of the works that treated this issue instill a negative opinion about legal considerations. Many laws were written without taking the technological advances in mind, and thus they seriously affect the technical solutions. To avoid misleading interpretations, computer forensic-specific regulatory texts should be applied.

## Improving Theory

Research in digital forensics is still in its infancy. Many important topics have not been addressed yet. The lack of efforts and cost estimation model for digital forensics has already been mentioned earlier. This issue is of prime importance because it would determine the accuracy of conducting the investigation. Moreover, it would help to schedule this activity. A cost model consists first of identifying the features that have an impact on the complexity of the investigation process. On the basis of these parameters, a model expressing this complexity should be built. It has to express suitably the evolution of the complexity according to the variables (e.g., linear and exponential).

The use of probabilistic reasoning can be enriched through the introduction of more elaborated data fusion techniques. Bayesian theory can be used to express the relation between the *a priori* information  $i$ , the available data  $(d_1, \dots, d_n)$ , extracted from  $n$  sources, and the event to be evaluated. Many approaches that rely on probability theory or fuzzy sets have proved their efficiency in other fields and can be adapted to investigation. An additional potential research issue concerns the role of investigators in the forensic process. Effectively, many specialists participate in the digital investigation and each of them has a particular view, oriented by his or her specialty of the problem. Their opinions may match, be slightly different, or may bluntly conflict. To obtain a single consistent representation that combines accurately the elementary views, collaborative intelligence techniques can be applied.

## Improving Industry Support

Organizations can participate at least at two levels to promote computer forensics. First, network equipment manufacturers should consider seriously the implementation of several theoretical approaches that have been discussed above. Currently available protection mechanisms in firewalls are limited to stateful inspection that prevents SYN. Flooding attack aims to start opening a large number of TCP connections on the victim machine and prevent them from occurring (in addition to traditional packet filtering).

Some routers include the ingress and egress filtering functionalities that cannot be efficiently applied without identifying precisely the malicious host. Moreover, enterprises should strictly apply computer security incident guidelines by putting the required monitoring infrastructure and building incident response teams (IRTs). This would allow to provide useful data by the investigators and to react in an acceptable response time.

Another category of operators that should particularly be active is ISPs. Network attack tracing approaches are more or less dependent on ISPs involvement. These, however, are often reluctant to participate in the investigation process because they refuse to give information about their private networks.

## Improving Human Skills

Technical capabilities are very important to ensure the efficiency of the forensic process. Primarily, employees should be aware of the security considerations and apply policies and procedures. In particular, IRT members should be well trained to conduct properly their tasks. Investigators should also possess the knowledge to study the digital crime scene. They typically submit the collected data to various specialists who perform the examination step. Then they should be able to analyze appropriately the results of this examination.

Finally, prosecutors, lawyers, and judges are also supposed to have minimum technical skills that allow them to understand digital crimes. Specialized trainings should be considered to address this goal.

## CONCLUDING REMARKS

Throughout this chapter, it can be said that forensic science, when adapted to computer science and information technology, possesses several characteristics that makes it particular and different from other traditional applications. In this section, these features are presented briefly to avoid redundancy:

1. Identification of sources of evidence becomes more complex when dealing with digital forensics. The available data, which potentially contains proofs, has a huge volume of information that is impractical to be readable by humans. Thus, identification is considered as a separate step of the computer forensic process and many automated tools are proposed to assist the investigators in performing it.
2. Digital evidence is very sensitive because it is affected by the properties of storage media and computer applications. Indeed, memory volatility or malicious codes

can make the evidence disappear before becoming legally recognized, which is frustrating for the forensic analysts.

3. Tracking a network's attacker is very complicated because the associated evidence seldom has legal value. Identifying the offender on the basis of his or her IP address or his or her password is not sufficient to indict him or her.
4. Evidence authentication techniques are weaker than in the case of traditional forensics. For example, if some fingerprints were found on a fire gun and if they match the suspect biometric templates, the probability that the suspect is the real attacker is greater than if the evidence were a computer. This simply results from the fact that forging fingerprints is much more difficult than spoofing some digital parameters (e.g., IP address and e-mail password).

## INTRODUCTION

Computer forensics involves the preservation, identification, extraction, and documentation of computer evidence stored in the form of magnetically, optically, or electronically stored media. It is a relatively new science that is becoming increasingly important as criminals aggressively expand the use of technology in their enterprise of illegal activities. Computer forensic techniques are not as advanced as those of the more mature and mainstream forensics techniques used by law enforcement, such as blood typing, ballistics, fingerprinting, and DNA testing. Its immaturity is partly attributable to fast-paced changes in computer technology and the fact that it is a multidisciplinary subject, involving complicated associations among the legal system, law enforcement, business management, and information technology.

This chapter is a *technical introduction and overview* to fundamental methods and procedures of computer forensics. To get the most out of this chapter, we have assumed readers will have technical skills with computers running a variety of operating systems.

*The Handbook of Information Security*, in particular volume 2, has several chapters related to numerous aspects of computer forensics, including the legal, law enforcement, and managerial aspects. To fully understand the practice and implications of computer forensics, we urge readers to carefully examine all related chapters. As you read this chapter, be aware that computer forensics is a set of technical activities that occurs within a complex setting of interacting stakeholders who often have conflicting goals. Before conducting a computer forensics investigation, we advise the reader to seek advice from legal counsel to ensure that no local, state, or federal laws are broken. Nothing in this chapter is intended to be legal advice and should not be construed as such.

In this chapter, we illustrate both *offline* and *online* analyses. An offline analysis occurs when an investigator powers down the computer and removes it from the network. This allows the investigator to create an exact copy of the computer's hard drive to ensure that the files remained unchanged and to ensure all evidence, condemning as well as exculpatory, is collected. In contrast, there are occasions when it is impossible to power down a computer, which then requires an online analysis. For instance, management may not permit the shutdown of a company's only e-commerce server. In this circumstance, the investigator must gather as much evidence as possible while the system remains running and connected to a network. From a purely forensic standpoint, the preferred situation is to "freeze" the computer's state by powering down the system. However, in reality this is not always possible, and investigators should be proficient in methods for gathering evidence from a running computer system.

We begin this chapter by describing an offline analysis involving desktop computers running versions of Microsoft Windows. Windows plays a prominent role because of its large worldwide market share and the fact that the law enforcement agencies (Dartmouth, 2002) and the FBI's Computer Analysis and Response Team (Pollitt, 2002, personal communication) have indicated that the majority of investigations involve computers running some version of Windows. We conclude this chapter by discussing an online analysis, such as a server running Linux or UNIX that cannot be shut down and that therefore requires the investigator to work on a running computer system.

## Computer Forensics Tools

Investigators have a variety of forensic tools from which to choose. Some tools run exclusively under Windows, others under Linux/UNIX, and some on several operating

systems. The focus of this chapter is on illustrating fundamental computer forensics *concepts*, not a particular tool. An important reason for *not* using point-and-click tools for our demonstrations is that these tools do not illustrate the fundamental, technical details that form the core of computer forensic procedures. For example, when an investigator clicks on a graphical user interface (GUI) button labeled Recover Deleted File from within a GUI-based tool, she should be able to explain *what* the program is doing to recover the files. In real life, of course, investigators are likely to use one of the many GUI-based tools that are available (some of these are described at the end of this chapter). Nevertheless, a fundamental understanding of these concepts is especially important for the credibility of the investigator should she be required to testify in a court of law as an expert or technical witness.

Accordingly, we use Linux-based tools for our demonstrations. Linux is an operating system kernel. The command line utilities we use to conduct our forensic procedures are part of the GNU utilities (<http://www.gnu.org>) that are included in every Linux distribution. A Linux *distribution* is a vendor compilation of the Linux kernel, GNU utilities, and hundreds of software programs, plus an installer. There are several dozen Linux distributions, although only a few are major commercial distributions, the largest of which are Redhat (<http://www.redhat.com>) and SuSE (<http://www.suse.com>). Readers are directed to <http://www.distrowatch.com> and <http://www.linux.org> to learn more about various Linux distributions. All demonstrations herein were tested with SuSE Professional 9.0/9.1, Fedora Core 1, and Redhat 9.

## Forensic Server

We assume that most computer crime investigations will involve at least one “subject” computer, that is, the source of the evidence we are seeking, as well as a “forensic server” that contains our forensics toolkits. For our demonstration purposes, we assume that the forensic server has a Linux distribution installed, or is dual-bootable Window/Linux, which is how all of our computers are configured. Although in theory the Linux distribution should be irrelevant, certain commercial versions such as Red Hat and SuSE are often preferred because they offer support services and are fairly easy to install and update.

The activities performed in a forensic analysis may easily tax the average computer. Therefore, it is important that a good deal of thought is put into the components that compose the forensic server to ensure that it is of sufficient quality and power so that imaging and analysis are not problematic. For instance, it is desirable to have as much physical RAM as one can afford, as well as a fast processor (all of which are relative and changing daily). The forensic server will need enough drive space to hold the operating system, several forensic tools, and all of the forensic images collected from the subject’s computer. Other considerations include the need to read and examine numerous portable disk formats, including old ZIP disks, superdrive disks, old floppy formats such as the 5.25 floppies, and so on. It is a good idea to have on hand many different types of disk readers

that can be placed into the forensic computer should the need arise. Should the investigator come upon a digital evidence format that is not common, eBay (<http://www.ebay.com>) or similar sites may have such equipment available.

## SOUND COMPUTER FORENSIC PRACTICE

There are numerous circumstances that may require a computer forensic investigation but not necessarily law enforcement intervention. For instance, a company employee suspected of sending sexually explicit e-mails or running a personal business may be subject to an investigation because these activities violate corporate acceptable-use policy and subject the employee to disciplinary action; however, they are not illegal and do not require law enforcement intervention. Nevertheless, it is good practice to work under the assumption that *any* investigation could end up in court. The reason is that there are countless stories of investigations that started off for one reason but escalated to a point requiring law enforcement intercession. For instance, an investigation instigated by allegations that an employee surfing pornographic Web sites on his lunch break may reveal evidence of a cache of child pornography on the employee’s hard drive, a federal crime under 18 USC 2251 and 2252. The situation must be reported to law enforcement and would likely end up in court.

The federal rules of evidence (<http://www.law.cornell.edu/rules/fre/overview.html>) govern the introduction of evidence in both civil and criminal proceedings in federal courts. These rules are strict regarding the handling of evidence. Evidence not collected in accordance with the federal rules of evidence may be disallowed by a judge. Sound forensic practices decrease the potential for a defense attorney to question the integrity of evidence and for the judge to disallow the introduction of evidence into a court proceeding.

Computer forensics procedures can be distilled into three major components:

- 1) Make a digital copy – sometimes called a forensic duplicate – of the original evidence. Investigators make a copy of the evidence and work with the copy to reduce the possibility of inadvertently changing the original evidence.
- 2) Authenticate the copy of the evidence. Investigators must verify the copy of the evidence is exactly the same as the original.
- 3) Analyze the digital copy. The specific procedures performed in an investigation are determined by the specific circumstances under which the investigation is occurring.

Our chapter will generally follow this outline. We begin by demonstrating two ways in which to make forensically sound copies of digital evidence, followed by a demonstration of a simple and effective way of verifying the integrity of a digital copy. The remaining portions of this chapter are devoted to procedures for analyzing digital evidence.

## ARRIVING AT THE SCENE: INITIAL RESPONSE

There are two important rules regarding the initial response to a computer crime scene. One of the most critical times at any crime scene is when the crime is first discovered. The first activity performed by law enforcement at a physical crime is to restrict access by surrounding the crime scene with yellow tape, something most of us have seen on television hundreds of times. It is just as important to *restrict access* to the computer at a computer crime scene to decrease the likelihood of changing the evidence.

The second rule is to *document* the crime scene and all activities performed. Good documentation is crucial for several reasons. First, it allows the investigator to refresh her memory should she have to testify. Second, it allows the court to verify that correct forensic procedures were performed. Finally, it allows for the recreation of the activities that were performed in the initial response.

Special Agent Mark Pollitt (retired), former Unit Chief of the Federal Bureau of Investigations Computer Analysis and Response Team (CART), has said, "Computer forensics is all about process" (Pollitt, 2002 personal communication). The process should be repeatable and predictable and should stay within the confines of the law. We underscore the importance of following sound forensic practice during investigations, as there is a significant potential for any investigation to have legal implications for the investigator, her employer, or the subject of the investigation. In subsequent sections, we outline the activities that should be performed as an initial response to a potential computer crime scene. The following is partly adapted from International Association of Computer Investigation Specialists (IACIS: [http://www.iacis.com/forensic\\_examination\\_procedures.htm](http://www.iacis.com/forensic_examination_procedures.htm)) as well as *U.S. Secret Service's Best Practices Guide for Seizing Electronic Evidence* (U.S. Secret Service, 2002).

1. Immediately determine if a destructive program is running on the computer. If one is running, the investigator should pull the power plug from the *back* of the computer (not at the outlet). This will ensure no further evidence is lost. Place tape across all open disk drives so that no media is inadvertently placed in the disk drives. The system date and time should be collected from the BIOS setup. This time should be compared with a reliable time source (e.g., one synchronized with an atomic clock) and any discrepancies noted. This may be important if it is necessary to correlate events between two computers or between the activities of a user and the times associated with particular files on the computer.
2. Document the computer and its surroundings. Videotape and photographs are good supplements to handwritten notes. Things to document include the computer's make, model, and serial number; attachments to the computer (e.g., external hard drives, speakers, cable modem, universal serial bus (USB) or network hubs, wireless network routers, and so on); the state of the machine, that is, whether it was on or not; and the surrounding environment.
3. If the computer is running, take a photograph of the screen. Photographs demonstrate that the computer was running as well as visually documenting what was running at the time of the initial response.
4. Take photographs of the front, side, and back of the computer. A photograph of the back of the computer will allow an investigator to recreate the computer setup should the computer need to be seized and taken back to a lab for further investigation. If the computer is to be seized, label connectors (network, USB, firewire, etc.).
5. Physically open the computer and take photographs of the inside of the computer. These photographs will show the number of hard disks connected, as well as any peripherals, such as network and sound cards.
6. *Bag and tag* of all potential evidence. "Bag and tag" is a law enforcement term that refers to the process of placing crime scene evidence (e.g., hairs, fibers, guns, knives, and so on) into bags and tagging them with relevant information including date and time collected, name of investigator, where collected, and so forth. All potential evidence such as floppy disks, compact disks (CDs), digital video disks (DVDs), papers surrounding the computer, and so forth should be subjected to a bag-and-tag.
7. Some situations require the confiscation of the source computer by law enforcement (Heverly & Wright, 2002). If the computer is to be transported to an off-site forensics laboratory, label each computer part and place in an appropriate container for transport.
8. Search for "sticky notes" or any other written documentation near the computer (including under the keyboard, under the desk, in desk drawers, etc.). Users often write down passwords and leave them in convenient places near the computer. Passwords may be necessary if the user has used encryption to obfuscate file contents. Make sure to look in the wastebasket as it may hold valuable information.
9. Take any computer manuals in case they are needed for reference back at the forensics laboratory.
10. If the original evidence is to be confiscated, it should be stored in a secure place.

### Creating a Forensic Image

The first step in acquiring digital evidence is to create an *exact physical copy* of the evidence. This copy is often called a *bit-stream image* (Kruse & Heiser, 2001), *forensic duplicate* (Mandia, Prorise, & Pepe, 2003), or *forensic image*. Creating a forensic image is important for several reasons. From a legal standpoint, courts look favorably upon forensic images because it demonstrates that *all* of the evidence was captured, condemning as well as exculpatory, following the spirit of the Federal Rules of Evidence. From an investigatory perspective, forensic images contain the contents of previously deleted files and other ambient data, information not available if only a logical copy of files is made.

Historically, a running computer was of little concern to law enforcement because the standard operating procedure was to remove the power source from the computer, that is, pull the plug, whether the computer was running or not. "Pulling-the-plug" follows general police

**Figure 1:** Direct connection to internal IDE controller.

investigative procedures to “freeze” the crime scene. Pulling the plug is analogous to the yellow “Do Not Cross Police Line” tape because it freezes the computer crime scene. This practice is no longer a hard-and-fast rule as pulling the plug may lose valuable evidence, for example, running network connections and the contents of RAM.

Options for freezing the computer include pulling the plug or gracefully shutting the computer down (i.e., through the mouse sequence: Start: Turn Off Computer: Turn Off). In personal experiments involving computers running versions of Windows 98 and Windows XP, we observed that a graceful shutdown results in changes to several hundred files on the disk. This could have a significant effect upon law enforcement’s ability to prosecute a case, especially trying to explain how the investigating officer managed to change several hundred files on the evidence media. Our advice is that the *circumstances must determine whether it is appropriate to pull the plug or perform a graceful shutdown.*

We must access the hard drive on the subject’s computer to create our image. How do we access the source hard drive? One way is to physically remove it from the source computer and connect it to the investigator’s forensics machine. For example, if the source drive is an Advanced Technology Attachment/Integrated Drive

Electronics (ATA/IDE), it is relatively simple to remove it and reconnect it to an open IDE ribbon cable connection in the forensics computer, as demonstrated in Figure 1.

There are two caveats to this method. First, if we are imaging using a Windows-based application, then we must use a write blocker (see Figure 2) to ensure that no data are written back to the subject’s hard drive, because Windows will automatically mount the hard drive as read + write, which may change files on the hard drive. If we are using Linux, then a write blocker is not required because we can manually mount the hard drive as “read only.” Forensic imaging under Windows therefore requires the use of a special “write blocker,” a hardware mechanism that allows reading from, but not writing to, the hard drive (see Figure 2). Write blockers are available from several sources, including FireFly from <http://www.digitalintel.com>, FireBox from [www.blackbagtech.com](http://www.blackbagtech.com), and FastBloc from <http://www.guidancesoftware.com>.

Second, directly connecting the subject’s hard drive to our forensic server’s IDE chain requires that the jumpers on the source drive be appropriately set to slave or cable select. Changing jumper settings will not change any files on the hard drive.

**Figure 2:** Write block with firewire connection.

Figure 2 demonstrates the use of a hardware write-blocker to connect a subject's hard drive to a forensic server using a USB or firewire cable.

Once we have connected our hard drive, we can begin the imaging process. In the following demonstration, we will create a forensic image of a floppy; however, the process is very similar for most media and any differences are indicated below. In subsequent sections, we will demonstrate how to image a hard drive over a network connection.

From a terminal window, we use the GNU utilities from a command prompt to make our forensic image. First, we write protect the floppy, then place the disk in our floppy drive on our forensic server. The commands we executed have been marked in brackets for ease of reference.

```
[1] jpc@simba:~> script case.1034
    Script started on Tue 23 Mar 2004 03:25:36 PM CST
[2] jpc@simba:~> date

[7] jpc@simba:~> exit
    Script done on Tue 23 Mar 2004 03:34:14 PM CST
```

A good investigator documents the crime scene as well as the procedures performed. We can supplement our handwritten notes with the `script` command. `script [I]`

makes a copy of everything printed on the screen (both input and output) and places it in a file, here descriptively called *case.1034*.

We then print the current date and time with `date` [2]. It is good practice to “sandwich” your forensic activities between two date commands [2] and [6] to demonstrate when and how long the activities required.

Next, we use the `dd` [3] command to create a forensic image of the floppy disk:

```
# dd if=/dev/fd0 of=1034.dd
```

`dd` takes as input a stream of bits and outputs a stream of bits, making an exact physical duplicate of a file, drive, and so forth. In this example, `dd` is reading from the

device `/dev/fd0`, a logical device associated with the floppy disk drive, and writing it to a file we have named *1034.dd*. In Linux, physical devices are logically associated with

**Table 1** Mapping from Logical to Physical Device

Logical Device	Physical Device
/dev/hda	First IDE hard drive on primary controller
/dev/hda1	First partition on the first hard drive on primary controller
/dev/hdb	Second IDE hard drive on primary controller
/dev/hdc	First IDE hard drive on secondary controller
/dev/hdd5	Fifth partition on second hard drive on secondary controller
/dev/sda	First SCSI device
/dev/sda1	First partition on first SCSI device
/dev/cdrom	First CDROM drive
/dev/fd0	First floppy disk

a file residing in the `/dev` directory. These associations are shown in Table 1. Note that the names of the logical devices may differ between Linux distributions or between versions of UNIX. The nomenclature below is fairly standard for most POSIX-compliant Linux distributions, including Redhat, SuSE, Mandrake, Slackware, Debian, and Gentoo.

The argument `if=` specifies the source image, here the logical device associated with the floppy drive. The argument `of=` specifies the output file's name. The `bs=` argument specifies the block size to read and write, and is optional. The default block size is 512 bytes. The `conv` argument specifies other command line arguments to include. For imaging we include `noerror`, continue after a read error; `notrunc`, do not truncate the output in case of an error; and `sync`, in case of a read error, pad input blocks with zeros.

After the `dd` operation is completed, it prints to the screen the number of records (i.e., blocks) it read and wrote. Here, it read 1440 records and wrote the same number. This is correct because we have specified a block size of 1024 bytes (1 kilobyte), and 1 kilobyte multiplied by the number of blocks (records = 1440) is 1.44MB, which is the size of a high-density floppy disk.

## Verifying Image Integrity

Next, we must verify that we made an exact bit-for-bit copy of the evidence. We use `md5sum` [4] to verify the integrity of image:

```
# md5sum /dev/fd0 1034.dd > 1034.md5
```

`md5sum` calculates an MD5 cryptographic hash, also known as a *message digest*, or simply *hash*. The MD5 message digest (Rivest, 1992) is a one-way hash algorithm that takes as an input a file of arbitrary length and outputs a 128-bit hexadecimal formatted number that is unique to a file's contents. Two files with the same contents will always result in the same 128-bit hash value. The file's contents alone determine a hash value, not associated metadata (e.g., file name, date and times, size, etc.). This fact will be important when we later consider ways to identify illegal or inappropriate files.

We verify the integrity of our evidence by calculating the MD5 hash for the original floppy disk (`/dev/fd0`) and the

forensic image (`1034.dd`). If the hashes are the same, we can rest assured the copy we made is a bit-for-bit duplicate of the evidence. We save the contents of the command by redirecting it to a file that can be printed and archived for safekeeping.

Any differences between the contents of the floppy disk and our forensic image are so indicated in the hash. To illustrate this phenomenon, we used a hex editor to add a single space into the boot sector of the `1034.dd` image, and then reran the MD5 hash on the image. The old and new hashes are different:

```
Old Hash: 04c09fa404ac7611b20a1acc28e7546c
New Hash: dbbbd457d0283103e7148075abb5b91e
```

## Imaging over a Network

An alternative to removing the hard drive from the subject computer is to use a network connection. A "network acquisition" requires both computers have network interface cards (NICs; i.e., Ethernet cards), a network crossover cable, and a bootable Linux CD. A network crossover cable allows the investigator to directly connect two computers without a hub or switch.

Several bootable Linux-based CD-ROMs are available. Most of these are based on the popular Knoppix CD (<http://www.knoppix.com>). Knoppix contains more than 1.7 gigabytes of software on a 700MB CD using compression. The CD contains utilities that are useful for forensics imaging and previewing. Knoppix loads itself into a ram disk during boot and will not access the hard drive of the subject's computer (as of Knoppix 3.3). Knoppix boots into a graphical user interface that allows the investigator read-only access to the hard drives on the subject computer, which is very useful for previewing the contents of the source drive.

As of 2004, there are several forensics bootable Linux CDs. These include Helix (<http://www.e-fense.com>), Local Area Security (<http://www.localareasecurity.com>), Knoppix Secure Tools Distribution (<http://www.knoppix-std.org/>), Penguin Sleuth Kit (<http://www.linux-forensics.com/>), and FIRE (<http://fire.dmzs.com/>), the first four of which are based upon Knoppix.

Although strictly speaking Knoppix is not "a forensics distribution," it contains enough tools to make itself extremely useful in these circumstances. It is so popular that

we would surmise that it will be around for a long, long time.

## Sterilizing Forensic Media

Before imaging the subject's hard drive, it is good practice to "sterilize" or "wipe" the destination media on the forensic server. A forensic wipe removes any vestiges of previous contents on the drive, ensuring that a defense attorney cannot claim that any evidence recovered from the subject's hard drive was from the previous contents on the disk, caused by the commingling of evidence.

A forensic wipe is different than formatting a hard drive. For instance, a quick formatting under Windows or DOS only deletes the bookkeeping portion of the file system (described in subsequent sections), including the root directory and the file allocation table. A quick format does not remove the actual files: these files will remain until overwritten by the operating system. A full format is the same as a quick format except that it also writes F6h over each of the sectors in the data area of the disk. It does not, however, overwrite areas of the hard drive that are unaddressable by the operating system (usually several clusters at the end of a drive).

A forensic wipe can be accomplished with the `dd` command:

```
# dd if=/dev/zero of=/dev/hdb1 bs=2048
```

The logical device `/dev/zero` is an infinite source of zeros. Because we have specified our output to be `/dev/hdb1`, it will write a series of zeros to every single sector of the first partition on the second IDE hard drive. The `bs` argument specifies that `dd` should read in blocks of 2048 bytes, overriding the default of 512 bytes.

We can verify that the procedure was successful using the `grep` command:

```
# grep -v '0' /dev/hdb1
```

`grep` is a utility that searches for keywords within files. We are searching for the string "0" on the logical device `/dev/hdb1`. The `-v` argument specifies somewhat of a reverse search, that is, display everything on the media that is *not* 0. If `grep` finds anything that is not 0 it will print the results to the screen. (We have personally never seen `dd` fail in this task.)

Wiping the drive removes the file system, so we must perform a high-level format before we can copy the image to our destination hard drive. Linux allows us to format a drive in several different file system formats, including Linux/UNIX-based such as EXT2 or EXT3 or Windows FAT16/32. Although Linux can read from and write to FAT32 formatted drives, in this instance it is not our best choice as FAT32 has a 4-GB ( $2^{32}$  bits) size limit for files, and most hard drives as of 2004 are much larger. Unfortunately, NTFS write support under the current Linux kernel (either 2.4 or 2.6) is experimental and is therefore not the best choice for critical tasks. For purposes of this chapter, we will create an EXT2 file system on the destination drive. File systems based on the Large File

System specifications can hold files up to  $2^{63}$  bytes in size ([http://www.suse.de/~aj/linux\\_lfs.html](http://www.suse.de/~aj/linux_lfs.html)).

```
# mkfs.ext2 /dev/hdb1
```

The `mkfs` command is a wrapper for several programs that create file systems. Here, we are creating a standard Linux EXT2 file system.

Once we have prepared our destination forensic drive, we can begin our imaging process. Here are the steps to use a bootable Linux CD to acquire and preview a subject's hard drive over a network:

1. Check the boot order of your subject computer. It is *crucial that the boot order of the subject's computer is set to boot from the CD before the hard drive*. If the reverse is true, then the hard drive will boot instead of the CD. This will result in changing the access and/or modification times on several hundred files on the hard drive. Boot order is managed from the computer's BIOS. To check the boot order, we first remove the power cable from the back of the source computer, not at the wall outlet. We then open the subject's computer and *remove the power supply connector* from all of the hard drives. This is critical because it guarantees that the source hard drive cannot boot inadvertently. We next replace the computer's power cable and power the subject's computer on. During the boot process the computer should display an onscreen message indicating a key to press to access the BIOS setup (e.g., F1, F2, [Delete], etc.). Press the appropriate key to access the BIOS. If you miss the chance to access the BIOS, the source hard drive cannot boot as its power source has been removed. Reboot and try again. Once in the BIOS setup, change the boot order to CD first, followed by the hard drive. Place the Knoppix CD into the source computer. Replace the power supply connectors to all of the hard drives. *Do not turn on the source computer yet*. This is also a good time to note the system's date and time setting in the BIOS.
2. We then connect the network crossover cable between the source and forensics server's NICs and then power on the subject's computer. It will boot into the Knoppix graphical user interface. Icons that represent the hard drive partitions found by Knoppix will appear on the desktop (see Figure 3). *These drives are not mounted*. You may preview the contents of the drives by clicking on the icons, which will open the drives read-only and display their contents in a file manager.
3. You must manually configure each computer with a network address because neither computer is connected to a DHCP server. Open up terminals on both computers. Figure 4 demonstrates how to set a network address under Linux. First, we switch to root on both computers using the substitute user [`su`] command. Under Knoppix version 3.3 and later, the `su` command does not require a root password. Set the network address using the `ifconfig` command: `# ifconfig <interface> <network address> <network mask>`. Do this for both computers (using different network addresses for each, of course). Make

Figure 3: Knoppix desktop.

sure that the network address was correctly set by issuing the command `[ifconfig]`. Ping the source computer to make sure you have a connection.

4. Before we can continue, we need more specific information on the hard drives from the subject's computer. From a terminal command line, run the command `fdisk -l` (that's a lowercase "L"). As illustrated in Figure 5, this command displays the number of hard drives connected, the number of partitions on each drive, and the formatting of each partition. Figure 5 shows that our subject's computer has a single 14-GB hard drive. (Note: Is our destination drive on our forensic server large enough to hold this image?) We note that the drive has five partitions, `/dev/hda1` through `/dev/hda5`. The fourth partition, `/dev/hda4`, is an extended partition (as noted from the `W95 Ext'd` tag) and was created because drives can only have four primary partitions. This system appears to be a dual-boot Windows/Linux machine based on how the system is partitioned and our own experience. `/dev/hda1` is formatted with Microsoft's New Technology File System (NTFS) and likely contains a Windows operating system, although we cannot guarantee this until we preview the image.
5. We have sufficient information to begin an acquisition over the crossover cable. We use the *netcat* utility (<http://www.atstake.com>) to create the network connection between the two computers. Netcat is a small, free utility available for several operating systems. *Netcat* reads and writes bits over a network connection. The command to run on the forensics server is as follows:

```
# nc -l -p 8888 > evidence.dd
```

This sets up the listen process on the forensics server prior to sending the data from the subject's computer.

From the command line arguments, `nc` is the netcat executable (it may be called *netcat* under SuSE). The `-l` argument (a lowercase 'L') indicates *listen* for a connection; the argument `-p` specifies the port on which to listen. We redirect the output to a file name of our choosing, here `evidence.dd`. If we do not redirect to a file then the output is directed to the standard output, the screen.

6. On the subject's computer, we use the `dd` command to read the first partition:

```
# dd if=/dev/hda1 | nc 192.168.0.2 8888 -w 3
```

We pipe the output of the `dd` command to *netcat*, which sends the bits over the network to the specified network address and port on our listening forensic computer. The argument `-w 3` indicates that *netcat* should wait 3 seconds before closing the connection upon finding no more data.

The time required to create a forensic image depends upon several factors, including the size of the source media, the speed of the connection (a directly connected IDE versus network acquisition), and the speed of the computer's hardware. Creating a forensic image of a floppy takes only a few minutes, whereas a 60-GB hard drive will take several hours.

After we create the image we must verify its integrity. We can calculate the hash of the source hard drive by issuing the following command from the subject's computer:

```
# md5sum/dev/hda1 | nc 192.168.0.2 8888 -w 3
```

This command calculates the MD5 hash of the source hard drive and pipes the results over the network to our forensic server. We capture this information by setting up a listening process on the forensic computer as demonstrated in

```
knoppix@tty0[knoppix]$ su
root@tty0[knoppix]# ifconfig eth0 192.168.0.5

# md5sum evidence.dd >> evidence.md5
```

calculates the MD5 hash of our forensic image and appends it to the previously created MD5 file. The ">>" command appends the output of the command to an existing file. Warning: If we were to use a single ">" the file evidence.md5 would have been overwritten by the output of the command, rather than appended.

If our hashes match, then we can assume success in our imaging process. We are now ready to begin an analysis of our image.

## ANALYSIS OF A FORENSIC IMAGE

Computer forensic procedures can be somewhat artificially divided between *logical* analysis and *physical* analysis. A logical analysis views the evidence from the perspective of the file system as in Figure 6.

The investigator can use graphical tools, for example, file managers or file viewers, that are normally used on a computer. In contrast, a physical analysis views the forensic image from a purely physical viewpoint—there is no file system to consider per se. Because physical analysis does not view the image from the perspective of a file system, it requires the use of a hex editor and similar tools.

Logical and physical analyses are discussed in turn. First we provide readers with a description of a hard drive, which will be important in understanding aspects of both physical and logical analysis.

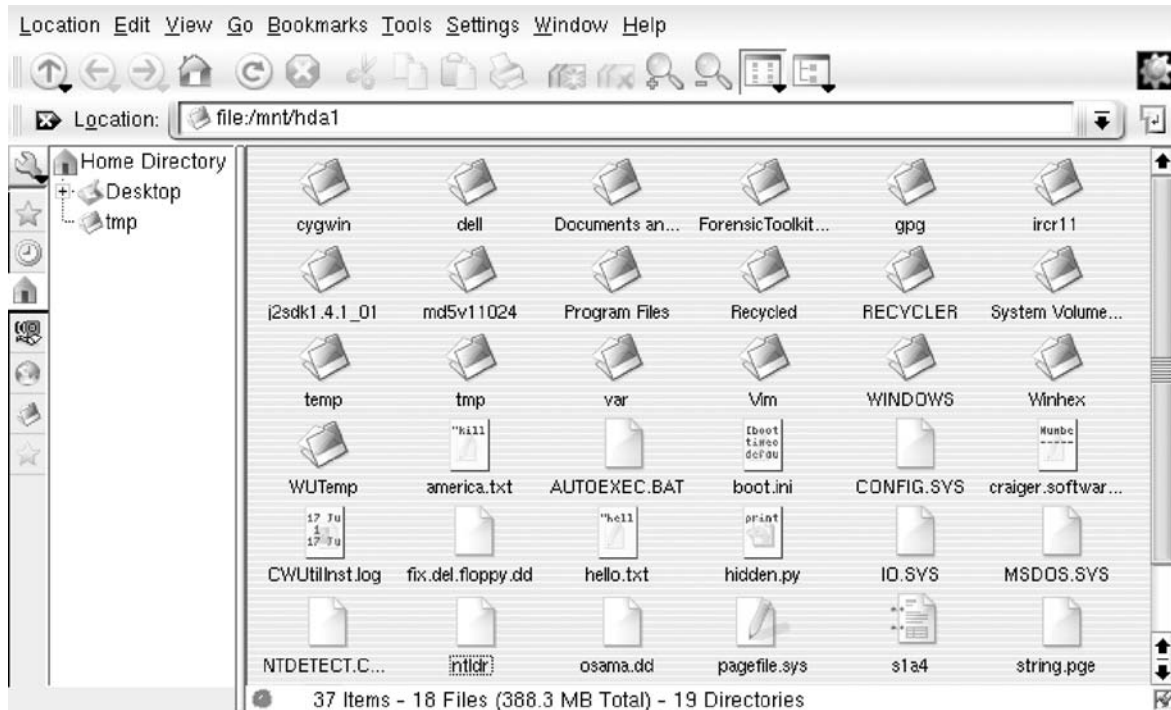

Figure 6: Forensic image preview under Knoppix.

Figure 7: Drive geometry.

## Drive Geometry

Figure 7 is a very simple, abstract model of a single magnetic disk. The single disk is called a *platter*. A hard drive will consist of multiple platters stacked on top of one another. Each platter is divided into a number of *tracks*. A *cylinder* is the column of two or more tracks on two or more platters (Nelson, et al., 2004). A *head* is a device that reads and writes data to a platter. Each track is divided into multiple *sectors*. Sectors are created via low-level formatting at the factory and are commonly 512 bytes in size.

High-level formatting places a file system on the disk. In the abstract, a file system is composed of a table to track file metadata (name, size, permissions, etc.) and an index of free disk space. File systems operate on specific size units of disk space. These units are called *clusters* in Windows, *blocks* in UNIX, or *allocation units* in the general. Each cluster consists of one or more hardware sectors. The size of a cluster will differ depending upon the size of the disk. For instance, on a high-density floppy disk, a cluster consists of a single sector. For efficiency, clusters on larger disks will consist of multiple sectors, in multiples of two.

Most modern file systems we discuss in this chapter have a default cluster size of four sectors, or 4096 bytes, although it is configurable. The default cluster size on a Windows 98 FAT32 formatted file system is 64 sectors, or 32,768 bytes/cluster. Cluster size is important for investigators because larger clusters leave more residual forensic information on the disk. To understand why cluster size is important, let us consider three conceptual categories of disk space:

1. *Allocated space* is composed of clusters allocated to a file and that are tracked by the file system.
2. *Unallocated space* is composed of clusters not in use by a file. Unallocated space may contain residual information, for example, from deleted files. We provide greater detail on unallocated space, and how to recover files in unallocated space, in the Physical Analysis section.
3. *Slack space* “is the space left over between the end of the data and the end of the last cluster or block” (Kruse &

Heiser, 2001, p. 75). Slack space may contain residual information, for example, from files previously deleted but which have been partially overwritten. We provide greater detail on slack space in the Physical Analysis section.

The procedures used to analyze the contents of each of the categories of space will differ. A logical analysis, which views our forensic image from the perspective of a file system, only examines information in allocated space. In contrast, a physical analysis allows us to examine information in unallocated and slack space as well.

## Mounting the Image

We must *mount* our forensic image to access the file system contained therein. Recall that mounting a disk or image makes a file system available to the operating system’s kernel. Once an image is mounted, we can use any tools that we would normally use to work with files (search, view, sort, print, etc.). We want to ensure that we do not (cannot) change our forensic image, so we mount our forensic image in read-only mode. This guarantees that we do not change anything on our image as we are analyzing it.

We use the *mount* command to mount our forensic image to an existing directory.

```
# mount -t vfat -o ro,loop image.dd image/
```

We first create a directory called “*image*” (which we could have named anything). Next, we execute the *mount* command with the following arguments: *-t* specifies the type of file system on the image, here *vfat* (virtual FAT, the same as FAT only able to understand long file names of 256 characters). The *-o* specifies options; here we want to mount the image read-only (*ro*), and we specify *loop* to interpret the image as if it contains a file system. The next arguments are the image to mount (*image.dd*), followed by the directory on which to mount the image (*image/*). If we receive no error message, the image should be mounted.

Depending upon the situation, it may be desirable to create a list of all the files contained on a disk. (Several law enforcement personnel have relayed stories where a prosecuting attorney demanded a list of all files on a disk, so this does occur in practice. This procedure is also listed as an important forensic procedure on the IACIS web site.) We can create a list of files and their associated hashes with the *file* and *md5sum* commands:

```
# find / -type f -print0 | xargs -0 md5sum > /evidence/files.md5
```

*find* starts searching for regular files at the root directory and pipes a list of the files as a single line (via the *-print0* argument) to the *md5sum* command. The results are directed to a file—not in a directory on the mounted image of course—for safe keeping. Here is a snippet from the *files.md5* file.

```

82f28b86ed26641a61a0b7a3ee0647a0 ./agenda.doc
093aa48b0b7ae587b9320ada28ae600a ./suzy.doc

0c8fb94c2b437896aa2d36ba7d3a2cab ./list.of.words

```

Once our image is mounted read-only, we can conduct searches, view or print the files, and treat the contents of the image as if it were a live mounted disk, without worrying about altering any files on the image because we mounted our image in read-only mode.

We can unmount the image using the `umount` command (note: *not* `unmount`).

```
# umount image/
```

## Reducing Our Search Space

What forensic procedures do we perform first? The answer is determined in part by the circumstances of our investigation. If we are investigating someone for distributing child pornography, then the primary evidence will be graphical images. (There may be other important evidence that should not be overlooked, including e-mails, electronic documents, etc.) In contrast, in an eBay Internet fraud case, we may be more concerned with e-mail messages, electronic documents, and the contents of Internet browser history and temporary files. Let the circumstances dictate the approach.

Simple cases where we know exactly what evidence for which we are looking may take half of a day. Complicated cases involving multiple hard drives and where we are not exactly sure what constitutes evidence may take weeks or even months. We want to make the best use of our time. The first activity is to distinguish which files are of probative value and which are not. The reason is that most computers contain anywhere from 10,000 to hundreds of thousands (or more) files. At some point, we will be forced to conduct a manual analysis of scores of files. We can make efficient use of our time if we can reduce to a manageable size the number of files we must manually analyze. Computer forensics is a very tedious and time-consuming task, and therefore the more we can use our tools to automate the process of identifying potential evidence the better. One automated way of filtering files is through a hash analysis.

### Hash Analysis

A hash analysis compares the hashes of the files to a set of hashes of files of a known content. Files in a hash set typically fall into one of two categories: *known* or *notable*. Known files are files that can be ignored, such as typical system files (`iexplore.exe`, `winword.exe`, `explore.exe`, and

so on). Notable files are ones that have been identified as illegal or inappropriate, such as hacking tools, pictures of child pornography, and so on. A hash analysis automates the process of distinguishing between files that can be ignored while identifying the files known to be of possible evidentiary value. Once the known files have been identified, these files can be filtered. Filtering out the known files may reduce the number of files the investigator must evaluate by half or more.

Hash analysis may be useful in an organizational setting in determining if there is any corporate espionage. Companies may be concerned that insiders are e-mailing intellectual property to competitors. Company IT staff could make a hash set by hashing all critical intellectual property-related documents. These hashes could then be compared against the hashes of files on the employee's computer to determine if the documents are located on the disk. (Note: before doing this, consult legal counsel as there are legal ramifications for this type of activity.)

Recall that only a file's contents, not its metadata, are used in calculating a file's hash value. (It is important to understand this point as subjects will try to hide evidence by changing various file attributes such as files' names, attributes, etc.) We conduct a small experiment to demonstrate this claim for the readers. We take a file and make three copies of it ([1], [2], [3]). We change the first file's name [4]; the second's owner and permissions [5], [6]; and leave the third unchanged. We then calculate the hash value for all three files [7]. Note that the hashes are the same. This fact is helpful when subjects have changed files' names, for example, the notable files previously described, to hide their true content and identity, as we demonstrate.

```

[1] jpc@simba:~> echo 'hello world\!' > file.1
[2] jpc@simba:~> cp file.1 file.2
[3] jpc@simba:~> cp file.2 file.3
[4] jpc@simba:~> mv file.1 file.changed
[5] jpc@simba:~> chown jpc.users file.3
[6] jpc@simba:~> chmod 751 file.2
[7] jpc@simba:~> md5sum file.changed file.2 file.3
7cf0564cb453a9186431ee9553f7f935 file.changed
7cf0564cb453a9186431ee9553f7f935 file.2
7cf0564cb453a9186431ee9553f7f935 file.3

```

To perform a hash analysis, we need to specify a list of MD5s. In this instance, say we are interested in finding several known bad files, including several files from a

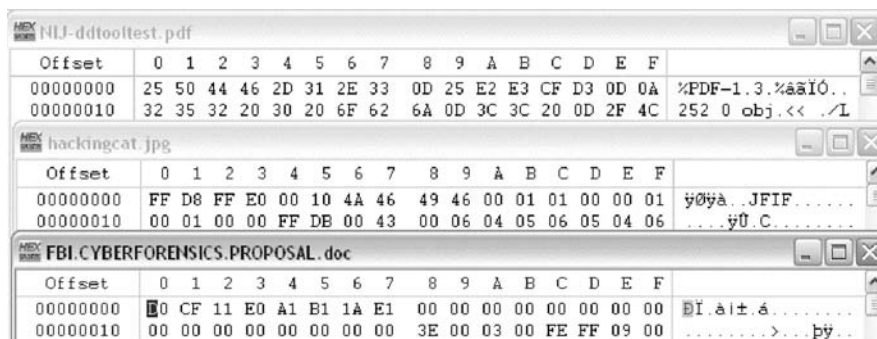

Figure 8: File signatures for three files.

rootkit as well as several illegal images. Here are the MD5s that compose our file (KNOWN.BAD) of notable files:

```
f53ce230616c1f6aafedf546a7cc0f0f Trojan ps
77f7628ee6fa6cd37ee8b06278149d1d Trojan netstat
64a3877b3105cd73496952c1ef8f48e8 Trojan ls
41791681dff33e3a492c72d3e7335f82 Trojan lsof
bbf3aeb654477c4733bddf9a6360d2c5 Illegal Image
2eff0db0a3cac3fc08add30e21257459 Illegal Image
d297c866310377f10b948d53b798c227 Illegal Image
```

We then run *md5deep* (<http://md5deep.sourceforge.net>) against all of the files in the directory, specifying the file KNOWN.BAD file for comparison.

```
pc@simba:~/chapter.stuff> md5deep -r -m KNOWN.BAD *
/image/chapter/.x
/image/chapter/misc/.y
/image/chapter/misc/preview.png
/image/chapter/misc/stuff.java
/image/chapter/misc/subset/bar
/image/chapter/preview.png
/image/chapter/large.jpg
/image/chapter/README.txt
```

The *-r* arguments indicate that *md5deep* should run recursively (recurse through directories). The *-m* argument indicates the file containing the list of known files. Note that this list may contain either known good (e.g., Windows system files) or known bad files (hacker tool kits, illegal images, etc.).

*Md5deep* reads in the list of known hashes and then proceeds to hash each file in the path indicated at the command line. It compares the file's hashes with the contents of the list of known hashes. If a match occurs, it lists it on standard out (the screen). This procedure is essentially how commercial forensic-application hash analyses function. As demonstrated above, *md5deep* found all of the files on the list of known hashes. Note that it appears that someone has changed the names of some of the notable files as a means of hiding their identity.

The National Institute of Standards and Technology (<http://www.nist.gov>) develops and maintains a very large set of hashes called the National Software Reference Library. (<http://www.nist.gov/nsrl>) The NSRL contained more than 6,000,000 hashes as of early 2005. Another

large hash set is the Hashkeeper hash set, which can be downloaded at <http://www.hashkeeper.org>. An investigator or IT staff can build a custom hash set easily by using the procedures outlined in this chapter, based on the company's need to protect intellectual property,

### Signature Analysis

A *signature analysis* is an automated procedure for identifying potential evidence. A *file signature* is a header or footer (or both) within a file that indicates the application associated with a typical file, that is, the type of file. For instance, we opened three files in a hex editor (Figure 8): a Word document, a JPG graphic, and an Adobe Acrobat file. The signatures (in hexadecimal) are

- 25h 50h 44h 46h for Adobe Acrobat Reader files (PDF),
- FFh D8h FFh, for JPEG graphical files, and
- D0h CFh 11h E0h A1h B1h 1Ah E1h for Microsoft Office files.

(Numbers in hexadecimal format are distinguished from decimal format by appending with an h.)

File signatures are useful for evaluating whether a subject is attempting to “hide files in plain sight” by changing file extensions. For instance, renaming a graphic *naked.body.jpg* to *homework.doc* can be effective in hiding a file from prying—albeit naïve—eyes. A cursory examination of files in a file manager will not reveal the fact that the *homework.doc* file is *not* a Word document but rather a graphical file. To make matters worse, Windows Explorer will happily display the graphical file that has a *.doc* extension with a Word icon, confirming to the user that the file is what it purports to be. This is true even if we request a thumbnail view in Windows Explorer. Only if the graphical file has a graphical extension (e.g., GIF, BMP, PNG, JPG, etc.) will it display as a graphical thumbnail.

How does an investigator find these hidden files? We simply compare the file's extension with its corresponding file signature. If the two match, then no effort was made to obscure the file type. If there is a mismatch between the extension and signature, then the file should be exposed to closer examination.

To illustrate how simple of a hiding technique this is, Figure 9 is a directory listing in Windows Explorer that shows files with several different extensions. We changed

02_23_Agenda.doc	31 KB	Microsoft Word Document

**Figure 9:** Viewing the contents of a floppy disk under Windows Explorer.

the extensions of several files to disguise their true identity. Can you tell which files were changed?

The `file` command uses several sources of information, including the file's signature, to verify a file's type. The example below illustrates the use of the `file` command against the files from Figure 9.

```
jpc@simba:~/chapter.stuff/> file *
02_23_Agenda.doc:      Microsoft Office Document
2004_02_23__Minutes.doc:  Microsoft Office Document
2004_03_01_Minutes.doc:  Microsoft Office Document
cat.jpg:               PDF document, version 1.3
EFE_Manual_English_rev418.pdf: PDF document, version 1.3
file.script:          empty
grandmaletter.txt:     Microsoft Office Document
school.ppt:            JPEG image data, JFIF standard 1.01
Yahoo.aba.txt:         raw G3 data, byte-padded
```

We ran `file` against every file in the current directory. We then manually compared the extensions against the known file type. (We could create a script to do this for us; however, this is beyond the scope of this chapter.) For example, the file `course.doc` exhibits the Word extension, and the signature confirms it is a Microsoft Office document. The file `grandma.txt` exhibits a text file extension; however, the signature indicates that it is a JPG graphical file. The file `homework.doc` has a Word extension, but its signature also indicates it to be a JPG graphical file. The remaining files appear to be what they claim.

How much credence should we put in the extension to denote the type of file? The simple answer: none. As demonstrated, changing the file extensions is a simple, and often successful, means of hiding inappropriate or illegal files.

## Searching a Forensic Image

Two common search tasks involve searching for specific keywords within documents or searching for particular types of files (e.g., graphical files in a child pornography case or Excel, Quicken, or Money files in a money-laundering case.) We first describe how to conduct keyword searches, followed by searching for particular types of files.

### Keyword Searches

Once the investigator reduces the search space by identifying and filtering known files, as well as identified suspect files via signature analyses, she can turn her attention to searching for specific keywords within the forensic image.

Below we use the `grep` utility to search for keywords on the image. `grep` has the capability to search for multiple keywords simultaneously. This is accomplished by creating a text file containing a list of keywords and then using the `-f` flag to indicate that we are using a file, instead of a single keyword, as input to `grep`. In this example our keyword text file contained the following key words, one per line, with no trailing blank line: marijuana, crack, crank, cocaine, oxycontin.

Again, it is important that there is *no blank line* at the end of our keyword file. Had we not used a file for our keywords, we would have had to perform five separate single keyword searches.

Now we are ready to search our forensic image for the keywords. We execute the following command:

```
# grep -i -r -f keywords /image/* >
/evidence/grep.results
```

The flags are interpreted as follows:

- `-i` indicates case insensitive search, thus “cocaine,” “COCAINE” and “CoCainE” are the same.
- `-r` indicates a recursive search, that is, traverse all of the subdirectories beneath the current directory.
- `-f` indicates the next parameter is the file containing our keywords.

We redirect the results of our `grep` search into a file so that we can more closely analyze the results and print it out if need be. Abbreviated results are displayed:

```
/mnt/evidence/bruce: WASHINGTON, D.C. U.S. Representative issued the following statement regarding the GAO Report to Congress titled, OxyContin Abuse and Diversion and Efforts to Address the Problem:
```

```
/mnt/evidence/bruce: This report reinforces what I suspected all along: Purdue Pharma has engaged in highly questionable practices regarding the marketing of OxyContin, leaving a plague of abuse and broken lives in its path...
```

```
/mnt/evidence/dynamic.dll: Cocaine Anonymous is a fellowship of men and women who share their experience, strength and hope with each other that they may solve their common problem and help others to recover from their addiction. The only requirement for membership is a desire to stop using cocaine...
```

```
/mnt/evidence/homework.doc: OxyContin is a trade name for the drug oxycodone hydrochloride. Manufactured by Purdue Pharma L.P., OxyContin is a controlled-release form of oxycodone prescribed to treat chronic pain. When used
```

properly, *OxyContin* can provide pain relief for up to 12 hours...

*/mnt/evidence/todo:marijuana: facts for teens...*

*/mnt/evidence/todo:teen boy quote that reads I used to be real athletic. When I started using drugs, I just stopped playing all together because I thought I had more important things to do. Q: What are the short-term effects of marijuana use?...*

*/mnt/evidence/todo:A: The short-term effects of marijuana include:...*

`grep` found instances of the terms marijuana, cocaine, and *OxyContin* in files contained on our forensic image. Note that there are several different cases used in the spelling of the terms (e.g., “Cocaine,” “cocaine”). A case sensitive search would have failed to find several instances of the keywords, therefore, it is usually best to include the `-i` flag if case does not matter.

### Finding Files by Type

Say we have been asked by law enforcement to find all graphics files on a subject’s hard drive that contains more than 500,000 files. What would be the most efficient means of conducting this search? Clearly we want to automate as much of the search as possible. We could search for files with the appropriate graphical file extension, for instance:

```
# find / -type f \( -name '*.gif' -or -name
  '*.jpg' -or -name '*.bmp' -or -name '*.png' \)
```

This command finds all files with the GIF, JPG, or BMP extension. This command would *not* find the files with changed extensions, however. One way to find graphic files whose extension has been changed is to combine three GNU utilities: `find`, `file`, and `grep`. The best way to

---

```
# find /image -type f ! \( -name '*.jpg' -or -name '*.png' -or -name
  '*.bmp' -or -name '*.tiff' \) -print0 | xargs -0 file | grep -f
  keywords
```

```
./agenda.doc:      PC bitmap data, Windows 3.x, 382 x 61 x 24
./suzy.doc:        PNG image data, 571 x 135, 8-bit/color RGB
./folder/.foo:     PC bitmap data, Windows 3.x, 536 x 177 x 24
./folder/school.ppt: JPEG image data, JFIF standard 1.01
./folder/.hiddenfile: PNG image data, 351 x 374, 8-bit/color RGB,
./bagheera.txt:    PC bitmap data, Windows 3.x, 536 x 307 x 24
./9.11.xls:        JPEG image data, EXIF standard, 10752 x 2048
./list.of.words:   PNG image data, 571 x 135, 8-bit/color RGB
```

---

explain the combined use of these commands is through a demonstration.

Our goal is to find all graphical files regardless of extension. We want to do the following:

Step 1: Use the `find` command to find all regular files on the hard drive (as opposed to directories, special devices, and so on). Pipe the results of this command to the

Step 2: `file` command, which returns the type of file using header information. Pipe the results of this command to the

Step 3: `grep` command to search for graphical-related keywords.

Here is our command to perform these steps:

```
# find /image -type f ! \( -name '*.jpg'
  -or -name '*.png' -or -name '*.bmp' -or
  -name '*.tiff' \) -print0 | xargs -0
  file | grep -f keywords.txt
```

The `/image` argument specifies the directory in which to start. The argument `-type f` specifies that we are interested in regular files as opposed to special files such as devices or directories. The `find` command is recursive by default so it is essentially recursively finding all files beginning at the `/image` directory. The exclamation mark (!) modifies the contents within the parenthesis and says that we want to process files whose extension is not `*.jpg`, or `*.png`, or `*.bmp`, or `*.tiff`. The `-print0` is a special formatting command that is required to format the output of `find` for piping to the next command.

We pipe the results of `find` to `xargs -0`, which hands each file from the previous command to `file`. `file` evaluates each file’s signature, returning a description of the type of file. These results are piped to `grep` to search for the specific keywords that are contained within the `keywords.txt` file. The arguments for `grep` include `-i` for case insensitive search and the `-f keywords.txt`, the file containing the list of keywords: PNG, GIF, bitmap, JPEG, and image.

The results are as follows:

We found eight graphical files, including instances of JPEG, PNG, and bitmap files. Note each of the files found were graphical files with misleading file extensions. What can we deduce from this result? Because applications will not arbitrarily change an extension of a graphical file, an investigator might reasonably deduce that a user has manually renamed the files, possibly in an attempt to hide their nature. This result is not incontrovertible but would warrant further investigation.

## E-Mail Searches

E-mail is ubiquitous, supplanting regular mail as a preferred form of communication for many. E-mail can be a rich source of evidence for many types of investigations.

There are several e-mail applications available in Windows, the most popular of which are Microsoft Outlook and Outlook Express, the latter of which is purportedly the most popular e-mail client as it comes with every version of Windows. Microsoft Outlook is a full-fledged personal information manager that includes e-mail, calendar, contact list, task list, and scheduler. There are several, less popular, e-mail applications available on other platforms, including Eudora, Netscape Mail, Mozilla Mail, and Thunderbird. Each of these applications includes an address book or contact list that may prove useful in an investigation.

Some e-mail applications store messages in proprietary binary formats, including Outlook, Outlook Express, and Eudora. Outlook uses a proprietary format that is different from its sibling Outlook Express. Netscape and Mozilla mail store mail in a nonproprietary *mbox* format that is easily readable in a text editor.

To conduct an e-mail investigation, we must locate the mailbox files. The mailbox locations differ depending upon the version of Windows and the application used:

- Outlook Express
  - Windows 2000/XP
    - C:\Documents & Settings\*<username>*\Local Settings\Application Data\Identities\*<unique string>*\Microsoft\Outlook Express\
  - Windows NT
    - C:\winnt\profiles\*<username>*\Local Settings\Application Data\Identities\*<unique string>*\Microsoft\Outlook Express\

- Windows 95/98/ME
  - C:\Windows\Application Data\Identities\*<unique string>*\Microsoft\Outlook Express
- Netscape/Mozilla Mail
  - Windows 2000/XP
    - C:\Documents & Settings\Application Data\Mozilla\profiles\*<username>*\iunique string>.slt\Mail
  - Windows NT
    - C:\winnt\Application Data\Mozilla\profiles\*<username>*\iunique string>.slt\Mail
  - Windows 95/98/ME
    - C:\Windows\Application Data\Mozilla\profiles\*<username>*\iunique string>.slt \Mail

Outlook Express stores e-mail messages and folders in files with a *dbx* extension. Each folder has a corresponding *dbx* file, whose name coincides with the folder's name. For example, the *outbox.dbx* file corresponds to the Outbox folder (<http://http://mail-repair.com/outlook-express-repair.html>). An investigator must use an application that understands the *dbx* proprietary format to extract the folders and messages in a human-readable format. The simplest method is to copy *dbx* or *pst* files to another Windows machine that contains the Outlook application and import the appropriate application, either Outlook Express (*dbx* files) or Outlook (*pst* files).

A second alternative is to use a non-Microsoft application that understands the mailbox formats and has the capability of extracting the messages and folders. For example, LibPST (<http://sourceforge.net/projects/ol2mbox/>) is an open source utility that converts messages from Outlook *PST* format to a standard *mbox* format. In our experiments, we used LibPST to extract the contents of the Outlook mailbox. This demonstrates it is always good to have a wide variety of tools in your forensic toolkit. Here is a sanitized e-mail that we recovered with LibPST:

Hi ya'll,

I won't be able to make it this Friday; I'm going out of town.

Philip

**Table 2** Yahoo! Mail and Hotmail Filenames

File Content	Yahoo! Mail	Hotmail
Login page	login[#].htm	uilogin[#].htm
Home page	Welcome[#].htm	mhome[#].htm
Inbox/folder	ShowFolder[#].htm	HoTMail[#].htm
View message	ShowLetter[#].htm	getmsg[#].htm
Compose message	Compose[#].htm	compose[#].htm

### Web-Based E-mail

Investigators are likely to encounter Web mail, the most common of which are Yahoo! Mail (<http://my.yahoo.com>) and Hotmail (<http://www.hotmail.com>). Web mail messages are stored in *HTML* format with the extension *html* or *htm* and are thus readable with any Web browser. The messages that are downloaded from or uploaded to the Web are stored in the four Windows temporary Internet folders.

We conducted a series of experiments to determine the file names associated with each of the Web mail messages from Yahoo! Mail and Hotmail. The results of our investigation are displayed in Table 2. These names may be used in conjunction with the *grep* search to identify the use of Web mail messages.

We can use any Web browser to view these HTML files. In Figure 10, we opened a Web mail message from our temporary Internet folders (note the message has been sanitized of names).

Unless a suspect took overt means to remove these files from the temporary Internet folders, we can easily access these files via a Web browser.

The temporary Internet folders may contain hundreds of files with an *htm* extension. To find the relevant e-mail-related files, the investigator can open up each file in a browser and conduct a manual search or use *grep* to search for the appropriate file names (see Table 2). Note that the terms “Yahoo” or “Hotmail” will appear somewhere in the e-mail files. We use this fact in our command to search for files from Hotmail.

To find all Hotmail files, we use the following command line to show all of the related files in the temporary Internet folders.

```
linux:~/Temporary Internet Files/Content.IE5 # find . -type f \( -name
'getmsg*.htm' -or -name 'uilogin*.htm' -or -name 'mhome*.htm' -or -name
'HoTMail*.htm' -or -name 'compose*.htm' \)
```

```
./31n6dkxa/getmsg[1].htm
./31n6dkxa/compose[1].htm
./2l4z6jel/uilogin[1].htm
./ybcpq9sz/compose[1].htm
./ybcpq9sz/compose[2].htm
./ojavstch/compose[1].htm
./ojavstch/uilogin[1].htm
./ojavstch/getmsg[1].htm
```

The directories with the funny-looking names are the temporary Internet file folders.

### Windows Swap File

A swap file is virtual memory that is used as an extension of the computer system's RAM (<http://whatis.techtarget.com>). Typically, the least-recently used contents of RAM are paged out (i.e., swapped) to the swap file and are read back into RAM on an as-needed basis. The swap file can contain evidence that has been previously removed, even if the file was forensically wiped from a hard drive, unless of course the swap file was forensically wiped; then the file within the swap is unrecoverable, although we may still find copies in unallocated or slack space.

The Windows swap file under Windows 9x/ME is named *win386.swp* and is typically found in the Windows root directory, although in the Windows system directory this may be changed by the administrator. Under Windows NT/2000/XP, the file is named *pagefile.sys* and is typically found in the root directory (e.g., C:\), and again may be changed to a different location.

The swap file is a binary file. We use the *strings* command along with *grep* to extract interesting information of possible evidentiary value. The *strings* command reads in a file and extracts the human-readable text of a certain length, the default of which is four characters. In the following example, we extract the human-readable text and then use *grep* to search for the string “hacker.” Note that we request two lines of context using the *-C* argument, which gives us two lines before and after the actual search string. There were approximately 25 hits extracted from the swap file.

```
linux: strings win386.swp | grep -C 2 hacker

## I Know What You Did with Your Computer Last Summer ...

Every time a user uses Windows Explorer or Internet Explorer to access a file or Web site, digital traces of these activities are placed on the hard drive. Most of these artifacts are kept in *index.dat* files. An *index.dat* file is a binary file that tracks user activities: files opened in Windows Explorer, Web pages opened in Internet Explorer, and so on.

Each time a file is accessed via Windows Explorer (as shown in Figure 11) or Internet Explorer, a record is placed in an *index.dat* file.

Windows uses several *index.dat* files to track various activities on the computer. The location of these files will vary depending upon the version of Windows used. Table 3 shows these locations.

*Index.dat* files are binary files and therefore not in human-readable format. *Pasco* (<http://www.foundstone.com>) is a small open source application that parses the contents of *index.dat* files and outputs the results into a tab-delimited file. To illustrate, we ran *pasco* against the *index.dat* file from a system and redirected the output to

a file that we subsequently imported into a spreadsheet application (see Figure 12).

```
# pasco index.dat > evidence.txt
```

This *index.dat* file in this example was from the *History.IE5* folder (see Table 3). Each row in the spreadsheet is an activity record that includes the type of access, the URL (which can be a regular file or a Web site), the modified and access times, filename, and directory (latter two not shown).

This particular *index.dat* contains information on files accessed from either Windows Explorer (the default file manager) or Internet Explorer, including

- files accessed and opened via Windows Explorer (rows 4 through 9),
- keywords used in searches over the Internet (rows 10 and 11), and
- URLs visited via Internet Explorer (rows 12 through 15).

This *index.dat* file included more than 487 files accessed within the last three weeks. An investigator can use the modified and last accessed times to determine the most recent date and time the user downloaded the file (modified time), as well as the last time the user visited the page or file (access time)

## Cookies

According to <http://www.cookiecentral.com>,

Cookies are pieces of information generated by a Web server and stored in the user's computer, ready for future access. Cookies are embedded in the HTML information flowing back and forth between the user's computer and the servers. Cookies were implemented to allow user-side customization of Web information. For example, cookies are used to personalize Web search engines, to allow users to participate in WWW-wide contests (but only once!), and to store shopping lists of items a user has selected while browsing through a virtual shopping mall (Mayer-Schonberger, February 3, 2003).

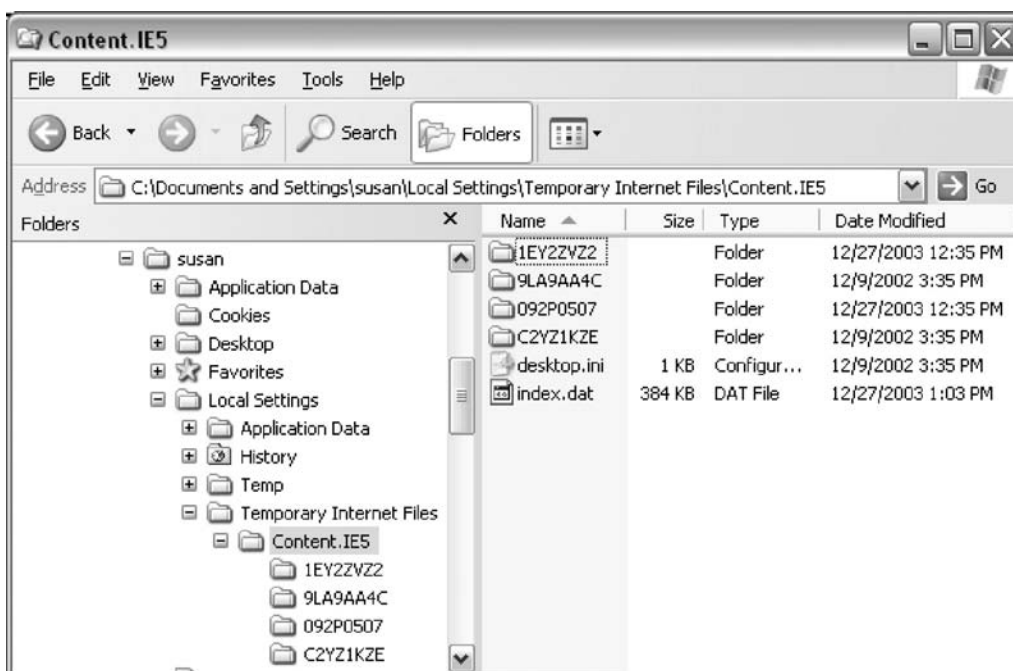

Figure 11: Location of an *index.dat* file in temporary Internet folders.

Unless a user's browser security is set to high, cookies are automatically—and quietly—placed on the user's hard drive. Most users may be unaware that these cookies are being saved on their hard drives.

The cookies directory contains the individual cookies as well as an *index.dat* file that consists of the activity records for each of the cookies in the directory, as shown in Figure 13. We used Pasco to parse the *index.dat*, the results of which are displayed in Figure 14. Note the activity records contain the cookies' URL (from whence it came), the modified and access times, and the cookies' file name.

```
#galleta jpc@microsoft [1].txt >ms.cookie.txt
```

As shown in Figure 14, the cookie is partitioned into six or more pieces of information, including a) the Web site from which the cookie came, b) a variable, c) its associated value (which will differ on its meaning depending upon the Web site), d) the creation time of the cookie, and e) its expiration date and time. Here the variable is apparently the GUID (globally unique identifier) for my copy of the

Windows OS that I am running, along with a hash of its value.

Care should be taken when interpreting cookies to infer user activity because cookies may be placed on user's hard drive from third-party sources, that is, from sources other than the Web site visited.

Table 4 lists the locations where cookies can be found.

### Deleted Files and the INFO2 File

Files that are deleted through *My Computer*, *Windows Explorer*, a Windows-compliant program, or any other way *except* from the command line, are removed from their original directory, and a copy is placed in either the *Recycled Bin* (FAT32) or *Recycler Bin* (NTFS). A binary file named *INFO2* within each bin tracks important information about the deleted files and may be an important source of evidence should the contents of deleted files be overwritten.

According to Microsoft (How the Recycle Bin Stores Files, January 18, 2004.), the following occurs when a file

Figure 12: A Parsed Index.dat File.

is deleted by one of the means described at the beginning of this section:

1. The deleted file is moved to the Recycled/Recycler Bin.
2. The following details are recorded in the INFO2 file for each deleted file:
  - a. The index, that is, the order in which the file was deleted.
  - b. The date and time the file was deleted.
  - c. Drive from which the file was deleted.
  - d. The full path.
  - e. The file size.
3. The deleted file is renamed, using the following syntax:

*D*<original drive letter of file><#>.<original extension>

The <#> is the order in which the file was placed in the bin. For example, if a file named c:\My Documents\Florence.doc is the first file placed in the Recycle Bin, its name is DC1.doc. A file named Beatles.MP3 deleted next would be renamed DC2.MP3. If the files were on the Z drive, they would be renamed DZ1.doc and DZ2.MP3, respectively.

The length for an INFO2 record under Windows 95/98/ME is 280 bytes and 800 bytes under Windows NT/2000/XP (Sheldon, 2002). When a user empties the Recycled/Recycler bin, the files within the bin are removed and the INFO2 file's contents are deleted.

Under NTFS, each user is tracked by a security ID (or SID), which is how the computer refers internally to each user. This allows user activity to be tracked by the operating system. Under NTFS, every user has a folder named

```
E:\Documents and Settings\jpc\Cookies>ls
index.dat                jpc@msn[1].txt
jpc@atdnt[2].txt         jpc@preview[2].txt
jpc@atwola[1].txt       jpc@questionmarket[1].txt
jpc@con[1].txt          jpc@real[1].txt
jpc@cos[1].txt          jpc@tucows[1].txt

jpc@info.winamp[1].txt  jpc@yahoo[2].txt
jpc@microsoft[1].txt
```

Figure 13: Cookies directory.

after his/her SID in the Recycler Bin. Each of the folders will contain an INFO2 file.

Figure 15 shows a Recycler Bin's contents from the command line. (We must demonstrate this from the command line as a user's SID is not displayed when viewed within Windows Explorer.) Note the SID-named folder.

The times displayed are the last modification times for each file, *not* the time the file was created in the bin. Recall the deleted times are kept in the INFO2 file.

We can use *rifuiti* (<http://www.foundstone.com>) to interpret the binary contents of the INFO2 file. *Rifuiti* takes as an argument the name of the INFO2 file. We redirect the results to a tab-delimited file that we can then import into a spreadsheet application (as demonstrated in Figure 16).

```
# rifuiti INFO2 > deleted.txt
```

Of what use is the INFO2 file? Even though its contents are deleted when the bin is emptied, we may be able to recover the contents from unallocated space during a physical analysis. We may even be able to recover the files that were emptied from the bin. (We deal with the recovering of information from unallocated and slack space elsewhere in the chapter.) Note that we are still able to extract important information from the INFO2 file concerning deleted files, including a) the date and time the file was deleted, b) the drive on which the file was deleted, c) the file's original path, and d) the file's size.

### Application Residual Files

Many Windows applications create *temporary* files that are usually written to the hard drive. These temporary files are usually deleted from the hard drive once the application closes or the user closes the file manually. As we have

Figure 18: Results of grep search.

previously noted, deleting files only removes the pointer to the file and marks the clusters occupied by the file as available: the information in the clusters is still recoverable until overwritten. (Note that when temporary files are deleted by applications they are *not* moved to the Recycler/Recycled Bins as described in the previous section.)

Microsoft Office applications are very good about creating temporary files. Microsoft Word, for example, creates temporary files that consist of the contents of previous versions of a file. Temporary files are created when Word's *autosave* feature is turned on or when the user manually saves the file. Word creates temporary files to provide some fault tolerance should Word or the operating system crash. In later versions of Office, if Word finds one of these files, it recognizes this as an anomaly and offers to recover the file.

Figure 17 illustrates several temporary files that Word created as we were editing a document. This explains why an investigator might find dozens of residual copies of the same text in unallocated space.

If an application or operating system misbehaves, it may leave temporary files (usually, but not necessarily, noted with a TMP extension) in allocated space on the hard drive. We can use the `find` command to search for these files.

```
# find / --type f \( -name '*.TMP' --or --name
  '*.tmp' \)
```

This command will find all files with the `*.TMP` or `*.tmp` extension. Of course, this only works if the temporary files are in allocated space (i.e., have not been deleted). Once the application closes, these temporary files will be deleted by the application. If we need to identify temporary files that have been deleted, we can use two procedures. The easiest method is if we know part of the text of the document, we can use `grep` to search our forensic image (that is, *unmounted* image) for that text using a physical analysis.

Say we are told that subject created a threatening letter using a word processor on his computer. We are also

told the subject has a "wipe" utility on the computer, and that a cursory examination of the computer showed no copies of the letter. As investigators, we assume that the word processor diligently created temporary files of the counterfeit document. We can use parts of the threatening letter in a keyword search to see if we can recover some of the temporary files.

A significant content of a hard disk will be unreadable binary data. Therefore, let us first extract all of the human-readable text from our forensic image. We use the `strings` command to extract the human-readable text from our forensic image.

```
# strings evidence.dd>/evidence/evidence.str
# grep -b -I -C 1 "Philip" evidence.str >
  /evidence/search.philip
```

`strings` extracts strings of size 4 bytes or greater in the 7-bit ASCII range. We redirect the results to a file, which we then use in our `grep` search. The `-b` flag in the `grep` search specifies that we want the byte offset printed for each result, that is, where in the file the match occurred. The `-C 1` specifies that we want one line of context before and after our match.

Figure 18 shows the results: five matches at byte offsets 41260, 41404, 41786, 45606, and 49673, with one line of context before and after each match. If we wish to further explore text associated with one of the matches, we can use the byte offset of the file to extract more of the text.

Say we are interested in the text at offset 41786, which appears to be a letter of some sort. We can use `dd` to extract the text as demonstrated in Figure 19.

The important arguments are `bs`, `skip`, and `count`. We set our block size to one so that we can ask for a specific number of characters (i.e., `bs=1` is equal to one character). We want to start extracting the data a little before our match at byte offset, so we chose to start at 41700. Note we specify offset 41700 because our block size is one. If we had used the default block size of 512 bytes, we

Figure 19: Command line to extract specific strings.

```
snoball:/evidence # dd if=evidence.str of=philip.txt bs=1 skip=41700 count=750
750+0 records in
750+0 records out
snoball:/evidence #
```

would be starting at offset  $41700 \times 512$  or 21,350,400, definitely not what we wanted. The block size also refers to our count: we are extracting 750 characters (not  $750 \times 512$ ). The 750 characters we extracted are shown in Figure 20.

As you can see through several demonstrations, `dd` is a very useful tool.

## UNICODE

There is a potential problem because text is represented in various formats. ASCII text is represented in 8 bits, which limits the number of characters it can represent to 256, that is,  $2^8 = 256$ . UNICODE is a 16-bit character representation that was created to overcome this limitation and to allow for the ability to represent characters from various countries, given that it can now hold 65,536 ( $2^{16} = 65,536$ ). So, ASCII text is represented in one byte, whereas UNICODE is represented in two bytes. The difference between the same text represented in ASCII and UNICODE can be seen in Figures 21 and 22.

The information for the figures was extracted from an INFO2 file.

The normal strings command as run in the previous examples will not find the text in Figure 22, given that each character is represented by two bytes. To extract UNICODE characters, the flags `-b1` (that's a lowercase "L") must be used.

The command to extract all UNICODE characters from a file named "evidence.txt" would be

```
# strings -a -b 1 evidence.txt > /evidence/
evidence.unicode
```

## Print Spool Files

When a file is printed in Windows, it is first converted to an enhanced metafile (EMF)—a graphic image—before it is printed. This file is written to the hard drive in the root Windows directory under `\system32\spool` directory (Windows XP and 2000). (Note: The default print spool directory can be changed by changing the values in Windows registry.) There are two files associated with each file printed: a header file with the extension SHD and the actual graphic image (EMF format) with the extension SHL. The SHD file contains information on the name of the file being printed, the name of the file to which it was printed, and the time and date stamp. The SHL file is the actual graphical file. If we can recover the SHL file, we can print it. Collectively, these files are called *print spool files*, and they demonstrate that particular documents were once printed from the computer. These files are typically found in the directory

```
c:\<Windows root directory>\system32\spool.
```

If a user creates a document in Windows, prints the document, then uses a forensic wipe utility to write zeros over the clusters composing the file, an investigator can still access the document by recovering the deleted print spool files.

Once the file has been printed, Windows will delete the header and EMF file. Until overwritten, the header and EMF file will remain in unallocated space and are recoverable with the techniques demonstrated in subsequent sections. However, if something happens and the file fails to print, the header and EMF file will remain in the direc-

tory. A `grep` search for files ending in `*.SHD` or `*.SHL` will find these files.

## Physical Analysis

A logical analysis can only examine the contents of allocated space: it cannot find files intentionally deleted by users, deleted temporary files, deleted print spool files, or other forms of information found in unallocated or slack space. The investigator must conduct a physical analysis to examine ambient information in the unallocated and slack space.

A physical analysis involves analyzing our evidence from a physical perspective, that is, without regard to a file system. Thus, we do not mount our forensic image but instead use a hex editor to view the forensic image as a single, flat file. This will permit us access to all categories of disk space: allocated, unallocated, and slack. Clearly, this is advantageous as often a great deal of evidence may be found in unallocated and slack space. The drawback is that we are no longer dealing with a file system, and therefore, our analysis can be very tedious and complex.

Figures 23 and 24 show a physical view of the floppy disk image that we created earlier. (The far left side of the figure shows the offset from the beginning of the file in hex; the middle section is the contents of the file in hex at the offset; the far right side is the ASCII representation of the contents of the file at that offset.)

Figure 23 displays part of the *root directory* of a FAT formatted floppy disk image as viewed from a hex viewer. A root directory is like a table of contents of a file system; it tracks metadata on each file including the filename: file size: time and date of creation, modification, and last access: where the file starts on the disk; and so forth. On our floppy disk, each root directory entry is 32 bytes, or two lines in Figure 23. The lines at offset 2700 through 2710 are the root directory entry for the file `KEYWORD.GIF`.

Figure 24 shows the beginning of the data area that starts at offset 4200h. Note that the contents of this first sector of the data area contain the file signature `FFh D8h FFh`, which is a JPEG graphic signature. Note that the data area on a floppy starts at physical sector 33, which translates to logical cluster 2. This will be explained in more detail in the section *Recovering Deleted Files*.

From an examination of the root directory entry displayed in Figure 23, we can tell that the file at offset 2600–2610 has been deleted. However, Figure 24 shows that the file still resides on the disk. Two questions come to mind. First, how did we know that the file had been deleted from viewing the root directory? Second, can we recover the deleted file displayed in Figure 24?

## What Happens When a File Is Deleted?

Before we explain what happens to a file when it is deleted, it is important to understand parts of a file system and how an operating system tracks files.

A disk formatted with a version of FAT is comprised of a reserved area and a data area. The reserved area consists of the following components:

- The boot record in the first sector of the disk;
- First file allocation table;

Figure 24: FAT12 data area: physical sector 33-logical cluster 2.

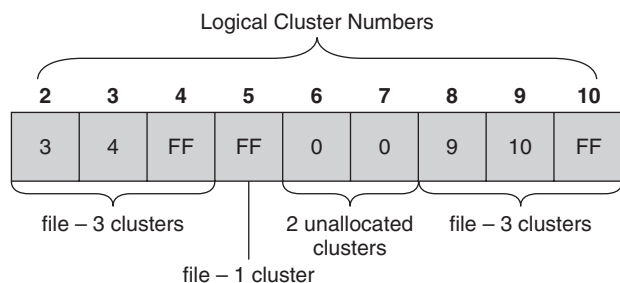

Figure 25: FAT explanation.

- Second file allocation table (a backup to the first);
- Root directory; and
- Data area. (On a floppy, it begins at physical sector 33/logical cluster 2. This will differ depending upon the size of the disk.)

The root directory entry for a file contains information on the starting cluster of the file. The remaining clusters that compose the file are kept in the file allocation table or FAT. A FAT is merely a singly linked list, as demonstrated in Figure 25.

Figure 25 illustrates an abstract model of a file allocation table. The numbers above the boxes indicate the FAT entry for a particular *logical* cluster. The numbers in the boxes are pointers to the next cluster in the file. For instance, the FAT entry for cluster two contains a three, which is a pointer indicating that the next cluster in the file can be found at cluster three. FAT entry three contains a four, indicating that the next cluster in the file is at logical cluster four. An FF in this instance is an end-of-file marker, indicating that this is the last cluster the file uses. If we assume that this is a FAT12 floppy disk, where each cluster is 512 bytes, we see that the file has a maximum size of  $3 \times 512$  bytes or 1,536 bytes. Because clusters two, three, and four are allocated to a file in the FAT, we know that the file resides in allocated space and should appear in a logical analysis.

FAT cluster entry five has a single FF, indicating that the beginning and ending cluster for this file is logical cluster number five, and has a maximum size of 512 bytes. This file too is in allocated space and should appear in a logical analysis.

FAT cluster entry six and seven are 0s. This has two possible interpretations. First, it could indicate that the two logical clusters have never been allocated, that is, they have never been used by a file. Second, it could mean that the file was deleted, and thus the clusters constituting the file were set for reallocation by placing 0s in the FAT entries. We can determine which interpretation is correct by

viewing the logical cluster six and seven with a hex editor. If these clusters contain any data, we know that the files were deleted. We could also look at the root directory to see if there are any files whose starting cluster is logical cluster six. This would also be supporting evidence that the file was deleted.

Finally, FAT cluster numbers eight, nine, and ten indicate a small file comprising three clusters.

What happens when a file is deleted in a FAT file system?

- The first character of the file's name in the root directory is changed to e5h.
- The FAT entries are set to 0.

The clusters that compose the file are not touched. However, should the operating system decide that the FAT entries and corresponding clusters are needed, say, to save a new file, then the clusters may be overwritten. That is the reason we freeze the computer: there is the potential for deleted files of possible evidentiary value to be overwritten by the operating system.

Although experiments we have conducted have varied in the exact details that occur, similar operations occur when files are deleted under most, if not all file systems, including NTFS, UNIX, and Linux file systems (EXT2, Reiser, etc.), that is, a file pointer is modified to indicate the file is deleted and the clusters used by the file are marked as available, with the actual file contents remaining on the disk.

### Unallocated Space Revisited

Revisiting Figure 23, we see that there are two root directory entries whose names begin with an "e5" (the hex section). These files are at offset 2600h (?EAL.JPG) and offset 2620h (?IDDEN.JPG). This is the character that the operating system places in the first position of the file's name to indicate that the file has been marked as deleted. If we look at Figure 24 at offset 4200h (which happens to be logical cluster number two), we see that cluster still contains information located in unallocated space. This is the deleted file ?ATA.JPG. We can recover this file, as described elsewhere in the chapter.

### Slack Space

Slack space is an interesting phenomenon that can hold a great deal of useful evidence. Recall that the smallest unit that can be allocated to a file is a cluster. If a file is 1 byte in size and the cluster size for a disk is 32,768 bytes (64 sectors per cluster), then the entire cluster will be reserved for the 1-byte file. Clearly, this is a tremendous amount of wasted disk space. On average, the last cluster of each file will only be half full, meaning each file will waste half a

Figure 26: Slack space illustration.

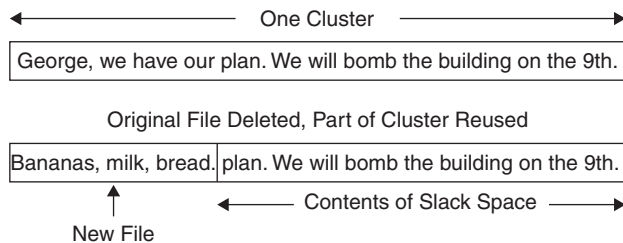

Figure 27: Cluster reuse and slack space.

cluster. Multiply the number of files on a hard drive by half the cluster size and you will see that there is a tremendous amount of wasted space on any hard drive. The larger the cluster size, the more wasted space.

Cluster size has an important implication for a forensic investigation: larger cluster sizes mean more slack space. To illustrate slack space, Figure 26 shows a single cluster composed of 64 sectors. Say we create a file composed of 20 characters. Although the physical size of this file is small (160 bytes), its logical size will be the size of the smallest allocatable unit, which is 32,768 bytes. This means that there are 32,608 bytes wasted (32,768 - 160) in this cluster. Those 32,608 bytes are *file slack*, that is, slack space.

File slack becomes most interesting when clusters containing data are reused. Figure 27 illustrates this phenomenon. Say a criminal creates a document that discusses his plans to bomb a building and then deletes the document. Later, the criminal creates a grocery list, and the operating system happens to reuse part of the previously allocated clusters, as demonstrated in the bottom of Figure 27. Part of the original bombing plans document still exists in file slack. A logical analysis would *not* uncover the contents of slack space. The reason is that when we open a file only the contents of the file, up until the end-of-file marker, are retrieved by the operating system. We must conduct a physical analysis to find the contents of slack space.

### Recovering Deleted Files

As mentioned previously, the delete operation does not remove the contents of the file from the media. It only marks the entry in the file table as deleted, and the clusters previously used for the file are marked as available. All of the metadata in the root directory entry remain, including modified, accessed, and created times; attributes; file size;

and so on. Also, the deleted file's FAT entries are marked as available by changing the FAT entries to 0. However, the data still remain on the disk (Figure 28). As long as the clusters are not overwritten, file contents can be recovered. And even if some of the clusters were overwritten, there is still the possibility that some of the file contents may still remain.

To demonstrate the ease with which a deleted file can be recovered, a small file was created, saved to a floppy, and then deleted. We created a forensic image of the floppy and then viewed the image with a hex viewer. Note that in this demonstration we do *not* mount the image, but rather simply open the image in a hex viewer.

To recover the file, we need two pieces of information: the starting cluster of the file and the size of the file. (It also helps if the file is not fragmented.) We can find both pieces of information in the root directory entry for the file.

As shown in Figure 23, the root directory of a FAT12 formatted floppy disk begins at hex offset 2600h. Note that, except for the first character, we know the remaining characters of the file name. The starting cluster of the file is two, 0002h, as shown by the brackets on the left. The size of the deleted file is indicated by the brackets on the right, 7D7Bh.

To calculate the starting cluster and file size we must perform a “byteswap” operation to put the hex characters in their correct order. The byteswap for the starting cluster results in 0002h or 2 in decimal. The byteswap for the file size is 7D7Bh or converted to decimal 32,123 bytes.

Once we know the starting cluster and file size, we can use `dd` to recover the file. Recall that the data area on a FAT formatted disk starts at logical cluster 2. This translates to physical sector 33 on a FAT12 formatted disk. (The boot sector, two file allocation tables, and the root directory constitute the first 32 sectors.) The file size in hex is 7D7Bh, which is 32,123 bytes. Recall that the default block size for `dd` is 512 bytes and each cluster of a FAT12 disk is equal to one sector. To determine the number of clusters to extract we divide 32,123 by 512 = 62.74. Because a file cannot use three quarters of a cluster, we round up to 63, which means we may also capture any contents of slack space, should it exist.

```
# ddif= image.dd of=_at.jpg skip=33
count=63
63 + 0 records in
63 + 0 records out
```

The `skip=` argument specifies at which *physical* sector to begin, here, physical sector 33. The `count=` argument specifies the number of blocks (sectors) to extract. The `dd` operation succeeds, indicating it both read and wrote 63 records (blocks). We can now open the `_at.jpg` file. As we can see from the recovered graphic in Figure 29, we can

```

**Figure 29:** Deleted file recovered manually with `dd`.

now complete the file name; the first letter was a “c” for `cat.jpg`.

### Dealing with Formatted Drives

If deleting a file does not remove all vestiges of a file from media, then surely formatting does, right? Not exactly. There are two types of high-level formatting in Windows: a *quick* format and a *full* format. A quick format performs two operations: it a) zeros out the root directory entries and b) zeros out the file allocation table entries. The data area is *not* touched. (This is a nice simple experiment we encourage the reader to conduct with a floppy disk). A full format, in contrast, performs the same two operations as the quick format, and in addition it writes the hex character `F6h` in every sector of the data area. Thus, a disk that has been subjected to a full format will hold no recoverable data, except by experts using expensive procedures such as magnetic force microscopy (MFM).

Given that information, let us reconsider our manual recovery of a deleted file. Can we recover the same file after a quick formatting of the disk? Recall that a quick formatting completely overwrites the root directory, therefore, we no longer know the starting cluster nor file size of the file. We still have enough information available to us to recover files as long as we know the type of file we wish to recover.

Say we are asked to recover all of the graphical files from a hard drive that has been quick formatted. Given the file signatures (listed in Table 5), we can search for these file headers in the image. Once we find the headers, which always occur at the beginning of a cluster, use the

**Table 5** Graphical File Signatures

File Type	Signature
JPG	<code>FFh D8h FFh</code>
BMP	<code>BM</code>
GIF	<code>GIF8[79]a</code>
PNG	<code>89h 50h 4Eh 47h</code>
TIFF	<code>49h 49h 2Ah 00h</code>

following steps to recover the files (only if the files are not fragmented):

1. Search for the file signature(s) within the forensic image.
2. When a file signature is found, note the hex offset.
3. Convert the hex offset to physical sector number.
4. Use the `dd` command, using the physical sector number from step 3 and a substantial count size.

Given that we are only guessing at the file size, what happens if we recover too many or too few clusters? Our experiences suggest that it should not hurt to recover more clusters than allocated to a file. Most of the time when we have recovered too little of the file, it is obvious. For instance, we conducted an experiment where we used the following commands to recover too few (50) and too many (100) clusters, and then viewed the resulting files to determine the difference.

```
# dd if=image.dd of=small.jpg skip=33
count= 50
# dd if=image.dd of=small.jpg skip=33
count= 100
```

Figure 30 shows the results of recovering too few clusters. Note that part of the image is missing, which is the result of recovering too few clusters from the image. We can correct this by rerunning the command and increasing our count value to recover more clusters.

Recovering too many clusters resulted in the same image as shown in Figure 29 for recovering the correct number of clusters. This is only a single example, and there may be differences depending upon the type of file recovered.

### Behavioral Time Lines: What Happened and When?

Sometimes investigators must create a timeline of computer activity based upon file information and other available evidence to determine the sequence of activities

**Figure 30:** Manual recovery of too few clusters.

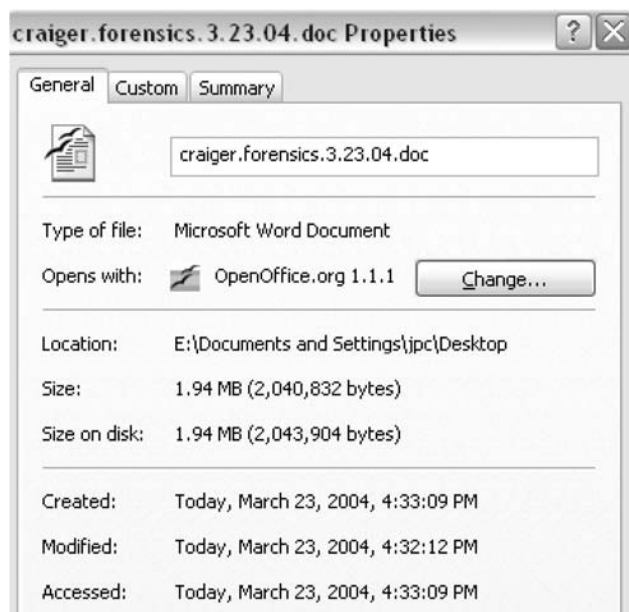

Figure 31: MAC times under NTFS.

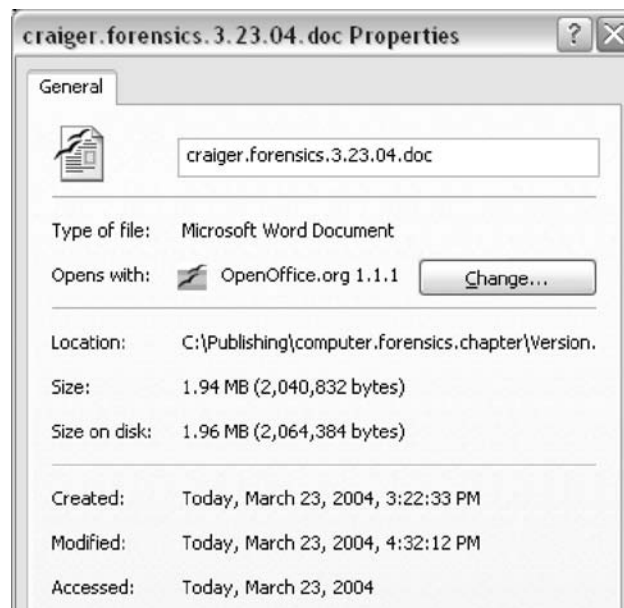

Figure 32: MAC times under FAT32.

occurring during a particular time frame. Examples of questions to be addressed through a timeline are these:

- What files were changed? This can be answered through the creation of a timeline based upon MAC times—modified, access, creation times—described below.
- How were the files changed? Deleting existing files, adding malicious code such as rootkits, or replacing old files with Trojaned versions can change the system. The latter is common, for example, with UNIX systems, where *ps* and *netstat* binaries are replaced with versions that will not report evidence of suspicious activity.
- Can the deleted files and/or other evidence be restored?

Every computer file on a Windows-based file system (FAT-based or NTFS) has associated with it three times: the time the file was created on the current volume (created or *ctime*), the time the file was last modified (modified or *mtime*), and the time the file was last accessed (accessed or *atime*). (Linux/UNIX file systems do not have a created time but a “changed” time. Additionally, Linux EXT2 file system has a deleted time, and NTFS has a ‘last written’ time.) These times provide information regarding the events that occurred on a computer, allowing the investigator to create a scenario that explains a user’s or intruder’s activities.

From within Windows, the MAC times can be accessed by right-clicking on the file and selecting *properties* as demonstrated in Figures 31 and 32. A file residing on an NTFS volume in Figure 31 was copied to another volume formatted FAT32, Figure 32. Note the modified times are the same. The created times are different because the created times changed when a file is copied to a new volume. Also, FAT32 only keeps track of last date access, not the time last accessed. (The reader should also note that we can determine that the volumes use different cluster sizes by looking at the “Size on disk” property.)

At the DOS command prompt, the *dir* command displays the file’s last modification time and date. To view the *created* times of all files in a directory, and to sort the file by date, use the command

```
C:\> dir <directory name>/* /tc /od.
```

To view by *access* times and sort by date, use

```
C:\> dir <directory name>/* /ta /od.
```

To view by *modification* times and sort by date, use

```
C:\> dir <directory name>/* /tw /od.
```

The command’s output is a listing of files within a directory sorted by date. Unfortunately, this formatting does not allow one to easily determine the activities that occurred on the computer.

We have found the best way to create a timeline is to use tools from the open source forensic toolkit Sleuthkit (<http://www.sleuthkit.org>). To illustrate the use of MAC timelines, say we wanted to know what files had been created on a system since October 9, 2003. We ran two tools from Sleuthkit, *mac-robber* and *mactime*, against a running computer. We ran the command from a Linux box that was connected to the Windows system using a Samba share.

```
# mac-robber /mnt/fred/desktop/ > /
evidence/fred.body
# mactime -b /evidence/whammo.body > /
evidence/fred.mac
```

The *mac-robber* command extracts all of the time and date information from the files, and the *mactime* command then processes that information by sorting it by date and time and putting the information into a human-readable timeline. Here is a small portion of the results:

*[Thousands of lines deleted for the sake of brevity]*

*[Hundreds of lines deleted for the sake of brevity]*

(Some of the information from the timeline, including the master file table number, file permissions, and links, has been deleted for brevity's sake.)

After the date, time, and size (in kilobytes) fields comes a three-character field that contains an indication as to whether the associated time is an *m*-, *a*-, or *c*-time, or combination thereof. Note that the MAC changes are organized by date and time. The first line displays the fourth version of this chapter (cforensics4.doc) and is a created time (note the “.c”). The next line is the modified time (“m.”) for the same file, indicating that the file was last saved a couple of minutes after it was created. Note that the last access time for that file is not displayed because it was last accessed after November 22 and therefore does not fall within the timeline. Each file will have three times in the timeline.

From the timeline, we can derive several interesting facts. First, the file cforensics6.doc was created on Friday, November 21, at 9:37 a.m. Note that at the same time, Word created a temporary file. Four minutes later, Word updated the modified time on the temporary file. Where is the modified and accessed time for cforensics6.doc? They come later in the timeline and are not displayed.

How are timelines used in computer forensics? MAC times can be used to verify or dispute a user's contention of whether the user created, modified, or accessed a file on a particular date and time. For example, if an employee's temporary Internet folders contained pornographic pictures, and the access times on these files coincided with the employee's work schedule, we have evidence that disputes the employee's contention that his Internet surfing habits do not include surfing for porn. (Of course, we have stronger evidence if the source computer system is running a secure version of Windows such as NT, 2000, or XP, which has separate personal directories for each user and which was periodically synchronized with an atomic clock.)

## COLLECTING EVIDENCE FROM LIVE SYSTEMS

Thus far, we have worked with a subject's computer, running Windows, which has been powered down and disconnected from a network. In some circumstances, it may

be difficult or impossible to power down and isolate a computer from a network. For instance, if a company's only e-commerce server was attacked, management may refuse to isolate the machine because it might cost the company more in lost revenue than the attack (Mandia, Prosis & Pepe, 2003; Casey & Seglem, 2002). In this situation, the investigator may be forced to work on a live system. This presents a problem because live systems are in a constant state of change, thus complicating the collection of evidence and investigation as a whole. Because the system is constantly changing, we need to collect any evidence before it is changed, deleted, or overwritten. Not all evidence is subject to change in the same time frame, however. Some evidence may be relatively stable, such as evidence on CDs or floppies, whereas other evidence may be ephemeral, such as the contents of RAM. These examples demonstrate that computer evidence may have different levels of volatility, which suggests that the investigator should prioritize evidence collection procedures and collect the most volatile information first.

Farmer & Venema (2000) proposed a volatility taxonomy, that is, a measure of the likelihood of change to digital information on running computer system. From most to least volatile, the list includes

- process register;
- virtual and physical memory;
- network state;
- running processes;
- disks, floppies, and tapes; and
- CD-ROM and paper printouts.

There is a correlation between the difficulty of collecting untainted evidence and its volatility. It is not possible—as far as we know—to collect the contents of registers without changing them. In contrast, printed materials and

CD-ROMS are fairly permanent and easy to collect without fear of contamination.

Farmer & Venema (2001) proposed an analogy between Heisenberg's uncertainty principle and the difficulty of working on live systems. Heisenberg's uncertainty principle states that attempting to measure both the location and momentum of an atomic particle affects the other measurement; therefore, one can never produce an accurate measure of both at the same time. Similarly, attempts to collect evidence from a live system will change the contents of the system. This principle is demonstrated in the following example. (We are assuming the live-running server in our subsequent demonstrations is running some version of Linux.)

On Linux systems, the file *kcore*, located in the */proc* directory, is a virtual file that maps to physical memory (RAM) of the system. The file can be examined using a debugger, or the *strings* command can be used to extract the human readable text from the file.

Similarly, */dev/mem* is a logical file associated with physical memory, and */dev/kmem* is associated with kernel virtual memory (Kruse & Heiser, 2001). One may access the contents of physical and kernel memory through */dev/mem* and */dev/kmem*, respectively.

To illustrate how a simple procedure can change a running system, we searched for the term "Heisenberg Uncertainty Principle" within */proc/kcore*. (Note that it is highly unlikely that this term would have been in physical memory prior to searching for the term.) The output of the search shows that the command we used to search for the term shows up, in various formats, several times, indicating that by attempting to collect the evidence we have changed the system.

```
simba:~ # strings /proc/kcore | grep 'Heisenberg Uncertainty Principle'
```

**[everything from here down are the results of the search]**

```
'Heisenberg Uncertainty Principle'
grep 'Heisenberg Uncertainty Principle'
grep 'Heisenberg Uncertainty Principle'
strings /proc/kcore | grep 'Heisenberg Uncertainty Principle'
strings /proc/kcore | grep 'Heisenberg Uncertainty Principle'
strings /proc/kcore | grep 'Heisenberg Uncertainty Principle'
strings /proc/kcore | grep 'Heisenberg Uncertainty Principle'
'Heisenberg Uncertainty Principle'
strings /proc/kcore | grep 'Heisenberg Uncertainty Principle'
simba:~ # strings /proc/kcore | grep 'Heisenberg Uncertainty Principle'
simba:~ # strings /proc/kcore | grep 'Heisenberg Uncertainty Principle
Heisenberg Uncertainty Principle
Heisenberg Uncertainty Principle
Heisenberg Uncertainty Principle
```

We found 14 occurrences of the term "Heisenberg Uncertainty Principle" within physical memory. This small experiment underscores the susceptibility of contaminating a running computer system through even the simplest interaction. Thus, care should be taken to minimize contamination when attempting to recover evidence from a live system. We can do this by having an incident response

plan for dealing with live systems, including prewritten scripts that can be run from a CD or floppy to minimize interacting with the system (e.g., because a typing error was made at the command line, requiring that the command be retyped, a common occurrence under stressful conditions).

## Volatile Evidence

Time is of the essence when collecting evidence from a running computer system. As discussed previously, volatile sources of evidence are purged after a brief period of time. Volatile and important sources of evidence on live systems, and the commands used to capture the evidence, include

- running processes (*ps* or the */proc* file system),
- active network connections (*netstat*),
- ARP cache (*arp*),
- list of open files (*lsof*), and
- virtual and physical memory (*/dev/mem*, */dev/kmem*).

Gathering volatile data is more easily accomplished on file systems where everything is a file, which includes Linux, UNIX, and NTFS file systems. For example, all running processes on a Linux system are written out to disk the *proc* file system in the */proc* directory. Figure 33 is a truncated example that illustrates the running processes on a Linux system (using the *ps aux* command), and the respective */proc* file system is shown in Figure 34. For each process running in memory (identified by the numbers under the column labeled PID in Figure 33), there is a

corresponding directory under the */proc* file system in Figure 34.

The */sbin/arp -v* command displays the contents of the ARP (address resolution protocol) cache. The example in Figure 35 illustrates that the ARP cache on this computer has two MAC addresses under the label titled HWaddress. The ARP cache holds MAC addresses (media access

Figure 33: Process list from running Linux system.

control addresses, i.e., the hardware addresses of the network interface cards, not to be confused with MAC times) of computers on the same subnet that have been recently communicating with the computer under investigation. These addresses are purged every so often; thus, it is important to gather this information quickly.

The netstat command displays network connections and listening ports. Figure 36 displays a portion of the results of running netstat. Note there are several established connections (under the “State” heading). The value “LISTEN” under the State heading indicates whether a port is open. Here we see we have three open TCP ports: port 22 (secure shell, SSH), *netbios* (139), and *CIFS* (445), the latter two of which are used with Samba (a service that supports connections between my Linux and Windows machines).

## Log Files as Digital Evidence

Log files can be very important sources of forensic evidence. A server’s log files will contain information about various system resources, processes, and user activities.

Protocol analyzers, sniffers, SMTP, DHCP, FTP, and WWW servers, routers, firewalls, and almost any system- or user-driven activity can be collected in a log file. However, if the systems administrator has not enabled logging, then the evidence necessary to associate an intruder with an incident may not exist. Unfortunately, knowledgeable intruders and criminals know this, and one of the first orders of business is to destroy or alter log files to hide their activities.

A second important piece of information, and one sometimes overlooked, involves the system clock. Anything logged to a file has an associated time and date stamp. Time and date stamps enable the investigator to determine the sequence of events that transpired. System clocks, unless explicitly corrected on an occasional basis, can be off anywhere from several seconds to hours. This can cause problems because any correlations between log files from different computers whose system clocks are different make it difficult or impossible to correlate events. A simple solution is to automatically synchronize clocks by having all systems run a daemon, an example of which is the UNIX *ntpd* daemon, to occasionally synchronize

Figure 35: ARP output.

the system time and date with a government-sponsored (e.g., NIST, National Institute of Standards and Technology) atomic clock. This is transparent to the user and takes little system resources.

## Reducing the Potential for Evidence Contamination

If the computer system is on, files will be changing. If the computer system is connected to a network, files will be changing. If we interact with the system, files will change. This is a large, probably unsolvable problem: the need to interact with a live system and gather evidence will cause some form of contamination. The best that can be done then is to limit contamination by limiting interactions with the system. This can be done through planning prior to the incident. It is important, for example, to have an incident response team and an incident response plan that can be executed once an incident has been identified. One aspect of this plan is a predefined set of command scripts that can be executed to collect evidence from a running system. Ideally, these scripts should be run to limit the number of errors to which we are all susceptible. (FIRE, Forensic Incident Response Environment, is a Linux-based bootable CD that includes scripts to recover system information for both Linux and Windows systems: <http://fire.dmzs.com>. It is highly recommended. Helix is another bootable CD that contains scripts: [www.e-fense.com](http://www.e-fense.com))

Here is a simple example of running a predefined script to gather system information and transport it offsite via a network connection.

```

# (ps aux; netstat -tupan; cat /var/log/
  message) | nc 192.168.1.1 4444

```

These commands collect the running processes (`ps aux`), list of open network connections (`netstat -tupan`),

copies the log file `messages` (`cat /var/log/messages`), and uses `netcat` to send them over a network connection to the local forensic machine. The number of commands that could be included within the processes is unlimited. This form of evidence collection is desirable because the script employed to capture the evidence can be preplanned and tested prior to its use in any real incident. Make sure to test it on various forms of UNIX and Linux as some versions differ just enough so that your commands may not work they way they are expected.

## COMMERCIAL TOOLS

This chapter would not be complete without a brief mention of some of the commercial tools available as of 2005. Unfortunately, space limitations guarantee that a discussion of the commercial forensics tools will be incomplete. Realize that this is not an advertisement for any particular tool, but rather a reference to existing tools that may warrant further examination by a serious investigator.

There are several Windows-based forensics tools that are capable of performing all of the procedures we have covered in this chapter and many we have not covered. The two tools we discuss here are Guidance Software's EnCase (Forensic or Enterprise Editions: <http://www.guidancesoftware.com>) and Accessdata's Forensic Toolkit (FTK: part of the Ultimate Toolkit: <http://www.accessdata.com>). We have had formal training and a good deal of experience with both EnCase and FTK; each has its strengths and weaknesses. Ideally, an investigator should be trained and have access to several tools. The reason is that it is often desirable to verify the findings from one tool with a different tool to ensure the validity and integrity of the findings.

FTK and EnCase support imaging, reading multiple file systems, reading multiple image formats, file viewing, advanced string searches, graphical/gallery views, e-mail

analysis, compressed file analysis, known file filters/hash analysis, bad file extension determination, electronic discovery, and numerous other capabilities. We have included screenshots of EnCase (Figure 37) and FTK (Figure 38), displaying the results of a string search, to illustrate their graphical interface.

Other commercial tools available as of 2004, in alphabetical order, include

- ARS Data's SMART (runs under Linux): <http://www.asrdata.com/tools/>,
- BlackBag Macintosh Forensic Software (<http://blackbagtech.com>),
- ILook Investigator (law enforcement only): <http://www.ilook-forensics.org/>,
- Maresware Forensic Tools: <http://www.dmares.com/maresware>,
- New Technologies Forensic Suite: <http://www.forensics-intl.com/tools.html>, and
- Paraben Forensic Toolkits (for PDAs and cell phone forensics): <http://www.paraben-forensics.com/>.

For the most up-to-date information on the availability of commercial and open source tools, we suggest doing a Google search for "computer forensic tool."

## CONCLUSION

This chapter provided a technical introduction and overview of computer forensic procedures. We attempted to cover the fundamental aspects of computer forensics methods and procedures, from acquiring and verifying the evidence through a complete logical and physical analysis. Our demonstrations were designed to illustrate fundamental concepts rather than how a particular commercial tool could be used.

Technology changes at an increasing pace, which creates several problems for investigators. For example, devices that may hold evidence have become more diverse, witness cell phones, personal digital assistants (PDAs) such as the Palm® handhelds and Compaq IPAQ®, Blackberry® wireless e-mail devices, compact flash and smart media, and so on. Investigators must have the necessary hardware and software to make a forensic image and analyze the information obtained from these diverse devices.

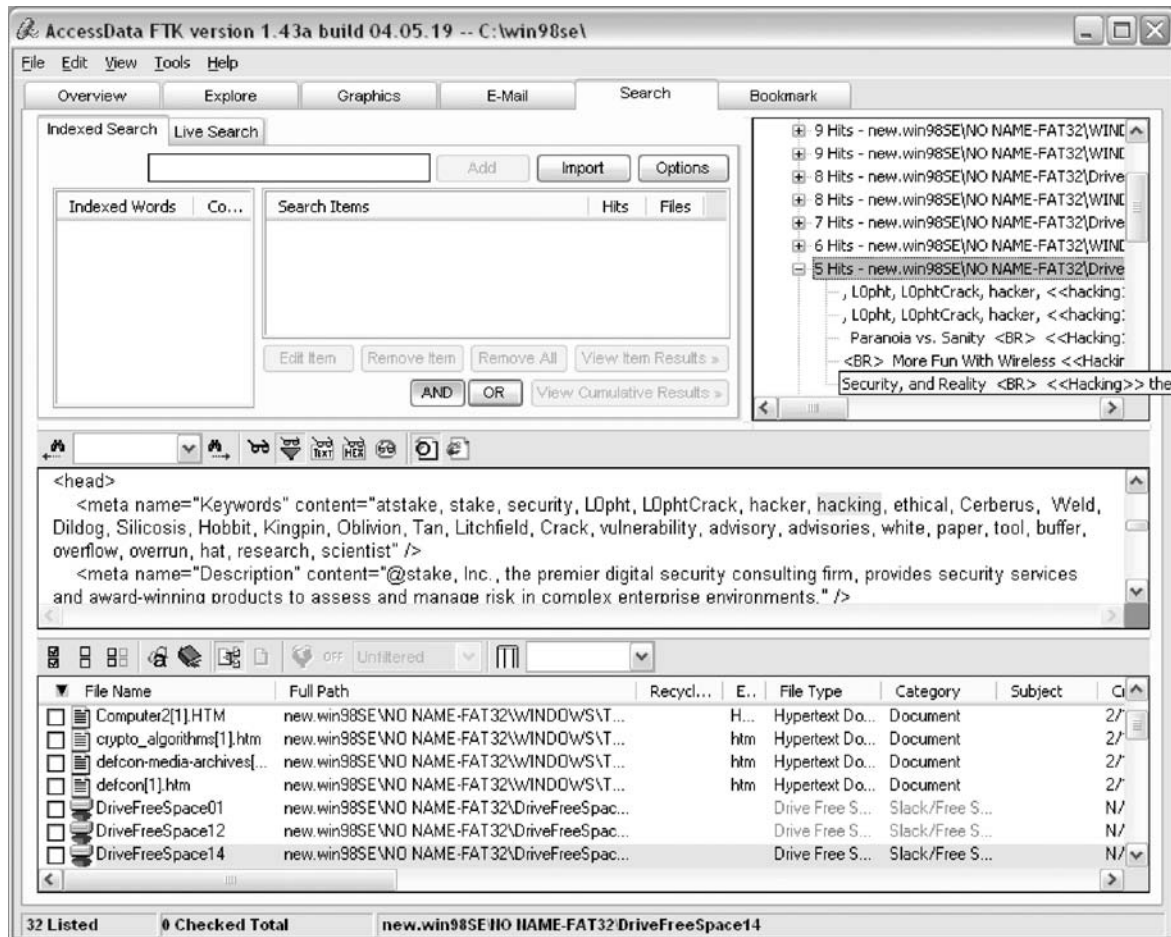

Figure 38: Accessdata's Forensic Toolkit interface.

Investigators are likely to encounter new types of media on a continual basis. Therefore, it is important that investigators be aware of these types of media, including any unique properties that may be important in understanding them for the acquisition process. Space limitations prevented us from describing the means of handling the more exotic types of evidence. Nevertheless, the investigator must also have the necessary knowledge, techniques, and tools available to make the forensic images as well as perform thorough logical and physical analysis. The best source for best practices on handling different types of media is the *U.S. Secret Service's Best Practices Guide for Seizing Electronic Evidence* (U.S. Secret Service, 2002).

Finally, storage technology is becoming exponentially larger and therefore more difficult and time consuming for investigators to analyze. For example, it is not uncommon to encounter personal home computers with hard disks in the 200+ gigabyte range. Moreover, terabyte-sized disk arrays are becoming more commonplace. Numerous law enforcement professionals and investigators with whom we have spoken have encountered such devices. This will create problems as the acquired images of a criminal investigation may outstrip an investigator's ability to hold and preserve the evidence. Fortunately,

technologies such as storage area networks, as they become less costly, may allow law enforcement and industry incident response teams to better deal with this problem.

## GLOSSARY

**Allocated Space** The clusters allocated to a file and which are tracked by the file system.

**Allocation Unit** The smallest unit of disk space that may be allocated to a file. Varies by file system.

**Bit-Stream Copy** A bit-for-bit copy of digital evidence.

**Block** UNIX terminology for an allocation unit (see allocation unit).

**Cluster** Microsoft Windows term for allocation unit (see allocation unit).

**FAT** Acronym for file allocation table. A common form of file system used with Microsoft Windows operating systems. Part of a FAT file system. A singly linked list of pointers to clusters constituting a file.

**Forensic Image** An exact, bit-for-bit copy of media.

**Hash** Also known as a message digest, cryptographic hash, or one-way hash. A hash is a hex value, typically 128- or 160-bit, that is unique to the contents of a file.

**Hash Set** A list of hash values for a set of files.

**Known Files** Files known to be of no evidentiary value that can be discarded from an analysis. Usually identified through a hash analysis.

**MD5 Hash** A 128-bit cryptographic hash algorithm created by Ron Rivest of MIT.

**Metadata** A file's metadata consists of all information about the file excluding its contents: file name, size, MAC times, starting cluster, permissions, attributes, and so forth.

**Notable Files** Files of known evidentiary value usually identified through a hash analysis.

**NTFS** Microsoft New Technology File System.

**Root Directory** File table under FAT systems that holds file metadata.

**Sector** Hardware unit of measure on a disk, typically 512 bytes. Multiple sectors make up an allocation unit. Individual sections of a disk track.

**Slack Space** Disk space left over between the end of the data and the end of the last cluster of a file. Slack space may contain residual information.

**Unallocated Space** The clusters not in use by a file. Where deleted files reside.

**Volume** Commonly, another name for a partition on a disk. A hard drive may have up to four primary volumes or partitions.

**Wipe** Forensic wipe. To remove vestiges of information from media by writing a series of characters over the information.

**Write Blocker** A physical device that allows data to be read from a hard drive but prevents data from being written to it. Typically, blocks interrupt 13h.

## INTRODUCTION

Forensics, by definition, is the application of law to science. In the case of computer forensics, computer science is used to identify evidence in criminal cases and civil lawsuits. Computer forensics is a relatively new forensic science, but its procedures and methodologies have been used for years in military and law enforcement agencies to gather intelligence and to identify criminal investigation leads and evidence. Computer forensics moved from the secret world of the military and law enforcement when New Technologies, Inc. (NTI) was created in 1996. Since that time, numerous commercial computer-forensics training courses have come into existence and several colleges and universities have incorporated computer forensics topics in their curricula. Several computer forensic software tools have also come into existence and computer forensics has become a popular and lucrative career field.

Today, computer forensics is the mainstay of corporate investigations and internal audits. Since 1996, military and law enforcement agencies have expanded their use of computer forensics because of the increased popularity of personal computers and the Internet. It is common knowledge that the U.S. military put a high priority on technology-based intelligence gathering in the Iraq war and in the identification of weapons of mass destruction (WMDs). Modern weapons development relies upon computers, and such activities leave a computer evidence trail of activities behind. It is no secret that the U.S. military relied upon computer forensics tools and processes to identify such activities in Afghanistan and Iraq. Computer forensic tools and processes are used to identify computers that contain classified weapons data and to identify the Arabic (and English) names of individuals stored on computers.

Most people do not realize that computer forensic tools and processes are also used by some of the same U.S.

government agencies to identify their own internal computer security risks and weaknesses. Personal computers have significant security weaknesses and a security solution for Microsoft-based personal computers is not anticipated in the near term. Until a security solution is developed, computer security risk assessments using computer forensic tools and methods will continue to be mandated by most classified U.S. government agencies.

## PERSONAL COMPUTER SECURITY WEAKNESSES: HISTORICAL PERSPECTIVE

Personal computers were never designed to be secure. This lack of security is the direct result of the development of personal computers over the past thirty years. Personal computers came into existence in the 1970s and the first personal computers were popular with hobbyists, who built their own personal computers from kits. These computers had limited power and were difficult to use. Preassembled personal computers could be purchased, but the personal computer market was primarily limited during the mid-1970s to technology-savvy hobbyists. Thus, cottage industries were the spawning grounds for personal computer research and designs. For example, the Apple computer company grew from a small business operated out of a garage.

No software standards existed in the 1970s, and custom operating systems were, of necessity, written for each personal computer system that came into existence. The operating systems and application programs that evolved were not interchangeable from one personal computer brand to another. Because of file incompatibility among brands, growth of the personal computer market was stifled and brand loyalties were strong. In the mid- to late 1970s, personal computers with brand names such as Altair, Apple, Atari, Commodore, Heath-Zenith, TRS-80, and

Osborne dominated the small and disjointed personal computer market in the United States. Personal computers were considered toys or electronic gadgets by most people. Their benefits were not defined and most people had no use for computers anyway. One possible exception was a personal computer developed by Wang Laboratories, Inc. (Wang), which marketed computer products dedicated to word processing and document management tasks.

The Wang personal computer-based word processing systems eliminated the need for carbon paper and the technology also provided spell-checking features that had not existed previously. Wang word processing systems quickly unseated the popular IBM Selectric typewriter in the private and public sectors. The U.S. government became one of Wang's biggest clients, and I fondly remember those big, 12-inch Wang floppy disks from my government days. I was a special agent with the Internal Revenue Service, Criminal Investigation Division, back then, and we used the Wang technology to create and edit memoranda search warrant affidavits and prosecution reports. Wang word processing systems saved much time in creating and editing documents but they also had a downside—Wang systems provided no security for the computer files they created.

The U.S. government adopted the use of Wang systems without security because it really had no other option. The Wang systems were state-of-the-art technology at that time, and the U.S. government had no place else to turn for similar technology. Its only option was to use the new Wang word processing technology, without security features, or to continue using typewriters, "whiteout," and carbon paper. Reluctantly, the U.S. government adopted Wang's technology because of the productivity benefits. This decision by the U.S. government had a significant effect on the future designs of all personal computers. Had the U.S. government required Wang to incorporate security into the design of its products, a benchmark would have been set for the computer security designs of the future.

In the late 1970s, Tandy Corporation developed a word processing application for use with the Tandy TRS-80 brand of personal computer. This was an attempt by Tandy to move its personal computer into the business world. Other computer manufacturers followed suit and developed similar word processing programs for use with their brands of personal computers but compatibility from brand to brand was still a problem. Word processing files created with one brand of computer could not be read, edited, or printed on another brand of computer and none of these personal computers were compatible with the popular Wang word processing computer systems. Therefore, the personal computer market remained segmented and there was no reason for computer users to switch their loyalties.

The development of the computer spreadsheet application also occurred in the 1970s. The first significant software spreadsheet application was VisiCalc, and its functionality and benefits supplemented word processing software applications developed for personal computers. The spreadsheet applications provided computer users

with new and powerful business calculation capabilities that had not existed previously. The spreadsheet applications were not a good complement to Wang's word processing systems because Wang's end users were primarily secretaries who created and edited word processing documents. Spreadsheet applications were more suited to business professionals who created and used their own custom spreadsheets. As technology-savvy business professionals began using personal computers to perform mathematical functions, it was a natural progression for the same professionals to begin using personal computer-based word processing software. Wang was never able to make the transition from a dedicated word processing system to a multipurpose personal computer system, and eventually the company became an artifact of the computer technology revolution.

Based on its success, Tandy Corporation promoted its TRS-80 model III personal computer in 1979 as a "business computer" and that promotion effectively moved personal computers from "toys" to business computers in the marketplace. Tandy's promotion of personal computers as tools for business quickly captured the attention of the computer mainframe giant, International Business Machines (IBM). Mainframe computers were expensive and well beyond the reach of many businesses. Tandy effectively changed the business mind-set about computing with its TRS-80 model III personal computer.

IBM followed Tandy's lead and conducted market research to determine the potential for its own personal computer. On the basis its market research, IBM released the IBM Personal Computer (IBM PC) in October 1981 for government agencies and businesses. The IBM PC was one of the biggest technology successes in modern times. However, IBM significantly underestimated the market demand for the IBM PC and it, like everyone else, did not anticipate the potential of the Internet. If IBM had foreseen the huge demand for personal computers, it is likely that security would have been a significant design feature. However, IBM knew that the U.S. government was willing to spend money for personal computers that did not have security, based on the successes of Wang Laboratory. They also knew that the U.S. government was the biggest user of computer technology, and it was likely that private sector businesses would follow suit. That is exactly what happened, and there was no business reason for IBM to secure the IBM PC initially.

Since 1981, the personal computer has become a powerful worldwide analysis and communications tool. Sensitive business and government documents are created and printed using these small computers. E-mail is routed around the world via the Internet. Database programs are used to store and access business information. Spreadsheet applications are used in financial calculations and PowerPoint is used to make most business presentations. Even photography has moved from film to digital flash memory. These wonderful technology tools are also used in classified government research and intelligence-gathering activities. They are even used to track the financial trail of terrorists in the war on terror. Regrettably, personal computer systems still are not secure but, as previously discussed, they were never intended to be

secure. As a result, an added layer of security risk exists today in classified government agencies, and computer forensic tools and methods are typically used to reduce those risks.

## SECURITY RISKS: WINDOWS XP AND NOTEBOOK COMPUTERS

The creators of the original IBM PC never imagined that their primitive computer design would become the mainstay of worldwide commerce and a critical component used in the operation of U.S. government agencies. Because of the need to provide upward compatibility for files and software, the basic foundation for the original IBM PC still exists in most of today's personal computers. Although the Microsoft NTFS-based operating systems (Windows NT, Windows 2000, and Windows XP) are more robust and provide better network security and auditing capabilities, no substantial security improvements have been made at the data-storage level. Unfortunately, these advanced NTFS-based operating systems can create a false sense of security for computer users and management in classified U.S. government agencies.

Microsoft-based personal computers can easily be compromised, and password and logon controls can quickly be circumvented using computer forensic tools and methods. For example, NTI's TextSearch NT (a forensic search tool) can completely evaluate and document all data storage areas on a Windows XP-based computer system. This U.S. Department of Defense (DoD)-certified forensic tool was designed for internal government security reviews but its uses could be twisted, in the wrong hands, to compromise computer security. TextSearch NT operates from a DOS-formatted floppy diskette and no logons or passwords are required to circumvent the minimal security afforded by Windows XP (or Windows NT and Windows 2000). The reader should note that this is the reason that some of the more powerful computer forensics tools are not made available for purchase by the general public.

Security problems are compounded when portable notebook computers are used with classified government data. Portable notebook computers are frequently used in classified executive briefings and sometimes in military and intelligence field operations, and they can be taken anywhere. Most notebook computers also feature hibernation modes of operation that create added security risks. Some computer manufacturers call them *suspense*, or *sleep*, modes and the features rely on a special file or a special partition that essentially captures and stores the work session when the computer is "asleep."

Notebook computers usually go into a sleep or hibernation mode when keyboard activity has not been detected for a predetermined period of time. This is a convenient feature that helps conserve battery power, but the trade-off is an added security risk. When the hibernation or suspense feature is triggered (either manually or automatically), the work session is frozen in time and part of the data from the work session is stored in a hibernation file or partition. You can think of it as an electronic bookmark used by the computer. The data stored in the hibernation

file can consist of any data tied to the work session, and, when the computer is awakened, its operation is restored using the data contained within the hibernation file. The hibernation file is not securely deleted after the computer is awakened, and the file contents remain behind for discovery using forensic tools and techniques. If classified data were involved in the work session before the computer went into hibernation, then it is likely that the hibernation file (or partition) contains classified data. Hibernation files are potentially huge. The hibernation file of the notebook computer I used to write this chapter has a capacity of more than 203 million bytes of data. That is the equivalent of approximately 507,000 printed pages!

## RISKS ASSOCIATED WITH AMBIENT DATA STORAGE AREAS

Most personal computer users are unaware of the background processes involved in the operation of the computer. The processes are transparent, and they potentially involve the leakage of sensitive computer data into "special" data storage areas. These obscure storage areas are referred to as ambient data-storage areas and include file slack, Windows swap files, Windows page files, temporary working files, work-session suspense files, and unallocated (erased file) storage space. Even the mere viewing of sensitive files on floppy diskettes or via the Internet can result in data seepage into ambient data-storage areas, and the computer user does not have to save any work to disk for the process to occur. Because of a general lack of knowledge of the security weaknesses of personal computers, government employees can unintentionally transfer classified data to unclassified computer systems. Ambient data storage areas constitute the biggest risk for classified data leakage and they are described as follows:

1. **File slack** is defined as the data storage space between the end of a file and the end of the last cluster assigned to the file. Files are stored in uniform blocks of data called clusters, and a more specific definition of clusters can be found on the Internet at <http://www.forensics-intl.def19.html>. Rarely does the size of a file exactly match the data storage capacity of the number of clusters assigned to the file. File slack is the residual storage area that exists in the last cluster assigned to the file and following the contents of the file. File slack consists of two separate components called RAM slack and drive slack, discussed in the following paragraphs.

Word processing documents, spreadsheets, databases, and e-mail messages are all stored in files on personal computer storage devices. The same is true of many temporary files that are created transparently by software applications and the operating system. File slack is created when a file is saved (closed), and it is a significant security risk on all Microsoft-based personal computers. You should also be aware that the data potentially stored in file slack is typically beyond the knowledge and control of most government computer users.

2. **RAM slack** is created from the buffers on Windows and DOS-based systems. Buffers can be thought of as

Figure 1.

plumbing used by the operating system, and the number of buffers on a Windows/DOS-based system is set in the CONFIG.SYS file, for example, buffers = 30. The buffers reside in the random access memory (RAM) of the computer system, and the contents of the buffers can potentially contain any data or data fragments created, viewed, or printed during a computer work session. RAM slack is written to the first sector of the last cluster of the file. In Microsoft-based computers, sectors are small storage blocks that hold 512 bytes of data. Clusters are made up of varying numbers of sectors, depending on the size of the storage device and the operating system involved. RAM slack will always be in the first sector of the last cluster of the file, but RAM slack cannot contain more than 512 bytes of data. Ram slack is only a concern on Windows, Windows 95, Windows 98, and DOS-based systems because Windows NT-, Windows 2000-, and Windows XP-based computer systems automatically scrub all relevant data contained in RAM slack.

3. **Drive slack** is a security risk on all Microsoft-based personal computer systems because it is not automatically scrubbed by the operating system. Unlike RAM slack, large quantities of data can reside in drive slack because its storage capacity is not limited to one sector, that is, 512 bytes. Drive slack can potentially store up to 63 sectors of data (32,256 bytes of data or the equivalent of approximately eight printed pages), depending on the operating system involved. Information stored in drive slack can contain remnants of previously deleted files and other information that resided on the storage media before the file was created.

The following example helps clarify file slack and its components. Assume that you create a file by writing the word "Hello," and no other data is contained in the actual file. The file is only five bytes in length. Assuming that the clusters assigned by the operating system to the file are two sectors in size, the data stored to disk and the file slack would be represented as follows in Figure 1.

The data are identified by the word "Hello." RAM slack is identified by the "\ " symbol and drive slack is identified by the horizontal line pattern. The "(EOC)" marker has been listed to identify the end of the last cluster of the file, but it has been provided for illustration purposes and such a marker is not actually stored on disk at the end of the assigned cluster. Rather, the end of the file is recorded in the directory area. In this example, only one cluster is needed to store the small five-byte file containing the word "Hello."

4. **Windows swap and Windows page files** act as an extension of memory for the operating system and are used when more memory is needed by the operating system. This happens when multiple software programs are running at the same time or when extremely large documents or graphics files are viewed or edited.

These files act as a "scratch pad" for the operating system when more memory is needed. Windows swap files and Windows page files are huge. Depending on the operating system configuration, the size of the swap or page file will be between approximately 50 and 700 million bytes. In the case of Windows, Windows 95, and Windows 98, the file is called the Windows swap file. For Windows NT, Windows 2000, and Windows XP, the file is called the Windows page file.

Most computer users are unaware of Windows swap and Windows page files, and they do not realize that fragments of their work products may transparently be written to these special files. Essentially any work performed in a Windows work session can end up in the swap or page file, including fragments of created files, edited files, and even fragments of files that were merely printed and not created or edited on the computer system. Swap or page files also capture fragments of Internet Web browsing activities, Internet e-mail addresses and messages, and even the directory listings displayed in a Windows Explorer session. Passwords and logons may also be written to the Windows swap and Windows page files. These special files are a wonderful source of investigative leads in computer evidence-based cases, but they are a significant security risk in classified government agencies. More information about these files is available on the Internet at <http://www.forensics-intl.com/def7.html>.

5. **Unallocated file space** is another ambient data source that should be of concern to government computer users. When files are "deleted" on personal computers, the data associated with subject file is not erased. Rather, the space assigned to the file becomes unallocated by the operating system and the storage space is made available for new files. However, the data from the former file can actually linger on storage media for months or even years. The same is true of the name of the former file. Only the first byte of the file name is overwritten and it is replaced with a lower-case Greek sigma character,  $\sigma$ .

An example of a deleted file directory file listing is shown in Figure 2. In this example, the deleted file was named FILE01 before it was erased, and the only change to the file name is the first character, which was replaced with the with a lowercase Greek sigma character. Note also that the particulars about file dates, sizes, and attributes remain behind.

Unallocated file space should not be confused with free storage space. Free storage space is the space that resides beyond allocated hard-disk drive partitions. Unallocated file space differs because it is contained within a logical hard disk drive partition, and it can

	Name	Ext	Size	Date	Time	Cluster
0	σILE01	DOC	4,088	08/17/00	8:27 PM	16009
	FILE02	DOC	82,712	08/19/00	10:15 PM	16035
	PROJECT	XLS	35,006	09/23/00	9:17 PM	16054
	FILE03	DOC	108,454	09/23/00	10:37 PM	16145

Figure 2.

contain both erased file data and the file slack associated with erased files. Unallocated file space is the largest source of ambient data, and it can potentially involve several billion bytes of data on a large personal computer hard-disk drive. Therefore, the security risks associated with unallocated storage space can be significant in a classified government agency.

6. **Temporary files** are created and used by most software applications. The operating system also creates and uses various temporary files to perform various tasks, for example, the printing of files. These specialized files are typically created as the result of background processes, and the user is usually unaware of their existence or purpose. When the need for a temporary file has passed, it is typically deleted by the background operation that created it. However, the data associated with the erased temporary file remains behind in unallocated file space. In this regard, erased temporary files are no different than other erased files.

Many Windows-based software applications create temporary files to facilitate sorting functions, to create indexes, for directory scrolling in Windows Explorer, and so forth. Temporary files potentially store fragments of the data processed during the computer work session. All allocated and erased temporary files should therefore be considered a security risk in classified government environments because the likelihood exists that they may contain classified information.

7. **Partition gaps and free space** can be a security risk on previously used personal computer systems. Partition gaps and partition free-space risks are some of the reasons that the U.S. government requires that security risk reviews include the search of all physical sectors on the subject hard-disk drive. Individual hard-disk drives are referred to as physical hard drives (physical devices), and the data storage area of a physical hard drive can be broken into smaller storage components, which are called logical hard drives. This is typically done with commercially available hard-disk drive partitioning software when operating systems are upgraded on used computer systems or the computers are transferred from one person to another. During the upgrade process, not all of the storage capacity of the physical hard drive may be needed and therefore a smaller partition is used. In such cases, partition gaps can also result between allocated partitions on the same physical hard-disk drive. As an unintended result, artifacts of the legacy data may remain behind in the partition free space or in partition gaps when multiple partitions are involved on the same physical hard-disk drive.

An example of a partition gap is illustrated in Figure 3. After partitioning, the resulting drive partitions are referred to as logical drives, and, in this example, they are referred to as drives C: and D:. Multiple logical disk drives can reside on one physical drive and multiple operating systems can also reside within different logical drives on the same physical hard-disk drive.

Many risks associated with partition gaps and partition free space can be identified through the use of a DoD-certified forensics text search utility, which has

Figure 3.

the capability of searching all areas of the physical storage device.

8. **Hibernation mode files and partitions** create added security risks for government employees who deal with classified information, as mentioned previously. Most notebook computers automatically capture and save a computer work session using hibernation mode files or dedicated partitions. This conserves battery power, and it provides a convenient way for computer users to resume their work sessions where they last ended. When the hibernation option is triggered, the notebook computer bookmarks the last work completed and puts the computer into a sleep mode. Computers that have this feature essentially capture the work session using a special file or, in some cases, a special partition. When the hibernating computer is awakened, the computer user can resume his/her work session at the point where he/she left off. This provides the computer user with benefits, but significant risks are created because artifacts of the suspended work session can remain behind on the hard disk drive for an indefinite period of time. The risks are substantial because hibernation files are huge, that is, more than 200 million bytes in size, and they should be factored into government computer security risk assessments when notebook computers are used to process or analyze classified government data.

## RISKS ASSOCIATED WITH COMPUTER-RELATED STORAGE DEVICES

Photocopy machines bring other risks to classified government agencies because copied classified data can be inadvertently stored on these machines. Photocopy machines typically rely on personal computer technology in their operation, and many of the devices contain internal computer hard-disk drives. Some photocopy machines can also be used as printers in a networked environment. If the photocopy machine is used with sensitive government data, then it is likely that the data will migrate

onto the photocopy machine's internal hard-disk drive. For this reason, photocopy machines should be treated as personal computers by government computer-security specialists. The security risks are the same as with personal computers, and, in some cases, the risks may actually be greater because some of the computer files created by photocopy machines are binary in nature and their contents cannot be evaluated using forensic text search utilities.

CDs and DVDs create additional risks in classified government agencies because of their portability and large storage capacities. These storage devices easily interact with personal computers, and they can be duplicated without leaving a trace of the duplication process behind. For these reasons, physical security is usually required for these storage devices in classified government agencies. However, computer-security risk assessments should include the review of nonclassified CDs and DVDs in classified government agencies because of the potentials of classified data leakage onto these storage devices.

Personal digital assistants (PDAs), digital cameras, and cellular telephones are all capable of exchanging data with personal computers, and they also create additional and significant security risks in classified government environments. Because they are portable and nonessential in classified agencies, these devices are typically not allowed in classified government environments. However, exceptions are made in some classified government agencies and computer security specialists need to be aware of the potentials for classified data leakage into the internal storage areas of these computer-related devices.

Floppy diskettes, USB memory sticks, and Iomega Zip disks all interact with personal computers, and they are portable data storage devices. Floppy diskettes were allegedly used in the Robert Hanssen spy case in the transmission of U.S. government secrets to the Russians. Even though their storage capacities are relatively small, floppy diskettes still pose a significant risk in classified government agencies because of their portability. As stated, their storage capacities are fairly limited when compared with newer technologies, for example, USB-compatible flash memory devices and Iomega Zip disks. If these devices are present or allowed in classified agencies, they should be considered a risk because of the potential for leakage of classified government data.

## CONCERNS SPECIFIC TO CLASSIFIED GOVERNMENT AGENCIES

The potential for leakage and the unintentional transfer of sensitive data to unclassified computer-storage devices is of great concern in classified government agencies. Unfortunately, classified data leakage is a common occurrence in classified government agencies. This is because most government employees are unaware of the inherent security weaknesses associated with personal computer usage, specifically the potentials for migration of sensitive government data into ambient data-storage areas. Security weaknesses are inherent in the design of personal computers and most of the security risks are not obvious to computer users. This is because the risks are highly technical

in nature and beyond the knowledge of most unsophisticated computer users who just want to get work done. For these reasons, most classified government agencies make it a priority to regularly scan nonclassified computer systems to identify the leakage of classified data. When the classified data leakage is identified, the data must be securely eliminated with DoD-certified data-scrubbing software tools or other approved methods.

Classified computer-security risk assessments are typically conducted with DoD-tested and certified computer forensic search tools that are executed from a bootable floppy diskette or a bootable USB storage device. By using floppy diskettes and/or USB devices, running under DOS or Linux, a government computer-security specialist can simultaneously review several personal computers. The practice also allows for the search of all sectors of the targeted hard-disk drives involved. It is a U.S. government requirement that such searches include the search of every sector of the storage media, and this requirement cannot be accomplished from a computer network or via the Internet. Therefore, government security reviews are usually conducted onsite and multiple computers are assessed for risk at the same time.

Most government computer-security review policies and procedures are outdated because they were developed under the assumption that classified data leakage would be limited to ACSII (text-based) data and files. Unfortunately, most of the policies were created before Microsoft PowerPoint and digital photography became popular in the workplace. For this reason, many of the current government security-review policies and procedures need to be updated to account for new risks tied to current technology. In addition to text-based files, the policies should take into account threats tied to compressed files, for example, Zip files, and graphics files, and proprietary file formats that are binary in nature. Such files can potentially mask the fact that they contain classified data, and they do not respond well to text-based computer forensic search tools. Some government security-review procedures do not take into account disk fragmentation. Fragmented data can result in targeted search terms being split between clusters and that can have a negative affect on ASCII text-based security reviews. For these reasons, existing policies should be reviewed to make sure that they are current with technology. If they are outdated, security review policies and procedures should be updated or supplemented to take into account new security risks associated with new file formats, storage devices, and other technology advances that have been adopted for use in the workplace.

Computer forensic search tools cannot adequately search some types of files, for example, graphics files, PowerPoint files, compressed files, and PDF files, and some suggestions have been provided in hopes of enhancing the quality of classified government security reviews and risk assessments. Until security is designed into personal computers, security reviews will remain as a standard practice in classified government agencies. It is also likely that similar security-review practices will be adopted by other U.S. government agencies in the future as U.S. homeland defense measures are implemented and expanded. As of this writing, the demand for government

computer-security specialists exceeds the supply of qualified individuals with computer forensics knowledge and experience. Private-sector businesses and Fortune 500 corporations will likely encounter the same shortages of qualified computer-security specialists as they deal with recently enacted laws regarding security of information, for example, HIPAA, Gramm–Leach–Bliley, and Sarbanes–Oxley. These laws require many businesses and organizations to establish safeguards and controls over the security and privacy of financial, health, and public corporation insider information. These new laws are discussed in more detail elsewhere in this book.

## FORENSIC SEARCH PRACTICES IN CLASSIFIED SECURITY REVIEWS

Most classified U.S. government agencies require the periodic review of all personal computers located in close proximity to computer systems that store and process classified data. Computer forensic search tools are the first line of defense in classified agencies for the identification of classified data leakage. The U.S. government requires that these reviews include the search of every sector of the storage media for classified text. Typically, DoD-tested and certified forensic text search utilities are used for this purpose, for example, NTI's TextSearch Plus and TextSearch NT, and government-developed tools such as D-Scan. As mentioned previously, government security reviews are lacking if they rely totally on text searches for the identification of classified data leakage. Forensic search tools are extremely helpful in security reviews but they provide no benefits when classified data are potentially stored in nontext file formats. The techniques discussed in the following pages are provided with the intent of helping improve the accuracy of risk assessments in government agencies.

### Creation of the Search Term List

The terms used in the computer forensic search are extremely important to the success of any computer-security risk assessment that involves the use of a computer forensic text search tool. The creation of the search term list is one of the most important parts of the security assessment. Lists that include small words, short terms, and abbreviations tend to generate false search results. Long strings of text may be missed in the search process because of disk fragmentation. The effectiveness of the security scanning process is only as good as the design of the search term list and the computer forensic search tool used in the search. In any case, the list of search terms should be crafted with much care and thought by a person who is trained in the use of computer forensic search tools. It is helpful if the person conducting the search has knowledge of personal computer technology and inherent personal-computer security weaknesses.

Search term lists can be created using DOS Edit, Windows NotePad, or even a word processing program. Depending on the computer forensic search utility used, search terms are usually stored in ASCII format and each search term is terminated with a carriage feed/line feed sequence. DOS Edit and Windows NotePad generate this

type of file output automatically and a word processor can be used to generate such a file using the "File Save As" feature. When using a word processor, the list of terms is saved in ASCII DOS text format.

Ideally, short words and abbreviations should not be used in the search term file. This is because the letter combinations associated with some relevant classified words or terms may also be found in common forms of data found on most computer systems. The following is an example of a flawed search term list that would likely result in hundreds or even thousands of false hits in a security review that relies on a forensic text search utility:

```
troll
lion
lie
secret
soft
copy
poly
roso
program
```

This listing of search terms may appear to be acceptable, but a close examination reveals several problems with the terms in the list; for example, these terms are substrings of larger words, or they are found in system files that are common to most personal computers. If this list were used in the search of a hard disk, hundreds of false leads would likely be identified by a text-based computer forensic search tool. To illustrate this important point, please consider the following:

1. **troll** is included in the words controller, controlled, and trolley.
2. **lion** is included in the words battalion and dandelion.
3. **lie** is included in the words believe, client, lien, earliest, families, and allied.
4. **secret** is included in the word secretary and the titles Secretary of State, Secretary of Commerce, Secretary of the Treasury, and Secretary of Defense.
5. **soft** is included in the name Microsoft Corporation and personal computer searches will identify thousands of occurrences of this word on most systems. The same situation exists with the search term "**roso**," which is also included in the name Microsoft Corporation.
6. **copy** is included in the words copyright, copying, and photocopy.
7. **poly** is a slang term for polygraph and is included in the word polygon.
8. **program** is a term that is stored in numerous locations on all personal computers; for example, the error message contained in all Windows-based programs, "program cannot be run in DOS mode."

This hypothetical list of search terms would need to be fine-tuned to enhance the search results and to eliminate as many false hits as possible. An example of the perfected search term list might look something like the following:

```
troll<space>
<space>lion
<space>lie<space>
secret<space>
<space>soft
<space>copy<space>
poly<space>
<space>roso or roso project
weapons program
```

The strategic insertion of spaces in the search term list is important when one or more of the targeted search terms are a part of larger words. This technique is called “space bracketing” in computer forensics, and it is very effective. However, the space-bracketing technique can create problems when punctuation immediately follows the term on the targeted storage device. Other problems occur when plurals of a word in the search term list exist on the targeted storage device.

To illustrate some of problems associated with space bracketing, consider a search for the word “secret.” Let’s assume for a moment that we are conducting a security review at a U.S. embassy, and we want to avoid false hits associated with the title “Secretary of State.” We would modify the search term list by adding a space behind the word “secret.” However, the addition of the trailing space would cause the forensic search software to skip the word “secrets,” and it would skip the word “secret” if it appeared as the last word in a sentence. This is because the trailing punctuation, that is, a period, would defeat the search results for some forensic search tools. DoD-certified forensic search tools, for example, TextSearch Plus and TextSearch NT, will not be fooled by trailing punctuation. To avoid missing the word “secrets” in the search, we could add that word to the search term list. Thus, the search term list would include both the word “secret” (followed by a space) and the word “secrets” to enhance the results of the search.

Repeated test scans are usually required to perfect the search term list to avoid false positives and to ensure that relevant search terms not missed. It is not uncommon in computer forensics to fine-tune the search term list during the search as false positive findings are identified. Once an accurate search term list has been created, it can be used on multiple computers in the security assessment. Every change to the search term list should be given much thought because even minor changes can affect the accuracy of the security search results.

### Logical Versus Physical Text Searches

The U.S. government requires that all sectors of storage device data be searched to identify the potential leakage of classified government data onto unclassified computers and related storage devices. This policy is based on sound computer forensics logic because of the possibility that classified data could reside between or beyond partitions on the storage device. As mentioned previously, this can occur when used computers are upgraded with new operating systems or when hard disk drives are repartitioned during hardware maintenance. Physical keyword searches involving the search of each sector will also identify allocated and “deleted” file names that may also contain classified terms. However, remember that the

Figure 4.

names of erased files will omit the first character in the file name. It will be replaced with a lowercase Greek sigma character. If the potential exists for file names to be a security risk, then this needs to be taken into account when the list of search terms is created.

Logical text searches of storage volumes will not identify risks associated with file names, data stored in the MFT on NTFS-based systems, and data potentially stored in the partition gap or partition-free space. However, logical searches can provide benefits that do not exist with physical searches when disk fragmentation is involved. To illustrate this situation, assume that our search term list includes the classified term “Aardvark55.” The length of this search term is not excessive, and it could be relevant in a classified security-risk assessment. For the purposes of this example, assume that the hard-disk drive involved is well used and the data storage areas are fragmented. On well-used disk drives, the potential of disk fragmentation is high and the potential exists for targeted search terms to be split between consecutive clusters. This is illustrated in Figure 4.

For the purposes of this example, assume that the file has not been deleted and that it is still an active file. If we were to perform a physical text search for the term Aardvark55, the data would be identified by the forensic search utility. The same would be true if we were to perform a logical search for the term using a forensic search utility.

Now let us look at the same fact pattern but factor in disk fragmentation. For the purposes of the example and to illustrate the effect of disk fragmentation, assume that the data previously stored in cluster 820 was written by the operating system to cluster 822. This would be the case, on a used hard drive, if clusters 820 and 821 were already occupied with data from another file. Because of disk fragmentation, the data would be stored on disk as illustrated in Figure 5.

If we were to conduct a physical text search, in this case, the search term, “Aardvark55,” would not be identified. A logical text search would identify the search term, however, because the File Allocation Table (FAT) (or Message Format Translation (MFT) on an NTFS system) would connect the clusters. However, neither the physical text search nor logical text search would identify the search term if the file was deleted. This is because the FAT (or MFT on an NTFS system) would no longer recognize clusters 819 and 822 as part of the same file.

The problem with fragmentation can be addressed in two different ways. First, it is recommended that both physical and logical searches be conducted using a

Figure 5.

DoD-certified forensic text search utility. Such tools will accommodate both physical and logical searches, and they can be run automatically in batch mode. Second, it always makes sense to split targeted search terms in the search term list to enhance the search potentials because of search weaknesses attributed to fragmentation. In the hypothetical Aardvark55 example, we could include Aardvark55, Aardv, and k55 in the search term list. Although this involves three separate search terms and it will likely generate redundant hits, the practice helps ensure that targeted data will not be overlooked. However, you must be aware that even this technique will not ensure positive findings when deleted files and fragmentation are involved, as stated previously.

## RISKS ASSOCIATED WITH NONTEXT (BINARY) FILES

Forensic text searches are not effective when certain types of files are involved. The files that cause concern include but are not limited to compressed files, graphic files, embedded text files, and compound files that include combinations of graphics files and text. Forensic text searches are also ineffective if files have been encrypted using any number of commercial and government encryption tools. The topic of encryption has not been discussed here because encrypted data in a classified government agency is not a security risk.

### Graphics File Formats

Digital photography has become popular and graphics files are abundant on the Internet. In today's modern world, some cellular telephones have the ability to take pictures and store the image in the form of graphics files. Because of advances in technology, we have become a more picture-based society. It is not uncommon for hundreds or thousands of graphics files to be stored on a well-used personal computer system. This causes problems in classified government agencies because forensic text-based search utilities cannot identify classified terms and words stored within graphics files. For this reason, it is currently necessary to identify and manually review the contents of all graphics files as part of a classified government security risk assessment given the state of current technology. As of this writing, no forensic search tools can reliably search graphics files and identify targeted key words or strings of text. The problem is compounded by the fact that some text-based file formats allow the embedding of graphics files in the files. This is the case with word processing, PowerPoint, and spreadsheet files. This means that computer forensic search utilities have limitations concerning the identification of all data leakage in classified government security-risk assessments.

In the past, I have recommended that file headers of known graphics files be included in the search term lists. Some forensic search tools do this automatically for the common graphics file formats, for example, BMP, GIF, JPG, and TIF. However, in high-stakes computer-security-risk reviews, I recommend that all graphics files be captured from the target media and that they be reviewed using a graphics file viewer. Although this is a tedious

process involving potentially large volumes of files, decisions can be made quickly by reviewing thumbnails of the extracted graphics files. The extraction process can be simplified through the use of a physical access capture of all graphics files contained on a target hard-disk drive using a tool such as NTI's Graphics File Extractor, and the process can be performed using a portable USB storage device. Floppy diskettes cannot be used because they do not have enough storage capacity.

### Compressed File Formats

File compression programs are popular, and they are used to combine and compress one or more files to save space. They were originally created to shrink file size back when files were downloaded from computer bulletin boards. Back then, modem transfer rates were very small and long-distance phone rates were high. To save money and time, file compression was used extensively with programs such as ARC, PKARC, and LHARC. Today the most popular file compression program is PKZIP, but other popular programs include RAR, ARJ, and ACE. In addition to compressing file contents, modern compression programs also provide security features through the use of encryption.

It is unfortunate, but forensic search utilities have no ability to reliably and quickly search compressed file formats. However, some forensic search tools do identify these files by either their file extensions or file header signatures. When the compressed files are identified in this fashion, a manual review is required. This can be a time-consuming and tedious process, and this is especially true if security features have been used with the compression. Because of the risks and problems created, many classified government agencies forbid the use of these programs.

### Embedded Text and Obscure File Formats

Not all files are stored as text, and this complicates the job of the computer security specialist who uses forensic search utilities in computer security reviews. In general, text searches involve the search for upper- and lowercase characters, numbers, and punctuation. All of these characters can be entered from the keyboard, but that is not to say that a computer application will store text in the same order it was entered.

Computer applications typically allow work to be stored in the form of a file. Unfortunately, there is no universal standard for file formats, and this is true of even commonly used computer applications such as word processors. Because of this lack of standardization, file formats vary dramatically, and some use special characters to identify unique characteristics about the stored data, for example, underlining of text, bold type, dropped capitalization, italics, and so forth, in word processing files. Some word processing files contain a mixture of ASCII text blended with binary characters. This situation can cause problems in classified security reviews that are based purely on the search of key words and strings of text in ASCII form. All computer security specialists should be aware of this fact, and they should realize that forensic text search tools have limitations. I have provided some examples of different file formats as food for thought for computer security specialists. This information is

intended to help in the crafting of search term lists and it is also intended to demonstrate the limitations of forensic text searches in classified government reviews.

To illustrate the weaknesses of forensic text searches in classified government reviews, let us assume that we have included the term "little lamb" in our search term list. The assumption would be that this is a term of interest or it could hypothetically be a classified project name. With this in mind, I created a one-sentence WordPerfect doc-

```
.....
.Q...../.=...8@/%.....Q...*0.....d.....$. )...3..
8.:=.....'.....%.....Q.....m.....8.....8.e.....Q.....K.....K.....K.....K.....M...
.]...M...].].....].].....H.....@...@...@+.....@...+...@...@...@...@...@...@...
K.....
```

ument that consisted of "Mary had a **little lamb** whose fleece was as white as snow." Note that the targeted search term, little lamb, was bolded in the sentence that I created. The file was then saved in the form of several different word processing file formats. You would think that this simple sentence would be stored identically in each file format, but that is not the case.

I have provided various examples here to illustrate how file formats differ from one application to another. Please note that I filtered all binary and control characters and replaced them with a period. Any replacement character

```
1.....
Mary had a little lamb whose fleece was as white as snow .....
.....w.....
.....=/. ...2...$.
.....<.....=.....
.....
```

could have been used, but I did this so that the results could be easily printed and reviewed. The results follow.

**AMI PRO Version 3.0**

Most word processing applications add information to the stored file that assists in the editing process. Therefore, word processing files are usually larger than the stored contents, and this is the case with the AMI Pro file format. The sentence "Mary had a little lamb whose fleece was white as snow" is 57 bytes in length, but the file size is 1,358 bytes in length and the filtered output is listed as follows:

```
[ver]...4...[sty]...[files]...[charset]...82...ANSI (Windows, IBM CP 1252)...[prn]...PCL / HP
LaserJet...[lang]...2...[fopts]...4...1...2880...0...[nopts]...0...Body
Text...[docopts]...5...0...[tag]...Body Text...2...[fnt]...Times New

elay]...[11]...0...[doc]...Mary had a < +! > little lamb < -! > whose fleece was as white as snow...>..
```

Note that the targeted text, **little lamb**, is surrounded with special characters that are used by the application to identify that the text is to be displayed and printed as bold text. In this example, a forensic search utility would easily identify the targeted search term.

**DisplayWrite Version 4.0**

The DisplayWrite file is smaller (407 bytes in length), and the filtered results are as follows:

```
.....
.Q...../.=...8@/%.....Q...*0.....d.....$. )...3..
8.:=.....'.....%.....Q.....m.....8.....8.e.....Q.....K.....K.....K.....K.....M...
.]...M...].].....].].....H.....@...@...@+.....@...+...@...@...@...@...@...@...
K.....
```

Note that none of the information was stored on disk in readable form. In this example, a forensic search utility would fail to identify any targeted key words.

**MS Word Version 4.0**

Microsoft Word has become the most popular word processing format and MS Word, version 4.0, is one of the older versions of the program. In this example, it created a fairly small, 772-byte file, and the filtered output is displayed as follows:

```
1.....
Mary had a little lamb whose fleece was as white as snow .....
.....w.....
.....=/. ...2...$.
.....<.....=.....
.....
```

In this example all of the text is displayed, and a forensic search utility would easily identify the targeted search terms.

**MS Word 97/2000 for Windows**

Microsoft has made many improvements to the MS Word program over the years. Current versions allow the tracking of changes and the incorporation of graphics. These improvements come with a penalty in the size of the file. In

the example, the converted file is 12,292 bytes in size and relevant parts of the filtered file are displayed as follows:

In this case, the sentence is stored on disk as text and a forensic search utility would easily identify the targeted

```

.....R.o.o.t.
.E.n.t.r.y.....@...“.....P.e.r.f.e.c.t.O.f.f.i.c.e._M.A.I.N.....
.&.....P.e.r.f.e.c.t.O.f.f.i.c.e._O.B.J.E.C.T.S.....
@...“...@...”.....R.o.o.t.

;“...”.....W.o.r.d.D.o.c.u.m.e.n.t.....G.....b.j.
b.j.....&.....P.....].
.....g.....
.....$.....R.....
.....b.t’.....
.....S.E.Q .C.H.A.P.T.E.R. \.h. \.r.1...M.a.r.y. h.a.d. a
.l.i.t.t.l.e .l.a.m.b. w.h.o.s.e. f.l.e.e.c.e. w.a.s. a.s. w.h.i.t.e.
.a.s. s.n.o.w.....*.....B. X.....mH. CJ.5...mH. CJ...U...CJ.mH.U.....
.....1$. $.../
..=!...” # ...$...%.....[.....(.....N.o.r.m.a.l.....CJ.
.mH.....<.A@<.....D.e.f.a.u.l.t. P.a.r.a.g.r.a.p.h. F.o.n.t.....P.....
P.....P.....@.....G.....
T.i.m.e.s. N.e.w. R.o.m.a.n ...5.....S.y.m.b.o.l...3&.....A.r
.i.a.l...#.....1...1.....!#.....
.....

```

This is one of the most popular word processing programs, and you should note that the application stores the sentence with binary characters inserted between each letter. Many of the older forensic search utilities would not recognize the targeted key words stored in this fashion. However, a DoD-certified forensic search utility such as NTI’s

string of text. In this case, the bolding is tagged with binary characters before and after the term “little lamb.”

**Professional Write Version 2.2**

The sentence is converted into a 1,151-byte Professional Write file and the filtered output is displayed as follows:

```

B.....N.....
.....#(-.2.7.<.A.F.....
.....
.....TYPE 4. 2.00.....
.....1.....K
.K.....N.....# (-27<.A.F... Mary had a ..... whose
fleece was as white as snow....N.....# (-27<.A.F.....

```

TextSearch Pro or TextSearch NT would identify the targeted strings of text.

In this case, the targeted strings of text are not visible because the word processing application converts them into binary characters to identify them as bolded text. For this reason, a forensic search utility would fail to identify the targeted strings of text.

**OfficeWriter Version 6.2**

When the file is converted into the OfficeWriter file format, it resulted in a 1,681-byte file, and the filtered output is displayed as follows:

```

6.0
01/08/04:. .wp.
85 110 10 10 10 n nfo n6..
.1.1.....
.....1.1.....
.....1.1.....
....Mary had a .little lamb. whose fleece was as white as snow.

```

## CONCLUSIONS

Unfortunately, personal computers were never designed to be secure. For this reason, inherent risks exist when sensitive data are stored on personal computer storage devices in government and business environments. Some of the risks associated with data leakage can be identified through the use of computer forensics tools and methods, but there are limitations. The limitations deal primarily with data stored in obscure file formats, graphics files, and compressed files, which do not lend themselves to forensic text searches. When these types of files are involved, the risks are increased in classified government agencies and manual reviews of specific files and data types are required. Once data leakage has been identified, the subject data can be eliminated through accepted data elimination processes.

## GLOSSARY

**Allocation unit** The smallest unit of disk space that may be allocated to a file. Varies by file system.

**Bit-stream copy** A bit-for-bit copy of digital evidence.

**Block** UNIX terminology for an allocation unit (see allocation unit).

**FAT** Acronym for File Allocation Table. A common form of file system used with Microsoft Windows operating systems.

**Forensic image** An exact, bit-for-bit copy of media.

## INTRODUCTION

The spreading use of distributed systems is forcing the development of increasingly varied investigative procedures in digital forensics regarding both the target and the analysis platforms. A “target platform” is one that has been attacked or used to perpetrate some policy or criminal violation, whereas an “analysis platform” is the one that supports the forensic workstation. In this chapter I discuss UNIX-based platforms and the various “dialects” such as Solaris, AIX, xBSD, and, of course, Linux.

### Some Basics of UNIX Forensics

The principles in forensic operations are essentially platform independent, though some file systems are not. In keeping with the rules of due diligence contained in the IACIS (International Association of Computer Investigative Specialists, <http://www.cops.org>) code of ethics, it is important to clarify several general characteristics of UNIX-based file systems.

However, first I want to make very clear what is meant in digital forensics by “investigative process.” Such a process comprises the sequence of activities that should be performed by the forensic examiner to ensure compliance with juridical requirements now common to all countries.

For the purposes of this chapter, the investigative process is subdivided into six phases (Spafford and Carrier, 2003), as illustrated in Figure 1.

1. **Notification.** This first report occurs when an attack is detected by an automatic device, by internal personnel, or through external input (for example, by a system administrator in another company or by another business unit in the same company). The action taken is usually to create or activate a response team, whose first task is to confirm that an attack has occurred.
2. **Preservation.** This is a critical phase in incident response and the first bona fide digital forensic action. The main objective here is to make sure that the scene of the crime is left intact so as not to preclude any future investigative or analytical measures. The “digital

crime scene” is usually duplicated, that is, an image disk is created, so that detailed analyses may be performed in a properly equipped laboratory.

3. **Survey.** This is the first evidence collection step. The objective here is to examine the scene of the crime for any *obvious digital evidence* and to develop hypotheses that will orient further investigation.
4. **Search.** The hypotheses developed in the survey stage are investigated with the help of analysis tools as needed. In this more detailed evidence collection phase, the “cold” trails are abandoned and the “hot” ones followed.
5. **Reconstruction.** This phase involves detailed testing to connect the pieces of evidence and reconstruct the event. In many cases this activity may indicate the need for or reveal further evidence.
6. **Presentation.** The final act in this process is to collect all the findings and present them to those who requested the investigation.

A forensic analysis is indicated in two fundamental cases: a) reconstruction of an attack (post mortem analysis) and b) examination of a computer that may have been used to carry out some sort of criminal violation. In the first case, the examined computer is the *target* of a violation; in the second, it is a *tool* used to commit a crime. The job of the forensic examiner is to carry out the investigative process.

### UNIX File Systems: An Overview

For a good understanding of the methods and objectives of an investigation, it is helpful to have some background on UNIX file systems. The logic behind these systems is simple, elegant, and powerful. In some ways, UNIX is similar to DOS; in others, it reveals a kinship with much more outdated operating systems (such as MULTICS); and in others, it is quite unique.

On the system level, directories are treated as files that contain other files or subdirectories instead of data. For the system, all files and directories are **i-nodes**, whose descriptors (name, attributes, authorizations, etc.) and

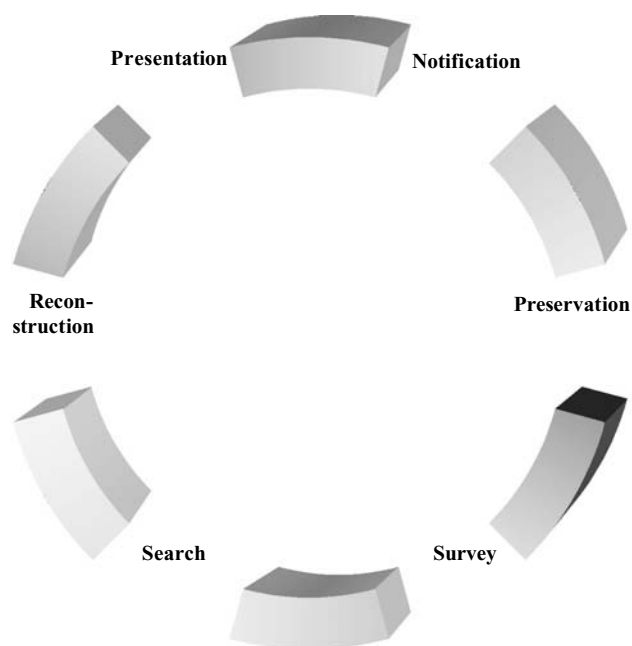

Figure 1: The investigative process.

contents (the data in the file or the files in a directory) are kept separate.

In terms of nomenclature, the files may contain any characters in their names except spaces, special characters for the shell, and CR (carriage return). In UNIX, the file extensions do not have a specific meaning but are used for convenience by certain commands. They are not indispensable and, on the file system level, do not even indicate the type of file.

As an example, a UNIX partition might distribute a file system as follows:

- Block 0, not used by UNIX, sometimes used for the system boot (the MBR if it is found on a primary device);
- Block 1, or Superblock, contains critical information on the structure of the file system (number of i-nodes, number of blocks on the disk, etc.);
- List of the i-nodes, numbered from 1 to a finite number, containing information on the individual files contained in the file system and on the position of the respective data; and
- Data blocks, with the data contained in the file.

The i-nodes contain information such as file type, authorizations, date of creation, modification and last access, proprietary user or group, position and dimension of the file, and so on. Via links, the same i-node can be shared by different objects in the file system.

## Details on File System Structure

Linux by default supports the file system ext2, which shares a host of characteristics with a typical UNIX System V file system. The Linux kernel also allows for the use of many other file systems such as ext3, reiserFS, jfs (*journaled* file systems that keep a log of all writing operations to allow easier data recovery in the event of a malfunction), Windows file systems (FAT, FAT32, ntfs),

those of many other operation systems (BeOs, AmigaOs, Mac, etc.), and network file systems such as NFS, SMB, and Novell. This last characteristic is very important for those who carry out forensic analysis and investigation on this type of file system.

A Linux file system, like all UNIX systems, has a hierarchical structure: all its objects (files and directories) are contained in the root [the main directory, indicated simply with a “/” (slash)], and the slash is also used to separate directory names [for example: /usr/bin/ indicates the directory “bin” contained in the directory “usr” contained in the root (/)].

The root not only contains all the other directories in a partition, but also all the file systems (partitions and hard disks, floppy disks, CD-ROMs, network links, etc.). The principle is radically different from what we see under Windows, where each device or resource has its own name or identifying letter (A:, C:, D:, etc.), under which we find the directories of its file system. For example, on many Linux systems, the files contained on a floppy disk are found in a directory named /mnt/floppy and not in something called A: as in Windows. Furthermore, the name of this directory can be changed at will by the user or by whoever set up the distribution (obviously, there are methods for finding out the residence directory of any device).

There are some standard UNIX notations for indicating the current directory, the parent directory, the home directory, and so forth:

/ indicates the root, the main directory at the base of the entire file system;

**/bin/** indicates the subdirectory “bin” (arbitrary name) in the root;

**bin/** indicates the subdirectory “bin” with respect to the current directory. Note that if the path begins with a “/” it is an absolute path that begins with the root. If it does not begin with “/” it indicates a path in relation to the current directory;

. indicates the current directory;

.. indicates the parent directory of the current one;

**./bin/** indicates the subdirectory “bin” that is found at the same level as the current directory;

~ indicates the home directory of the current user (coincides by default with /home/login\_username). An absolute path, then, will look something like this: usr/local/bin and will be operative regardless of the current directory.

A relative path will look something like local/bin and refers to different directories depending on the current directory. In this case, local/bin coincides with /usr/local/bin only if the user is in the directory /usr/.

The following sections provide additional information on the hierarchy and position of information regarding UNIX that is useful for computer forensics operations.

This is the typical scenario you may find when examining a UNIX-based file system. However, you may be pleased to know that a large group of technicians is hard at work on a standard hierarchy to be used by all UNIX

machines: Filesystem Hierarchy Standard (2003). Now in version 2.2, it may be a useful reference for forensic investigators.

## TOOLS AND TECHNIQUES FOR FORENSIC INVESTIGATIONS

This section addresses investigation methodologies as they apply to the various investigation phases. The objective here is to provide the reader with the initial guidelines needed to approach the problem.

### Preservation Phase: Imaging Disk under UNIX

The generation of an image disk under UNIX is an essential part of the preservation phase. One of the most common errors involves making a “nonforensically reliable” copy of disks. This obviously would be the lesser of two evils if we consider the fact that there are still quite a few operators who work (and often even write) on the original disks. Although it may be admissible to work on nonrewritable CD-ROMs, the same can certainly not be said for hard drives. For this reason, the first necessary step is to make a copy, or “image disk,” of the original disk, which thereafter is referred to as the “source.” There are various methods and tools for accomplishing this.

There are guidelines regarding preparations for doing the imaging. In most cases, the machine is turned off before it is delivered to the incident response investigator. It may also be left on but disconnected from the network. In the former case, the computer must not be turned on except by trained operators; otherwise, data may be modified in a way that compromises the investigation. When in doubt, the golden rule is “if the machine is off it has to stay off; if it is on it has to stay on until further orders.”

It goes without saying, but I will say it anyway: the original support must be carefully protected (for example, apply write-protect where possible).

The image of the support is obtained using software tools to create a bit-by-bit image. The preferred method is to use a trusted workstation for the acquisition regardless of whether the source disk is a single hard disk, a floppy disk, or a CD. Otherwise, if conditions permit, the investigated computer may be booted from a floppy (drive A:) rather than from the hard disk. In this case, the computer boots up with a minimal operating system that contains additional programs and drivers so that the computer recognizes an external memorization device as a removable hard disk. Then a program is booted from the floppy that creates the image of the hard disk(s) on the external device. This image will include both visible and hidden files, the parts of the disk that contain information on details of the directories (file name, dimension, date, and time stamp) and also certain other fragments of files that had been previously deleted but not yet overwritten. The image file can be easily read or examined, although in some cases (especially during the reconstruction phase), it may be necessary to carry out a reverse procedure on a second computer with similar characteristics to the first, that is, an exact clone of the original disk so that all details can be completely reproduced. In any case, the

images are copied onto write-once/read-many CD ROMs that cannot be altered.

Remember, the disk image destination drive must be wiped. The procedure involves the complete cancellation of the entire contents of the hard disk. There are a number of ad hoc tools for this purpose, including one known as “Wipe.” Keep in mind that the wiping operation must be documented in the forensic analysis report whether or not the report relates to incident response operations. It is recommended that the disk image destination hard disk be wiped upon completion of an examination. In any case, it must be done (and documented) prior to any subsequent image acquisition.

### Disk Imaging Tools

Forensic analysis operations require a number of software tools and dedicated hardware devices. The tools have different functions, such as backup and restore, file comparison, checking and comparison of encrypted checksums, system setup check, list of services and processes, and systems for backtracing the attacking sites and their Internet service providers (ISPs). We next examine the tools that preserve evidence by creating an image of it.

### Creating Disk Images in a UNIX Environment

I personally believe that in addition to ensuring the integrity of the evidence base, one of the main objectives of the preservation phase is to allow for the image to be examined with the greatest possible variety of investigation tools. To this end, the format I prefer for the image disk is DD. This tool has been tested by the National Institute of Standards and Technologies as part of their Computer Forensics Tool Testing (CFTT) project, thus guaranteeing that it will enjoy some recognition in court. For further information on DD, check out the Web site at <http://www.opengroup.org/onlinepubs/009695399/utilities/dd.html>

DD copies a file (by default from the standard input to the standard output) with preset input and output block dimensions and may convert the file. It reads the input one block at a time according to the dimensions specified for input blocks (default value is 512 bytes). If the **bs** = *byte* option is present and no conversion other than **sync**, **noerror**, or **notrunc** is required, it writes the data (which might be less than required) into a separate output block. This output block has the same length as the input block unless the **sync** option is specified, in which case spaces are added to the end of the data.

Otherwise, the input, read one block at a time, is processed, and the resulting output is collected and written in blocks that have the specified dimension. The final output block may be shorter.

The numerical operations that follow (bytes and blocks) may be followed by a multiplier:  $k = 1024$ ,  $b = 512$ ,  $w = 2$ ,  $c = 1$  (“w” and “c” are GNU extensions; “w” should never be used: it means 2 in System V and 4 in 4.2BSD). Two or more of these expressions may be multiplied by placing an “x” between them.

It is possible to import the images created with DD using the most recent versions of the best known forensic investigation tools, both GNU and commercial, such as FTK, Encase, or Smart. The basic concept is that DD

makes a bit-by-bit copy from one location to another using the syntax

```
dd if=<src> of=<dst>
```

where <src> and <dst> may be files, file system partitions, or an entire hard drive. DD is not a network program; you can use “netcat” to extend it to a network. Netcat is used to make TCP/UDP connections to a server and is also an excellent diagnostic tool. Netcat typically works in two modes, server and client:

```
server% nc -l -p 30000 ==> (Awaiting input via port
                          30000 on <server>)
```

```
client% nc <server> 30000 ==> (Connection to <server>
                              via port 30000)
```

Even though a computer forensics investigation is carried out on copies and not on the originals, the tools must still not alter the evidence. Even with copies, you have to make sure that their content is not altered during the investigation. To ensure this, you have to have a checking mechanism that lets you be sure that the evidence (and copies of it) has not been altered or damaged. The best technique is to create a hash of the image produced.

A *hashing algorithm*, starting from a data sequence of any length, such as the entire contents of a disk, generates another, much shorter data sequence called a *hash* whose contents strictly depend on the original data. The feature of the hashing algorithm that makes them so useful is that even minimal changes in the input data will produce a completely different hash. There are many hash-generating algorithms. The most important and widely used are SHA-1 (secure hash algorithm, RFC 3174) and MD5 (message-digest algorithm, RFC 1321). The critical issue with these algorithms is not so much a question of generating a hash that does not let you get back to the original data but that of avoiding overlapping results, that is, making the relationship between the input data and the hash as unambiguous as possible. At this moment, a group of Chinese cryptologists has presented a paper related to MD5 and SHA-1 cracking. However, we are pretty far from a practical implementation of the proof of concept expressed in the paper itself. The forensic community advises examiners to perform either SHA-1 and MD5 on the same image file.

There are many tools, both freeware and commercial, that can generate hashes of files. For example, a tool included in F.I.R.E. (Forensic and Incident Response Environment) generates images of disks and a hash of the file created. The tool in question is called DCFLDD (or EDD for “Enhanced DD”). This software was specially created for F.I.R.E. and is a tool that extends the potentials of DD (the basic tool) with a feature that allows the creation of an MD5 hash of the disk image. Depending on the options, it is possible to create the hash in a separate output file. It can also create hashes of subsections of disks (or in general of input data flows) specifying the dimension of the hash window, that is, specifying the data intervals at which hashes should be created. We get into a little more depth on F.I.R.E in the section on First Response CDs.

DCFLDD, hence, is a modified version of DD that calculates the hash value of the created image.

Example:

```
# dcfldd -hashwindow=BYTE -hashlog
=FILE if=Dev of=dev
```

“Hashwindow” indicates the number of bytes for which a hash should be created, and Hashlog generates the text file containing the calculated values.

Another handy freeware tool for generating hashes is Hashish. This tool has the sole objective of generating a hash on the basis of an input file or a simple data string. The potential of this tool derives from the number of its algorithms. It is a complete and easy-to-use tool with a graphical user interface (GUI). The fact that it can run both under Windows and Linux/UNIX is also very helpful.

DD, furthermore, may also be used in the event of memory dumping. This occurs when the machine is still on when delivered to the forensic examiner. In this case, the procedure is as follows:

```
dd if= /dev/kmem of=output
dd if= /dev/mem of=output
```

Regarding how to handle memory images, it should be mentioned that a number of examiners have encountered systems that freeze up following this procedure. As an alternative, Memdump, written by Wietse Venema, can be used. The MemDump utility is designed to dump any part of 4-GB linear memory address space under MS-DOS and Windows 9x DOS to a console or a text file. This utility provides transparent access to memory with or without installed memory managers. The software can be downloaded from <http://www.porcupine.org/forensics/memdump-1.0.README>.

To dump physical memory:

```
memdump | nc host port
memdump | openssl s_client -connect host:port
```

In the meantime, research is looking into alternative methods for acquiring the memory contents based on hardware cards (Carrier & Grand, 2004). These cards would dump the memory without performing any operations on it and without interacting with the operating system kernel of the compromised machine, and might solve a lot of problems. However, from the practical point of view, there are a lot of limitations, mainly in the deployment phase.

At any rate, the memory dump is generally more useful in the “pure” investigation phases, rather than for subsequent appearances in court. Whatever the case, do not forget that all imaging operations, including the description and specifications of the tools used, must be documented in the report.

## Survey and Search Phase: Seeking Evidence under UNIX

This section covers issues and techniques in performing digital forensics, including searching, file recovery techniques, and other topics.

There are certain basic differences between a forensic exam done on a target platform such as UNIX and one done under Windows. The problems that are often

encountered regard mainly the reconstruction of data that has been deleted or scattered around the file system. These problems are even more noticeable when you are dealing with tapes and/or various types of backup units, often containing only distributed portions of backup. In UNIX, furthermore, a term may not mean the same thing it would in a Windows-based operating system. The concept of *slack space*, for example, is slightly different in UNIX. Because UNIX files are stored compactly, except for the unavoidable wastage in the last block or fragment, it might be said that UNIX has no slack. However, certain ISV forensic analysis software producers also identify this type of space as “slack.”

A forensic analysis under UNIX may have two main goals: a) reconstruction of events (e.g., an attack) and b) search for evidence of other violations (e.g., pedophilia or any other abuse of the technology). Depending on the reason for acting, investigators will carry out searches that may be focused on log files rather than fragments of evidence. Usually, following an intrusion, the decision is made whether to turn off and disconnect the compromised system. If the system is left on and online to collect more information on the intrusion and the intruder, it is good to keep in mind that the system could be or could have been used as a stepping stone for attacking another site. In such case, it is very important that the police be contacted immediately and that the recommended measures be taken to decrease the likelihood of this happening. In many cases, when the system cannot be turned off, another machine is “associated” on the same network segment and set up in promiscuous mode with Tcpcdumpp to monitor network traffic in and out of the target in question.

At any rate, one of the first things that has to be decided on regards turning off the system prior to actually seizing it. The turning off procedure under UNIX has always been a source of debate among operators; there is no common agreement, at least not among the community of practitioners, on what operations have to be performed. Hence, it is recommended that the standard operating procedures (SOP) of one’s agency or office be followed. Some, for example, believe that before you turn off a UNIX machine, you should change the root password, if the user is logged as root. The reasoning is that it would otherwise be extremely difficult to recover the root password later on. This procedure is a part of rather outdated SOP; it is currently common opinion that any operations carried out on the “original” machine may compromise the integrity of the evidence and hence should be avoided. In the jargon, a machine that has been altered is known as *tainted fruit*.

Other operators think that the best thing to do is turn off the machine simply by pulling the plug. This is a rather widespread practice even though it has certain contraindications, not least among them the loss of critical information or the risk of irreparable damage to the file system. In many cases, however, the swap file remains unaltered and may contain very important information.

An alternative method for “crystallizing the scene of the crime” often used by certain investigators is the following:

- Photograph the screen and document which programs are running.

- Right click on the menu.
- Select **Console**.
- If the prompt is not on the user root, get there by typing **su -**.
- If the root password is not available, pull the plug on the computer.
- If the root password is available, enter it. At the pound sign (#), type **sync;sync;halt;** and the system will shut down.
- Unplug the machine.

The sequence **sync;sync;halt;** is often discouraged because it might write something. However, numerous guidelines (Department of Energy, n.d.) indicate this as the most suitable option.

As always, whatever approach is taken, it is critical that all operations be documented in a report.

### Search Tools and Data Left in the System by an Intruder

Intruders generally install customized tools to enable them to monitor the system and/or access the machine in the future.

The main tool categories are the following:

- network sniffer,
- Trojan horse,
- backdoor,
- vulnerability exploit,
- other (denial of service, use of processing resources), and
- communication systems with other compromised systems.

When a system is compromised, the intruder may install a network monitoring program (on UNIX systems) commonly known as sniffers or packet sniffers, with the goal of intercepting information regarding user accounts and passwords. The first step in determining whether there is a sniffer in the system is to check if there is a process that uses a network interface in promiscuous mode. It is not possible to detect promiscuous mode interfaces if the machine has been rebooted after the discovery of the intrusion or if it is operating in single user mode. It should be kept in mind that certain legitimate network monitors and protocol analyzers could set the network interface to promiscuous mode. Thus, the discovery of a promiscuous interface does not necessarily mean that an illegitimate sniffer is at work in the system.

Another aspect to consider is that the log files of a sniffer tend to grow quickly; hence, a utility such as *df* might come in handy for determining whether a part of the file system is bigger than expected. Remember that *df* is often replaced by a Trojan horse in cases where a sniffer has been installed; so make sure you have a clean copy of the utility before you use it. If a sniffer is found in the system, you should examine the output files to determine what other machines are at risk, that is, what other machines appear in the destination field of the intercepted packets. In cases where the same passwords are used, or the source and destination machines have a trusted relationship, the

source machine is at risk nevertheless. In certain cases, the sniffers encrypt their logs; hence, it is important to check files that increase rapidly in size. Also keep in mind that there may be other machines at risk in addition to those that appear in the sniffer log. This is because the intruder may have obtained previous logs from the system or through other types of attack.

Another operation is the search for files that are open at a specific time. This may be useful (especially on a machine that has not yet been turned off) to check for backdoors, sniffers, eggdrop Internet relay chat (IRC) bots, port redirectors such as “bnc,” and so forth. The program that may be used for this purpose is called LSOFF (LiSt of Open Files). It is advisable to run it from a CD-ROM with statically precompiled binaries, so as not to fall into an attacker’s booby trap and making a Trojanized version of this tool “available” to investigators.

There are also tools that are used to search for *rootkits*, that is, tools that are installed by the attacker after the target machine has been compromised. One of the most widely used tools is *chrootkit* (<http://www.chrootkit.org>), which has a list of rootkits of varying degrees of sophistication that it should be able to recognize.

For certain types of analysis, to identify the features of rootkits or other tools installed by the attacker, a debugging or even a reverse engineering operation may prove necessary. This type of activity may require some minimum legal assessment to ensure that no laws prohibiting reverse engineering are broken, such as DMCA.

### More on Keyword Searching

Once an image has been obtained of the disk and prepared for examination, it is possible to view the contents of the restored disk or the mounted image. If you are working on an X window system, then you can use your favorite browser to carry out the disk searches.

In many cases, the line commands are much more useful and powerful for handling the analysis, and thus are used in the following example.

The commands have `/mnt/analysis` as their default mount point.

To display the list of all hidden files in the current directory plus the special directories “.” and “..”, you can use

```
ls -la | grep “^.”
```

“`ls -la`” displays the contents of the directory. `grep “^.”` reads the output of `ls` and keeps only lines beginning with the character “.”

### Compile a File List

Among the various possibilities for handling file lists, you can use this command to search for files and compile the output in another file list:

```
find. -type f -print > /root/evidence/filelist.list
```

If you then use the command

```
grep -i jpg filelist.list
```

you will be able to select files with the extension *jpg* from the output.

### Compile a File List by Type

What do you do if you are looking for JPEG files, but the file name has been changed or the extension is wrong? You can use the command **file** on each file and check its contents:

```
file filename
```

If there are a lot of files to check, you can use the **file** command on all the files on a disk; furthermore, we can also use the **find** command with the option `-exec` in this case:

```
find. -type f -exec file{} \; > /root/evidence/filetype.list
```

You can view the list with the **more** command and if you are looking at a particular image, you can use the **grep** command:

```
cat/root/evidence/filetype.list | grep image
```

This should subdivide the contents of our *filetype.list* using **cat** and producing the output via **grep**.

### Viewing Files

For text and data files you should use **cat**, **more**, or **less** to view the contents:

```
cat filename
```

```
more filename
```

```
less filename
```

In any case, the best way to view the files is probably by using the **strings** command, which can be used to analyze the regularity of the text for any file (Excel, etc.), and it might be interesting as well to uncover strings of hidden text in binary files. The **less** option can be used to transmit the output:

```
string filename | less
```

Once you have finished exploring, you have to demount the disk (or image), making sure you are positioned at the right point in the tree:

```
umount/mnt/analysis
```

### Search for Nonallocated and Slack Space

The restored disk (or the loop-mounted image) allows you to check all files and all directories. But what can you check regarding nonallocated or slack space? The image created, because it is a bit-by-bit copy, also includes these disk areas.

Let’s consider the hypothesis that a letter threatening to infect a company network with a powerful virus has been received by management, and that as a result a floppy disk has been seized from an employee suspected of being the perpetrator. The analysis is focused on searching for the text of the letter in a deleted file in the nonallocated area of the disk.

Once the preliminary measures described previously have been done (image, mount, etc.), the next thing that

has to be done from the forensic workstation is to get positioned in the working directory:

```
cd/root/evidence
```

Now, you can use the **grep** command to search for the image of any element of an expression or pattern. There are several options that make the **grep** output more useful:

```
grep -options <pattern> <search_range>
```

The first step is to create a list of search keys. You can open a text editor and build this list of terms for which you want to search (for example, “pay a price,” “€50,000,” and “unleash a virus”): words and phrases that are contained in the letter. Once you have completed the list, it is a good idea to save it in `/root/evidence/searchlist.txt`, making sure that each term to be used in the search is on a different line and that there are no empty rows anywhere in the list:

```
pay a price
€ 50,000
```

```
unleash a virus
```

Now you can start the search with

```
grep -aibf searchlist.txt image.disk1 > hits.txt
```

Taking a look at the syntax of this command, we can see that the list `searchlist.txt` (option `-f listfile`) is used as search key in `image.disk1`, with the output of the search being compiled in `hits.txt` for later analysis. The option `-a` tells **grep** to rewrite the whole line where the target word was found and not the name of the file from which it comes, the option `-i` tells **grep** to ignore the case, and the option `-b` tells **grep** to provide the byte offset of each word found so that its hexadecimal position can be located with the command **xxd** or with any other graphical hexadecimal editor, such as GHex.

The contents of the file `hits.txt` may be viewed and explored with the commands **less** and **more** or with any text analyzer.

Although the **string** command is still the most effective, in this case we will use the simpler **cat** to analyze the entire contents of the standard file output:

```
cat hits.txt
```

```
75441: you will have to pay a price (. . .)
```

```
75500: I am sick of your company's pirating and am not going to wait any longer (. . .)
```

```
75767: Do not try to stop me and do not notify the police: if you do, I will unleash a virus that will shut down the network and destroy customer information (. . .)
```

To view the search results, you can use the following command:

```
xxd -s offset image.disk1|less
```

## UNIX AND NETWORK FORENSICS

Logging under UNIX is not an easy task. This section addresses the most important log files in UNIX and how to manage and analyze them.

Figure 2: Log flow.

First and foremost, it must be clear that log file correlation is related to two distinct activities: intrusion detection and network forensics. It is more important than ever that these two disciplines work together to avoid points of failure.

### Logs: Characteristics and Requisites

Every IT and network object, if programmed and configured accordingly, is capable of producing logs. Logs must to have certain fundamental requisites for network forensics purposes:

- *Integrity*: The log must be unaltered and not admit any tampering or modification by unauthorized operators.
- *Time Stamping*: The log must guarantee reasonable certainty as to the date and hour a certain event was registered. This is absolutely essential for making correlations after an incident.
- *Normalization and Data Reduction*. *Normalization* is the ability of the correlation tool to extract a datum from the source format of the log file that can be correlated with others of a different type without having to violate the integrity of the source datum. *Data reduction* (a.k.a. *filtering*) is the data extraction procedure for identifying a series of pertinent events and correlating them according to selective criteria.

### Need for Log Integrity: Problems and Possible Solutions

A log must guarantee its integrity right from the moment of registration. Regardless of the point of acquisition (sniffer, agent, daemon, etc.), a log usually flows that in (Figure 2).

Acquisition occurs the moment a network sniffer, a system agent, or a daemon acquires the event and makes it available to a subsequent transmission process directed to a machine that is usually different from the one that is the source of the event. Once the log has reached the destination machine (called the *log machine*), it may be temporarily memorized in a preassigned slot or input to a database for later consultation. Once the policy-determined disk capacity has been reached, the data are stored in a predetermined location. The original logs are deleted to make room for new files from the source object. This method is known as *log rotation*.

Log file integrity can be violated in several ways. An attacker might take advantage of a unencrypted transmission channel between the acquisition and destination points to intercept and modify the transiting log. He might also spoof the IP sending the logs, making the log machine think it is receiving log entries and files that actually

come from a different source. The basic configuration of *Syslog* makes this a real possibility. It states that *Syslog* transmissions are based on UDP, a connectionless protocol and thus one that is unreliable for network forensic purposes unless separate local area networks (LANs) are used for the transmission and collection of log files. Even here there might be some cases that are difficult to interpret. For this reason, the examiner must carefully select, especially during the search phase, which method to implement the logging system on the UNIX machine being investigated.

Another integrity problem regards the management of files once they have arrived on the log machine. If the log machine is compromised, there is a very high probability of integrity violation. This usually happens to individual files whose content is modified or even wiped. The integrity issue also regards how the *paternity* of log files is handled; in many juridical contexts, you have to be certain as to which machine generated the log files and who did the investigation.

There are several methods for resolving the problem. The first is specified in RFC 3195, which identifies a possible method for reliable transmission of *Syslog* messages, useful especially in the case of a high number of relays (intermediate record retransmission points between the source and the log repository). The main problem in this case is that RFC 3195 has not been incorporated into enough systems to be considered an established protocol.

Hence, practically speaking, most system administrators and security analysts view SCP (secure copy) as a good workaround. The most evident contraindication is the unsuitability of such a workaround for intrusion detection purposes, because there is no real-time assessment of the existence of an intrusion via log file reading. The problem remains of security in transmission between the acquisition and the collection points. In response to the problem, in UNIX-based architectures, the practice of using *Cryptcat* to establish a relatively robust tunnel between the various machines is gaining wider acceptance.

The procedure is as follows:

On log-generating host:

1. you must edit `/etc/Syslog.conf` in this mode:  

```
*.* @localhost
```
2. then run command:  

```
# nc -l -u -p 514 | cryptcat 10.2.1.1 9999
```

On log-collecting host:

1. run *Syslog* with remote reception (`-r`) flag (for Linux)
2. run command:  

```
# cryptcat -l -p 9999 | nc -u localhost 514
```

This configuration will establish an encrypted connection among the various transmission nodes. An alternative would be to use a *Syslog* replacement such as *Syslog-ng*, which performs relay operations automatically and with greater security potentials.

From the practical standpoint, these methods offer a good compromise between operational needs and the theory that a hash must be generated for each log entry (something that is impossible in a distributed environment). The objective still remains of achieving transaction atomicity (transactions are done or undone completely) and log file reliability. The latter concept means being sure that the log file does not get altered once it has been closed, for example, via interception during the log rotation phase. The most important aspect of this phase is the *final-record message*, indicating the last record written in the log, which is then closed and hashed. This sequence of processes may turn out to be critical when, after correlation, a whole and trustworthy log has to be provided to the judicial authorities.

### Log Time Stamp Management: Problems and Possible Solutions

Another problem is managing log-file time stamping. Each report has to be 100% reliable, not only in terms of its integrity in the strict sense (IP, ports, payloads, etc.), but also in terms of the date and time of the event reported. Time stamping is essential for two reasons: atomicity of the report and correlation. The most common problems here are the lack of synchronization and the lack of uniformity of the time zones.

The lack of synchronization occurs when the acquisition points (network sensors and *Syslog* devices) are not synchronized with an atomic clock but only within small groups. Reliance is usually placed on NTP in these cases, but this may open up a series of noted vulnerabilities, especially in distributed architectures connected to the public network. Furthermore, the use of NTP does not guarantee uniformity unless a series of measures recommended by certain RFCs is adopted for certain types of logs. Some technology manufacturers have come out with appliances equipped with highly reliable processors that do time stamping for every entry, synchronizing everything with atomic clocks distributed around the world. This sort of solution, albeit offering a certain degree of reliability, increases design costs and obviously makes management more complex. In a distributed architecture, a time stamping scheme administered by an appliance is set up as shown in Figure 3.

The appliance interacts with a PKI that authenticates the transaction nodes to prevent the problem of report repudiation.

Although this type of architecture may be implemented in an environment with a healthy budget, there are applications for less extensive architectures that may be helpful in guaranteeing a minimum of compliance with best practices.

Because one of the most commonly used log format is *Libpcap*-compatible (used by *TcpDump*, *Ethereal*) via TCP connections (hence three-way), it is possible to attribute a further level of time stamping, as per RFCs 1072 and 2018, by enabling the SackOK option (selective acknowledgment OK). This option can return even a 32-bit time stamp value in the first 4 bytes of each packet, so that reports among transaction nodes with the SackOK option enabled are synchronized and can be correlated. This

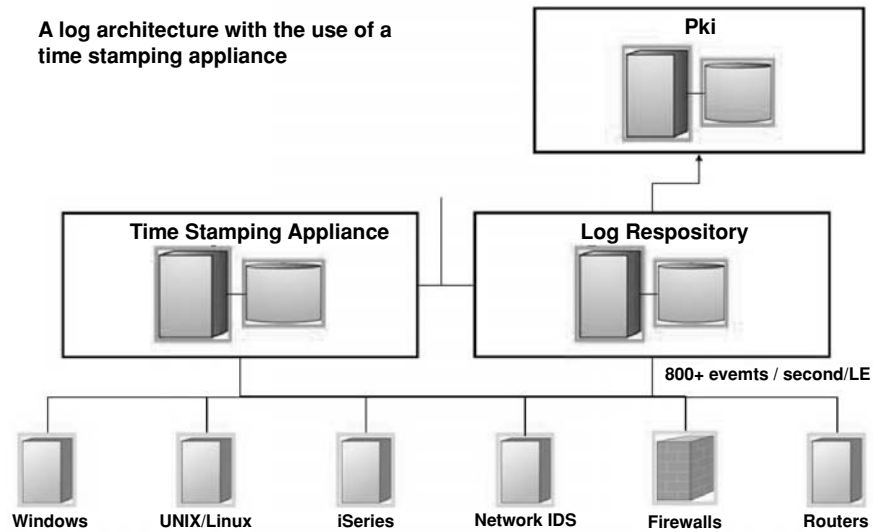

Figure 3: Log architecture utilizing time stamping.

approach may be effective provided that the entire system and network is set up for it.

Another factor that is not taken into consideration are time zones. In distributed architectures on the international scale, some information security managers believe it is wise to maintain the time zone of the physical location of the system or network object. This choice has the disadvantage of making correlation more complicated and less effective because of time zone fragmentation. We are currently witnessing an increase of times zones that are simply based on GMT, which has the advantage of simplifying management even though it still requires that the choice be incorporated into a policy.

**Normalization and Data Reduction Problems and Possible Solutions**

Normalization is identified in certain cases with the term *event unification*. There is a physiological need for normalization in distributed architectures. Numerous commercial systems prefer the use of extensible markup language (XML) for normalization operations. This language provides numerous opportunities for event unification and management of digital signatures and hashing. There are two basic types of logs: system logs and network logs. If the reports all had a single format, there would be no need for normalization. In heterogeneous architectures, it is obvious that that is not the case. Let us imagine, for example, an architecture in which we have to correlate events recorded by a Web site, by a network sniffer, and by a proprietary application. The Web site will record the events

in W3C format, the network sniffer in Libpcap format, and the proprietary application might record the events in a nonstandard format. It is clear that unification is necessary here. The solution in this case consists of finding points in common among the various formats involved in the transaction and creating a level of abstraction according to Figure 4.

It follows in this case that an attacker can once again seek to violate log integrity by zeroing in on the links between the various acquisition points and the point of normalization. Regarding the correlation, the point of normalization (normally an engine) and the point of correlation (an activity that may be carried out by the same module, for example, in an IDS) may be the same machine. It is clear that this becomes a potential point of failure from the perspective of network forensics and thus must be managed both to guarantee integrity and to limit possible losses of data during the process of normalization. For this purpose, the state of the art is to use MD5 and SHA-1 to ensure integrity and to perform an in-depth verification of the event unification engine to respond to the data reduction issue, keeping the “source” logs in the normalized format. In Figure 5, where each source log is memorized on ad hoc supports, another layer is added.

To manage the secure repository section and still use a series of “source log files” that guarantee a certain reliability, the machines in the second line of Figure 5 have to be *trusted*, that is, hardened, and have cryptosystems that can handle authentication, hashing, and reliable transmission.

Figure 4: Normalization.

Figure 5: Multilayered log architecture.

### Correlation and Filtering: Needs and Possible Solutions

In performing log correlation and filtering, the security architect and the manager have to deal with these problems. Here, the perspective on the problem shifts to the architecture.

Before we discuss this, it would be useful to make a clear statement of the definition of “correlation”: “A causal, complementary, parallel, or reciprocal relationship, especially a structural, functional, or qualitative correspondence between two comparable entities” (dictionary.com, n.d.). I use “correlation” here to mean the activity carried out by one or more engines to reconstruct a given complex event that may be symptomatic of a past or current violation.

By “filtering,” I mean an activity that may be carried out by the same engines to extract certain kinds of data and arrange them, for example, by protocol type, time, IP, MAC address, and so on.

### Interpretation of One or More Log Files

In most cases, the security administrator reads the result of a correlation done by a certain tool, but he or she only sees the tip of the iceberg. If you look at the figures in this chapter, the set of processes upstream of the GUI display is much more complex. Whatever the case may be, the literature indicates two basic methods for analyzing logs called *approaches*.

#### Top-Down Approach

This is the approach most frequently used in network forensics when the examiner is working with an automated log and event correlation tool. Whereas in intrusion detection, a top-down approach means starting from an attack to trace back to the point of origin, in network forensics, it means starting from a GUI display of the event to get back to the source log, with the dual purpose of

- validating the correlation process used by the engine of the automatic log and event correlation tool that is displayed to the security administrator and
- seeking out the source logs that will then be used as evidence in court or for subsequent analysis.

#### Bottom-Up Approach

The tool applies this approach starting from the source log. It is a method used by the IDS to identify an ongoing attack through a real-time analysis of events. In a distributed security environment, the IDS engine may reside in the same machine hosting the normalization engine. In this case, the IDS engine will then use the network forensic tool to display the problem on the GUI. You start from an automatic low-level analysis of the events generated by the

points of acquisition to arrive at the “presentation” level of the investigative process. Such an approach, furthermore, is followed when log analysis (and the subsequent correlation) is performed manually, that is, without the aid of automated tools. Here, a category of tools known as *log parsers* comes to your aid. The purpose of these tools is to analyze source logs for a bottom-up correlation. A parser is usually written in a script language like Perl or Python. There are, however, parsers written in Java to provide a cross-platform approach to network forensics examiners, perhaps on a bootable CD-ROM

### Requisites of Log File Acquisition Tools

Regardless of which vendor is chosen to represent the standard, the literature has identified a number of requisites that a logging infrastructure must have to achieve forensically compliant correlations:

- Tcpdump support, both in import and in export;
- use of MD5 or other state-of-the-art hashing algorithms;
- data reduction capabilities as described in previous sections;
- data recovery, the ability to extract from the intercepted traffic not only the connections, but also the payloads for the purpose of interpreting the formats of files exchanged during the transaction;
- ability to recognize covert channels (not absolutely essential but still highly recommended);
- “read only during collection and examination,” an indispensable feature for this type of tool;
- “complete collection,” one of the most important requisites because it is important that all packets are captured or else that all losses are minimized and documented; and
- intrinsic security, with special emphasis on connections between points of acquisition, collection repositories, administrative users, and so forth.

### Log File Analysis

At this point, now that we have gone over the fundamental issues of log correlation associated with the search, analysis, and, quite often, reconstruction phases, we are now ready to understand where we have to look for signs of intrusion. Although the search for fragments or key words may provide detailed information about traces left by the intruder (or by the criminal who used the machine for illicit purposes beyond simple hacking), the analysis of the log files may help provide a clearer idea of how a machine has been compromised, what happened during the attack, and which remote hosts participated in it.

While analyzing any log file from a compromised machine, remember that the intruder may have modified any or all of the data.

On UNIX systems, you should check the file `/etc/Syslog.conf` to see where Syslog memorizes messages.

NT systems generally memorize events in one of the three NT events logs, each of which may be viewed using event viewer. Other NT applications may memorize their log files in other locations.

Here is a list of some of the more common UNIX log files, their function, and the elements that need to be examined in each of them. These files may or may not be present, depending on how the system is set up:

**/var/log/messages** and **/var/adm/messages**: These contain a great variety of information; check anything out of the ordinary and all events around the time of the intrusion (suspicious IPs that have been removed, logging blocks, and so forth).

**.bash\_history** and **.sh\_history**: When an intruder generates a buffer overflow, he or she generally alters **sh** or **bash**. When a new shell is loaded, a history is created in the folder where the server was attacked; there is a good chance that you will be able to retrace the name of the remote host.

**logs/\*\_log** (Web site access log): This is important in the event of defacement of a Web site or the collection of sensitive data from it. You may be able to retrace in this log file the IP address of the attacker or files uploaded by him or her into the directories `htdocs`, `root`, or `/` to monitor the success of the defacement. You can also place the Web site logs in a special directory so that the intruder cannot easily find them (and thus modify them).

**Coredumps**: Usually the daemons initiated by the script `SysV Init` do not carry out this function by default for reasons of security; however, administrators often start the services manually and this means that during an exploit the dumping is done into the current directory. If the compromised server has executed the command `getpeername`, it is possible that the intruder's IP address is memorized in a variable of the process core dump.

**Proxy server**: The presence of a server in front of all the hosts usually simplifies auditing. Transparent proxies have a log of all the connections made through them; in many cases, the attacker can get around this by using unconventional ports and create a shell, but not the first time that he or she launches the exploit.

**Router log**: By default the routers do not keep records of every connection, but if they have some network access control, it is possible to retrace the entrance of the intruder.

**xferlog**: Useful when the compromised system has a functioning FTP server; this file contains the logs of all FTP transfers. Check to see what tools were uploaded into the system and what information was downloaded from the system by the intruder.

**utmp**: Contains information in binary format on each currently logged user. Use the command "who" to access it.

**wtmp**: A binary file that contains information on logins, logouts, and reboots. You will need a tool to access the file (for example, `last`, whose output contains a table in

which user names are associated with login times and host names where the connection originated). Checking this file for suspicious connections (for example, from unauthorized hosts) may be useful in determining other hosts that may have been involved and finding out which system accounts may have been compromised.

**Secure**: Each time a connection is established to a server that uses a TCP wrapper running outside `inetd`, a log message is added to this file. You should check anomalies, such as services accessed but not habitually used, or connections from unknown hosts.

## Experimentation: Using GPL Tools for Investigation and Correlation

Thus far I have introduced logs, correlation techniques, and the associated security issues. Regarding the tools used for this type of analysis and investigation, there are GPL or open source projects that provide the necessary tools for a bottom-up investigation, which is a less costly and less complicated alternative to the top-down approach based on automated correlation and GUI display techniques. In this section, I introduce some projects and tools that may be used for this purpose.

It bears emphasizing that the internal tool validation process remains one of the most pressing problems in digital forensics.

### Forensic Investigation Tools Under UNIX

This section deals with forensic tools in two different regards. The first one is forensic tools versus UNIX file systems and the second is UNIX-based forensic tools. Only a brief mention is made of commercial tools, whereas an explanation is given as to how Sleuthkit and other freeware tools work.

As was stated at the beginning, UNIX is also used as forensic analysis platform, particularly with open source tools. In this section, I describe some that are very often used for carrying out examinations and investigations, with a major emphasis on tools that are available under GNU/GPL licenses.

The tools mentioned in Table 1 are used mainly in the search and analysis phases. Most of them are based on or emulate TCT: The Coroner Toolkit. Written by Dan Farmer and Wietse Venema, TCT (downloadable from <http://www.fish.com>) is a tool that is still widely used even though the ones listed in Table 1 (especially Sleuthkit) are more evolved forms.

A special mention should be made of Glimpse. Glimpse (GLOBAL IMPLICIT SEArch) is a UNIX tool that indexes and performs very fast searches of large file systems. It supports many of the options in `agrep`, a modified version of `grep`, and can perform searches for an arbitrary number of errors in the input pattern. It supports Boolean queries.

To use Glimpse, the contents of the directories to be examined have to be indexed with `glimpseindex`.

An example of its use is this:

```
# glimpseindex -o ~
```

This command generates files that will be used by Glimpse to search the home directory.

**Table 1** Disk Investigation and Analysis Tools

Tool	Web Site	Features
Sleuthkit, authored by Brian Carrier	<a href="http://www.sleuthkit.org/index.php">http://www.sleuthkit.org/index.php</a>	Open source initiative that offers an alternative to normal Windows-based forensic programs. The tool is an HTML browser that displays the image of compromised disks. It supports both UNIX and Windows file systems to detect deleted files, creates timelines of disc activities, and does word searches. It is a unintrusive, remote analysis tool. No time stamp of the files is modified during the analysis. All files generated by the tool are associated with an md5 value that may be checked during the analysis. I-node searches may be carried out, and the resulting files displayed.
Test Disk	<a href="http://www.cgsecurity.org/index.html?testdisk.html">http://www.cgsecurity.org/index.html?testdisk.html</a>	Allows investigators to analyze compromised disks and undelete the partitions. The following file systems are supported: FAT12, FAT16, FAT32; Linux; Linux SWAP (versions 1 and 2); NTFS (Windows NT); BeFS (BeOS); UFS (BSD); Netware; and ReiserFS.
Wipe	<a href="http://wipe.sourceforge.net/">http://wipe.sourceforge.net/</a>	Wipe completely eliminates all data on any writable support. It sets each bit on the disk to 0, which is indispensable for formatting a disk that will be used in forensic analysis.
Mac-Robber	<a href="http://www.atstake.com/research/tools/forensic/">http://www.atstake.com/research/tools/forensic/</a>	Mac-Robber is a forensic analysis tool that can recover the date of access, the last modification, and changes (MAC) of date of any file. This information may be analyzed with the tool, Task, in order to compile a timeline of file activities in a system.

`.glimpse_exclude` contains the list of all files to be ignored by Glimpse during the search.

`.glimpse_filter` is used to create search filters activated with the option `-z`.

`.glimpse_filenames` contains the list of all files in the index.

`.glimpse_index` is an index file that associates each letter with a list of block numbers.

`.glimpse_messages` contains the output which is viewed with `-w`.

`.glimpse_partitions` contains a partition of the index generated.

`.glimpse_statistics` statistics regarding the index generated.

`.glimpse_turbo` is only to be used with options `-b` and `-o` to accelerate searches.

Glimpse also includes a new compression program called "cast," which allows you to do searches in compressed files.

Here is a simple example of the use of Glimpse:

```
# glimpse -i -1 'pattern'
```

The command searches the index for all instances of the word "pattern," allowing a maximum of one error (-1) and ignoring upper case letters (-i).

```
# glimpse -F '\.c$' pattern
```

searches for all instances of "pattern" in all files that end in ".c."

It is often a good idea to use Glimpse because in many cases you have to do live system analyses, and this program, in spite of the fact that it was not specifically developed with digital forensics in mind, may be the right tool for the job. Some forensic investigators believe that the tool is valuable for dealing with large dimension restored images. As always, you are wise to carefully weigh the pros and cons of this method before beginning your analyses.

### Log Analysis Tools

There are also tools that correlate the findings generated by the tools in Table 1 and the log analysis activities.

### Tcpdump

Log correlation is based on tried and true file formats and tools. The most commonly used file format is lbpcap compatible, that is, the one used by Tcpdump. Tcpdump can be downloaded from <http://www.tcpdump.org> and is a network-level data acquisition tool developed under UNIX and then transported onto almost all other operating systems. Tcpdump is basically operated from the command line and is able to delegate the acquired logs onto external machines, filtering them on the basis of protocol and payload. Tcpdump is strongly indicated when you want to "monitor" a machine that appears to have been hacked to verify whether the attacker is still "inside," and if so, how. Furthermore, an lbpcap compatible module is also used by Snort. Among the pluses of Tcpdump are its light weight (it does not use much of the machine's resources), the widespread use of its file format, and its extreme flexibility. On the minus side, the command line control has a very large number of switches, which makes it very hard to handle for the average user.

## Ethereal

A good compromise between the power of Tcpcap and user friendliness is Ethereal (<http://www.ethereal.com>). According to its documentation, Ethereal is still technically beta software, but it has a comprehensive feature set and is suitable for production use. Like Tcpcap, data can be captured “off the wire” from a live network connection or read from a capture file. Unlike Tcpcap, Ethereal can read capture files from a very broad range of formats and tools. Captured network data can be browsed via a GUI, or via the TTY (Teletype) mode “tethered” program. Capture files can be programmatically edited or converted via command-line switches to the “editcap” program. Many protocols (512) can currently be dissected.

Ethereal is free, too, but in many cases it proves to be unstable, which makes it better suited for offline traffic analysis than for real-time work. Nevertheless, its exceptional graphic layout and enormous filtering potential (which can be used in simplified form via the menus) make it a well-loved tool by some log examiners.

## FLAG

FLAG may be the most complete tool among those mentioned in this section. According to the project documentation, FLAG was designed to simplify the process of log file analysis and forensic investigations. Often when investigating a large case, a great deal of data needs to be analyzed and correlated. FLAG uses a database as a back end to assist in managing the large volumes of data. This allows FLAG to remain responsive and expedite data manipulation operations.

Because FLAG is Web based, it is able to be deployed on a central server and shared with a number of users at the same time. Data are loaded into cases, which keeps information separated. FLAG also has a system for reporting the findings of the analysis by extensively using bookmarks.

FLAG started off as a project in the Australian Department of Defense. It is now hosted on Sourceforge. PyFlag is the Python implementation of FLAG: a complete rewrite of FLAG in the much more robust Python programming language. Many improvements have been made.

Table 2 describes the characteristics of FLAG.

## Using First Response CD-ROMs for Forensic Investigations

One of the most wide-reaching recent trends is to integrate the tools that I have been talking about here into a single platform to ensure a faster, validated response to the incident. This has all naturally led to the creation of a toolkit that resides on a first response CD-ROM.

The great advantage of this choice lies in always having at hand a prevalidated toolkit with all the necessary statically compiled and therefore fundamentally trusted instruments.

One example of such an approach has been provided by IRItaly (Incident Response Italy), which is a project developed at the Crema Teaching and Research Center of the Information Technology Department of the Università Statale di Milano. The project, which includes more than 15 instructors and students (BSC and MSC), is divided

into two parts. The first relates to documentation and provides broad-ranging and detailed instructions. The second is a bootable CD-ROM. The issues addressed regard information attacks and especially defensive systems and computer and network forensics for incident handling and data recovery methods.

Best practices are presented for response procedures to information incidents, including analyzing the victim machines to retrace the hacking episodes and understand how the attack was waged, with the final aim of providing a valid response to the intrusion. This response should be understood as a more effective and informed hardening of the system to reduce the possibility of future attacks. It does not mean the generation of a counterattack.

All the operations described so far are carried out with special attention to the method of identification, storage, and possible use of evidence in a disciplinary hearing or in court. The unifying theme of the CD-ROM is the set of actions to undertake in response to an intrusion. It contains a number of sections offering a detailed analysis of each step:

- the intrusion response preparation phase;
- the analysis of available information on the intrusion;
- the collection and storage of associated information (evidence);
- the elimination (deletion) of tools used for gaining and maintaining illicit access to the machine (rootkits); and
- the restoration of the systems to normal operating conditions.

Detailed information is provided on the following:

- management of different file systems;
- procedures for data backup;
- operations for creating images of hard and removable discs;
- management of secure electronic communication;
- cryptographic algorithms and their implementation; and
- tools for the acquisition, analysis, and safeguarding of log files.

The CD also proposes a number of standardized forms to improve organization and facilitate interactions between organizations that analyze the incident and the different targets involved in the attack. Specifically, an incident report form and a chain of custody form are provided. The latter is a valuable document for keeping track of all information regarding the evidence.

The CD-ROM may be used to do an initial examination of the configuration of the compromised computer.

The tools included offer the ability to carry out analyses of the discs, generate an image of them, and examine logs to carry out a preliminary analysis of the incident. The IRItaly CD-ROM (<http://www.iritally.org>) is bootable and contains a series of disc and log analysis tools. All the programs are on the CD in the form of static binaries and are checked before the preparation of the magnetic

**Table 2** Characteristics of FLAG

Action	Features
Disk forensics	<p>Supports NTFS, Ext2, FFS, and FAT.</p> <p>Supports many different image file formats, including sgzip (compressed image format), Encase's Expert Witness format, and the traditional DD files.</p> <p>Advanced time lining, which allows complex searching.</p> <p>NSRL hash support to quickly identify files.</p> <p>Windows Registry support, includes both the Windows 98 variant and the Windows NT variant.</p> <p>Unstructure Forensics capability allows recovery of files from corrupted or otherwise unmountable images by using file magic.</p>
Network forensics	<p>Stores Tcpdump traffic within an SQL database.</p> <p>Performs complete TCP stream reconstruction.</p> <p>Has a "knowledge base" that makes deductions about network communications.</p> <p>Can construct an automatic network diagram based on Tcpdump or real time.</p>
Log analysis	<p>Allows arbitrary log file formats to be easily uploaded to database.</p> <p>GUI-driven complex database searches using an advanced table GUI element.</p>

support. After booting, the tool launches a terminal interface that the examiner can use to start certain applications such as Tcpdump, Ethereal, Snort, Swatch, and so on.

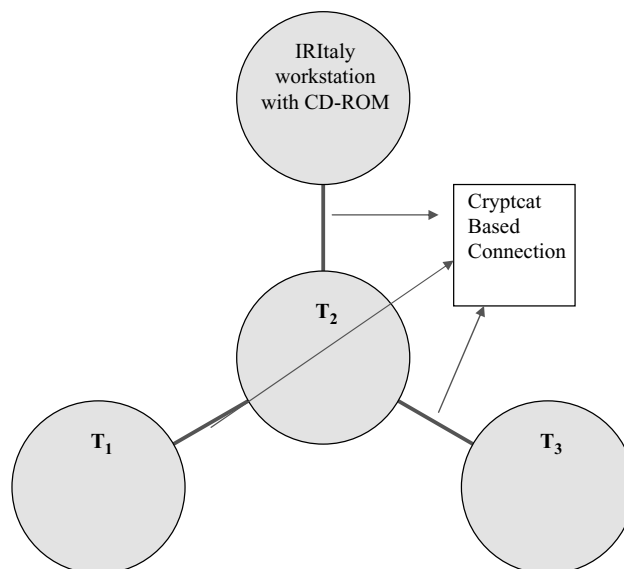

The CD, currently based on the extremely powerful F.I.R.E., can thus be used for a preliminary analysis of the logs present on the machine or for an analysis of the machine using the Sleuthkit tool, which is more specific to the analysis of the hard disc. The correlation process, in this case, involves the comparison of logs present on the machine with others on other machines. In this case, the IRItaly CD essentially works in very small environments or even in one-to-one contexts, as illustrated in Figure 6.

Here, T1, T2, and T3 represent various targets that may be booted with the IRItaly CD and connected to the main forensic workstation with the aid of Netcat or

Cryptcat. As stated, the main limitation of the use of the completely functional CD is that it cannot be used in a distributed architecture because of obvious management difficulties. However, the IRItaly workgroup is carrying out a series of tests of a new version of the CD that should resolve some of these problems with the aid of other tools.

The IRItaly project has already begun work on two fundamental tasks for the resolution of several of the issues illustrated in this chapter. The first regards the release of a new version of the CD-ROM, which will contain a full implementation of Python FLAG.

The ultimate objective is to integrate PyFlag into IRItaly's CD-ROM to provide first responders with a tool that can guarantee a minimum of correlation that is significantly broader than that offered by the current version.

**Figure 6:** IRItaly CD-ROM normal use.

## Initial Attack Analysis

- IDS logs revealed hack originated from a German ISP's Web server.
- Began coordination directly with German authorities.
- IDS logs showed transfer of root kit from a hacked university computer.
- Began coordination directly with university officials.

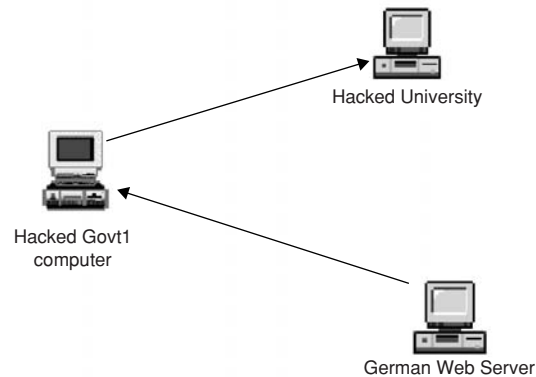

Figure 7: Attack reconstruction.

### Applying UNIX Forensics in a Coordinated Incident Response Procedure: A Case History

#### Background

In mid-2002, two groups of malicious hackers were identified by the Italian Financial Police as being responsible for a series of attacks on more than a thousand targets throughout the world. The backtracing procedure was seriously complicated by the fact that the groups used numerous stepping stones and camouflage techniques, such as Ipv6 tunneling. In this section, we take a general look at the attack methods and illustrate the techniques and steps used to backtrace them. For reasons of privacy, I do not name the targets but use letters instead:

- A: the German target used as an initial stepping stone to attack the American governmental sites indicated;
- B: the main American governmental target attacked by the group;
- C: another American governmental target attacked by the group, which served as the starting point for the investigation; and
- SS1: a university machine used as a repository to hide rootkits and other tools used in the post-intrusion phase.

#### A Coordinated Attack

In September 2001, the owner of C realized that one of his machines (an IRIX) had been attacked. The exploit had

been launched from a German machine, which had previously been compromised by an exploit from its resident Web server. The system administrators for C later reported that commands had been sent from the German machine to download certain postintrusion tools (including rootkits) from a third machine, SS1, located at an American university. Figure 7 shows the general scheme.

Reconstructing what happened to C was possible thanks to the presence of an IDS that monitored the target. Although this did not permit a response in real time, it did make it possible to recover a series of logs that illustrated what had happened. The logs were usable because they were not on the attacked machine. In the meantime, a postmortem exam was carried out on the German machine, A, that had been used as a stepping stone. The method used to compromise the German machine was generally conventional but had a number of personalized touches added by the attackers.

#### Requirement 1: Reconstruct the Events

One of the first steps in this sort of investigation is to check how much time passed between the last update of the machine and the attack. This may help identify the exploit used to achieve the intrusion. In this case, it was a Linux machine that was not running the latest release. At the time of the intrusion, the bug exploited to compromise the box was the then-known wuftp site command exploit.

When an attacker penetrates a machine, he or she installs a rootkit to keep it compromised. One of the group's characteristics was the use of completely self-made rootkits along with materials known to the security community.

The choice depended on the type of target (in the case we are examining, there were nearly a thousand boxes compromised worldwide).

The t0rn rootkit was chosen for the German machine and installed in /usr/info/t0rn. Evidently, the reasoning used in this case was that the system was generally poorly administrated and therefore it was not worthwhile to keep it compromised with something exotic because it was unlikely that the administrator would realize what was happening. In any case, it may be helpful to consult /usr/src/ to try to determine what is happening. In the specific case, a lot of information was found in /usr/src/r00t.

The t0rn rootkit, like most tools of its ilk, is configured to hide certain network connections. This is the usual syntax found during a postmortem (the IP addresses are fictitious):

```
65.93.*.*
195.242.20.*
```

where \* is used to hide all the address of the block. The first instance occurs usually to hide classes of dynamic IPs to which the attacker has access (e.g., ADSL and dial-up based on DHCP). In the second instance, an entire class is indicated that includes one or more machines compromised for the long term by the attacker.

Once the groundwork is laid, the hacking tools are installed. The choice of tools is completely up to the attacker. In our case, the hack tools installed were

```
7350wu [exploit to hack into the wuftp (used on this system, too)],
massroot (exploit for a bug in the telnetd of IRIX systems),
statdx (exploit for the rpc.statd of Red Hat),
mirkforce (attack tool to disrupt IRC communication),
papasmurf (smurf attack tool is a denial of service tool),
and
seclpd (exploit for lpd in Red Hat 7.1).
```

Please note that we are talking about an attack that occurred in 2001. One interesting finding was several text files that made it clear that A was the machine used to attack the governmental sites. The attacked networks, in fact, were in the 136.\*.\* and 137.\*.\* nets. In these cases, it might be useful to seek subdivisions by operating system in these files. In this case FreeBSD, IRIX, Linux, and SunOS were found along with a “.txt” file that contained progress info of the scanning.

This proves how important it is to correlate what is found on one machine with what is found on the one that appears to be directly connected to it. The correlation, especially if done on more than two machines, can map out the events with a certain margin of certainty and point back to a single source.

Another item usually installed is psyBNC IRC Bounce BOT. In this case, it was used as a deflector to participate in IRC communication without revealing the hacker’s IP number and thus avoiding DOS attacks to the hacker’s machine. Usually the attacker installs BOT with the sup Nick, which, in many cases, turns out to be very important for final backtracing.

This list presents the main steps taken by the attacker after the intrusion:

1. System is penetrated through an exploit.
2. Rootkit is installed.
3. ncftpd is installed.
4. Port scanner is installed.
5. A sniffer is installed.
6. A psyBNC BOT is compiled and installed.
7. Rootkit is fine tuned.
8. A file with IP numbers is created.
9. The “real use activity” is begun.

The compilation of the items downloaded by the third machine (SS1 in this case) is generally either carried out on the attacker’s machine or directly on the compromised machine. Both choices have their pros and cons. For example, compiling on the attacker’s machine might speed things up but risk instability because of potential differences in platforms. On the other hand, one cannot be sure that there is a compiler on the compromised machine, even though it is quite probable for relatively simple cases.

### Further Correlations

In the case in question here, there was another positive factor for the investigation: cross checking of the SS1 machine. When a machine is used as a repository for tools that will be downloaded onto target machines, it may happen, with a bit of luck, that additional cross references can be found to correlate all the necessary information. Given that most of such “containers” are located on university networks, we find ourselves confronted with the following situation:

- University officials provide system logs and image of the compromised computer.
- The compromising of the U.S. university machine is linked to the compromised third-party computer.
- The university computer was used as a “tool box.” All links between the .edu computer and the real target require a physical level search that, very often, reveals a dial-up connection.
- A proper HD analysis can uncover the intruder’s rootkit.

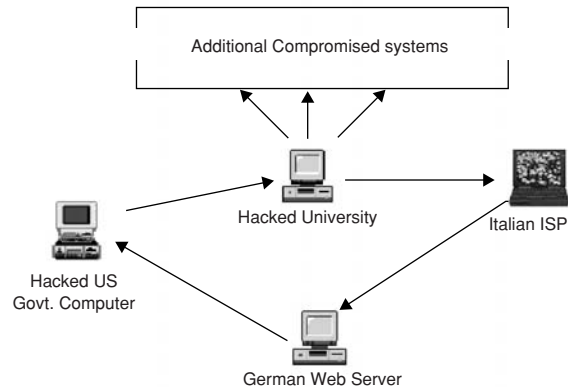

## CONDUCTING INTERNATIONAL FORENSIC OPERATIONS IN INCIDENT RESPONSE: SOME OBSERVATIONS

Another successful aspect of the investigation was that all the investigators spoke the same technical language. Terminology, log type, image format, tools, and PGP keys were agreed before beginning the investigation, proving the fundamental importance of setting things up well before getting started.

We have only touched the tip of the iceberg in this section and discussed only those parts of the investigation free of nondisclosure restrictions. The investigation was anything but simple. The operation, known as “Rootkit,” took more than one year and involved five European and

# The German Investigation

- German source computer belonged to a large corporation – it had also been hacked.
- The German corporation identified the compromise of their server. Hired a forensic firm in Germany to do forensic analysis.
- The forensic analysis matched the fingerprint of the govt. machine and the university machine. Source was in Italy.

**Figure 8:** Basic correlation.

American investigative agencies (military and civilian). Fourteen people were charged (including four minors). Most of them worked as security consultants or managers in large multinational companies. More than 40 computers were seized, and almost one TB of data and thousands of CD-ROMs and DVDs were seized. Many credit card files were recovered. If it had not been for the close international collaboration, it may not have been possible to track down the perpetrators of more than 1000 worldwide attacks, who were so active and so skillful as to be able to write their own rootkits and log wipers, which were used on the most “important” machines, and so crafty as to use IPv6 tunneling. Unfortunately (or fortunately), it is a small world for everybody. Some of the people charged as a result of this investigation had also punched holes in a Mexican honeynet, going so far as to get into the honeynet project’s famous “scan of the month.”

## GLOSSARY

**Audit Trail** An audit trail may be on paper or on disk. In computer security systems, a chronological record of when users log in, how long they are engaged in various activities, what they were doing, and whether any actual or attempted security violations occurred.

**Computer Forensics** Computer forensics is the use

of specialized techniques for recovery, authentication, and analysis of electronic data when a case involves issues relating to reconstruction of computer usage, examination of residual data, authentication of data by technical analysis, or explanation of technical features of data and computer usage. Computer forensics requires specialized expertise that goes beyond normal data collection and preservation techniques available to end users or system support personnel.

**Deduplication** Deduplication (“deduping”) is the process of comparing electronic records based on their characteristics and removing duplicate records from the data set.

**Deleted Data** Deleted data are data that, in the past, existed on the computer as live data and which have been deleted by the computer system or end user activity. Deleted data remain on storage media in whole or in part until they are overwritten by ongoing usage or “wiped” with a software program specifically designed to remove deleted data. Even after the data itself have been wiped, directory entries, pointers, or other metadata relating to the deleted data may remain on the computer.

**Deleted File** A file with disk space that has been designated as available for reuse. The deleted file remains intact until it has been overwritten with a new file.

**Deletion** Deletion is the process whereby data are removed from active files and other data storage struc-

tures on computers and rendered inaccessible except using special data recovery tools designed to recover deleted data. Deletion occurs in several levels on modern computer systems:

- 1) File level deletion—deletion on the file level renders the file inaccessible to the operating system and normal application programs and marks the space occupied by the file's directory entry and contents as free space, available to reuse for data storage.
- 2) Record level deletion—deletion on the record level occurs when a data structure, such as a database table, contains multiple records; deletion at this level renders the record inaccessible to the database management system (DBMS) and usually marks the space occupied by the record as available for reuse by the DBMS, although in some cases the space is never reused until the database is compacted. Record level deletion is also characteristic of many e-mail systems.
- 3) Byte level deletion—deletion at the byte level occurs when text or other information is deleted from the file content (such as the deletion of text from a word processing file); such deletion may render the deleted data inaccessible to the application intended to be used in processing the file, but may not actually remove the data from the file's content until a process such as compaction or rewriting of the file causes the deleted data to be overwritten.

**Hashing Algorithm** Starting from a data sequence of any length, such as the entire contents of a disk, it generates another, much shorter data sequence called a *hash* whose contents strictly depend on the original data.

**Image** In data recovery parlance, to image a hard drive is to make an identical copy of the hard drive, including empty sectors. Akin to cloning the data. Also known as creating a "mirror image" or "mirroring" the drive.

**Keyword Search** A search for documents containing one or more words that are specified by a user.

**RAM (Random Access Memory)** The working memory of the computer into which application programs can be loaded and executed.

**Residual Data** Residual data (sometimes referred to as "ambient data") refers to data that are not active on a computer system. Residual data includes a) data found on media free space, b) data found in file slack space, and c) data within files that has functionally been deleted in that it is not visible using the application with which the file was created, without use of undelete or special data recovery techniques.

## INTRODUCTION

Digital forensics is the science and practice of identifying, preserving, collecting, validating, analyzing, interpreting, documenting, and presenting digital evidence for the purpose of facilitating or furthering event reconstruction (DFRWS, 2004). Although a common goal of digital forensics is the presentation of evidence for a legal proceeding by a forensic practitioner, this chapter focuses on the general principles of digital forensics used by first responders and system administrators for diagnosing unauthorized actions that are shown to be disruptive to organizational processes and policies.

Forensics is *not* intrusion detection, although the two share some techniques. It should be noted that digital forensic analysis starts after the investigator already suspects that an intrusion or policy violation has occurred. In addition, although intrusion detection provides some initial clues about the violation, only digital forensic analysis can thoroughly validate these clues and determine the full extent of the system penetration.

Because more complete and complementary descriptions of digital forensics can be found in other chapters, we only briefly summarize general forensic issues. We then provide guidance on specific techniques as they apply to Windows NT systems so as to provide useful investigative information. Windows 9x and ME platforms are not covered in this chapter, in part because of their decreasing market presence and the significant architectural differences in 9x and ME from the NT generation—9x and ME do not provide adequate assurance that basic system services and logs have not been subverted.

## Applications of Digital Forensics

Each passing day presents fresh examples of how the digital domain can be exploited for unintended purposes. The

first responder will apply forensic techniques to assess four characteristics of the incident:

- **Current System State.** Is there any ongoing computer activity that is destructive, that is in violation of system policy, or that will hamper future investigative efforts? Has malware been left behind to monitor investigative progress or conduct future surveillance? Is the intruder still on the computer? Are there open network ports that would allow remote control of or access to the computer? Much of this volatile information is lost under typical computer evidentiary procedures.
- **Extent of the Violation.** An intrusion detection sensor may have alerted us to a violation, but there may more to the attack that the sensor was not tuned or designed to see. Did the intrusion only involve the reading or modification of files? Did it also include changing the system configuration? Have new login accounts been installed that enable the intruder to return later?
- **Timelining.** Placing validated event and log information into a timeline can serve to help eliminate improbable investigative leads, hence focusing investigative resources. Incomplete timelines or timelines with discontinuities can serve as a vital indicator that further probing into the computer is necessary to explain the entire violation. Finally, when timelines are reconciled with physical world events, association of digital identity and physical identity may be possible.
- **Attribution.** Sensors may have indicated that a particular user committed the violation or attack, but how can we be sure that critical audit logs have not been altered? In the instance of a remote attack or port scan from another IP address, what can be done to validate the authenticity of the information (e.g., that the return address was not spoofed)? Perhaps there is hidden information in disk slack space,

deleted files, or Registry entries that are indicative of a particular individual or motive. Finding this information, and associating it with an individual, is perhaps the most challenging part of the forensic investigative process.

## Evidence-Gathering Process

The process of forming attack hypotheses, finding evidence, evaluating evidence, and presenting a final conclusion is not a linear but an iterative process. It is very likely that the initial theory of attack pursued by the first responder will evolve significantly as evidence is discovered and its worth measured. As a result, it is very important that the first responder preserve the digital investigation scene as best as possible so as to be able to return as many times as possible to gather additional information. It is therefore incumbent upon the first responder to “do no harm” to the Windows computer as it is examined. That is, one’s actions must not destroy, damage, or compromise evidence that may exist in a computer, thereby rendering it useless. The utility of evidence lies in two areas: as input to a logical chain of reasoning to determine the extent, method, and culpability of an incident; and as input to a legal process for exacting civil or criminal justice. Other chapters give a more extensive treatment of the general topic of digital evidence. Because this chapter provides a treatment of forensic analysis for the first responder, we are not concerned to prescribe a process that meets civil or criminal evidentiary guidelines. However, some basic steps to minimize alteration of the Windows computing environment during examination are considered in the following sections.

## Information of Potential Interest to a First Responder

To determine expeditiously the full nature of the intrusion or attack, a first responder will forego pulling the plug on a Windows computer. Instead, the first responder will try to collect the following four categories of information:

1. **Volatile Information.** Information on a running computer system is either volatile or nonvolatile. Volatile information is transient and may not survive examination, much less cycling power. Volatile information is also sensitive to use of the operating system. In a fashion analogous to the Heisenberg uncertainty principle applied to subatomic particles, the very act of measuring the Windows environment changes the environment, such as the contents of memory or slack space. There are several types of volatile information, each with a particular application:
  - (a) current system time and date, to measure drift or tampering;
  - (b) current users and processes running on the system, to determine potential actors or victims of the investigated incident;
  - (c) existence of running spyware, keyloggers, and remote system administration tools, to identify attempts by the attacker to monitor or sabotage the investigation;
  - (d) active network connections, daemons, remote-mounted file systems, and exported directories, to determine avenues by which sensitive data, rootkits, or system configuration may have been exported or imported to the investigated computer;
  - (e) network configuration parameters, to determine if network parameters have been temporarily altered to enable remote communication with the attacker but are otherwise reverted to normal configuration upon reboot); and
  - (f) system swap file (pagefile.sys) to find trace documents, passwords, and preencrypted documents that were temporarily written to disk during routine Windows memory management.
2. **Nonvolatile Information.** Nonvolatile information can be thought of as stable information that would survive a power cycle of the machine, such as data stored on the hard drive, CD-ROMs, or transient removable storage media. The investigator will be interested in finding the following information:
  - (a) the number and types of locally mounted file systems, including the boot drive, CD/DVD-ROMs/RAMs/RWs, and USB storage devices;
  - (b) the number and types of remotely mounted file systems such as network drives;
  - (c) the file system directory tree and file listing, to help determine whether the standard operating system directory structure has been altered or augmented by the attacker with special tools or application directories;
  - (d) hidden files and deleted files, to identify avenues that the attacker may have employed to help cover his or her tracks; and
  - (e) the existence of encrypted data, encryption tools, or other data obfuscation utilities, again used to cover the attacker’s trail or motives.
3. **Recent Operating System Activity.** Recent system-level configuration changes or activity can be instrumental in determining root causes of intrusive behavior. The investigator will make note of the following types of information:
  - (a) Modifications to system date, time, or time zone, as these can cause the Windows system to log events out of temporal order and with incorrect timestamps.
  - (b) System log files, to record events internal to the operating system, such as driver performance, module status, and startup and shutdown actions. Based on a collection of these logs, the forensic analyst can create a rough picture of network, user, and system activity that provides the context for forensic analysis.
  - (c) Security log files, to record conformance to and violation of security policy, such as logins, access violations, and network connections.
  - (d) Server log files, to determine activity of corporate databases and Web servers (such as IIS, the Microsoft Web Server). Record requests, actions, and responses are stored in these log files at the

discretion of the server administrator. Sometimes, performance goals can override the need for auditing, leaving the investigator with little to go on.

- (e) Current software applications, as well as those that have been removed (such as encryption or cracking tools) to avoid suspicion.
  - (f) Current hardware configuration, previous configurations, and devices that have been detached by the attacker. Such devices may include storage drives, input devices, or required authentication devices that, once removed, allowed the attacker access.
  - (g) Registry entries, to include critical system behavior parameters, computer network identity, and the list of programs that will run or load every time the system is restarted or a user logs on. The latter is a key place for attackers to insert links to make malware persistent on the computer.
4. Recent User Activity. Recent user activity can be indicative of a single user's attempts to search for information, download malicious software, and run programs. The investigator will look to find evidence of four types:
- (a) Software applications run, shell commands executed, and files downloaded, to determine if a given user's actions led to a system compromise or failure.
  - (b) Internet sites visited or searched, Instant Messengers (IM) buddy lists, and cookie information, to help determine the general communication tendencies of the user and the possible sources of malware or worms that are found elsewhere on the computer.
  - (c) Internet Web browser security settings, again, to help determine if the user may have inadvertently let malicious Java or ActiveX controls run on the compromised system.
  - (d) User and Windows temporary directories. The user has a dedicated directory for temporary Internet files, graphics, and downloads. The Windows operating system has a temporary directory (C:\Windows\Temp) for the same purpose for single-user computers.

The remainder of this chapter gives an overview of the Registry, issues in the NT file system and storage, and logging in Windows. This is followed by suggestions for creating a forensics toolkit and the use of that toolkit in a simple investigation.

## OVERVIEW OF THE WINDOWS REGISTRY

The Windows Registry is a database used by both application programs and the operating system. It contains settings, options, and general information for programs, hardware, and users. The Registry is most often changed indirectly by the user, either through using program and system configuration menus, or changing file associations or the control panel. However, it can be edited directly through programs such as regedit.exe. Although its full

structure is more complicated, we can consider the Registry to be a set of (entry, value) pairs. We discuss how attackers can hide data by adding their own Registry entries or overwriting existing entries.

The Registry is actually a combination of five distinct binary configuration files, known as hive files. Four of them are located in %system\_root%\System32\config:

- SAM (Security Account Manager). Contains information pertaining to local user accounts and group accounts, as well as other security settings.
- Security. Contains information pertaining to machine-specific password policy, local rights, and group assignments.
- Software. Lists machine-specific information pertaining to the location where applications are installed and their properties, as well as similar information about the Windows operating system.
- System. Contains current system control set, as well as the default configuration and the "last known good" configuration to be used when recovering from an unrecoverable configuration failure (Harback, 2004).

The last type of hive file is ntuser.dat. There is one unique instance of this type of file for each defined user. It is created once a user has logged on for the first time, and is located in Documents and Settings\\ntuser.dat.

There is not a one-to-one mapping of hive keys (Hkey) to a hive file, and some hive key contents change between system boots and user logins. Figure 1 shows the different Hkeys:

- Hkey\_local\_machine (HKLM). Several subkeys are mapped directly from the hive files of the same name. Subkey hardware is dynamic and enumerates all system devices currently active since this system boot.
- Hkey\_users (HKU). Consists of the ntuser.dat files of each active user profile.
- Hkey\_current\_user (HKCU). A pointer to the currently logged-on user's profile in hkey\_users. The contents in this key are dynamic.
- Hkey\_classes root (HKCR). Is actually a dynamic join between the software class subkeys of local\_machine and current\_user hive keys.
- Hkey\_current\_config (HKCC). Current configuration profile of hardware identified under hkey\_local\_machine\hardware (Harback, 2004).

There are thousands of (key,value) pairs in the Windows Registry. Some intuition is required to know where to find a key that pertains to a particular configuration item, but once you know the role of each of the major hive keys, finding the key types becomes easier. We identify several Registry subkeys and entries of interest as we go along. Because Registry data are saved in binary format, the Registry also provides a convenient place for attackers to save data, fragments of files, and even complete programs.

The most common use of Registry keys by attackers is to start processes on a system reboot. To accomplish this, the attacker adds his program(s) to one of the Run

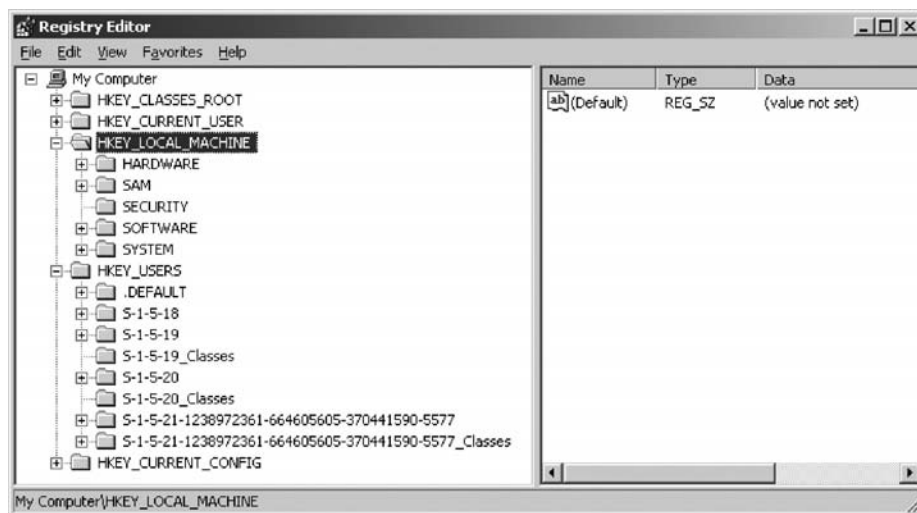

Figure 1: Registry editor.

or Load keys in the Registry entries for the system or one of the users. Several automated attacks, including the SouthPark and Slammer worms, modify Registry entries in exactly this fashion. As pointed out in Carvey (2005), attackers can also hide data in the values associated with standard, but unused, keys such as the DaylightName and StandardName strings associated with the Time Zone Information structure.

It is therefore recommended that administrators monitor changes to Registry contents, either through regular backups and checks or using a software package designed to track Registry changes. There are several freely and commercially available packages that monitor the Registry, including Registry Watcher, RegRun, and products from Symantec and Network Associates. These tools provide a user-friendly graphical use interface (GUI) to browse, edit, and monitor Registry entries.

## WINDOWS NTFS FILE SYSTEM AND STORAGE

### Application-Specific File Types

There are several explicit and implicit attributes of files that affect how Windows treats and displays them. The most obvious one is the name: Windows associates handler programs with files according to the suffix of the file name. For example, .txt files are opened by Notepad by default, and .doc files are opened by Word, and so forth when a file is double-clicked in Windows Explorer. Changing the name of a file so that it no longer ends in .exe will cause Windows to not execute the file.

Windows, like UNIX, includes a file signature that indicates the type of the file (in UNIX, this is in the first 2 bytes; in Windows, the first 20). For example, this value is 25504446 for PDF files. There is not necessarily a one-to-one mapping between file signatures and suffixes; a .doc file can have several different legal signatures, including 7FFE340A as a generic Word document or 1234567890FF for a Word 6.0 document. These signatures can be useful

in detecting a file that has had its name, but not its signature, changed. The ProDiscover forensics toolkit includes a tool to detect mismatches between file signatures and extensions.

Another way in which attackers hide files from casual search is to turn on the “hidden” attribute. By default, Windows Explorer and the “dir” command do not display hidden files. Although it is not difficult to override this default behavior, it does take additional work by the administrator. Windows stores a set of time stamps with each file, called the Modification, Access, and Creation times, or MAC times for short. Unfortunately, any user with write access to a file can set these time stamps, so a last modification time stamp should not be accepted at face value as evidence that the file has remained unchanged since then. A file system integrity tool such as Tripwire (Kim & Spafford, 1994) can help to understand when a file has changed, regardless of what is indicated by the time stamps.

### Application-Level Data Hiding

Applications, particularly document preparation applications, often embed metadata in data files. For example, Word includes the document creator, modification history, machines where the file was edited, comments, and invisible portions of embedded OLE objects. Because this information is not displayed under normal operation, attackers can hide data in comment fields and so forth.

In addition, OLE-structured objects allow multiple complete files to be merged into one. This is often done to link an Excel spreadsheet to a chart in a Word document or to include a graphics object. However, abuse of this facility enables attackers to hide entire programs or data files within documents. Interestingly, if one merges multiple Office files (such as Powerpoint and Word files), which portion of the file is accessed upon opening depends on its suffix. For example, double-clicking on file.ppt will open the Powerpoint presentation, while double-clicking on file.doc will open the Word document. The

**Figure 2:** Sample IIS log record. 128.230.14.20, sjc, 11/20/04, 10:42:00, W3SVC, SERV1, 192.168.0.10, 3217, 165, 17328, 200, 0, GET, /OttoOrange.jpg, -

Code Project (CodeProject, 2004) offers a Structured Storage Viewer that can view this “file system within a file,” as Microsoft has dubbed this type of storage.

## Windows-Specific Special Files

The Apple Macintosh pioneered the use of secondary data files affiliated with primary files (in Mac terms, these are called resource and data forks) with its hierarchical file system. Microsoft’s NT file system supports this type of file with the Alternate Data Streams (ADS) facility. Because a file can have multiple ADS associated with it, attackers can hide programs and data out of plain sight by hiding them in ADS added to existing files.

Programs that list the contents of the file system, such as “dir” or Windows Explorer, do not show special files. A file with an attached ADS appears no different than it did before the attachment. This creates a prime opportunity for data to be hidden in ADS files. Beneficial uses of ADS include support for Mac files, storage of icons associated with a program, thumbnail images for graphics files, and checksums or hashes for security programs. Malicious use of ADS includes storage of entire programs out of sight, where they can be executed when the attacker needs them. In addition, modifying the ADS associated with a file does not update the time stamps or size of the file visible from Windows Explorer or dir.

Of course, for an ADS to be useful, it cannot be completely inaccessible. Executable programs stored in ADS can be run by naming them explicitly from the command line or a program; similarly, they can be read or written using the Win32 API backup calls (backupread, backupseek, and backupwrite). There are several freeware packages that can list ADS streams, including LADS (LADS, 2004) and Sysinternal’s Streams package. The Code Project’s ADS Detector (CodeProject, 2004) makes ADS visible to Windows Explorer.

## LOGGING AND AUDITING IN WINDOWS

Correlating information from logs along with that obtained from forensics tools, the investigator can test hypotheses about the method of entry and chain of events. Unfortunately, at this point, there are no automated analysis tools, so building this chain is a painstaking, manual process. Windows provides the Event Viewer as a built-in service.

### Server Logs

Server logs contain information about the transactions processed by the server, such as the Internet protocol (IP) address of the client, parameters of the request, and the returned status and/or result of the request. For the sake of brevity, we relate our comments to Microsoft’s Internet Information Services (IIS) server (Microsoft, 2004a), the Web server for Windows NT/XP.

By default, IIS logs to the `\%SystemRoot%\system32\Logfiles` directory, which is on the system partition. Because this is usually of limited size, it is a good idea to configure IIS to log to a different partition if a remote server is not available. The best option, to prevent local log corruption and facilitate log analysis, is to have servers log to a remote location.

IIS logs are configurable; as of IIS 6.0, the administrator may choose one of several file formats: the W3C extended log file format, IIS file format, the NCSA common log file format, and in an open database connectivity-compliant SQL database. IIS format is the default and is in a fixed ASCII format. An IIS record, as shown in Figure 2, contains 15 fields: client IP address, user name, date, time, service and instance, server name, server IP address, time taken to fulfill the request, bytes received, bytes sent, service status code, Windows status code, request type, target of operation, and script parameters. Fields that have no data are represented by a hyphen; a service status code of 200 indicates success, as does a Windows status code of 0.

The example in Figure 2 shows that user “sjc” from IP address 128.230.14.20 sent an HTTP GET request to server SERV1 (IP 192.168.0.10) on November 20, 2004, at 10:42 a.m. The object of the request was `/OttoOrange.jpg` (a picture of the Syracuse University mascot). The request was 165 bytes long, and the server successfully returned 17,328 bytes of data after 3.2 seconds (3,217 milliseconds).

When examining logs, one must keep in mind that log entries might be the result of spoofed packets (those in which the client’s IP address is forged). In that situation, the log record will not help to trace the activity back to its source. Client-server interactions that span multiple messages (and particularly those where later messages depend on earlier ones) have a low likelihood of using spoofed addresses. Even if the IP address is forged, we can study the logs to find abnormal activity. Recognizing abnormal traffic requires knowledge of the local environment and services, but such traffic could include large incoming messages to Web servers, activity against little-used accounts, or messages with a high incidence of 8-bit (non-ASCII) characters.

### Security Logs

Windows XP permits logging of security events related to user logon/logoff, account management, object accesses, policy changes, system events, process tracking, and the use of backup and restore privileges, among others. The default configuration depends on the manufacturer of the system (for example, the default on a leading-brand laptop was to log nothing), so the administrator should access the local security settings to ensure that what is being logged conforms to local policy. To access the LSS, select Start → Control Panel → Administrative Tools → Local Security Policy. This will open a window similar to that shown in Figure 3. Logging options are set under Local Policies → Audit Policy and Local Policies → Security Options.

Figure 3: Windows local security policy window.

## System Logs

System logs include error and information messages from device drivers, including those for the network, mouse, and the CD-ROM, as well as for operating system components such as Windows Update. Typical entries include the acquisition or loss of IP addresses through the dynamic host configuration protocol (DHCP), notices that the mouse buffer has overflowed, or problems with the Windows Browser service. The Windows Browser service provides a list of shared resources available on the network, and because of its close relationship with NetBIOS, events from the Browser service should be monitored closely.

## PREPARING THE ANALYSIS TOOLKIT

When examining any Windows computer, a first responder must assume that an attacker may have already compromised significant parts of the operating system and logging capabilities. Furthermore, the responder will seek to minimize the use of victim system applications so as not to inadvertently modify system logs, file access times, swapfile contents, or the contents of free memory. Accordingly, the examiner will minimize dependence on system utilities and services that are resident on the computer being examined.

To meet these goals, the examiner should develop a portable Windows response toolkit. The toolkit typically consists of an assemblage of Windows utilities, freeware, and commercial tools that can be run from an externally mounted medium such as a CD-ROM or a USB thumb drive. There are pros and cons to using each medium, but for a nonevidentiary analysis, the USB drive affords the greatest flexibility to store tools as well as their output.

Ideally, one will want to set up one's thumb drive with separate directories for the toolkit and for saved data. Under the drive's root directory, one creates a subdirectory called Tools and copies all forensics executables and downloaded tools. One can create an additional subdirectory called Data to hold captured output redirected from the forensic tools. One *should not* redirect output to the victim's storage media, as it may be lost later, may corrupt the file system, or may diminish the ability to recover deleted files. Redirection of output to a text file can be accomplished by appending `>G:\Data\outputfile.txt` to the end of a command line (for this example, and the discussion in the next session, we assume that the thumb

drive has been mounted on G:). Each output file must have a unique name or it will be overwritten, for example, `G:\>netstat -r > G:\Data\routingtable.txt`.

Some responders will develop a toolkit on a case-by-case basis, depending on what types and how much information is to be collected from the victim computer. Others will create an all-purpose toolkit that contains utilities and tools to meet virtually any type of probing that is necessary. The choice is up to the first responder and his or her investigative style.

We present some tools that can be used to analyze a Windows NT system. Many can be obtained from a pristine system, installation CDs, or the Resource Kit. Others are freely available on the Internet. Keep in mind that there are many other tools that will provide similar output; the ones listed are for illustrative purposes only, and not all possibilities can be discussed in the limited space available. There are also a number of commercial tools with advanced interfaces that can expedite the investigative process.

## Tools in Windows

The following executables are already available on the victim operating system, but to avoid using a compromised version, they should instead be copied first from a pristine system for inclusion in the toolkit:

**arp.exe** displays MAC address of host interface, as well as those of recently communicated machines on the network.

**cmd.exe** is the WinNT, 2K, and XP command line interface (CLI).

**netstat.exe** displays various network configuration parameters as well as open TCP connections.

**regedit.exe** allows for the display, manipulation, and exporting of contents in the Windows Registry.

## Tools in the NT Resource Kit

Some of the tools that the investigator will find useful can be found on the Windows NT/2000/XP Resource Kit CDs. Two are found in the NT Resource Kit:

**rasusers.exe** lists remote and local logged-on users.

**rmtshare.exe** lists shares that are accessible on a remote computer.

**Table 1** Tools from the PsTools Collection

Tool	Use
PsFile	Show files opened remotely
PsGetSid	Display the SID of a computer or a user
PsKill	Kill processes by name or process ID
PsInfo	List information about a system
PsList	List detailed information about processes
PsLoggedOn	See who's logged on locally and via resource sharing (full source is included)
PsLogList	Dump event log records
PsService	View and control services
PsShutdown	Shut down and optionally reboot a computer
PsSuspend	Suspend processes
PsUptime	Show how long a system has been running since its last reboot (PsUptime's functionality has been incorporated into PsInfo)

## Free Tools

The following free utilities can be found on the Internet. Some have augmented the basic functionality afforded by the Windows tools and executables, whereas others provide an exceptional capability leap.

**Dcode** (Wilson, 2005): This utility by Craig Wilson decodes raw hexadecimal date and time values in the Windows Registry.

**Forensic Toolkit 2.0** (Foundstone, 2004): This set of tools enables the investigator to find hidden files, enumerate user accounts and file shares, and retrieve attributes without altering them for individual files.

**Fport** (Foundstone, 2004): *fport.exe* reports all open TCP/UDP-IP ports and in addition names the owning application.

**PsTools** (Russovich & Cogswell, n.d.): The Sysinternals Web site contains many utilities and tools that are useful for digital forensics. Two examples are Process Explorer and PsTools.

- Process Explorer: This GUI displays information about running processes, handles, and .dlls in a two-panel application window.
- PsTools: This is a collection of a dozen forensics command line tools, shown in Table 1.

## CONDUCTING THE INVESTIGATION

The responder, Reggie, will generally approach the victim computer (called Destiny) and observe the screen prior to performing any activity. To avoid entering data into a Trojan login program, Reggie presses <CTRL-ALT-DEL> to invoke the secure login/task manager window. An account with administrator privileges will be required to use some of the toolkit tools. Once the login is complete, Reggie opens the My Computer icon on the desktop, inserts his thumb drive into an unused USB port, and notes the new drive letter that appears (for our demonstrations, we assume that the drive letter is G:). He navigates into the Tools directory on the USB drive and launches cmd.exe to create a command prompt. It is from this prompt that most initial information will be collected.

### Capturing Volatile System Information

Reggie starts by gathering the time and date on the system and noting any discrepancy from the current time and date (see Figure 4). These may have been manipulated to invalidate log file time stamps or to misrepresent data file access and modification times and dates.

He next checks for other logged-on users who could interfere with his investigation. In our example (see Figure 5), there does not seem to be any other user logged on, so that is good. Now he checks for active NetBIOS connections, as well as any other remote network

connections that could be used to monitor what he is doing, control the computer, or manipulate system information.

The nbtstat program collects NetBIOS statistics, giving us the list of recently cached partner node names, the local NetBOIS name table, and statistics pertaining to number of past connections. We can see in Figure 6 that there are no names in the cache, so there are no active connections. Reggie moves on to check non-NetBOIS network connections to see if there are any FTP, IRC, SSH, or other suspicious connections running to the system.

Netstat (see Figure 7) provides a listing, including the port numbers, of active TCP and UDP connections to the

victim computer. If the port number is common, netstat will insert the name of the service in lieu of the port number. Netstat -r lists the victim computer’s network interfaces and current routing table. This should later be compared with the permanent routing table in the Windows Registry to determine whether tampering has occurred to enable covert or unconventional communication.

There does not seem to be an imminent threat to his investigation, so Reggie continues his examination. He can use the psinfo command, shown in Figure 8, to find out how long the system has been up and a little about the Windows environment Reggie can see from the output that this computer has been up for only about 5 hours.

G:\Tools>

```

Figure 9: Output of the “pslist” command.

It is a Win2K Professional OS (installed 6/4/2001) with Service Pack 4 applied, and he can also see to whom it is legally registered. This system has seemingly been intact for several years. The Windows root directory is the default C:\WINNT, which will be useful to know when we investigate the Registry and other system files.

Reggie now proceeds to get the status of currently running processes to see if there is anything suspicious that could be malware, spyware, or a remote administration tool such as SubSeven or NetBus. Many attacks leave processes running on the system. These processes can provide back doors into the system and wait for network connections, monitor system activity to report to a remote host, or attack other hosts. It is essential, then, that he includes an analysis of the running processes. Although the Windows TaskManager gives a list of processes, it does not give crucial information such as the arguments given when the process started or the path to the executable

file. Attackers take advantage of these weaknesses by giving their programs the same name as common Windows processes such as svchost.exe or inetinfo.exe.

Most of the processes listed here look familiar; however, there are a few that may require further inquiry. For example, Reggie is not familiar with the process called instan~1 and wants more information. Furthermore, there are several instances of svchost, each of which is responsible for managing several system and network services, as defined in the Windows Registry. Attackers can take advantage of the Registry to insert links to malicious code under the svchost process. Reggie decides to get more information on what these processes do.

Reggie invokes the GUI-based Process Explorer, shown in Figure 10. In the upper window, he can see a dynamic update of the processes running on the system as well as a description of each and its CPU utilization. Shaded in red are system services, and in blue are user processes. By

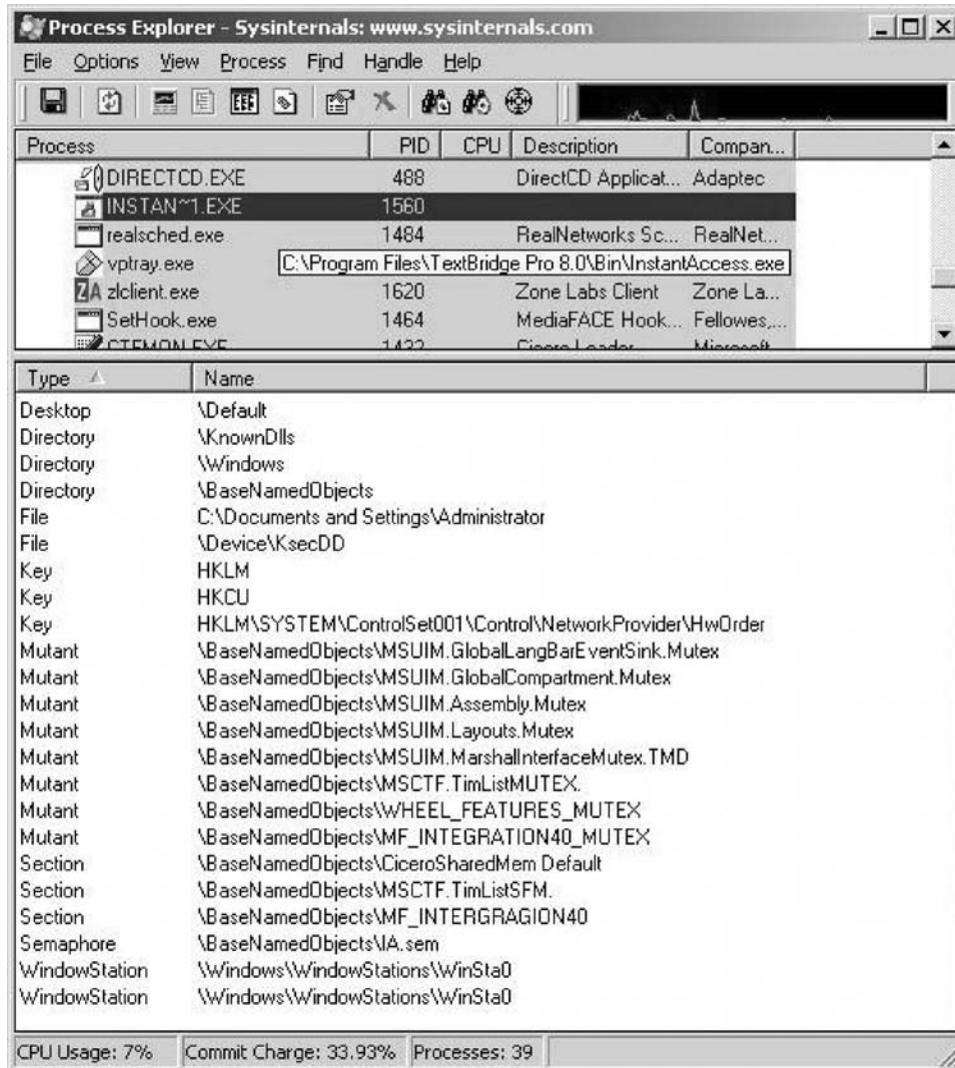

Figure 10: The Process Explorer program.

clicking on a questionable process in the upper window, he sees the list of associated .dlls and file handles that the process uses.

By clicking each of the svchost processes, he can see the list of files and services that each provides. Reggie can also see if there are any additions to these lists from unconventional directories, which might have been added by an attacker. When Reggie lets the cursor rest over the questionable process, a “tooltip” bubble appears, revealing the entire pathname of the invoked service. In this case, the suspicious instan~1 process turned out to be TextBridge Pro, a benign optical character recognition (OCR) conversion program.

### Capturing the File System

Next, Reggie wants to capture information about the current system directory structure, files, and attributes. He wants to do this before analyzing the files because the process of reading a file changes a file’s attributes. For example, the NTFS file system maintains information pertaining to when a file was first created, last modified, and last

accessed. Simply highlighting a file using the Windows Explorer interface changes the “last accessed” attribute of the file to the current date and time, which is undesirable. So, Reggie will make a permanent record before going further. He could use disk imaging software such as Encase (Guidance, 2004), but use of such tools and the recovery of hidden file systems is beyond the scope of this chapter.

First, Reggie gets a list of currently mounted storage drives on the system: he will use the Registry to obtain this information, so he launches the Registry editor (see Figure 11). In the left window, he expands hkey\_local\_machine\system\MountedDevices+. In the right window, he notices a number of (entryname, value) entries and takes note of any that start with \DosDevices\. These entries depict the currently allocated drive letters on the system and are the volumes he will want to explore. If Reggie wants to identify the type of hardware represented by the drive letter, he can double-click on the key name. A binary entry box will open, displaying the hexadecimal values (and corresponding ASCII representations) of the key and showing whether the drive is fixed, removable, a CD-ROM, and so forth.

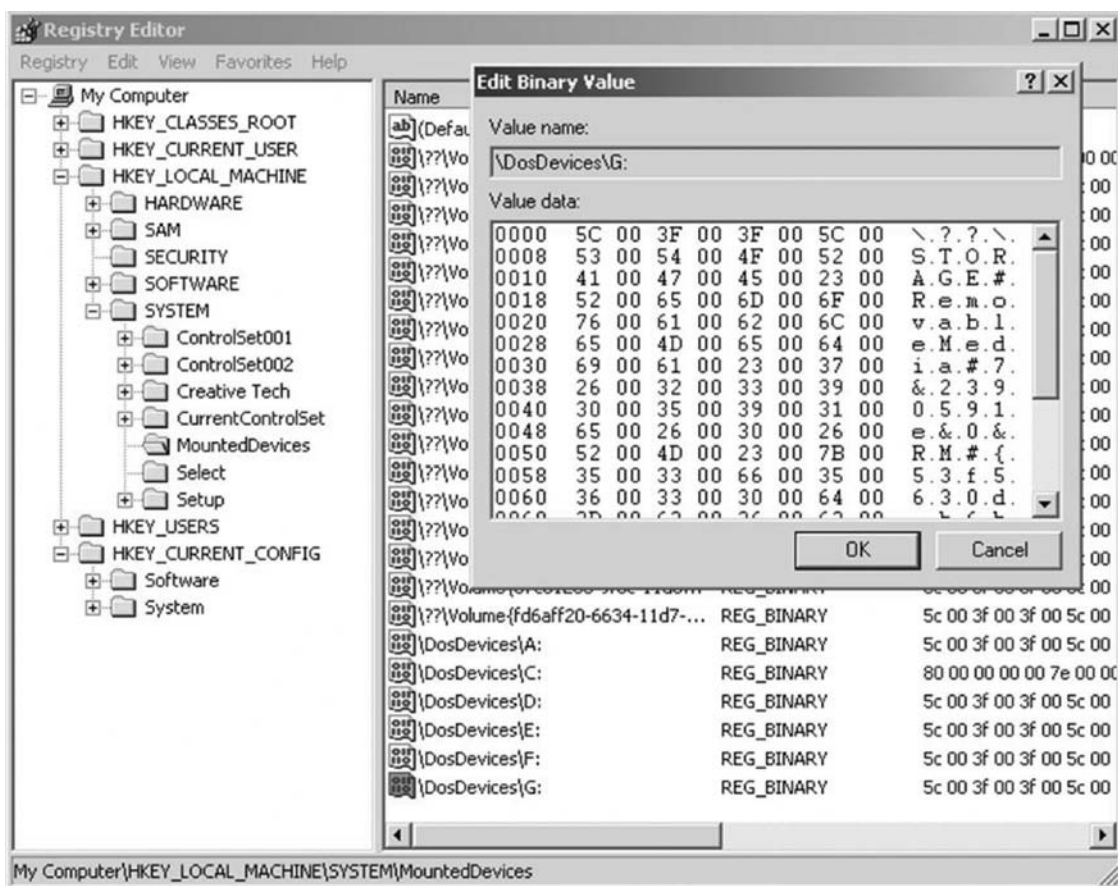

Figure 11: The Registry editor.

Now Reggie would like to get a recursive directory listing of all files. Without any special tools, he can obtain file names, dates and times created, and sizes. With some additional tools, such as the toolkit included with Carvey (2005), he could also get additional attributes such as owner, last time/date accessed, and last time/date modified. If Reggie directs the listing to an output file on his USB thumb drive, he can view that listing without risk of changing the original file system. Note that he will see no output to the screen; he will have to use the utility “more” to confirm the file has been written. To derive and view a listing for the C:\ drive, for example, he uses these:

```
G:\Tools>dir C:\ /s > G:\Data\Cdrivelist.txt
```

```
G:\Tools>more G:\Data\Cdrivelist.txt
```

This listing will yield all files except those that have the hidden attribute set. There are a number of ways to expose those files. One simple tool is HFind.exe from Foundstone’s Forensic Toolkit. To find all hidden files on the C:\ drive, we simply type

```
G:\Tools>HFind C:\ > G:\Data\HFind_C_Output.txt.
```

Because this listing will probably be quite large, we have redirected the output to a logfile on our thumb drive.

Next, Reggie wants to recover any recently deleted files on the storage drives. File deletion in Windows actually consists of two steps. When a file is dragged to the recycle bin or the Delete key is pressed while it is highlighted, Windows marks the file for deletion and removes it from view. The file is not deleted, however. It still exists in the file system and is simply relinked to a special hidden recycle folder. A tool such as Rifiuti (Foundstone, 2004) can easily find and recover files from the recycle bin.

Once the recycle bin is emptied or a file is expressly deleted (via SHIFT-DEL), the file can only be recovered by a specialized tool that can compare the NTFS inodes with allocated drive space. There are literally dozens of utilities available for file recovery, either as freeware or as part of commercial utilities packages, so they will not be covered here. Time is of the essence, though, as the longer the system runs after a file is deleted, the more likely it is that the disk blocks from that file will be reused. Avoiding disk block reallocation is a primary reason why all tool output should be stored on removable media or a remote system, rather than on the victim computer. On a typical Windows system, a large percentage of the files are standard operating system components and applications. These files will be the same across any installation, and so, as long as they are unchanged, they can be ignored for forensic analysis. Finally, you may want to determine whether Windows system files have been compromised or replaced. This comparison can be accomplished in one of two ways:

- Because all file attributes have now been documented, you can now walk the directory tree and use one of many MD5 (Rivest, 1992) or SHA1 (NIST, 1995) message digest tools to compute and save hashes of the victim computer's files. These hashes can be compared with one of two national databases of hashes for well-known Windows files, maintained by the National Drug Intelligence Center and National Institute of Standards and Technology.
- Use a disk-imaging package such as Access Data's Forensic Toolkit, Guidance Software's Encase Forensic Edition, or ASRData's SMART. These tools can automatically generate hashes as well as make comparisons to hash databases.

### Recent System Activity and Configuration

At this point, Reggie has captured most volatile and file system configuration items and can now consider using built-in Windows applications to facilitate his investigation. Most of these are already well documented, so we will not go into detail on how they are used. Many of these tools read information from the system Registry, so if the tool has been replaced with a compromised version, Reggie's best bet is to still use the Registry and associated log files as the ultimate authoritative source. Table 2 shows tools that can be launched from the Control Panel or administrative tools under the Start menu.

Local and remote event logs can be viewed and saved via the PsTools utility PsLogList. Because this log is quite lengthy, Reggie redirects the output to his thumb drive.

There are several Registry keys of interest (Harback, 2004). The first four start with hklm\software, and the latter four start with hklm\system:

- This key is actually just hklm\software\: Lists all installed software, by vendor. Applications often leave remnants here after they have been uninstalled. Useful for detecting the current or past existence of encryption and steganography tools. Other subkeys contain information pertaining to installation date, installation location, and so forth. All registered file extension classes are listed under the \Classes subkey. Some information exists about the launching application as well.
- \Microsoft\Windows\CurrentVersion: Subkeys Run, RunOnce, RunOnceEx, and RunServices contain entry lists of programs and services that will run each time the

system is started. This is a good place for an attacker to launch malware persistently. This key also contains unique Run and RunOnce entries for each user at logon.

- \Microsoft\WindowsNT\CurrentVersion\WinLogon\Userinit: Multiple programs can be started at logon with this entry. Attackers place entries at the end, beyond the viewing window, so as not to be noticed.
- \Microsoft\WindowsNT\CurrentVersion\Windows\Load: Same issues as the prior item (...Userinit), except multiple programs are loaded at system start.
- \ControlSet001\Control\TerminalServer: If fDenyTSConnections = 0, WinXP allows remote users to log in and take control of a user's desktop!
- \Select: Entries are pointers to the Current, Failed, and LastKnownGood control sets. These values correspond to hklm\system\ControlSet00x, where x is the value listed for the entry. Inspection of these other (noncurrent) configuration sets and dates can reveal potential causes for system failures or existence of devices that are no longer found with the victim system.
- \ControlSet001\Control\Windows\ShutdownTime: Time of last graceful shutdown. Use Dcode.exe to decode raw hexadecimal date.
- \CurrentControlSet\Control\TimeZoneInformation: These entries determine system settings for time zone offset, when daylight savings time occurs, etc. Use Dcode.exe to decode raw hex time values to verify correct time zone, DaylightStart, and StandardStart dates. Verify that time zone names have not been altered so as to store hacker information.

### Recent User Activity and Preferences

The system tools mentioned in the previous section already enumerate users, security settings, and login behavior. This section will provide additional insight into recent user activity, application settings, search terms, and buddy lists.

A user's application profile is established upon first logon. A user's profile and default directory will be located under Documents and Settings/<username>. Here is where Reggie can find folders (and several hidden ones) for this information:

- Application Data: User-specific settings for many of the installed software packages, organized by vendor or package name.

**Table 2** Windows Applications Useful for Forensics

Tool	Contents/Description
System information	View logs, shares, sessions, users and groups, performance logs, device manager, drive usage, and running services
Computer management	View logs, shares, sessions, users and groups, performance logs, device manager, drive usage, and running services
Local security settings	Password, account, auditing, and user policies. Security options, file encryption options, software policies, and IPSEC policy
Services	Same service information as "Computer management"
User accounts	Enumerates all active accounts and privileges

- **Cookies:** Cookies from recent Web sites visited.
- **Desktop:** Listing of user-placed folders, links, and files on the desktop.
- **Favorites:** Listing of the user's favorite MS Explorer destinations.
- **Local Settings:** Contains several subfolders that maintain additional user-specific application data, history of Web sites visited with MS Explorer, and temporary downloaded Internet files. This folder does not get cleaned much, so some interesting relics may still exist here.
- **My Documents:** Default file save location for the user.
- **NetHood:** User's favorite NetBOIS or NFS directory locations.
- **PrintHood:** User's favorite network printers.
- **Recent:** List of recent documents accessed by the user. This list can be quite large and can be useful in ascertaining a user's involvement in an incident.
- **Sendto:** Configurable list of folder and application destinations.
- **Start Menu:** The user's tailored Windows Start menu. Are there any unregistered applications launched from here?
- **Templates:** Office application templates that the user has configured. Note: This is also where `ntuser.dat` and `ntuser.dat.log` are stored, and referenced from the Windows Registry.

Reggie can also use the Windows Registry to find other information about recent user activity (Harback, 2004). For example, the Registry contains many most recently used (MRU) entries. The Microsoft applications maintain these lists here. Other application do so also but may have other subkey structures. Microsoft MRUs are listed as examples. Each starts with `hku\ <userid> \software`:

- `\Microsoft\Windows\CurrentVersion\Explorer\RunMRU`: List of recent programs executed from the Run dialog box.
- `\Microsoft\InternetExplorer\TypedURLs`: List of recent data entered into the IE address bar, where "url1" is the most recent entry.
- `\Microsoft\MediaPlayer\Player\RecentFileList` and `\Microsoft\MediaPlayer\Player\RecentURLList`: Displays recent files and URLs for Windows Media Player.
- `\Microsoft\SearchAssistant\ACMrU\5603`: Displays most recently searched terms and files using the XP Search Assistant.

Here are some Registry entries to find a user's recently saved files, again starting with `hku\ <userid> \software`:

- `\Microsoft\InternetExplorer\DownloadDirectory`: Shows directory path of last downloaded file.
- `\Microsoft\Office\<version>\Outlook\Security\OutlookSecureTempFolder`: Shows path where temporary file attachments are stored.

A special part of the Registry points to a private user information store known as the Protected Storage

System Provider. It can password information for applications such as Outlook, Web site passwords, auto-complete fields, and SSL certificates. The amount of information stored there is depends on the application setup options. It is accessed via `hku\ <userid> \software\Microsoft\ProtectedStorageSystemProvider`. This data are encrypted and will require third-party tools to decrypt, such as Access Data's Registry Viewer.

## Investigation Overview

Using the techniques described in this section, the investigator can obtain information on the current system state, including volatile system information and file system state, recent user activity, and recent system activity. We showed how to discover active users, processes, and network connections; how to search the Registry for suspicious entries; and how to capture this information without compromising the system being investigated. Putting this information together helps to paint a picture of what has taken place on the system.

## CONCLUSION

The Windows operating system family is the most widely used in the world and is therefore the primary target of digital attackers. We have described where to find key forensic information in Windows NT/XP systems; unique features of Windows that require special attention from forensic investigators; and tools, techniques, and practices for conducting digital forensics on Windows systems. Our recommendations are for system administrators and first responders interested in establishing a logical chain of reasoning to explain an incident, not for those interested in collecting evidence for civil or criminal legal proceedings.

## GLOSSARY

**Digital Hash** A value computed from a data block such that a modified data block will almost certainly generate a different value; that is, it is nearly impossible to change a file and not have its digital hash change.

**Forensics** The science of ex post facto examination to extract evidence of earlier activity.

**Log Files** On-disk records of system activity, written by server programs.

**Message Digest** See Digital Hash.

**Metadata** Data, generally not visible to the user, that describes other data.

**Nonvolatile Data** Data that is saved on stable storage and persists across rebooting of the system. Compare to Volatile Data.

**Steganography** Literally, "covered writing." The practice of hiding data within other data.

**Volatile Data** Data that are not saved on permanent storage and that will be lost if the system is rebooted or that may change if it is examined. Compare to Non-volatile Data.

## FURTHER READING

More information on the general topic of digital forensics can be found in Casey (2004). For readers interested in

research on digital forensics, the Digital Forensics Research Workshop (DFRWS, 2004) is an annual meeting where practitioners discuss advances in the state-of-the-art of digital forensics. Harlan Carvey's book *Windows Forensics and Incident Recovery* (2005) is an excellent overview of the area. It also includes a CD-ROM of forensic utilities written in Perl. The Microsoft Windows Registry Web site (Microsoft, 2004b) has a complete description of the structure of the Registry. The Dartmouth Institute for Security Technology Studies has published a report (Security Technology Studies, 2004) that includes a survey of available forensics tools and their capabilities. The e-Evidence (Seidsma, 2004) Web site of the Computer Forensic Research and Development Center at Utica College has a wealth of references on the topic of digital evidence. The WinterNals (2004) software package is an additional source of forensics tools. Those interested in incident handling in general and how forensics fits in should see Grance, Kent, and Kim (2004), and those interested in disk-imaging tools should see NIST (2004). Although we did not go into detail on steganography in this chapter, it can be used to hide data from investigators. For more information on steganography, see Jackson, Gunsch, R. Claypoole, and Lamont (2003) or Katzenbeisser and Petitcolas (2000).

## INFORMATION PROTECTION AND SECURITY

The growth in the use of time-sharing systems and, more recently, computer networks has brought with it a growth in concern for the protection of information.

A publication of the National Bureau of Standards (Bransted, 1978) identified some of the threats that need to be addressed in the area of security:

1. Organized and intentional attempts to obtain economic or market information from competitive organizations in the private sector.
2. Organized and intentional attempts to obtain economic information from government agencies.
3. Inadvertent acquisition of economic or market information.
4. Inadvertent acquisition of information about individuals.
5. Intentional fraud through illegal access to computer data banks with emphasis, in decreasing order of importance, on acquisition of funding data, economic data, law enforcement data, and data about individuals.
6. Government intrusion on the rights of individuals.
7. Invasion of individual rights by the intelligence community.

These are examples of specific threats that an organization or an individual (or an organization on behalf of its employees) may feel the need to counter. The nature of the threat that concerns an organization will vary greatly from one set of circumstances to another. However, there are some general-purpose tools that can be built into computers and operating systems that support a variety of protection and security mechanisms. In general, the concern is with the problem of controlling access to computer systems and the information stored in them. Four types of overall protection policies, of increasing order of difficulty, have been identified (Denning, and Brown 1984):

- **No sharing:** In this case, processes are completely isolated from each other, and each process has exclusive control over the resources statically or dynamically assigned to it. With this policy, processes often “share” a program or data file by making a copy of it and transferring the copy into their own virtual memory.
- **Sharing originals of program or data files:** With the use of reentrant code, a single physical realization of a program can appear in multiple virtual address spaces, as can read-only data files. Special locking mechanisms are required for the sharing of writable data files, to prevent simultaneous users from interfering with each other.
- **Confined, or memoryless, subsystems:** In this case, processes are grouped into subsystems to enforce a particular protection policy. For example, a “client” process calls a “server” process to perform some task on data. The server is to be protected against the client discovering the algorithm by which it performs the task, while the client is to be protected against the server’s retaining any information about the task being performed.
- **Controlled information dissemination:** In some systems, security classes are defined to enforce a particular dissemination policy. Users and applications are given security clearances of a certain level, whereas data and other resources (e.g., I/O devices) are given security classifications. The security policy enforces restrictions concerning which users have access to which classifications. This model is useful not only in the military context but in commercial applications as well.

Much of the work in security and protection as it relates to operating systems can be roughly grouped into three categories.

- **Access control:** Concerned with regulating user access to the total system, subsystems, and data, and regulating process access to various resources and objects within the system.
- **Information flow control:** Regulates the flow of data within the system and its delivery to users.

- **Certification:** Relates to proving that access and flow control mechanisms perform according to their specifications and that they enforce desired protection and security policies.

This chapter looks at some of the key mechanisms for providing operating system (OS) security.

## REQUIREMENTS FOR OPERATING SYSTEM SECURITY

### Requirements

An understanding of the types of threats to OS security that exist requires a definition of security requirements. Computer and network security address four requirements:

- **Confidentiality:** Requires that the information in a computer system only be accessible for reading by authorized parties. This type of access includes printing, displaying, and other forms of disclosure, including simply revealing the existence of an object.
- **Integrity:** Requires that computer system assets can be modified only by authorized parties. Modification includes writing, changing, changing status, deleting, and creating.
- **Availability:** Requires that computer system assets are available to authorized parties.
- **Authenticity:** Requires that a computer system be able to verify the identity of a user.

### Computer System Assets

The assets of a computer system can be categorized as hardware, software, and data. Let us consider each of these in turn.

The main threat to computer system **hardware** is in the area of availability. Hardware is the most vulnerable to attack and the least amenable to automated controls. Threats include accidental and deliberate damage to equipment as well as theft. The proliferation of personal computers and workstations and the increasing use of local area networks increase the potential for losses in this area. Physical and administrative security measures are needed to deal with these threats.

The operating system, utilities, and application programs are the **software** that makes computer system hardware useful to businesses and individuals. Several distinct threats need to be considered.

A key threat to software is an attack on availability. Software, especially application software, is surprisingly easy to delete. Software can also be altered or damaged to render it useless. Careful software configuration management, which includes making backups of the most recent version of software, can maintain high availability. A more difficult problem to deal with is software modification that results in a program that still functions but that behaves differently than before. A final problem is software secrecy. Although certain countermeasures are available, by and large the problem of unauthorized copying of software has not been solved.

Hardware and software security are typically concerns of computing center professionals or individual concerns of personal computer users. A much more widespread problem is **data** security, which involves files and other forms of data controlled by individuals, groups, and business organizations.

Security concerns with respect to data are broad, encompassing availability, secrecy, and integrity. In the case of availability, the concern is with the destruction of data files, which can occur either accidentally or maliciously.

The obvious concern with secrecy, of course, is the unauthorized reading of data files or databases, and this area has been the subject of perhaps more research and effort than any other area of computer security. A less obvious secrecy threat involves the analysis of data and manifests itself in the use of so-called statistical databases, which provide summary or aggregate information. Presumably, the existence of aggregate information does not threaten the privacy of the individuals involved. However, as the use of statistical databases grows, there is an increasing potential for disclosure of personal information. In essence, characteristics of constituent individuals may be identified through careful analysis. To take a simple-minded example, if one table records the aggregate of the incomes of respondents A, B, C, and D and another records the aggregate of the incomes of A, B, C, D, and E, the difference between the two aggregates would be the income of E. This problem is exacerbated by the increasing desire to combine data sets. In many cases, matching several sets of data for consistency at levels of aggregation appropriate to the problem requires a retreat to elemental units in the process of constructing the necessary aggregates. Thus, the elemental units, which are the subject of privacy concerns, are available at various stages in the processing of data sets.

Finally, data integrity is a major concern in most installations. Modifications to data files can have consequences ranging from minor to disastrous.

### Design Principles

Saltzer and Schroeder (1975) identify a number of principles for the design of security measures for the various threats to computer systems. These include the following:

- **Least privilege:** Every program and every user of the system should operate using the least set of privileges necessary to complete the job. Access rights should be acquired by explicit permission only; the default should be “no access.”
- **Economy of mechanisms:** Security mechanisms should be as small and simple as possible, aiding in their verification. This usually means that they must be an integral part of the design rather than add-on mechanisms to existing designs.
- **Acceptability:** Security mechanisms should not interfere unduly with the work of users, while at the same time meeting the needs of those who authorize access. If the mechanisms are not easy to use, they are likely to be unused or incorrectly used.
- **Complete mediation:** Every access must be checked against the access-control information, including those

accesses occurring outside normal operation, as in recovery or maintenance.

- **Open design:** The security of the system should not depend on keeping the design of its mechanisms secret. Thus, the mechanisms can be reviewed by many experts, and users can therefore have high confidence in them.

## PROTECTION MECHANISMS

The introduction of multiprogramming brought about the ability to share resources among users. This sharing involves not just the processor but also the following:

- memory;
- I/O devices, such as disks and printers;
- programs; and
- data.

The ability to share these resources introduced the need for protection. Pfleeger (1997) points out that an operating system may offer protection along the following spectrum:

- **No protection:** This is appropriate when sensitive procedures are being run at separate times.
- **Isolation:** This approach implies that each process operates separately from other processes, with no sharing or communication. Each process has its own address space, files, and other objects.
- **Share all or share nothing:** The owner of an object (e.g., a file or memory segment) declares it to be public or private. In the former case, any process may access the object; in the latter, only the owner's processes may access the object.
- **Share via access limitation:** The operating system checks the permissibility of each access by a specific user to a specific object. The operating system therefore acts as a guard, or gatekeeper, between users and objects, ensuring that only authorized accesses occur.
- **Share via dynamic capabilities:** This extends the concept of access control to allow dynamic creation of sharing rights for objects.
- **Limit use of an object:** This form of protection limits not just access to an object but the use to which that object may be put. For example, a user may be allowed to view a sensitive document, but not print it. Another example is that a user may be allowed access to a database to derive statistical summaries but not to determine specific data values.

The preceding items are listed roughly in increasing order of difficulty to implement, but also in increasing order of fineness of protection that they provide. A given operating system may provide different degrees of protection for different objects, users, or applications.

The operating system needs to balance the need to allow sharing, which enhances the utility of the computer system, with the need to protect the resources of individual users. This section considers some of the mechanisms by which operating systems have enforced protection for these objects.

## Protection of Memory

In a multiprogramming environment, protection of main memory is essential. The concern here is not just security, but the correct functioning of the various processes that are active. If one process can inadvertently write into the memory space of another process, then the latter process may not execute properly.

The separation of the memory space of various processes is easily accomplished with a virtual memory scheme. Either segmentation or paging, or the two in combination, provides an effective means of managing main memory. If complete isolation is sought, then the operating system must simply assure that each segment or page is accessible only by the process to which it is assigned. This is easily accomplished by requiring that there be no duplicate entries in page and/or segment tables.

If sharing is to be allowed, then the same segment or page may appear in more than one table. This type of sharing is most easily accomplished in a system that supports segmentation or a combination of segmentation and paging. In this case, the segment structure is visible to the application, and the application can declare individual segments to be sharable or nonsharable. In a pure paging environment, it becomes more difficult to discriminate between the two types of memory, because the memory structure is transparent to the application.

Segmentation especially lends itself to the implementation of protection and sharing policies. Because each segment table entry includes a length as well as a base address, a program cannot inadvertently access a main memory location beyond the limits of a segment. To achieve sharing, it is possible for a segment to be referenced in the segment tables of more than one process. The same mechanisms are, of course, available in a paging system. However, in this case the page structure of programs and data is not visible to the programmer, making the specification of protection and sharing requirements more awkward. Figure 1 illustrates the types of protection relationships that can be enforced in such a system.

An example of the hardware support that can be provided for memory protection is that of the IBM System/370 family of machines, on which OS/390 runs. Associated with each page frame in main memory is a 7-bit storage control key, which may be set by the operating system. Two of the bits indicate whether the page occupying this frame has been referenced and changed; these are used by the page replacement algorithm. The remaining bits are used by the protection mechanism: a 4-bit access control key and a fetch-protection bit. Processor references to memory and direct memory access (DMA) I/O memory references must use a matching key to gain permission to access that page. The fetch-protection bit indicates whether the access control key applies to writes or to both reads and writes. In the processor, there is a program status word (PSW), which contains control information relating to the process that is currently executing. Included in this word is a 4-bit PSW key. When a process attempts to access a page or to initiate a DMA operation on a page, the current PSW key is compared to the access code. A write operation is permitted only if the codes

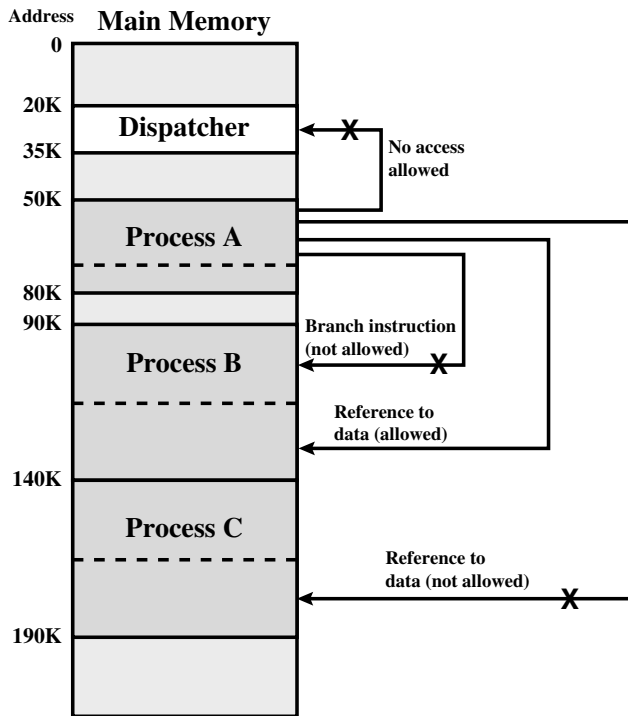

Figure 1: Protection relationships between segments.

match. If the fetch bit is set, then the PSW key must match the access code for read operations.

### User-Oriented Access Control

The measures taken to control access in a data processing system fall into two categories: those associated with the user and those associated with the data.

The control of access by user is, unfortunately, sometimes referred to as authentication. Because this term is now widely used in the sense of message authentication, it is not applied here. The reader is warned, however, that this usage may be encountered in the literature.

The most common technique for user access control on a shared system or server is the user logon, which requires both a user identifier (ID) and a password. The system will allow a user to log on only if that user's ID is known to the system and if the user knows the password associated by the system with that ID. This ID/password system is a notoriously unreliable method of user access control. Users can forget their passwords and accidentally or intentionally reveal their password. Hackers have become very skillful at guessing IDs for special users, such as system control and system management personnel. Finally, the ID/password file is subject to penetration attempts.

User access control in a distributed environment can be either centralized or decentralized. In a centralized approach, the network provides a logon service that determines who is allowed to use the network and to what the user is allowed to connect.

Decentralized user access control treats the network as a transparent communication link, and the usual logon procedure is carried out by the destination host. Of course, the security concerns for transmitting passwords via the network must still be addressed.

In many networks, two levels of access control may be used. Individual hosts may be provided with a logon facility to protect host-specific resources and application. In addition, the network as a whole may provide protection to restrict network access to authorized users. This two-level facility is desirable for the common case, currently, in which the network connects disparate hosts and simply provides a convenient means of terminal-host access. In a more uniform network of hosts, some centralized access policy could be enforced in a network control center.

### Data-Oriented Access Control

Following successful logon, the user has been granted access to one or a set of hosts and applications. This is generally not sufficient for a system that includes sensitive data in its database. Through the user access control procedure, a user can be identified to the system. Associated with each user, there can be a profile that specifies permissible operations and file accesses. The operating system can then enforce rules based on the user profile. The database management system, however, must control access to specific records or even portions of records. For example, it may be permissible for anyone in administration to obtain a list of company personnel, but only selected individuals may have access to salary information. The issue is more than just one of level of detail. Whereas the operating system may grant a user permission to access a file or use an application, following which there are no further security checks, the database management system must make a decision on each individual access attempt. That decision will depend not only on the user's identity but also on the specific parts of the data being accessed and even on the information already divulged to the user.

A general model of access control as exercised by a file or database management system is that of an **access matrix**, illustrated in Figure 2a, based on a figure in Sandhu and Samarati (1994). The basic elements of the model are as follows:

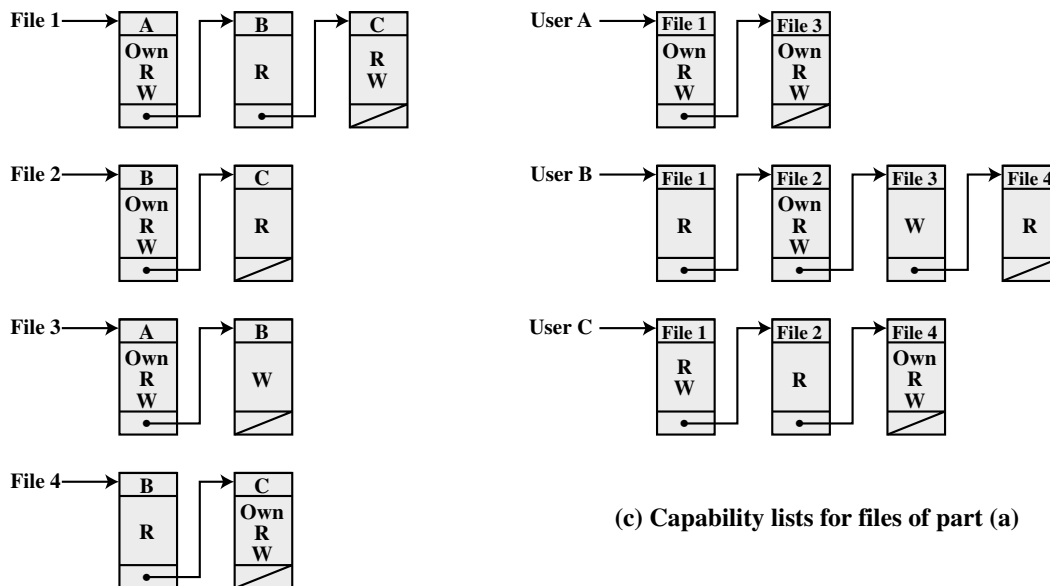

- **Subject:** An entity capable of accessing objects. Generally, the concept of subject equates with that of process. Any user or application actually gains access to an object by means of a process that represents that user or application.
- **Object:** Anything to which access is controlled. Examples include files, portions of files, programs, and segments of memory.
- **Access right:** The way in which an object is accessed by a subject. Examples are read, write, and execute.

One dimension of the matrix consists of identified subjects that may attempt data access. Typically, this list will consist of individual users or user groups, although access could be controlled for terminals, hosts, or applications instead of or in addition to users. The other dimension lists the objects that may be accessed. At the greatest level of detail, objects may be individual data fields. More aggregate groupings, such as records, files, or even the entire database, may also be objects in the matrix. Each entry in the matrix indicates the access rights of that subject for that object.

	File 1	File 2	File 3	File 4	Account 1	Account 2
Process A	Own R W		Own R W		Inquiry Credit	
Process B	R	Own R W	W	R	Inquiry Debit	Inquiry Credit
Process C	R W	R		Own R W		Inquiry Debit

(a) Access matrix

(b) Access control lists for files of part (a)

(c) Capability lists for files of part (a)

Figure 2: Example of access control structures.

In practice, an access matrix is usually sparse and is implemented by decomposition in one of two ways. The matrix may be decomposed by columns, yielding **access control lists** (Figure 2b). Thus for each object, an access control list lists users and their permitted access rights. The access control list may contain a default, or public, entry. This allows users who are not explicitly listed as having special rights to have a default set of rights. Elements of the list may include individual users as well as groups of users.

Decomposition by rows yields **capability tickets** (Figure 2c). A capability ticket specifies authorized objects and operations for a user. Each user has a number of tickets and may be authorized to loan or give them to others. Because tickets may be dispersed around the system, they present a greater security problem than access control lists. In particular, the ticket must be unable to be forged. One way to accomplish this is to have the operating system hold all tickets on behalf of users. These tickets would have to be held in a region of memory inaccessible to users.

Network considerations for data-oriented access control parallel those for user-oriented access control. If only

certain users are permitted to access certain items of data, then encryption may be needed to protect those items during transmission to authorized users. Typically, data access control is decentralized, that is, controlled by host-based database management systems. If a network database server exists on a network, then data access control becomes a network function.

## Protection Based on Operating System Mode

One technique used in all operating systems to provide protection is based on the mode of processor execution. Most processors support at least two modes of execution: the mode normally associated with the operating system and that normally associated with user programs. Certain instructions can only be executed in the more privileged mode. These would include reading or altering a control register, such as the program status word; primitive I/O instructions; and instructions that relate to memory management. In addition, certain regions of memory can only be accessed in the more privileged mode.

The less privileged mode is often referred to as the **user** mode, because user programs typically would execute in

**Table 1** Typical Kernel Mode Operating System Functions

<b>Process Management</b>
<ul style="list-style-type: none"> <li>• Process creation and termination</li> <li>• Process scheduling and dispatching</li> <li>• Process switching</li> <li>• Process synchronization and support for interprocess communication</li> <li>• Management of process control blocks</li> </ul>
<b>Memory Management</b>
<ul style="list-style-type: none"> <li>• Allocation of address space to processes</li> <li>• Swapping</li> <li>• Page and segment management</li> </ul>
<b>I/O Management</b>
<ul style="list-style-type: none"> <li>• Buffer management</li> <li>• Allocation of I/O channels and devices to processes</li> </ul>
<b>Support Functions</b>
<ul style="list-style-type: none"> <li>• Interrupt handling</li> <li>• Accounting</li> <li>• Monitoring</li> </ul>

this mode. The more privileged mode is referred to as the **system mode**, **control mode**, or **kernel mode**. This last term refers to the kernel of the operating system, which is that portion of the operating system that encompasses the important system functions. Table 1 lists the functions typically found in the kernel of an operating system.

The reason for using two modes should be clear. It is necessary to protect the operating system and key operating system tables, such as process control blocks, from interference by user programs. In the kernel mode, the software has complete control of the processor and all its instructions, registers, and memory. This level of control is not necessary, and for safety is not desirable for user programs.

Two questions arise: How does the processor know in which mode it is to be executing and how is the mode changed? Regarding the first question, typically there is a bit in the program status word (PSW) that indicates the mode of execution. This bit is changed in response to certain events. For example, when a user makes a call to an operating system service, the mode is set to the kernel mode. Typically, this is done by executing an instruction that changes the mode. When the user makes a system service call or when an interrupt transfers control to a system routine, the routine executes the change-mode instruction to enter a more privileged mode and executes it again to enter a less privileged mode before returning control to the user process. If a user program attempts to execute a change-mode instruction, it will simply result in a call to the operating system, which will return an error unless the mode change is to be allowed.

More sophisticated mechanisms can also be provided. A common scheme is to use a ring-protection structure. In this scheme, lower numbered, or inner, rings enjoy greater privilege than higher numbered, or outer, rings. Typically, ring 0 is reserved for kernel functions of the operating system, with applications at a higher level. Some utilities or operating system services may occupy an intermediate ring. Basic principles of the ring system are as follows:

1. A program may access only data that reside on the same ring or a less privileged ring.
2. A program may call services residing on the same or a more privileged ring.

An example of the ring protection approach is found on the VAX/VMS operating system, which uses four modes:

- **Kernel:** Executes the kernel of the VMS operating system, which includes memory management, interrupt handling, and I/O operations.
- **Executive:** Executes many of the operating system service calls, including file and record (disk and tape) management routines.
- **Supervisor:** Executes other operating system services, such as responses to user commands.
- **User:** Executes user programs, plus utilities such as compilers, editors, linkers, and debuggers.

A process executing in a less privileged mode often needs to call a procedure that executes in a more privileged mode; for example, a user program requires an operating system service. This call is achieved by using a change-mode (CHM) instruction, which causes an interrupt that transfers control to a routine at the new access mode. A return is made by executing the REI (return from exception or interrupt) instruction.

## FILE SHARING

In a multiuser system, there is almost always a requirement for allowing files to be shared among a number of users. Two issues arise: access rights and the management of simultaneous access.

### Access Rights

The file system should provide a flexible tool for allowing extensive file sharing among users. The file system should provide a number of options so that the way in which a particular file is accessed can be controlled. Typically, users or groups of users are granted certain access rights to a file. A wide range of access rights has been used. The following list is representative of access rights that can be assigned to a particular user for a particular file:

- **None:** The user may not even learn of the existence of the file, much less have access to it. To enforce this restriction, the user would not be allowed to read the user directory that includes this file.
- **Knowledge:** The user can determine that the file exists and who its owner is. The user is then able to petition the owner for additional access rights.

- **Execution:** The user can load and execute a program but cannot copy it. Proprietary programs are often made accessible with this restriction.
- **Reading:** The user can read the file for any purpose, including copying and execution. Some systems are able to enforce a distinction between viewing and copying. In the former case, the contents of the file can be displayed to the user, but the user has no means for making a copy.
- **Appending:** The user can add data to the file, often only at the end, but cannot modify or delete any of the file's contents. This right is useful in collecting data from a number of sources.
- **Updating:** The user can modify, delete, and add to the file's data. This normally includes writing the file initially, rewriting it completely or in part, and removing all or a portion of the data. Some systems distinguish among different degrees of updating.
- **Changing protection:** The user can change the access rights granted to other users. Typically, only the owner of the file holds this right. In some systems, the owner can extend this right to others. To prevent abuse of this mechanism, the file owner will typically be able to specify which rights can be changed by the holder of this right.
- **Deletion:** The user can delete the file from the file system.

These rights can be considered to constitute a hierarchy, with each right implying those that precede it. Thus, if a particular user is granted the updating right for a particular file, then that user is also granted the following rights: knowledge, execution, reading, and appending.

One user is designated as owner of a given file, usually the person who initially created a file. The owner has all of the access rights listed previously and may grant rights to others. Access can be provided to different classes of users:

- **Specific user:** Individual users who are designated by user ID.
- **User groups:** A set of users who are not individually defined. The system must have some way of keeping track of the membership of user groups.
- **All:** All users who have access to this system. These are public files.

## Simultaneous Access

When access is granted to append or update a file to more than one user, the operating system or file management system must enforce discipline. A brute-force approach is to allow a user to lock the entire file when it is to be updated. A finer grain of control is to lock individual records during update. Issues of mutual exclusion and deadlock must be addressed in designing the shared access capability.

## TRUSTED SYSTEMS

Much of what has been discussed so far has been concerned with protecting a given message or item from passive or active attack by a given user. A somewhat different

but widely applicable requirement is to protect data or resources on the basis of levels of security. This is commonly found in the military, where information is categorized as unclassified (U), confidential (C), secret (S), top secret (TS), or beyond. This concept is equally applicable in other areas, where information can be organized into gross categories and users can be granted clearances to access certain categories of data. For example, the highest level of security might be for strategic corporate planning documents and data, accessible by only corporate officers and their staff; next might come sensitive financial and personnel data, accessible only by administration personnel, corporate officers, and so on.

When multiple categories or levels of data are defined, the requirement is referred to as **multilevel security**. The general statement of the requirement for multilevel security is that a subject at a high level may not convey information to a subject at a lower or noncomparable level unless that flow accurately reflects the will of an authorized user. For implementation purposes, this requirement is in two parts and is simply stated. A multilevel secure system must enforce the following:

- **No read up:** A subject can only read an object of less or equal security level. This is referred to in the literature as the **simple security property**.
- **No write down:** A subject can only write into an object of greater or equal security level. This is referred to in the literature as the **\*-property** (pronounced *star property*).

These two rules, if properly enforced, provide multilevel security. For a data processing system, the approach that has been taken, and has been the object of much research and development, is based on the *reference monitor* concept. This approach is depicted in Figure 3. The reference monitor is a controlling element in the hardware and operating system of a computer that regulates the access of subjects to objects on the basis of security parameters of the subject and object. The reference monitor has access to a file, known as the *security kernel database*, that lists the access privileges (security clearance) of each subject and the protection attributes (classification level) of each object. The reference monitor enforces the security rules (no read up, no write down) and has the following properties:

- **Complete mediation:** The security rules are enforced on every access, not just, for example, when a file is opened.
- **Isolation:** The reference monitor and database are protected from unauthorized modification.
- **Verifiability:** The reference monitor's correctness must be provable. That is, it must be possible to demonstrate mathematically that the reference monitor enforces the security rules and provides complete mediation and isolation.

These are stiff requirements. The requirement for complete mediation means that every access to data within main memory and on disk and tape must be mediated. Pure software implementations impose too high a performance penalty to be practical; the solution must be at least

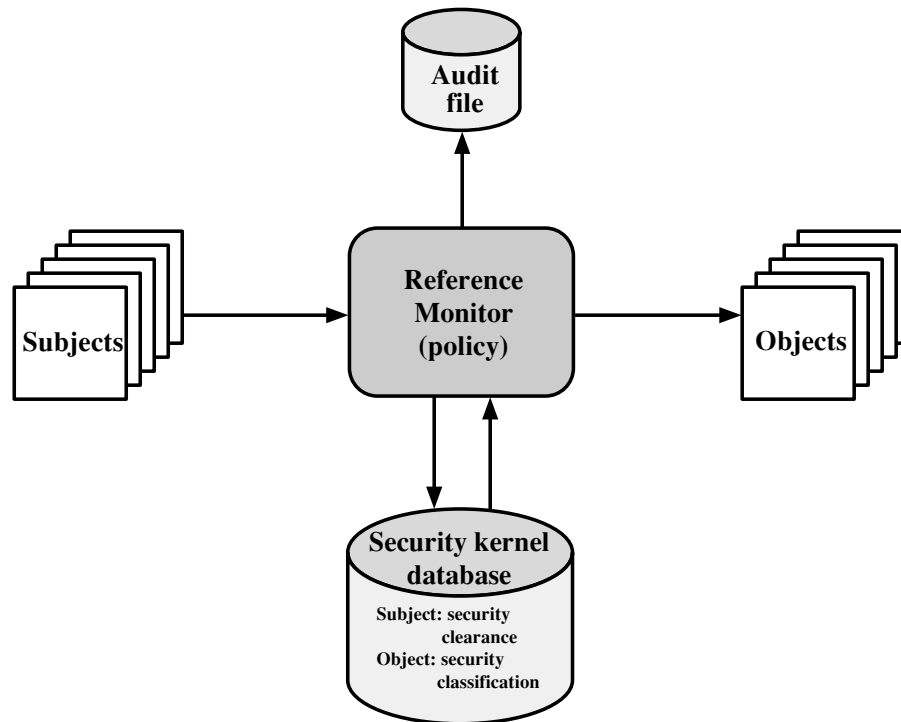

Figure 3: Reference monitor concept.

partly in hardware. The requirement for isolation means that it must not be possible for an attacker, no matter how clever, to change the logic of the reference monitor or the contents of the security kernel database. Finally, the requirement for mathematical proof is formidable for something as complex as a general purpose computer. A system that can provide such verification is referred to as a **trusted system**.

A final element illustrated in Figure 3 is an audit file. Important security events, such as detected security violations and authorized changes to the security kernel database, are stored in the audit file.

To encourage the widespread availability of trusted systems, standards bodies and interested government agencies worldwide have worked to define architectural principals and evaluation criteria. The goal is to be able to validate products that are designed to meet a range of security requirements. These product validations can serve as guidance to commercial customers for the purchase of commercially available, off-the-shelf equipment. Key to this effort is ISO (International Standards Organization) Standard 15408, known as the Common Criteria for Information Technology Security Evaluation. Based on this standard, there is a multinational effort, known as the Common Criteria Project, to further develop requirements, evaluation criteria, and product validations. The U.S. effort is conducted jointly by the National Security Agency and the National Institute of Standards and Technology.

### Trojan Horse Defense

A Trojan horse is a computer program with an apparently or actually useful function that contains additional

(hidden) functions that surreptitiously exploit the legitimate authorizations of the invoking process to the detriment of security. One way to secure against Trojan horse attacks is the use of a secure, trusted operating system. Figure 4 illustrates an example (Boebert, Kain, & Young, 1985). In this case, a Trojan horse is used to get around the standard security mechanism used by most file management and operating systems: the access control list. In this example, a user named Bob interacts through a program with a data file containing the critically sensitive character string "CPE170KS." User Bob has created the file with read/write permission provided only to programs executing on his own behalf: that is, only processes that are owned by Bob may access the file.

The Trojan horse attack begins when a hostile user, named Alice, gains legitimate access to the system and installs both a Trojan horse program and a private file to be used in the attack as a "back pocket." Alice gives read/write permission to herself for this file and gives Bob write-only permission (Figure 4a). Alice now induces Bob to invoke the Trojan horse program, perhaps by advertising it as a useful utility. When the program detects that it is being executed by Bob, it reads the sensitive character string from Bob's file and copies it into Alice's back-pocket file (Figure 4b). Both the read and write operations satisfy the constraints imposed by access control lists. Alice then has only to access the back-pocket file at a later time to learn the value of the string.

Now consider the use of a secure operating system in this scenario (Figure 4c). Security levels are assigned to subjects at logon on the basis of criteria such as the terminal from which the computer is being accessed and the user involved, as identified by password/ID. In this example, there are two security levels, sensitive (gray) and

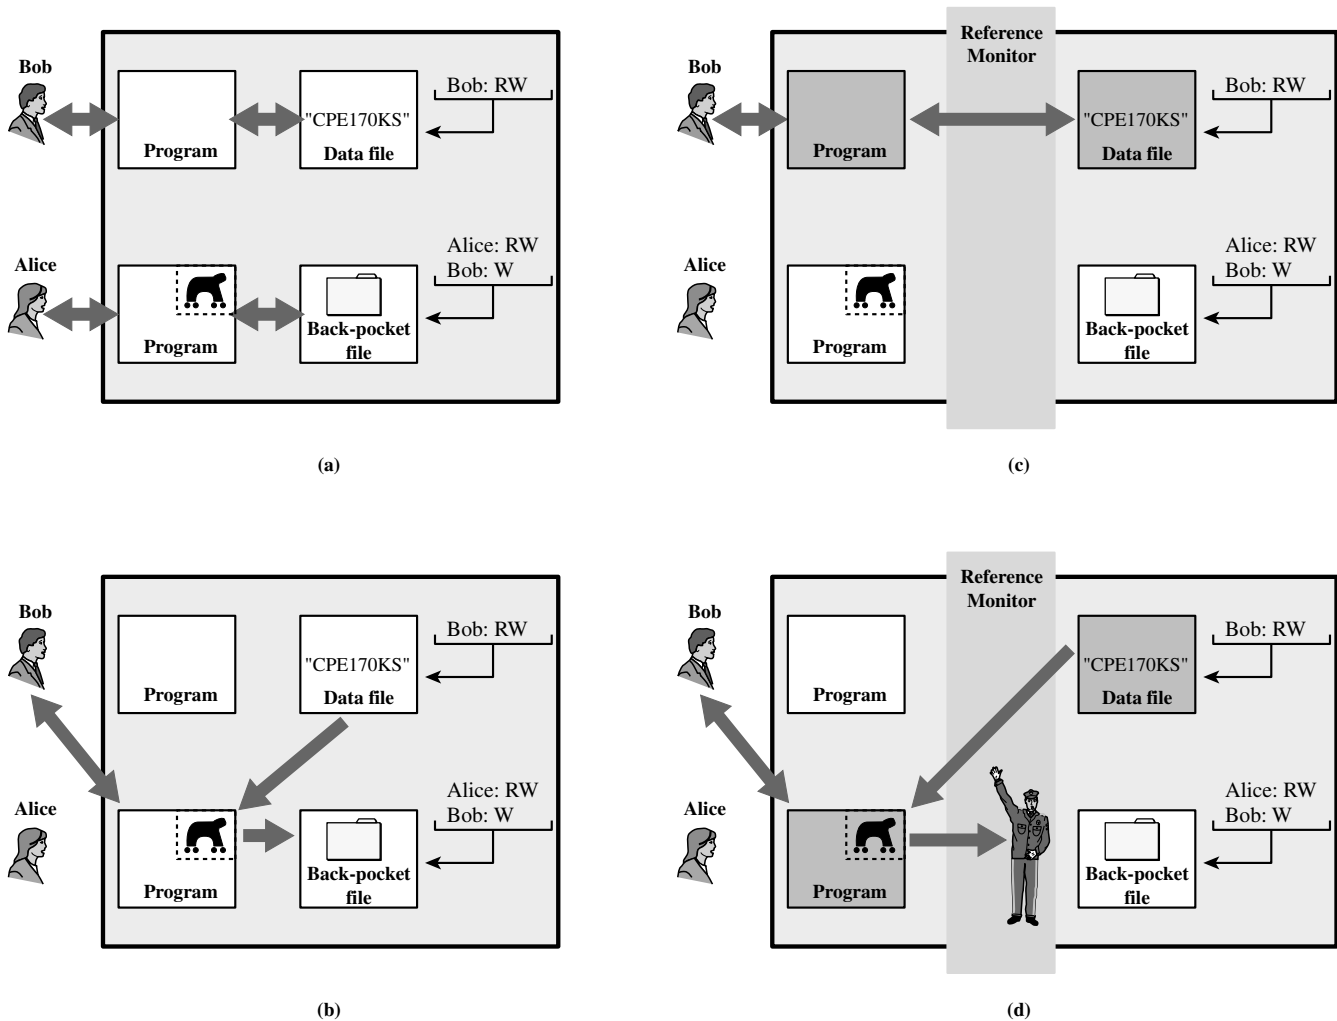

Figure 4: Trojan horse and secure operating system.

public (white), ordered so that sensitive is higher than public. Processes owned by Bob and Bob's data file are assigned the security level sensitive. Alice's file and processes are restricted to public. If Bob invokes the Trojan horse program (Figure 4d), that program acquires Bob's security level. It is therefore able, under the simple security property, to observe the sensitive character string. When the program attempts to store the string in a public file (the back-pocket file), however, the \*-property is violated and the attempt is disallowed by the reference monitor. Thus, the attempt to write into the back-pocket file is denied even though the access control list permits it: The security policy takes precedence over the access control list mechanism.

## GLOSSARY

**Access Control** Techniques and mechanisms that ensure that only authorized users have access to a particular system and its individual resources and that access to and modification of particular portions of data are limited to authorized individuals and programs.

**Authenticity** The requirement that a computer system be able to verify the identity of a user.

**Availability** The requirement that computer system assets are available to authorized parties when needed.

**Confidentiality** The requirement that the information in a computer system only be accessible for reading by authorized parties.

**Integrity** The requirement that computer system assets can be modified only by authorized parties. Modification includes writing, changing, changing status, deleting, and creating.

**Password** A character string used to authenticate an identity. Knowledge of the password and its associated user ID is considered proof of authorization to use the capabilities associated with that user ID.

**Trojan Horse** A computer program with an apparently or actually useful function that contains additional (hidden) functions that surreptitiously exploit the legitimate authorizations of the invoking process to the detriment of security.

**Trusted System** A computer and operating system that can be verified to implement a given security policy.

## WHAT IS SECURITY?

The topic of security in general, and of UNIX security in particular, is a vast subject. The word security comes from the Latin *securitas*, which literally means “without care.” Thus, being secure, at least according to the Romans, meant feeling “safe,” without a care in the world. The irony is that most people, when it comes to computers, take this approach toward security initially—they feel secure, even though, in fact, it is a false sense at heart. Computer crime is a growing business, and the threat of cyberterrorism is growing at an alarming rate. Every year for the past eight years, the Computer Security Institute and the Federal Bureau of Investigation have produced a report detailing the losses incurred by a number of industries, which includes input from 530 respondents representing sectors as diverse as government, retail, medical, high-tech, transportation, telecom, financial, and manufacturing, among others. The most recent report available, the 2003 Survey, reports the following staggering statistics:

- The most expensive form of loss was theft of intellectual property (proprietary information) with an average cost of \$2.7 million *per incident*.
- The second most expensive form of loss was a denial of service attack, with an annual cost of \$65 million and a per-incident cost of around \$590,000. This figure was up 250% from the previous year.
- More than half of the respondents reported some form of unauthorized use (break-in) of their systems in the past year, with at least one out of five being a break-in from outside the organization.
- 82% of the responding companies had experienced a virus in the previous year.

The only good news in this report is that for the year 2003, the severity and cost of these attacks trended down for the first time since 1999, particularly in the area of

fraud (Computer Security Institute & Federal Bureau of Investigation, 2003, 2004).

Part of this comes from the evolution of computing in general. Most home users have had “personal” computers for some years and only just now are connecting them a good deal of the day to a network (the Internet). Thus, a computer that is not connected to a network is a great deal more secure than one that is so connected. With the advent of low-cost Internet access, the world itself is literally connected and, as such, has generated, along with the inadvertent cooperation of bugs and limitations in software, a critical security problem.

## Physical Versus Data Versus Privacy

When we examine the topic of security, we must make a distinction among the various ways in which computers and data can be compromised in terms of security. These ways include:

- The compromising of the physical security of the computer system.
- The compromising of the physical security of the data contained within the computer system.
- The compromising of the privacy protection surrounding the data on the computer system.

Any one of these can undermine security. For example, a computer system may be physically compromised if it is stolen from one’s premises or if it is lost in a fire. In such cases, the physical computer itself is compromised but not *necessarily* the data. Certainly, in the case of a fire, the hard disk will almost certainly be damaged beyond repair, and if there are no copies (backups) of the data safely stored away, the data that were physically on a disk on the computer will be lost too. In this case, both the physical security of the computer as well as its data are compromised. However, in the case of a stolen computer, one of the key risks is that the physical security

of the data is compromised, and if steps have not been taken to protect the privacy of the data contained within the computer, its data will be compromised in terms of its content—that is to say, others may be able to view the data and possibly modify it as well. On the other hand, if someone cracks into your computer network and accesses the data on your computer system, the cracker has effectively obtained access to your data, and if its privacy is not protected, the cracker can copy your data and your systems, or in some cases, given the level of capability of the cracker, copy it and then delete it, so that the cracker now owns your data and you do not.

### Loss Versus Stealth

There are also different kinds of data loss. One type of loss involves the physical loss of data, such as in a fire, a stolen computer, a crashed disk, water damage from burst pipes, and so forth. The second type of loss deals with loss of information or privacy of information, in which the data are somehow compromised by unauthorized access for the purpose of stealing the information. There is also intentional vandalism—where data are accessed and then either modified or deleted or otherwise disabled, with the intention of damaging the owner of the information in some way, either financially or otherwise.

From this, we see that securing a computer system involves a number of different dimensions. First, we need to secure and protect the physical computer itself. This might involve obvious measures such as locking doors and securing entry, but also strategies such as providing climate-controlled storage, redirecting water, upgrading electrical supply, and so forth. Second, we need to secure access to the data on the computer system so that the data is not visible to unauthorized users. The latter can be effected by a robust authentication mechanism, access control, and possible encryption of data. All of this involves defining what it is that we need to secure. Once we know what we need to secure, we then have to define how we are going to secure it.

## IMPORTANCE OF A SECURITY POLICY

### Cost–Benefit Analysis

Defining how we are going to secure our UNIX system involves first doing some form of a cost–benefit analysis (CBA). All efforts at protecting data come with costs, and not all of them are monetary. Certainly, there are monetary costs involved with physically protecting our systems in terms of additional locks, doors, and security systems, which deter a physical break-in. But how much do we want to spend on our security system? Should it be the equivalent of a new lock on a door with a passkey or should it more resemble Fort Knox? Obviously, the latter will cost significantly more and may not be necessary. We need to define what the *likely* events are that would threaten our security, and direct our resources at shoring up *those* shortcomings rather than trying to protect against any conceivable threat. For example, the requirements for ensuring the protection of both the data and systems of a medical center are significantly different than the requirements for protecting the data and systems for the local

yacht club. In the former case, patients can be lost, people can die, and legal issues abound, whereas in the latter case, it is primarily an issue of inconvenience because the data for the membership can be recreated (with possible exposure of sensitive information such as credit card numbers, home addresses, etc.). However, the costs incurred in a security effort are not only monetary. There are costs in terms of inconvenience as well. If you impose too stringent a password policy on your customer base, for example, you may find that you have fewer customers to worry about. A solid CBA can be used to justify expenditures to those who will eventually pay for it.

After a CBA has been prepared and approved, a security strategy should be defined that details plans for implementing various security strategies and disaster plans for when those strategies (perhaps inevitably) fail. Few security strategies are foolproof, and those that are will generally be rejected by your user base except in the most stringent of security requirement circumstances (as in the case of national security). Thus, the strategy is to firmly define standard practices by which security will be achieved and enforced at your organization, and then plan what you are going to do in case of disaster—in case despite all your good plans a significant loss still does occur. Examples of disaster include a flood that crashes 50% of your disk arrays or a break-in that has compromised (or damaged) certain data. A disaster plan would categorize data into critical levels and will provide direction on what to do in case each level is breached. In the end, it really does not matter much whether your database was destroyed intentionally by a malicious cracker on the payroll of a competitor or accidentally destroyed by one of your own employees who was given too much power and not enough education. In both cases, you are out one database and will need to recover it somehow. It is your disaster plan that will define, among other things, the strategy for recovery of the database.

A security policy therefore defines the standard practices that will be implemented across an enterprise. It should include rules and regulations pertaining to user accounts and passwords (password length and characters, password aging); proper and improper use of computerized assets (no automated search bots, no pornography downloads, no creation of worms or viruses, etc.); various conditions under which a user can forfeit access to the computers, usually tied in tightly with improper use; and possibly a signed form consenting to monitoring and auditing of account activities, including the possible reading of email.

### Audits

Merely having and even enforcing a security policy is insufficient if one does not take the time to track how well the security policy is being implemented. For this reason, security audits should take place periodically to provide input and review of how well or poorly a given policy is being implemented in an organization. A security audit can help provide metrics that may be useful later on in future CBAs or policy modifications. Audits can be conducted internally by the security staff or they can be contracted from by a consulting firm that specializes in security

audits (almost always a better choice if affordable). In the end, security is a people matter. The more educated your users are concerning things such as password protection and, more important, why passwords need protecting, the more smoothly your security policing will run and the more successful you will be, with your users on board and assisting in the protection of the systems they use.

## Personnel Checks

The users of the system are often the last line of defense and too often the first line of opportunity for those less than scrupulous. One of the things a security policy should take into consideration is background checks on personnel and other users of the system, if possible. It sometimes is not practicable, for instance, in a university where the user base is mostly made up of students. In corporations, personnel checks can easily be performed and should always be performed, regardless of the business. A personnel check that includes background checks can be priceless in the security efforts.

## Open Source Versus Private Vendor Issues

A security policy should also define the policy regarding the use of open source software within the computer systems. Open source software is software that is released not only in binary compiled form but also with accompanying source code. The source code is in a programming language such as the C language. To some degree, the history of UNIX goes hand in hand with the notion of open source software. Indeed, when UNIX was first released, it was released with the source code. Since the early days of UNIX, there has been a concerted effort on the part of several different organizations to release software for UNIX that is open source. Most notable among these different efforts is the GNU effort of Richard Stallman.

The issues with open source from a security standpoint are somewhat complex, a bit like a double-edged sword. Because the source code is publicly available, many different eyes can examine the software's source code and can spot potential or actual defects in the source code. This means that responsible people can more easily spot and diagnose a security issue in open source and repair it more quickly than with closed source. There are fewer "surprises" in open source code. The risk here is that irresponsible people can also more easily spot those same security defects and potentially capitalize on them, if they quietly notice a problem before anyone else has discovered it. It is also possible that an unscrupulous person might use the source code to deduce other potential problems with some closed source systems, often because the same algorithms are used for both closed source as well as open source solutions. With closed source, the detection of security holes is much more difficult both for the would-be cracker and for those trying to diagnose how a breach has been conducted. Thus, *should* a breach be made on the basis of a defect discovered by a cracker in closed source code, there is a much smaller group of people available to discover the problem and fix it. There are arguments that open source software is actually *more* secure than non-open source because the features and limitations of the

code are readily present for anyone to view. In actual fact, open source software has proved itself quite resilient to security breaches, although not immune. It is also possible, however, that because most cracker activity of late has been directed at the Windows operating system, the full weight of the cracker community has not turned its full attention toward open source systems and software, most notably Linux. For every Linux virus, there are hundreds written that attack various vulnerabilities in the closed-source Microsoft Windows environment.

## Keeping Up With Patches and Releases

One of the effects of discovering a security bug in software, either closed source or open source, is the release of a software patch that attempts to fix the problem. A patch may be released in either source code or binary form or sometimes in both. A system administrator would then use the patch to update her software system to keep it "up to date" from a security standpoint. Although all patches are not necessarily security related, in general, security patches make up the vast majority of software patches released for an operating system and a good percentage of the patches released for standard end-user software applications. You can think of a security patch as an update to software that makes the software more secure than it was before. An example of a security patch is an update to a virus-scanning software system. When a new virus is identified, the way to remove it is encoded, and the virus software is thus patched, or updated, with the new capabilities. When a system administrator receives notice that a security patch is available, she will generally immediately download or otherwise obtain the patch and will update her software accordingly. This closes off one potential "hole" whereby a cracker might attempt to gain access to the system or otherwise create havoc.

When software is updated in a more general form, a new release may be offered to users of the software, whether that software is an operating system or an end-user application. Keeping up with new releases of software and security-related patches can allow a system administrator to feel more secure than she might otherwise be if she had not applied the patches and updated her software.

## UNIX SECURITY

### Login Security

Let's talk about system access first. Because UNIX is a multiuser environment, the system needs to provide a way for multiple users to use the system at the same time. This is done through a process known as the "login process." When a typical UNIX system starts up or "boots" (known as "bootstrapping"), the master boot sector of the primary hard disk partition is read into the computer's memory. It does several things, but eventually the UNIX kernel is started (a program on the disk called something like "unix" or "vmunix"). The kernel sets up the system, including initializing process tables, creating memory areas, establishing certain buffers and caches, and so forth. After the kernel has established a sane state, the kernel spawns (or "runs") a program known as "init." The init

program is important because it ensures that the system is always ready in a particular “state.” The UNIX operating system has various states, including boot (initialization), restart, shutdown, single, and multiuser. The normal state is multiuser, and when init begins this state, another program known as a “getty” (spelled from “get” and “tty” which is itself short for “teletype”—indicating a terminal) is started on a particular terminal. The getty process listens for activity from a terminal, and when a terminal is connected, getty runs another process known as “login,” which prompts a user to log in to the UNIX system.

It is the login program that the average user first sees as the interface to a UNIX system. The user is prompted to enter her username. Once that has been entered, the user is prompted to enter her password. Once the user has entered her username and password, the login process examines her entries and compares the username and password (encrypted) entered by the user with the information that the superuser has entered for that user. (Users are usually allowed to alter their password within certain security constraints.)

If the user has *not* entered the correct information, the user is advised of the failure and is not allowed access to the system. At this point, the getty program spawns another login program and the user is prompted to log in again. If the user *has* entered the correct information, the user is logged on and the login process spawns yet another program, known as a command “shell,” which prompts the user to enter commands to the system. The shell interfaces the user with the rest of the UNIX system and prompts the user to enter new commands. (A UNIX prompt usually is made up of a “\$” character or a “%” character, depending on which type of shell is being used, or a “#” character in the case of the root administrator.)

Now let us turn our attention to file permissions. Files do not exist on the system accidentally. They are owned and created by users of the system. UNIX systems have users that operate in the user environment. Users have numbers associated with them known as a “userid.” Each user also has a username that is associated with their particular userid. The username is the name under which the user accesses the system. Users also have passwords that authenticate them as legitimate users of the system. A user can use her userid and password to gain access to the system by logging on to the system.

Users may be arranged according to logical groupings for organizational as well as security purposes. For instance, the users tom, dick, and harry may be attorneys and therefore belong to the “attorneys” group. The users jane, linda, and ann may be members of the “clerks” group, and the users ken, donna, mary, and tom might be all members of the “partners” group. Groups are used to organize users into various categories, allowing for the ability to assign certain access rights to groups of individuals rather than on an individual basis.

There is one special user on every UNIX system, and that is the system administrator, sometimes called the “superuser” or “root.” The superuser administers the system, which includes tasks such as managing the user community (creating accounts for users and managing groups), changing permissions on files, managing the system as

a whole, scheduling system backups, installing software, and so forth. The superuser can do almost anything on a UNIX system, so access to the superuser’s password (sometimes called the “root” password) is highly controlled. Anyone logged in as the superuser can, for example, read other users’ mail, read their files (unless the user has performed additional steps such as encrypting their file data), modify other users’ files, delete files, and so forth. A nefarious user who has obtained the root password could, if he desired, delete every file on the UNIX system so that the system would no longer even start up.

Security on a UNIX system is a layered approach defined in terms of access to the system itself and its resources, including files and directories. Access to the system is managed by encrypted passwords associated with usernames during the login process.

## File Systems Protection

Files may be read from, written to, and executed, depending on individual permissions. Every file in the UNIX file system (directories in UNIX are files) has a particular user who “owns” the file, as well as a group that is associated with the file. Groups collect users and give the ability to assign rights to a file to a group of users in addition to the single user who owns the file. You can see the file permissions for most any file in the system by typing the “ls -l” command. For example, if we have a file called contract.doc that is owned by the user “bob” and associated with the group “attorneys,” we might see a long directory listing such as the following:

```
-rw-rw-r-- 1 tom attorneys 23872 March 15 2003
contract.doc
```

This set of information tells us the following:

- The file’s name is “contract.doc.”
- The user “tom” owns the file.
- The file is associated with the group “attorneys.”
- The file contains 23,872 bytes.
- The file was last modified on March 15, 2003.
- There is one hard link to the file.
- The file’s access permissions are -rw-rw-r--.

If we look at the symbolic rights of the legal contract.doc file, we see that the permissions are represented as “rw-rw-r--.” This means that the owner would be able to read and write to the file (the first “rw-” in the triad) and the members of the group associated with the file would also be able to read and write to the file (the second “rw-” in the triad), but all others would only be able to read the file (the final “r--” in the triad). This would mean that only tom, the owner of the file, and all the members of the attorneys group, namely, dick and harry, could read and write to the file, whereas, all others (regardless of group) could not access the file for writing at all, with the exception of the superuser, who can read all files on the system. This brings us to the next topic of discussion, where we concern ourselves with data privacy and encryption.

## Data Security

### Backup Strategies

When we turn our attention to UNIX-specific data security, we need to talk about data security, both from a preservation standpoint and a privacy standpoint. Preservation of data simply means that there exist one or more backups of the software, usually stored on magnetic tape, so that if the original disk containing the data is somehow lost or corrupted, the backup copy of the data can be restored from the tape, thus saving the data from permanent loss. Magnetic tape is not the only storage solution for backup software. Some backup programs are able to back up to regular physical hard drives, magneto-optical disks (optical disks), writeable CD media, and writeable DVD media. Software applications designed to make copies of data and then restore that data in the event of loss are called “backup programs.” Examples of popular backup solutions for UNIX include tar and cpio, with the traditional UNIX backup solutions called “dump” and “restore.” An example of using tar to perform a backup follows:

```
tar -cf dev/rmt/0/home/opt/var/etc
```

This would back up the contents at the absolute path locations /home, /opt, /var, and /etc to the rewinding tape device associated with /dev/rmt/0. Rewinding tape devices are usually named something like /dev/rmt/0 or /dev/rmt/1 by convention. Tape devices which are nonrewinding are usually called something like /dev/rmt/0n (with the “n” somewhere denoting the device as nonrewinding).

A currently popular open source software solution is AMANDA, the Advanced Maryland Automated Network Disk Archiver, an open source utility developed at the University of Maryland. It has an advanced set of features and a wide user base. AMANDA allows you to set up a single master backup server to back up multiple hosts to a single backup drive. AMANDA relies on dump and/or tar and can back up any number of computers running multiple versions of UNIX. It can also be used to backup Microsoft Windows computers. There are other backup-like solutions, such as rsync and rdist, which allow you to make automatic copies of directory structures from one system to another. Each commercial UNIX operating system will generally offer some form of backup software solution for its users. Very often, these will be simple solutions such as dump, restore, tar, or cpio. There are commercial backup solutions available as well, including BRU (Backup and Restore Utility), Solstice Backup Utility for Solaris, SAM for HPUX, and so forth.

A backup strategy should be defined as part of a security policy, as it pertains to the protection of data. Backup strategies should define, among other things, what files need to be backed up and how often, who should perform the backups, where the backup should be directed and to what type of media (tape, optical, etc.), how long the backups need to be retained before being destroyed or overwritten, and how long it should take to be able to restore a particular file from the backup media. One important question that should also be considered is where to store the backup media themselves. For example, if you

store the backup tapes onsite, then you risk the potential loss of the backups as well as the originals in certain situations such as theft and flood. Storing the backup tapes offsite may give more physical protection to the tapes (it is doubtful that the home office on Omaha would burn down at the same time the backup center in Cleveland also ignites). Storing the tapes on site will allow for quicker restores, however, as they are readily accessible, whereas it would take a while to retrieve and restore a tape that is stored offsite.

Backups are usually of two types: a full backup of the system or a partial backup of the system. A full backup will do what it says, back up every single file on the system, regardless of whether or not it has changed since the last time the data was backed up. This gives a full “snapshot” of the entire system at a given point in time, but at the cost of time and tape. It usually takes a significant amount of time to back up a complete system, and this is one reason why backups are often performed overnight or over the weekend. Finding a particular file on a full backup can be quite time-consuming, as in nonindexed media solutions, the entire tape might need to be scanned just to find one file. Partial backups are backups that are either of a fixed subset of the data on a system or an *incremental* backup that only backs up the data that has *changed* since the last time a full backup was made. Partial backups generally take much less time to perform, and restores from incremental backups tend to be much faster than restores from full backups. The best practice is to set up a backup schedule that defines when full and partial backups are to be made, as well as specifying rotation of tapes. For example, a security policy might prescribe that a full backup of the systems is performed on Saturday night of every week, and incremental backups are taken every other night of the week, all on separate tapes. The policy might also specify that there must always be on hand the past 8 weeks’ worth of full and incremental backups before a given tape can be “reused.” The policy might also specify that if an error is encountered at any time during the backup, the physical tape is not to be reused but is rather to be replaced, even if it is brand new. The policy might also state that redundant copies are to be made and stored separately from the primary set to ensure added protection. Some businesses simply would be out of business if their data should be permanently lost.

### Data Encryption

Once the physical security of the systems is ensured and the data are protected from permanent loss by a secure backup strategy, there remains the issue of data privacy.

Data privacy is the protection of data by making it unreadable by parties not authorized for such viewing and reading. Primary strategies for ensuring data privacy include file access protection and data encryption.

If the superuser’s account is compromised by an unscrupulous user who has discovered the password or otherwise figured out how to gain access to the root shell (a command interface that allows commands to be issued to a UNIX system), that unscrupulous user can now access any file on the system, regardless of the access permissions of the given files themselves. This means that the superuser could read Bob’s contract file, even though the root

user does not own the file nor is the root user a member of the group attorneys. The reason for this is that the superuser essentially does “own” access to the entire filesystem and thereby all the files on it. This means that the superuser could open the contract.doc file, change some of its contents, and no one would be any wiser if this was not noticed by some other party. Encryption is the primary method of protecting the privacy of the data so that the actual content is transformed into a meaningless series of characters, usually using some kind of secret key, known only to the owner of the file who chooses to encrypt it.

Historically, encryption has tended to be used primarily by lovers seeking secure communications and by the military, that is to say, for love and war. In Victorian England, lovers would occasionally place encrypted messages in the London newspapers for their partners to decrypt and read. David Kahn has written an excellent history of encryption called *The Code Breakers* (1996), in which he details cryptography all the way back to ancient Greece and Rome. Ancient ciphers used to be based on a technique of substitution. The Caesarian cipher, for example, substituted every letter with the third next letter, so “a” would become “d,” “b” would become “e,” “c” would become “f,” and so forth, with the last three letters wrapping around to the beginning of the alphabet.

Modern cryptography is partially based on an algorithmic strategy known as transposition. Original text is compressed and transposed as part of the algorithm’s progress. Once a file is encrypted, not even the superuser can “decrypt” it, not unless she knows the secret key for “unlocking” the encrypted file. This does not mean that the superuser cannot open the file up, say, in an editor. She can. However, what she would see is a meaningless series of gobbledygook and therefore it would be unintelligible.

## Encryption

Figure 1 shows the user typing out a file called legal.contract.doc, encrypting the file using an encryption tool called Pretty Good Privacy, or PGP, and then typing out the garbled contents of the resulting encrypted file.

You can see that when the user issues the command `pgp -c legal.contract.doc`, the user is prompted for a secret key that only he knows. Once he enters the key (in this case, the key was “asdf,” but you cannot see it typed), he is prompted to enter the same key (“asdf”) once again. This second entry ensures that the user did not make an error when he entered the key in the first place. If the second key matches the first key entered, the file is encrypted using a default cipher and stored (in the case of PGP) in a file called `legal.contract.doc.pgp`. The figure shows the user then typing out the contents of the newly encrypted file, and you can easily see that the contents of the encrypted file are quite inscrutable.

PGP (and GnuPGP) are based on a type of encryption known as public key encryption. Public key encryption uses two separate but mathematically related keys and is technically referred to as asymmetric encryption (symmetric encryption uses the same key to both encrypt and decrypt data). In asymmetric encryption, one key is *public*, meaning that it can be freely published and made available to the entire world. The second key is *private* and known only to the owner of the keyset. Only public keys can be used to encrypt text. The public key cannot be used to decrypt text; only the owner’s private key can be used for decryption. This means that if I have established a keyset based on a particular cipher (see the chapter on public key algorithms for more detailed information on particular ciphers), my friends can encrypt files with the public key that I have provided to them, perhaps on my Web site,

```

Figure 1: Encrypting a file with pgp.

and anyone who uses that public key can encrypt files that only I can read. This allows me to decrypt an e-mail message sent from a friend who has my public key, and I (and only I) can decrypt it and read its contents using my private key. If she has herself established a public/private key pair, I can then encrypt a response to her using her public key, and she can decrypt and thus read my response that I encrypted using her private key.

This means that file encryption can be used to protect the privacy of data. Once a file is encrypted, it can only be decrypted by someone who knows the right (private) key for decryption. A user can create her own key pair (using PGP) by issuing the command

```
pgp -kg,
```

which instructs the `pgp` program to generate (g) a key (k) pair for her. The encryption strategies used in these types of public key systems (128 bits and above) is secure enough that it would take millions of years for all the computers on the earth to crack the encryption and decrypt the original text. However, often one does not have to go to great lengths to decrypt someone else's text. A woman who enjoys riding Harleys might have a key whose plaintext is based on the string "bikergirl," so one's interests can greatly reduce the difficulty of guessing a key. Family member names (including pets) are also ripe for the picking. If someone has children named anna and danny, a good guess for a key would be "dannyan" or "annadanny," or "9294," signifying the years of their respective birthdays (1992 and 1994). As long as keys are created that are not too easy for someone to guess, modern cryptographic algorithms make a brute force attack on the keys rather unlikely. The actual difficulty of a brute force attack is primarily dependent on the length of the key itself. When creating a key, the same principles should be employed as are employed in creating a strong password. See the chapters on PGP for more information on `pgp` and the chapter on encryption basics for a more general introduction.

## Passwords

As we said earlier, each user on a UNIX system is given a userid and a password. Generally, the users can change these passwords when they want, and often a security policy will specify the number of times a password can be reused ("lifetimes") before the system forces a user to change her password. The way UNIX deals with passwords is ingeniously simple. A program called *crypt* is used to encrypt the password a user enters when changing her password. The encrypted password is then stored on the system associated with that user (usually in a file called `/etc/passwd` or `/etc/shadow`). A password entry in `/etc/passwd` has the following form:

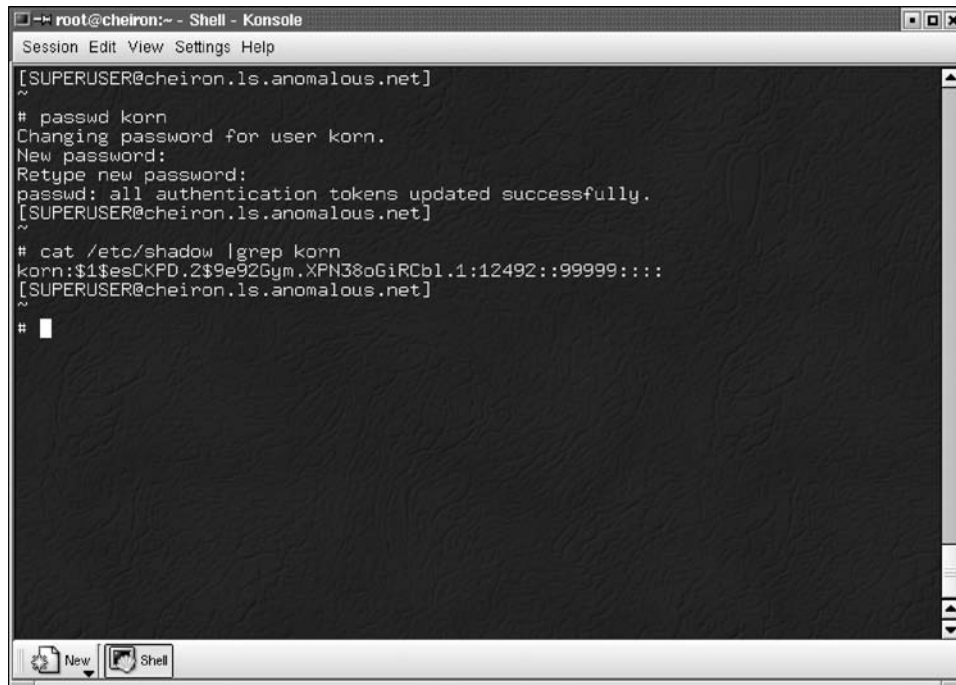

```
root:x:0:1:System Administrator:/:bin/sh
bobby:x:1234:23:Bobby Burns:/home/bobby:/bin/ksh
```

These entries specify two users in the system: root, the system administrator, and "bobby." The root user has a userid of 0 and a groupid of 1, is named "System

Administrator," and has a home directory of / and a default shell of /bin/sh. The bobby user has a userid of 1234 and a groupid of 23, his full name is Bobby Burns, his home directory is /home/bobby, and his default shell is the Korn shell: /bin/ksh. What is interesting about this from a security standpoint is the "x" that appears in both entries. This indicates that shadow passwords are in effect. Shadow passwords are often used because the `/etc/passwd` file by default is a plain text file and is generally world-readable. Prior to shadow passwords, the actual encrypted password would appear in the publicly readable `/etc/passwd` file. With the introduction of shadow passwords, only someone with root privileges can see the actual encrypted passwords. The actually encrypted password (passwords are never stored on the system in an unencrypted state) is held in a separate file that only the system administrator or root can read, usually called something like `/etc/shadow` or something similar. The actual algorithm used is based on the DES 56-bit standard. When a user wants to change her password, the system selects something called a *salt* value, based on the time of day. The salt value is a number between 0 and 4095 that Morris and Thompson, who developed the DES algorithm, used to alter slightly the encryption process so that the same password can be encrypted in  $2^{12}$  (4096) different ways. The result is that the user's password is used as an encryption key to encrypt a 64-bit block of 0's, with the salt value modifying the process. The resulting 64-bit ciphertext is then encrypted again with the user's password, and this process is repeated as often as 25 times. The final 64 resulting bits are then converted into a "plaintext" string of often 11 or more printable characters, prepended by the plaintext of the salt value, and it is these characters that are stored into the password file. An example of the root user changing the password for a user named "korn" to the password text "nobadaddy" is shown in Figure 2.

When we `grep` the `/etc/shadow` for the user korn, we see that the resultant encryption of the password "nobadaddy" is stored as "\$1\$esCKPD.2\$9e92Gym.XPN38oGiRCbl.1." For reference, the salt value of this password is "\$1."

Then, every time that user logs in, she is prompted to enter her password to gain access. When she enters her password, it is immediately encrypted using the same default key, and the result is matched with the encrypted password stored for that user on the system. The system also does not echo what she is typing to her terminal screen, lest someone is watching over her shoulder or a transcript of her session is being recorded (using something such as *script*, for instance). If the encrypted passwords match, the user is "authenticated" and allowed to log in. If they do not match, the user is denied the right to log in to the system. Many organizations will establish rules within their security plan that specify what types of passwords are allowed. For example, some systems will have a six- or eight-character minimum limit, which would disallow passwords such as "mike" and "tom." Some organizations will also require that there be at least some combination of different types of characters, such as requiring at least one numeric character or some non-alphanumeric character such as #, !, or %. A good password is one that is not easy to guess, is random, and is not

Figure 2: Changing a password in Unix.

based on any word in any human language. For instance, a bad password for William Rogers would be “bill” and a good password would be “Wstmzoe%76.” However, there are difficulties with these approaches, and this brings us back to the human factor. A system that hands out default passwords to its users (without allowing them to choose their passwords—even within certain limitations) in the form of “Wstmzoe%76” and then changes it every several months is virtually guaranteeing that the user is going to write that down on a sticky note in their desk! Who in the world could remember that? Organizations can achieve better security (because sticky notes are not necessary) by suggesting that users create acronyms that exceed the minimum character length and requiring the use of numeric and other character types. For example, no one would figure that the password “amsr#1” in reality stands for “Ann, Mary, Sarah Are Number 1”—a good password for a mom whose daughters are named Ann, Mary, and Sarah. This might only be guessable by someone who knows that mother rather well. Examples of bad passwords would be your name or the name of anyone in your family, your pet’s name, your company name, your birthdate, your social security number, obvious geekisms such as “bilbo,” “gandalf,” “UNIXguru,” or “albus.” Other examples would include any word in any dictionary in any human language, passwords of the same or repetitive letters, and simple typing examples such as “qwerty” or “asdf.”

UNIX users will generally use the `passwd` or `yppasswd` programs to change their passwords. Sometimes, depending on the exact policy in place, a user is forced to change their password every 100 logins or every three months. Generally, when such a policy is in place, they are required to change it to something other than a recently used password. This ensures that users actually do *change*

their passwords rather than just reenter the same password they have been using for 10 years.

### Authentication Versus Authorization

When we talk about passwords, we generally make a distinction between the concepts of *authentication* and *authorization*. Authentication is the process of proving one’s identity to the system—that of logging on and entering the correct password. Once we have authenticated ourselves to the system, there is still the question of exactly what we are authorized to see and modify. Authentication with passwords is not the only means of authentication. Authentication can be performed by attaching physical devices to systems, such as biometric scanning with a retina scanner or a hand scanner, a voice scanner, or even a simple card scanner. In the case of the card scanner, a physical key card is entered (like an ATM machine card) into a device and is read. Often, more security can be obtained by coupling various methods, for example, authenticating with both a good password scheme as well as a hand-geometry scan. There are many companies that offer biometric scanning devices that can be added to an authentication system.

### Smart Cards

Perhaps one of the most secure forms of authentication is the use of one-time passwords (OTPs). OTPs generally come in two forms, either as smart cards or as conventional passwords that are used only one time and then discarded. OTPs are an expensive and fairly major overhaul for most UNIX systems but nevertheless can be a highly effective deterrent to conventional authentication with remembered passwords. The concept here is that the user has some kind of key card that is interactive to the degree

that data can be entered and displayed. When someone logs into a UNIX system with such a hardware token system, the computer presents a “challenge” that can then be “looked up” in the smart card device. For example, the challenge is “harry”; the result that the key card or smart card would display might be “sushjli23876t4,” which is the OTP for logging in to the computer. The next time the user wants to log in, a different challenge is presented and therefore a different password is used. The card is protected because the user still must have a password, or PIN, to enter in the challenge into the card. Of course, if the smart card is compromised as well as the PIN, anyone can log in to the system. The combination of biometrics and hardware tokens is very powerful. Instead of entering a numeric PIN to authorize access to entering the challenge into the smart card, a scan is made of your fingerprint to verify that it is indeed you who is holding the key card (although fingerprints may be fabricated).

One of the more interesting developments over the past several years in the world of authentication is Sun’s creation of the PAM (Pluggable Authentication Module) architecture. PAM delivery has become so popular and makes so much sense that most major UNIX vendors have adopted it, including Linux. A PAM abstracts out *the way in which* authentication takes place and places that implementation in a PAM. Examples of PAMs include implementations for secure cards, for Kerberos, for the chroot command, for ftp, and so forth. Understanding the reasons for PAMs requires understanding why they are needed. The problem is easily seen in Kerberos itself, in that any application that wants to authenticate over Kerberos must be rewritten to do so. We need a Kerberos telnet, a Kerberos ftp, a Kerberos rsh, and so forth. The reason for this rewriting is that the means of authentication is hard coded within each of these applications. The default telnet application assumes a standard UNIX login authentication, not Kerberos. The question is, why not extract out the code that performs the authentication into some external module that the main program loads and then accesses, much like a shared library? With that approach, various modules that provide authentication services differently could be “plugged and played” with various applications quite easily. Thus, to switch from a basic UNIX authentication to a Kerberos implementation does not require rewriting telnet but rather using the Kerberos PAM as opposed to the basic login authenticator. Then, if we wanted to switch telnet to use a smart card, we might use the SecurID PAM, which allows for that capability. As you can see, using PAMs for authentication is highly beneficial, and this is why there have been PAMs written to provide many different forms of authentication, all with a “plug and play” capability.

## Access Control Lists

Just because someone has been authenticated to the system does not mean she is *authorized* to do whatever she wants. Authorization means determining whether an authenticated user is authorized to access in one way or another some resource, whether it be a file, directory, device, or whatever. Authorization can be implemented in a variety of ways. The primary means of authorization is in

the standard UNIX use of file permissions. If I am not the owner of a file nor a member of the group associated with the file and others have no access to the file, I am not authorized to view or modify its contents. Another means of authorization is in the form of access control lists, or ACLs for short. ACLs extend the standard UNIX permissions concept to allow for a finer-grained control of individual files and directories. A directory, for instance, can be wrapped in an ACL, which would then allow you to specify individual user’s rights that go beyond file ownership and group ownership. We can say that the user bob has read only access, user steve has read/write access, the groups lawyers and partners have read/write access, and the group accountants has only read access. We can also specifically deny access to any group or individual, or to everyone, and then specifically add the particular access rights we wish. ACLs are available for most modern UNIX systems, include AIX and HP-UX. Linux and Solaris implement POSIX ACLs. Thus, ACLs help extend the normal UNIX access permission concept to implement a broader range of permission possibilities.

## Role-Based Access Control

Another modern extension to the standard UNIX permissions is the concept of role-based access control, or RBAC for short. By defining roles, permissions can be associated with a given role, users can be added to a role, and those permissions can apply to the role irrespective of the particular target (file or directory) in question. RBACs can be used to give a user or set of users a specific permission to perform a specific activity (and only that activity) that usually needs to be done by the superuser. A role is therefore a subset of activities generally reserved for the superuser. RBACs are specifically supported in AIX and Solaris, and some efforts to support them are under way in other UNIX operating systems, including Linux. Solaris can specify a number of roles that constitute logical accounts, which can assume additional privileges when needed using the su (superuser) command. Both Solaris and AIX support a number of commands specifically tailored to managing the RBAC environment. For example, the chuser command can be used to change role assignments:

```
Chuser roles = ManageBackup bill
```

## Network Security and Firewalls

One of the problems with the introduction of the personal computer was the implicit assumption that security, outside of physical security, was not a problem. This is why early DOS, CPM, and Windows operating systems did not require you to log in when first turning on the computer. UNIX, on the other hand, was always dedicated to the concept of multiple users, and it was not long before the University of California at Berkeley had introduced a good solution for networking UNIX computers together. When one computer is networked to another, a whole new set of security concerns arise, and we need to talk about these as well because there are a number of different types of security problems that are available to keep us up at night. Sometimes network services are designed to allow for minimum security (often because network latency is

always a problem and security further slows things down), such as the original Sun Network File System (NFS) and MIT's X11 XWindows system. Many different bugs were identified early on, and some people gained inappropriate access via those bugs. Equally problematic are bugs in network software (a prime example is the sendmail program), whereby the unscrupulous can cause a program to crash because of a buffer overrun and thereby gain some unauthorized access. Networks communicate via a wire by passing packets from one host to another. Each host assumes that the "host" it is talking to is indeed the legitimate host it thinks it is talking to, but IP spoofing allows one host to impersonate another and thereby possibly allows sensitive information to be derived that can then be used to further penetrate the systems. Most software is written with the legitimate user in mind. It took a while for developers to understand that they also needed to write their software with the more mischievous in mind as well. Of course, the flippant counter to network security is that if you want your computers totally secure, take them off the network. This is akin to saying if you want to rid your body of an infection, shoot yourself. We have to have computers networked to operate our businesses, universities, and governments, and now, even our homes. UNIX has developed a number of technical solutions that are directed toward making network security more of a reality.

### rsh, rexec, and ssh

One of the first attempts to ease networking use in the UNIX environment was to give users the ability to log in remotely to another computer, one that they were not physically in front of. The primary utilities that allowed this were a set of commands known as the "r" commands: rsh, rexec, and rlogin. For example, rsh would allow a user to remotely log in to a shell on another computer on which he had permission. Permission is given either locally to a specific user or globally for a specific computer. Thus, we could allow the user bob to log in to the machine cheiron from the host machine bubba by adding an entry in a file called .rhosts in bob's home directory on cheiron. This way, whenever bob was logged in to bubba and wished to rsh or rlogin into cheiron, he could do so *without having to enter a password*. This is the notion of equivalence. When we add an entry to the .rhosts file, we are essentially saying that the system should consider the hosts cheiron and bubba as being *the same machine* as far as the user bob is concerned. That is to say, once bob has successfully authenticated himself to bubba, cheiron will automatically trust him. The obvious problem here is that once the bob account is penetrated on bubba, further penetrating the host cheiron becomes a walk in the park. The problem is further complicated because there can exist a system wide access file called /etc/hosts.equiv, which allows you to enter all the hosts that are equivalent to this one, so that anyone logged in on one of the equivalent hosts is automatically trusted without having to enter a password to gain access. This creates a wide-open door for unscrupulous users, so much so that the r commands are generally not supported via /etc/hosts.equiv and ~user/.rhosts files anymore. The problem gets worse. Most UNIX systems, if you have physical access, can be booted in something called "single user mode," which is a special

mode designed for system repair and maintenance. The problem is that once booted in single user mode, the user can su to any account she wishes. She can become anyone she wants! Now, if the bob account has an .rhosts file that includes the node that has been booted in single user mode, or if the /etc/hosts.equiv file includes that node, the user can now become root on the remote computer as bob, or anyone else she wants! This user can read other's files and do whatever she wants with impunity under that remote user.

The r commands grew up in the days of the local network that did not have much open access to the outside world. In this sense, these closed networked environments had much to gain from trusted access among the peer computers on the local network. An example of such a small network environment would be the computer network at a local community college, for instance. Common r commands include rwho, rlogin, rsh, rexec, and rcp, a program that lets you remotely copy a file from one computer to another.

However, the r commands can still be used even if global and user access is not defined in the /etc/hosts.equiv and ~user/.rhosts files. The user is simply prompted for a password, and once she enters the correct password, she is authenticated on the remote computer. Simple. Other programs, such as FTP and the common utility telnet, which gives a remote terminal as well, do essentially the same thing. The user enters the computer they wish to connect to, they are prompted to enter their password, and once they enter the password, it is passed over the net to the remote computer and the user is authenticated (or not) and allowed or disallowed access. The problem with the r commands as well as telnet is that when the password is passed over the wire, the password is passed in plaintext! That is to say, if the password is "nobadaddy," the literal string "nobadaddy" is passed over the network, which might well venture through routes that have a sniffer listening for network traffic. The passing of a password over the network in plaintext is tantamount to broadcasting your password on a bulletin board. For this reason, most UNIX networks today do not support the r commands out of the box, and most network firewalls have blocked port 23, which is the port for telnetd.

A nice solution to this problem is delivered with the Secure Shell suite of tools, most notably, ssh and scp. Ssh is a secure shell that allows you to log in to another computer on a network and works just like rsh, with the exception that the entire communication, including password authentication, is conducted over a secure encrypted channel. Scp works basically the same way as rcp except over an encrypted channel, allowing you to copy one file to another computer. Not only is the password sent over in encrypted form, but the entire session is conducted over an encrypted channel. Thus, the ssh suite of tools (which includes sftp) provides a much-needed and highly useful solution to security, and it is based on the familiar protection mechanism of public key cryptography, which we have already discussed. Sshd, the ssh server daemon, allows for significant variations, some would say nontrivial, in management and configuration. For example, administrators can choose to allow or deny port forwarding, RSA authentication, and forwarding of XWindows communication.

There is a commercial version of Secure Shell as well as various open source solutions, the most common of which is Openssh, available at <http://www.openssh.com>. See the chapter on public key standards for more detailed information.

### NIS and NIS+

One of the problems faced by networked UNIX computers is the sharing of a single network-wide password file, which essentially allows any user defined on the network to log into any computer on the network. An administration nightmare arose as system administrators were constantly having to go into each individual node and update the password file there when a new user would come or go. And then there were the ubiquitous exceptions, where user bob would be granted access to all computers with the exception of bubba, whereas user sue would be granted access to all computers, including bubba, with the exception of cheiron. It was a maintenance nightmare full of risks and clearly a centralized solution for the handling of common login definitions was needed. Several different solutions were presented in UNIX, most notably Sun's NIS and NIS+, and Kerberos.

With NIS+ (we will talk about the improved version of NIS only), a single computer is designated as the NIS root domain server (there can be redundant secondary and tertiary servers as well). When a new user is added to the network, the password database (such as `/etc/passwd`) on the root domain server is the only one that is updated. This change is then automatically propagated to the other redundant servers, and all computers that are part of the NIS+ domain are updated so that the new user can log on to any of the machines. This means that once a user has been added into the NIS+ domain, she can log into any computer on that domain to which she has not been specifically denied access. All communication between principals (clients) and the NIS+ root domain server is done via Secure RPC, which offers encrypted communication channels.

NIS+ also supports the notion of groups, which basically simplifies the management of the NIS+ environment and makes it less likely to make mistakes. It is a lot easier to say that bob, sue, debbie, sandy, ralph, and steve are members of the backupadmin group, and to give the Netgroup backupadmin certain access permissions, than it is to individually list all the individual users, especially when it becomes necessary to remove sandy from the list! If we are using groups, all we do is remove sandy from the particular group, and she is removed from all referencing nodes as a backupadmin.

The downside of all this is that the original NIS has often been the initial target of the unscrupulous and the first line of access into a UNIX network. Because NIS manages network access, it is obvious that if you can convince it that you are who you are not, then you can gain additional access information that could be used to further penetrate a UNIX network. NIS+ has shored up many of the easier access points into the network, but some still remain and are sometimes used to break into a network. There are several commands associated with NIS+ that can be used to administer the NIS+ server as well as several user commands, including `nispasswd`, which will allow a user to change his password on the NIS+ server.

### Kerberos

In the early 1980s, MIT, in collaboration with IBM and DEC, attempted to solve the same problem that NIS was designed to solve, but for DEC computers running BSD UNIX. This was how to simplify the administration of multiple users who all need access to various machines on a local network and to do this in a secure fashion. The security is delivered by Kerberos through its use of DES cryptography (see the chapter on data encryption standard for more information on DES). When someone logs in to a Kerberos network, the user is issued something called a *ticket* from the Kerberos server. Log in is done by issuing the command `kinit`. This ticket is encrypted, and all access along the network from that point on is done by passing around this encrypted ticket. This initial ticket delivered is sometimes referred to as the ticket-granting ticket (TGT), because it is used to derive further access tickets from the Kerberos system. By using multiple tickets, audits can be done recording a user's activities throughout the system, something that would be difficult to do with a single ticket per user. Each ticket has a default time to live (TTL), which defaults to eight hours, after which the ticket expires and a new one must be obtained from the server by reauthentication. Thus, whereas the `r` commands used static files to grant equivalent access so that the user did not have to keep reentering his password, Kerberos uses the concept of an expiring ticket to provide basically the same ability. Thus, because Kerberos transactions operate via an encrypted channel, familiar programs such as telnet can be run on Kerberos systems with security. The difference between Kerberos-modified `rsh` and `ssh`, for example, is that by default Kerberos only encrypts the authentication process and the remainder of the session goes over in plaintext. You can pass the `-x` option to Kerberos `rsh`, and then the entire `rsh` session is encrypted, not simply the encrypted ticket negotiation. Kerberos, similar to NIS+, has a number of administration utilities as well as user commands. The user command to change a password in Kerberos is `cpw`, and if the user bob wanted to change his password on a Kerberos system (after an initial authentication), the command might look like this:

```
$ cpw bob
Enter password for principal "bob":
Re-enter password for principal "bob":
Password for bob@MYNET.COM changed.
```

Kerberos is available for most major versions of UNIX, including AIX, Solaris, Mac OSX, Linux, and BSD. It is also available on modern Microsoft Windows servers (2000 and XP, for example). MIT Kerberos source code can be obtained from <http://web.mit.edu/kerberos/www/>. See the chapter on Kerberos for more detailed information on Kerberos and its configuration.

### NFS

One of the things administrators of a network want to do is to make available networked hard drives for access by multiple computers. Very often, on an average UNIX network, the `/opt` mountpoint, for instance, will actually

be a shared directory on a drive on a remote file server. All authorized networked computers will be able to see this drive, and it will appear to the user on the local computer that this drive is actually physically local to the computer in Chicago, whereas in reality it could exist on a file server running in Tokyo. This sort of magic is generally conducted in the UNIX world by using a technology known as Network Filesystem (NFS), originally developed by Sun Microsystems beginning in the early 1980s, first for its SunOS operating system and then later for Solaris.

NFS allows one computer, a file server, to designate certain drives as available for access by clients. This allows a client computer, so authorized, to be able to “mount” the drive or directory on the file server and have that mount appear as “local” to the client node. For example, a file server could have a directory called /opt, it could designate that directory for NFS clients, and then a client machine could mount that remote directory locally, even under /opt if it wanted. Thus, any user could access the “local” /opt directory but all traffic would actually be silently redirected via the network to the remote file server’s /opt directory. Most UNIX networks utilize NFS, and most UNIX users never know that a given directory is NFS mounted, unless, of course, the NFS connection is disrupted, which renders the files unavailable. That is usually the user’s first clue that a particular directory is not actually local but NFS mounted. From a security standpoint, we should mention that NFS is based on Sun’s ONC RPC (remote procedure call) protocol and uses secure RPC for authentication. However, like Kerberos by default, only the process of authentication is encrypted via a secure channel. All further access is done in plaintext, unencrypted. Therefore, when you edit a file that exists on an NFS server, the text of that file is transported over the network as unencrypted plaintext.

An NFS server can designate certain directories it wishes to publish for NFS clients and can also specify which clients have access to that drive and what the character of that access is. This configuration is done by modifying a file called /etc/exports on the NFS server. If we specify an entry in the /etc/exports file on the NFS server called charon, it looks like this:

```
/home  bubba(rw) cheiron(r) lsmtsrvr(rw)
```

We have stated that the directory /home (and all its subdirectories) is accessible by three different nodes: bubba, cheiron, and lsmtsrvr. We have also specified that both bubba and lsmtsrvr have both read and write access (rw) but the cheiron node can only read the data in /home. This is precisely how UNIX manages common home directory structures regardless of to which machine a user logs in. By default, there would be a home directory on every individual computer. NFS allows a file server to store everyone’s home directory, and all client machines can mount that remote directory, making your home directory look the same regardless of from which client computer you are logging in. The way a client computer mounts this home directory (say it is the bubba computer) would be this way:

```
mountcharon:/home/home
```

This tells NFS to attempt to mount the remote /home directory on the NFS server charon under a *local* directory, also called home. Once this is successful, a user on the local machine bubba can do an “ls /home” and see all the subdirectories of the /home directory on the NFS server charon. Because bubba is given both read and write access, individuals can (depending on their standard permissions) manipulate and modify those remote files (obviously primarily only those files that are within their particular home directory). When a client computer is finished with a particular remote mount, it can unmount that NFS directory and it will be rendered unavailable at the client.

NFS uses standard Transmission Control Protocol/Internet Protocol (TCP/IP) for communication, and authentication is based on standard IP host addresses and hostnames. NFS packets are not encrypted nor are they digitally signed. This allows for the possibility that data on its way to an NFS server can be spoofed, which gives a hijacker the opportunity to impersonate a remote client. There are various guidelines offered for making NFS more secure, including not making an NFS client also be a server, not allowing NFS access from outside the local network (i.e., across the Internet), and minimizing the number of server mounts per client so that a single NFS server acts as the file server for an entire organization rather than having multiple servers each export a single directory. You also do not want to export users’ home directories, unless you are running NFS via secure RPC. The possibility of eavesdropping on users’ sessions is one reason for this. Another reason is that an unscrupulous user could gain access to another user’s home directory, plant a .rhosts file there, be able to log in without password authentication to the remote machine as that user, and further attempt to penetrate the network. You should never export directories on the server that expose server binaries, and you should never allow ordinary network users to be able to log into the NFS server. It should be dedicated to serving only NFS mounts and should only be able to be logged in to by the root account.

We should note that there are a number of historical problems with both NIS+ and NFS on UNIX systems, and there exist well-known ways to hack in through these vulnerabilities to wreak havoc. Ways to mitigate these risks, in addition to those previously discussed, include making sure that you are using secure RPC, that all directories to be exported are owned by root, and that certain commands cannot be issued on certain directories (usually /usr/sbin commands operating on central server directories such as /dev). When precautions are taken, both NIS+ and NFS can be run generally within a safe environment as long as the system administrator remains vigilant with patches and updates.

Very often UNIX security begins and ends at the level of TCP connections into the computer network. For this reason, certain security efforts have been directed at this connectivity point, the level of socket connections. We talk about three major areas of interest: TCP wrappers, firewalls and packet filtering, and dial-up security.

### TCP Wrappers

TCP wrappers increase control over incoming TCP connection requests. When a TCP request comes in to a UNIX

computer running TCP wrappers, the `inetd` daemon actually forwards the incoming request not to the daemon that eventually will service the actual request but rather to a wrapping daemon called `tcpd` that implements TCP wrappers. At this point, several things happen automatically. First, the TCP wrappers' subsystem is handed the request, it opens the `/etc/hosts.allow` file, and it reads in access permissions for any incoming computers and requests. Next, it executes the particular program associated with the rule for that particular incoming service (say, for FTP or telnet). If none is found, TCP wrappers will open the `/etc/hosts.deny` file, look to see if any particular node or group of nodes is denied, and if so, will shut down the connection request. If no rule is found in either `hosts.allow` or `hosts.deny`, by default the connection is accepted. Modern versions of TCP wrappers allow you to specify more complex rules in the `hosts.allow` file, giving you the ability to put a single rule in the `hosts.deny` file: "ALL:ALL," which effectively sets forth default policy to deny all hosts. Then, specific rules in the `hosts.allow` file can be issued that specify specific rights for specific hosts. TCP wrappers basically wrap incoming requests within a security blanket of sorts and perform several useful functions, from determining access rights for given nodes via ACLs, logging of results and actions within `syslog`, displaying legal notices as banners to remote connections, performing a double reverse lookup of the IP address of the client, and making sure that the client is really who he claims to be (this option is appropriately termed "PARANOID"). If he is not, the connection is dropped and the attempted spoof is logged. TCP wrappers provides a centralized mechanism for handling network secure connections that may be overlooked or insufficient in any particular network service (FTP, for example). Finally, if everything is allowed and the connection looks legitimate, TCP wrappers will forward the actual connection request to the target daemon dedicated to service such requests.

### Firewalls and Packet Filtering

Another method of handling incoming network requests is the use of a firewall. Most modern UNIX systems come with a default firewall already in place. A firewall is the digital equivalent of a firewall that wraps the interior compartment of a car and sits behind the engine block. It is designed to slow down any explosion or fire that may result from the engine catching fire. An Internet firewall is implemented by a machine that sits publicly on the Internet at the entrance point to the internal network. As such, the firewall intercepts all incoming requests and determines what to do with them. A firewall can be designed to provide up to three core sets of responsibilities: packet filtering, application protection, and IP traffic forwarding.

Packet filtering is a low-level kernel-intensive capability that examines every single incoming packet and filters out those packets that appear to be suspicious in any way. Generally, filtering firewalls will filter on the IP packet's contents itself, source, destination, protocol, and so forth; will filter both incoming and outgoing packets; filter on certain known (problematic) routes; and can disable source routing, as well as specify that the firewall cannot be changed via a network connection but only at the physical console.

IP-forwarding firewalls can be used to protect computers within an internal network but masquerade as an internal computer to the outside world (Internet). This allows internal computers full access to the Internet (for browsing, ssh, etc.) but without having to expose that computer physically to the outside by giving it a public IP address.

Configuring a firewall is nontrivial. The strategy in setting up a firewall on a UNIX system is first of all to disable all inessential protocols and applications. This means if you use ssh instead of telnet, disable the telnet port. If you use scp instead of ftp, disable the ftp port. If you do not need to expose CORBA distributed objects to the outside world, disable the IIOP port (535). If you do not need to run a daytime server, then disable port 13, and so forth. Next, secure the local filesystems on the firewall machine. Definitely disable all NFS and NIS+ access. Mount `/usr` as read only, so sensitive files cannot be overwritten. Make sure minimal permissions exist on files, make files only writeable if absolutely essential. Restrict log in to the machine to root only, and make it available only through a console login. Disable or restrict all outside access to access only via secure channels (such as ssh).

In addition to proprietary firewalls for standard UNIX operating systems, there exist several public/free firewalls, including Socks, `ipchains`, `netfilter`, `ipforward`, and `ipfirewall`, each of which offers various protection capabilities. In addition, many routers and gateways offer internal default firewall capabilities, and often these are even more powerful than their software-based counterparts. See the chapters other chapters in this *Handbook* for more detailed information on firewalls.

## Software Security

Once we have secured the physical computer, the operating system, and access to the system via password protection and authentication, as well as securing the perimeter of the system from potential attacks via the network, we must turn our attention to the various strategies used to secure software applications that our users will be running on a daily basis. The first of these security strategies is application security, and the second is component security.

### Application Security

Application security is usually provided by application vendors themselves. For example, a database system such as Sybase or Oracle will have a system administrator and an associated password that the DBA (database administrator) would keep secret and for which they would be responsible. Applications used by organizations contain highly critical data, and the same precautions concerning password privacy and protection apply to application passwords. As part of the backup strategy, strategies to ensure the integrity of an application and its data should be defined clearly and adhered to, so that if a particular application is lost, the entire application with its associated data can be restored with confidence and integrity.

### Component Security

With the advent of object-oriented software engineering, we now have the potential need to secure distributed objects that have a life of their own. A distributed object

might be provided in the form of a Web service that provides some critical information to an organization, a CORBA (Common Object Request Broker Architecture) object that provides sensitive pricing information, or an EJB (Enterprise Java Bean) object that delivers competitive analyses. Each of these types of distributed components will need to be protected to make sure that anyone who is talking to one of these services is legitimate. Different strategies are employed depending on the precise technology used, but often these strategies follow operating system metaphors, and some more capable and integrated platforms (such as J2EE application servers) will provide ACLs to specifically control which users and applications can call particular features of a particular distributed component.

## SECURITY STRATEGIES

There are several key things a UNIX administrator can remember to do to secure her system. First, allow in only what you know you need and disallow absolutely everything else. Offering every service that is available and accepting incoming connections is a potential avenue for an unscrupulous person to gain access. By limiting your exposure to only those essential services that your system or network must allow in, you can greatly reduce your risk.

Second, keep up to date with all security-related updates, fixes, and patches. Do not fall behind because these patches are designed to protect against known vulnerabilities. If you are behind in your system maintenance, you are exposing yourself to greater risk than is necessary. Certain denial of service attacks are designed to target specific services, and if those services are turned off, it can help to lessen the effect of such attacks (although not always). Along with this, try to use software that is as bug free as possible. Solid software is more stable, and stability is directly correlated with security. One of the most frequently used avenues of entrance into an otherwise secure system is through a known bug in some daemon or server that allows for buffer overruns. Software that is patched to close off a buffer overrun is significantly more secure than unpatched software.

Make sure that your security policy states that your system will perform significant monitoring and logging and auditing of activity. The main way that detection of a break-in occurs is often through examining audit logs. If those logs are not in place, such detection is often slower if it comes at all. The key to recovering from an attack is to first of all recognize when you are under attack. Audit logs and system monitoring can go a long way toward giving you a heads up in case of a breach. Use monitoring software that can give you a heads up whenever changes take place. Software such as Tripwire can be configured to provide a checksum on certain files and will watch for changes to those files, even changes that do not affect the last changed value in the inode.

Always do whatever it takes to secure root access. Never, under any circumstances, give out the root password to anyone who is not officially an administrator of the system. Change the root password often; every day is not too often. Understand that once a cracker has possession of your root password, your entire system is owned

by him and is vulnerable. He can literally do whatever he wants to the system, including planting back doors for future access, deleting or destroying files, stealing data, and so forth.

Make sure your users understand that their participation is required in maintaining a secure system. Make sure your security policy states clearly how passwords are to be managed, including that no one is to ever write their password down on a piece of paper or a sticky note attached to their computer's monitor. Pick good passwords that cannot be guessed either by another person or by a software password cracking system. Never send your password in an e-mail. Never give out your password to anyone, even in an e-mail "apparently" sent by the system administrator. Definitely consider using one-time passwords and smart cards as an overall part of your security system.

## CONCLUSION

UNIX security has been an issue since the introduction of the operating system by Bell Laboratories in 1969. As one of the first hierarchical file systems that has a multiuser system, and therefore the necessity of managing access among multiple users, UNIX has dealt with file security and authentication issues from the beginning. Since then, as threats have increased and the means and methods of invasion have become more sophisticated, especially with the addition of networking in the 1970s, new tools have been added to UNIX to shore up security deficiencies. Managing security threats successfully is an expensive, time consuming, and endless task. It is also a task that must be done diligently or negative consequences are virtually certain.

## GLOSSARY

**Closed Source** Closed source software is software that is released in binary form only. The software source code is not included nor is it made publicly available. See Open Source. Examples of closed source operating systems include Microsoft Windows and, in the UNIX arena, Solaris and HPUX.

**Crack** A program designed to guess hashed UNIX passwords by working off a base password list. It examines an existing passwd file and reports on any "hits."

**Daemon** A program that is specifically written to be run without a console, usually as a system service to provide core system services.

**Data Privacy** The protection of data by making it unreadable by parties not authorized for such viewing and reading. Examples include encryption and compression.

**DNS** Domain naming service. A distributed system that provides mapping between fully qualified domain names and numeric IP addresses.

**Firewall** A hardware-based or software-based solution that provides protection against Internet connection requests, usually to prevent unauthorized access.

**FTP** File transfer protocol. A daemon service that provides an implementation (both server and client) of the FTP protocol, which allows for one or more files to be transferred from one computer to another.

**GNU** GNU's not UNIX. A Free Software Foundation project to provide free UNIX software in source code for multiple platforms.

**GPL** GNU public license. The public source code license for the GNU project. Specifically, the "CopyLeft" license.

**IDEA** A 64-bit block cipher algorithm that uses a 128-bit key for encryption.

**Inetd** A daemon service that manages incoming connections for a list of daemons defined in `/etc/inetd.conf`. Inetd listens for incoming connections and defines the types of services used to satisfy them.

**MD5** An RSA Data Security Inc. message digest algorithm that produces a 128-bit hash of data.

**NFS** Network file system. A protocol and daemon implementation for providing access to remote filesystems.

**NIS and NIS+** Network information service. A service and daemon implementation that provides a centralized database, primarily for common user authentication.

**One-Time Password (OTP)** A password authentication system that provides the ability to have each user have a unique password every single time they log in to the system.

**Open Source** Open source software is software that is made publically available along with the source code. Having the source code available is useful because it allows many different programmers to be able to spot and fix problems with the source code. See Closed Source. Examples of open source operating systems in UNIX are Linux and FreeBSD.

**Pretty Good Privacy (PGP)** A collection of utilities that implement an asymmetric public key cryptography primarily used to secure e-mail transmissions through encryption.

**RSA** An asymmetric public key cryptographic algorithm.

**Secure Shell (SSH)** A protocol and daemon implementation of utilities that allow a user to securely open a remote shell on another computer to which he has access or to copy files via an encrypted channel from one computer to another.

**SHA-1** A cryptographic algorithm that produces a highly secure 160-bit hash.

**Shadow File** A private file associated with `/etc/passwd` that holds the hashed password values for users on a UNIX system.

**Superuser Sudo** A program that provides configurable, controlled root access and a log of activities.

**Syslog** A daemon that handles systemwide logging of information dynamically.

**TCP** Transmission control protocol. A connection-oriented protocol that offers dependable delivery, guaranteed retransmission, and ordering of packets for delivery across a network.

**TCP Wrappers** TCP wrappers increases control over incoming TCP connection requests by providing a single daemon that wraps individual incoming requests in a secure layer.

**Telnet** An insecure daemon implementation and client protocol that establishes a terminal session with a remote computer.

**Tripwire** A utility that records status of UNIX files and notifies you of any changes to those files.

## INTRODUCTION

This chapter was written based on version 9 of the Red Hat Linux and the Red Hat Fedora Core 1 and 2 distributions. Although the examples used in this chapter may focus on a limited set of Linux distributions, the fundamental concepts can be used with nearly every Linux distribution. Each section remains focused on hardening the core operating system using the tools and capabilities of the base installation. The sections do not go into detail on other additive security controls as there are far too many variations to adequately address within the scope of this chapter.

The reader should have an intermediate or greater understanding of Linux/UNIX. Once Linux has been installed, all configuration steps outlined within each section can be performed by the command either via the console or through telnet or SSH (Secure Shell; recommended).

Before beginning a new installation, ensure that the system is deployed within a test environment that best represents the production environment. It is recommended that the system remain unplugged from the production network until the system has been sufficiently hardened.

This chapter covers some of the fundamentals of building and hardening a Linux platform. The topics include hardware security, installation considerations, system initialization, kernel security, networking security, file system security, application security, patch management,

account security, system auditing, backups, and legal protections.

Only after the system has been hardened, patched, and tested should the system be deployed within the production environment.

## THE BASICS

This section covers some of the basic considerations that should be addressed when building a secure Linux system. At the conclusion of this section, the base system should be up and running and the administrator should have a complete understanding of the server's requirements when placed into production.

Following the defense-in-depth model, this section picks up where physical security controls that protect the server itself leave off.

## BIOS

The BIOS (Basic Input Output System) is the first line of defense of any hardened system and there are several features that are available in nearly every BIOS variant.

One feature is the ability to set the order in which the BIOS queries boot devices to look for a boot record. It is recommended that the boot order be set to check the primary hard drive first, followed by the floppy, and CD-ROM devices. Your system's BIOS may also support booting

from a network device in which case this option should be disabled when deploying servers. The important part is that your primary hard drive containing your hardened version of Linux be loaded first. Configuration of the BIOS boot order can be done after you have completed the Linux installation to allow for CD-ROM-based install methods.

Another feature that should be considered is setting a user and administrator password in the BIOS. By setting the user password, you are able to limit who is able to boot the system to only those who know the user password. This is typically limited to system administrators who may be required to reboot the server to perform maintenance. Note that this setting will prohibit a system administrator's ability to remotely reboot the system; a BIOS password will be required after the system is cycled. On the other hand, this will prevent attackers who have physical access to the system from rebooting the server and loading tools that may be used to disable other security controls, thereby granting them uninhibited access to the system. By setting the administrator password, you are able to control who has the ability to modify the BIOS settings, specifically the settings previously modified. This is regarded as a best practice for nearly all production deployment scenarios.

The system administrator should refer to the BIOS software manual for the specific steps to enable these features for the system.

## Installation Considerations

### Getting Started

Before beginning a Linux installation, decisions must be made to determine for what purpose the final system will

---

### Minimum Recommended Partitions and Sizes (20-GB Drive)

<u>Directory</u>	<u>Use</u>	<u>Recommended Partition Size</u>
/	(Root):	2 GB
/boot	(Kernels images):	50 MB
/usr	(System and user binaries):	8 GB
/home	(User directories):	5 GB (50–100 MB per user, e.g., 50 users)
/var	(Application working directories):	3 GB (depends on the application)*
/tmp	(Temporary directory):	1 GB
SWAP	(Linux virtual memory):	1 GB (RAM in MB* 2 up to 1 G)

\*If the server will support a database, then /var will need to be bigger to support the database because it is stored by default in /var.

be used. This may seem like a simple question on the surface; however, several factors and requirements must be taken into consideration before building the server to ensure an optimal configuration. Questions similar to the following must be answered as they will affect various aspects of the installation, configuration, and deployment:

- What type of services will the server provide?
- Will the server host a single service or multiple services?

- Will these services be publicly available or available only on the intranet?
- What are the risks to these services and what is the impact if the server is compromised?
- Where will the server be logically placed on the network?
- What kinds of controls are in place to protect and monitor the server and its services?
- What kinds of controls will need to be installed locally to protect the server and its services?
- Will remote users be allowed to access the server and use local applications and services?
- How will remote access be controlled?
- What type of information will be stored on or passed through the server?
- What is the sensitivity of that information?
- What type of monitoring will be required for this server?
- How granular do the reports and logs have to be?
- How will the server be monitored?

### Partitioning

During the Linux installation process, you will have the opportunity to establish system partitions, allocate space, and determine their mount points. Creating separate partitions for each major file system directory on your Linux system is considered to be a best practice. By creating separate partitions, you can reduce the risk of denial of service attacks that are caused by filling all usable drive space with garbage, limit the impact of exploited SUID (Set User ID) programs, and increase system performance, to name a few.

Note: If the system will be hosting an application that is resource intensive, the SWAP partition may need to be increased. If you notice that the SWAP partition is heavily utilized after deployment, consider increasing the amount of physical RAM.

It should also be noted that if the server is to be deployed as a public service such as an Apache Web server, DNS (Domain Name System), or an FTP (File Transfer Protocol) server, another partition should be created and mounted as

---

<u>Directory</u>	<u>Use</u>	<u>Recommended Partition Size</u>
/chroot	(Chroot jail)	512 MB (dependent on the application)

It is from this directory (or partition) that these public services should be configured and be initialized to operate. See more on *chroot* in the Applications and Services Daemons section.

### Boot Loader

During installation, you will have to choose between the LILO (LI<sup>n</sup>ux LOader) boot loader and the GRUB boot loader. It is recommended that the GRUB boot loader be used to boot the Linux system because of its advanced features and additional security controls. See the next section, Boot Loaders, for more information about how to specifically configure each of these components once the installation is complete. Once the GRUB boot loader is specified, you will be prompted to set a boot loader password. It is recommended that a password be set for the boot loader. This will ensure that only authorized administrators are able to bring up the system. Additionally, this will prevent users with physical access to the system from passing kernel-level boot options that may be used to circumvent or disable other system security controls.

Note: As with the BIOS password, by setting the GRUB boot loader password the system will not be able to be remotely rebooted, because the boot loader password will be required and can only be entered from the system console.

### Host-Based Firewall

During installation, after the network configuration step, you will have an option to enable an *ipchains* firewall. It is recommended that this be enabled and the default configuration set to high with no trusted interfaces and with SSH access allowed (and DHCP if needed). This will provide basic assurances that, out of the box, the system can be trusted to be brought online to take advantage of Red Hat's auto-update capability, *up2date*. Once the system has been adequately hardened and updated, it is recommended that the older *ipchains* be disabled and the newer *iptables* be enabled. See the section on *iptables* for more information.

### Root Password

After the firewall and network interfaces are set up, you will need to set a root password. The password should be nontrivial and contain at least eight characters, including at least one uppercase character, one number, and one special character.

### Authentication Configuration

During this phase of the installation, it must be determined how the system will authenticate users. At a minimum, "Enable MD5 passwords" and "Enable shadow passwords" should be enabled to securely perform local authentication. The other authentication mechanisms take advantage of centralized authentication servers. The optional authentication methods available during installation are NIS, LDAP, Kerberos 5, and SMB or NT domain authentication.

### Application Installation

Most Linux installations out of the box are extremely powerful and flexible. However, to build a properly hardened system, unnecessary packages must not be installed.

Unneeded packages occupy valuable hard drive space, even more valuable memory, and most importantly provide additional avenues for attack and compromise. It is during this phase of the installation that many of the answers to the questions noted earlier must be considered.

It is important that *all* of the "Package Groups" be deselected during this phase. By selecting the "Select Individual Packages" check box and clicking the Next button, you will be able to install only those packages that are needed to fit the deployment requirements of this server. Select only those individual packages that are required; the installation scripts will automatically solve and install other dependent packages.

Note: It is recommended that Linux servers should not have XWindows or any of its components installed. This will significantly reduce the amount of drive space used for the operating system while eliminating a wealth of local and remote attack vectors.

### Boot Disks

During installation, you will be given the option to create a Linux Rescue Disk or boot disk. If you are doing a network-based Linux install and do not have the bootable Linux CDs available, it is highly recommended that you allow the installation program to create these floppy disks for you.

Creating a Linux Rescue Disk under Linux in case bootable Linux installation CDs or floppies are not available can be accomplished as follows:

Note: The boot image can be obtained from the RedHat Linux installation CD under */images* or retrieved via FTP from any RedHat Linux installation mirror. See <http://www.redhat.com/mirrors.html>.

If using the installation CD, mount the first CD, and in either case change directories to the location of the boot image file.

```
[root@TheBox/]# mount /dev/cdrom/mnt/cdrom
[root@TheBox/]# cd/mnt/cdrom/images
```

Insert a blank formatted floppy disk into the disk drive and use the *dd* command to write the image to the disk.

```
[root@TheBox images]# dd if=boot.img of=/
dev/fd0 bs=1440k
[root@TheBox images]# cd ..
[root@TheBox mnt]# umount/mnt/cdrom
```

## SYSTEM INITIALIZATION

Aside from the hardware BIOS, the boot loader is the first opportunity for interaction with the system. If the system is to be deployed within an environment where the lack of physical security controls will allow an attacker access to the console, it is important to ensure that interaction with the boot loader and initialization scripts is limited. This will prevent an attacker from booting the system from other media, simply gaining a root shell on the system by passing boot options, or by booting into single user mode. These recommendations will ensure that the integrity of the system initialization process is maintained.

## Boot Loader

LILO (LInux LOader) is the legacy Linux boot loader that is used to manage the Linux boot process, whether it is from a floppy disk or a hard drive. LILO can also be used to manage the boot process of other operating systems. The following is an example of a default LILO configuration file (*/etc/lilo.conf*). Changes to the configuration file are noted inline.

```
prompt                (remove to prevent console accessible boot options)
timeout=00             (set to zero to prevent console interaction during boot)
default=linux
boot=/dev/sda
map=/boot/map
install=/boot/boot.b
message=/boot/message
linear
restricted           (add this line to ensure a password is required)
password=<bootpassword> (add this line and set the password to set the boot PW)
                        (this password applies to the booting of all images)

image=/boot/vmlinuz-2.4.18-14
    label=linux
    initrd=/boot/initrd-2.4.18-14.img
    read-only
    append="root=LABEL=/"
```

Once */etc/lilo.conf* has been modified and saved, the changes need to be reapplied to the Master Boot Record (MBR). This can be accomplished with the following command executed as root:

```
[root@TheBox etc]# lilo-v
```

GRUB (GRand Unified Boot loader) is the newer, more advanced replacement for the LILO boot loader. The GRUB boot loader, a much more powerful boot loader, has the ability to use MD5 encrypted passwords, and does not require the MBR to be rewritten after a change is made. The following is an example of a GRUB configuration file (*/boot/grub/grub.conf*). Several recommended changes are shown inline.

```
boot=/dev/sda        (specify the primary boot device for all images)
default=0
timeout=00          (set to zero to prevent console interaction during boot)
password-md5<cut&paste hash> (add this line to set the boot PW, the md5 option)
                        (specifies that the password is encrypted, see below)
                        (this password applies to the booting of all images)

splashimage=(hd0,0)/grub/splash.xpm.gz
title Red Hat Linux (2.4.18-14)
root (hd0,0)
kernel/vmlinuz-2.4.18-14 ro root=LABEL=
initrd/initrd-2.4.18-14.img
```

To create the GRUB boot loader password, the utility *grub-md5-crypt* must be run to generate the MD5 hash. This hash must be copied to the `<cut&paste hash>` field.

GRUB does not need to be reloaded to apply these changes. Once the */boot/grub/grub.conf* file has been

modified and saved to disk, changes take effect during the next boot.

## Runlevels

After the Linux kernel is loaded by the boot loader and the system has been initialized, a series of scripts will begin executing to complete the system initialization.

---

The set of scripts are called init scripts and they control how the system is brought up and what services will be available. These scripts reside in the */etc/rc.d/* directory. Initially, */etc/rc.d/rc*, */etc/rc.d/rc.sysinit*, and */etc/rc.d/rc.local* will be executed, followed by the set of scripts within the */etc/rc.d/rc#.d/* directory, where the number (#) is the specific runlevel in which the system will be operating. Runlevels are defined as the following:

- 0: Halt (do not set *initdefault* to this),
- 1: Single user mode (administrative mode),
- 2: Multiuser, without NFS (the same as 3, if you do not have networking),

- 
- 3: Full multiuser mode (server mode),
  - 4: Unused,
  - 5: X11 (workstation mode), and
  - 6: reboot (do not set *init default* to this).

Just before the scripts defined by the system runlevel are executed, by default the system allows console user interaction to define the runlevel into which the system will boot. This interaction should be disabled by modifying the last line in the `/etc/sysconfig/init` file:

```
[root@TheBox sysconfig]# cat init
# color => new RH6.0 bootup
# verbose => old-style bootup
# anything else => new style bootup without ANSI colors or positioning
BOOTUP=color
# column to start "[ OK ]" label in
RES_COL=60
# terminal sequence to move to that column. You could change this
# to something like "tput hpa ${RES_COL}" if your terminal supports it
MOVE_TO_COL="echo-en\\033[${RES_COL}G"
# terminal sequence to set color to a 'success' color (currently: green)
SETCOLOR_SUCCESS="echo-en\\033[1;32m"
# terminal sequence to set color to a 'failure' color (currently: red)
SETCOLOR_FAILURE="echo-en\\033[1;31m"
# terminal sequence to set color to a 'warning' color (currently: yellow)
SETCOLOR_WARNING="echo-en\\033[1;33m"
# terminal sequence to reset to the default color.
SETCOLOR_NORMAL="echo-en\\033[0;39m"
# default kernel loglevel on boot (syslog will reset this)
LOGLEVEL=3
# Set to anything other than 'no' to allow hotkey interactive startup...
PROMPT=no
[root@TheBox sysconfig]#
```

administrator to build the system drivers as kernel objects as opposed to modules. The trade-off is the reduction of system flexibility to the introduction of new hardware; the kernel will have to be recompiled to support the new device.

## KERNEL SECURITY

The Linux kernel is the core of the Linux system and there are several kernel configuration options that should be considered when building a hardened Linux system. One of the primary steps involved in hardening a Linux system is to recompile and install a new optimized Linux kernel. This section will provide some insight into some of the various kernel modifications that can be made as well as make several recommendations for modifying the running kernel.

### Recompiling

Although the process and caveats involved with recompiling and installing a new Linux kernel are outside the scope of this chapter, it is highly recommended, after the installation of a new Linux system, that a new Linux kernel be recompiled and installed. The kernel should be rebuilt from pristine source with only the modules, drivers, and features that are absolutely required to operate the system. This reduces system complexity, increases performance, and ultimately increases overall system security by reducing the number of avenues by which an attacker can exploit the system. Additionally, if the system will be deployed within a hostile or untrusted environment, an additional control can be applied to the system during kernel configuration. LKM (Loadable Kernel Modules) support can be disabled to prevent the installation of LKM rootkits and other backdoors but will require the system

The current kernel source code can be downloaded from <http://www.kernel.org>. All of the necessary documentation and instructions for compiling and installing a new Linux kernel are also available on this site.

There are several configuration options that should be taken into consideration when compiling the new kernel. These options and their respective setting are listed here. For more information, use the Help feature in the kernel configuration menu.

- Networking options --->
  - [\*] Network packet filtering (replaces ipchains)
  - [\*] IP: TCP syncookie support
  - IP: Netfilter Configuration --->
    - (all options should be enabled)
  - [ ] IP: multicasting
  - [ ] IP: advanced router
- File systems --->
  - [\*] Quota support
  - <\*> Ext3 journalling file system support
  - [\*] JBD (ext3) debugging support

After the new kernel has been compiled, installed, and verified to work properly, the kernel source tree should be deleted to prevent the modification and recompilation of the kernel or any of its modules by an attacker. This would also be a good time to remove the compiler to prevent the compilation of attack tool source code that may be uploaded to the system by an attacker. See the section on

RPM (RedHat Package Manager) for more information about how to remove packages.

## Kernel Modifications

Several patches have been made available by the open source community to add various security features into the stock Linux kernel. Among many of the features provided by each of the patches, buffer overflow protection, role-based access control, and SUID/SGID (Set Group ID) controls are common additions. Each of the patches listed here should be reviewed and fully tested before using the new kernel in a production environment.

- **Openwall Project** (<http://www.openwall.com/linux/>). This patch adds a variety of features such as stack protection, */tmp* restrictions, */proc* access control, user process, and shared memory destruction. This patch is available for 2.4, 2.2, and 2.0 Linux kernels.
- **Grsecurity 2.0 RBAC** (<http://www.grsecurity.net/features.php>). This patch brings Role-Based Access Control (RBAC), process-based Mandatory Access Control (MAC), chroot restrictions, stack protection, and kernel auditing among many other features to the 2.4 Linux kernel.
- **LIDS** (<http://www.lids.org/>). LIDS is short for Linux Intrusion Detection System. LIDS adds Mandatory Access Control (MAC) with a userspace administrator tool, port scan detection, process and file protection, and process network access restriction. The LIDS kernel patch supports the 2.6, 2.4, and 2.2 Linux kernels.
- **SE-Linux** (<http://www.nsa.gov/selinux/>). Security Enhanced Linux was developed by the National Security Administration to improve the security of the Flask operating system. The project is a kernel replacement that provides Mandatory Access Control (MAC), stack protection, Role Based Access Control (RBAC), and was designed with many of the high-assurance security principles from the Trusted Operating System (TOS) model.

## */proc*

The */proc* directory is the pseudo-file system that is used as a real-time interface to kernel variables. This is a logical directory that does not exist on the physical drive but instead is created and mounted by the kernel during system boot. The special */proc* directory contains subdirectories and files that can be modified to affect system performance and security. Following are several suggested */proc* changes to improve the security of the system. It is important to note that every system is different and the effect of each change should be taken into consideration given the system, its environment, and planned deployment. Inappropriate or invalid changes may crash the system.

The files within */proc* can be modified directly with any text editor; however, the tool */sbin/sysctl* can be used to quickly display and modify (with the “-w” switch) any */proc* kernel parameter. Note that using *sysctl* or by editing a */proc* file directly, the system administrator will be

modifying parameters of the running Linux system and these changes are not persistent across system reboots. The file */etc/sysctl.conf* can be modified to ensure */proc* changes are maintained.

Additional documentation can be found with the kernel source code (if installed) in the following directory on the local system: */usr/src/linux-2.4/Documentation/sysctl*.

## Net.Core—Configure the Networking Subsystem

- **Window Size.** By increasing the maximum window send buffer size, a server can take advantage of the larger data queue for its client connections. The default size is 64 k for workstations and it is recommended that at least 1 Mb be used for servers (1Mb is 1000 \* 1024 = 1,024,000). This setting will improve network performance for servers.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.core.wmem_default=1024000
[root@TheBox root]# sysctl -w net.core.wmem_max=1024000
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Increase Maximum Window Size
net.core.wmem_default = 1024000
net.core.wmem_max = 1024000
```

## Net.IPv4—Configure the IPv4 Protocol

- **Source Routing.** Packets received through a specific set of routes specified by the sender should be dropped.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.conf.default.accept_source_route=0
[root@TheBox root]# sysctl -w net.ipv4.conf.all.accept_source_route=0
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Ignore Source Routed Packets
net.ipv4.conf.default.accept_source_route = 0
net.ipv4.conf.all.accept_source_route = 0
```

- **IP Spoofing.** By setting this parameter to 1, the system will verify the source address of new connections by validating the reverse path as specified in RFC 1812 (Baker 1995).

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.conf.default.rp_filter=1
[root@TheBox root]# sysctl -w net.ipv4.conf.all.rp_filter=1
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Ignore Spoofed addresses
net.ipv4.conf.default.rp_filter = 1
net.ipv4.conf.all.rp_filter = 1
```

- **Logging.** By telling the kernel to log “martians,” all IP packets that are received with impossible addresses will be logged via SYSLOG.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
  conf.default.log_martians=1
[root@TheBox root]# sysctl -w net.ipv4.
  conf.all.log_martians=1
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Log All Out of Spec Packets
net.ipv4.conf.default.log_martians = 1
net.ipv4.conf.all.log_martians = 1
```

- **Forwarding.** Unless the system will be deployed as a router or firewall, IP packet forwarding should be disabled across all interfaces.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
  conf.default.forwarding=0
[root@TheBox root]# sysctl -w net.ipv4.
  conf.all.forwarding=0
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Disable Forwarding
net.ipv4.conf.default.forwarding=0
net.ipv4.conf.all.forwarding=0
```

- **Local Ports.** This setting allows the system administrator to control which source ports the Linux system will use for initiating new requests. This may be useful when the system is required to initiate new connections to other systems when there is firewall in between them. A system deployed in a DMZ (Demilitarized Zone) is an example of this scenario where all ingress connections from the DMZ into the intranet need to be tightly controlled.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
  ip_local_port_range='32768 61001'
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Set the local port range
net.ipv4.ip_local_port_range = 32768 61000
```

## Net.IPv4.ICMP—Configure ICMP

- **Ignore ICMP Ping.** If the system will be publicly available without the protection of a firewall, it is recommended that the system be configured to ignore ICMP pings (echo requests). Aside from adding a layer of obscurity to the system, ignoring ICMP Ping also prevents an attacker from using covert channel tools such as LOKI that take advantage of slack space within ICMP echo packets to communicate with compromised systems.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
  icmp_echo_ignore_all=1
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Ignore Echo Requests
net.ipv4.icmp_echo_ignore_all = 1
```

- **Ignore ICMP Broadcast.** To prevent the system from being a part of an ICMP broadcast storm denial of service, ICMP echo broadcasts should be ignored. This setting also adds a layer of obscurity by making broadcast ICMP echo request mapping techniques ineffective for this host.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
  icmp_echo_ignore_broadcasts=1
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Ignore ICMP Broadcasts
net.ipv4.icmp_echo_ignore_broadcasts = 1
```

- **Ignore ICMP Redirects.** ICMP redirects can be used to modify the system’s routing table and should be ignored. Note that with networks that employ complex routing schemes where more than one router serves as a default gateway for the system, this capability should not be disabled.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
  conf.all.accept_redirects=0
[root@TheBox root]# sysctl -w net.ipv4.
  conf.default.accept_redirects=0
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Ignore ICMP Redirects
net.ipv4.conf.all.accept_redirects = 0
net.ipv4.conf.default.accept_redirects = 0
```

- **Bad ICMP Error Messages.** By setting this parameter, the system will ignore malformed and invalid ICMP error messages from other hosts. This usually caused by

routers that violate RFC 1122 (Braden 1989) by sending bogus ICMP responses to broadcast frames.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
icmp_ignore_bogus_error_responses=1
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Ignore Bogus ICMP Error Messages
net.ipv4.icmp_ignore_bogus_error_responses=1
```

### Net.IPv4.TCP—Configure TCP

- **SYN Cookies.** Enabling SYN cookies will help to reduce the risk of SYN flood denial of service attack. SYN cookies are only used when the TCP SYN receive buffer is full and the system is unable to accept new legitimate connection requests. At this point, the system will begin to use SYN Cookies to eliminate the need to store previous connection requests (TCP SYN packets), thus clearing the receive buffer. For more information on SYN Cookies, see the references at the end of this chapter.

Modify the running kernel:

```
[root@TheBox root]# sysctl -w net.ipv4.
tcp_syncookies=1
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Use SYN Cookie Protection
net.ipv4.tcp_syncookies = 1
```

- **TCP Backlog.** Set an upper limit to the backlog queue of new connection requests. This is used to throttle the number of new connection requests to prevent the system from being overloaded by a SYN flood. As long as SYN Cookies are enabled, once the queue is full, the kernel will begin to use SYN Cookies and the system will not drop new connection requests (SYN packets).

Modify the running kernel:

```
[root@TheBox root]# sysctl-w net.ipv4.
tcp_max_syn_backlog=4096
```

Modify the */etc/sysctl.conf* file by adding the following lines:

```
#Set max per socket backlog queue
net.ipv4.tcp_max_syn_backlog = 4096
```

## NETWORK SECURITY

One of the fundamental requirements for securing a Linux system is the ability to control not only what services are externally available but also the ability to control the network traffic to and from those services. This capability is

provided by the NetFilter mechanism, which is used to build a stateful packet-filtering host-based firewall. This section reviews some of the basic network interface management tools and configuration files. In conclusion, the NetFilter mechanism is reviewed by demonstrating some of the basic capabilities of the firewall as well as by providing a sample configuration that includes some of the “must haves” of any stateful packet-filtering host-based firewall. It is assumed that the system administrator has a basic understanding of the TCP/IP protocol suite.

## Network Interface Configuration

This section quickly outlines the steps and files involved with configuring a system once it is brought into the test network environment.

### Interfaces

Interfaces on a Linux system can be controlled and configured in a variety of ways. One such way is by using the */sbin/ifconfig* tool. This utility will allow a system administrator to display and modify enabled network interfaces.

Another way to control network interfaces is by using the */sbin/ifup* and */sbin/ifdown* scripts provided by the *initscripts* RPM. These scripts read a set of files from within */etc/sysconfig/network-scripts* directory to configure and enable (or disable) network interfaces. An example configuration file for an Ethernet interface would be named *ifcfg-<devicename#>* and would have contents similar to the following:

```
[root@TheBox network-scripts]# cat ifcfg-eth0
IPADDRESS=10.1.1.50
NETMASK=255.255.255.0
GATEWAY=10.1.1.1
BOOTPROTO=none
ONBOOT=yes
DEVICE=eth0
```

The */sbin/ifup* script will source this configuration file when executed by using */sbin/ifup eth0* on the command line.

### DNS

DNS configuration is maintained in the */etc/resolve.conf* file, the contents of which should look similar to the following:

```
[root@TheBox etc]# cat resolv.conf
search localdomain
nameserver 10.1.2.100
nameserver 10.1.1.100
```

If there are hosts whose names are not maintained by the DNS servers previously specified, their names and respective IP addresses can be configured in the */etc/hosts* file. This is also an easy way to configure the hostname of the Linux system, considering many of the startup scripts will identify the system name though DNS. The contents of the *hosts* file should look similar to the following:

```
[root@TheBox etc]# cat hosts
# Do not remove the following line, or various programs
# that require network functionality will fail.
127.0.0.1          localhost.localdomain localhost
10.1.1.50         TheBox

#Other obscure unresolvable hosts (hosts not within DNS tables)
10.1.132.54      Hiddenbox
```

## Routing

To set up the default route for the system, the `/sbin/route` tool can be used. If the `/sbin/ifup` script was utilized and the configuration file had a valid GATEWAY defined, the default route should already be set up. Using this example, the default route can be verified with the route command:

```
[root@TheBox/]# route -n
Kernel IP routing table
Destination     Gateway         Genmask         Flags   Metric      Ref     Use    Iface
10.1.1.0        0.0.0.0        255.255.255.0   U       0           0       0     eth0
127.0.0.0      0.0.0.0        255.0.0.0       U       0           0       0     lo
0.0.0.0        10.1.1.1       0.0.0.0         UG      0           0       0     eth0
```

The default route can be set by using

```
[root@TheBox/]# route add default gw 10.1.1.1
```

## Link Speed and Duplex

Once the Ethernet interface is up and is configured properly, it is recommended that the link speed and duplex be set manually using the `/sbin/mii-tool` that is distributed with the `net-tools` RPM. Note: The Ethernet interface must have a Media Independent Interface (MII) unit to use this tool. If not, reference the Ethernet driver documentation to determine if the media state can be set via the driver software. Run the tool on the command line with no options to see if the interface has an MII.

As long as the interface and the switch, or hub, to which the system is connected supports it, both the switch port and the network interface should be set to 100 (or 1000 if supported) BaseTx-FD (Full Duplex). Note: Coordinate with the network administrators to ensure the switch is properly configured as well.

```
[root@TheBox/]# mii-tool -F 100baseTx-FD eth0
```

## Netfilter

Netfilter is the stateful packet filtering, network address translation (NAT), and packet mangling framework that has been built into the 2.4.x Linux kernel. The framework consists of four major components: Netfilter (the kernel hooks), connection tracking, NAT, and IPTables (the administration tool). The Netfilter framework has been developed as the improved replacement for IPChains of the 2.2.x Linux kernels and ipfwadm of the 2.0.x Linux kernels.

System administrators can use NetFilter/IPTables to build stateful packet filtering firewalls (or host-based firewalls) that are capable of network address translation (NAT), port address translation (PAT), connection tracking, packet manipulation, and QoS.

## IPTables Overview

The configuration tool, IPTables, is used by administrators to build chains that contain filter rules through which all packets traversing a network interface will pass. Figure 1 shows NetFilter/IPTables packet flow. Depending on the rules within each chain and default policies, the fate (or target) of each packet will be

- **DROP:** drop the packet,
- **ACCEPT:** allow the packet to pass through,
- **QUEUE:** (if supported by the kernel) pass the packet to userspace, or
- **RETURN:** stop traversing the chain and continue with the next rule (or use the chain default policy if match is at the end of the built-in chain).

Packets traverse NetFilter as follows:

## IPTables “Filter” Tables

One of the primary steps when hardening a Linux system is to implement a host-based firewall. The “Filter” tables in the Netfilter suite provide the administrator the ability to control all types of IPv4 traffic into and out of the system. The other two tables, “Mangle” and “NAT,” have advanced capabilities that can be used to increase network performance (IPv4 TOS) or help to obscure running services. See the Netfilter (<http://www.netfilter.org>) Web site for more information.

There are three built-in chains where other user-defined chains or filter rules are linked or defined, respectively. These chains are the following:

- **INPUT:** Defines the chain that all packets entering an interface traverse.
- **OUTPUT:** Defines the chain that all packets leaving an interface traverse.

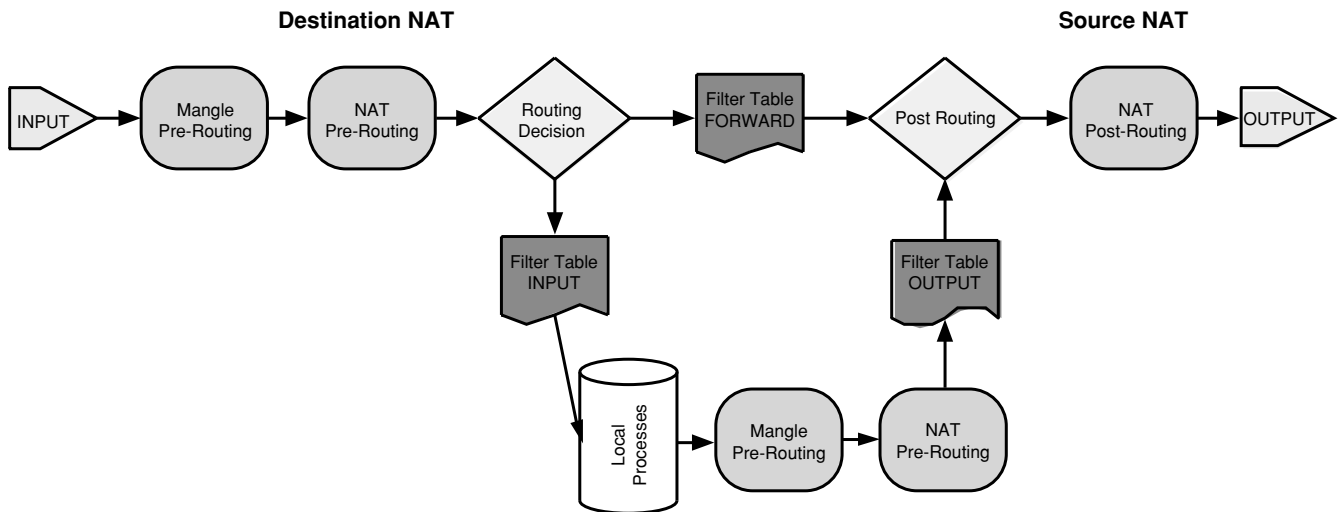

Figure 1: Netfilter/IPTables packet flow.

- **FORWARD:** Defines the chain that all packets traverse if a packet is forwarded across two interfaces.

Chains can be manipulated using the IPTables administration tool as follows:

Rules within a chain follow this syntax:

```
/sbin/iptables -< command> <chain name> [match parameter][match extension] -j [target]
```

### Commands

---

-A	Append a rule to a chain
-D	Delete a rule from a chain
-I	Insert a rule into a chain
-R	Replace a rule in a chain
-L	List the rules in a chain (or all chains)
-F	Flush a chain of its rules
-N	Create a new chain
-X	Delete a user defined chain
-P	Set the default policy (target) of a chain

### Match Parameters

-p	TCP/IP OSI Layer 4 protocol (TCP/UDP/ICMP)
-s	Source IP address
-d	Destination IP address
-i	In interface (used for INPUT and FORWARD chains)
-o	Out interface (used for OUPUT and FORWARD chains)

### Match Extensions

(Sample; see Netfilter Documentation for more information.)

--sport	Source port for TCP/UDP protocols
--dport	Destination port for TCP/UDP protocols
--state	Maintain state for TCP
NEW	Match on new TCP connections
ESTABLISHED	Match on established TCP connections
RELATED	Match on related TCP connections
INVALID	Match on invalid TCP connections
--icmp-type	Specify ICMP type to match on

**Table 1** RFC 1918 Allocation for Private Networks

Prefix	Range	Block
10/8 prefix	10.0.0.0–10.255.255.255	Single class A block
172.16/12 prefix	172.16.0.0–172.31.255.255	16 continuous class B blocks
192.168/16 prefix	192.168.0.0–192.168.255.255	254 continuous class C blocks

The last parameter, “target,” as described previously, is the policy on how to treat the packet once a match is made.

## Host-Based Firewall

This section outlines two considerations when building a host-based firewall and provides a sample configuration of an IPTables firewall.

### RFC 1918 (Rekhter 1996): Address Allocation for Private Internets

This RFC specifies which IPv4 addresses are allocated for private internets or intranets. The address ranges specified within this RFC should only be used on private networks and should not be allowed to traverse the Internet. As such, these IPs should not be permitted to enter or leave the network. The Bogon list, Table 1, and the example that follows address this.

### Bogon List

Bogons are network prefixes that have not yet been allocated by IANA, Internet Assigned Numbers Authority (<http://www.iana.org>), and therefore should never be routed across the Internet. Traffic that appears to originate

from these networks is not valid and should be dropped. Rob Thomas maintains the Bogons list in various formats at <http://www.cymru.com/Documents/bogon-bn.html>.

IANA updates this list periodically as new networks are allocated to corporations, agencies, or other registries. This list should be reviewed periodically and updated for changes.

### Connection Tracking

One of the components of the Netfilter suite is the connection tracking system. This is the Netfilter component that brings the ability to maintain connection state to the Linux kernel. As such, the total number connections Netfilter is able to simultaneously track or maintain the state of should be increased, or decreased, depending on the total number of connections the system can handle. The sample setting shown at the end of the sample script should be adequate for most systems.

### Sample Basic IPTABLES Script

This script should be modified to take into consideration the services the system may be running as well as the IP addressing scheme of the network in which the server will reside. Specifically, the Bogon list may have to be modified to allow local private, RFC 1918 addresses.

```
#!/bin/sh

## FILE SYSTEM SECURITY

One of the easiest and yet most effective ways to ensure the integrity of the Linux platform is maintained is through the file system. There are a number of ways a system administrator can configure and set permissions on partitions, directories, and files to prevent the disclosure and modification of system files. This section will outline several of these controls and provide guidance on a few file types and permissions that the system administrator should periodically look for while performing regularly scheduled system maintenance.

---

```

ro:                Mount the partition in read-only mode.
rw:                Mount the partition in read-write mode.
nouser            (user):  Prevent users from mounting the partition.
noexec           (exec):  Prevent program execution on the partition.
nosuid           (suid):  Disable the SUID/SGID bits for the partition.
nodev            (dev):  Do not interpret character or block devices on the partition.
defaults:        Pass default options (rw, suid, dev, exec, auto, nouser, async).

```

---

## Mount Control

One of the more effective controls that can be implemented for a Linux system is the control over partition permissions. There are several options that can be used when mounting a file system to ensure that various permissions are enforced partition-wide. For example, the

system administrator can disable the ability of users to execute programs from a given partition. It is because of this ability to define access and execution permissions during system boot that the partitioning scheme chosen during system installation (refer to Installation Considerations) was used.

The */bin/mount* utility is used to mount disk partitions. It is this same program that is used during system boot when the startup scripts begin to mount the disk partitions. Some of the access control mount options that can be passed via the */bin/mount* utility are listed here:

Note: The permissions pertain to the Linux ext2 and ext3 file systems. Refer to the <http://www.kernel.org> documentation for additional options that may be specific to other file systems.

The file */etc/fstab* contains all of the mount options for each partition. This file is sourced when the system boots and begins mounting the file systems or when the system

administrator uses the `/bin/mount` utility without supplying options. If the drive was partitioned as shown above (refer to Installation Considerations), the default `/etc/fstab` will look similar to this:

```
[root@TheBox/etc]# cat /etc/fstab
LABEL=/                /                ext3                defaults            11
LABEL=/boot            /boot            ext3                defaults            12
LABEL=/usr              /usr             ext3                defaults,nosuid,ro  12
LABEL=/home            /home           ext3                defaults            12
LABEL=/var              /var             ext3                defaults,nodev      12
LABEL=/tmp              /tmp            ext3                defaults,noexec,nosuid 12
LABEL=/chroot           /chroot         ext3                defaults            12
None                   /dev/pts        devpts             gid=5,mode=620     00
None                   /proc           proc               defaults            00
None                   /dev/shm        tmpfs              defaults            00
/dev/sda3               swap            swap              defaults            00
/dev/cdrom              /mnt/cdrom      iso9660            noauto,owner,ro   00
/dev/fd0                /mnt/floppy     auto               noauto,owner      00
```

The recommended changes are shown in bold. There is one important recommendation that should be noted; the “RO” (read-only) option for `/usr`. This is an extremely effective control as it prevents users and ultimately attackers from modifying scripts, binaries, or any other file on this partition. The trade-off is that before the system can be updated, this partition will have to be remounted as “RW” (read-write) so that files on this partition can be overwritten with the updates. This may be a problem for patch management solutions where the update scripts cannot be modified to take this into consideration.

Once the `/etc/fstab` configuration file has been modified, the system administrator can remount the partition using the new options by issuing the following command for each partition that was updated:

```
[root@TheBox/]# mount <mountpoint> -oremount
```

## Files and Directories

There are several steps that can be taken to further enhance the security of the Linux file system. These additional measures are outlined and should be reviewed periodically once the system goes into production. The following should be checked and verified on a weekly basis by the system administrator during regularly scheduled system maintenance:

- Check files and directories for valid owners and groups.
- Check for unowned files and directories.
- Check and validate world writable files.
- Check and validate world writeable directories.
- Check for the existence of unusual files.
- Check and validate root-owned SUID/SGID programs.

Note: All of these checks can be automated and their results e-mailed to the system administrator. See the section on Unusual Files for additional information.

## System Files

The utilities `/usr/bin/chattr` and `/usr/bin/lsattr` allow a system administrator to change and list the ext2 and ext3 file system attributes of a file. With `/usr/bin/chattr`, the system administrator can set the immutable flag (+i)

on any file to prevent it from being accidentally or maliciously deleted or overwritten. The `/usr/bin/lsattr` simply lists files within any particular directory and displays the ext2/ext3 file attributes. See ext2/ext3 file system documentation for more information. The following changes are recommended:

```
[root@TheBox etc]# chattr +i /etc/services
[root@TheBox etc]# chattr +i /etc/passwd
[root@TheBox etc]# chattr +i /etc/group
[root@TheBox etc]# chattr +i /etc/shadow
```

```
[root@TheBox etc]# lsattr /etc
...
---i----- /etc/group
...
---i----- /etc/passwd
...
---i----- /etc/services
...
---i----- /etc/shadow
```

The utility `/bin/chmod` can be used to change the mode or permissions of a file or directory. Each file or directory can be assigned three basic permissions: read, write, or execute. Additionally, each of these permissions can be assigned to three classes of users: owner, group, and other or world. The permission format is as follows:

The output of the `/bin/ls -l` command will be a list of files within any particular directory and all of their permissions:

```
[root@TheBox etc]# ls -l
total 2388
-rw-r--r-- 1 root root 15228 Aug 5 2002 a2ps.cfg
-rw-r--r-- 1 root root 2562 Aug 5 2002 a2ps-site.cfg
-rw-r--r-- 1 root root 50 Dec 19 17:08 adjtime
drwxr-xr-x 4 root root 4096 Oct 23 2002 alchemist
...
```

Figure 2: file and directory permissions.

File and directory permissions can be modified by using octal notation to specify each bit of the permissions specifically or by using the first letter of the permission group to modify (u: user, g: group, o: other or world) followed by a + or -, then the permission that needs to be added or removed (r: read, w: write, x: execute), as indicated in Figure 2. The files within the following directories should have their default permissions changed to ensure that users cannot accidentally or maliciously modify them. (Note: The default install of RedHat 9 and Fedora Core has many of these permissions already set. However, it is still a safe practice to follow up and ensure that each permission is set correctly.)

---

```
[root@TheBox/]#chmod 0700/home/*          (-rwx-----)
[root@TheBox/]#chmod 0640/etc/xinetd.d/*  (-rw-r-----)
[root@TheBox/]#chmod 0751/etc/sysconfig   (-rwxr-x--x)
[root@TheBox/]#chmod 0751/var/log         (-rwxr-x--x)
[root@TheBox/]#chmod 0750/etc/pam.d       (-rwxr-x---)
[root@TheBox/]#chmod 0750/etc/security    (-rwxr-x---)
[root@TheBox/]#chmod 0750/etc/rc.d/init.d (-rwxr-x---)
[root@TheBox/]#chmod 0750/etc/init.d      (-rwxr-x---)
```

---

The following files should have their default permissions changed to ensure that users cannot accidentally or maliciously modify them.

---

```
[root@TheBox/]#chmod 0700/etc/init.d/*    (-rwx-----)
[root@TheBox/]#chmod 0550/etc/cron.hourly/* (-r-xr-x---)
[root@TheBox/]#chmod 0550/etc/cron.daily/* (-r-xr-x---)
[root@TheBox/]#chmod 0550/etc/cron.weekly/* (-r-xr-x---)
[root@TheBox/]#chmod 0550/etc/cron.monthly/* (-r-xr-x---)
[root@TheBox/]#chmod 0644/etc/passwd       (-rw-r--r--)
[root@TheBox/]#chmod 0644/etc/group        (-rw-r--r--)
[root@TheBox/]#chmod 0400/etc/shadow       (-r-----)
[root@TheBox/]#chmod 0600/boot/grub/grub.conf (-rw-----)
[root@TheBox/]#chmod 0600/etc/sysconfig/iptables (-rw-----)
[root@TheBox/]#chmod 0600/etc/sysctl.conf  (-rw-----)
[root@TheBox/]#chmod 0600/etc/inittab      (-rw-----)
[root@TheBox/]#chmod 0600/var/log/messages (-rw-----)
[root@TheBox/]#chmod 0640/etc/logrotate.conf (-rw-r-----)
[root@TheBox/]#chmod 0660/var/log/wtmp     (-rw-r-----)
[root@TheBox/]#chmod 0400 /var/log/lastlog (-r-----)
[root@TheBox/]#chmod 0640/etc/hosts.allow (-rw-r-----)
[root@TheBox/]#chmod 0640/etc/hosts.deny  (-rw-r-----)
[root@TheBox/]#chmod 0600/etc/securetty   (-rw-----)
[root@TheBox/]#chmod 0640/etc/xinetd.conf (-rw-r-----)
```

---

## SUID/SGID

SUID/SGID (Set User ID/Set Group ID) bit is used to allow a program to run in the context of either the file owner or group. This may be useful when a program needs a higher privilege level to execute than the user running the program has been granted. Conversely, this capability is also dangerous because this may also allow a malicious user to take advantage of the program to escalate their privilege level. SUID/SGID programs become particularly dangerous when the file is owned by root. Unchecked buffers within root owned SUID/SGID program could allow a local attacker to gain root privileges. The following command will help a system administrator identify all programs on the system that have the SUID or SGID bit set.

Note: Do not indiscriminately remove the SUID/SGID bit from all programs because some are required for the system to operate. Removing the SUID/SGID bit from certain files will also disable capabilities that users should be able to do, such as changing their password.

```
[root@TheBox/]#find/-type f \(-perm-04000-o-perm-02000\) -exec ls-l{} \;
-rwsr-xr-x 1 root root 37624 Feb 12 2003/usr/bin/chage
-rwsr-xr-x 1 root root 34972 Feb 12 2003/usr/bin/gpasswd
-r-xr-sr-x 1 root tty 10224 Jul 18 2002/usr/bin/wall
-rws--x--x 1 root root 16835 Aug 30 2002/usr/bin/chfn
-rws--x--x 1 root root 15664 Aug 30 2002/usr/bin/chsh
-rws--x--x 1 root root 6999 Aug 30 2002/usr/bin/newgrp
-rwxr-sr-x 1 root tty 18605 Aug 30 2002/usr/bin/write
-rwxr-sr-x 1 root root 37140 Jul 24 2002/usr/bin/at
...
```

Once the SUID/SGID root files have been found, the */bin/chmod* utility can be used to remove the SUID/SGID bit. It is recommended that the following root-owned programs have their SUID/SGID bits removed. Note: There are several root-owned programs with the SUID/SGID bits set that are required for normal system operation. Be sure to use discretion when removing the SUID/SGID bits on other programs.

```
[root@TheBox /]# chmod -s /usr/bin/chage
[root@TheBox /]# chmod -s /usr/bin/gpasswd
[root@TheBox /]# chmod -s /usr/bin/wall
[root@TheBox /]# chmod -s /usr/bin/chfn
[root@TheBox /]# chmod -s /usr/bin/chsh
[root@TheBox /]# chmod -s /usr/bin/newgrp
[root@TheBox /]# chmod -s /usr/bin/write
[root@TheBox /]# chmod -s /usr/sbin/ping6
[root@TheBox /]# chmod -s /usr/sbin/traceroute6
[root@TheBox /]# chmod -s /usr/sbin/usernetctl
[root@TheBox /]# chmod -s /usr/sbin/traceroute
[root@TheBox /]# chmod -s /bin/ping
[root@TheBox /]# chmod -s /bin/mount
[root@TheBox /]# chmod -s /bin/umount
[root@TheBox /]# chmod -s /sbin/netreport
```

### Unusual Files

Files and directories whose names start with "." (dot) are considered hidden because by default they are not displayed by the */bin/ls* command. Attackers, once they have gained access to the system, will typically use hidden and obscure files and directories to avoid detection. Additionally, files or directories that have world-writable permissions set should be kept to a minimum as well. Typically, these types of files and directories are temporary directories and program caches, both of which must remain world-writable. Look for hidden and unusual files:

```
[root@TheBox/]#find/-name ".*"-print-xdev
```

Find world-writable directories and files:

```
[root@TheBox/]#find/-type d-perm-2-exec ls-l{} \;
[root@TheBox/]#find/-type f-perm-2-exec ls-l{} \;
```

Find group-writable directories and files:

```
[root@TheBox/]#find/-type d-perm-20-exec ls-l{} \;
[root@TheBox/]#find/-type f-perm-20-exec ls-l{} \;
```

Do not allow files or directories, without owners and/or groups assigned to them, to reside on the system. If any are found and it can be verified that the system has not been compromised, assign the file/directory an owner. Otherwise, an investigation may be necessary to determine if the system has been compromised.

Find files without owners:

```
[root@TheBox /]# find / -nogroup -o -nouser
```

## APPLICATIONS AND SERVICE DAEMONS

After the installation of a new Linux system, there are several application and service daemons that are initiated by default. Many of these default services are insecure and are typically unneeded; as such, these services should be disabled and uninstalled to ensure that they cannot be used as an avenue of attack.

Additionally, it is important to note that the Linux system should provide a single service to the organization. The system administrator should avoid using the system for multiple applications and services as each additional service adds another layer of management, an additional point of compromise, and also affects the effectiveness of an intrusion detection system to specifically monitor for attacks upon each service.

This section takes the system administrator through several system components that control the initialization of system services while providing general guidance on each service.

### */etc/init.d*

*/etc/init.d* is a directory that contains several scripts that are used to control various system and application daemons. It is from this directory that various scripts are executed during system boot to load various services. Depending on the runlevel, there are several services that are enabled by default and that should be disabled if they are not being used. Considering that these services themselves are also in a default configuration, they potentially may provide an avenue for attack.

These services and recommendations listed in Table 2 are based on a minimalist install base. Installation considerations from the first section should be kept in mind when reviewing these recommendations.

### Terminating Init.d Services

Change directories to the `/etc/init.d/` directory. Note: `/etc/init.d` is a symbolic link to `/etc/rc.d/init.d` and can be referenced from its full or symbolic path.

```
[root@TheBox/]# cd /etc/init.d/
[root@TheBox init.d]#
```

Terminate the daemon by executing the respective script with the “stop” parameter.

```
[root@TheBox init.d]# ./<script> stop
Stopping <script>: [ OK ]
```

If the script was successful in terminating the service, this response will be printed to the console. You may receive a “[ FAILED ]” response if the service is not currently running or if the script was not able to disable the service. In the case of the latter, using the `ps -aux` command to identify the service process ID followed by the `kill` command with the “-9” parameter and the process ID will forcibly unload the daemon that is controlled by the `/etc/init.d/` script. Once a service has been terminated, be sure to disable the service to prevent it from reloading on the next reboot.

### Disabling *init.d* Services

*Init.d* services are configured using the `/sbin/chkconfig` command line utility. This utility can be used to quickly ensure that scripts either start up in the appropriate order or are disabled (or enabled) during system boot for any particular runlevel.

It is important to first determine which runlevel the system will be operating in when in the production environment. The default runlevel for a multiuser Red Hat Linux system is 3. The current runlevel can be determined by using the `runlevel` command:

```
[root@TheBox init.d]# runlevel
N 3
```

In this example, `/sbin/chkconfig` will be used to modify the scripts under `/etc/rc.d/rc3.d`. If the current runlevel is not 3 and the intention is to use runlevel 3 once the server is deployed, then `/etc/inittab` must be modified to ensure that your `/etc/init.d` changes take effect during subsequent system boots. Modify the line in `/etc/inittab` from

```
id:5:initdefault:
```

to

```
id:3:initdefault:
```

To disable a particular script from executing and loading the respective service during system boot, use the `/sbin/chkconfig` command as follows:

```
[root@TheBox init.d]#chkconfig--level 3
<service>off
```

The “level” parameter is the runlevel in which the service will be modified, followed by the script name, followed lastly by the switch on/off.

The command `/sbin/chkconfig`'s only function in this case is to toggle the name of a symbolic link to the script that is being disabled. There are several `/etc/rc#.d` (links to `/etc/rc.d/rc#.d`) directories, one per respective runlevel, that house these symbolic links. A `/bin/ls -la` from any of the `/etc/rc#.d` directories will show this. `/sbin/chkconfig` simply reads the script from `/etc/init.d` and determines shutdown or startup order:

```
[root@TheBox rc3.d]# more ../init.d/xinetd
#!/bin/bash
#
# xinetd This starts and stops xinetd.
#
# chkconfig: 345 56 50
```

Then, rename the symbolic link to this script from

```
[root@TheBox rc3.d]# ls *xinetd
S56xinetd
```

or “Start” to

```
[root@TheBox rc3.d]# ls *xinetd
K50xinetd
```

“Kill.” Simply list the files in the respective runlevel directory to ensure that the script in question has a “K” as the first letter of its name. The initialization script will ignore these files during system boot for this runlevel.

### Uninstalling *init.d* Services

After shutting down and disabling unneeded services, the service or application package should be removed from the system. The RedHat Package Manager (RPM) can be used to quickly uninstall any package using the following command:

```
[root@infosec/]# rpm -e <package name>
```

See the section on Patch and Package Management for more information on how to use RPM.

### Xinetd

*Xinetd* is the Extended Internet Services Daemon. This daemon is used to control several of the small services within RedHat Linux. *Xinetd* replaces the older *inetd* and introduces several new features. Table 3 lists services that can be controlled out of the box with *Xinetd*. It is recommended that each of these services, and ultimately *Xinetd*,

Table 2 /etc/init.d Services and Scripts

Script Name	Service Description	Recommendation
Anacron	<i>anacron</i> is a daemon that will execute jobs at a specified frequency as opposed to a set time like <i>cron</i> .	DISABLE,UNINSTALL (unless system will not be up 24/7)
APMD	<i>apmd</i> is used for monitoring battery status and logging it syslog(8). It can also be used for shutting down the machine when the battery is low.	DISABLE,UNINSTALL (unless system is a laptop)
ARPwatch	The <i>arpwatch</i> daemon attempts to keep track of ethernet/ip address pairings.	ENABLE (useful for network forensics)
ATD	Runs commands scheduled by the <i>at</i> command at the time specified when <i>at</i> was run, and runs batch commands when the load average is low enough.	DISABLE,UNINSTALL (vixie-cron supersedes atd)
Autofs	Automounts file systems on demand. This is typically invoked during system boot time to control the <i>automount</i> daemon.	DISABLE,UNINSTALL (unless using remote NFS file systems)
Cron	<i>crond</i> is a standard UNIX program that runs user-specified programs at periodic scheduled times. <i>vixie cron</i> adds a number of features to the basic UNIX <i>cron</i> , including better security and more powerful configuration options.	ENABLE
Firstboot	Firstboot is a druid-style program that runs the first time a machine is booted after install. It checks for the existence of an <i>/etc/sysconfig/firstboot</i> file. If it does not find the file, then the firstboot program needs to run. If it finds the file, firstboot will not be run. If <i>/etc/reconfigSys</i> exists, run the reconfiguration program and remove <i>/etc/reconfigSys</i> when done. (Also will run if 'reconfig' is on the kernel cmdline.)	DISABLE,UNINSTALL (Once the system has been built, this script will not be used again.)
Functions	This file contains functions to be used by most of the shell scripts in the <i>/etc/init.d</i> directory. This file is sourced by other <i>/etc/init.d</i> scripts to simplify several common functions.	IGNORE (This is not a service.)
GPM	<i>gpm</i> adds mouse support to text-based Linux applications such the Midnight Commander. It also allows mouse-based console cut-and-paste operations, and includes support for pop-up menus on the console.	DISABLE,UNINSTALL (This is only useful on the console.)
Halt	This file is executed by <i>init</i> when it goes into runlevel 0 (halt) or runlevel 6 (reboot). It kills all processes, unmounts file systems, and then either halts or reboots.	IGNORE (This is not a service.)
Iptables	Automates a packet-filtering firewall with <i>iptables</i> .	ENABLE
Irda	This shell script takes care of starting and stopping IrDA support IrDA stack for Linux (Infrared).	DISABLE,UNINSTALL (unless IR access is required)
ISDN	This shell script controls ISDN support for Linux.	DISABLE,UNINSTALL (unless native ISDN support is required)
Kdcrotate	Rotate the list of KDCs (Key Distribution Centers) listed in <i>/etc/krb5.conf</i> .	DISABLE,UNINSTALL (unless the system is part of a Kerberos domain)
Keytable	This package loads the selected keyboard map as set in <i>/etc/sysconfig/keyboard</i> . This can be selected using the <i>kbdconfig</i> utility.	ENABLE
Killall	Shell script that will bring down all services, defined on the command line, that are still running (there should not be any, so this is just a sanity check).	IGNORE (This is not a service.)
Kudzu	This runs the hardware probe and optionally configures changed hardware.	DISABLE (This may be convenient if the system is upgraded.)
LPD	<i>lpd</i> is the print daemon required for <i>lpr</i> to work properly. It is basically a server that arbitrates print jobs to printer(s).	DISABLE,UNINSTALL (unless printing directly from the system is required)

(Continued)

Table 2 (Continued)

Script Name	Service Description	Recommendation
Netfs	Mounts and unmounts all Network File System (NFS), SMB (Lan Manager/Windows), and NCP (NetWare) mount points.	DISABLE (unless using remote file systems)
Network	Activates/deactivates all network interfaces configured to start at boot time.	ENABLE
NFS	NFS is a popular protocol for file sharing across TCP/IP networks. This service provides NFS server functionality, which is configured via the <code>/etc/exports</code> file.	DISABLE, UNINSTALL (unless the system will be a NFS server)
NFSlock	NFS is a popular protocol for file sharing across TCP/IP networks. This service provides NFS file locking functionality.	DISABLE, UNINSTALL (unless the system will be a NFS server)
NSCD	Name Switch Cache Daemon. This is a daemon which handles password and group lookups for running programs and cache the results for the next query. You should start this daemon if you use slow naming services such as NIS, NIS+, LDAP, or hesiod.	DISABLE, UNINSTALL
NTPD	<i>ntpd</i> is the NTPv4 daemon.	DISABLE, UNINSTALL (unless system will be a time server)
PCMCIA	PCMCIA support is usually to support things such as Ethernet and modems in laptops.	DISABLE, UNINSTALL (unless system is a laptop)
Portmap	The <i>portmapper</i> manages RPC connections, which are used by protocols such as NFS and NIS.	DISABLE, UNINSTALL (unless system is a servers which makes use of the RPC mechanism)
Postfix	<i>postfix</i> is a Mail Transport Agent, which is the program that moves mail from one machine to another.	DISABLE, UNINSTALL
Random	Saves and restores system entropy pool for higher quality random number generation.	ENABLE
Rawdevices	This scripts assigns raw devices to block devices (such as hard drive partitions). This is for the use of applications such as Oracle. You can set up the raw device to block device mapping by editing the file <code>/etc/sysconfig/rawdevices</code> .	ENABLE
RHNSD	This is a daemon which handles the task of connecting periodically to the Red Hat Network servers to check for updates and notifications and perform system monitoring tasks according to the service level to which this server is subscribed.	DISABLE (manually perform update checks)
Saslauthd	<i>saslauthd</i> is a server process which handles plaintext authentication requests on behalf of the cyrus-sasl library.	DISABLE, UNINSTALL
Sendmail	<i>sendmail</i> is a Mail Transport Agent, which is the program that moves mail from one machine to another.	DISABLE, UNINSTALL (unless system is a mail server)
Single	This file is executed by init when it goes into runlevel 1, which is the administrative state. It kills all deamons and then puts the system into single user mode. Note that the file systems are kept mounted.	IGNORE (This is not a service.)
SNMPD	Simple Network Management Protocol (SNMP) Daemon	DISABLE (unless system will be monitored using SNMP)
SNMPTRAPD	Simple Network Management Protocol (SNMP) Trap Daemon	DISABLE (unless system handling SNMP traps from other systems)
SSHD	OpenSSH server daemon	ENABLE
Syslog	Syslog is the facility by which many daemons use to log messages to various system log files. It is a good idea to always run syslog.	ENABLE

(Continued)

Table 2 (Continued)

Script Name	Service Description	Recommendation
Winbind	Starts and stops the Samba <i>winbind</i> daemon	DISABLE,UNINSTALL (unless system will be part of an Windows domain or will be a MS file and print server)
XFS	Starts and stops the X Font Server at boot time and shutdown. It also takes care of (re-)generating font lists.	DISABLE,UNINSTALL (unless system has Xfree installed)
Xinetd	<i>xinetd</i> is a powerful replacement for <i>inetd</i> . <i>xinetd</i> has access control mechanisms, extensive logging capabilities, the ability to make services available based on time, and can place limits on the number of servers that can be started, among other things.	DISABLE,UNINSTALL (See section on <i>xinetd</i> below.)
YPbind	This is a daemon which runs on NIS/YP clients and binds them to a NIS domain. It must be running for systems based on <i>glibc</i> to work as NIS clients, but it should not be enabled on systems which are not using NIS.	DISABLE,UNINSTALL (unless system is part of a NIS/YP domain)

Table 3 /etc/xinetd.d Services

Service Name	Service Descriptions
Chargen	An <i>xinetd</i> internal service that generates characters. The <i>xinetd</i> internal service that continuously generates characters until the connection is dropped. The characters look something like this: !"#\$%&'()*+,-./0123456789;<=>?@ABCDEFGHIJKLMN0PQRSTUVWXYZ[\]^_`abcdefg This is the tcp version.
chargen-udp	An <i>xinetd</i> internal service that generates characters. The <i>xinetd</i> internal service that continuously generates characters until the connection is dropped. The characters look something like this: !"#\$%&'()*+,-./0123456789;<=>?@ABCDEFGHIJKLMN0PQRSTUVWXYZ[\]^_`abcdefg This is the tcp version.
Daytime	An internal <i>xinetd</i> service that gets the current system time then prints it out in a format like this: "Wed Nov 13 22:30:27 EST 2002". This is the tcp version.
daytime-udp	An internal <i>xinetd</i> service that gets the current system time then prints it out in a format like this: "Wed Nov 13 22:30:27 EST 2002". This is the udp version.
Echo	An <i>xinetd</i> internal service that echoes characters back to clients. This is the tcp version.
echo-udp	An <i>xinetd</i> internal service that echoes characters back to clients. This is the udp version.
Finger	The finger server answers finger requests. Finger is a protocol that allows remote users to see information such as login name and last login time for local users.
rsync	The <i>rsync</i> server is a good addition to an ftp server, as it allows crc checksumming, etc.
servers	An internal <i>xinetd</i> service, listing active servers.
Services	An internal <i>xinetd</i> service, listing active servers.
sgi_fam	FAM is a file monitoring daemon. It can be used to get reports when files change.
time	An RFC 868 time server. This protocol provides a site-independent, machine-readable date and time. The time service sends back to the originating source the time in seconds since midnight on January first 1900. This is the tcp version.
time_udp	An RFC 868 time server. This protocol provides a site-independent, machine-readable date and time. The time service sends back to the originating source the time in seconds since midnight on January first 1900. This is the udp version.
Wu-ftpd	The <i>wu-ftpd</i> (Washington University) FTP server serves FTP connections. It uses normal, unencrypted usernames and passwords for authentication.

be disabled. If one or more small service is required, the *Xinetd* service cannot be disabled, however, the other small services should be disabled. The *Xinetd* services are located in */etc/xinetd.d*. The configuration for the *Xinetd* daemon itself is */etc/xinetd.conf*.

Each service that is controlled by the *Xinetd* daemon is configured by modifying the parameters defined in each of the respective service files in the */etc/xinetd.d* directory. For example, the content of the *wu-ftpd* configuration file is shown as follows:

```
[root@TheBox xinetd.d]# pwd
/etc/xinetd.d

[root@TheBox xinetd.d]# more wu-ftpd
# default: on
# description: The wu-ftpd FTP server serves
  FTP connections. It uses \
# normal, unencrypted usernames and passwords
  for authentication.
service ftp
{
    socket_type           = stream
    wait                 = no
    user                 = root
    server               = /usr/sbin/in.ftpd
    server_args          = -l -a
    log_on_success       += DURATION USERID
    log_on_failure       += USERID
    nice                 = 10
    disable              = no
}
[root@TheBox xinetd.d]#
```

### Disabling Services in *Xinetd*

Disabling individual services that are controlled by *Xinetd* is as easy as editing a text file. In the example shown, simply edit each configuration file and add:

```
disable = yes
```

Finally, simply reload the *Xinetd* daemon from the */etc/init.d/* directory to reread the service configuration files and apply the changes.

```
[root@TheBox xinetd.d]#/etc/init.d/xinetd reload
Reloading configuration: [SUCCESS]
[root@TheBox xinetd.d]#
```

Note: For quick shortcut to determine which services are enabled for each runlevel as well as which *Xinetd* services are enabled use *chkconfig -list*.

### Verification

Once the default *init.d* services have been stopped and disabled from reloading during the next system boot, it is important to verify that the services have in fact been stopped. The verification step is also important as it allows the system administrator to determine if there are any other services enabled that are unneeded.

There are several tools that are available with a default Linux install that will allow the administrator to quickly determine if there are additional services running in the background. These tools will list running services that are both accessible remotely and those that are accessible by local users. (More information about these tools can be found by typing “*man <toolname>*” on the command line.)

<i>/bin/ps -A:</i>	List running processes with their process IDs. (-A switch shows all processes.)
<i>/bin/netstat -l:</i>	Prints information about processes listening on TCP/UDP ports.
<i>/usr/bin/lsof -i:</i>	Lists open files. (-i switch lists all open files using an IP socket.)
<i>/sbin/service -status-all:</i>	Script to quickly output the status of the services configured to start during startup of the current init runlevel.

If any process is found that is unknown, unneeded, or unauthorized, the “*/sbin/kill <ps id>*” command can be used to stop or “kill” the running process.

### Restricting Applications and Services

Although the details of hardening an application or service that may be installed on the Linux platform is outside the scope of this chapter, there are a few Linux system capabilities that are available to the system administrator that will help to control and limit application or service access to the underlying Linux platform. Each of these capabilities including the steps taken so far introduces an additional layer of defense against would-be attackers.

#### Chroot Jail

Outside of the configuration of an application or service itself, as shown previously, there are several steps a system administrator can take to ensure that the integrity of the operating system is not compromised even after an application or service has been. One additional method is provided by using */usr/bin/chroot*, also referred to as a process “jail.”

By using */usr/bin/chroot* or “change root,” the system administrator effectively “jails” the application or service into a particular location on the file system. When the application or service is executed, the effective “root” directory is defined by the system administrator. This is to ensure that if the application or service is compromised, the attacker will have far less access to the operating system than if the process was executed from its absolute program path.

Any program can be jailed using */usr/bin/chroot* by using the syntax shown here.

```
[root@TheBox/]#chroot /<newrootdir>/bin/<program>
```

There are, however, a few caveats when using */usr/bin/chroot*. The command works well with statically linked binaries; however, it would prevent dynamically

linked binaries from executing as the binary is linked to libraries that are no longer available via the relative path. To use `/usr/bin/chroot` with dynamically linked binaries, the libraries used by the executable will have to be copied into the new relative path of the *chroot'd* binary. For example, if a service is jailed within the `/chroot` directory from above, the binary would have to be copied to its relative path under the `/chroot` directory as well as all of its libraries and configuration files.

```
[root@TheBox chroot]# pwd
/chroot
[root@TheBox chroot]# ls -lF
total 157
drwxr-xr-x 2 root chroot 4096 Feb 13 2003 bin/
drwxr-xr-x 18 root chroot 86016 Sep 17 17:06 dev/
drwxr-xr-x 43 root chroot 4096 Sep 18 16:05 etc/
drwxr-xr-x 6 root chroot 4096 Sep 18 16:05 lib/
drwxrwxrwt 4 root chroot 4096 Jan 12 04:02 tmp/
drwxr-xr-x 16 root chroot 4096 Sep 18 14:42 usr/
drwxr-xr-x 19 root chroot 4096 Feb 14 2003 var/
[root@TheBox chroot]#
```

### TCP Wrappers

TCP wrappers is a TCP/IP daemon wrapper that provides host- and user-based access control for the *Xinetd* (*Inetd*) services such as telnet, FTP, finger, RSH, TFTP, and several others. TCP wrappers was written and continues to be maintained by Wietse Venema. Additional information on TCP wrappers and the source code is available from <http://ftp.porcupine.org/pub/security/index.html>.

If any of the *Xinetd* services will be used, it is recommended that TCP wrappers be configured to allow only known, trusted hosts to use these services. Service access control or the trust relationships are implemented and managed through two files, `/etc/hosts.allow` and `/etc/hosts.deny`.

Following the “default deny” or “permit by exception” rules, the following line should be added to the `/etc/hosts.deny` to explicitly deny all connections to wrapped services unless they are specified within `/etc/hosts.allow`:

```
[root@TheBox etc]# cat hosts.deny
#hosts.deny This file describes the names
of the hosts which are
#      *not* allowed to use the local INET
      services, as decided
#      by the '/usr/sbin/tcpd' server.
#Deny access to everything
ALL: ALL
[root@TheBox etc]#
```

Entries can now be made within `/etc/hosts.allow` to allow access to specified services from specified hosts and users. Here is a sample format of this file:

```
<Xinetd daemon>: <client, client2> :<options> :<shell command>
```

For additional information, it is recommended that the manual pages for TCP wrappers be referenced for the specific configuration options.

## PATCH AND PACKAGE MANAGEMENT

Once the system has been built, it is important to ensure that all of the installed services and applications are and remain up to date. There are two tools that ship with Red Hat Linux and distributions based on Red Hat Linux that make the maintenance task of patch and package management easier for a system administrator: *Up2date* and *RPM*. This section reviews some of the capabilities of these tools.

### RPM (RedHat Package Manager)

The RedHat Package Manager is an extremely powerful tool that allows the system administrator to quickly install, uninstall, upgrade, query, and verify *RPM* packages. Following is a list of some of the commands that can be used to quickly perform a variety of package management tasks. For more information, use *man rpm* on the command line to bring up the *RPM* manual.

#### Installing an RPM Package

The switch “*ivh*” will have “*rpm*” install the package, with verbose output turned on, and will print out status hash marks to show installation progress.

```
[root@TheBox/]#rpm-ivh<packagename.(version) .
(release).(arch).rpm>
```

### Uninstalling an RPM Package

When uninstalling an *RPM* package, only the package name is required.

```
[root@TheBox/]#rpm -e <packagename>
```

### Upgrading an RPM Package

The “-U” switch will upgrade an rpm package that was previously installed. The problem with this option is that if “rpm” does not find a previous install, *rpm* will install this package as new without warning.

```
[root@TheBox/]#rpm-Uvh<packagename.(version).
(release).(arch).rpm>
```

To be safe use the “-F” or Freshen switch to have *rpm* perform an upgrade only if the rpm package has already been installed.

```
[root@TheBox/]#rpm-Fvh<packagename.(version).
(release).(arch).rpm>
```

### Querying an RPM Package

The query switch can be used to quickly verify if a particular package and version has been installed. The switch can be used in conjunction with “-” and “-l” to show additional package information and/or to list the contents of the installed package, respectively.

```
[root@TheBox /]# rpm -q <packagename>
```

Additionally, the “-qf” switch can be used to quickly identify which *RPM* package installed a particular file on the system.

```
[root@TheBox /]# rpm -qf <filename>
```

The “-qp” switch can also be used to query information about a package file before it is installed (the “p” switch provides this capability). The list switch “-l” or the “-” switches shown can be used with this type of query as well.

```
[root@TheBox /]# rpm -qp ./<packagename.(version).
(release).(arch).rpm>
```

### Verifying an RPM Package

Another powerful feature of rpm is the ability to verify installed rpm packages and their associated files. The verify switch will have rpm validate the file specified on the command line and its associated rpm package against the *RPM* database to ensure that each of the files associated with the package have not been modified or corrupted. The rpm package name can be specified on the command line as well. Descriptive errors will be returned if the file or package has been modified in any way.

```
[root@TheBox /]# rpm -Vf <filename>
```

## Up2date

As the name of the tool suggests, *up2date* is an *RPM* package update tool that works with RedHat’s online service (<http://rhn.redhat.com>) to maintain *RPM* packages and to ensure the system is kept up to date with the latest rpm package releases. *Up2date* is a simple-to-use graphical and text-based update tool. The tool can be used either via the command line or via the GUI to quickly query the “package updates” list on RedHat Linux distribution servers (<ftp://ftp.redhat.com/pub/redhat/linux/updates/current/en/os/>). For more information about up2date, bring up the manual by typing *man up2date* on the command line.

## ROOT, USER, AND GROUP ACCOUNTS

Regardless of the application or service that will define the purpose of the Linux platform, invariably users and other system administrators will require access to the system itself. Whether it is for system administration, system and application maintenance, backups, or auditing, multiple users will need access to the system. This section will review some of the best practices for granting system access to both system administrators and generic users.

### Note About Passwords

Given enough time and sufficient resources, any password can be broken. The trick is to choose a password that is complex enough so that the only possible method to recover the password is through brute force attack, barring of course, social engineering or the yellow sticky note recovery hack. Choosing an appropriate lock-out policy will greatly affect the success of brute force and other password recovery attacks as well as provide a simple mechanism to alert the system administrator of the recovery attempts.

Picking an appropriate aging policy is also important. A period should be chosen so that the approximate time that it would take to brute force the password is significantly longer than the age of the password.

A few things to keep in mind:

- Consider the criticality of the system. Take into account the installation considerations.
- Enforce password complexity requirements that require at least eight characters, at least one special character, and at least one number.
- Passwords should not be trivial. They should not be personalized or based on a dictionary word in any language.
- Password aging policies should be enforced.
- Lock-out policies should be enforced as appropriate for the system user base.

### Root Account

The root account is the \*NIX system administration account. This is the central and most privileged account on the system. The system does not enforce any restrictions of any kind on this account. As such, the use of the root account should be controlled and limited. System administrators should have personalized user accounts created

for them and only use the `/bin/su` command to become root when absolutely necessary.

Once logged into the system as a user, the system administrator can “Super User” to root with the `/bin/su` command. The “`-l`” command line switch instructs `/bin/su` to load the root user’s login scripts. (This may be useful when running commands that are only in the root user’s path variable.)

```
[sysadmin-1@TheBox sysadmin-1]$ id
uid=500(sysadmin-1) gid=500(sysadmin-1)
groups=500(sysadmin-1)
[sysadmin-1@TheBox sysadmin-1]$ su -l
Password:
[root@TheBox root]# id
uid=0(root) gid=0(root) groups=0(root),1(bin),
 2(daemon),3(sys),4(adm),6(disk),10(wheel)
[root@TheBox root]# pwd
/root
[root@TheBox root]#
```

One way to enforce the use of personalized system administrator accounts is by specifying on which TTYs and VCs (virtual consoles) the root user can login. This will help to ensure that administrators log into the system with their user account and `su` to root or use `sudo` to execute a command. Comment out all of the lines *except* “`tty1`” and “`vc/1`” out of the `/etc/securetty` file. The login program (`/bin/login`) will read this file and will deny a root login on any TTY or VC that is not specified in this file.

## User and Group Accounts

### Basic Maintenance

There are five basic commands that are used to maintain accounts on the system. They are as follows:

```
/usr/sbin/useradd: Used to create user accounts.
/usr/sbin/groupadd: Used to create user groups.
/usr/sbin/userdel: Used to delete user accounts.
/usr/sbin/groupdel: Used to delete user groups.
/usr/bin/passwd: Used to set and change account passwords.
```

All user accounts are maintained in the file `/etc/passwd`. Because this file must be world-readable, it is not a good idea to leave the encrypted account passwords in this file. Following the installation guidance, SHADOW passwords should be enabled, which would store the encrypted account passwords in the file `/etc/shadow`, which is only readable by root.

### Unused System Accounts

During system installation, there are several accounts that are created to support a variety of system activities, most of which will never be used. Consider what services the system will be supporting and delete all accounts not directly related to each service. As an example, the MySQL database daemon runs as the “mysql” user account for security reasons. This account would be needed to run this type of database server.

These accounts and their corresponding groups are safe to remove from a minimalist install base:

```
[root@TheBox etc]# cat /etc/passwd
root:x:0:0:root:/root:/bin/bash
bin:x:1:1:bin:/bin:/sbin/nologin
daemon:x:2:2:daemon:/sbin:/sbin/nologin
adm:x:3:4:adm:/var/adm:/sbin/nologin
lp:x:4:7:lp:/var/spool/lpd:/sbin/nologin
sync:x:5:0:sync:/sbin:/bin/sync
shutdown:x:6:0:shutdown:/sbin:/sbin/shutdown
halt:x:7:0:halt:/sbin:/sbin/halt
mail:x:8:12:mail:/var/spool/mail:/sbin/nologin
news:x:9:13:news:/etc/news:
uucp:x:10:14:uucp:/var/spool/uucp:/sbin/nologin
operator:x:11:0:operator:/root:/sbin/nologin
games:x:12:100:games:/usr/games:/sbin/nologin
gopher:x:13:30:gopher:/var/gopher:/sbin/nologin
ftp:x:14:50:FTP User:/var/ftp:/sbin/nologin
nobody:x:99:99:Nobody:./sbin/nologin
rpm:x:37:37:./var/lib/rpm:/sbin/nologin
vcsa:x:69:69:virtual console memory owner:/dev:
  /sbin/nologin
mailnull:x:47:47:./var/spool/mqueue:/sbin/
nologin
sysadmin-1:x:500:500:./home/sysadmin-1:/bin/bash
[root@TheBox etc]#
```

Be sure to review `/etc/groups` and remove any reference to the deleted user accounts. Note that there may be additional user groups without associated user accounts that should also be removed. This one is safe to remove from a minimalist install base:

```
dip:x:40:
```

### Account Timeouts

To set account idle timeouts, the system administrator will have to modify the `/etc/profile` file. Make the following additions to this file to set the timeout for all accounts:

```
HOSTNAME=`/bin/hostname`
HISTSIZE=1000
TMOUT=<some time in seconds>
...
export PATH USER LOGNAME MAIL HOSTNAME
  HISTSIZE INPUTRC TMOUT
```

### Shell Command Logging

The BASH shell (the default command shell provided to the user after logging in via console, telnet, or ssh) has the ability to log (`~/.bash_history`) any number of previously executed commands to assist users with recalling earlier commands. The default length of this buffer (1000) should be significantly reduced (20).

```
HOSTNAME=`/bin/hostname`
HISTSIZE= 20
```

In addition, the log file (`~/.bash_history`) should be deleted once the user logs out. Make the following additions

to have BASH wipe the history file upon logout for all users:

```
HOSTNAME=`/bin/hostname`
HISTSIZE=1000
HISTFILESIZE=0
...
export PATH USER LOGNAME MAIL HOSTNAME
HISTSIZE INPUTRC TMOUHISTFILESIZE
```

### Account Aging

Users should be required to periodically change their passwords. Depending on the criticality of the system that users are accessing, the recommended settings should be adjusted. Edit the `/etc/login.defs` configuration file and make the following modifications. (note: The minimum password length setting is depreciated and no longer works.)

```
[root@TheBox etc]# cat login.defs
...
PASS_MAX_DAYS 90
PASS_MIN_DAYS 15
PASS_WARN_AGE 10
...
```

### PAM

Linux uses PAM (Pluggable Authentication Modules) to take authentication schemes out of the individual applications and to provide a shared mechanism for all system and application authentication. For more information on PAM, see <http://www.kernel.org/pub/linux/libs/pam/modules.html>.

The default password length of 5 characters is not sufficient and should be changed to at least 10 characters. Edit `/etc/pam.d/system-auth` and make the following additions to enforce the password definitions:

```
password required /lib/security/pam_cracklib.
so retry=3 minlen=10 lcredit=-1 ucredit=-1
password sufficient /lib/security/pam_unix.
so nullok use_authtok md5 shadow
remember=15
```

`PAM_tally` is a PAM module that provides account lockout services to PAM. This module will keep track of failed login attempts and if the number of login attempts exceeds a specified threshold, `PAM_tally` will lock the account for a period of time. Edit `/etc/pam.d/system-auth` and make the following additions to enable account lockout:

```
account required/lib/security/pam_tally.
so deny=4 no_magic_root
```

### SUDO

To support the delegation of system administration duties without supplying the root account password to multiple users and other system administrators, the `/usr/bin/sudo` utility can be used to run various programs or scripts

in the context of the root user. The `/usr/bin/sudo` program is configured by modifying the `/etc/sudoers` file. For more information on SUDO, see <http://www.courtesan.com/sudo/>.

## SYSTEM AUDITING

Although the level of granularity may vary depending on system criticality, every system deployed within a production environment should have system logging enabled. The system should be reporting user, system, and process activity to a centralized location either on the local system or, better yet, on a remote logging server. Additionally, with the help of system log file analysis and audit tools, the log files should be reviewed periodically for system modification, errors, and intrusions. The following is a list of events that should be logged and reviewed:

- system startup and shutdown (unsuccessful and successful),
- system administration actions (unsuccessful and successful),
- security personnel actions (unsuccessful and successful),
- logon (unsuccessful and successful) and logout (successful),
- unauthorized access attempts to files (unsuccessful),
- use of privileged commands (unsuccessful and successful),
- application and session initiation (unsuccessful and successful),
- use of print command (unsuccessful and successful),
- access control permission modification (unsuccessful and successful),
- export to media (successful)
- files and programs deleted by users (successful and unsuccessful).

### Syslog

`Syslog` is the primary system logging daemon for the Linux system. The `Syslog` daemon can be used to log system messages locally or to a remote `Syslog` server. The daemon is configured by the `/etc/syslog.conf` file. Initialization of the `Syslog` daemon is controlled by `Init` and is configured when the system initializes with `/etc/sysconfig/syslog`. By default, the `Syslog` daemon is configured to log messages locally (`/var/log/`) and to not accept messages from other systems. If the system is to be configured as a `Syslog` server, please see manual pages for specific server configuration options.

The `/etc/syslog.conf` file contains rules that define how the `Syslog` daemon should handle messages from the kernel. Each rule consists of two fields: the *selector*, which consists of two parts, and the *action* field. The *selector* field is comprised of the *facility* and the *priority*, separated by a "." (period). The *facility* defines a *rule* for the corresponding subsystem that produced a particular message. For example, all kernel messages are handled by the *kern facility* and `Syslog` will handle all kernel messages as defined

Table 4 Syslog Facilities

Facility	Description
Auth	The authorization system: login, su, getty, etc.
Authpriv	The same as “auth,” but logged to a file readable only by selected individuals.
Cron daemon	The cron daemon: cron. System daemons, such as routed, that are not provided for explicitly by other facilities.
kern	Messages generated by the kernel. These cannot be generated by any user processes.
lpr	The line printer spooling system: lpr, lpc, lpd.
mail	The mail system.
mark	For internal use only and should not be used by applications.
news	The network news system.
security	Same as “auth.” This is deprecated and should not be used anymore.
syslog	Messages generated internally by syslogd.
user	Messages generated by random user processes. This is the default facility identifier if none is specified.
uucp	The UNIX-to-UNIX copy system.
localn (n = 0 – 7)	Reserved for local use. n is 0–7.

by */etc/syslog.conf*. The *facility* keywords and descriptions are listed in Table 4:

The *priority* field defines the severity of a message. The *priorities* are listed in Table 5 with their definitions in order of severity:

The rules within the */etc/syslog.conf* file are formatted as follows:

```
<facility>.<priority>          <action>
```

Where *<facility>* is one of the *Syslog facilities* list above in Table 4, *<priority>* is one of the *Syslog priorities* list in Table 5. (Note: Either of these can be replaced by the asterisk “\*” wildcard.) When *Syslog* receives messages that match these two criteria (or with a higher priority level), the message is logged to the file or remote server specified by *<action>*. Typically, *<action>* is a file within the */var/log/* directory. Local *Syslog* message can be forwarded to remote *Syslog* server by specifying “@servername” in the *<action>* field. (Note: Be sure to update */etc/hosts* with the IP address of the server specified.)

## Log Administration

The *Syslog* daemon does not include support for log maintenance; as such, the default installation of Red Hat Linux includes the *logrotate* script to manage the system logs.

Table 5 Syslog Priorities

Priority	Description
none	Disables logging for a particular facility.
panic	Same as emerg. Deprecated and should not be used.
emerg	A panic condition. This is normally broadcast to all users.
alert	A condition that should be corrected immediately, such as a corrupted system database.
crit	Critical conditions, e.g., hardware failures.
err	Application error messages.
error	Same as error. Deprecated and should not be used.
warn	Same as warning. Deprecated and should not be used.
warning	Warning messages.
notice	Conditions that are not error conditions, but should possibly be handled specially.
info	Informational messages.
debug	Messages that contain information normally of use only when debugging a program.

The script will rotate, compress, and, if need be, mail the system logs to a system administrator. The default installation should be effective for most system deployments though the manual file should be referenced for additional information.

Because *Syslog* does not ensure the integrity of the log files, the system administrator must rely on the operating system to provide this integrity. In this case, integrity controls are provided by the */usr/bin/chattr* utility as seen in the File System Security section. Specifically, integrity controls are provided by the “append-only” and “immutable” file system flags set by */usr/bin/chattr*. By setting these flags on each of the log files, the *logrotate* script will no longer be able to rotate the log files because the script will no longer be able to zero the log file after rotation. Fortunately, *logrotate* makes provision for this situation with the “*prerotate/endscript*” directive within its log file definition file */etc/logrotate.d/syslog*. The */usr/bin/chattr* utility must be called before and after each log file rotation. Modify the *logrotate* configuration file as follows:

```
[root@TheBox logrotate.d]# cat syslog
/var/log/messages/var/log/secure/var/log/maillog
/var/log/spooler
/var/log/boot.log/var/log/cron{ sharedscripts
prerotate
    /usr/bin/chattr -ia /var/log/messages*
    /usr/bin/chattr -ia /var/log/secure*
    /usr/bin/chattr -ia /var/log/maillog*
    /usr/bin/chattr -ia /var/log/spooler*
    /usr/bin/chattr -ia /var/log/boot.log*
    /usr/bin/chattr -ia /var/log/cron*
endscript
```

```

postrotate
/bin/kill -HUP `cat /var/run/syslogd.pid 2>
/dev/null` 2> /dev/null || true
/usr/bin/chattr +ia /var/log/messages*
/usr/bin/chattr +ia /var/log/secure*
/usr/bin/chattr +ia /var/log/maillog*
/usr/bin/chattr +ia /var/log/spooler*
/usr/bin/chattr +ia /var/log/boot.log*
/usr/bin/chattr +ia /var/log/cron*
endscript
}
[root@TheBox logrotate.d]#

```

## Audit Tools

System log files should be reviewed daily by the system administrator to identify system problems and should also be reviewed by a security analyst to ensure the system has not been compromised. Because daily log review can be a resource-intensive task, it is recommended that a log audit tool be implemented to assist with the log review process. Following are several options, each having own capabilities and unique features.

- **Logcheck** (<http://doug.hunley.homeip.net/tools/>). Maintained by Doug Hunley, Logcheck is a modified version of Psionic Logcheck that periodically parses through the administrator-specified log files and e-mails a report of suspicious entries to system administrators or security analysts.
- **WOTS** (<http://www.hpcc.uh.edu/~tonyc/tools/>). A Perl script that parses through the system log files and will generate reports or take action based on its configuration.
- **Logwatch** (<http://www.logwatch.org>). Logwatch is a customizable log analysis system. Logwatch parses through the system's logs for a given period of time and creates a report analyzing areas that the system administrator specifies at varying levels of detail.
- **Swatch** (<http://swatch.sourceforge.net/>). Swatch is short for "simple watchdog" and is an active system log file monitor that can parse, analyze, and send reports to designated personnel.

## Syslog Replacements

Unfortunately, the *Syslog* daemon has a long history of security problems. Aside from problems that have arisen within the daemon itself, the implementation is lacking many of the security features that are required for most system deployments today. Namely, *Syslog* does not include authentication support. This is a significant problem for *Syslog* servers, which must rely on the security of trust relationships to receive log messages. Additionally, *Syslog* does not check for log file integrity to ensure that log files have not been modified by another application or malicious user. *Syslog* also lack support for encryption and log file maintenance.

There are several alternatives to using the default *Syslog* daemon. Each replacement is backward compatible with *Syslog* and provides unique enhancements to the logging subsystem. Each implementation should be

evaluated and tested before implementing within a production environment.

- **Modular Syslog** (<http://www.corest.com/products/corewisdom/CW01.php>). A *Syslog* replacement that includes data integrity checks, easy database integration, strong encryption, and output redirection using regular expressions.
- **Nsyslog** (<http://coombs.anu.edu.au/~avalon/nsyslog.html>). *Nsyslog* supports TCP connections for log transfer, and with SSL allows for encrypted delivery of *Syslog* messages across the network.
- **syslog-ng** ([http://www.balabit.com/products/syslog\\_ng](http://www.balabit.com/products/syslog_ng)). A flexible, secure replacement for *Syslog*.

## BACKUPS

One of the most fundamental responsibilities of a system administrator is the periodic backup of all sensitive, application, log, and configuration information. Backups reduce downtime resulting from hardware failure and ensure that the system can be recovered in case of a compromise. System failure of some form or another is not a question of if but rather a question of when, and it is the responsibility of the system administrator to ensure that the system is recoverable. Forensic and security analysts have a particular interest in backups as they also provide a means to analyze system changes after a compromise. This section will review some of the basic backup and recovery tools that are provided with a default Linux installation.

### Backup Considerations

Before performing system backups, there are several questions that must be taken into consideration. Here are several questions that should be addressed prior to developing a backup solution:

- What data will be archived?
- Will the data be archived to local or remote media?
- If remote, will the location on the production network allow it? Will it be secure?
- If local, what type of media will be used? Tape, CDRW, DVDRW, file?
- What is the archival scheme and period?
- Will a combination of incremental and full backups be used?
- How will the media be rotated, handled, and stored?

### Backup Targets

Generally, any piece of data that is unique to the system and is not readily available from other sources such as installation disks should be backed up. Typically, this usually includes paths that contain user data, unique system configuration files, logs, or custom applications. Without taking specific applications or services into consideration, here is a list of recommended paths that should be included in the archive scheme:

```

/etc/:      System configuration files.
/home:     User home directories.
/root:     System administrator home directory.
/var/log:  System log files (unless using a remote Syslog server).
/usr/etc/: Application configuration files.
/usr/local: Applications and configuration files.
*/chroot: Chroot'd applications and configurations files.
*/boot:   Kernel and boot configuration.

```

\* These paths may not be unique to the system.

The following paths can be ignored as they are typically not used to store applications or data.

```

/mnt:      Removable media mount directory.
/proc:     Pseudo-file system created by the kernel.
/tmp:      Temporary slack space used by
           applications.

```

### Backup Scheme

There are several archival schemes that a system administrator can use to backup the system. The scheme is typically based on organizational data retention and backup policies. Policies should include guidance on archive targets, naming conventions, archival tools, archive periods, and backup types (incremental vs. full or both), media, and storage locations.

If guidance does not exist, it is recommended that backups be performed nightly (or during a window of limited system use) over a weekly period. A full backup should be performed and verified once a week with an incremental backup being performed each evening for the remainder of the week. Each archive should be time stamped and moved off of the system either by writing to tape, burning to CD, or securely copied to another system. Additionally, it may be a good idea to physically store the archive media in a separate part of the building or even offsite, depending on the criticality of the data.

### Permissions

It is recommended that all backup archives be protected by either moving the archive off of the system or by storing them in a directory on the system that is only accessible by root. Set the permission of "0700" using `/bin/chmod` on the backup directory. If using removable media such as tape, ensure that the permission of "0660" or more restrictive is set on the device `/dev/tape` (or other device name). This will prevent users from extracting files from the archive, whether it is on the physical drive or on tape. Note: Whenever possible, all system archives should be moved off of the system, either by removable media or by an NFS mount on a central redundant file store.

### Backup Utilities

The following is one of the more commonly used Linux backup utilities. There are many other open source utilities available, some installed with a Linux installation, and others are readily available online. Depending on the archival scheme chosen, any of these utilities can be used to back up and restore a system.

### Tar Example

Tar is the GNU version of the *tar* archival utility. It was originally developed to archive data to tape drives but it is commonly used to write archives to regular files. Following are examples of how tar can be useful when performing a backup or recovery.

**Full Backup:** This command will back up the system to a file or device, such as a tape drive or library; file and directory permissions will be preserved; the archive will be labeled; various files and directories listed within the exclude file will be ignored; and the archive will be verified.

```

[root@TheBox/]# tar-cpXf<backup file or
device>/etc/backup/exclude_list/
--directory/--label="Full Backup `date`+
%d:%b:%y'`" . --verify

```

**Incremental Backup:** This command will back up changes to the system that have been made since the previous backup to a file or device, such as a tape drive. As with the full backup, file and directory permissions will be preserved, the archive will be labeled, various files and directories listed within the exclude file will be ignored, and the archive will be verified.

```

[root@TheBox/]#tar-upXf<backup file or
device>/etc/backup/exclude_list\
--directory/--label="Incremental Backup
`date`+%d:%b:%y'`" .--verify

```

### Recovery

Following are a list of examples of how tar can be used to restore the system or individual files and directories.

**Full restore using TAR:**

```

[root@TheBox/]#tar-xpvf<backup file or
device>--directory/

```

**Partial restore using TAR:**

```

[root@TheBox/]#tar-xpvf<backup file or
device>--directory/<directory/file>

```

### Additional Utilities

**CPIO** (<http://www.gnu.org/software/cpio/cpio.html>). *Cpio* is another archival tool similar to tar, with many of the same capabilities. The utility is compatible with tar and provides several archival enhancements. *Cpio* is available on many default Linux installations.

**Dump** (<http://dump.sourceforge.net>). The backup utility *dump* is different from *tar* and *cpio* in that it reads the ext2 Linux file system directly without stepping through the directory structure. This allows the utility to be quick and efficient. Unfortunately, the tool does not allow an administrator to selectively choose which files or directories to back up, though this may not be an issue if the intent is to perform full system backups.

**Additional Backup Resource** (<http://linuxmafia.com/pub/linux/backup/>).

## LEGAL PROTECTIONS

Because of recent criminal court case precedents involving unauthorized system access, when applicable, it is important to display logon warning banners to anyone who accesses the system. The warning banner ensures the forfeiture of user privacy on the system and effectively grants the system owner the “right to monitor.” This will help to ensure that all evidence collected from an intrusion is admissible in court.

### Implementation

There are several ways to implement a logon warning banner in Linux. Many of the interactive services that are supplied with a default installation of Linux will typically use */etc/motd* to display a banner to users. Note: Logon warning banners cannot be implemented on the Linux system itself for noninteractive services where users will not see the banner or for custom and proprietary services that lack support for logon banners. In the latter case, it may be possible to customize the application to add support for the displaying of logon banners to users. A custom HTML page is an example of one such modification.

Simply editing the */etc/motd* file and adding the logon warning banner will ensure that the banner is displayed for many of the text-based services within Linux such as SSH, Telnet, SMTP, and POP3.

If any of the running services are controlled by the *Xinetd* daemon, the configuration file */etc/xinetd.conf* can be modified to add support for logon banners. Edit the configuration file and add the following:

```
[root@TheBox etc]# cat xinetd.conf
#
# Simple configuration file for xinetd
#
# Some defaults, and include /etc/xinetd.d/

defaults
{
    instances          = 60
    log_type           = SYSLOG authpriv
    log_on_success     = HOST PID
    log_on_failure     = HOST
    cps                = 25 30
    banner             = /etc/motd
}

includedir /etc/xinetd.d
[root@TheBox etc]#
```

## Sample Logon Banner

This banner should be customized to fit the organization’s specific legal requirements. Consult the organization’s legal department for details on the implications and requirements for implementing a banner similar to this one:

THIS IS A <COMPANY NAME> COMPUTER SYSTEM. THIS COMPUTER SYSTEM, INCLUDING ALL RELATED EQUIPMENT, NETWORKS, AND NETWORK DEVICES (SPECIFICALLY INCLUDING INTERNET ACCESS), ARE PROVIDED ONLY FOR AUTHORIZED <COMPANY NAME> USE. <COMPANY NAME> COMPUTER SYSTEMS MAY BE MONITORED FOR ALL LAWFUL PURPOSES, INCLUDING TO ENSURE THEIR USE IS AUTHORIZED, FOR MANAGEMENT OF THE SYSTEM, TO FACILITATE PROTECTION AGAINST UNAUTHORIZED ACCESS, AND TO VERIFY SECURITY PROCEDURES, SURVIVABILITY, AND OPERATIONAL SECURITY. MONITORING INCLUDES ACTIVE ATTACKS BY AUTHORIZED <COMPANY NAME> ENTITIES TO TEST OR VERIFY THE SECURITY OF THIS SYSTEM. DURING MONITORING, INFORMATION MAY BE EXAMINED, RECORDED, COPIED, AND USED FOR AUTHORIZED PURPOSES. ALL INFORMATION, INCLUDING PERSONAL INFORMATION, PLACED ON OR SENT OVER THIS SYSTEM, MAY BE MONITORED.

USE OF THIS <COMPANY NAME> COMPUTER SYSTEM, AUTHORIZED OR UNAUTHORIZED, CONSTITUTES CONSENT TO MONITORING OF THIS SYSTEM. UNAUTHORIZED USE MAY SUBJECT YOU TO CRIMINAL PROSECUTION. EVIDENCE OF UNAUTHORIZED USE COLLECTED DURING MONITORING MAY BE USED FOR ADMINISTRATIVE, CRIMINAL, OR OTHER ADVERSE ACTION. USE OF THIS SYSTEM CONSTITUTES CONSENT TO MONITORING FOR THESE PURPOSES.

## CONCLUSION

The fundamental point of system hardening is to minimize the operating system exposure to compromise, in addition to providing various basic protections to the application or service itself. Hardening of the system platform will ensure that even after a service has been compromised, the integrity and resiliency of the underlying operating system will be maintained. System hardening will prepare the system administrator and ultimately the organization for a compromise and will help to minimize its effects.

Hardening of the service or application that the Linux platform will be supporting is the last remaining step of system self-defense. It is after this point where other network based controls provide additional protective (defense-in-depth) measures.

## GLOSSARY

**ACL** Access Control List

**AES** Advanced Encryption Standard

**Authentication** Verification of the claimed identity of a client or service

**BIOS** Basic Input Output System

**CERT** Computer Emergency Response Team (copyright held by the Carnegie Mellon CERT/CC)

**DAC** Discretionary Access Control (a means of restricting access of files to those with appropriate access permissions)

**Daemon** A process/program that, once activated, starts itself and carries out a specific task

**Data Integrity** Concept of ensuring that data is not manipulated or accessed in any way other than what was originally intended

**DES/3DES** Data Encryption Standard/Triple Data Encryption Standard

**DHCP** Dynamic Host Configuration Protocol

**Group** Collection of users with common computer resource requirements

**GUI** Graphical User Interface

**Host** A computer that acts as a client and/or server

**I&A** Identification and Authentication

**Identification** The process or means by which an information system recognizes an entity

**Incremental Backup** An archival type that only archives new and changed data from the previous backup

**IP** Internet Protocol: Protocols on which the Internet is based. IP allows a packet to traverse multiple networks on the way to the packet's final destination

**LAN** Local Area Network

**MD5** A commonly used message-digest hashing algorithm

**Octet** Set of eight (8) bits.

**Packet** Data consisting of header, origination address, data, and destination

**POP** Post Office Protocol

**Port** Number that identifies a particular Internet application (also, a physical connection for an input/output channel)

**Protocol** Set of rules governing how computers communicate

**Root** Common term applied to the superuser in UNIX/Linux

**RPM** RedHat Package Manager

**SA** System Administrator

**Server** Computer supplying services to users or other computers

**SGID** Set GroupID: A program permission that imparts all the privileges of the program group to anyone executing it

**SNMP** Simple Network Management Protocol

**SSH** Secure Shell. A secure replacement of telnet whereby all traffic to and from the server is encrypted

**Sticky Bit** A world-writable directory permission allowing world-writable files to be written to a directory (usually /tmp) where they may be deleted or changed only by the user or root

**STIG** Security Technical Implementation Guide

**SU** Switch User

**SUID** Set UserID: A program permission that imparts all the privileges of the program owner to anyone executing it

**Superuser** User (hopefully, root) with unlimited access to all system resources unless limited by other software means

**System Files** Operating system files defined as native Linux files and delivered with, or without, a full operating system install

**TCP** Transmission Control Protocol: A protocol upon which the most popular networking is based. The protocol with which it is paired is the Internet Protocol, IP. Together, they are TCP/IP. TCP is a connection-oriented, reliable protocol

**Telnet** A terminal emulation protocol that allowing users to log on to other computer systems

**UDP** User Datagram Protocol: An Internet-based protocol providing connectionless, unreliable communications

**UID** User identification number (a unique user number assigned to each user in a UNIX system)

**umask** Built-in shell function to restrict *read/write/execute* permissions

**UNIX** An operating system written between 1969 and 1972 at Bell Laboratories. UNIX was designed as a multiuser, multitasking operating system. Many versions of UNIX now exist including BSD, System V, Solaris, AIX, OMUS, and Linux, with more to come

**User** Person or machine authorized to access a computer system

**Username** User logon name (mechanism used to uniquely identify a user of system resources). One is assigned for each user by the system administrator

**WAN** Wide Area Network

**Workstation** Typically a more powerful personal computer configured to access a network

## INTRODUCTION

OpenVMS is a system with a unique history. It has a system architecture designed to produce a high-efficiency, high-integrity environment. High-security operation is a direct consequence of these goals. Philosophically, this has been crucial to its success. Thus, OpenVMS avoids the vulnerabilities plaguing systems that do not have security and integrity as part of their initial design. This chapter begins with a full examination of OpenVMS architecture, followed by a detailed examination of its integral security-specific design and related features.

The original OpenVMS design was a combined hardware/software architecture project. The protection modes, memory management, and privileged instruction set of the VAX processor were designed with the collaboration of the operating system's engineering team.

This coengineering process produced an operating system with a unique character. The design blends the knowledge and experiences gained from earlier operating systems together with the supporting hardware elements. The design provides a rich collection of facilities with an unusual degree of consistency and reliability.

These hardware elements are not legacies of the original VAX processor but are the echoes of the coengineering process and reflect the fact that the original VAX architecture was specifically engineered to support VAX/VMS.

Today, OpenVMS is fully supported on three processor architectures: VAX, Alpha, and Intel's IA-64 Itanium. There are almost no differences between them at the applications level. The differences between the versions are limited to

- differences between the hardware environments (such as subroutine calling standards),
- low-level trap/interrupt handling, and
- 64-bit memory support (which is only available on Alpha and IA-64).

This multiple hardware architecture environment is achieved through common code and well-defined interfaces. The overwhelming majority of the 10 million lines of code are common to all three processor platforms. In the case of Alpha and IA-64, the commonality is greater than 95%. The multiple platforms are released on the same schedule and use a common documentation kit, supplemented by manuals specific to each of the hardware architectures. OpenVMS Clusters are frequently constructed with all combinations of the supported architectures interoperating with a fully shared file system.

Configured as recommended, OpenVMS provides an extremely well-protected environment for the user, with fine control over access rights and privileges. It is also the first system to use a common run-time library with a consistent calling standard across all supported languages, from MACRO-32 (the VAX assembler language) to higher-level languages including FORTRAN, BASIC, PL/I, C/C++, and others.

The design emphasizes correctness, completeness, and fine levels of detail in privileges and access rights, together with an overall refusal to specify issues that need not be decided at the operating system level. The combination of detail and deferral of unneeded decisions makes OpenVMS able to support a high degree of nuance. Nuance is the ability of an operating system to be sculpted to express the subtleties of an end user's requirements without losing its essential form or character.

## History

The initial design, in 1977, was a combined hardware/software effort at Digital Equipment Corporation (since merged with Hewlett-Packard), comprising both the VAX hardware architecture and the VAX/VMS operating system. The VAX reflected a trend in 1970s technology toward higher-level language support directly in hardware, particularly in the areas of bounds checking, flow control, and common operations. In 1991, reflecting

the breadth of industry standards supported by VAX/VMS, the operating system was renamed OpenVMS.

Semiconductor technology changes in the late 1980s favored processors with simplified instruction sets. Earlier limits in memory bandwidth had favored more complex instructions. Later VAX processors were simplified and their implementations pruned to remove functions from central processor microcode. Program compatibility was maintained through emulation of these rarely used instructions.

This trend toward processor simplification resulted in the design of Digital's 64-bit RISC Alpha, unveiled in 1992. The Alpha architecture combined support for larger memory spaces with a reduced instruction set designed for high-speed implementations in CMOS technologies.

In 2001 the decision was made to adopt Intel's IA-64 architecture, referred to as Itanium, as the follow-on architecture to Alpha. The first bootstrap of OpenVMS Itanium occurred on January 31, 2003.

## BASIS IN ARCHITECTURE

Philosophically and structurally, OpenVMS is the descendant of two streams of operating system evolution within Digital Equipment Corporation:

- The RSX-family operating systems for the 16-bit PDP-11 processors and
- TOPS-20, the operating system for the 36-bit DECsystem-20 series.

Each of these antecedents contributed thoughts and philosophies to OpenVMS, including internal structures, file systems, and command languages. Problems and shortcomings in earlier designs were also considered in the new design. The OpenVMS architecture is a particularly impressive achievement when one considers that few operating systems running today were in existence 25 years ago, much less in a form that allows many programs to continue to run without recompilation or change.

OpenVMS exemplifies that it is possible to significantly characterize the architectural requirements of applications in many areas, including file formats. It is then possible to provide operating system layers to implement those characterizations as an enabling technology. The OpenVMS Run-Time Library (known as *VMSRTL*) is, in many respects, an object-oriented toolkit, although its design predates the popularity of that paradigm by a decade. This is in contrast to other operating systems, which have entirely omitted this software level of abstraction.

## Implementation Techniques

OpenVMS is characterized by an embrace architectural approach, coupled with an emphasis on quality and performance. The architectural focus is on providing the user/developer with a complete toolkit for the implementation of both software and environments for users to build and employ a wide range of applications. The security aspects of the operating system follow naturally from the focus on robustness, integrity, and efficiency. There is

also an overall emphasis on ensuring that system components interoperate reliably through supported building blocks.

### Multiple CPU/Memory Access Modes

The design uses four access modes, each with its own access rights. From least privileged to most privileged, these are *User*, *Supervisor*, *Executive*, and *Kernel*. The overwhelming majority of users (and their applications) are restricted to *User* mode, which does not allow the execution of machine instructions or memory accesses that can affect the operation of the machine as a whole.

Access to inner (more privileged) access modes is provided through appropriate system services, subject to privilege controls. Elevating privileges requires a hardware trap and validation of the request for execution at a more privileged level (see Figure 1).

### Memory Protection Model

The memory protection model provides for accesses to be controlled on a page-by-page basis. Access is controlled on a Read, Write, or Execute basis. Each access mode can have different access rights, a capability fundamental to maintaining the integrity of the operating system's internal functions. This contrasts with other operating systems that store information in areas readable and writable by user programs, rendering them vulnerable to compromise.

The OpenVMS memory protection model permits operating system components to store process-specific information on behalf of a user process securely within the process's own address space. However, such pages are protected to only permit access to the inner access modes and are invisible and unmodifiable from *User* mode access (Figure 2). This secures information within a process, avoiding security breaches caused by commingling structures in a shared area maintained by the system kernel.

Command line interpreters, such as DCL (Digital Command Language), execute in *Supervisor* mode but within the context of each user's process.

System components requiring access to higher levels of privilege execute in *Executive* mode. The Record Management System (RMS) has some components that execute in *User* mode and some components that execute in *Executive* mode. For example, global buffering and cluster-wide locking would not be directly available to a nonprivileged *User* mode process.

The system kernel, device drivers, and similar components execute in *Kernel* mode, which allows access to all of the hardware of the host machine.

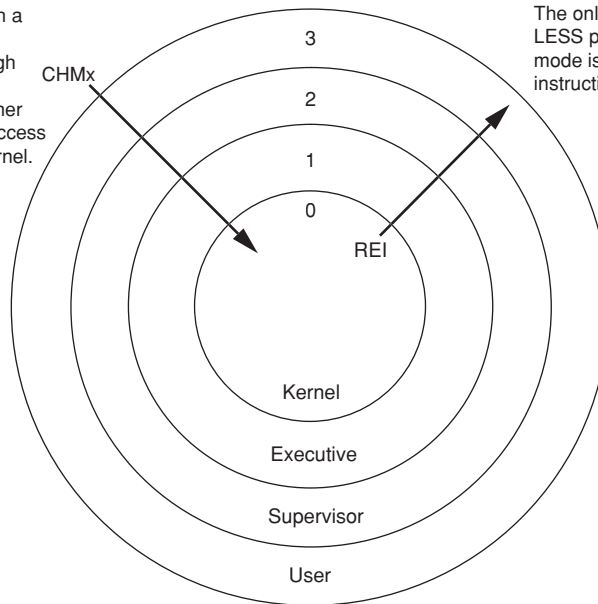

### Fine Granularity of Privilege

Fine gradations of privilege are also characteristic of OpenVMS. Where some operating systems are distinguished by a binary approach to privilege (a user or process is either fully privileged or fully not privileged), OpenVMS from the outset has had a more nuanced approach. Presently, basic OpenVMS has 36 different privileges (three additional privileges are only available under SEVMS, the OpenVMS version with mandatory access controls). In many instances, an OpenVMS application or user can perform very powerful system

Access mode fields in the PSL are not directly accessible to the programmer or to the operating system.

A process can reach a MORE privileged access mode through a CHMx Instruction. In addition, most other exceptions cause access mode change to kernel.

The only way to reach a LESS privileged access mode is through the REI instruction.

The boundaries between the access modes are nearly identical to the layer boundaries pictured in Figure 5. Nearly all system services execute in kernel mode. RMS and some system services execute in executive mode.

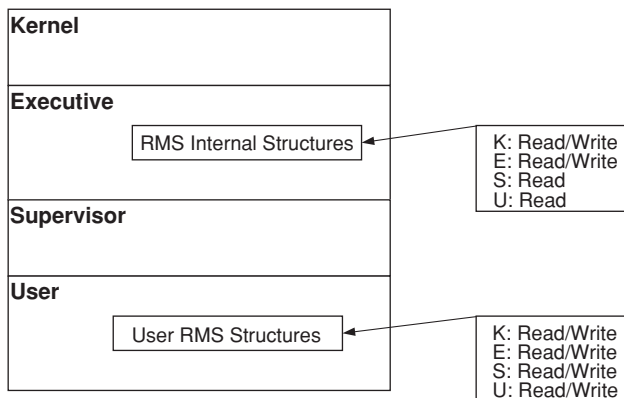

Command language interpreters normally execute in supervisor mode. Utilities, application programs, run-time Library procedures, and so on normally execute in user mode. Privileged utilities sometimes execute in kernel or executive mode.

**Figure 1:** OpenVMS memory/processor access modes (from *VAX/VMS Internals and Data Structures, Version 5.2 [1991]*, p. 16).

management functions, such as managing print queues or storage volumes, with a single or a small number of relatively innocuous privileges, rather than full system management functions.

**String Descriptors**

The programmer's interface to OpenVMS uses descriptors for references to most data types (see Figure 3). The overwhelming majority of internal interfaces also use descriptors. The exception to the use of descriptors is simple parameter references of the call-by-value (familiar to C/C++ programmers) and simple call-by-reference (familiar to FORTRAN/C programmers).

**Figure 2:** Information is stored in a process's address space but is not modifiable by the *User* mode program.

The pervasive parameter checking enabled by the use of descriptors has rendered native OpenVMS code relatively immune from string overflow and similar errors. String and buffer overflows have plagued other systems, particularly systems written in C, which have used C's ubiquitous 0x00 (null) terminated strings.

Descriptors allow system library functions to completely check their input and output arguments before processing. System library routines check the validity of input and output parameters, returning errors if they are not in appropriate locations.

**Embrasive Architecture**

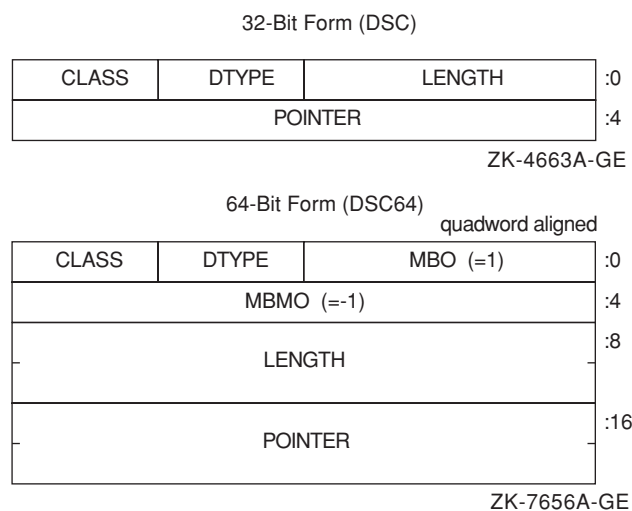

From the outset, OpenVMS has had a substantial focus on well-reasoned architecture, which provides a solid basis for the implementation of robust software. OpenVMS's architecture strikes a balance between specification as needed to ensure correctness and specification that leaves enough open space within the architecture to ensure sufficient room for growth.

This approach has proved successful in that it has ensured compatibility for a huge corpus of code, consisting of OpenVMS itself, layered products, and third party and user code over a 25-year period. Incompatible changes from the original specification have been rare.

**Scaling**

OpenVMS, in its latest releases, is officially qualified to run on a wide range of hardware, from the MicroVAX 3300 (2.5 MIPS) to Alpha and Itanium systems well into

**Figure 3:** OpenVMS string/other descriptors were extended to include 64-bit lengths and addresses with the 1992 advent of the 64-bit Alpha processor (diagram from *OpenVMS Calling Standard, 2001*, p. 5-3).

the billions of instructions per second (1000+MIPS). Only within the last few years has official support for the original VAX-11/780 been withdrawn, as main memory requirements have increased beyond its capabilities.

Systems supported on OpenVMS range from uniprocessors to 32-way processors. The minimum supported memory configuration is 14 Mbytes on a VAX, 64 Mbytes on an Alpha. Alpha systems are able to efficiently exploit gigabytes of memory.

### Platform Independence

Most users have been unaware that translated and interpreted images have been part of the base OpenVMS system since its original release in 1977. The original VAX/VMS contained numerous 16-bit PDP-11 images that were hardware interpreted. To this day, certain commonly used programs have been translated rather than recompiled. The TECO text editor and the MONITOR utility (pre-OpenVMS release 7.3-2) are the products of binary translation from VAX to Alpha.

There is little doubt that recompilation is the most effective way to make use of the power of a new processor architecture. The availability of image translation represents a viable trade-off between the costs of rebuilding applications and lost processor performance against schedule and engineering costs.

The interpretation/translation/recompilation approach on a system with a common API is both viable and effective. It is another case, where OpenVMS provides a nuanced approach, allowing project managers to take advantage of system facilities to shorten schedules in ways that are functionally transparent to users.

### Environment Portability

OpenVMS is designed for use in a data center because it provides the mechanisms for implementing a tightly controlled environment. It is always simpler and less error prone to relax tightly controlled environments than it is to impose stricter controls on relaxed environments. Adding

security and integrity controls after the fact is often an underlying source of security problems.

### OpenVMS Clusters

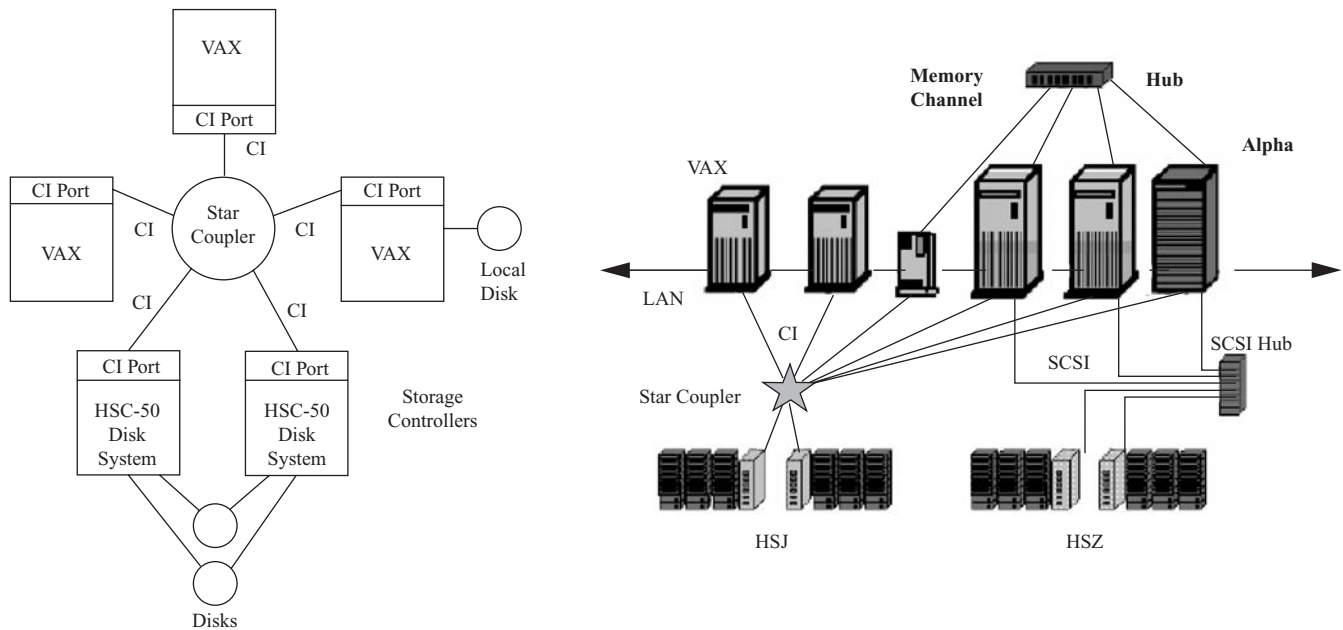

OpenVMS clusters, announced in 1983, remain a unique concept. An OpenVMS cluster is composed of multiple, independent CPUs, each running an independent copy of the operating system, with the cluster members coordinating access to a shared file system, down to the record level in individual files. By contrast, a conventional multiprocessing system comprises multiple CPUs with common memory sharing a single memory-resident copy of the operating system. Individual cluster members are often themselves multiprocessors. Although the individual cluster members are running separate copies of OpenVMS, the cluster itself operates as a single security domain (see Figure 4).

In an OpenVMS cluster, the CPUs and mass storage controllers communicate via a high-speed local area interconnect, originally the CI (Computer Interconnect, a proprietary dual 70 Mbit/sec CSMA/CD LAN). Today, IEEE 802.3/Ethernet (10 M/100 M/1 Gbit/sec) is often used. Usually, the entire file system is shared, with access to file system structures, files, and even byte ranges or records within files controlled via the Distributed Lock Manager.

The Distributed Lock Manager implements a shared locking domain. This unique characteristic of OpenVMS clusters allows the entire cluster to act as one system for the purpose of file-based applications. Each OpenVMS system has a copy of the Distributed Lock Manager. In an OpenVMS cluster, the Distributed Lock Managers on each cluster member exchange information about which system holds locks on which resources. Architecturally more important, the Distributed Lock Manager only deals with resource names. Thus, the Distributed Lock Manager represents a fundamental building block for end-user developers to implement synchronization tasks other than those envisioned by the OpenVMS engineering team.

File locking is controlled by the file structure support component, known as the XQP (extended QIO Processor). Record Management Services, known as RMS, supplements the file-level access provided by the XQP with facilities used to access the contents of files and is responsible for locking on granularities smaller than entire files. RMS supports a wide range of file contents, including simple sequential files, byte stream files, relative files, and indexed files.

Officially, an OpenVMS cluster is limited to 96 nodes with a maximum radius of 500 miles (800 km). Customers have configured OpenVMS clusters that exceed these limits in one or more ways, primarily in terms of the number of nodes in the cluster. This is a wider and more flexible scope than other products. When extreme emergencies and catastrophes occur, OpenVMS clusters, configured in a disaster-tolerant mode with multiple sites separated geographically, have continued IT operations unscathed. Even the 9/11 destruction of the World Trade Center complex in New York City did not stop several disaster-tolerant OpenVMS cluster systems that had cluster members within the Twin Towers or surrounding buildings. The other sites continued operating with an imperceptible pause.

**Figure 4:** Unchanging fundamentals of OpenVMS cluster: 1983–2004 (diagrams from Kronenberg, Levy, & Strecker, 1986 and *HP OpenVMS: The World's Leader in Clustering*, 2003).

## Software Basis

Architecturally, the approach is a classic, layered approach in the spirit of Dijkstra's classic paper on THE (1968). There are few special-purpose components in the system. The approach is one of conceptual and implementation uniformity. The libraries and supporting infrastructure used to implement the operating system are the same tools available to support user development (see Figure 5).

## Processes

OpenVMS processes consist of page tables, logical name tables, thread contexts (including register states), stacks, mapping to common shared memory regions, and process-private memory regions.

Historically, OpenVMS processes had single-register contexts, and therefore a single thread of execution associated with each process. On the 64-bit platforms, beginning with version 7.0, support for multiple threads per process was added, allowing a single process to simultaneously use multiple processors in a multiprocessor system.

## Privileges

OpenVMS implements a fine-granularity privilege model. There are a number of different privileges, and many of them permit operations personnel to do their jobs without giving them unrestricted management access to the system.

Some privileges, such as **NETMBX** (the ability to create network mailboxes; which is needed to use DECnet or TCP/IP) and **TMPMBX** (the ability to create temporary mailboxes) are innocuous and can be routinely issued to students in a college course without cause for worry.

Some privileges, although less innocuous, only affect members of an individual group but are not dangerous to the system as a whole. These can be issued in safety in a properly configured system.

Other privileges have potentially greater side effects. Privileges classed as **DEVOUR** can, in the words of the *HP OpenVMS Guide to System Security* (2003), “consume noncritical systemwide resources.” Privileges classed as **SYSTEM** can similarly “interfere with system operation.” Those classed as **OBJECTS** can “compromise the protection of protected objects.” Class **ALL** privileges have the “potential to control the system.”

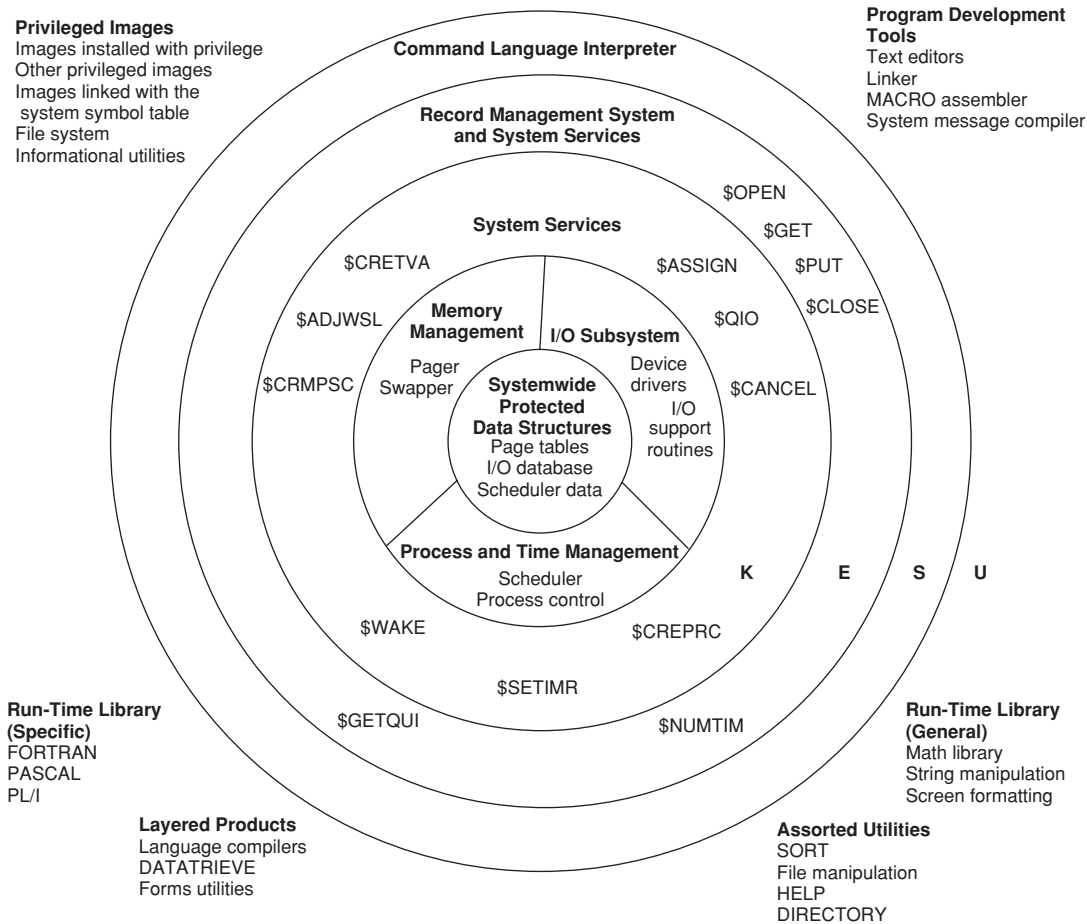

Assigning privileges is important in the context of security but is inevitably a compromise. A common trade-off is to provide certain privileges, particularly **OPER**, **READALL**, and sometimes **MOUNT**, to operators to permit normal operations such as managing queues and performing backups.

The privileges categorized as **DEVOUR**, **SYSTEM**, **OBJECT**, and **ALL** have the ability to affect system operation, whether it is merely resource starvation (as in a runaway program with **EXQUOTA**, the ability to ignore disk space quotas) or crash the system (through the misuse of the **WORLD** privilege). Others, such as those classified as **SYSTEM**, can totally compromise the security of the system.

Some privileges fall into barely safer categories, such as **SYSPRV**, which allows a variety of system management functions, including modifications to the **SYSUAF** file. The danger here is subtler. Because access to the **SYSUAF** permits the changes to the list of authorized users, as well as changes to the authorized and default privilege masks for an account, it effectively permits a user to give themselves (or a confederate) full privileges.

## Implications of Privileges—Security Issues

When planning a security environment, it is important to consider the security implications of routine tasks. System backups are an interesting case in point. Backup operators frequently are issued the **READALL** privilege to ensure

**Figure 5:** A schematic view of OpenVMS system architecture (diagram from *VAX/VMS Internals and Data Structures, Version 5.2, 1991, p. 10*).

that the backups are able to read all the files on mass storage when producing backup tapes. Thus, they must inherently be trustworthy.

Some files, however, may need to be omitted from the routine backups. The reasons for this omission are varied. Some or all of the reasons for omissions may apply to particular installations. For example,

- some files may be both large of size and transitory in nature. It may be substantially easier to recreate the file in the event of a problem than it is to allocate sufficient time and archive space for the backups.
- some information is sufficiently sensitive that it should not be part of the normal backup process. In this case, the information can be located on different disks or marked in a way that it will be omitted from the normal backup process.
- some files may be subject to retention or archiving restrictions that are different from the overall backup and retention policies of the installation. For example, a file may be subject to a court protective order requiring that all copies be destroyed as part of the proceedings. Such files should not be included in routine backups. They should, however, be part of a project or activity backup.

OpenVMS, through its file system and **BACKUP** utility provide mechanisms to manage file migration and backup for all of these possibilities. The **BACKUP** utility is designed specifically to seamlessly incorporate all of these needs without requiring external, special-purpose utilities.

### Quotas

OpenVMS has extensive facilities for the management of system resources by processes, whether they are privileged processes belonging to the system or conventional user processes. These limits are known as *quotas*. Used properly, they prevent an individual process from impairing system operation by causing a depletion of significant system resources, such as system dynamic memory or disk space. Other quotas, such as the quotas on aggregate buffered and direct IO operations, serve to prevent a single process or job from monopolizing the overall system.

Disk quotas allow system managers to control the amount of disk space on each volume used by an individual. Quotas may be associated with UICs or Rights Identifiers. Rights Identifier-specific quotas allow space to be allocated on a project basis. These mechanisms are complementary, not exclusive.

### Threading and Asynchronous System Traps (ASTs)

Hierarchically preemptible processing is central to the OpenVMS architecture. Fundamental to its structure, OpenVMS supports a single-threaded environment, with support for a very lightweight FIFO (first in, first out) event-processing thread for each access mode. These event-processing threads, which preempt the main thread of processing, are called *Asynchronous System Traps (ASTs)*.

Speaking in terms of evolution, ASTs are descended from the RSX family of operating systems. They have proved to be a highly efficient mechanism for processing asynchronous events (such as timers and IO completions) without excessive overhead. ASTs are extremely lightweight because they do not have any context of their own but preempt the main thread of execution. Their inherent synchronization is one of their simplest yet most powerful features. Within a particular access mode, AST processing is FIFO and nonpreemptible. This implicit synchronization makes it unnecessary to explicitly synchronize different ASTs in the same access mode within a particular process. Inner access mode ASTs can preempt outer mode ASTs.

They can be used with few limitations, other than quotas, by any process. OpenVMS makes extensive use of AST processing in system libraries and the file system. The importance of the AST mechanism can be seen from the ongoing attention paid to AST implementation on the VAX, Alpha, and Itanium processors.

This is in contrast to the signal model used in UNIX-style operating systems, which are structured in a less modular, less general basis and where blocking of signals is commonplace (to prevent preemption), with the resulting synchronization issues.

### Common Run-Time Library

From the outset, OpenVMS was designed to be programming language agnostic. It was the first operating system with a defined, cross-programming language run-time library. From its origin on the VAX architecture, routines written in one programming language have been effortlessly able to invoke other routines written in different languages. It is common to encounter individual programs written using a variety of languages, particularly so in cases where one language has a clear advantage in clarity of expression or functionality over the other (e.g., BAS-BOL: BASIC with COBOL subroutines and COB-FOR: COBOL with FORTRAN subroutines). This feature is used within OpenVMS itself, where components have been written in VAX MACRO-32, BLISS, BASIC, FORTRAN, PASCAL, PL/I, and C/C++.

The run-time library also provides a rich underpinning of functionality for user and third-party programs. Seemingly complex mechanisms in system-provided utilities are nothing more than calls to run-time library routines, accessible to all users.

### System Services

The lowest-level, user-visible interfaces to OpenVMS are referred to as system services. These services are a diverse group, including:

- very simple building blocks, such as those which format ASCII output, `$FAO` and `$FAOL` (which run in User mode),
- functions that perform extensive processing in privileged modes (e.g., `$QIO` and `$QIOW`) to make a system capability available to a user program in a safe manner, and
- gateways (e.g., `$CHKPRO`, `$CHMKRNL` and `$CMEXEC`) to the rare programs that need inner access modes.

The `$QIO` and `$QIOW` system services (Queue IO Operation and Queue IO Operation Wait) act as gatekeepers to IO resources for all system components. `$QIO` is an excellent example of the OpenVMS philosophy, in that it provides a rich set of functions and common processing for IO requests, including:

- parameter checking,
- common device driver initiation and completion processing, and
- definitions for operations, based upon common models of device functionality (e.g., file systems) without imposing inappropriate demands at the interface level. For example, the 16-bit IO function codes have defined meanings for file opens (read-only, read-write, and read-write-extend), file attributes (read/write attributes), and various values for control of communications channels (see Table 1).

`$QIO` does not attempt to specify all possible operations so much as it announces a framework for expressing the possibilities for interfacing to an external (or pseudo) device. It also provides an intermediation between requesting programs and the actual details of managing a physical device.

### Device Drivers

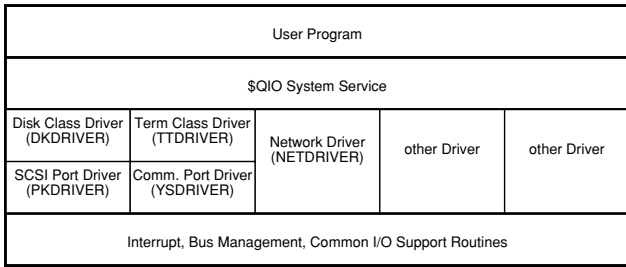

In common usage, the term *device driver* has become overloaded, acquiring multiple meanings. Originally, a device driver was a software component that formed the privileged interface between a particular IO device and the

**Table 1** OpenVMS IO Function Codes by Category

Function	Symbolic Value	Value (hexadecimal)
Create file	IO\$_CREATE	0x0051
Access file	IO\$_ACCESS	0x0050
Read virtual	IO\$_READVBLK	0x0049
Write virtual	IO\$_WRITEVBLK	0x0048
Deaccess file	IO\$_DEACCESS	0x0052
Delete file	IO\$_DELETE	0x0053
Modify file	IO\$_MODIFY	0x0054
Read with prompt	IO\$_READPROMPT	0x0055
ACP control	IO\$_ACPCONTROL	0x0056
Mount volume	IO\$_MOUNT	0x0057

**Figure 6:** OpenVMS device drivers in relation to the kernel and the QIO system service. An OpenVMS *device driver* does not operate in a vacuum, but in the context of the User Process and the overall direction, policies, and scaffolding provided by the system kernel.

operating system kernel. Some operating systems and applications have muddled the definition by using device driver to refer to nonprivileged components that address device idiosyncrasies, such as printer escape codes.

OpenVMS uses the term device driver in the original meaning of the phrase. Device drivers are the components that actually manage the operation of specific devices. In OpenVMS, device drivers are loadable kernel subroutines that interface between the kernel, particularly the program accessible \$QIO system service, and the actual hardware (see Figure 6). Although device drivers do not have a full context, they do not exist in a vacuum. Device drivers are subroutines of the kernel, and, in the case of IO initiation, operate in the mapping context of the requesting process. OpenVMS device drivers do not form the lowest layer of the software architecture but are an intermediate layer between the routines that actually perform hardware accesses and the QIO layer providing generic IO services. Architecturally, the lowest layer is populated by the an extensive collection of routines that allow device drivers to perform common functions, from managing the mapping of transfers to interrupt management.

As an example of OpenVMS's flexibility, adding storage volumes to OpenVMS does not require a reboot but merely a command to bring the new device online.

OpenVMS device drivers have substantial capabilities and act as more than mere filters or funnels of information between the generic IO services provided by the kernel and the device. Device drivers do significant processing, perform transformations of data, and are solely responsible for dealing with the idiosyncrasies of the different devices. However, some operations, such as managing the disk file structure, looking up files, and locating file segments on the disk, require additional operations that are beyond the capabilities and context of an OpenVMS device driver.

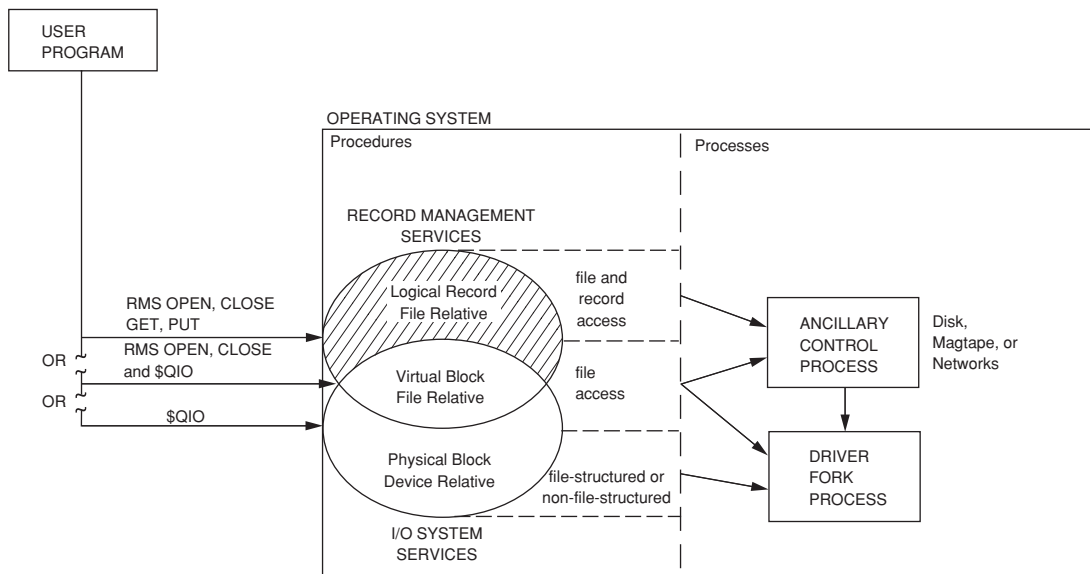

**Ancillary Control Processes**

File structure management is one such class of operations. Structurally, IO operations must belong to a process. Device drivers, being kernel subroutines, do not have a process context of their own. If the IO request requires more than straightforward processing, a helper process with a full process context is used. These helper processes are referred to as an *Ancillary Control Processes (ACPs)* and are associated with the device used. ACPs are privileged OpenVMS processes whose function is an intermediate level of device-specific management. An ACP effectively extends the conceptual IO model supported by the device (see Figure 7).

An ACP is associated with a particular device or a class of devices. ACPs are employed where IO related tasks, such as file system management or network connection management, require more extensive processing.

Often, as in the cases of mass storage devices, an ACP will create and manage driver-accessible data structures that permit the driver to directly map or translate future requests without the need to invoke ACP processing. This eliminates the context switches to and from the ACP.

In the case of conventional file processing, even this efficiency was deemed insufficient, and the FILES-11

**Figure 7:** Record Management Services as an example of the multiple exposed steps of OpenVMS interface (from VAX-11 Software Handbook, 1979, Digital Equipment Corporation, 1979).

Level 2 ACP was reimplemented as a kernel-mode library, invoked by the driver in the calling process's context, without the need for additional context changes (Goldstein, 1987).

### Shared Libraries

OpenVMS makes extensive use of shared libraries. In most cases, a user image will contain few, if any, actual run-time library routines. The majority of the references are to shareable libraries. Qualitatively speaking, this means that updates to run-time environments rarely require recompilation or relinking of user applications but merely an exit and reinitiation of the running image. Nor is a system restart needed. Applications need only be recompiled or relinked on the rare occasions when the interface between a run-time library and its callers change.

As with most OpenVMS features, there is nothing structurally special about a shareable library. Users, organizations, and software providers frequently use shareable libraries as the preferred mechanism to access executable code referenced by a program.

### Privileged Shareable Libraries

Shareable libraries can be created with inherent privilege. Although this capability has a potential for abuse, it is a source of significant strength.

Privileged libraries permit the construction of services to provide particular functions that require privilege without requiring the entire requesting application to be privileged. This allows the OpenVMS mail facility to be implemented as a very small "mail delivery" privileged library, with very limited capabilities, thereby reducing the risk that the privileges needed to deliver mail are misused for other purposes.

By way of comparison, making the entire mail-delivery process privileged, as is done in UNIX sendmail, is an ongoing source of security holes. The OpenVMS philosophy, separately implementing only that small portion of the facility that requires elevated privileges, is a far safer alternative.

### Command Language Support

The standard command language on OpenVMS is known as DCL (Digital Command Language). It is intended to be somewhat English-like, with commands consisting of a verb, qualifiers, and operands. (See Table 2.)

Command and file name parsing is performed by a set of standard utility subroutines, which, together with tools

for expressing the syntax of a command, allow a high degree of consistency without restricting the capability to the original development team.

Used properly, these tools permit OpenVMS to make extensions (as were made to support filenames with lowercase and special characters) without requiring extensive modifications to every program.

Command qualifiers permit the same verb to activate different programs depending on the qualifier specified. For example, the default editor is known as **TPU** (Text Processing Utility). The older, but still popular, **EDT** editor is still accessible through the use of a qualifier (**EDIT/EDT**). Wrappers, based on the TPU editor, are used to edit Access Control Lists and file definitions.

## SECURITY-SPECIFIC ARCHITECTURE

OpenVMS security functionality is based on a UIC (User Identification Code), rights list, and privilege list associated with each user login. Although OpenVMS does not directly enforce a requirement that UICs be uniquely associated with a user, it is the recommended practice.

A UIC is a 28-bit code broken into two elements:

- a 12-bit Group number
- a 16-bit User number

Each process has an associated UIC, privilege mask, and rights identifier list. These form the foundation for all subsequent security-related checking, whether it is the basic traditional set of OpenVMS protections or the more versatile rights identifier-based protections.

The traditional OpenVMS access checks are first based on the UIC, with privileged access (**BYPASS**, **READALL**) only used if the requested access is denied. System accesses are available to those processes whose group does not exceed **MAXSYSGROUP** (a system parameter whose normal value is 10<sub>8</sub>) or whose **SYSPRV** bit is enabled in the process's privilege mask.

### Traditional Protection/Ownership Hierarchy

The basic and most efficient resource access control mechanism in OpenVMS is the traditional System/Owner/Group/World protection scheme based upon these factors:

- the UIC and privilege mask of the accessing process; and
- the protection mask of the target resource, which

**Table 2** Common Example of OpenVMS Commands

DCL Command	Meaning
DIRECTORY	List files in current directory
DIRECTORY *.FOR	List all files in current directory of filetype FOR (Fortran-77 source files)
SET DEFAULT [.FOX]	Set current directory to the FOX subdirectory
TYPE X.TMP	Type (on the standard output, SYS\$OUTPUT) the contents of the file X.TMP
CREATE X.TMP	Create a sequential file X.TMP (from the standard input, SYS\$INPUT)

**Figure 8:** User identification codes and identifiers from the basis of OpenVMS security facilities.

specifies which accesses, Read, Write, Execute, or Delete, are permitted for each category of user.

The traditional UIC-based identification works by categorizing users into four categories:

- Owner: Processes whose UIC is the owner of the object.
- System: Processes whose UIC is in the System range.
- Group: Processes whose UIC is in the same Group as the owner of the object.
- World: Processes whose UIC is not in one of the previous categories.

## Rights Identifiers

*Rights identifiers* are the basic building block of the non-UIC based security and auditing mechanisms. Externally, identifiers are represented by ASCII strings of 1–31 characters. Internally, these strings are mapped to 31-bit binary values. Non-UIC-based identifiers all have the 32nd [high-order] bit set; identifiers referring to UICs are equal to the UIC and have the high-order four bits clear (see Figure 8). This allows UICs to be used as identifiers in their own right. The mapping between printable and binary forms are stored in a file known as the **RIGHTSLIST**, generally **SYSSYSTEM:RIGHTSLIST.DAT**.

Most references to rights identifiers refer to the conceptual identifier externally represented by the printable identifier. In any event, these identifiers are the mechanism used to resolve access to resources.

System services (**\$ASCTOID** and **\$IDTOASC**) and the DCL lexical function **F\$IDENTIFIER** (with subfunctions for both sets of conversions) are available to convert identifiers from the ASCII string form to the 32-bit binary form and vice versa, respectively.

## Identifier-Based Access

The mechanism used to allow access to a protected resource under OpenVMS with discretionary access controls is a matching undertaken between a the set of access rights (called “identifiers”) held by a process and the Access Control List (ACL) associated with the resource.

## Reference Monitor Concept

The conceptual framework of OpenVMS access control is that of a reference monitor, a central entity responsible for the monitoring of all accesses by processes (and hence by users) to system objects (see Figure 9).

A reference monitor creates a single point of responsibility for access control and auditing. In OpenVMS, it

is implemented as a small number of gatekeepers for different resource classes, generically known as *objects* (see Table 3). Reference monitor terminology refers to all entities that act as initiators of security-related requests as *subjects*. In the OpenVMS context, a *subject* normally represents a process (or thread of a process). There is no loss of generality, as users cannot make requests for access to objects without in some way going through a process (or thread of a process).

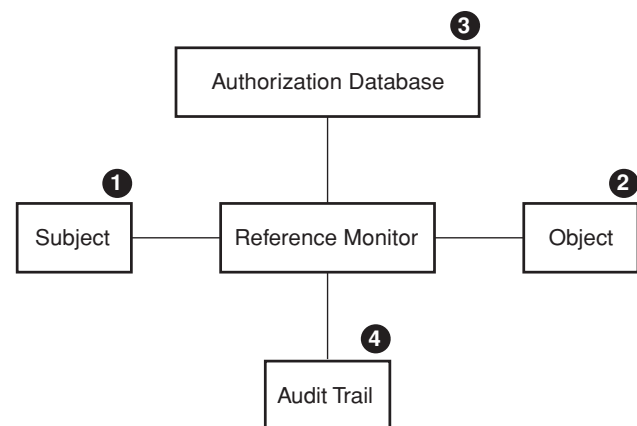

It should be remembered that access control through identifiers and ACLs operate in the absence of access through other means, such as the System/Owner/Group/World protection mask, and the privilege mask. If a resource is to be protected based on ACLs and identifiers, then care must be taken to ensure that access is not available through the other mechanisms.

Access to **SYSPRV** and other so-called ALL-class privileges should be carefully controlled. Systems programming and systems management staffs routinely need these privileges to maintain the operating system. Applications development, testing, and most production activities do not require privileges.

The identifier/ACL mechanism provides an excellent tool to permit the delegation of management activities and privileges to users without the need to grant DEVOUR-class privileges to a wide circle of individuals.

## Resources

The OpenVMS reference monitor model controls access to 11 different classes of objects (see Table 3).

VM-0994A-AI

**Figure 9:** Reference monitor model used by OpenVMS to implement security related facilities (from *OpenVMS Guide to System Security*, 2003, Figure 2-1, p. 28).

**Table 3** Classes of Objects Subject to Protection by the Reference Monitor

Capability	A capability of the host system, presently the only such capability is the vector processor on certain VAX CPUs.
Common Event Flag Cluster	A named set of 32 event flags that are shared between collections of different processes.
Device	A hardware or pseudodevice connected to the system.
File	A file on a file structured mass storage medium (e.g., disk).
Group Global Section	A shared memory section available to a collection of processes.
Logical Name Table	A table of logical names accessible to a collection of processes.
Queue	A set of jobs to be processed in a batch, print, or other queue.
Resource Domain	A namespace controlling access to the lock manager's resources.
Security Class	A data structure containing the elements and management routines for all members of the security class.
System Global Section	A shareable memory region potentially available to all processes in the system.
Volume	A volume mounted on a device (e.g., tape, disk).

Source: *OpenVMS Guide to System Security*, 2003, Table 2-1.

References to resources are controlled according to the ownership, protection masks, and ACLs associated with each object. The checking is performed in a defined order and eliminates the need for many, if not all, applications-based security checks (see Figure 10).

### Access Control Lists

Each object with the potential for restricted access has provisions for an optional ACL. The ACL contains a list of identifiers and the types of access to be granted to the holder of the identifier. Although they may be associated with any file, other Access Control Elements (ACEs) generally have meaning only when attached to directory files, providing for the propagation of ownership, protection masks, and access control lists to new files.

Order of appearance of the ACEs in an ACL has significance. The matching of identifiers to rights enumerated in the ACL proceeds one ACE at a time until a match is detected. Thus, if a process holds multiple rights identifiers, as is typical, the ACL must be ranked as follows:

- Denials of access (ACEs with the **ACCESS=NONE** term)
- High-grade access (ACEs with the most access). For example:  
**ACCESS=READ+WRITE+EXECUTE+DELETE+CONTROL**)
- Lesser degrees of access
- Minimal access (ACEs that solely contain **ACCESS=READ** or **ACCESS=EXECUTE** terms)

To summarize, the first ACE whose rights identifier matches a rights identifier held by the process (or thread) will be used to determine whether the access is permissible.

### Audit Server

Significant security-related events are reported to the audit server; a process which writes those events to an audit log (by default, **SYS\$MANAGER: AUDIT\_SERVER.DAT**). Operator messages are also written to those terminals that have been set to display operator messages of class **AUDIT**.

If there is insufficient space for the audit log file, system operation will be suspended, with no log-ins permitted (with the exception of the physical system console).

### U.S. Government Security Certification

VAX/VMS version 4.3 was the first (1986) system certified to support the requirements of the Department of Defense's *Trusted Computer System Evaluation Criteria*, colloquially referred to as the *Orange Book*. This standard, originally developed by the National Computer Security Center and now administered through NIST, divides systems into a variety of categories. The lowest useful category is C2, described as "Discretionary Access Controls." Systems that provide mechanisms for security managers to mandate the use of security controls are categorized as level B systems.

In 1987 and again in 1993, OpenVMS was reevaluated against both the C2 and B1 levels of trust. The OpenVMS variant with the facilities required for operation at the B levels is referred to as SEVMS. SEVMS was first released, unevaluated, in 1987. The next release, corresponding to OpenVMS 6.0, was released in 1993. The security rating is maintained by a process supervised by the National Center for Secure Computing, with the bulk of the effort undertaken by the OpenVMS engineering team.

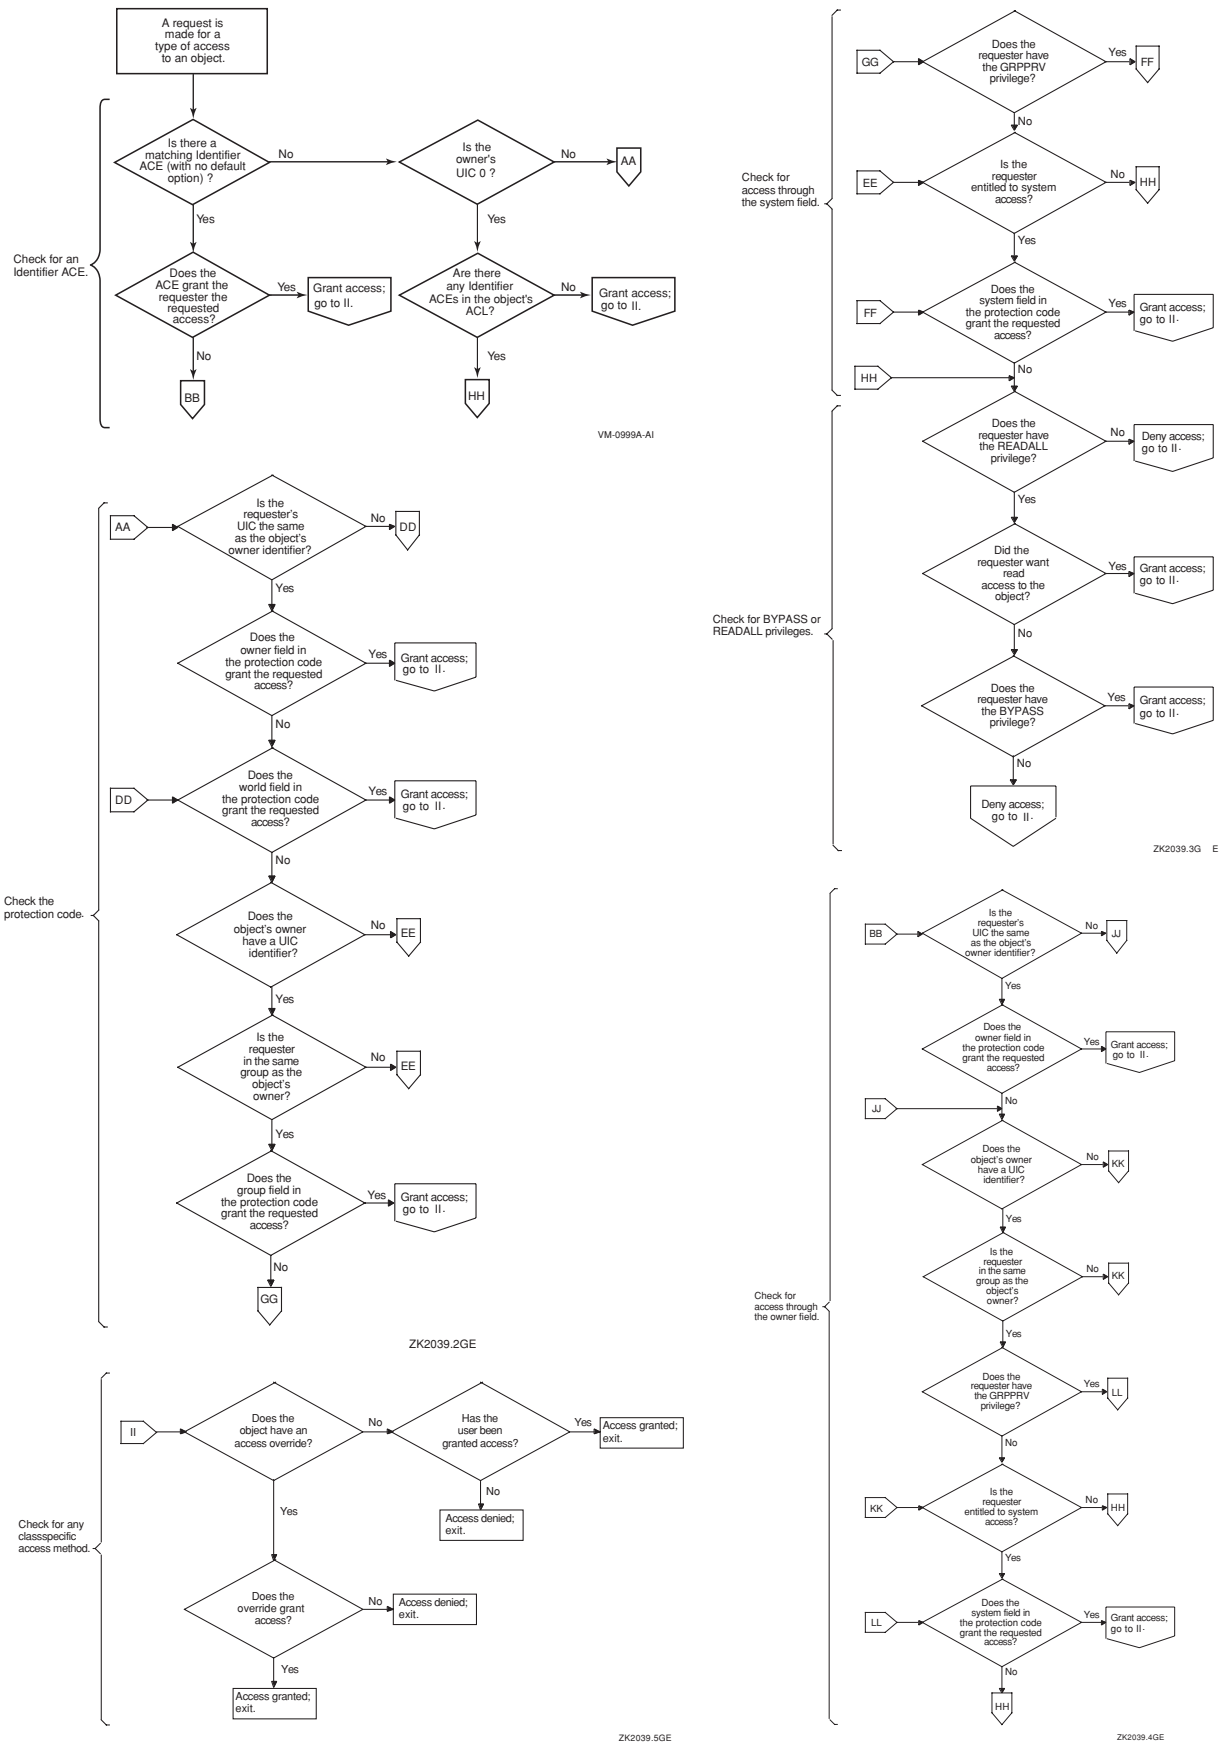

## IMPLEMENTING SECURE USER ENVIRONMENTS

Implementing a secure user environment requires utilizing the facilities to maximum advantage. The implicit security facilities provided through inheritance and the user authentication mechanisms are both efficient and auditable.

### Implicit Security

It is less complex than it would first appear to implement a large-scale, secure OpenVMS environment. The key to building an environment that works is to leverage the strengths of the system.

**Figure 10:** Security checks performed by OpenVMS when accessing objects controlled by the security system (from *OpenVMS Guide to System Security*, pages 71, et seq.). These checks, performed by OpenVMS, eliminate the need for applications-based security checks.

**Table 4** Different Classes of Users for a Typical Application

Maintainer	An individual responsible for maintaining the files.
Operator	An individual responsible for day-to-day maintenance (e.g., backups).
User	Normal user authorized to access and modify records in the file.
Query Clerk	Low-level user authorized to only access (not modify) data within the file.

Although it may seem complex, the recommended technique of creating categories of personnel and assigning access rights to those categories is straightforward, secure, auditable, and efficient.

Identifiers are created to refer to collections of users. These collections are often based upon departments or applications (e.g., Accounting, Payables, Human Resources) and level of personnel (e.g., Supervisor, Clerk, Inquiry Clerk; see Table 4). These identifiers are then granted to individual users using the **AUTHORIZE** utility (**AUTHORIZE** can also be used to display the identifiers held by a given user). When the user logs onto the system, their process will be granted the identifiers associated with their username.

Beginners often try to add ACLs with ACEs for every individual user. Putting individual access rights onto each and every resource is a poor approach for many reasons, including:

- It is not maintainable. As users come and go, each and every ACL will have to be reviewed and updated accordingly.
- As job responsibilities ebb and flow, each and every ACL will have to be reviewed and updated accordingly.
- When access controls are audited, as is common in larger companies, each and every ACL and each and every ACE will have to be verified.
- The resulting large ACLs will require excessive time to evaluate, compromising system performance.

The role-based approach is far more efficient, maintainable, and auditable. In a role-based approach, files have ACLs composed of ACEs referencing a set of defined roles. In effect, the system dynamically constructs the matrix of individual user's access rights based upon their identifiers and the ACLs, eliminating the need for special access checking code in programs, privileges, or other cumbersome mechanisms.

Users will hold a list of identifiers as a form of electronic badge endorsement. In effect, the rights identifiers provide management the tools to separate user validation from user clearances.

If job responsibilities change, or if a user's access must be suspended because of an investigation, it is a simple matter to remove critical rights identifiers from the authorization profile, while still permitting access to the system for other matters (e.g., electronic mail, time sheet filing, benefits filing). If the access environment is properly implemented, security and audit managers can be confident that the prohibitions will be effective.

## File Protection

Properly categorized, the same program, running on the same machine at the same time, can operate on different files with dramatically different protection regimes. The security mechanisms and logical name environment provide a framework to control access. The degree of access available is implicit in the individual user (or the group with whom the user is associated), from wide open to strictly controlled.

The different permutations of the elements, and their inherent flexibility, permit a wide range of choices as to degree of security, even within an organization. This is especially important for organizations and systems that have differing security needs in different units or departments. There is no need for separate systems and variant applications when a proper security regime is implemented.

## Limited Accounts

OpenVMS also has provisions for limited user log-ins, known as **CAPTIVE** accounts. Users whose accounts are **CAPTIVE** are restricted in several ways:

- no ability to specify options at login,
- no access to the **DCL** command prompt, and
- if the command script ever exits, the session is automatically terminated.

These restrictions, which allow a user access to specified command procedure or an application menu with controlled choices, are a good security measure for non-IT applications users. Such an account, together with the other security controls, enables the construction of user environments with multiple levels of protection and control, with no corresponding need to develop and maintain special-purpose code.

## Secure Subsystems

The OpenVMS security mechanisms are powerful; yet, there are situations where controlled access to an object is desired beyond the constraints expressible in the basic security model. OpenVMS has a facility for addressing these exceptions called *protected subsystems*. Protected subsystems work because the user holds the identifier(s) needed to access the application, whereas the applications image itself holds the identifiers needed to access the object.

## Results of Security Violations

The action taken when a security violation occurs has important implications. Merely preventing the inappropriate (or undesired) reference is essential but, generally speaking, an insufficient response. Auditors and security personnel need to know that an unauthorized attempt to access resources has occurred. The realities of large-scale systems operations complicate this task. Protecting resources too tightly can result in voluminous alarm indications, which serve no purpose other than making it harder to identify true security violations.

OpenVMS, through the combination of its integrity-based design, resource monitor, and audit server, provides good mechanisms to tailor security reporting to those security-related events that are desired, without reporting

false alarms, and still protect the overall system from misuse.

### Damage Limitation

The central goal of the implicit security-related mechanisms is to limit damage to other system users and the overall system. In a direct sense, as mentioned earlier, it is a consequence of the integrity, robustness, and safety aspects of the design philosophy.

The initial provision of System, Owner, Group, and World categories of access represent a good first approximation as to the structure of many organizations. The brick wall protection, and resulting near total encapsulation of system internal details, renders it simpler for application programs to ignore the specifics of the configuration and the environment than to delve into them.

### Ease of Programming Model

The programming model for using ACLs and rights identifiers is straightforward. In most cases, the presence of the security system is implicit, yielding the same results as the implicit security provided by the original, traditional OpenVMS security model.

There is full support for defining default ACLs, file protections, and ownership of new files on a directory-by-directory basis. This reduces security-related issues to a management issue, irrelevant to the applications programmer. Removing the security-related issues from applications programming also allows security issues to be driven by the data being managed, rather than the applications program being used. As an example, consider that the same applications can be used to process data subject to HIPAA (Health Insurance Portability and Accountability Act of 1996, Public Law 104-191; the applicable Department of Health and Human Services Privacy regulations may be found at 45 CFR Parts 160 and 164) as data that is not subject to such restrictions.

The integrity of the security-related environment is also assured by using a resource monitor implementation for enforcing security not code embedded in the applications program. In fact, the application itself is subject to protection. For example, restricting access to executable images represents a mechanism to ensure compliance with training standards in an auditable manner subject to documentation.

The security and access checking facilities are fully available to the programmer. The **\$CHKPRO** system service provides the developer with full access to the access checks used throughout OpenVMS. The list of identifiers held by a process is also available, both within executable images and within command procedures (using the **\$GETJPI** system service and the **F\$GETJPI** lexical function, respectively).

## APPLICATION PROGRAMMING INTERFACES

Outside of areas that virtually obligate replication, mostly because of the different higher-level language-formatting models, there are few examples of parallel functionality that serendipitously differ. Interfaces that can execute completely in user mode do so; functions, such as system services requiring privileged processing, do

**Table 5** DECnet Phase IV/V Protocols

DDCMP	Digital Data Communications Message Protocol
NSP	Network Services Protocol
DAP	Data Access Protocol
CTERM	Remote Terminal Protocol
MOP	Maintenance Operations Protocol

so below the user's visibility, albeit using documented interfaces.

Access to system services is via conventional CALL-type interfaces; if the system service requires supporting processing from system components operating in inner (more privileged) access modes, the system service is responsible for generating all requests of lower level system functions.

### File System Access

The normal user and programmer access files using Record Management Services (RMS). RMS provides a toolkit of functionality to create, delete, and manipulate files and records within files. Within files, RMS provides support for fixed and variable record files, relative files, indexed files, and byte-stream files.

When files are being shared between processes and between different machines in an OpenVMS cluster, RMS is the system component responsible for requesting locks on the files and the records within files to ensure orderly access.

RMS also provides for buffering on a per-process and global basis for the different types of files. Buffering is controlled by a variety of parameters.

### Network Access

Network access in OpenVMS occurs in two modes: transparent and nontransparent. Transparent access is a facility provided by cooperating elements of RMS and DECnet to allow access to files over the network using the same semantics that would be available were the files located on local storage. Sequential, direct, relative, and indexed files can be accessed at the record or block level. A demonstration of the transparency of this facility is that one can run assemblies and compilations of files located on different network-accessible machines by setting one's default to a remote directory and running the compiler.

### DECnet

The DECnet protocol suite has its origins in the late 1970s, predating the widespread use of local area network (LAN) technology. DECnet implements point-to-point and multipoint links and, since the mid-1980s, has included IEEE 802.3 LAN connections. DECnet is based on a series of protocol specifications developed by Digital (see Table 5).

DECnet Phase V, released in 1991, incorporated support for the ISO-developed OSI protocols in addition to those defined by Digital. Support has also been included to tunnel DECnet connections over Internet protocol (IP) infrastructure.

A significant architectural difference between the TCP/IP protocol stack and the DECnet protocol stack is

the presence in the DECnet stack of a Session Control layer, including authentication as part of the network-provided functionality.

### TCP/IP

Although the definition of TCP/IP occurred at approximately the same time as the design of OpenVMS, TCP/IP remained an essentially educational and research network until the mid-1990s. Digital did not develop a TCP/IP stack until 1988.

There are, at the time of this writing, three TCP/IP implementations actively available for the OpenVMS platform:

- TCP/IP Services for OpenVMS (HP),
- Multinet (Process Software Corporation), and
- TCPware (Process Software Corporation).

Multinet and TCPware have been growing closer in functionality since Process Software's acquisition of Multinet.

### OPEN SOURCE SOFTWARE

There is a wealth of open source and other low-cost software for OpenVMS. Some of this software is shipped with the operating system distribution on the freeware and open source tools disks. Other programs are available from their authors.

Some standard components provided by HP are open source or closely based on industry widely available sources. Tools such as Kerberos, SSH (secure shell), SSL (Secure Session Layer), and Apache are fully supported (see Table 6).

There is, however, a duality to the use of open source software. Open source software is, by definition, implemented across a variety of different platforms, with a wide range of engineering practices. Some of these practices are state of the art in software engineering, and some of them are less robust.

It is the less-robust software engineering practices that represent a challenge to the OpenVMS community. Widely adopted technologies are a highly valued form of leverage for quickly developing applications to address business needs. On the other hand, some of these technologies

have come with preexisting security weaknesses that undermine OpenVMS's longstanding record of security and integrity.

As an example, consider software with two different types of shortcomings, one at the implementation level and one at the architectural level.

At the implementation level, programs written in C are often victim to buffer overflows, caused by the failure to check requests for situations that can overflow buffers.

At the architectural level, more than a few programs have been designed in a manner that presumes an all-or-nothing security environment, often exemplified by UNIX's *setuid*. The ubiquitous *sendmail* program fits into this category. Modifying *sendmail* to operate with a more nuanced approach to security is possible, but it represents a major engineering undertaking, which is often as complex, if not more complex, than reengineering the entire application from the beginning.

Software that does not invoke privileges in its operation, except for the implicit ability to access files through the normal mechanisms, poses a far lesser threat to the integrity and security of the OpenVMS system.

The challenge is to find ways to assimilate the leverage represented by open source software while not sacrificing the bulletproof security and integrity that are OpenVMS's strengths.

### SUMMARY

OpenVMS is a world-class operating system, with a long history of solid, reliable operation and is considered to be the "Gold Standard in clustering," as eloquently stated by David Freund in his 2002 paper on UNIX clusters.

The OpenVMS architecture and approach have proved to be a strong, viable foundation, with many impressive achievements over a quarter century. Long-lived is not legacy. OpenVMS, starting on the original VAX-11/780, has gone on to manage systems more than a thousand times larger with a high degree of efficiency and reliability and with little to change in its fundamental structure or architecture.

OpenVMS presents a reliable, solid system with unlimited growth potential.

**Table 6** Low-Cost/Freeware/Open Source Software Available for OpenVMS

INFO-ZIP	File compression utility, file compatible with PKZIP on Windows
UNZIP	File decompression utility, file compatible with PKZIP on Windows
APACHE	Web server developed by the Apache Software Foundation
TCL/TK	Tool Command Language/Tool Kit, and interpretive scripting language, by John Ousterhout
PERL	Practical Extraction and Report Language, by Larry Wall
PHP	Personal Home Page, originally by Rasmus Lerdorf
TOMCAT	A Java servlet and Java Server Pages implementation for Apache
XML	Extensible Markup Language
SOAP	Simple Object Access Protocol
NetBeans	Modular, standards-based IDE for Java
BISON	A parser-generator, developed by the GNU Project
GHOSTSCRIPT	A freeware (under the GPL) PostScript <sup>®</sup> interpreter

## ACKNOWLEDGMENTS

I thank the numerous people who generously took the time to speak with me about their roles and recollections of events. I thank members of OpenVMS Engineering, including Leo Demers, Susan Skonetski, Andrew Goldstein, Stephen Hoffman, and others, who contributed recollections and pointers to information. I also thank John Streiff, James Gursha, Jerrold Leichter, and others who read drafts and contributed their comments. I also thank Fern Hertzberg for her assistance in organizing and copy-editing this chapter.

## GLOSSARY

**Asynchronous System Trap (AST)** A lightweight thread of execution within a processes context. ASTs are queued on a first-in, first-out basis by Access mode, with Kernel mode ASTs executed first, and User mode ASTs executed last. Although a higher-priority (inner mode) AST may preempt a lower-priority (outer mode) AST, ASTs are not otherwise preemptible within a process. This preemption is an intraprocess issue; ASTs have no effect on interrupt servicing or scheduling interaction between different processes.

**DECnet** A proprietary networking scheme architected and implemented by then-Digital Equipment Corporation in the late 1970s. DECnet provides most of the services identified in the ISO's Open System Interconnect model of networks. On OpenVMS, DECnet is used as a basis for several tools, including transparent remote file access, system management, and remote terminal handling.

**Object** An entity belonging to the classes of objects that can be subject to access controls.

**Queue IO (QIO)** The user-accessible system service that serves as the gatekeeper for all IO operations on OpenVMS.

**Reference Monitor** The software component responsible for checking a subject's degree of access to an object.

**Subject** An OpenVMS user process.

**User Identification Code (UIC)** A 28-bit binary number, split into a 12-bit Group number and a 16-bit Member number which uniquely identifies a user for access purposes on an OpenVMS system.

## ABOUT W2K

The first section of this chapter discusses W2K, its major functions, its major capabilities, and how it works.

### What Is W2K?

W2K is an operating system product that includes both workstation (Windows 2000 Professional) and server (such as Windows 2000 Server and Windows 2000 Advanced Server versions). (Still another W2K product is W2K Data Center, which is designed for large hosts that require high amounts of RAM, fault tolerance, and high-end multiprocessor support.) It supports not only desktop and office automation applications, but can also be used to run network applications that support mail services, Web services, file transfer services, a domain name service (DNS) server, and even routing and firewalling network traffic. W2K also includes many features that were not available in W2K's predecessor, Windows NT (NT), the most notable of which is W2K directory services (called "Active Directory"). Active Directory provides an infrastructure and related services that enable users and applications to both locate and access objects, such as files and printers, and services throughout the network. Active Directory is a directory service (similar to Novell's Netware Directory Service) that acts as the main basis for holding and distributing data about accounts, groups, Organizational Units (OUs), security policies, services, domains, trust, and even Active Directory itself. (An OU is a "nested group"—one that is either above or below other OUs (or both) in a hierarchy—with special properties that are discussed shortly in this chapter.) This directory service not only stores data of this nature, but also makes it available to users and programs, providing updates as needed. Active Directory also supports security by storing security-related parameters and data and supporting services (e.g., time services) needed for achieving system and network security. Active Directory is in fact in many respects the "center of the universe" in W2K.

## HOW W2K WORKS

A good starting point in exploring how W2K works is W2K domains, the focus of the next part of this chapter.

### Domains

W2K machines can be configured in either of two ways—as part of a domain or as part of a workgroup consisting of one or more machines. A domain is a group of servers and (normally) workstations that are part of one unit of management. Each domain has its own security policy settings. Policies are rules that affect how features and capabilities in W2K work; policies can determine allowable parameters (such as the minimum number of characters in passwords), enable functions (such as the right to increase or decrease the priority with which a program runs), or restrict the ability to perform these functions. (We will cover policy in more detail elsewhere in this chapter.) Domain controllers (DCs) hold information related to policies, authentication, and other variables. When a change to a policy is made, a new account is created or deleted, or a new OU is created, the changes are recorded by a DC within a domain, and then replicated to all the other DCs within the domain within a designated time interval.

Domains are good for security, provided, of course, that they are set up and maintained properly. Why? Because it is possible to set domain policies so that (with a few exceptions) they will be applied to virtually every server and workstation within a domain. This decreases the likelihood that any system within the domain will be a "weak link" system, one that is an easy target for attackers. Additionally, domain functionality includes important features such as the ability to limit the workstations and servers that may be added to a domain.

The other option is to belong to a "workgroup." By default a system that is not part of a domain is a member of its own workgroup. In workgroups anyone with Administrator privileges on a workstation or server and who

knows the name of a certain workgroup can add that machine to the workgroup, something that makes it possible to discover a great deal of information about each machine and users in the workgroup. This information can advantageously be used to attack the other systems. Access to resources (such as files, folders (directories), printers, and so forth) is determined locally by the particular server or workstation within the workgroup that contains the resources. No built-in central control capabilities exist. Users whose machines are part of workgroups can engage in functions such as sending mail, transferring files, and so forth, but workgroups are not at all conducive to security. Why? First, as just mentioned, there is no mechanism within W2K to limit workgroup membership. If an attacker discovers the name of a workgroup, that person can add a malicious system to that workgroup. Additionally, the lack of centralized control in a workgroup necessitates setting security parameters and adjusting configurations on every machine within the workgroup; in contrast, domains have settings (embedded in "Group Policy Objects" or GPOs) that can be set from a single domain controller (to be defined shortly) within the domain.

Next we will consider various possible relationships between domains and the implications of each.

**Trees and Forests**

W2K domains can be arranged in a hierarchical fashion starting with a root domain at the top, then domains at the level immediately below the root domain, then possibly still other domains at the next level(s). One option is to nest domains in a manner such that they form a "contiguous namespace." In simple terms, this means that there is one common root domain; all subordinate (lower) domains' names are derived from their parent domains. Consider the name of one domain, `research.entity.org`. Consider also `marketing.entity.org`. If the domains are nested in a contiguous name space, both of the domains in this example will have the same parent domain, `entity.org`. If `research.entity.org` is a parent domain, every one of its children will have a first name followed by `research.entity.org` (see Figure 1). Contiguous namespaces characterize W2K "trees." In contrast, if the namespace is not contiguous, then there is no common namespace. "Forests" (as opposed to "trees") are characterized by non-contiguous namespaces. In a tree or forest, every domain connected directly to another domain (as are `entity.org` and `research.entity.org`) by default has a two-way trust relationship with every other domain. Note that if domains are not directly connected to each other (as in the case of `marketing.entity.org` and `research.entity.org` in Figure 1), they nevertheless have transitive trust between them because `entity.org` has a two-way trust relationship with each of its child domains. Trust is a property that allows users,

groups, and other entities from one domain to potentially access resources (files, directories, printers, plotters, and so forth) in another; provided of course that the appropriate access mechanisms (e.g., shares) and sufficient permissions are in place. Trust is in fact an essential element in characterizing domains that are linked together to form trees or forests. These domains may be either in "mixed mode" or "native mode," as the next section explains.

**Mixed Mode versus Native Mode**

Domains can be deployed in two modes, "mixed mode" and "native mode." In mixed mode, a domain contains both W2K and NT DCs, or has all W2K DCs, but nobody has migrated the domain to native mode. In native mode, a domain contains all W2K DCs and the domain has been migrated to this mode. Native mode is better from a security viewpoint in several ways.

**Domain Controllers**

DCs are a special type of server used for controlling settings, policies, changes, and other critical facets of W2K domain functionality. In W2K mixed mode, DCs may consist of both W2K and NT servers. One W2K server must serve as a primary domain controller (PDC) in mixed mode, however. A PDC receives changes, such as changes to the authentication database, and replicates them to the other DCs within the domain. In W2K native mode, however, there is no PDC per se (one DC, however, functions as an "emulated PDC" within each domain for purposes such as achieving compatibility with trusted and trusting NT domains); all DCs are capable of picking up and replicating changes to the other domain controllers. Every DC in a native mode deployment holds a copy of Active Directory. In W2K mixed mode or in the case of a NT domain, if the PDC crashes, some degree of disruption invariably occurs. In W2K, however, if any DC crashes there is no particular problem—all DCs function as equals to each other.

Active Directory is so important in understanding how W2K works that it merits further examination. The next section describes Active Directory functionality in greater detail.

**A Deeper Look at How the W2K Active Directory Works**

Each object in a W2K tree or forest has an X.500-compliant distinguished name (DN), one that uniquely refers to the object in question (e.g., `/O=Internet/DC=COM/DC=Example/CN=Users/CN=Jill Cooper`). Each object also has a Globally Unique ID (GUID), a 128-bit identifier unique to the object within a particular namespace. X.500 properties and naming conventions are beyond the scope of this chapter, but suffice it to say they provide an orderly way to organize and refer to objects. However, the

**Figure 1:** Example of how namespace is organized within a tree.

X.500 directory structure is quite detailed and cumbersome; the Internet Engineering Task Force (IETF) consequently created the lightweight directory access protocol (LDAP) to provide a kind of scaled-down, simplified version of X.500. W2K Active Directory is actually based on LDAP.

Active Directory objects are organized in various manners. Each object has one or more attributes. “Containers” are higher-level objects that hold objects. Directories, for example, are containers that hold one type of objects called “files” and another called “directories.” The types of objects that each container holds and the properties (e.g., names) of the objects are determined by the “schema.”

Microsoft designed Active Directory with the goal of reducing barriers to locating and accessing resources throughout a tree or forest, regardless of whatever network boundaries (e.g., separation of networks from each other) exist. Each machine within a tree or forest contains objects (resources). The “Global Catalog” service enables users and programs that run on users’ behalf to discover available resources within a tree or forest. When a trust link between domains is established, Global Catalog services extend across domain boundaries. When a request to access a resource occurs, the Domain Name Service (DNS) not only resolves hostnames into IP addresses and vice versa, but also resolves objects; that is, when given an object name, it identifies exactly to which object the name refers. In effect, therefore, DNS is also the locator service for Active Directory. Service Resource Records (SRRs) are the basis for locating services and objects and to keep DNS tables up to date. Dynamic DNS, a service available in more recent releases of BIND, updates Service Resource Records (SRRs) to ensure that global catalog and other directory service–related services can perform their functionality properly. (BIND is Berkeley Internet Name Domain, an implementation of the domain name system [DNS] protocols.) DDNS also registers systems with dynamic addresses that connect to the network.

Replication of Active Directory changes involves a number of steps. The update process (e.g., when a user changes a password or when an Administrator adds a new user to a group) begins when an update occurs in the copy of Active Directory within the DC that receives a change. Each DC that receives updates becomes part of a “replication topology” that specifies the particular connections within a tree or forest formed to synchronize the contents of Active Directory within each DC. At the designed time interval the connections are established and updates are sent to each DC within the tree or forest. The Update Sequence Number (USN), a 64-bit number associated with an object, and Property Version Number (PVN), a version number for each object and the object’s attributes, for the changed object are both incremented by the DC that records the update. Additionally, the DC captures the time stamp for the change. Each DC updates its copy of Active Directory if the USN and PVN are higher than the values it has for the object in question. In case of a “conflict,” that is, more than one change to the same object, the change with most recent time stamp will be recorded in any DC’s copy of Active Directory. Each DC that initiates one or more updates and each DC that receives these updates constitutes a “replication partner.” Several mechanisms are in place

to protect against one or more rogue machines from replicating bogus changes—replication partners authenticate to each other, changes on every DC are tracked, and access control mechanisms (“permissions”) determine who can modify Active Directory objects.

### Group Policy Objects

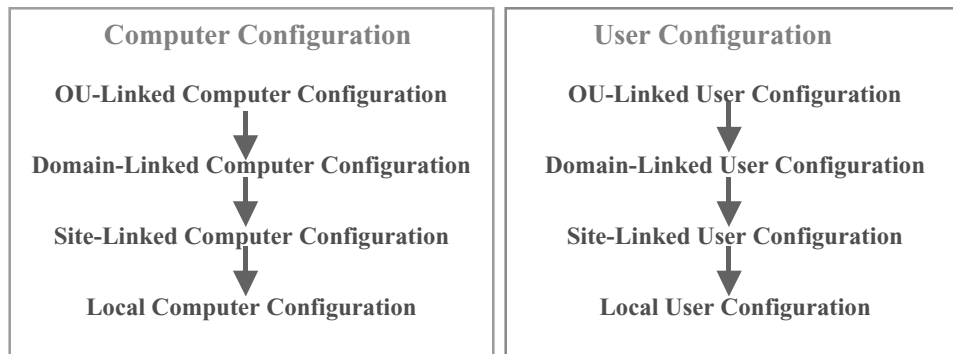

Group Policy Objects (GPOs) are a collection of configuration settings related to computer configuration and user profiles. They provide a powerful way to store and flexibly apply policy settings. Several types of GPOs exist, including the following:

- Local GPOs (LGPOs)—these are intended mainly for computers that are not part of any Active Directory domain.
- Active Directory Group Policies—these are designed to be linked to various Active Directory containers, such as sites (a defined network topology), domains, or OUs.
- System Policies—these are legacy groups of settings from NT system policies if NT domains have been migrated to W2K systems.

Many different GPOs can be created and linked, some at the OU level, others at the domain level, others at sites (subnets or groups of subnets used in controlling replication of Active Directory changes), and still others at the local level. GPOs are applied in a predictable order. For computers, any local computer GPOs are applied first, then site-linked computer GPOs, then computer GPOs linked to domains, then local-linked computer OUs. The last GPO applied normally is the one with the settings that go into effect. This means that if there is a domain policy governing, say, account lockout parameters and a local policy governing the same, the domain policy settings will be the effective settings. The same basic principle applies to user GPOs—local GPOs that apply to users are applied first, followed by site-linked GPOs, and so forth. Another way of saying all this is that OU-linked GPOs normally have precedence over all other levels, followed by domain-linked GPOs, followed by site-linked GPOs, and followed by local GPOs (see Figure 2).

There is one important exception to the principle, however. In terms of place within the object hierarchy, sites are above domains, and domains are above OUs. Parent OUs are always above child OUs, too. If someone with sufficient privileges (e.g., a Domain Administrator) sets a “No Override” for a GPO that is linked at a higher level within this hierarchy, conflicting settings of GPOs set at lower levels will not apply (as shown in Table 1). The “No Override” setting thus becomes a good way for Domain Administrators to “gain the upper hand” by linking GPOs to domains and OUs, and then setting a “No Override” on domain-linked GPOs. This for the most part ensures that any OU administrators will not be able to negate domain group policy.

If there are multiple GPOs within any single level of precedence (e.g., OU level), the policy that has been most recently linked to that level is by default the one that is applied. So, the default GPO that is linked to a domain will be overridden by linking a new GPO to the same domain.

**Figure 2:** Precedence of GPOs at different levels.

Still, a Domain Administrator or someone else with sufficient privileges can reverse the order of precedence—the default GPO can go into effect simply by using the policy editor to reverse the order. Note that in Figure 3 there are two policies, EES policy and default domain policy, that are linked to the domain ees.test. EES policy is listed first and will prevail over the default domain policy link. However, by highlighting “EES policy” in the Group Policy sheet shown in Figure 3 and then clicking on Down, the default domain policy can be made to prevail.

Further complicating the situation is the fact that GPO settings can be inherited, that is, from one site container to its children or from one OU to its children. “Block inheritance” settings can be in place at the level of children containers, however. “Block inheritance” does exactly what it implies. But if there is a “No Override” at the higher-level container (e.g., a parent site or OU), the “No Override” prevails; GPO settings from the parent are put in effect at the level of the child containers. Furthermore, inheritance does not work from one domain to its children. To have the same GPO settings for a parent domain and its children, therefore, it is necessary to link all the domains to the same GPO.

GPOs can profoundly affect W2K security. Consider password policy, for instance, as shown in Figure 4. Settings such as minimum password length and password complexity (i.e., whether passwords can consist of any set of characters or whether they must be constructed according to specific rules, e.g., that they may not contain the username and must include at least three of the following four categories of characters: uppercase English characters, lowercase English characters, numerals, and special characters such as “&” and “/”) are embedded in GPOs.

These settings affect how easily W2K passwords can be cracked. GPOs can be applied to a wide variety of entities, including accounts, local computers, groups, services, the W2K Registry, the W2K Event Log, objects within Active Directory, and more. (The Registry is a group of settings relevant to hardware, system configuration, groups and users. The Registry must be accessed via a Registry editor.)

**IntelliMirror: How Group Policy Can Be Used**

IntelliMirror, a new feature in W2K, provides a powerful example of how group policy can be used advantageously. IntelliMirror is a set of features that enable user data, applications, and computing environments to be available and user-specific settings to be applied regardless of the computer the user is using and whether or not the user is on-line. If worse comes to worse (e.g., if the user’s workstation becomes unusable), IntelliMirror can recover, restore, or replace the user’s information, applications, and user-specific settings. IntelliMirror can be configured to control and administer user data, including documents, presentations, spreadsheets, and other objects with which users work. It can synchronize the contents of files automatically whenever a user moves a document to My Documents. IntelliMirror can also install, configure, repair and delete software (including software upgrades), service packs, and hot fixes. When a user invokes an application or an application needs to access a file, IntelliMirror uses the Windows Installer Service to ensure that every file and necessary parameter are available. IntelliMirror also saves critical, specific user and computer settings such as desktop configuration, volume settings, and so on, and ensures that these settings are applied whenever each user is logged on.

Group policy comes into play because it is typically used to define the settings that affect what IntelliMirror controls. Group policy is particularly advantageous in that one collection of settings can be applied to entire groups of users, alleviating the need to configure settings on a user-by-user basis. Once the policy settings are applied, the automatically system keeps a “steady state” for these settings. Policy is not necessary for IntelliMirror to work, however, and some of its features such as offline file access are not dependent upon policy.

**Table 1** How “No Override” Works

Level	“No Override” Applies to GPOs Linked to
Site	Child sites Domains OUs Child-OUs
Domain	OUs ChildOUs
OU	ChildOUs

Figure 3: Viewing group policy object links for a domain.

### Accounts, Groups, and Organizational Units

As in NT, each W2K system has a default local Administrator account, the built-in superuser account for administering that system. A default Administrator account also exists within each domain for the purpose of administering systems and resources throughout the domain.

Additionally, there is a default local Guest account and also a domain Guest account, both of which (fortunately) come disabled by default. Any additional accounts must be created by people or applications with the appropriate level of rights.

W2K groups are more complicated than accounts. W2K has four types of groups: local groups (for giving access and rights on a local W2K system), domain local groups (which can encompass users or groups from any trusted domain), global groups (which can allow access to resources in the domain or forest where they exist, and are backward compatible with NT global groups), and (only in native mode) universal groups (which can consist of users and groups from any native mode domain within a tree or forest). Universal groups provide the most flexible way of forming groups and providing access to them at the risk of potentially allowing too much access to these groups unintentionally.

Some types of groups can be included within other groups. Group inclusion means that any users from one group can also become members of another group by adding the first group to the second. For example, global groups can be added to domain local groups and in a native mode domain, global groups can even be included in other global groups. W2K's group inclusion properties provide a very convenient way of setting up access to resources, especially when trusted access is required. System administrators can, for example, include a universal group from another domain in a domain local group in their own domain to give users in the other domain the access they need. The users in the universal group from the other domain will have the same access permissions to the resources in question as the users in the domain local

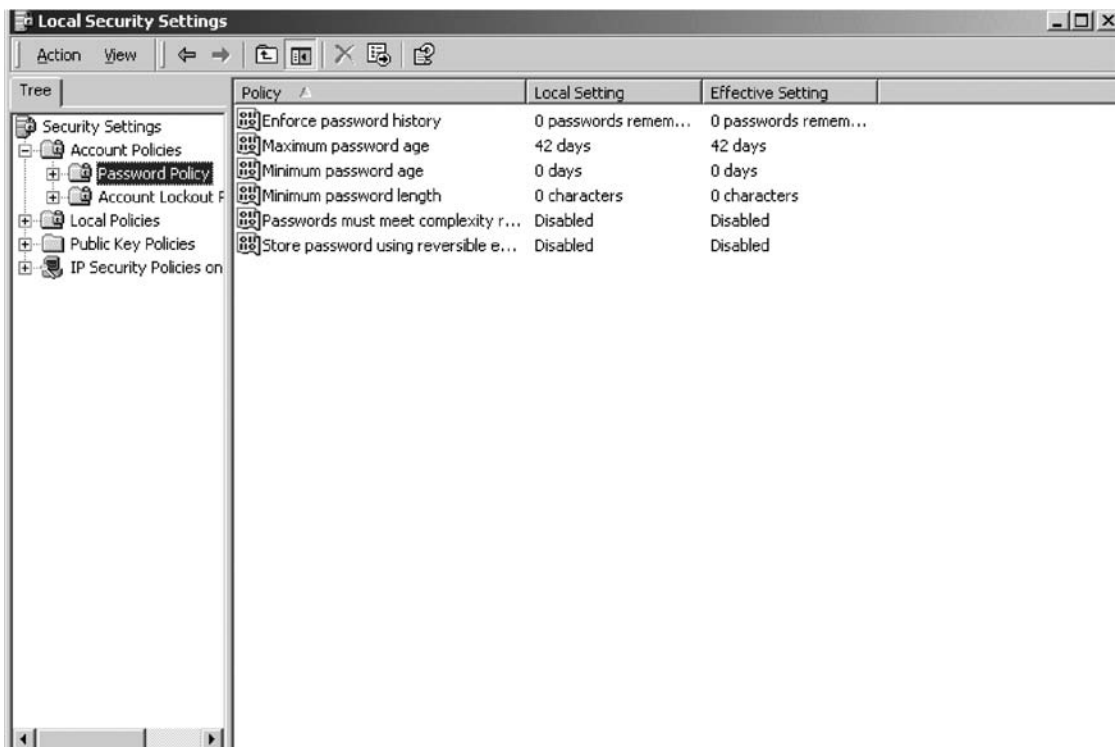

Figure 4: Default password policy settings.

**Table 2** Default Groups in W2K

Global Groups	Domain Local Groups in DCs	Local Groups in Workstations and Servers
Domain Administrators	Administrators (Local)	Administrators (Local)
Domain Users	Account Operators	Backup Operators
Domain Guests	Server Operators	Guests
Certificate (Cert) Publishers	Backup Operators	Power Users
Domain Computers	Print Operators	Replicator
Domain Controllers	Replicator	Users
Group Policy Creator Owners	Users	Interactive Users
Enterprise Controllers	Guests	Network Users
	Interactive Users	Everyone
	Network Users	Creator/Owner
	Everyone	Dial-up
	Creator/Owner	Batch
	Dial-up	Terminal Server Users
	Batch	
	Terminal Server Users	

group. Table 2 lists the default domain and local groups in DCs and also in workstations and servers in W2K.

The Everyone group consists of all users on a given system, regardless of whether they have been authenticated. Fortunately, the potentially dangerous Everyone group is at least not afforded any kind of special privileges. Still, it is best to not assign file, folder, and/or share access to this group—Authenticated Users is a much better group if universal access to these objects is necessary. Groups such as Interactive Users, Network Users, Dial-up, Batch, and Terminal Server Users are volatile groups. When users are engaged in certain tasks, they are included in these groups. When they are done with the tasks, they are removed from these groups. For example, someone who performs a local logon into a system is included in the Interactive Users group as long as that user stays logged on locally. Additionally, some groups even apply to an entire tree or forest. For example, Enterprise Controllers consist of every DC in Active Directory.

**Privileges**

The previously mentioned default local administrator account and default domain administrator account have superuser privileges—full privileges, meaning that while logged into this account someone can create or delete accounts and groups (unprivileged and privileged); disable accounts; add new users to groups; set the system time; make backups; take ownership of every file, folder, and printer; create or delete shares to folders or devices such as printers; set up and run a scheduled job; unlock a locked computer; read and purge the security log; and can do many other things. Any account that is a member of the Administrators group on a local system has the same privileges as the default local Administrator account. The default domain Administrator account also has Administrator privileges, but they apply to every server and workstation within the domain in which this account exists. Anyone who is a member of Domain Administrators (of which the default domain Administrator account is initially the only member, but others can be added) can

use Administrator privileges on every machine within a domain.

There are two additional superuser groups that have superuser rights within an entire tree or forest. The first (and most powerful of all) is Enterprise Administrators, who not only have Domain Administrator rights in every domain within a tree or forest, but also other powerful rights such as the ability to make changes in Active Directory and add or revoke trust between any domains within a tree or forest. The second is Schema Administrators, who can modify the Active Directory schema. One unauthorized schema change could cause severe malfunction in Active Directory functionality. Needless to say, drastically limiting the number of members of both of these groups is a must because of the potential for damage that both pose.

W2K, like NT, has default groups that have some but not all Administrator privileges. Account Operators, for example, can create, disable, and delete any account that does not have elevated privileges as well as perform other tasks. Server Operators can perform many server administration tasks, including setting system time, logging on locally, and others. Backup Operators can backup systems as well as others. Print Operators can create and delete print shares, assign permissions for shares, install or delete print drivers, and also engage in a few other system administration tasks.

**Organizational Units (OUs)**

OUs are an important new feature of W2K Active Directory. OUs are in the most basic sense groups that are part of a hierarchical structure, with some groups being above others in this structure. The root OU is the uppermost one in this structure; OUs can exist at other levels of this structure, too. Any second-tier OUs, OUs immediately below the root OU, will all have the root OU as their parent OU. OUs are not unique to W2K, however; other network operating systems that adhere to X.500 or LDAP standards such as Novell Netware 4.X and up have OUs, for instance.

OUs can be used very advantageously. In W2K any OU can be assigned conventional privileges or “rights” (also

see the next section, which covers privileges) and/or “delegated rights,” the capability to administer that OU by engaging in tasks such as adding users to the OU. Default children OUs inherit the privileges and policy settings of their parent. However, privileges and policy settings can be blocked for any OU, allowing fewer privileges to be assigned to children than to their parent OU. (Someone with sufficient privileges can also set the “no override” property on a parent OU, causing any blocks at lower OUs to not work.) Additionally, when it comes to delegated rights, a child OU can never have more delegated rights than its parent. These properties and features can help guard against rights proliferation in which too many users have too many privileges, which translates to a security catastrophe waiting to happen.

## Access Permissions

NT featured version 4 of the NT File System (NTFS). W2K features version 5, or NTFS-5. NTFS-5 offers many more permissions than does NTFS-4, allowing very precise control over levels of access to resources. There are 14 “base” or individual permissions:

- Traverse Folder/Execute File—determines whether someone can go from one folder to another below it as well as to run executables;
- List Folder/Read Data—determines ability to list contents of folder or read a file;
- Read Attributes—determines ability to read “normal” file attributes, that is, those created by file system;
- Read Extended Attributes—determines ability to read extended file attributes, that is those created by applications;
- Create Files/Write Data—determines ability to create new files and add new data to them;
- Create Folders/Append Data—determines ability to create new folders within a particular folder and append data to files;
- Write Attributes—determines ability to modify file attributes;
- Write Extended Attributes—determines ability to modify extended file attributes;
- Delete Subfolders and Files—determines ability to delete subfolders and files, regardless of whether a specific Delete permission has been assigned;
- Delete—allows the person who has this permission to delete an object such as a file or directory;
- Read Permissions—determines ability to inspect file permissions;
- Change Permissions—allows someone to modify current permissions of someone else with respect to a particular object;
- Take Ownership—allows taking ownership of objects such as files and folders; and
- Synchronize—synchronize external data (e.g., on Web server) with file contents.

There are also five combined permissions, each of which includes a number of base permissions:

- Full Control—all base permissions;
- Modify, which consists of the following base permissions:
  - Traverse Folder/Execute File,
  - List Folder/Read Data,
  - Read Attributes,
  - Read Extended Attributes,
  - Create Files/Write Data,
  - Create Folders/Append Data,
  - Write Attributes,
  - Write Extended Attributes,
  - Delete,
  - Read Permissions, and
  - Synchronize;
- Read and Execute, which consists of the following base permissions:
  - Traverse Folder/Execute File,
  - List Folder/Read Data,
  - Read Attributes,
  - Read Extended Attributes,
  - Read Permissions, and
  - Synchronize;
- Read—same as Read and Execute, except no ability to Traverse Folder/Execute File; and
- List/Create Files/Write Data, which consists of the following base permissions:
  - Create Folders/Append Data,
  - Write Attributes,
  - Write Extended Attributes,
  - Read Permissions, and
  - Synchronize.

Each permission includes both an Allow and Deny setting. So, for example, one user could be allowed to Read Folder/Read Data in a certain folder and another could be assigned the Deny setting for the identical permission for the same folder, preventing the second user from being able to read the folder and the data therein.

The FAT32 file system is also available, but this alternative file system has nothing to offer as far as security goes. There are, for example, no access permissions in FAT32. FAT32 features attributes such as Read-only, but these attributes are easy for an everyday user to change. NTFS-5 also has some nice built-in reliability- and performance-related features.

Inheritance also applies to NTFS permissions and ownerships in W2K. Suppose that a subfolder or file is created below a parent folder. By default a newly created child folder or file will inherit the permissions of the parent folder. It is also possible to block inheritance for any child folder or file. When an access request occurs, the Security Reference Monitor (SRM), an important subsystem within W2K, obtains information about the requesting user’s security identifier (SID), groups to which the user belongs, and ownership of resources. The SRM next obtains the access control entries (ACEs) for the resource in question and evaluates them in a defined order. The SRM evaluates any Deny Non-inherited ACEs first, and then if there are no such ACEs evaluates any Allow Non-inherited ACEs. If there are no Allow Non-inherited ACEs for that resource, the SRM next evaluates any Deny

Inherited ACEs, and if there are none, finally any Allow Inherited ACEs. If there is more than one ACE for one type of ACEs, e.g., Deny Non-inherited, the most recently created one is applied.

## Kerberos

Kerberos provides strong network authentication by both authenticating users in a manner that keeps passwords from going across the network and also by encrypting sessions and providing users with tickets (“service tickets”) that enable users to connect to servers to access resources and services therein. Kerberos security is based on “Key Distribution Centers” (KDCs), servers that store user credentials and set up encrypted sessions on behalf of users who need to authenticate and then access resources and services. Each KDC distributes a unique, short-term session key for the client and KDC to use when they authenticate each other. The server’s copy of the session key is encrypted in the server’s long-term key. The client’s copy of the session key is encrypted in the client’s long-term key (which is usually based on the user’s password).

In Kerberos when a client wants to connect to a server (e.g., via a share), the following chain of events transpires:

1. The client sends a request to the KDC.
2. The KDC sends the client two copies of a session key. The client’s copy of the session key has been encrypted using the key that the KDC and the client share. The server’s copy of the session key and data concerning the client are contained in a “session ticket” that then becomes encrypted with the key that the KDC shares with the resource server that the client wants to access.
3. Once the client receives a reply from the KDC, it removes both the ticket and the client’s session key, and then caches them.
4. When the client wants access to the server, it transmits a message containing the ticket and an authenticator that contains data about the user and a time stamp from the client to the resource server. The ticket will still be encrypted by the server’s secret key; the authenticator will be encrypted by the session key.
5. The KDC now sends a user ticket (often termed the “Ticket Granting Ticket” a TGT) to the client.
6. The client fetches the appropriate logon session key from its cache, uses this key to create an authenticator, and then sends the authenticator, the user ticket, and a request for a service session ticket to the KDC.
7. The client sends both the authenticator and user ticket back to the KDC. The KDC responds by giving the client a server session key.
8. The client needs to send the service ticket that is encrypted with the server session key to the resource server. (Note that successful Kerberos authentication is really only a prelude to access to any file, folder, and so on. Once Kerberos authentication is complete, the security reference monitor on the resource server compares user credentials to ACEs to determine whether the user is authorized to access a resource at the attempted level of access [i.e., read, write, and so on]).

Each W2K DC also functions as a KDC. Kerberos is the default authentication protocol for W2K in a domain setting regardless of mode—native or mixed. In native mode other, older authentication protocols (LM and NTLM) are disabled. This makes native mode more secure, but also disallows operating systems prior to W2K from further accessing the W2K servers unless they are running a special client, DSCLIENT.EXE, which is available at Microsoft’s technet site. Kerberos not only authenticates users and authorizes access to resources and services, but also serves as the basis for trust relationships between domains in W2K. When trust is established between domains, Kerberos keys for each domain are sent to the other domain for each KDC there to use in authenticating and authorizing trusted access for users in the first domain. Another nice thing about Kerberos is that it is almost entirely transparent to users.

## Security Support Provider Interface (SSPI)

SSPI consists of a Win32 interface between security-related “service providers” (dynamic link libraries or DLLs) and applications that run at the session level of networking as well as between other types of authentication packages. SSPI supports a variety of interfaces, enabling applications to call security providers to obtain authenticated connections. SSPI is potentially a big plus for security in W2K systems because it provides an interface for third-party authentication products, such as the products developed by smart card vendors. Third-party authentication is much stronger than conventional, password-based authentication in that third-party authentication generally requires “something that you have” or “something that you are” plus “something that you know” (e.g., a personal identification number or PIN) instead of only “something that you know” (i.e., a password).

## Auditing

W2K can provide up to six types of logging, depending on the particular types that the system administrator enables. Types of logging include the following:

- system logging—this reports events concerning errors, warnings, and information about the status of system operations and is non-configurable;
- security logging—this configurable logging capability captures data about successful and failed access to objects such as files, directories, and printers; logons/logoffs; user of rights; policy changes; and so on;
- application logging—this logging capability, which is configurable by application programmers, records application-related events (e.g., such as when Norton AntiVirus finds and eradicates a virus);
- directory service logging—this configurable logging capability, which is applicable only to DCs, captures access (reads, writes, deletions, and so forth) to Active Directory objects;
- DNS server logging—various DNS-related events are recorded by the DNS server logging capability, which is configurable; and

- file replication logging—this configurable logging capability reports events related to Active Directory replication.

Of these six types of logs, the security log (as its name implies) is the most fundamental to security. The security log can be configured to capture successful and failed events from each of the following nine event categories:

- audit account logon events;
- audit account management (e.g., creating, disabling and deleting accounts; group changes; and so on);
- audit directory service access;
- audit logon events (e.g., every service logon);
- audit object access;
- audit policy change;
- audit privilege use;
- audit process tracking (e.g., user attempts to start or stop programs); and
- audit system events (e.g., system startups and shutdowns).

GPOs can be used to set the audit policy for all the DCs within a domain as well as for member servers and workstations. Additionally, property settings for each of the types of logs determine the maximum size of each log and the retention method (e.g., whether to overwrite log entries only when the maximum log size is reached or to not overwrite events (i.e., clear the log manually).

### Encrypting File System (EFS)

EFS provides encryption of folders and/or files stored on servers and workstations. EFS encryption is an advanced attribute for each folder and/or file. When a user enables encryption for a file, for example, a file encrypting key (FEK) is used to encrypt the file contents. When the user accesses the file (e.g., through an application), the FEK (which is used in connection with secret key encryption) decrypts the file. (In secret key [sometimes called “symmetric”] encryption, the same key is used for encryption and decryption. In public key (sometimes called “asymmetric”) encryption, a pair of keys, one called the “public key,” the other called the “private key,” is used. One of the keys is used for encryption and the other is used for decryption.) When the user finishes accessing the file, the FEK once again encrypts it. A key encrypting key (KEK), one of an asymmetric key pair, is used to encrypt a copy of the FEK. If something goes wrong, for example, the KEK is deleted, authorized persons (by default, Administrators) can access the Data Recovery Agent snap-in, which uses the other key of the key pair to decrypt the FEK. Unfortunately, EFS in W2K is beset with a number of problems, including not only unreliability that can result in users being unable to read their own EFS-encrypted files, but also the necessity of sharing a user’s FEK with others when more than one user needs to access an EFS-encrypted file. Despite the potential utility of folder and file encryption, the use of EFS in W2K is thus not in general advisable. Fortunately, many of the problems in the W2K version of EFS have been fixed in the Windows XP version of this function.

### Encryption of Network Transmissions

W2K offers a number of ways to encrypt data sent over the network, including IPsec, the Point-to-Point Tunneling Protocol (PPTP), and other methods. IPsec is the secure IP protocol that features an authenticating header (AH) and encapsulated security payload (ESP). The AH provides a cryptographic checksum of the contents of each packet header that enables machines that receive “spoofed” packets, that is, packets with falsified source addresses, to reject them. The ESP provides encryption of the data contents of packets, such that if anyone plants a sniffer on a network, the perpetrator cannot read the packet contents in cleartext. W2K provides IPsec support, although its implementation of the IPsec protocol limits the range of other systems with which W2K systems can set up IPsec sessions. W2K policy settings allow system administrators to set variables such as the conditions under which IPsec is used, the strength of encryption, and others. PPTP can also provide confidentiality of data sent over the network, although PPTP cannot verify the integrity of packets.

### Routing and Remote Access Service (RRAS)

RRAS, another important W2K service, can be used to manage parameter settings for the W2K Remote Access Service (RAS), PPTP, and the Layer 2 tunneling protocol (L2TP). Among other things RRAS can be used to elevate security in that this service can fix the method of authentication to be used (Kerberos, the older NTLM authentication method, and so forth) as well as filter and log incoming IP packets. IP packet filters can selectively determine whether packets will be received and/or forwarded on the basis of source IP address, destination IP address, and type of protocol. RRAS also allows system administrators to log all incoming IP traffic, something that is potentially very useful in identifying and investigating remote attacks.

### Certificate Services

W2K also offers certificate services. These include creation and release of X.509v3 certificates and in W2K Advanced Server, even public key infrastructure (PKI) capabilities. PKIs provide a hierarchical structure of certification authorities (CAs) that issue and validate certificates.

### Distributed File System (DFS)

DFS is a function that enables system administrators to create and administer domain shares through a centralized function on each DC. DFS also allows administrators to assign permissions to shares, thus potentially limiting the level of access to resources throughout each domain.

### Microsoft Management Console (MMC)

Microsoft provided the MMC in W2K to provide a uniform interface to control a wide variety of functions. The MMC features “snap-ins,” objects that allow control of settings (group policy settings, in particular). Some of the snap-ins allow control of certificates, others are for computer

management, others are for the event viewer, others are for group policy, and still others are for security templates. Security templates provide groups of settings that affect security and can be used to either evaluate the security level or to change unsafe settings to ones that are more suitable for security.

The services, functions, and properties discussed in this section are of course not the only ones that W2K offers, but they represent some of the most important services from both a functionality and security standpoint. In the next section we will consider the strengths and weaknesses of W2K security.

## HOW SECURE IS W2K?

How secure is W2K? After all the problems that organizations and the user community had with NT security, this is an important question to ask. The question really decomposes into two questions: 1) how secure is W2K out-of-the-box and 2) how high a level of security can W2K achieve?

### How Secure Is W2K by Default?

Some of the same security-related problems that plagued NT are still present in W2K systems immediately after an installation of W2K. The permissions for the critical %systemroot%\winnt directory, for example, allow Full Control to the Everyone group in W2K. Additionally, in W2K Server and W2K Advanced Server, the IIS Admin Service runs by default. Anyone whose system was infected by Code Red, Nimda, or another worm will appreciate the dangers of running a vulnerability-ridden Web server, namely the Internet Information Server (IIS), by default. In other respects, W2K is more secure than NT was by default. When unprivileged access to Active Directory objects is necessary, for example, access is by default granted to Authenticated Users rather than the ever-dangerous Everyone group. The point here is that W2K may be somewhat more secure than NT out of the box, but leaving W2K settings as they are is a huge mistake if security is a consideration. W2K systems need quite a bit of work if they are to run more securely.

### Major Types of Vulnerabilities

W2K has had more than its share of security-related vulnerabilities. One of the most significant ones is a weakness in the way reversible password representations for each account are created. This encryption process produces password representations that are relatively easy to crack using dictionary-based cracking techniques. [In dictionary-based password attacks a password cracking tool starts with a large number of possible passwords. It determines what the encrypted representation(s) of each password would be, and then attempts to match the encrypted entries in a victim system's password file to the computed representation for each possible password is. If there is a match, the cracking tool has cracked the password.]

Another significant set of vulnerabilities concerns susceptibility of W2K systems to denial of service (DoS) attacks. Programs for many W2K services are not

particularly well written. An attacker may send input to these services that contains parameters that are out of range, or that exceed memory limitations. The result is often DoS—either the programs or the W2K system itself will crash. The W2K telnet server, for example, has a bug that will cause it to crash if certain types of input are sent to it. Similarly, massive Simple Network Management Protocol (SNMP) input may cause the receiving system to go into a buffer overflow condition in which there is too much input for available memory. This problem will normally cause a W2K system to crash, but if the excessive input is specially crafted, it is possible to execute rogue commands and programs on a system.

Some of the services that run in W2K systems pose much higher levels of risk than others. W2K Terminal Services, for example, provide a convenient way for users to remotely connect to other systems if these services are not properly configured, protected, and patched. The same is true for the W2K telnet server, the IIS Admin Service, SNMP, and many others.

Another vulnerability has been briefly mentioned earlier in this chapter. The default Administrator account is a very attractive target for attackers in that by default it does not lock after an excessive number of unsuccessful logons. Additionally, this is a well-known account—one with a well-known name. Furthermore, being able to break into this account provides superuser-level privileges to attackers. Lamentably, many successful attacks on W2K are attacks in which perpetrators have broken into the Administrator account, which may even not have had a password!

A few additional types of vulnerabilities in W2K that have been identified include the following:

- Buffer overflow conditions in which a program does not perform bounds checking on input, enabling a malicious program to send excessive amounts of input, some of which is written to a system's memory, resulting in execution of rogue commands that can cause denial of service or privilege escalation.
- Vulnerabilities in the interface between the Remote Procedure Call (RPC) and the Distributed Component Object Model (DCOM) that allow an attacker to send specially formatted input that results in denial of service or privilege escalation.
- Unprotected shares that allow anyone or any network program to among other things write to shared folders, enabling them to modify files and/or install malicious programs.
- NetBIOS-related vulnerabilities (in mixed mode); this layer of networking is beset with many security-related problems, including providing a wealth of information about systems, users and current sessions to potential attackers,
- Bugs that can give attackers unauthorized access to Active Directory objects, and
- Poorly protected dial-in connections that require only a "normal" password for access instead of something stronger, such as smart card or biometric authentication. Unauthorized dial-in access is one of the greater threats in any operating system, W2K included.

Although a large number of vulnerabilities in W2K have surfaced, Microsoft has fixed most of them. Microsoft generally initially produces and releases a hot fix to repair each vulnerability or sometimes a set of vulnerabilities. Microsoft also releases service packs (SPs) that incorporate previously released hot fixes. The current SP for W2K is SP4.

Patch management in W2K and virtually all other versions of Windows operating systems is a major issue. A huge proportion of security breaches in Windows systems can be traced directly to failure to install hot fixes and SPs in a timely manner. The fact that many hot fixes and SPs that Microsoft initially releases are flawed to the point that they may cause a system to become dysfunctional further exacerbates this problem. One possible solution is to enable Automatic Updates to ensure that patches are downloaded when they become available. Automatic Updates are, however, far less than ideal in that they result in the first patch that becomes available being downloaded (and, if the system administrator so chooses, automatically installed). Microsoft has also developed the Systems Update Server (SUS), something that can be used within an organization's network to push patches to systems of one's choosing at the desired time. SUS is not perfect either, however, in that it sometimes fails to install patches on some systems. Commercial software such as Update Expert by St. Bernard Software provides yet another option. Products such as Update Expert not only allow control over when patches are pushed to systems, but also provide quality control, ensuring that patches have been properly installed. Whatever solution an organization chooses, one thing is certain—patching Windows systems is no easy task.

Now that we have explored the major types of vulnerabilities in W2K, let's turn to another, related consideration, namely how secure W2K systems can be.

## How Secure Can You Make W2K Systems?

W2K has numerous security features that can boost its security substantially. As mentioned previously in this chapter, however, you will have to make quite a few changes to W2K if you want it to run securely. W2K has great security potential, but to achieve that potential requires considerable effort. The most important consideration is achieving a baseline level of security.

## BASELINE SECURITY MEASURES

Establishing at least a baseline level of security is essential if W2K servers and workstations and servers are going to be able to withstand the most basic kinds of attacks. Baseline security requires implementing the most fundamental steps in securing a system or application, not implementing a complete (more perfect) set of measures. The intention is to make a system “just secure enough.” Implementing the following measures in W2K systems will produce a baseline level of security:

- Install W2K from trusted media—a vendor-provided CD.
- Ensure that your system's hard drive consists of a minimum of two partitions, C: and D: Use C: as the

installation drive; this partition will contain critical system directories and files. Do not set up user shares to this partition. In workstations and member servers use D: to hold other files and folders; set up user shares to D: as needed. In domain controllers use D: to hold Active Directory files and folders; *do not set up user shares to this partition*. Set up the E: drive in domain controllers to hold user files and folders, and set up the user shares to this drive that are needed to allow users to access the resources they need to access.

- Format each partition as an NTFS partition. (The only potential limitation is that 16-bit applications are likely to break if they are installed on NTFS partitions. If you have 16-bit applications that need to run in the W2K environment, create another, small FAT32 partition for these applications. But do not jeopardize other applications by putting them on a FAT32 partition—FAT32 has no access permissions whatsoever.) If any volume is FAT-formatted, enter

```
convert <partition letter>: /fs:ntfs
```

For example, to make the D: partition into NTFS partition, enter

```
convert d: /fs:ntfs
```

- Ensure that W2K systems are part of a domain. As mentioned earlier, workgroups provide few barriers to attackers. To check whether your system is part of a domain or workgroup, right click on My Computer to Properties, and then click on Network Identification.
- If your W2K system has been upgraded from Windows NT 4.0, that is, it is not a native installation, use `secdit` to bring the default level of security to the level that is present in a native installation. `secdit` allows W2K security templates to be used in analyze and configure modes. In workstations and member servers, change your current directory to `c:\%systemroot%\security\templates`, then enter a command such as the following:

```
secdit /analyze /cfg securews.inf /db
%TEMP%\secdit.adb /verbose /log \%TEMP%
\sceolog.txt
```

Security templates are `.inf` files in the `%systemroot%\security\templates` directory. `securews.inf` is a template that changes system settings to be more secure than a default installation in workstations and servers (but not DCs.).

- Install the latest SP. To check the version of service pack a W2K system is running, go from Start to Run, then enter “winver.” You can obtain SP4 from <http://www.microsoft.com/windows2000/downloads/servicepacks/sp4/>
- Install the latest hot fixes, many of which fix the most recently discovered security-related vulnerabilities. Download post SP4 hot fixes by going to the Windows Update site: <http://windowsupdate.microsoft.com/>
- Download and run the Microsoft Baseline Security Analyzer (MBSA), a free Microsoft-provided tool that

enables system administrators to determine whether all W2K, IIS, IE, and other hot fixes have been installed. This tool can be run either from a graphical user interface (GUI) or from a command line. MBSA can be obtained from <http://www.microsoft.com/technet/treeview/default.asp?url=/technet/security/tools/Tools/MBSAhome.asp>

- Lock down access to the system drive (and, in the case of domain controllers, the drive on which Active Directory resides). In general, do not assign anything more than Read-Execute permissions to Everyone, but always assign Full Control to Creator Owner and Administrators.
  - Assign Everyone Read-Execute access to c:\%systemroot% (which by default is c:\winnt) and c:\%systemroot%\system32.
  - Assign Everyone Read-Execute access to the sysvol, sysvol\sysvol, and ntds folders (wherever they may reside in the file system).
  - Remove all access (*but do not assign any Deny access*) to c:\%systemroot%\repair for the Everyone group.
- Lock down permissions for files and folders on other drives. In general, avoid sharing folders if you do not need to do so. Allow Creator, Owner, and Administrator to have Full Control over each share. Remove Everyone’s access (*but do not assign any Deny access*) and then assign Authenticated Users the Read level of share access, which is normally sufficient for most users. If users need to create, modify, and/or delete files within folders that are share-accessible, a Change share permission is appropriate. Change, which allows users to add files and subfolders, modify data, and delete files and subfolders, will not necessarily be the level of access Authenticated Users will get, however. If NTFS permissions for the files and folders that users can access via the share are more restrictive (e.g., they may allow only a Read and Execute), they will determine the actual level of user access to these resources. The least access between what NTFS and share permissions allow a particular user or group is what is actually granted. So, for example, if a user connects to a share that allows Change to Authenticated Users and Read-Execute to that user, Read-Execute represents the least access among all the permissions. To check or change permissions for domain shares, or to delete shares, go from Administrative Tools to DFS to the DFS root. Open up the tree under DFS root until you get to the share you want to get to, then right click to Properties.
- Go to Administrative Tools, then either Computer Management and Local Users and Groups or to Domain Security Policy, then Active Directory Users and Groups (depending on the particular version of W2K). If your W2K system is a domain controller, always go to Domain Security Policy. Domain Security Policy settings prevail over any local policy settings.
  - Rename the default Administrator account to an innocuous name (to do this you will need to enable a security option setting, “Rename Administrator Account”), change the account description to “User account,” enter a ridiculously long (up to 104 characters) password that is as difficult to guess as possible. Write the password down on the piece of paper that you

keep in your personal possession, e.g., in your wallet or purse whenever you are at work. Never share this password with others and do not leave the slip of paper on which this password is written anywhere where others might see it. Use the default Administrator account, which in W2K does not lock after excessive bad logon attempts, only for emergency access.

- Create one additional account that is a member of the Administrators group for yourself and another for each person who needs to administer your system. Create an unprivileged account for each Administrator, also. Use the unprivileged account when you are engaged in normal activities such as web surfing, obtaining ftp access, and downloading mail. Use the superuser account only when you are involved in system administration duties.
- Create a new, unprivileged account named “Administrator.” Ensure that this account is in only the Guest group. Look at your logs frequently to determine whether people are trying to logon to this account—a decoy account designed to deflect genuine attacks against your system.
- Leave the Guest account disabled.
- Severely restrict the membership in the Enterprise Admins, Schema Admins, and Administrators groups, all of which have an incredible amount of power.
- Go to Administrative Tools, then either Domain Security Policy or Local Security Policy (depending on the particular version, workstation or server, of W2K), then to Security Settings:
  - Go to Account Policies, then Password Policy to set the parameter values such as the following:

<i>Enforce password history</i>	24
Maximum password age	90 days
Minimum password age	5 days
Minimum password length	8
Passwords must meet complexity requirements	Enabled
Store passwords using reversible encryption	No (but in some cases, Yes)

[Reversible encryption is the weaker form of encryption (based on the much maligned data encryption standard (DES) encryption algorithm) in W2K. If no other system needs to connect to shares or to authenticate to your system, you can choose No for this setting—something that is much better for security, but if other systems need share or authentication connections, you would do better to choose Yes here to prevent unnecessary disruption of service and functionality.]

- Go to Account Policies, then Account Lockout Policy to set the following parameters:
 

Account lockout duration	60 min.
Account lockout threshold	5
Reset account lockout after	60 min.
- Go to Domain Security Policy, then Active Directory Users and Groups or Local Security Policy, then Computer Management (again depending on the particular

version of W2K you are running). Find the Users and Groups Container and double-click on it. For each user account, set the following Account Options:

- User must change Password at Next Logon—ensure this is clicked whenever a new account is created to help ensure privacy of user passwords.
  - User Cannot Change Password—*do not* click on this.
  - Password Never Expires—do not click on this except in the case of the default Administrator account and special accounts that have been installed for the sake of applications.
  - Account is Disabled—be sure to confirm that the following accounts are disabled: Guest, accounts of employees who are no longer with your organization, accounts of employees who are on leave, and (unless your system is running an IIS Web server) the IUSR\_ and IWAM\_ accounts. Disable these accounts by clicking on Account Is Disabled for each if they are not already marked with a red “X.”
- Set the following Security Options by going to Administrative Tools, then either Domain Security Policy or Local Security Policy (depending on the version of W2K each system runs), then to Security Settings, then to Local Policies, and finally to Security Options. Double click on the Security Options container. Double click on the option of your choice to either enable or disable it.
    - Enable “Security restrictions for anonymous” to prevent anyone who connects to a W2K system via a null session from being able to enumerate shares and SIDs (security identifiers).
    - Enable “Clear virtual memory pagefile when system shuts down” to protect against an attacker gleaning sensitive information from pagefile.sys if the attacker is able to gain physical access to a system and boot from a Linux or other disk.
 

*Do not* choose “Shut down the computer when the security log is full” (unless you don’t mind unexpected shutdowns in systems), “Recovery Console: Allow automatic Administrative logon,” and “Allow Server Operators to schedule tasks.”
  - Set a baseline of logging. Go to Administrative Tools, then either Domain Security Policy or Local Security Policy (depending on the version of W2K your system runs), then to Security Settings, then to Local Policies, then to Audit Policy. Double click on the Audit Policy container to view the audit options. To enable any type of auditing, double click on the name and in the sheet that will appear (under Audit These Attempts) click on both Success and Failure. At a minimum enable Audit Account Logon Events. If you need higher levels of auditing, you may choose to enable additional types of auditing such as Audit Logon Events, Audit Account Management, Audit Policy Change, and Audit Privilege Use.
  - Set logging properties for the security log properly. Go to Administrative Tools, then Event Viewer. Click on Security and right click to Properties. Set Maximum Log Size to at least 5000 K and (under When Maximum Log Size is reached) click on Overwrite as Needed. Check your system’s logs regularly (daily, if possible) to determine whether your system has been attacked or tampered with.

- Ensure that the bare number of services that you need are running. Disable any unnecessary services by going to Administrative Tools, then Services. Highlight the name of each unnecessary service, double click, then under Service Status click on Stop, and under Startup Type set this to Manual. The following are services that are usually *not* needed in W2K:

- Alerter,
  - Computer Browser,
  - FTP,
  - IIS Admin Service (this is needed for IIS Web servers),
  - Indexing Service,
  - Messenger,
  - Print Spooler,
  - Remote Access Service,
  - SNMP,
  - Telnet,
  - Windows Installer Service (except when you are installing software), and
  - World Wide Web Publishing Service (this is needed for IIS Web servers).
- Ensure that rights are given only as they are needed. Check User Rights by going to Administrative Tools, then either Domain Security Policy or Local Security Policy (depending on the version of W2K your system runs), then to Security Settings, then to Local Policies, and finally to User Rights Assignment. Double click on the User Rights Assignment container. To assign or revoke a right, double click on the right of your choice, then add or remove the right to/from the user or group of your choice. Ensure at a minimum that the Everyone group *does not* have any of the following rights:
    - Act as part of the operating system,
    - Add workstations to domain,
    - Backup files and directories,
    - Create a pagefile,
    - Create a token object,
    - Debug programs,
    - Enable computer and user accounts to be trusted for delegation,
    - Force shutdown from a remote system,
    - Increase quotas,
    - Increase scheduling priority,
    - Load and unload device drivers,
    - Lock pages in memory,
    - Logon as a batch job,
    - Logon as a service,
    - Logon locally,
    - Manage auditing and security log,
    - Modify firmware environment variables,
    - Replace a process level token,
    - Restore files and directories,
    - Shut down the system, and
    - Take ownership of files and other objects.
  - Install and run antivirus software.

A further caveat is appropriate at this point. It is important to not only *establish*, but also to *maintain* suitable levels of W2K security. Security is an ongoing process. You cannot simply set certain parameters in a W2K or any other type of system and then forget about security. Good security requires inspecting systems to ensure that there are no unexpected changes in permissions, rights, directories, and files within directories. Antivirus software has to be constantly updated if it is to be effective. Good security requires systematic monitoring of logs to spot and investigate suspicious activity. Good security also requires making full and incremental backups as well as an emergency repair disk at appropriate time intervals. In short, good security for W2K or any other operating system is an ongoing process.

## CONCLUSION

This chapter has provided the foundation for understanding W2K security capabilities, limitations, and solutions. W2K is a complex operating system. Its potential for security is higher than its predecessor, NT, yet its out of the box configuration leaves a lot to be desired.

This chapter cannot in any way be considered a complete coverage of the topic of W2K security. Entire books on the topic of W2K security have been written (see the References section), yet even they do not cover everything pertinent to the complicated subject of W2K security. Some that are likely to be helpful in gaining a deeper understanding of W2K security include books by Bragg (2000), Cox and Sheldon (2000), Norberg (2000), Schultz (2000), and Scambray and McClure (2001). As mentioned previously, the recommendations in this chapter are designed to provide a *baseline* level of security in W2K. Recommendations for achieving higher levels of security are provided in other, longer documents (see <http://www.cisecurity.org>) and books such as the ones listed.

## GLOSSARY

**Active Directory** A directory service that provides an infrastructure and related services that enable users and applications to both locate and access objects and services throughout the network.

**Containers** Higher-level objects that hold objects.

**Delegation** Giving rights that allow administration of OUs.

**Distributed File System (DFS)** A function that enables system administrators to create and administer domain shares through a centralized function on each domain controller and also allows administrators to assign permissions to shares.

**DNS** Domain name service, a service that resolves IP addresses to hostnames and vice versa.

**Domain** A group of servers and (normally) workstations that are part of one unit of management.

**Domain Administrators** Users who have superuser privileges within a domain, allowing them to perform a variety of system administrator tasks such as setting up and deleting shares, setting time, and making backups.

**Domain controllers (DCs)** Machines that hold information related to policies, authentication, and other variables.

**Domain Local Groups** that can encompass users or groups from any trusted domain.

**Encrypting File System (EFS)** Provides encryption of folders and/or files stored on W2K servers and workstations.

**Enterprise Administrators** Superusers who have Administrator-level privileges throughout an entire forest or tree. They can, for example, create or revoke trust between any two domains within a forest or tree.

**Forests** (As opposed to “trees.”) Trust-linked domains that are characterized by noncontiguous namespaces.

**Global Catalog** A service that enables users and programs that run on users’ behalf to discover available resources within a tree or forest.

**Global Groups** Groups that can allow access to resources in the domain or forest where they exist.

**Group Policy Objects (GPOs)** A collection of configuration settings related to computer configuration and user profiles.

**Hot Fix** Microsoft’s term for a patch that fixes security and other types of problems in Microsoft products such as W2K.

**Inheritance** The default propagation of access rights and user rights (privileges) from higher-level objects to child objects.

**IntelliMirror** A set of features that enable user data, applications, and computing environments to be available and user-specific settings to be applied.

**IPsec** The secure IP protocol that has an authenticating header and encapsulated security payload.

**Kerberos** A method that provides strong network authentication.

**Key Distribution Centers (KDCs)** Kerberos servers that store user credentials and set up encrypted sessions on behalf of users who need to authenticate and then access resources and services.

**LDAP** Lightweight Directory Access Protocol (LDAP), a protocol that provides a kind of scaled-down, simplified version of X.500 directory services.

**Microsoft Baseline Security Analyzer (MBSA)** A free tool available from Microsoft that allows system administrators to scan systems to identify vulnerabilities in them.

**Microsoft Management Console (MMC)** A management tool that features “snap-ins,” convenient objects that allow control of settings (group policy settings, in particular).

**Mixed Mode** A deployment mode in which a domain contains both W2K and NT domain controllers, or has all W2K domain controllers, but nobody has migrated the domain to native mode.

**Native Mode** A deployment mode in which a domain contains all W2K domain controllers and the domain has been migrated to this mode through an Active Directory setting.

**NTFS** The NT File System that is conducive to strong access control—W2K offers version 5 of NTFS or NTFS-5.

**Organizational Unit (OU)** A “nested group,” one that is either above or below other OUs (or both) in a hierarchy of OUs, with special properties that allow for delegation of rights and inheritance of rights.

**Primary Domain Controller** A domain controller that receives changes, such as changes to the authentication database, and replicates them to the other domain controllers within the domain.

**Replication** The distribution of changes in Active Directory objects, properties, settings, and so forth from one domain controller to the others.

**Schema** An Active Directory characteristic that determines the types of objects that that each container holds and the properties (e.g., names) of the objects.

**Schema Administrators** Superusers who are allowed to do virtually everything they want to the schema, something that can have drastic consequences on Active Directory functionality.

**Security Support Provider Interface (SSPI)** Interface that consists of a Win32 interface between security-related “service providers” (dynamic link libraries or DLLs) and applications that run at the session level of networking as well as between other types of authentication packages.

**Service Pack (SP)** A set of bundled hot fixes.

**Service Resource Records (SRRs)** The basis for locating services and objects and to keep DNS tables up to date.

**Syskey** Microsoft’s attempt to make passwords less crackable by adding an extra 128-bit encryption

step when passwords are encrypted before they are stored.

**Tree** A group of trust-related domains that form a contiguous namespace.

**Trust** A property that allows users, groups, and other entities from one domain to potentially access resources.

**Universal Groups** Groups in native mode that can consist of users and groups from any native mode domain within a tree or forest.

**Workgroup** A set of Windows and possibly other systems that are known to each and that facilitate access to each others’ resources.

## INTRODUCTION

This chapter, which has for its title the subject of many books, focuses on current observations, practices, consideration, and techniques that appear most effective in producing secure and trustworthy software. This chapter does not address related software engineering issues, such as obtaining predictions of release readiness, software quality metrics and quality models, or modularization and layer models. With reference to the common criteria EALs (evaluation assurance levels), the content is appropriate for low- and medium-assurance software projects (EALs 1–4). Because commercial, off-the-shelf software (COTS) rarely reaches EAL 4, this chapter is relevant for most COTS projects. Another chapter in this handbook focuses on high-assurance efforts (EALs 5–7).

The current state of COTS is grim. The ICAT (<http://icat.nist.gov>) vulnerability database contains more than 6,600 vulnerability entries (as of May 2004). Crackers think that they are clever for finding them and releasing exploits. Spam e-mail marketing, after getting banned and pursued away from legitimate hosts, uses hosts compromised on a large scale by worms and viruses, for which they pay crackers (Leyden, 2004). Patches are issued at a pace that leaves system administrators dazed and breathless. Patches break previous patches, sometimes in unclear circumstances, and other patches are issued to fix the problems introduced by previous patches. Sometimes patches attempt to block an exploitation path to a vulnerability, without fixing the coding or design errors that enable the vulnerability itself. However, a new exploitation path is found later, which results in a new set of patches. What is wrong with our current software development processes, and why are we flooded with such vulnerable software?

Some business-models value time to market highly. The ability to deliver patches “easily” over the Internet favors a quality debt attitude stated as “deliver now, fix later.” As a result, patching is now the nightmare of the information technology world. Often repeated mistakes have become noticeable in vulnerability databases. Can these often-repeated mistakes be avoided without significantly impacting time to market?

The market for COTS software has changed enormously over the past 10 years, with an increasing emphasis being put on security. Vendors have an increasing awareness that vulnerabilities cost money, reputation, and customers. The same development methods that produced faulty software cannot be expected now to produce correct software and patches. Which development methods are appropriate to these changing requirements? How are security requirements captured, validated, and verified? Are formal methods too theoretical? Can better programming languages help? What have we learned about secure programming?

Whereas the importance of the development and quality assurance methods may be easy to grasp, choosing the correct or near-optimal ones to produce good, reliable, secure software in a timely and cheap manner remains a conundrum. Bad choices can compound because being late may prompt programmers to hurry and work while tired, thus creating more flaws that take longer to fix or result in more patches.

## METAISSUES IN SOFTWARE DEVELOPMENT

Software development traditionally is concerned with delivering software that meets customer needs as defined and “captured” by software requirements. This delivery has a number of constraints, such as time, cost, reliability, low number of faults, maintainability, and functionality. There are three types of metaissues of importance that help address these constraints and manage development activities. The first type is development models, such as the waterfall, the spiral, and the agile class of development models; these define practices, processes, and activities carried out during development. The second type is capability maturity models, such as the system security engineering capability maturity model (SSE-CMM), which provide a framework for the assessment of the presence, quality, and improvement of the practices and processes used during development. The third type is postdelivery certifications, such as the common criteria, which assess security assurance and security features of the produced

software artifacts. It is theoretically correct to select any one construct for each type because they are separate dimensions of the software development process. However, the particularities of development models can affect the usability of the other constructs (discussed later).

## Software Development Models

Software development models define processes, activities, and methods or at least provide an ordered framework for their definition. There are a large number of models available, from the classical waterfall model, spiral development models (Boehm, 1988), and the more recent “lightweight” or “agile” models (Cohen, Lindvall, & Costa 2003). Some models apply at different organizational levels; the Software Engineering Institute’s Team Software Process (TSP, Humphrey, 1999) and the Personal Software Process (PSP) apply respectively at the team and personal levels (Humphrey, 2002), as their name suggests. Interesting questions are how the choice of a model may affect the number and severity of security defects (including vulnerabilities) and whether vulnerabilities were enabled during requirement and design or coding phases. Reports on the performance of these models typically do not differentiate security flaws from other flaws. Nevertheless, several observations can be made.

### The Waterfall Model

In the waterfall model, a development phase is fully completed before another is started. These phases consist of requirements definition and analysis, design, implementation and unit testing, integration and system testing, and operation and maintenance. Requirements and design are stated in documents before coding starts and therefore do not benefit from the insight into problems that coding sometimes yields. These steps can also be seen as brittle because if requirements change, time has been wasted working on them. If requirements change faster than the time needed to produce the matching design documents, then code never gets written. The documents may also need to change not because of a change in the problem space but because of customers’ or the software development team’s improved understanding or improved communications between the two. The frustration experienced in these situations has led to the development of “lighter” (the spiral) and “lightweight” (agile) development methods (see the following sections). Therefore, the waterfall model is appropriate and should be used for projects where the following assumptions of the model are true (Boehm, 2000):

1. The requirements are knowable in advance of implementation.
2. The requirements have no unresolved, high-risk implications, such as risks due to COTS choices, cost, schedule, performance, safety, security, user interfaces, and organizational impacts.
3. The nature of the requirements will not change much during either development or evolution.
4. The requirements are compatible with all the key shareholder’s expectations, including users, customers, developers, maintainers, and investors.

5. The right architecture for implementing the requirements is well understood.
6. There is enough calendar time to proceed sequentially.

### The Spiral Development Model

The spiral development model (Boehm, 1988) holds the middle ground between agile methods and the waterfall model. It was created for use in situations where the assumptions needed for the waterfall model could not be made or were found false. It has six invariants, designed to minimize project risk (Boehm, 2000):

1. Concurrent determination of key artifacts (ops concept, requirements, plans, design, code).
2. Each cycle does objectives, constraints, alternatives, risks, review, and commitment to proceed.
3. Level of effort driven by risk considerations.
4. Degree of detail driven by risk considerations.
5. Use of anchor point milestones (life-cycle objectives, life-cycle architecture, and initial operating capability).
6. Emphasis on system and life-cycle activities and artifacts.

Invariant 1 shows that it does not, contrary to common misconception, comprise many incremental cycles of a miniwaterfall model with sequential phases of requirements, design, implementation, and so on. Invariants 3 and 4 make obvious that its use requires the understanding of the relevant risks, and it may therefore be inappropriate for inexperienced programmers and project managers. Spiral development look-alike models that violate these invariants expose projects to significant risks (Boehm, 2000).

### The Agile Programming Movement

Agile software development favors “individuals and interactions over processes and tools; working software over comprehensive documentation; customer collaboration over contract negotiation; and responding to change over following a plan” (Agile Alliance, 2001). Agile methods were reviewed by Cohen et al. (2003). They are particularly appropriate whenever the requirements are difficult to capture (e.g., the customer does not know what is needed), are changing, when the project could be terminated at any time and some partially functioning software is desired, or as soon as possible. Their main weakness is that long-term vision in the architecture and design is necessarily lacking, and correctness is difficult to establish. If possible, it would be interesting to perform a study relating agile programming to secure programming, number of vulnerabilities or security issues. Are agile programming development models favorable to security? Are there fewer or more vulnerabilities in software developed that way?

“Extreme Programming” (Wells, 2003) is the most well-known of the agile development models. It advocates programming in pairs, which has the advantage of providing an instant code review. Pair programming was shown to enhance the learning and increase the quality of code produced by undergraduate students (Williams & Upchurch, 2001). Among its benefits, pair programming

can help catch obvious cases of well-known programming errors leading to the most common vulnerabilities (e.g., buffer overflows), provided that at least one in the pair is knowledgeable in this area. However, this author believes that it is not a complete replacement for code reviews because it is not favorable to reflection and the careful consideration of the security implications of some operations or combinations thereof.

In Extreme Programming, the design and requirements are in flux until the last version is released. Focus is on releasing (tested) functionality as early as possible. Design periods are short (ideally 10 minutes), followed by implementation sessions. Therefore, it is unlikely that emerging risks posed by the changing designs, and matching security requirements, will be identified before they are implemented. Correcting security problems after implementation has known security limitations; “products claiming security that are created from previous versions without security cannot achieve high trust because they lack the fundamental and structural concepts required for high assurance” (Sullivan, 2003).

An intriguing aspect of Extreme Programming is the practice of creating unit tests first, as a way of encoding functional requirements. Software is validated by passing all the tests. Therefore, the security of programs depends on whether tests were included for unexpected, malicious inputs and behavior; this practice essentially replaces security requirements and security analyses in other models. Some of the tests are to be provided by the customer, who may not be knowledgeable in the area of security. This software development method can be compared with the two classic ways to test the security of software: black-and white-box (a.k.a. structural) testing. Black-box testing assumes or has no knowledge of the implementation, whereas white-box testing has access to all the information. Writing tests before the implementation (and part of the design) is similar to black-box testing, which is less powerful than white-box testing. Security testing requires broader coverage than normal testing and also focuses particularly on the least used aspects of security functions (Sullivan, 2003) and “what if” malicious scenarios. These are the least likely to be emphasized and captured during test creation before coding. Therefore, establishing the trustworthiness of software artifacts produced using Extreme Programming is more difficult than in other development models and may require separate, additional security testing or code reviews.

These observations are not fatal flaws but are pointed out so that programmers and customers will be aware of the risk factors they pose and knowingly accept or mitigate them with other practices. It should be noted that Extreme Programming also requires complete adoption of all its activities because each activity assumes that the others are performed to cover the risks that each poses individually. As a result, it can be seen as a risky or unstable development model (Stephens & Rosenberg, 2003).

It would be a mistake to form an opinion of all agile development models based solely on this brief analysis of Extreme Programming. Whereas none specifically address security concerns, other models put a greater emphasis on the definition, analysis, and documentation of require-

ments (Cohen et al., 2003). This author feels that this is preferable to the exploration of security risks and threats and to the generation of security requirements and appropriate, thoughtful changes in the architecture and design. One way to strengthen agile programming development models is to use them in conjunction with the SSE-CMM (discussed later) to provide higher assurance and security, inasmuch as the original software capability maturity model can be seen as compatible with agile methods (Cohen et al., 2003).

### **Cleanroom**

The Cleanroom development model (Mills, Dyer, & Linger, 1987; Linger, 1994) uses incremental development, which bears some similarities with agile methods, but under statistical quality control. Cleanroom is not considered an agile development model because it involves a strict sequence of phases in which code execution comes last; specification must precede design and correctness verification through review precedes code execution. Each increment delivers functionality to the end user.

### **The Personal Software Process (PSP)**

PSP specifies activities and a discipline to be performed by the individual programmer to gather metrics, improve estimation and prediction capabilities, and reduce errors. Its benefits are documented in more than 30 journal publications (not listed here). However, it is not a free and open system. Instructors who are interested in teaching PSP courses to third parties must sign a license agreement with the SEI (see also TSP, which follows).

### **The Team Software Process (TSP)**

TSP (Humphrey, 2000) was created to bridge the gap between the PSP and the SE-CMM and specifies activities that apply at the team level. It has phases similar to those of the waterfall model; requirements, design, implementation, and test. However, phases can and should overlap. Marketing material and reports state impressive reductions in the number of defects (including security defects) and time required (Davis & Mullaney, 2003). However, a disadvantage of the TSP at this time is that it is not a free and open system; licensing is required. Moreover, this author was unable to find publications on TSP independent from the SEI (Software Engineering Institute) except for a few teaching experiments. Training must be done by the SEI, their approved partners, or organizational trainers trained and licensed by the SEI. As it is proprietary, attempts at improvement, or unlicensed teaching, would breach the SEI’s intellectual property rights. Nevertheless, the combination of the PSP and TSP deduces results unmatched by other development practices (Davis & Mullaney, 2003) and is most likely (in the absence of independent reports, this author is somewhat cautious) the best available for the development of secure software (in combination with a CMM such as the SSE-CMM).

### **Correctness by Construction (CbyC)**

CbyC focuses on bug prevention or early removal, rather than bug detection in traditional validation and verification efforts, through the careful selection of powerful

language tools and analysis methods (Amey, 2002). By using unambiguous languages that support strong static analyses (see SPARK later in the chapter), faults can be prevented or caught very early. This and the use of formal methods at early stages lowers the cost of verification and validation efforts (Hall & Chapman, 2002). This process was compared favorably with TSP (National Cyber Security Partnership Task Force, 2004). The usage of formal methods in CbyC can help certification (discussed later in this section).

### Capability Maturity Models

Capability maturity models are frameworks to assess the existence, effectiveness, and maturity of development activities, practices, and processes. These are grouped by areas (domains, a.k.a. process areas, PAs) and levels of maturity (ratings) and are called Base Practiced (BPs). They describe what needs to be done, but not how to do it. They usually require performance measurement and reproducibility in the first levels because a fundamental axiom of CMMs is that without measurements, it is impossible to know if performance has been improved or not through a change or through the use of one development model instead of another. Development environments and models that resist the implementation of measurements as being too “heavyweight” are limiting themselves, from the viewpoint of CMMs, to make anecdotal, qualitative, or unsupported and doubtful quantitative claims of performance. Consequently, this author expects development models that persist in resisting or preventing measurements to face fates similar to those of diet fads or to become closed belief systems (“religions”).

The capability Maturity Model Integration (CMMI). The CMMI product suite replaces the older software capability maturity model (SW-CMM). CMMI melds together several CMMs and so links the software development phase to the greater context of systems engineering, configuration, environment, life-cycle management, and more.

#### SSE-CMM

The SSE-CMM addresses the management of the software development processes, with an emphasis on security practices. The SSE-CMM became an ISO (International Standards Organization) standard in 2002 (ISO/IEC 21827:2002). It used the systems engineering capability maturity model (SE-CMM) as starting point and added to the engineering process area.

INFOSEC Assurance Capability Maturity Model (IA-CMM). IA-CMM applies to providers of Information Security (INFOSEC) assurance services but not directly to the development process. However, it is relevant to this chapter because it is based on SSE-CMM and links software development to information security.

#### ISO-9001

This international effort bears similarities to CMMs and promotes quality. It specifies both systemic (processes, documentation, etc.) and management (quality policy, quality objectives, customer requirements, and satisfaction) requirements. ISO-9001 certification helps CMM

certification and vice versa through overlaps (see Paulk, 1994).

### Certification

Common Criteria. The Common Criteria for Information Technology Security Evaluation (Common Criteria Project Sponsoring Organizations, 1999) specify functional and assurance requirements of software artifacts (targets of evaluations), which can be matched against desired assurance properties (protection profiles). Common criteria (CC) do not certify that a product is free from defects or vulnerabilities. Rather, CC evaluate the presence, quality and proofs of assurance in the form of architectural decisions, access control mechanisms, development methodology, testing, and other evidence of security assurance and security functionality. These assurance properties provide trust in the software artifact, for example, that requirements were captured, designed, and implemented correctly and that protection mechanisms limit the possible damage should a fault occur or a vulnerability be found. In this manner, CC rate the trustworthiness of the software artifact. CC certification is slow and expensive because it is time consuming to assess, prove, and demonstrate these properties. However, CC are used and recognized internationally (through the signature of the Common Criteria Recognition Arrangement, CCRA) and have supplanted other certifications (for new software). Another chapter of this handbook describes the Common Criteria and high-assurance software engineering in more detail.

## REQUIREMENTS AND DESIGN

It is useful to think of security problems as being enabled at three times: design and architecture (including requirements), implementation, and operations (Graff & Van Wyk, 2003). Fixing security bugs with a patch costs 60 times more than catching them at design time (Soo Hoo, Sudbury, & Jaquith, 2001). Because this chapter does not cover operation and configuration issues, this leaves design, covered in this section, and implementation, covered in the next section.

In the general case, the security of a particular design and its implementation are undecidable (Cervesato et al., 1999; Even & Goldreich 1983; Heintze & Tygar 1996) Some security properties can be formally proved, or shown to be broken, under some circumstances (Meadows, 2003). Requirements specification and good design and development processes do not deterministically guarantee secure programs. However, they provide assurance that the systems will be reasonably secure for the intended use, especially when combined with formal methods (see Correctness by Construction earlier in the chapter). The scope of the following considerations is limited to EALs 1–4; another chapter of this handbook focuses on high-assurance software engineering (EALs greater than 4).

### Requirements

There are several types and level of requirements; Wiegiers (1999) discussed business, user and functional

requirements, as well as “other non-functional requirements.” Security objectives, policies, and requirements would then fall into the last catchall category and are discussed for less than a page in a 350-page book (Wieggers, 1999). The objective in mentioning this is not to criticize this book, but to provide a typical example of the priority and coverage given to security requirements in the industry. Is this a lack of attention, or does it reflect what we really know about how to specify security requirements? Has academia not come forward with ideas applicable in real situations? Crook et al. (2002) contended that conventional requirements modeling is inadequate to represent the organizational procedures that underpin a security policy. The difficulty in specifying security requirements contributes to the security problems and the nonstop patching environment we are now experiencing. Security requirements define goals and what must be done to secure a system against likely threats and to mitigate risks; without security requirements, your system is already secured by this definition. Possible results are the surprise of finding that your product is vulnerable, that customers were hacked, and that they are now blaming you. We ride from surprise to surprise and patch to patch.

Security requirements are harder to capture than other requirements. Typically the customer has thought about desired features and behavior but not about all the ways things could go wrong in the technology that supports its business model when faced with a malicious, clever user. The concept of antirequirements is that of requirements formulated by crackers, to subvert existing requirements (Crook et al., 2002). However, although it is possible to interview management and end users, it is not possible to interview a panel of crackers and trust the results. Security requirements can be captured based on risk assessments (Brown, 1989). A difficulty with deriving security requirements from risk and hazards assessments is that some unforeseen risks emerge out of particularities of design, implementation and coding choices, and low-level interactions (Berry, 1997), and a failure to foresee inconsistencies. These discoveries may require revisiting earlier development phases.

In quality assurance, requirements comprise security objectives, policies, and security requirements; it is easy to confuse “requirements” and “security requirements.” Security objectives help define policies and are higher-level goals than security requirements. An example security objective would be “all money transfers must be legal.” A policy specifies whether activities, states, and processes in the system are acceptable or not; one could be that “money transfers can be authorized only by the owner(s) of the account or designated parties.” Security requirements prevent, deter, or provide accountability for policy violations; one could be that “the authorization credentials of people authorizing money transfers shall be verified and audited within a reasonable time period.” Security requirements can be further divided into security functional requirements and security assurance requirements. Vetterling, Wimmel, and Wisspeintner (2002) provided an illuminating account of the determination of all these for a system designed to be evaluated with the Common Criteria.

## Requirements Documentation and Specifications

We wish to formulate security requirements and derive specifications from them with better assurance that the requirements were complete, will be well understood, and that the specifications are correct. The Unified Modeling Language (UML) “use cases” that help capture functional requirements were adapted to provide “abuse cases,” which can also be represented in regular UML (McDermott & Fox, 1999). A similar idea is that of “misuse” cases (Sindre & Opdhal, 2000). UML has recently been extended with UMLsec, and mathematical tools can be used to verify UML specifications against formal security requirements (Juerjens, 2004).

## Determination of Requirements

Baskerville (1993) identified three categories of methods: checklist, mechanistic engineering, and logical (i.e., formal). Using the SSE-CMM as an inspiration to generate security requirements (Phillips, 2003) is similar to a checklist method. Requirements are greatly influenced by the system’s architecture and intended usage contexts. Consideration of how the system must operate inside an organization with a social context shows how responsibility modeling leads to security requirements (Strens & Dobson, 1993). From a theoretical approach, Petri nets are suitable for modeling information flow security requirements in distributed systems (Varadharajan, 1990). Requirements can be statically verified using finite-state techniques (Ahmed & Tripathi, 2003). Example security requirements, and the processes used to derive them, are available for open systems (Kolstad & Bowles, 1991), medical applications (Hamilton, 1992), cooperative work (Ahmed & Tripathi, 2003; Coulouris & Dollimore, 1994), and mobile agents (Reiser & Vogt, 2000). Missing are follow-up studies showing how well these requirements fared in practice several years later and whether the ways they were derived are applicable elsewhere.

## Secure Design Principles

There are eight secure design principles, described by Saltzer and Schroeder (1975), that are still relevant and important today.

### Least Privilege

A subject should only be given those privileges it needs to complete its task. An example of excessive privileges was Microsoft IIS version 5 and earlier, which ran under the Local System Account (strictly speaking, it was “possible” to create and configure a special account with fewer privileges). Taken to an extreme, this may translate into an access control problem. The complexity of the access control mechanism and its configuration may increase to model the needed privileges (e.g., capabilities).

### Fail-Safe Defaults

Unless a subject is given explicit access to an object, it should be denied access to that object. An example using the Apache access control through `htaccess` files, to deny by default and allow only specific clients, would be:

```
deny from all
allow from...
```

This issue is related to the issue of failing “safe” versus failing “functional,” as exemplified by network switches that unexpectedly fail “open” and function as hubs when overwhelmed under unusual circumstances. This failure policy in practice removes any security benefit from using switches instead of hubs.

### **Economy of Mechanism**

Security mechanisms should be as simple as possible because complex mechanisms may not be correctly understood, modeled, configured, implemented, and used. Moreover, complex mechanisms may engender partial implementations and compatibility problems between vendors (see the IPSEC-related RFCs; compatibility between IPSEC implementations is a problem).

### **Complete Mediation**

All accesses to objects must be checked to ensure that they are allowed. This is a performance versus security issue; the results of access checks are often cached. Permissions may have changed since the last check; if caching is used, there must be a mechanism to flush or invalidate caches when changes happen. An example vulnerability resulting from a failure to apply this principle was observed in `xinetd` 2.3.4 (CVE: CAN-2002-0871), which leaked file descriptors for the signal pipe to services it launched. This allowed those services (e.g., if compromised) to attack `xinetd`.

### **Open Design**

The security of a mechanism should not depend on the secrecy of its design or implementation. This is because if the details of the mechanism are leaked, reverse engineered, or otherwise found, then it produces a catastrophic failure for all users at once. By contrast, if the secrets are abstracted from the mechanism, for example, inside a key, then leakage of a key only affects one user or one group of users. Examples of failures of open design abound, from electronic voting machines to the old days when various word processors and spreadsheets offered to “encrypt” all documents with the same key. Failure to follow this principle also results in insider threats, because insiders may know enough to compromise the mechanism everywhere it is in use (which is especially disturbing in the case of electronic voting machines). Note that this principle does not require the capability to audit the code, nor does it require that designs and implementation details be revealed or made public. However, providing assurance that this principle was followed is difficult without revealing a good part of the design, at least to a trusted party.

### **Separation of Privilege**

A system should not grant permission based on a single condition. This removes a single point of failure and is analogous to the separation of duty principle. By requiring multiple factors, “collusion” (the compromise of several factors) becomes necessary and risks due to bribery or a single vulnerability are reduced.

### **Least Common Mechanism**

Mechanisms used to access resources should not be shared. The idea is to avoid the transference of risks (or data, e.g., covert channels) from one task or service to another. An example is the vulnerability CVE-1999-1148; because under Microsoft NT architecture, the FTP (file transfer protocol) and Web services shared a common thread pool, exploiting a denial-of-service attack in the FTP server (keeping all threads busy) resulted in a loss of Web services.

### **Psychological Acceptability**

Security mechanisms should not make the resource more difficult to access than if the security mechanism were not present. This is to avoid presenting an incentive for users (or help desks) to disable, bypass, or defeat security mechanisms. In practice, difficulty proportionate to the value of the protected assets is accepted. An example is even the mild annoyance of entering passwords many times to access resources. The “rhosts” mechanism can bypass password security checks. However, authentication is then based on Internet protocol (IP) addresses, which can be mapped to a different host through Address Resolution Protocol (ARP) poisoning, so the resources become vulnerable.

### **Best Practices**

Over the years, the repetition of mistakes resulted in the generation of some best practices. Although not as hallowed as the previous eight principles, these can avoid several of the issues listed later in “Quality Assurance in Coding and Testing.”

### **Separate Control From Data**

Many problems, from phone “phreaking” to metacharacter and character encoding issues, Structured Query Language (SQL) injection vulnerabilities, cross-site scripting vulnerabilities, and so on, are due to the fact that the same channel is used to transmit both data and code (commands). Whenever databases are queried with a search term provided by a user, chances are that the data (the search term) were simply inserted inside a command string sent to the database engine. The malicious composition of data to contain commands (shell commands, SQL, javascript, etc.) and to trigger a context switch to command interpretation inside the software processing the channel is the class of code injection attacks. Using separate channels will defeat these attacks. A partial example of using separate channels is the use of stored procedures in databases. The commands were sent to the database engine ahead of time and setup as functions, and during execution only the data are sent (with a specification of which function to use). Then, allowing only function calls in the data channel prevents the execution of arbitrary SQL commands injected by attackers into data. This is not entirely safe because attackers could still trigger unwanted executions of functions. However, it shows that even partial compliance to this principle reduces risks. Another example is the use of the `exec` UNIX family of functions instead of the “system” call; by using separate arguments (“channels”), some interpretations and possibilities for code injection are made impossible.

### Use Whitelists Instead of Blacklists

Blacklists of “bad” things are rarely complete. Whether character encodings, escape sequences or globbing (see Glossary) are involved, it is difficult to list all combinations (CERT Coordination Center 1998). The “wrapper” problem is especially difficult, whereas a script or program attempts to sanitize input for an unsafe program. The wrapper has to understand fully and model how the unsafe program will parse and interpret its arguments and keep up-to-date with changes, as well as to use the calling mechanism correctly. Wrappers can be entire programs in their own right, such as the wu-ftpd FTP server. FTP conversion processes files through a program that does the conversion (e.g., tar or uncompress). Wu-ftp allowed an attacker to execute commands via malformed file names, because the conversion program interpreted and parsed differently the command passed to it (CVE-1999-0997). Wrappers should only allow known good commands.

### Use Operating System Provided Services

Only the operating system (OS) can provide guarantees about the atomicity of the creation of temporary files with correct permissions and a unique name, and thereby avoid race conditions and symlink vulnerabilities. Random number generation is another problem best solved by the OS. Cryptographically good random number generation is a difficult problem, and it is doubtful that custom solutions will be good unless the programmer is an expert cryptologist. Moreover, only the OS has access to certain sources of entropy that help provide superior random number generation. Use virtual devices such as `/dev/urandom` to obtain random numbers from the OS.

### Manage Trust

The designers and programmers should be aware at all times of which objects, variables, and inputs they can trust. There should be well-defined “trust boundaries” that act like a country’s customs. Untrusted inputs should be validated to become trusted. This boundary is formalized in some languages (e.g., Perl’s “taint” mode). The custody of data and code affects the trust that can be put in it. There are more than a dozen CVE entries relating to shopping cart applications that stored the price of items in the client browsers, and then trusted the prices given back to them by the client. Likewise, there are numerous software artifacts that trust the integrity of their execution on client computers, such as javascript or Java authentication code. These trust management failures would be similar to unsupervised and unmonitored self-checkout lanes in supermarkets.

### Protect Resources

Anonymous, unauthenticated requests should be given minimal or no resources unless it is a policy to serve their requests. The ordering of operations should be such that authentication, followed by permissions and credentials verifications, and any check that might fail should be performed before expensive operations. Sometimes, resources owned by the requester can be used instead.

In transmission control protocol (TCP)/IP networking, a security problem known as “SYN flooding” was due to the consumption of memory to keep track of connections. It was solved by using “SYN cookies,” in which local memory was replaced by remote resources through the encryption of data. This effectively traded central processing unit time against memory usage.

## Languages

The choice of language has important security ramifications. When programming in a low-level language such as “C,” proper checks for safe and proper handling of buffers and string formats are tricky, extremely tedious, and time consuming to get right. As a result, the temptation is great for programmers cut corners and omit some checks whenever they feel they are not needed. The result is that buffer overflows and string format vulnerabilities are common. Even programmers trying their best to avoid these vulnerabilities occasionally get the code wrong with a boundary error (a.k.a. “off-by-one” error) or by forgetting to ensure that strings are terminated correctly in all circumstances. Then follows the call to `strlen` that produces a segmentation fault, or an exploit that benefits from the effective concatenation of two adjacent buffers (because the last NUL byte was not written, string functions will treat the two buffers as one). Better languages, such as C#, Perl, or Java, and variants of the “C” language (discussed next) prevent these two kinds of vulnerabilities from happening. Coding style can also reduce the probability of software faults (see next section).

### Cyclone

The Cyclone programming language is a safer version of C and prevents buffer overflows and string format vulnerabilities while preserving the power of the C language (Jim et al., 2002).

### SPARK

The Spade Ada Kernel (SPARK) is an Ada derivative in which some features of Ada were removed and annotations added to allow proving properties of the code. As a result, delta and information-flow static analyses are possible. It is also interesting in that SPARK tools link formal specification and verification (Amey, 2001). “Proof of the absence of pre-defined exceptions offers strong static protection from a large class of security flaws” (Hall & Chapman, 2002). “SPARK code was found to have only 10 percent of the residual errors of full Ada; Ada was found to have only 10 percent of the residual errors of code written in C” (Amey, 2002).

## QUALITY ASSURANCE IN CODING AND TESTING

There are a number of security issues that can not be prevented by cryptography or clever requirements. Noticeably, the same mistakes keep being repeated by programmers and fall within well-understood broad categories. Using key-word searches on the description of CVE entries from 2000 to 2002, vulnerabilities related

to buffer overflows, directory traversal attacks, format string vulnerabilities, symlink attacks, cross-site scripting vulnerabilities, and shell metacharacter issues represented, respectively, 20%, 11%, 9%, 4%, 4%, and 3% of all vulnerabilities. This means that at least 51% of vulnerabilities are repeated basic mistakes. Whereas it could be argued that some are design issues, they are such simple ideas (in principle; some are extremely tricky to get right in practice) and low-level design issues that we like to think of them as implementation problems (i.e., in the realm of secure coding).

## Coding Style

Coding style affects readability, understandability, and maintainability. Obfuscated C code makes it harder to find mistakes and vulnerabilities—for both the original author and others doing a code review or maintenance. On the other hand, some coding styles help the programmer think more clearly and avoid mistakes and make the intent of the programmer easier to understand. MISRA (the United Kingdom's Motor Industry Software Reliability Association) recognized this and established a set of 127 guidelines for the use of C in safety-critical systems (MISRA, 1998). Some guidelines are mandatory and some are advisory, but all are copyrighted and the guidelines are only available from MISRA; nevertheless, they are increasing in popularity because they are effective and make sense.

There is no absolutely wrong or right coding style; however, to reduce the occurrence of bugs, code should be produced to be easily understandable by as many people as possible, as quickly as possible, with the least chance of misunderstandings. Maintaining a consistent coding style throughout a project also speeds up code reviews (discussed later). Coders producing brilliant but indecipherable code are bad coders because they significantly increase the cost of code reviews, maintenance, and the risk that their code contains a vulnerability or be called by others in such a way as to create a vulnerability. Assume as an axiom the following: if the functionality of the code is hard to understand, then the security implications will be obscure.

Coding style is more than indentation; it is also how functions are called and their side effects. Consider this "if" statement:

```
if ((A = fn3(G, H)) == B) myfunc (A, D, E) else{
    s1
    s2
    s3...
}
as opposed to
A = fn3(G,H); // comment on fn3
if (A == B){ // comment on what it means if they are equal
    myfunc (A, D, E) // comment on myfunc
} else {
    s1
    s2
    s3...
}
```

Typically, the first one takes longer to understand and is more error prone. In this example, there was an assignment, a function called, and a test condition within the "if" statement; moreover, the first branch was on the same line as the if statement, without brackets. Brackets ease the insertion of additional code and make obvious that a branch is happening; they also maintain a consistent usage for semicolons. Bugs happen where brackets would have prevented them. Here is another example of bad style, in PHP:

```
if (!$z || $y ==") {
    s1
    s2
    s3...
}
```

Did the author mean to test against the integer zero, a NULL value possibly indicating an error, or is \$z a Boolean, which the "!" operator will all happily convert to something that will pass the "if" test? Additionally, in PHP a NULL value tests true against an empty string, so the test for \$y is also ambiguous. The answer can be found by investigating the code, or perhaps the author was thoughtful enough to write a comment about it, but it is better to make it explicit. PHP has a triple equal operator that verifies type as well; it should be used everywhere possible:

```
if ($z === false || $y === NULL) {
    s1
    s2
    s3...
}
```

This is obviously not an exhaustive list but demonstrates how to be aware of unclear or ambiguous code.

## Secure Programming

Secure Programming (a.k.a. secure coding) is the awareness and understanding of the security consequences of implementing requirements in various possible ways. Secure programming classes at Purdue University teach students to avoid common mistakes (Meunier, 2002) or teach awareness and how to work around security defects in widely used protocols (Meunier, 2003). Secure programming documents oriented toward UNIX

(Wheeler, 1999), Web programming (Open Web Application Security Project, 2002), and a functionality-oriented book (Viega & Messier, 2003) are available. I describe here the two kinds of vulnerabilities specific to the C language because they are very common and refer the reader to the best practices section and the above citations for other secure programming issues.

### Buffer Overflows

Buffer overflows occur when manipulating strings, arrays, and regular buffers. Fixed buffer sizes used to hold inputs from untrusted (or misidentified as trusted) sources are the easiest targets of buffer overflow attacks, but not the only ones. In arrays, they occur when counting from 1 instead of 0, or when the programmer forgets that the index “ $n$ ” actually refers to the  $n + 1$ th element. In string manipulation, they occur when or after strings are not null terminated, when strings are concatenated in a buffer that is too small, or when the programmer forgets to count the byte holding the null byte in the total buffer size. Although the concept is obvious, it is in practice tricky to catch all cases, especially when the standard C string functions are not safe and sometimes return strings that are not null terminated. Strings that are not null terminated are not safe to use with C functions, so the standard C functions are not even self-consistent. Using the C functions that take buffer sizes as arguments is a step in the right direction but is insufficient because even those are not self-consistent. Moreover, they sometimes require as argument the remaining available space in the buffer, instead of the original buffer size, which allows the programmer to make arithmetic mistakes. The new `strncpy()` and `strncat()` functions should be strongly preferred because these guarantee null-termination and avoid unnecessary arithmetic.

### Format String Vulnerabilities

Format string vulnerabilities occur in part because of the inability of the C language to know how many arguments were passed to a function. Format strings violate the recommendation to avoid mixing code and data because they contain formatting instructions mixed with characters to display. In addition, format strings under the control of an attacker can specify where to write values almost anywhere in memory. Because a format string that contains only data will simply result in that data being printed, the most common mistake is to use data as a format string. If an attacker can change the data, then perhaps formatting commands can be inserted, with disastrous results. Always make sure that format strings are specified even when only printing a string, that they are constants, and that they cannot fall under the control of an attacker.

### Code Reviews

Code reviews are an expensive but effective technique for identifying software quality issues, including vulnerabilities. Code reviews involve having other people read your code and pointing out mistakes, vulnerabilities, and bad practices, or simply asking questions about parts of the code they did not understand and comparing the code to specifications and documentation. Few developers like being the author in a code review because it can be somewhat humiliating when others find stupid mistakes and point them out. On the other hand, the reviewers should be sharp, knowledgeable, and critical people. They

should be familiar with the most common secure coding errors and vulnerabilities and with secure programming principles.

### Reducing the Cost

The number of people involved in the code review can be as few as one plus the author. Obviously, the more people involved, the greater the assurance provided, but also the more likely that code reviews will be abandoned under time pressure. Code reviews are less time consuming when a coding style standard emphasizing clarity and comments has been adopted. The human mind seems to find mistakes much more easily on printed pages than on computer screens, so most code review processes require printing everything. Numbered lines of code speed up references during discussion. It is essential to perform the reviews individually to enable reviewers to concentrate fully without distractions and then meet to discuss issues. Meeting lengths are shorter if the reviews are performed before the meeting rather than during the meeting (“online”); online meetings proceed at the pace of the slowest and therefore time is wasted, or the slowest reviewer is hurried and cannot review the code properly, which is another waste of time. Durations depend on the number of issues found, so the duration is somewhat unpredictable. It is also more efficient if someone other than the author takes notes, freeing the author to discuss issues without distractions.

### Code Review Goals

The main goal of code reviews is to gain a different perspective and apply a different set of skills to the code. However, it is useful to put emphasis on helping the author with a particularly difficult problem on securing one part of the code against a likely kind of vulnerability, or on providing assurance that the code meets specifications and security requirements. Code reviews also provide signals and warning signs of design flaws. If the review of a section of code requires the reviewers to “jump around” between different files stored in different directories and carry most of the project’s code along for reference, it is likely that the organization of the code (modularization or layers) is incorrect.

### Testing

Testing is an important and a costly phase of the software development life cycle and is part of validation and verification activities. There are many books on software testing, so the coverage in this section focuses on the security aspects of testing.

### Scenario Testing

Scenario testing is used to ensure that requirements capture is complete and consistent. This is a validation effort. At this stage, “abuse cases” (McDermott & Fox, 1999) and “misuse” cases (Sindre & Opdhal, 2000) are particularly relevant.

### Specification Testing

There are a variety of specification testing methods, including formal proof and symbolic execution. These attempt to prove the completeness and correctness of the specification, often represented in an intermediate language. This is both validation and primarily verification. An example is the use of mathematical tools to verify

UMLsec specifications against formal security requirements (Juerjens, 2004).

### Statistical Testing

Whereas specification-based testing aims at finding as many defects as possible (effectiveness), statistical testing aims at running as few test cases as possible with maintained high-quality efficiency (Olsson, 2002). For security purposes, we find specification testing more attractive because of the emphasis on complete coverage, whereas statistical testing considers complete coverage that is neither possible nor very effective.

### Inline Testing

Inline testing (including uses of ASSERT macros, pre- and postconditions, etc., . . .) are a form of execution testing to verify adherence to specifications. These are normally built into the code at the time of development. For security, these should verify that the internal state of the software is an allowed and expected state for the algorithm, is self-consistent, and is consistent with a state approved by policies and requirements.

### Unit Testing

Unit testing is performed during construction and is a form of local testing to verify proper behavior of sub-routines, functions, modules, libraries, and so on. This stage is appropriate to detect several of the vulnerabilities enumerated at the beginning of section 4, such as buffer overflows, directory traversal, and format string vulnerabilities. However, testing for issues such as symlink vulnerabilities is difficult because race conditions are not reproducible. Moreover, it is unlikely that the testers will think of the metacharacter issues that the coders forgot (especially if they are the same people) and even less likely that random input will produce them.

### Integration Testing

Integration testing is when the interfaces and common interfaces of modules are tested during linking and loading. One could argue that the syntactic-semantic checks of arguments in calls is a form of testing at this stage if it is done statically, at link time. Otherwise, it is a form of inline testing. In either case, it is a form of verification. It is at this stage that discrepancies in assumptions and the assignment of responsibilities for various parts of the software can create vulnerabilities. An example would be if Part A makes a call to Part B, relying on Part B to perform access control, whereas Part B assumes that the caller did it. At this stage, security testing should ensure that all operations and requests that should be denied, are denied, and that partial accesses are allowed only what they should.

### Final Testing

Final testing is what most people mean when they talk about testing. This is where test cases are developed and run against the entire software artifact. Lots of different methods can apply here, some of which have already been mentioned. Theoretically, testing should exhaustively exercise all the execution paths in a program, with all possible values and kinds of inputs, but this can be rather complicated and time consuming. In its simplest form, random input can be used, such as that generated by the “fuzz” testing program (Miller, Fredriksen, & So, 1990) or IP Stack Integrity Checker (Frantzen, 1999). In large or

complex systems, however, the cause of a given malfunction can be difficult to pinpoint even if the random input is replayed. Using binary search to isolate the input responsible for the malfunction ignores accumulated state in the system and can result in contradictory results, such as the “critical input” (which may not exist independently) being in a set of inputs but being absent from both halves of the set. More sophisticated approaches involve creating a grammar describing inputs and testing the running program with various inputs designed to find flaws; this technique has proved powerful but requires significant investment and deep understanding of the program’s function to bear fruit (Oulu University Secure Programming Group, 2001). The effectiveness of software testing can also be improved based on partitioning the input domain, which reduces the number of test cases needed (Vagoun, 1996).

### Acceptance Testing

Acceptance testing is done for contracts and is a validation step. This is when the customer uses the software to ensure that it meets the needs of the customer in real use. Customers should try to include tests of every threat that can be tested. Interoperability testing may also occur to ensure that the new artifact works with other necessary hardware and software. Of course, these needs should be in the requirements but are often overlooked.

### Maintenance Testing

Maintenance testing is done after changes in the system or its platform. This may include regression testing to ensure that no old bugs (or new bugs) are (re-)introduced in the process of fixing a flaw. Vendors have a much bigger maintenance testing load than most hackers understand, and this is one reason it takes so much time to build and release a good patch.

## CONCLUSION

Programmer brilliance is not a substitute for security knowledge and discipline. Moreover, coding secure programs is different from producing assurance so that customers or third parties can trust that the programs are reasonably secure. Revealing the entire source code (as in open source) does not in itself produce assurance or increase security; however, it may enable auditing and testing. Auditing and testing are of benefit only if performed by qualified people. Although this chapter did not provide exhaustive coverage of these issues, it is hoped that the discussions and questions asked will inspire the application of these ideas as well as further research.

## GLOSSARY

**Commercial Off-the-Shelf (COTS)** Basic software, as opposed to more expensive special purpose software.

**Common Vulnerabilities and Exposures (CVE)** A project started by MITRE to identify all vulnerabilities; the project homepage is <http://cve.mitre.org>

**Evaluation Assurance Level (EAL)** The Common Criteria standardized evaluations. Note that the use of the Common Criteria is not limited to specifying EALs. The seven EALs are described at <http://csrc.nist.gov/cc/Documents/CC%20v2.1%20-%20HTML/PART3/PART36.HTM>

**Globbering** A UNIX term for the shell's process of wildcard filename expansion to develop a list of literal filenames that the shell then passes to a command. The C shell permits the user to disable globbing by default; the Bourne, Korn, and POSIX shells require the user to quote or escape metacharacters in file names if globbing is not desired. (Digital UNIX Documentation Library)

## INTRODUCTION

The Common Criteria is a framework for comparing the technical security of as-built products. The term *product* is used in a general way, to include any information technology component that might be constructed, not just those that may be for sale. Products are expected to be primarily software but the Common Criteria is not limited to software. By long-established convention, the Common Criteria is referred to as though it were a single document rather than a plural collection of criteria.

The Common Criteria framework (Common Criteria Project Sponsoring Organizations, 2000a, 2000b, 2000c) is used to define a set of criteria for measuring a single product. Different products that satisfy various requirements from the Common Criteria may then be compared against the criteria they have in common. The Common Criteria framework is essentially hierarchical so that it allows ordered comparisons, when used properly. The Common Criteria refers to the process of measuring a specific information technology product as *evaluation* (Common Criteria Project Sponsoring Organizations, 2000d).

The Common Criteria captures the important idea that security is defined in terms of both features and *assurance*. In the Common Criteria, the term *assurance* means the confidence we have that a product's features work as claimed. The best possible features provide little security if their implementation is flawed. Likewise, a high-assurance implementation of the wrong features provides no protection against the actual threats faced by an information technology product. So the requirements defined by the Common Criteria framework contain both *functional* and *assurance* requirements [as shown in Figure 1].

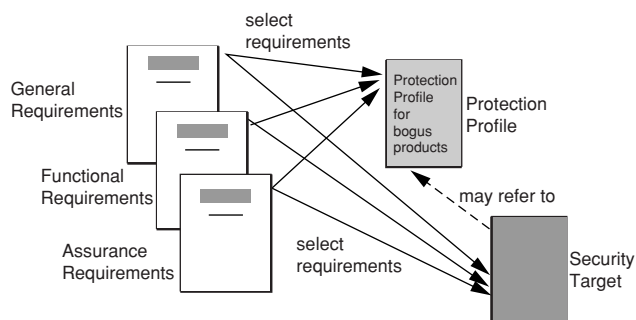

The Common Criteria is focused on measurement of completed products but is not limited to that. The framework also includes criteria for software development processes. The security of a product can only be defined in terms of the as-built product itself, not by the process that was used to build it. On the other hand, as-built

quality depends on the process used. For this reason, the development process components of the Common Criteria framework are assurance components associated with higher levels of assurance.

The Common Criteria is useful to many kinds of people. Information technology consumers or procurement officials can use it to choose and describe their security requirements. The Common Criteria can help users decide whether to trust their data to an information technology product. Information technology vendors can use the Common Criteria to communicate the security features and quality of their product. Developers can use the Common Criteria to understand and interpret the security requirements they must satisfy. Evaluators, certifiers, and accreditors can use it to assess the security of an information technology product. (I explain the terms *certifier* and *accreditor* shortly.) Finally, students can use validated sets of Common Criteria requirements to see how security functional and assurance requirements are properly related.

The Common Criteria is not a cookbook for security. It is complex and easily misused. It assumes a firm understanding of general information technology, security features, and assurance techniques. For these reasons, it is best to look at several validated sets of Common Criteria requirements as well as the criteria themselves.

The Common Criteria does not address all issues of security. It has no criteria for physical, operational, or personnel security even though all three of those disciplines have an impact on practical security. It does not explain how technical security evaluations are to be performed but only the necessary relationships between the work products it requires. It does not describe the follow-on use of Common Criteria evaluations in accreditation or certification activities. Even though the Common Criteria is mutually recognized by a number of countries, this recognition is not addressed by the criteria. Finally, the Common Criteria does not explain the administrative, economic, political, or legal context under

**Figure 1:** Structure of the Common Criteria.

which it is used. Ross Anderson's (2001) book on security engineering is a good treatment of these and other pertinent nontechnical issues not covered by the Common Criteria

The Common Criteria is a multipart standard that is structured into three volumes:

- Part 1: Introduction and General Model
- Part 2: Security Functional Requirements
- Part 3: Security Assurance Requirements

Part 1 defines the structure and application of the Common Criteria including the rules for building well-formed sets of security comparison criteria; parts 2 and 3 contain the framework of criteria. A well-formed collection of security features and assurance requirements can be either a *Protection Profile* or a *Security Target*, depending on the intended target of the collection.

If you are interested in using the Common Criteria to build an evaluated product, you should first get a copy of one of the Security Targets listed under Further Reading at the end of this chapter. A good one to look at initially is the Security Target for Netscape Certificate Management System 6.1. A Security Target is a kind of document produced using the Common Criteria. Have a brief look at it before continuing.

## Essential Terminology

The Common Criteria uses very precise terminology that can seem pedantic but is necessary for some of its applications. Because the sets of criteria defined by the Common Criteria framework may be used in contractual situations, precise language is necessary. Precise language is also needed for the evaluation process, to avoid problems caused by misunderstandings between the developers and the evaluators. Finally, it is also needed for fair comparison of different products.

Before we go any further, it is best to look at some of this terminology. The following terms are the most basic definitions used in the Common Criteria:

**Target of Evaluation:** More frequently seen as the abbreviation TOE. The product to be evaluated. This includes all developer and user documentation as well as the actual product. The notion of TOE is for a very specific instance of a product, as in Linux Kernel 2.4.21-9.0.1.EL rather than just *Linux*. This is because

small changes to a product can introduce significant new security vulnerabilities.

**Protection Profile:** Frequently seen as the abbreviation PP. A product-independent set of security criteria for a class of products. A (fictitious) example might be the high-assurance firewall protection profile. A Protection Profile is a document derived from the Common Criteria.

**Security Target:** Frequently seen as the abbreviation ST. A document that includes a product-specific set of security criteria. Security targets include a specification of a TOE and describe the assurance measures that were actually applied to it. Security targets also include an abbreviated assurance argument that explains why the specified security features and applied assurance measures satisfy the criteria. A security target for a TOE that falls into a general class of products, for example, high-assurance firewalls, may refer to the applicable PP. A security target may be written without an associated PP, if the TOE is a one-of-a-kind product. A security target is a document derived from the Common Criteria.

**TOE Security Functions:** Most frequently seen abbreviated as TSF. The collection of all the software, hardware, and firmware that must be relied on for the correct enforcement of the TOE security policy.

**TOE Security Policy:** Frequently seen abbreviated as TSP. The set of rules that define how resources or assets are managed and protected by the TOE.

**TSF Scope of Control:** Most frequently seen abbreviated as TSC. The set of all interactions (both allowed and illegal) that can with a TOE. These interactions are constrained by the rules of the TSP.

**Evaluation:** The assessment of a TOE, a protection profile, or a security target, against criteria chosen from the Common Criteria framework.

**Evaluation Authority:** An oversight body that applies the Common Criteria for a specific community. An evaluation authority usually does not conduct actual evaluations but sets standards, provides interpretations, and oversees the quality and consistency of evaluations. The rules and procedures used by an evaluation authority are referred to as an evaluation scheme.

**Evaluation Scheme:** The regulatory and administrative framework used by an evaluation authority to implement the Common Criteria.

## History

The Common Criteria grew out of work on similar national standards for several North American and European countries. It is an international standard, ISO (International Standards Organization) 15408, developed by a group of agencies known as the Common Criteria Project Sponsoring Organizations.

The USA's Trusted Computer System Evaluation Criteria (TCSEC or Orange Book) was the first initiative for standardized security evaluation of information technology products that led to the Common Criteria. It was published in 1985 by the NSA. In 1991, the European Commission published the Information Technology

Security Evaluation Criteria (ITSEC) as the outcome of a joint project involving the United Kingdom, Germany, France, and the Netherlands. In 1993, Canada published the Canadian Trusted Computer Product Evaluation Criteria (CTCPEC), which combined the TCSEC and ITSEC schemes. At the same time, a draft Federal Criteria for Information Technology Security (FC) was developed in the United States. In 1993, the sponsors of the CTCPEC, FC, TCSEC, and ITSEC began a joint project, the Common Criteria Project, that ultimately lead to the ISO standard.

### National Schemes

Eight countries are now part of the Common Criteria Recognition Agreement (CCRA) that supports mutual recognition of Common Criteria evaluation results under each country’s evaluation scheme. This mutual recognition increases the number of evaluated security products available to each country and increases the uniformity of evaluations across national boundaries. Member countries share evaluation knowledge and work together to improve the evaluation process and the quality of the results. Other countries that do not have their own evaluation schemes have agreed to recognize CCRA evaluation results. This increases the size of the potential market for vendors who build information technology to the Common Criteria standard.

At the time of this writing, CCRA mutual recognition applies to evaluations at EAL 4 and below. Higher EAL evaluations are not mutually recognized because they are used for national security systems, and it is not clear that evaluation results would be shared for such products. Table 1 lists the members of the CCRA that have their own schemes.

### STRUCTURE

The organization of the Common Criteria is related to the *hierarchical definition of security* as shown in Figure 2. Security in an information system is a complex property that depends on the usage of the system and the assets it handles and the specific protection its users expect. The protection users should expect depends on the threats present in the system’s environment. Although the full

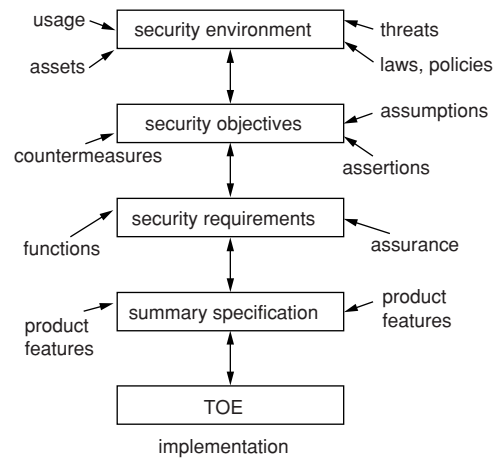

Figure 2: Hierarchical definition of security.

range of threats includes a variety of problems, security emphasizes (primarily malicious) human-sponsored actions. These human actions cause damage or loss to the assets. From a computer science perspective, damage may be characterized as loss of confidentiality, loss of integrity, or loss of availability. The loss of availability refers primarily to features of the information system itself that may be destroyed or disabled. Risk is a measure of the degree of exposure to loss; generally it is a product of likelihood and asset value. For example, a threat with high likelihood presents high risk to assets of almost any value. On the other hand, low likelihood threats can still present a significant risk, if the value of the assets is sufficiently high. The Common Criteria framework supports the specification of countermeasures to specific threats, coupled with a level of confidence that the countermeasures reduce the risk by an acceptable amount, hence the need for assurance requirements in the third part of the criteria.

Information technology products and systems are also subject to laws and regulations established by governments, for example, regulations concerning medical information. These laws or regulations may require the presence of specific countermeasures or the enforcement of specific security policies.

Table 1 Mutual Recognition of Evaluation Schemes of the Common Criteria Recognition Agreement (CCRA)

CCRA Scheme	Country
Australian Information Security Evaluation Program (AISEP) Defense Signals Directorate	Australia
Communications Security Establishment	Canada
Bundesamt für Sicherheit in der Informationstechnik	Germany
Service Central de la Sécurité des Systèmes d’Information	France
Japan Information Technology Security Evaluation and Certification Scheme (JISEC)	Japan
Government Communications Security Bureau	New Zealand
Communications-Electronics Security Group and Department of Trade and Industry	United Kingdom
National Information Assurance Partnership (NIAP) Common Criteria Evaluation and Validation Scheme (CCEVS)	United States of America

In either case, the Common Criteria framework requires an explicit discussion and analysis of the usage, assets, threats, and security policies that define the *security environment* of an information technology product. A description and analysis of the security environment is required for either protection profiles or security targets.

A security environment forms the top level of a hierarchical definition of security. Below this level, the Common Criteria requires the notion of *security objectives*. The Common Criteria uses the term *security objectives* to mean the most abstract security requirements for a product or system. These abstract requirements are derived from the stated security environment. The security objectives identify the countermeasures needed to address the threats, risk, and assets identified in the security environment. A critical part of the security objectives is the separation of abstract requirements into *assertions* (called security objectives for the TOE) and *assumptions* (called security objectives for the environment). Some countermeasures to threats are based on procedures and practices carried out in the environment of an information technology product. The product itself is not expected to provide these countermeasures. Other countermeasures are technical mechanisms that the information technology product provides to mitigate or reduce risk. The statement of security objectives should contain an argument that the abstract security requirements cover all of the threats from the security environment, in an appropriate manner. Explicit definition and analysis of security objectives is required for any well-formed set of Common Criteria requirements.

The Common Criteria security requirements form the next level of the hierarchy. These requirements are taken from the criteria, following a set of rules for constructing well-formed protection profiles or security targets. These functional and assurance requirements are shown to be a refinement of the security objectives.

The next level in the hierarchical definition of security is called the TOE Summary Specification. The TOE Summary Specification is an abstract description of the TOE itself (i.e., the interface of the product or system itself). The concrete TOE proper is the lowest level of the hierarchical definition of security. The logic of this hierarchical definition is that the final product provides the right kind of security, in the environment described in the applicable protection profile or security target.

Nothing in this definition implies a particular process or life-cycle model. (At the highest assurance levels, the chosen process or life-cycle model must be documented and the chosen model must have some community acceptance.) The relationship between levels is one of forward design refinement and backward correspondence analysis. This hierarchical relationship is continued in the assurance requirements, as discussed shortly.

The three parts of the criteria define a modular framework for constructing well-formed sets of security requirements, as either protection profiles or security targets. The first part, *Introduction and General Model*, defines the framework and gives rules for constructing well-formed sets of requirements. The two parts *Security Functional Requirements* and *Security Assurance Requirements* contain the functional and assurance requirements, respectively.

Figure 3: Organization of Common Criteria requirements.

The requirements in Parts 2 and 3 are organized into *classes*, which contain *families*, which contain *components*, as shown in Figure 3. A component is the smallest unit of security requirement selection. Components are broken down into *elements*. Elements are the smallest unit of security requirement evaluation.

A well-formed set of security requirements may be selected from the classes of Parts 2 and 3 by applying four operations: *iteration*, *assignment*, *selection*, *refinement*. Iteration allows a component to be used more than once; assignment allows specification of values for component parameters (e.g., allowable covert channel capacity); selection allows choice from a list inside a component, to narrow the scope of an element; refinement is the process of adding details to a component, to restrict the allowable implementations. Refinements may not extend the scope of requirements or alter the dependencies that one requirement may place on another. The Common Criteria requirements include specific dependencies between requirements when components are not self-sufficient. These dependencies must be included in any well-formed set of security requirements.

## EVALUATIONS, CERTIFICATIONS, AND ACCREDITATIONS

In the Common Criteria and in documents associated with it, you will encounter the terms *evaluation*, *certification*, and *accreditation*. The term evaluation is usually applied in only one way and its meaning is clear, as given earlier. (Recall that protection profiles and security targets must be evaluated.) The other two terms may be used in more than one way, and it is worthwhile to understand each usage.

The system, hardware, and software engineering activities of measuring an information technology product are referred to as evaluation, certification, or accreditation depending on the purpose of the activity. Evaluation looks at a single information technology product, with respect to its Security Target, and confirms that the product meets both the security and assurance requirements in the Security Target.

If several products are to be integrated into a single larger system, then another measurement of security and assurance requirements should be performed. Although the Common Criteria uses the term *certification* to refer

to the validation of the results of an evaluation, I also use the term to refer to the measurement of an integrated collection of information technology products. The context will make it clear which kind of certification is meant. Notice that this second kind of measurement may be required when only one of the products to be integrated has security features. The presence or application of the other products may influence the security of the overall system. Common Criteria documents may use the term accreditation to mean either an official decision to operate a system with sensitive production data or it may use it to mean the vetting of an evaluation vendor to perform Common Criteria evaluations under a certain evaluation scheme. Accreditation in the first sense uses the evidence produced during the evaluation or certification (for integration of security products) activities.

## Evaluations

The Common Criteria contains both *evaluator notes*, in Part 2, and *evaluator actions*, in Part 3. The evaluator notes serve as commentary on specific security requirements. Evaluator notes are used to provide clarifications, interpretation guidance, and warnings to evaluators. Evaluator actions cover two kinds of evaluation: validation of a PP/ST and verification that a TOE satisfies its PP/ST. Evaluator actions explain specific steps to be taken by evaluators to validate or verify. For example, the term *confirm* is used to indicate to the evaluator that he or she needs to review someone else's work in detail and independently assess the sufficiency of that work. In contrast, the term *determine* is used to refer to independent analysis in contrast to review of a developers work. There are many other such terms defined in Section 2.4 of Part 3 of the Common Criteria.

The success of an evaluation depends on the general independence of the evaluator from the developer. Conflicts of interest can arise in many ways. One form of conflict that is difficult to avoid is financial. Someone must pay for each evaluation, but then the one who pays usually has an expectation of success. So evaluations that are paid for directly by the developer are less credible than evaluations by an independent-funded organization. Also, it is best if the organizations that perform evaluations do not sell or build security products. This creates a tension because the evaluators themselves should be persons who have significant experience in building information technology products with security. In fact it is preferable that at least one member of the evaluation team have some experience in building a similar product or at least a product that involves similar construction technology. Evaluators also need to understand general independent verification and validation concepts, project management, and analytical thinking, as well as mathematics, computer science and engineering. Maintaining skilled evaluation teams is difficult because the personnel with the necessary skills and qualifications can become burned out very quickly. The first or second evaluation such a person performs is interesting and challenging, but the appeal begins to fade rapidly after that. This suggests that the best strategy is to have the evaluation be a short-term responsibility, with rotation to other forms of work after two or three years.

Evaluation results are stated as pass/fail. For a protection profile or a security target, the results mean that the set of requirements is complete, consistent, and technically sound. If a protection profile passes its evaluation by the relevant evaluation scheme authority, it is usually entered into a registry for that authority. When a TOE is evaluated, the results mean that the evidence supplied with the TOE gives the specified level of confidence that the TOE meets its security requirements. A TOE evaluation results also explains what set of security requirements it met, as either *conformant* or *extended*. Conformant means that the TOE met the associated requirements and extended means that the TOE met the associated requirement and other requirements not in the Common Criteria or the relevant protection profile or security target. A result of extended can be misleading because it only requires a small difference to qualify as extended.

## Certifications

The Common Criteria provides little guidance on certification, for either sense of the word. The Common Criteria uses certification as a means of increasing the uniformity of evaluation. Because evaluation is a technical assessment based on specialist expertise, the results are somewhat subjective. If each assessment is validated by a common authority, the likelihood of individual bias is reduced.

For certification as validation of evaluation results, the chief difficulty is dealing with interpretations of the requirements. An evaluation of a product may raise a question about the application or meaning of a Common Criteria requirement. The question may be raised by the product developer or by the evaluation team. The resolution of the question may be applicable only to the evaluation where the question was raised. This can be handled by the evaluation scheme authorities. It may be necessary to incorporate the interpretation into the Common Criteria, however. This is done by consultation with members of the Common Criteria Recognition Agreement, and a final decision is made by the Common Criteria Interpretations Management Board.

When the term certification is used to mean evaluation of an integrated collection of information technology products that have each been evaluated separately, there are two issues:

1. Integrated systems are usually built under a contract that is not how products are built
2. The process of evaluating an integrated system is less understood.

When the context of integrated system construction includes contracts, those contracts can help or hinder application of the Common Criteria. It is difficult to meet contract schedules when the certification (evaluation) process is not part of the contract. On the other hand, it is difficult to believe a certification (evaluation) that is paid for by the contract performer. A further complication is the approach to certifying a system that integrates several evaluated products or subsystems. If the complete results of evaluation are available for each product, the approach

to integrating the products would seem to trivial. If, however, the assumptions about the threats and usage of a product in the integrated system differ from those made for its evaluation as a product, then certification can be problematic. It may be necessary to repeat the entire process for each product. A further complication can arise if the evaluation results for a product are not made public and are thus not available for the certification effort. This is particularly difficult when a flaw is discovered in a product but not reported as part of the evaluation results. Because the Common Criteria results are essentially pass/fail against a stated protection profile or security target, it is possible for an evaluation authority to withhold this information and still comply with the Common Criteria.

## Accreditations

Assuming no problems with the individual product evaluations or system certification (evaluations) the process of accreditation can be quite straightforward. The essential challenge is to understand the risk that entails from actual use of the product. The key to understanding this is to analyze the differences between the various security environments and security objectives from the protection profiles and security targets that apply. If the risk is too great because of differences in threat levels or characteristics then the accreditation authority must identify measures to reduce the remaining risk. A less obvious source of excessive risk is a difference in asset value from that assumed by a product's protection profile. If the assets in the deployed system have significantly more value than the product's evaluators assumed then the risk may be too high, even though the threats and usage match. An example of this would be using a product to protect national security information when it had not been designed with this in mind.

## PROTECTION PROFILES

The most frequently seen collection of Common Criteria requirements is the protection profile. A protection profile defines an implementation-independent set of security requirements, both functional and assurance. It is used when there is a class of similar information technology products or systems produced by different vendors. The difference between a protection profile and a security target is that the latter includes a description of a specific product but the former does not. Security targets that claim *conformance* to protection profile do not repeat the security requirements but include them by reference to the protection profile.

A protection profile can be written by either a producer of information technology or by a consumer. In the latter case, the consumer writes the protection profile and then seeks developers who will try to meet it. Instead of writing a profile, a consumer may search for an existing profile that meets its needs. Because the existing protection profile may already have been certified and entered into an evaluation scheme's registry, the consumer can reduce risk as well as save time and money.

Construction of protection profile can be a delicate matter. It is clear from both plain reason and the Common

Criteria's own requirements for protection profile evaluation that the resulting document must be complete, consistent, and technically sound. An important aspect of this not found in other technical documents is *balance*. As the beginning of this chapter pointed out, the Common Criteria framework defines security in terms of both function and assurance. This is where balance is needed. Not only must the functional and assurance requirements of the protection profile be matched to the security objectives but also the assurance requirements must be balanced with the functional requirements. Special security expertise is required to ensure this.

Some security mechanisms or functions are intrinsically weak, no matter how flawless their implementation. An example that is easy to see is encryption for confidentiality with a small key, say, 16 bits. For assurance of this hypothetical security function, we could formally analyze the cryptographic protocols that use this key and expend significant engineering effort in construction of flawless software to implement the verified protocols. This level of assurance would be unbalanced and excessive because the key is too small; the cryptosystem can be broken with brute force methods no matter what the assurance. The most frequently seen imbalance lies the other way. A strong security mechanism or function is chosen, but the assurance requirements are set too low. If a product is to provide strong security protections for high-value assets in a high-threat environment, then the level of assurance used to build it must correspond. Choice of a correct assurance level is not just a technical matter but depends on the value of the resources presumed and the threats defined for the product.

The impact of unbalance on a protection profile can be serious. If the assurance requirements are too strong, no vendors will develop products to match the profile. On the other hand, if the protection profile is unbalanced because of weak assurance requirements, then many vendors could supply inadequate products that fail in actual use. Consumers will be misled in to expecting sufficient protection when it is not there.

The best approach to constructing a complete, consistent, technically sound but also balanced protection profile is to follow the Common Criteria's hierarchical definition of security. Begin with an analysis of the intended use, planned asset characteristics and values, and the applicable laws or regulations the protection profile will support. Follow this with an analysis of the threats to be countered by the product. Threat analysis requires specialist security expertise corresponding to the anticipated asset values; that is, high-asset values require more experience in defining the threats. (Security expertise is primarily knowledge of threats and the effectiveness of possible countermeasures.)

Once the security environment for the protection profile has been defined, we should move on to analysis of the security objectives. The security objectives analysis matches countermeasures to threats based on a division of responsibility between the product (assumptions) and its environment (assumptions). Trade-offs can be made between countermeasures, assumptions, and assertions. Specialist security expertise is needed in both the analysis and trade-off studies.

The third step in the process is composing a set of functional and assurance requirements from the Common Criteria. The selected functions and assurance measures must be mapped back to the security objectives. The completed protection profile must also supply a rationale for its choice of requirements. This rationale captures all of the analysis that led to the requirements and justifies them against the security objectives and environment. The rationale is a defense of the completeness, technical soundness, and balance of the protection profile.

Writing a good rationale can be difficult. There is a tendency to reduce it to a tabular mapping or listing of requirements because this is a necessary part of the rationale. However, the rationale as whole must constitute a valid argument for the protection profile's completeness, technical soundness, and balance. Some validated protection profiles have indifferent rationales in this respect, so they do not serve as good examples. Rationales for protection profiles with higher evaluation assurance levels tend to have better rationales and are thus more likely to be good examples.

We can compensate for lack of specialist security expertise during protection profile construction by using an extremely precise fine-grained model of the intruder. Intruder models should define both the initial knowledge of an intruder and the intruder's capabilities. Persons with appropriate general backgrounds in mathematics, computer science, and computer engineering can approximate security specialist expertise by looking at the implications of this intruder model.

It is also possible to construct protection profiles by survey and analysis of a collection of existing security products to summarize their functions and assurance measures. In some sense, this also compensates for a lack of security specialist expertise but does not remove the need for it. Expertise is needed in choosing the products or systems to be included in the collection. Expertise is also needed in analyzing the shortfalls or weaknesses of the particular products. On the other hand, if a set union approach is taken to constructing a protection profile by analysis and summary of existing products (i.e., take the sum of all functions and all assurance measures), then there is a risk that the result will be too difficult to satisfy.

## SECURITY TARGETS

Protection profiles are the most important sets of criteria defined by the Common Criteria framework because most information technology products are members of a family of similar products. Nevertheless, all Common Criteria evaluations are performed against a security target not a protection profile. The security target forms the basis for TOE evaluation, for each product. It may be thought of as an instantiation of a protection profile.

Security targets must contain everything that appears in a protection profile and more. The additional contents are

- Common Criteria conformance claim
- Qualification of uncompleted protection profile requirements operations

- Summary specification of the TOE
- Statement of assurance measures
- Protection profile conformance claims

The Common Criteria conformance claim is simply an evaluable statement of the specific version of the Common Criteria that applies to the security target and whether the evaluation results are supposed to be "conformant" or "extended." It is a necessary part of establishing the context for the actual security evaluation.

The security target may also claim conformance to a protection profile as the source of its requirements specifications. If the protection profile states all of its requirements in complete form, the security target need not restate those requirements. However, some protection profile requirements may be unfinished, with some parts to be filled in for specific products. In Common Criteria terminology, the requirements operations are not completed. In this case, the security target will complete those requirements. In other instances, the security target will contain refinements of protection profile requirements. In all three cases—no change, completion, or refinement—there must be an explicit claim of protection profile conformance. Any differences or additions must be pointed out and justified in a protection profile claims rationale.

The two most significant differences between a security target and a protection profile are the *summary specification* and the *statement of assurance measures*. The summary specification for the TOE is just that, an abstract description of the product features. The summary specification is used to demonstrate how the product (TOE) meets its claimed functional security requirements of the security target. The statement of assurance measures is a summary of the specific tools, techniques, and procedures used to meet the claimed assurance requirements of the security target. The statement of assurance measures is used to demonstrate how the assurance measures will be applied to the development of the TOE. Both the summary specification and the statement of assurance measures are justified and mapped to the security target requirements by a separate rationale. This rationale is critically important.

First of all, the evaluators will study this rationale statement to decide whether the TOE is a suitable candidate for evaluation. Evaluation is a labor intensive process that requires security (and evaluation) specialist expertise, expertise that is currently in short supply. For this reason, evaluation organizations must be careful not to commit time and expertise to an evaluation that is not likely to succeed. To accomplish this, the Common Criteria provides a rationale for the summary specification and the statement of assurance measures. A complete, consistent, technically sound, and balanced security target will represent a product that has a good chance of passing its evaluation.

A second reason this rationale can be important is that it serves as a description of the product's features and quality. In this role, the rationale gives the prospective user or consumer of the information technology product a detailed explanation of the product's benefits.

Some information technology products are evaluated under the Common Criteria without a protection profile. If a product or subsystem is unique and there is little chance of it leading to a class or family of products, there is no benefit from an implementation-independent set of criteria. For these products, a security target is constructed directly from the criteria. Constructing a security target directly from the Common Criteria is the same as constructing a protection profile except that there is no need to provide for a general class of products.

It is also possible to use a Common Criteria security target structure as a (security) development plan for a product or system. The security target provides organization of requirements and relationships between work products in a convenient form. When a security target is used this way, it is constructed as a guide to developers, to show what work products are needed and how they relate. Use of a security target in this way does not require use of a particular life-cycle model or approach. Furthermore, using a security target as a development plan does not imply that the developers intend to have the resulting product evaluated.

## SECURITY FUNCTIONAL REQUIREMENTS

Part 2 of the Common Criteria contains the collection of security features that a protection profile or security target developer chooses from to create a well-formed set of security requirements. The 11 classes of functional security requirements are listed in Table 2.

The functional requirements of the Common Criteria are subject to revision although not frequently. New technology introduces new security requirements. Research, development, and experience improve security for existing technology. Researchers and security experts propose, analyze, and discuss possible additions or interpretations. An example of this process is the privacy functional requirements (FPR) that were not part of earlier versions of the Common Criteria but were added after various groups pointed out the growing need for these kinds of features in some information technology products. Now I briefly summarize each of the 11 classes of functional security requirements that a protection profile or security target from which designer can choose.

**Class FAU: Security Audit**—This class contains six families of requirements. Each family of the class defines requirements for auditing security-relevant events. Two (FAU-SAA and FAU-ARP) are concerned with recognizing and responding to events; two (FAU-GEN and FAU-SEL) are concerned with recognizing events; one (FAU-STG) is about storing and protecting event data; and one (FAU-SAR) is about review and analysis of events.

**Class FCO: Communication**—The two families of this class (FCO-NRO and FCO-NRR) are concerned with proof of origin or receipt, respectively, of transmitted data.

**Class FCS: Cryptographic Support**—The two families of this class (FCS-CKM and FCS-COP) provide requirements for cryptographic key management and cryptographic operation, respectively.

**Table 2** Security Functional Requirement Classes of Part 2 of the Common Criteria

Class	Identifier	Scope
Security audit	FAU	Capture, storage, and analysis of security events
Communications	FCO	Confirming identities during data exchange
Cryptographic support	FCS	Key management and cryptographic operations
User data protection	FDP	Access control, information flow, integrity, import-export, and recovery
Identification and authentication	FIA	Verifying user identity, authorization, association
Security management	FMT	Management of security data, roles, and attributes
Privacy	FPR	Anonymity, pseudonymity, unlinkability, and unobservability
Protection of the TSF	FPT	Self-protection requirements
Resource utilization	FRU	Denial of service, quality of service, and fault tolerance
TOE access	FTA	Session management
trusted path	FTP	Trusted communication between human users and the TOE

**Class FDP: User Data Protection**—This large class contains the Common Criteria requirements for protecting end user resources, the ultimate reason for providing security. It includes families of requirements for security policies, user data protection mechanisms, import and export of user data, and transfer of data between the TOE and other security products.

**Class FIA: Identification and Authentication**—This class provides requirements for identifying authorized users and assigning them the correct identity, group, role, session, or set of security privileges associated with their user identity. It includes requirements for dealing with authentication failures and handling secrets associated with authentication and identification.

**Class FMT: Security Management**—This class provides a collection of incomplete (i.e., the requirements must be completed by assignment, selection, or refinement). All of the requirements cover security management, so there are requirements for protecting and restricting management functions, assigning and revoking privileges or security attributes, and defining security management roles for the TOE.

**Class FPR: Privacy**—This class provides a means for selecting anonymity, pseudonymity, unlinkability, or unobservability. By proper selection and refinement of these requirements a protection profile designer can specify protection against a wide range of identity misuse.

**Class FPT: Protection of the TSF**—This class specifies self-protection requirements for the TSF of the TOE; that is, requirements that the product protect its security functions from tampering and bypass. The families in this class form a list of generic ways of tampering with or bypassing a security mechanism. They include confidentiality, integrity, and availability of TSF data that has left the TOE scope of control; fail safe and trusted recovery; safe internal movement of TSF data; resistance to physical tampering; replay detection; and consistency of distributed TSF components.

**Class FRU: Resource Utilization**—Requirements from this class can be used to specify fault tolerance, quality of service, or resource management functions for a TOE.

**Class FTA: TOE Access**—This class specifies a set of session management requirements. Each interaction of a user with the TOE constitutes a session. The user is identified and authenticated, negotiates any selectable security attributes for the session, and does some work using the TOE. When the session is terminated, the user is no longer able to use the resources that were available. Specific requirements include limitations on concurrent sessions, initiating a session, session locking, session history, user-visible session labels or banners.

**Class FTP: Trusted Path**—Trusted path requirements are available for specifying trusted path or trusted channel functions in the TOE. These functions are used to protect human users from spoofing attacks that present a deceptive interface to the user. A trusted path provides a means for a human user to confirm that he or she is communicating with the TSF and not some masquerading unauthorized process.

A reader wanting deeper understanding of the functional security requirements should consult Part 2 of the Common Criteria.

## ASSURANCE REQUIREMENTS

The assurance requirements in Part 3 are perhaps the least understood aspect of the Common Criteria. The seven classes of security assurance requirements are listed in Table 3. It is clear that security-relevant product functions should be developed carefully to avoid the introduction of security flaws, thus the popularity of books on “secure programming.” What is less clear is the relationship between various system or software development activities on one hand and assurance per se on the other. Some activities advance the design and implementation of the developing product but do not significantly increase the assurance we have in the information technology product’s security. In fact, many software practitioners, researchers, and others

do not have a clear understanding of assurance. This is reflected in the fact that the U.S. government has adopted the term *information assurance* to mean “measures that protect and defend information and information systems” (Committee on National Security Systems, 2003) that is, security functions. Many have confused the notion of security functions with assurance.

It is important to understand the issue of balance between assurance and the strength of the security mechanisms used in the TOE. Some security weaknesses are inherent in the mechanism itself. For example, so-called discretionary access controls on resources that can be set by the user or owner of a resource are weaker than mandatory access controls that cannot be set by the user or owner. No matter how flawlessly they function, discretionary access controls can be turned off or otherwise changed by malicious software, even though the controls themselves are not compromised. Because of this, the highest assurance levels do not balance with discretionary access controls. For the same reason, higher assurance levels do not balance with weak cryptographic protocols. For example, at the time of this writing, the wired equivalent privacy (WEP) protocol had been shown to contain fundamental flaws. No matter how well this protocol could be implemented in hardware or software, it would still be vulnerable because of its design flaws. So higher assurance would not balance with a product that used the WEP protocol.

## CLASS ACM: CONFIGURATION MANAGEMENT

This class of assurance requirements describes how to monitor and track changes, including refinement, made to the various work products. Full use of all of these requirements would also ensure the integrity of the TOE and increase our confidence that we can trace each implementation artifact back to a function security requirement. This tracing not only improves attempts to simplify and minimize the implementation but also helps prevent the introduction of malicious code. Without effective configuration management, the tracing is not believable.

Requirements in this class include not only automated configuration management but also plans and procedures for using the configuration management tools. The required automation includes protecting the work products and implementation from unauthorized modification, deletion, or addition of components or evidence.

## CLASS ADO: DELIVERY AND OPERATION

Assurance requirements for distribution of the TOE describe the measures that must be taken to protect it during distribution. The specific protection that must be provided is for the threats described in the security environment of the applicable security target or protection profile. These protections might include detecting bogus copies of a TOE; preventing substitution of the wrong version of a TOE; and preventing an end user from replicating the distribution service. The protections not only address delivery or distribution of a TOE but also include

**Table 3** Security Assurance Requirement Classes of Part 3 of the Common Criteria

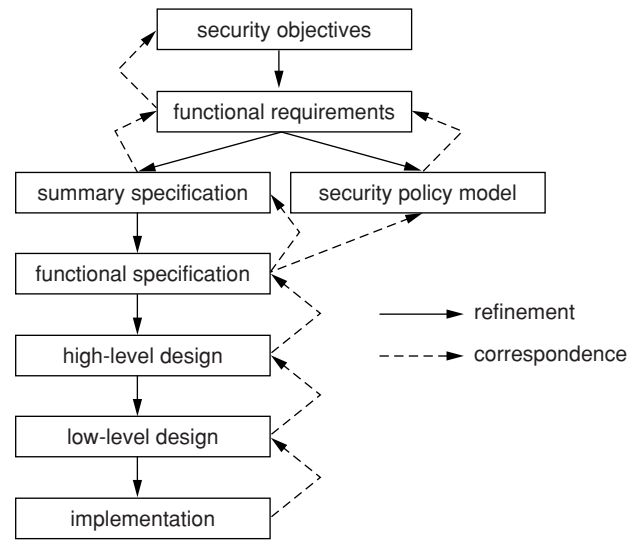

Class	Identifier	Scope
Configuration management	ACM	Procedures and tools for tracking changes to work products
Delivery and operation	ADO	Measures for protecting the distribution of a product
Development	ADV	Defines requirements for system and software engineering work products needed for assurance
Guidance documents	ADG	Administrator and user guidance
Life-cycle support	ALC	Requirements for securing the development process itself and for suitable development processes
Testing	ATE	Demonstration of functional requirements
Vulnerability assessment	ADV	Independent adversarial analysis and testing

mechanisms or procedures to protect the installation, generation, and startup of a TOE once it has been distributed.

**CLASS ADV: DEVELOPMENT**

This class comprises the requirements targeted at the work products needed for high-assurance software. It requires a collection of descriptions or specifications of the TOE that provide different levels of abstraction. A mapping from the more abstract to the less abstract description is required to show correspondence, demonstrate the absence of malicious code, and justify the residual complexity of the implementation. This mapping must be produced for each pair of required specification documents, using the same degree of rigor as the target specifications. Figure 4 shows the full set of required TOE representations. (These documents may be thought of as a fine-grained refinement of the hierarchical definition of security shown in Figure 2, inserted between the summary specification and the TOE.)

This class includes requirements for modularity, explicitly justified simplicity, and high-level architecture beyond modularity. The more rigorous requirements call for the TOE software modules to contain only security-relevant code, with an explanation of why the code in

**Figure 4:** Target of evaluation representations from class ADV.

each module is security-relevant. The most rigorous requirements also specify that the TOE software must be organized into layered abstract virtual machines, such that each abstract machine can be evaluated separately.

The more rigorous requirements call for the use of formal methods for the more abstract specifications. Levels of assurance are increased by requiring formal methods for the less-abstract descriptions.

The explicit abstraction and refinement required by this class may be misunderstood to call for a particular development approach, such as the much-maligned waterfall model. That would be a misunderstanding; what is required is a final set of documents and an explicitly justified refinement from the abstract to the concrete. The author asked the builders of one of the highest assurance software products that has ever been built what life cycle model they used. “Crazed rat,” was the reply. Nevertheless, the work products associated with the product had essentially flawless justified refinement from the abstract models to the concrete concrete code.

The existence of the ALC life-cycle support assurance requirements indicates the importance of development processes in the Common Criteria model, but no particular life-cycle model is required. The choice of development approach can be critical to the final security of a product, so it should be addressed in higher-assurance protection profiles and security targets. Which development approach should be chosen is outside the scope of the Common Criteria. The chapter “Software Development and Quality Assurance” should provide more information on development approaches for security.

**CLASS ADG: GUIDANCE DOCUMENTS**

The ADG requirements specify the documentation that should be provided for the security administration of the TOE. Not only should this guidance cover installation, configuration, and management but also the meaning of all warnings, reports, or exceptional operating states. The

administrator guidance should also describe appropriate or recommended management actions to be taken in response to each security-relevant event.

The ADG requirements also call for user documentation that explains any nonadministrative interfaces for the TOE. This might include programming as well as user-supplied security settings. In particular, the user guidance should clarify the kind of protection supplied and what assumptions must be satisfied by the users for the TOE to provide the expected protection. An indication of the importance of this is built into the Common Criteria. During an evaluation, vulnerability assessment required by class AVA will check both user and administrative guidance to see if any inconsistencies or ambiguities can be exploited to defeat the security of the product.

The brevity of this section can be misleading. Human factors and usability are vital to security. Few products can provide security if they are misused; on the other hand, if the product is difficult to operate, then users may put their high-value assets and resources into a system that is not secure but easy to operate.

## CLASS ALC: LIFE-CYCLE SUPPORT

This assurance requirements class calls out the measures that should be used to provide security for development work products, bug fixes and flaw removal, and tool support for the development process. The most rigorous assurance requires that development work products must not only be managed but also protected from tampering or the insertion of malicious code. Development security must address operational and physical security measures coordinated with the protection features of the configuration management tools. Flaw removal requires procedures for fixing vulnerabilities discovered after product release. It also requires that user or administrator guidance explain how to report vulnerabilities and how to receive vulnerability reports. Procedures for checking the proposed fix must also be in place along with a method of distributing the corrected software. This class also sets out requirements for programming languages, development tools, use of generally accepted notations and consistency in use of these tools and techniques. Requirements for libraries and third-party software are also defined.

Finally, at the highest degree of rigor, class ALC contains requirements for use of life-cycle models. Not only must the development follow an explicitly defined process, as for lower degrees of rigor, but also it must use a generally accepted process or life-cycle model. This highest degree of rigor also requires the use of metrics to establish the quality of the work products produced by the process.

## CLASS ATE: TESTING

The goal of the testing required by this class is demonstration that the TOE meets its functional security requirements. It include both confirmation of correct function and checks for undesirable behavior that violates the requirements. It does not include penetration testing or related activities, as described in the next subsection, AVA Vulnerability Assessment.

This class separates requirements for *test coverage* and *test depth*. Test coverage has the usual meaning and includes requirements for analysis of coverage, to varying degrees of rigor. The term test depth is used to refer to the use of the various TOE representations as a basis for the test cases. Shallow testing uses only the most abstract TOE representations, such as the functional requirements or the summary specification, as the basis. The deepest testing will include the abstract representations and all the refinements, including the implementation representation.

Class ATE also provides for independent (evaluator) testing. The evaluators will design and conduct their own functional tests under these assurance requirements. The evaluators will also repeat some or all of the developer's functional testing, depending on the specified level of assurance.

## CLASS AVA: VULNERABILITY ASSESSMENT

Like the development requirements, vulnerability assessment requirements are also poorly understood. Vulnerability assessment is based on an adversarial analysis of the TOE and its requirements. This adversarial analysis seeks to locate vulnerabilities in the TOE that could be exploited to violate the security policy. It provides some measure of understanding about the residual risk of insider attacks on the TOE.

The vulnerability assessment class is organized into four families

- Covert channel analysis
- Misuse
- Strength of function
- Vulnerability analysis

Covert channels are unwanted artifacts in the TOE implementation that can be exploited, usually by malicious software, to signal information contrary to the security policy of the TOE. Covert channel analysis is covered by the chapter "Information Leakage" of this *Handbook*. Covert channel analysis requirements of increasing rigor are defined in terms of the approach used and the basis for the analysis. The most rigorous requirement is for analysis that is justified as exhaustive and is based on complete detailed specifications.

The term misuse is interpreted to mean accidental misuse of the TOE due to problems with its usability, or with the guidance documents provided according to class ADG. In higher levels of this family, the developer is required to conduct human factors analysis of the guidance documentation (and, by implication, the interfaces used by humans) to discover and remove inconsistencies or other failings such as omission of a warning or unreasonable expectation. At the highest level of assurance, the evaluators independently try to misuse the TOE and put it into an insecure state or operating mode.

Class AVA also includes requirements for assessing the strength of proposed security mechanisms. Conventionally, strength of function is only applied to mechanisms

that depend on stochastic properties, such as passwords and encryption. Strength of function is also an issue for other security mechanisms, however, such as access control, virtual machine monitors, and integrity lock architectures. Protection profile writers have been careful to avoid strength of function for these latter, more problematic mechanisms.

Finally, the Common Criteria uses the term vulnerability analysis to refer to what is more commonly called *penetration testing*. The term *vulnerability analysis* is probably a better term; the best penetration testing does not involve much testing per se. The small amount of testing that is done is directed toward showing the impact of a vulnerability discovered through analysis. The lowest level of assurance is that the developer will perform a vulnerability analysis. Higher levels require independent and systematic vulnerability analysis and independent penetration testing to confirm the developer's results. The highest levels of assurance require that the TOE be found to have a certain level of resistance to penetration.

## EVALUATION ASSURANCE LEVELS

Because assurance is less well understood, the Common Criteria provides seven predefined Evaluation Assurance Levels (EALs). An EAL is a predefined collection of assurance requirements that is consistent and addresses all dependencies. The EALs constitute a hierarchy of assurance, with EALs Level 1 being the lowest. That is, EAL 1 has the least rigor and scope for assurance evidence and EAL 7 has the most (Table 4). The degree of difficulty does not increase in a linear way. The first four levels are intended to approximate various levels of commercial development practice. Only the highest of these levels, EAL 4, requires any source code analysis and then only examination of "sample" selected by the developer rather than the evaluator. The logic for this is sound because these lower levels do not require extensive modeling and specification of security, internal structuring, architectural arrangement, and life-cycle restrictions. Without these measures, source code analysis is not particularly effective (Anderson, 2001). On the other hand, these same assurance measures are either too costly or specialized for application to large products.

The remaining three levels, EAL 5 through 7, are essentially aimed at products that will be developed using

security specialists and security-specific approaches. At present, CCRA mutual recognition does not extend to these higher levels. The rigor of these levels is increased not only because of the use of formal methods but also internal structuring, architectural, and life-cycle requirements.

The predefined EALs do not use all of the possible Common Criteria assurance requirements. It is possible to *augment* an EAL by adding assurance requirements or substituting a more rigorous requirement (as in EAL 5 +). The Common Criteria does not allow definition or use of a "minus" EAL (as in EAL 5 -), where one or more requirements are omitted from an EAL. If such a collection of assurance requirements is needed, it should be defined by augmenting the next lower level to contain all of the necessary requirements.

Level EAL 1 is for environments where security threats are not considered serious. It involves independent testing of the product with no input from its developers. EAL 2 increases the assurance provided by including review of a high-level design provided by the product developer. It also includes a requirement that the developer conduct a vulnerability analysis for well-known flaws. There is no independent vulnerability analysis at EAL 2. The original intent was to provide an EAL that could apply to legacy systems that had some security features. The next higher level, EAL 3, increases assurance by requiring some security measures be used in the development environment and independent assessment of the security test coverage. Although it does not require more modeling and specification than EAL 2, it does require that the design separate security-relevant components from those that are not. It also requires the design models or specifications to describe how the security is enforced. That is, the design document must support detailed analysis for design flaws in the security mechanisms. Finally, it requires testing to be based on both the interface and high-level design of the product, that is gray-box testing as opposed to black-box testing. EAL3 does not require independent vulnerability analysis.

EAL 4 requires a significant step up in developer effort but not one that is considered beyond best commercial practice. In addition to a security-enforcing high-level design, EAL 4 also requires a low-level design. Assurance is also increased by requiring that the interface specification of the product be complete, a nontrivial requirement. EAL 4 also introduces a requirement for an explicit security model, that is, an abstract model that defines security for the product. Finally, EAL 4 also includes a (low-attack-potential) independent vulnerability analysis.

EALs 5 through 6 are for products developed using security specialists and security-specific design and development. Although the Common Criteria has defined these levels, there is no common acceptance of evaluations at these higher levels. There is also no corresponding common understanding of what measures and approaches satisfy each level. Readers interested learning about these higher levels or in developing products for these levels should contact the appropriate national evaluation scheme authorities or a consultant specializing in these matters.

**Table 4** Common Criteria Evaluation Assurance Levels

EAL	1	Functionally tested
EAL	2	Structurally tested
EAL	3	Methodically tested
EAL	4	Methodically designed, tested, and reviewed
EAL	5	Semiformally designed and tested
EAL	6	Semiformally verified design and tested
EAL	7	Formally verified design and tested

## CONCLUSIONS

The Common Criteria has potential to provide good, balanced sets of security requirements. It captures the central idea that security is a matter of assurance as much as function and that assurance should balance function. Application of the Common Criteria has been hampered by its national security sponsorship and the politics of government regulation. In such an environment, it is difficult to proceed rapidly or make painful decisions. This is particularly true when one of the stakeholders in a protection profile, security target, or evaluation has motives other than ultimate protection of user resources. Despite this, the Common Criteria can be useful if it is employed with consideration of the latest security technology and threats, by stakeholders who mean to produce security technology that meets the user's needs.

There are two other assurance-related standards for safety in information technology systems that might be of interest. The first is the avionics related DO-178B standard, (Radio Technical Commission for Aeronautics, 1992) for software in aircraft and aviation technology. The second, IEC 61508 (International Electrotechnical Commission, n.d.), is a more general international standard for electrical and electronic systems with safety requirements. The reader who is interested in issues of assurance and certification should investigate these standards.

## GLOSSARY

This glossary complements the essential terminology of provided in the second section of this chapter.

**Assurance** Grounds for confidence that an entity meets its security objectives. This definition is taken directly from the Common Criteria. It is sufficient for many uses but could be improved. For example, security objectives are not granular and might be met by a system that did not have the desired security functions. Also, the definition does not distinguish assurance evidence, that is, the engineering work products, from the degree or level of confidence that the evidence provides.

**Assurance Argument** An organization or arrangement of assurance evidence into a logical structure that shows how the evidence is (a) interrelated and (b) gives confidence that the security objectives are met. The Common Criteria does not use this concept but instead employs a more simple tabular arrangement in the rationale parts of protection profiles and security targets.

**Attack Potential** The perceived potential for success of an attack, expressed in terms of an attacker's expertise, resources, and motivation.

**Formal** Expressed in a restricted syntax language with defined semantics based on well-established mathematical concepts. Under this definition, most UML is not formal.

**Product** A package of information technology software, firmware, or hardware that provides functionality. This definition omits the Common Criteria's additional qualification, "designed for use or incorporation within a multiplicity of systems" as unnecessarily restrictive.

**Security Objective** A statement of intent to counter identified threats or to satisfy identified organization security policies and assumptions.

**Security Function** A part (or parts) of the target of evaluation (TOE) that has to be relied on for enforcing a closely related subset of the rules from the TOE security policy.

## FURTHER READING

There are many research issues regarding the Common Criteria. Most of them arise in practical or research projects that target the highest levels of assurance (Alves-Foss, Rinker, & Taylor, n.d.; Ross, 2001).

Application of the Common Criteria is a complex topic that can fill a whole book. Fortunately, there is such a book, one that provides examples that make the Common Criteria requirements more concrete:

Herrmann, D. S. (2002). *Using the Common Criteria for IT security evaluation*. Auerbach.

For technical issues regarding security engineering and assurance, Ross Anderson's (2001) book is recommended.

The study of actual protection profiles and security targets is still one of the best ways to understand practical application of the Common Criteria. Presentation

of a complete protection profile and its corresponding security target would take more room than this entire chapter, even for a relatively simple product. There is also a wide variation in details and approach, depending on the target of evaluation. Ultimately, the best understanding comes from looking at examples for several kinds of products.

The protection profiles and security targets listed here are not flawless. The protection profiles tend to be of much higher quality because they undergo more review. On the other hand, a protection profile does not refer to a specific product and lacks the concrete relation to a product that may be found in a security target. Security targets are working documents; they are formal and of relatively good quality, but they have not undergone as much internal and external review as a well-used protection profile. The following protection profiles and security targets were available from the U.S. Common Criteria Evaluation and Validation Scheme, as of October 2004, from the corresponding Web site: <http://niap.nist.gov/cc-scheme>.

- EAL 4 Augmented Security Target for *Netscape Certificate Management System 6.1 Service Pack 1*. This security target is a good one to study and has a corresponding Protection Profile which is listed next. The Security Target shows how the requirements of a Protection Profile may be augmented to achieve a higher EAL.
- EAL 3 Augmented Protection Profile for *Certificate Issuing and Management Components (CIMC), Security Level 3*.
- EAL 3 Security Target for *Marimba Desktop/Mobile Management and Server Change Management*.
- EAL 4 Augmented Security Target for *XTS-400/STOP 6.0E*.
- EAL 3 Protection Profile for *Controlled Access Protection Profile*. This protection profile addresses basic host operating system security, for nonhostile environments where attempts to breach security are casual or inadvertent.
- EAL 4 protection profile for *Single-Level Operating Systems in Environments Requiring Medium Robustness*.

The following three documents were available from the United Kingdom Communications Electronic Security Group Web site: <http://cesg.gov.uk> in October 2004. The first two are security targets for database systems. The third document is the corresponding DBMS protection profile that can be obtained from the same site. It is

interesting to see how the discrepancy in EALs is resolved:

- EAL 4 augmented security target for *Oracle 9i Release 9.1.0.1.0*. This security target refers to the database management system (DBMS) protection profile listed last.
- EAL 4 augmented security target for *Oracle 9i Label Security*. This security target also refers to the DBMS protection profile.
- EAL 3 Protection Profile for *Database Management System, ver. 2.1, May 2000*.

Readers that are interested in protection profiles and security targets for higher EALs should contact the applicable national scheme authorities and request examples. This exercise itself should provide additional enlightenment.
