the difference between life and death for the parents and grandparents of today's European lawmakers.

### Cross-Border Data Flow

The issue of cross-border data flow has been particularly vexing for U.S. corporations, especially given the number of Internet-based firms with operations in the E.U. that depend upon data flows from the E.U. back to the United States. Because the United States does not have broad privacy-protecting statutes on par with the E.U., U.S. corporations face the prospect of being unable to communicate customer data, or even personnel records, back to U.S.-based facilities.

Recognizing the potential for numerous disputes, the United States and E.U. entered into a series of negotiations in the late 1999 and 2000, culminating in an agreement to create a **Safe Harbor** program. This program permits U.S. corporations to assert their adherence to an array of basic privacy requirements, with the assumption that those who certify compliance and bind themselves to enforcement measures in the event of misbehavior will be permitted to continue transferring data from the E.U. into the United States (DOC, 2000).

## BALANCING PRIVACY AND LAW ENFORCEMENT

In post-“September 11” America, a great deal of public concern centers around the extent to which new anti-terrorism intelligence gathering will negatively impact the privacy of average citizens. While few individuals will ever believe they merit the kind of surveillance activities implemented for mafia dons, drug kingpins, or terrorists, many are concerned that ubiquitous surveillance capabilities will result in less privacy for everyone, average citizens and mafia dons alike. Therefore, it is appropriate to briefly discuss the kinds of issues raised by increasing surveillance capabilities, and to discuss a number of programs and laws that are adding to the pressures on personal privacy. More significantly, given the extent to which American business is increasingly becoming the repository of detailed information about the lives and business transactions of individuals, it is also appropriate to discuss how businesses are increasingly being called on to aid law enforcement in their investigatory efforts, and why businesses need to exercise some judgment in deciding when and how to comply with law enforcement requests.

Surveillance, searches, and wiretaps raise extremely complex legal and technical issues that are impossible to cover in this brief space. Should these issues arise in your personal or professional activities, it will not be possible for you to deal with them without the assistance of qualified legal counsel. There are, however, some things to keep in mind that will help you to understand how an organization may be affected.

Most domestic wiretapping is governed by the Electronic Communications Privacy Act of 1986 (ECPA). In addition, the Foreign Intelligence Surveillance Act of 1978 (FISA) governs wiretaps and surveillance of those considered “agents of a foreign power.” Both the ECPA and the FISA were modified, clarified, and in some cases expanded

significantly, by the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism Act of 2001, or “USA PATRIOT Act” for short. While some provisions of the USA PATRIOT Act were due to expire in 2004, some portions have been further expanded upon by more recent acts of Congress and remain an issue of much contentious debate.

## ECPA

The ECPA generally prohibits providers of communications services (e.g., Internet service providers) from disclosing the contents of an electronic communication, whether it is in transmission or in storage, to any person other than the intended recipient. However, the ECPA also contains a number of exceptions, some of which include:

- Service providers may make disclosures to law enforcement, if proper warrants are presented. The ECPA explains those procedures in some detail.
- The ECPA’s limitations only apply to services offered to the public, not to operators of, for example, an internal corporate system.
- The ECPA does not restrict the collection, use, or disclosure to non-governmental entities, of transactional information such as email addressing and billing information.
- Disclosures to private parties pursuant to subpoenas issued by civil courts may also be permitted.

In addition, the ECPA permits the government to request “dialing and signaling” information from telephone companies. Under these so-called “trap and trace” orders, law enforcement can use devices known as “pen registers” to capture the numbers being called and other information about the communications, short of the actual contents of the calls themselves. The contents of the calls can also be gathered, but only under a separate warrant that requires much more rigorous procedures and additional judicial review.

## FISA

In cases where information is sought about the activities of agents of foreign powers, such as terrorists or spies, law enforcement may seek disclosure of information relevant to an investigation through a special warrant procedure. There are two noteworthy differences between standard warrants and FISA warrants: First, the FISA creates a system of special “FISA courts” in which judges meet, hear evidence, and issue warrants in total secrecy. Second, FISA warrants are much more sweeping than normal warrants and are not required to meet the same evidentiary standards as normal warrants. These differences raise significant Constitutional questions that have been raised in recent challenges to the activities of the FISA courts. Ironically, the FISA courts themselves have not been oblivious to the questions their seemingly unchecked powers have raised: a recently released decision of the FISA appeals court—the first document ever released publicly by the body—cited dozens of cases in which law enforcement provided deceptive or outright false information to the court in support of wiretap applications. Appealing to the

US Supreme Court, the Bush Administration successfully overrode the FISA appeals court’s objections to expanded wiretap procedures (EPIC FISA Archive, 2003).

Concerns about state-sponsored collection of data about individuals are nothing new. Privacy watchdogs and investigative journalists have widely publicized programs like the FBI’s “Carnivore” (a device for intercepting and recording Internet-based communications) (EPIC Carnivore Archive, 2001), “Magic Lantern” (a piece of software that can be surreptitiously installed on a targeted computer, allowing law enforcement to capture every keystroke) (Sullivan, 2001), and the rumored international wiretapping consortium called “Echelon” (EU Parliament, 2001).

In 2002, the U.S. Department of Defense sought funding of an anti-terrorism program called “Total Information Awareness” which would have compiled electronic records on nearly every business, commercial and financial transaction of every U.S. citizen. The massive database would then be analyzed in an effort to uncover transactions and patterns of behavior that could be deemed suspicious. While the Total Information Awareness program was stripped of most of its funding by Congress in early 2003, the Department of Defense has vowed to keep researching the issues and technologies needed to undertake such a program (EPIC TIA Archive, 2003). In a September 10, 2003, op-ed piece for the *New York Times*, Department of Defense official (and controversial figure from the Reagan Administration’s Iran-Contra affair) Admiral John Poindexter defended the rechristened “Terrorism Information Awareness” program (Poindexter, 2003). However, as of this writing, the program has not regained support, or funding, in Congress.

## Business Issues Under Wiretap Laws

The wiretap activities under the ECPA and the FISA have until recently been relatively limited in their effects on businesses. Aside from telephone companies and some Internet service providers, few businesses were affected by these procedures. But under recent changes to the FISA made by the USA PATRIOT Act, law enforcement is now permitted to request business records from nearly any business to assist it in foreign intelligence and international terrorism investigations.

Previously, the FISA only allowed law enforcement to request business records from certain categories of businesses, such as common carriers, hotels, and car rental facilities. But under the new rules, subpoenas can be issued without limit to particular categories, including banks, retailers, and any other entity within the government’s reach. The USA PATRIOT Act also expanded the search and seizure from merely “records” to “any tangible things,” such as computer servers.

The pen register and trap/trace provisions of the ECPA have been expanded under the USA PATRIOT Act to add “routing” and “addressing” to the phrase “dialing and signaling,” making it clear that these activities now include Internet traffic, not just telephone calls. The act does specify that the information retrieved through this process “shall not include the contents of any communication.” There will undoubtedly be significant litigation in coming

years to define where the dividing line falls between “content” and “addressing.” For example, entering a search term or phrase into a search engine may cause the content of that search to be embedded in the address of the Web page on which the results are displayed.

## PRIVACY ISSUES FOR BUSINESSES

Similarly, the Society for Human Resource Management (SHRM) reported in January 2004 that 57 percent of HR professionals are somewhat or very concerned about workplace violence in part as a result of the terror incidents of September 11, 2001. Eighty percent of human resources professionals now say they conduct background checks on employees, up 29 percent from a similar survey in 1996, and 35 percent conduct credit checks to screen potential employees, an increase of 16 percent from 1996. Eighty-two percent of human resources professionals report their organizations investigate the background of potential employees, up from 66 percent in 1996 (SHRM, 2004).

Workplace privacy concerns do, however, predate the September 11 security concerns. For example, in a widely published 2000 survey of over 2,000 U.S. corporations, the American Management Association (AMA) discovered that 54 percent of companies monitor their employees’ use of the Internet, and 38 percent monitor their employees’ e-mail. In a follow-up survey in 2001, the percentage of companies doing Internet monitoring rose to 63, with 47 percent monitoring e-mail (AMA, 2001). The rise in monitoring tracks with the rise in potential problems that can flow from providing access to the Internet. Along with the ability to work more efficiently, companies are now finding themselves held responsible when bad things find their ways into employees’ desktops. In the same AMA study, 15 percent of the companies surveyed have been involved in some kind of legal action concerning employee use of e-mail and/or Internet connections. In several noteworthy cases, companies have been held liable for sexual harassment-related claims from

- harassment occurring over employer-operated message boards;
- employees leaving pornographic images on computer monitors; and,
- employees distributing sexually explicit jokes through office e-mail.

In response to these concerns, many companies have installed filtering mechanisms on their e-mail traffic looking for unacceptable language. Other companies have implemented software that blocks pornographic Web sites. Still others have opted for the low-tech approach of implementing zero-tolerance policies regarding the use of office computers for anything inappropriate.

Unfortunately in some instances, these measures have resulted in confusion and in some cases have wound up creating problems for both innocent and not-so-innocent people. For example, it was widely reported in 1999 that 23 employees of the *New York Times* were fired for trading dirty jokes over the office e-mail system (Oakes, 1999).

Yet, in other cases, recipients of unsolicited e-mail have opened the fraudulently labeled mail and been subjected to a barrage of pornographic images and salacious Web pop-up ads (Levine et al., 2002).

Because Web monitoring logs and filtering systems may not be able to differentiate between Web pages viewed accidentally and those viewed purposefully, innocent workers can (and have) been left fearing for their jobs. For these reasons, companies are beginning to adopt internal privacy policies that help set better guidelines and establish reliable procedures for dealing with trouble when it arises.

## Employee Privacy Policies

In most circumstances, there are very few legal restrictions on what employers can do with their own computers and networks, up to and including monitoring of employee’s communications. While some firms quietly implement employee monitoring policies and wait to catch unsuspecting employees in unauthorized activities, many firms give notice to their employees that they may be monitored. Still others require employees to relinquish any claims of privacy as a condition of employment.

Increasingly, however, companies are recognizing the negative impact of paternalistic monitoring practices on employee morale. So to engender trust, rather than inspire fear, increasing numbers of firms have begun providing their employees with privacy statements in their corporate employee handbooks, or by publishing policy statements on company-internal Web sites. According to the AMA’s 2001 survey, four out of five respondent firms have a written policy for e-mail use, and 77 percent for Internet use; 24 percent have training programs to teach these policies to employees, and an additional 10 percent plan one (AMA, 2001).

As noted earlier with regard to the European Union’s Data Privacy Directive, companies with operations in the E.U. are already familiar with the mandate to provide data subjects—in these cases, employees—with information about the company’s data gathering and usage policies. While there is currently no U.S. equivalent to these requirements, a growing number of firms are proactively recognizing that a well-defined set of privacy policies and practices can avoid misunderstandings and can even provide the basis of a legal defense in cases where companies are accused of failing to act on claims of Internet-based sexual harassment.

## Developing an Employee Privacy Policy

The creation of a privacy policy for internal use in an organization can be as simple or as complex as the organization itself. Most companies collect information from their employees in the form of personnel records. Firms may also collect personal information from customers or clients. An internal privacy policy should address acceptable practices with regard to each type of information maintained by the company.

A good internal privacy policy should define what standards of behavior are expected of those who have responsibility over the data held by the company—including both employee data and the personal data of a company’s

customers—and should inform employees about the consequences of noncompliance. Additional topics that can be covered in a privacy policy include procedures for reporting breaches, procedures for allowing employees to access and correct their own personnel records, procedures regarding access to proprietary records such as customer lists, and procedures for auditing compliance and for training employees how to comply with the company's guidelines.

## CONSUMER INTERNET PRIVACY

Before the Web existed, companies gathered whatever information they could get about their customers from a variety of sources, such as real estate transaction records, credit bureaus, court documents, and motor vehicle records. But for many companies, among the most elusive, and hence the most valuable information—what you are interested in buying and exactly when you are ready to buy—was largely unavailable. Occasionally, a clever marketer could devise an algorithm or a statistical model that might be used to infer some purchase preference from the tidbits of information that might be gathered about a customer from scattered sources. But the Internet has made such information gathering much more commonplace.

### Browser Privacy Issues

Much of the average computer user's online activities revolve around the two most popular Web browsers, Internet Explorer and Netscape. Browsers continue to evolve and improve, especially where privacy and security issues are involved. However, even the most recent versions have some fundamental privacy problems that arise not by accident but by design. In many cases, there are default settings that permit the collection and storage of usage data. These include

- Browsers regularly tell Web sites what kind of browser it is, what version, what operating system it running on, and even what Web site "referred" you to the current page you are visiting.
- Some browsers have settings that permit users to automatically capture and enter user IDs and passwords for Web sites, as well as other personal information such as credit card numbers. These "wallet" features provide convenience, but also present a privacy risk should anyone gain access to that machine and use it to log into sites or access your personal information.
- Browsers can be instructed by Web sites to store little text files, called **cookies**, on your local hard drive. Cookies can be used to store personal information or to assign unique identifiers that allow sites to identify you individually on future visits.
- Browsers can keep a log of every Web site you visit and may even keep copies of the pages and images you have viewed. The "history" function can log this data for days, weeks, or even months. Depending on the size of the hard drive and the default settings for a browser, it may also store days or weeks of Web page files and images in a "cache" folder.

Internet Explorer and Netscape have their own built-in privacy settings and controls. However they do vary in the level of control they allow over elements like cookies. The Help file that comes with each browser explains the browser's privacy settings and describes how to control them.

### IP Addresses and Browser Data

In 1990, an engineer at a Swiss physics laboratory, Tim Berners-Lee, invented a new data exchange standard in an effort to speed the sharing of information between researchers at widely dispersed locations. His creation was the hypertext transport protocol, or http, and it made data sharing across the Internet literally as easy as point-and-click (Cailliau, 1995).

But when the first Web servers and Web browsers were developed, not much attention was paid to subjects like security and privacy. Because Berners-Lee and other engineers needed to troubleshoot their fledgling Internet connections, they built many automatic reporting features, that would let them easily get to the root of the problem when something went haywire. This need for information such as browser type, version, operating system, and referring page, was built into the earliest browsers and persists there today.

While not a tremendous privacy concern, the collection of this browser data is a standard function of most web server software. Most sites collect this data for troubleshooting purposes and then delete it after some period of time, mostly because it can become very voluminous very quickly, and its usefulness diminishes over time.

One element of the data that is also captured in the process of requesting and serving Web pages is the **IP address** of the user's computer. An IP, or Internet Protocol, address is a formatted string of numbers that uniquely identifies your computer out of all of the other computers connected to the Internet. IP addresses, which look something like 192.168.134.25, are assigned in blocks to Internet service providers, who in turn dole them out to their customers. With most dial-up Internet access accounts, users are assigned a "dynamic" IP address, meaning that the IP address assigned to your computer changes every time you log onto your ISP, and gets tossed back into the ISP's pool of addresses when you disconnect. By contrast, dedicated servers and some desktop computers in corporate or academic settings may have a "static" IP address, which is unique to that machine and may persist for the life of the equipment.

But in this age of always-on Internet connections, such as those provided by DSL or cable modem services, it is possible for an average user's computer to have the same IP address for days, weeks, or months on end. From a privacy perspective, a static IP address can compromise one's privacy because an unchanging IP address make it easier for the truly determined to track an individual's Internet usage. For example, a site that collects IP addresses in their server logs may be able to correlate with other transactional records (e.g., purchase history or search parameters) to associate a unique IP address with a unique user and their online activities.

Given that most consumers use Internet service providers that regularly use dynamic IP addressing (as most of the DSL and cable modem providers claim), IP addresses are not considered a very reliable means of allowing Web sites or online advertisers to track users uniquely. However, this lack of reliability should not be confused with anonymity. As a routine bookkeeping matter, many service providers log which IP address was allocated to which user's account at a given period of time. These connection records are frequently sought by prosecutors investigating criminal activities perpetrated via the Internet and by parties in private lawsuits over online activities. In recent years, dozens of companies have successfully uncovered the identities of "anonymous" critics by obtaining court orders for the release of user identities. Not every Internet service provider has willingly provided that information; in 2002, Verizon Internet fought attempts by the Recording Industry Association of America to release records identifying users accused of illegally trading music files. As of this writing, the federal district court in Washington, DC, held that Verizon was required to reveal the user's identity, however Verizon has appealed (McCullagh, 2003). Ultimately courts ruled that the recording industry needed court approval for subpoenas seeking the identity of alleged music pirates (Borland, 2003).

## Cookies

Connections made using http are called "stateless," which means that after your computer receives the content of a requested page, the connection between your computer and the far-away Web server is closed. Rather than maintain a constant open connection "state," each file that makes up the page (e.g., each of the graphics on a page) creates a new and separate connection. This is why, for example, it is sometimes possible to receive all the text of a Web page, but not the images; if the Web browser breaks the connection, or the distant server is too busy, it will not be able to open additional connection to receive the additional data.

The benefit to a stateless connection is simple: it enables one machine to serve a much higher volume of data. However, the downside to a stateless connection is that on occasion it might be helpful for a server to remember who you are. For example, when someone logs onto their stock portfolio, privacy and security dictate that the server not reveal your account information to anyone else, however, efficiency demands that every time you load a page, you should not have to reenter your user ID and password for every new connection your browser makes to the remote computer. So how do you make a server remember who you are? You do so by creating a constant state in an otherwise stateless series of connections. And the method for doing this is the cookie.

Cookies contain a piece of data that allows the remote Web server to recognize a unique connection as having a relationship to another unique connection. In short, the cookie makes sure that the server can remember a visitor through many steps in a visit or even when time has passed between visits. As a basic security measure, it should be noted that cookies are designed to be read only by a server within the same domain that created it. So, for example,

only a server in the yahoo.com domain can read cookies set by a server in the yahoo.com domain.

Cookies enable a myriad of helpful features, such as the ability to personalize a Web site with your choice of colors, or language, or stock symbols on a stock ticker. It also enables features such as shopping carts on e-commerce Web sites, permitting you to select multiple items over the course of a long visit and have them queued for purchase at the end of your visit.

Not all cookies are used for collecting or retaining information over a long period of time, such as those used by advertisers. For example, many Web sites contain a great deal of frequently changing content and generate their Web pages from large databases of text. In some of these cases, the Web servers require cookies to help determine, for example, what page it should serve up to you based upon the search terms that you entered into a search engine.

A special type of cookie, called a **session cookie**, is set to be automatically deleted after a relatively short period of time, usually within about 10 minutes after you leave a site. This type of cookie is typically used for remembering information over a short duration, such as what you may have stored in a shopping cart. Because session cookies are so short lived, they do not have quite the same privacy implications as their longer-lived cousin, the **persistent cookie**. Persistent cookies often have expiration dates set many years in the future.

Most web browsers have settings that allow a user to accept or reject certain cookies. For example, an alternative brand of Web browser called Opera, favored among the privacy community, allows users to accept or reject cookies based on whether it is a **first-party cookie** being set by the site the user is actively visiting, or whether it is a **third-party cookie**, being set by some other entity, such as an advertising service via an ad banner appearing on the site.

## Web Bugs

Another popular technology for tracking users' activities online is the **Web bug**, also called "Web beacons," "1-by-1 pixels," or "clear GIFs." (GIF, which stands for Graphics Interchange Format, is a particular type of file format for images.)

Web bugs are special links embedded in Web pages, or other HTML-coded documents such as some types of email, that allow the link's creator to track every instance in which the document is viewed (Smith, 2001). As discussed earlier, every time a Web page is loaded, images on the page are loaded in a separate transaction with the Web server. When a Web bug is programmed into a Web page, its code looks similar to the code for just about any graphic image appearing on that page. In reality, though, it has three differences:

- The Web bug graphic can be called from any site, most often from a third-party site, allowing that site to record deals about your visit.
- The Web address used to call in the Web bug graphic is often encoded with specific data relating to the page being visited, or in the case of HTML email, it

may be encoded with information about your e-mail address.

- The graphic image associated with the Web bug is deliberately made to be so tiny that it is invisible to the naked eye.

Most Web bugs are the size of a single screen pixel. What is a pixel? Every image on a computer screen is comprised of very tiny dots. The smallest unit of dot on your computer screen is the pixel. But even a single pixel can still be visible, so Web bug images are often made of a graphic image called a clear GIF, or a transparent GIF, which allows the background color or image to show through it, rendering it effectively invisible.

Because Web bugs can be embedded in any Web page or HTML document, they can also be included in e-mail, allowing sites to track details about when a message is read, and to whom the message might be sent. This versatility is why Web bugs have become so widely used. It is also why an industry group called the Network Advertising Initiative, which represents a growing category of online advertising firm called **ad networks**, responded to pressure from privacy advocates and legislators by agreeing to a set of guidelines for notice and choice when Web bugs are in use.

## Ad Networks

Some sites rent out space on their Web pages to third parties, often for placement of advertisements. Along with those ad banners, many third-party advertising companies also try to set their own cookie on your browser. These cookies can be used for things like managing ad frequency (the number of times an advertisement is shown to a particular individual), and to track users movements between the many sites on which the advertising companies place their cookies. These ad networks are a type of advertising agency that rents space on dozens or hundreds of websites, and frequently uses cookies placed on all of the sites in their network to build a profile about the kinds of Web sites a particular user likes to visit.

What is increasingly a marketer's paradise is becoming a consumer's nightmare: the deluge of commercial messages in e-mail inboxes, parades of pop-up advertisements, and even solicitations arriving by cellular phone and pager are making consumers leery of the alleged benefits of this ubiquitously wired world. In response to growing consumer concerns, companies have sought to develop privacy policies that help consumers better understand how their information is gathered and used.

## PRIVACY POLICY FUNDAMENTALS

According to the Federal Trade Commission (FTC), if a company makes a promise that it does not deliver on, that is considered an unfair or deceptive trade practice, for which the offender can be fined up to \$11,000 per violation, in addition to other legal remedies (FTC OGC, 2002). Central to the FTC's advocacy of greater consumer privacy protections has been the call for companies to adopt privacy policies that provide consumers with useful information about how their personal information is

gathered and used. While there are no federal laws that require the publication of a privacy policy, except where data collection from children is involved, it is widely considered an industry "best practice" to publish a privacy policy on any public Web site.

Considering the liability created by writing a privacy policy that a company cannot deliver on, the drafting of a privacy policy is not something to be undertaken lightly or without advice of legal counsel. However, good privacy policies tend, at minimum, to address those elements contained in the widely accepted fair information principles, which have also been endorsed by the FTC: notice, choice, access, and security. We will discuss the FTC's role in policing privacy matters later in this section, but it should also be noted that legal actions by state Attorneys General, as well as private lawsuits, are also driving companies toward some level of uniformity in privacy disclosures.

Those privacy policies cited by privacy advocates as being "best of class" also include the elements of the OECD's principles of fair information practices. There are also a number of online privacy policy generators that allow you to create policies by picking and choosing from predefined language based on the applicable situation. According to the privacy organization, TRUSTe, their recommended Model Privacy Statement has several key elements that echo the OECD principles:

- What personally identifiable information the company collects.
- What personally identifiable information third parties collect through the Web site.
- What organization collects the information.
- How the company uses the information.
- With whom the company may share user information.
- What choices are available to users regarding collection, use and distribution of the information.
- What types of security procedures are in place to protect the loss, misuse or alteration of information under the company's control.
- How users can correct any inaccuracies in the information. (TRUSTe, 2004)

Once a company has surveyed their data practices and articulated them clearly in a privacy policy document, the next most important task is to assure that the company lives up to its promises. There are three ways to do this: manage privacy matters internally, look to industry-sponsored groups for guidance on compliance, or wait for law enforcement to come after you.

## Chief Privacy Officers

As the importance of privacy has grown in the corporate setting, and as the risks from privacy problems have increased, companies have begun to create a new management position, the Chief Privacy Officer (CPO), as the designated point-person for managing privacy policies and practices.

Since the first CPO position was created in 1999 at the start-up Internet advertising firm AllAdvantage.com, the CPO job description (if not always the title) has been

rapidly adopted across corporate America; by the end of 2000, a significant number of Fortune 100 firms had a CPO-type position, often reporting to the seniormost levels of the organization. According to the Privacy Working Group of the advocacy group Computer Professionals for Social Responsibility, there are many benefits to appointing a CPO:

A talented and properly-positioned CPO will add value across corporate divisions from development to customer relations, from liability mitigation and risk management to increased market share and valuation. Perhaps most importantly, the Chief Privacy Officer promotes an essential element of new economy corporate citizenship—Trust. (Enright & McCullough, 2000)

The CPO has both an internal and an external role at his or her company. The internal role includes participation in companywide strategy planning, operations, product development and implementation, compliance monitoring and auditing, and employee training and awareness. The external role of the CPO involves enhancing the company's image as a privacy sensitive organization, through fostering positive relationships with consumers and consumer groups, privacy advocates, industry peers, and regulators.

In many respect, the CPO becomes the focal point for a company's privacy activities, and in turn can become the company's public face on the privacy issue. The position is most effective if it is perceived as objective, with ombudsman-like qualities, serving as a protector of consumer interests while seeking balance between those interests and the interests of the company. Yet there are other organizations offering assistance in the ombudsman role: trustmark organizations.

## Trustmarks

There are several independent, industry-sponsored organizations that will certify a company's privacy policy in order to improve consumer perceptions. Upon certification, they permit sites to use their "seal of approval," sometimes referred to as a **trustmark**, to demonstrate to the public their commitment to privacy concerns. The most popular privacy seal programs—BBBOnline, CPA WebTrust, and TRUSTe—certify the validity of the policies on many thousands of Web sites. And the growing use of these trustmarks does seem to be having an effect: an August 1999 study found that 69 percent of Internet users said that they recognize the TRUSTe seal, the most widely adopted of the privacy seal programs.

Seal programs verify that a Web site's privacy policy covers certain privacy topics (e.g., the use of cookies and sharing data with third-party marketers). However, the seals do not set any specific quality standards, benchmarks, or specific data handling practices. As such, a site could, theoretically, earn a seal for making the required disclosures, even if in the course of the disclosure it reserves for itself the right to make whatever use of personal information it sees fit. This has been one of the criticisms leveled at the seal programs, as has their dependence on licensing fees from those entities they are asked to police.

## Federal Trade Commission

Under their broad legislative mandate to proscribe deceptive and unfair trade practices, the FTC began reviewing online marketing practices back in 1996. Soon the FTC's investigators were uncovering evidence of what they felt was egregious behavior by a few online marketers. Major corporations quickly distanced themselves from the alleged "bad actors," but acknowledged that privacy was a growing concern for online consumers, and promised the FTC that the industry would do better at policing itself.

After numerous public controversies over well-known corporations continuing to abuse consumer privacy, and despite repeated pledges to adhere to standards promulgated and policed by the industry itself, surveys have continued to show that consumer perceptions of the potential for privacy abuses (whether perceived or actual) by online marketers continues to be a factor in consumer hesitance to fully embrace Internet commerce. In response, the FTC has sought on numerous occasions to assist companies in adopting practices that are more conducive to consumer confidence. These efforts have focused on the well-worn mantra: notice, choice, access, and security.

In December 1999, the FTC convened an Advisory Committee on Online Access and Security to provide advice and recommendations to the agency regarding implementation of these basic fair information practices. The committee, consisting of representatives from the online industry, trade groups, academia, and privacy advocates, sought to provide guidance on how to solve the last two elements of fair information practices: access and security. Their report outlines many of the problems with setting universal standards for access and security, and in the end came to few conclusions (FTC ACOAS, 2000).

Some six years after first looking into online privacy issues, the FTC is still warning online companies that if they do not clean up their act, stricter measures might be required. During the intervening years, however, the FTC has not been completely idle:

- In 1998, the FTC reached a settlement with GeoCities, a personal Web site hosting service, over charges that it misrepresented how user information would be used and engaged in deceptive practices relating to its collection of information from children. Part of the settlement required GeoCities (now owned by Yahoo!) to post, "a clear and prominent Privacy Notice, telling consumers what information is being collected and for what purpose, to whom it will be disclosed, and how consumers can access and remove the information." The notice, or a link to it, was required on the Web site's home page and on every page where information was collected (FTC, 1998).
- In 1999, the FTC issued regulations implementing the Children's Online Privacy Protection Act, which requires online businesses to seek permission from parents before gathering personally identifiable information from children under age 13. It has since brought several enforcement actions to punish Web sites that have ignored those regulations (FTC "Kidz Privacy," 2003).

- In recent years, the FTC has filed numerous actions against Internet-based fraudulent schemes, get-rich-quick scams, and quack medical remedies promoted via e-mail and on the Web.
- In 2000, the FTC intervened in the bankruptcy sale of a customer list belonging to defunct online toy retailer Toysmart.com. The basis of the action was to prevent the list from being used in any way inconsistent with the privacy policy under which it was gathered (FTC, 2000).
- In 2001, the FTC settled with pharmaceutical firm Eli Lilly and Company over an e-mail that improperly disclosed the e-mail addresses of hundreds of users of a prescription reminder service at the Web site Prozac.com, in violation of the site's privacy policy (FTC, 2002).
- In 2003, the FTC settled with clothing manufacturer Guess? Jeans, Inc., over security breaches in the database associated with their online sales Web site. The FTC claimed that Guess? Jeans had failed to use reasonable measures to protect the privacy of consumers' credit card and other personal information when they failed to implement a security patch to remedy a well-known security vulnerability in their database software (FTC, 2003).

The FTC has steadfastly refused to seek greater legislative authority than its already broad mandate under the Federal Trade Act to police unfair or deceptive trade practices. However the agency has threatened the industry that it will indeed seek more specific privacy-oriented enforcement authority if companies do not improve their self-regulatory efforts. It must also be noted that the FTC is just one governmental authority with the ability to prosecute privacy violations: most state Attorneys General have state versions of the Federal Trade Act that enable them to seek remedies similar to those available to the FTC. Indeed, Attorneys General in Michigan, Washington, California, and Massachusetts, have all been active in undertaking privacy-related enforcement actions, and the National Association of Attorneys General has held many seminars on investigating and prosecuting Internet privacy matters (NAAG, 2001).

## CONCLUSION

Consumers and businesses alike are grappling with the complex privacy concerns that the Internet era has brought to the fore. This chapter is a necessarily brief overview of the privacy landscape. Indeed, entire books can—and have—been written about the ways Internet technologies have created new challenges to the average person's desire to "be let alone." But as this chapter has shown, there are a number of concepts that find their way into privacy-related policies and practices. Among them, the fundamental principles of notice, choice, access, and security, are driving both consumer expectations and business planning. Keeping these principles in mind, many who are called on to seek privacy solutions in their own particular business or personal context have a conceptual framework within which to arrive at their own conclusion.

## GLOSSARY

**Ad Network** A consortium of Web sites linked together by an advertising agency for purposes of aggregating advertising placements and tracking consumers movements among and between member sites.

**Cookies** A small file saved by your Web browser, at the direction of a Web site, containing data that may be later retrieved by that Web site. See also persistent cookies, session cookies, third-party cookies.

**COPPA** Children's Online Privacy Protection Act of 1998. Legislation that limits operators of commercial Web sites and online services from collecting personal information from children under age 13.

**ECPA** Electronic Communications Privacy Act of 1986. Legislation governing the use of wiretaps for domestic law enforcement activities.

**FISA** Foreign Intelligence Surveillance Act of 1978. Legislation governing the use of wiretapping and physical searches in investigations involving terrorists and agents of foreign powers.

**GLB** Gramm-Leach-Bliley Act, also known as the Financial Services Modernization Act. Legislation that instituted major changes to the U.S. banking system. In pertinent part, GLB requires that organizations providing financial services disclose their data collection practices to customers, and to provide the ability to opt-out of those practices.

**HIPAA** Health Insurance Portability and Accountability Act of 1996. Legislation that instituted a number of changes to health insurance practices. In pertinent part, HIPAA included privacy-related provisions applicable to health information created or maintained by health care providers, health plans, and health care clearinghouses.

**Internet Protocol (IP) Address** The unique numerical address assigned to each computer connected to the Internet. An address may be assigned temporarily (called a dynamic IP address) or may be assigned for long periods (called a static IP address).

**OECD** Organization for Economic Cooperation and Development. A group of 30 democratic, market economy countries working collaboratively on economic, social, and trade issues.

**Persistent Cookies** Cookie files designated to be stored for long periods, sometimes as long as 10 years.

**Privacy** Freedom from unauthorized intrusion. A state of being let alone and able to keep certain especially personal matters to oneself.

**Safe Harbor** A legal concept which permits an entity to reduce and/or avoid legal liability by agreeing to adhere to certain standards or procedures. In the context of Internet privacy, Safe Harbor refers to an agreement between the United States and the European Union that permits U.S. companies to certify that they adhere to the stricter privacy standards required by European law, thereby avoiding a more burdensome set of country-by-country registration procedures.

**Session Cookies** Cookie files designated to be stored for only the duration of a visit to a Web site; usually ten minutes or less.

**Third-Party Cookies** A cookie file set by some entity other than the operator of the Web site being visited by the user. Third-party cookies are often used by advertising services to track user movements between multiple Web sites over periods of times.

**Trustmark** A symbol used to identify those Web sites who have subjected their privacy policy to review by a third-party watchdog organization.

**Web Bugs** (also called Web Beacons, 1-by-1 Pixels, or Clear GIFs) Special links embedded in Web pages, or other HTML-coded documents such as some types of email, that allow the link's creator to track every instance in which the document is viewed.

## INTRODUCTION

This chapter discusses the controversial topic of censorship in cyberspace. Censorship is sometimes undertaken in the name of securing a local network and client systems from the insidious exogenous influences emanating from the global Internet. Censors often seek to protect impressionable or vulnerable individuals from objectionable forms of speech that might be laced with pornographic images, xenophobia, or racism. Digital technology has enabled the privatization of censorship because it can be carried out not only by government authorities but also by private parties, including corporations and private schools, or libraries. Censorship can be achieved through public law or through software programs that constrain expression more opaquely than the law. As a result, to some degree censorship has become easier to achieve in cyberspace thanks to the use of such programs.

Although I refrain from reaching any normative conclusions about the use of censorship, this chapter argues that it should not be confused with security. Censorship is triggered by content that is unwelcome for various ideological reasons, but the goal of digital security should not be limitations on expression for the sake of its content. Rather, the purpose of security should be protection against the physical impact of another's conduct, which can result from malicious code, denial of service attacks, hacking, or trespass. Arguably, a country that filters out unwanted sexual images or political speech is engaged in censorship and should not attempt to justify such activities under the pretext of providing “security” for its citizens. Given that the tools used to secure the network from alien influences are the same ones used to censor that network, it is all too easy for countries and organizations to align their security procedures with a censorship agenda.

## WHAT IS CENSORSHIP?

Censorship is a value-laden term that defies a simple formulation. It has been broadly defined by philosophers, however, as the intentional suppression or regulation of expression based on its content (Williams, 1998). Also, according to Williams, the activity in question “has at least to be publicly recognized in order to count as censorship.” Thus, it is usually associated with a government

or a “legally constituted” authority's prohibition of a publication or speech that has a certain content. However, censorship should include any act that is intended to restrict, encumber, limit, or deter in some way the expression of another. It is possible to restrict and limit another's expression in a nontransparent fashion, especially given the tools of digital technology. It is also possible for private individuals or organizations to suppress expression. Therefore, a modification of the traditional definition seems appropriate: Censorship is the public or covert suppression or regulation of speech based on its content conducted by a legally constituted authority or by private parties.

In addition to direct censorship or suppression of content, there is *circumstantial censorship* defined as “any factor that restricts or suppresses desired communications.” Such indirect censorship encompasses a person's lack of resources or the problematic material conditions (such as economic structures) that hinder one's ability to engage in speech (Baker, 1996). Although this form of circumstantial censorship is important, the primary concern of this chapter is with direct intentional censorship originating from either the public or private spheres (see the chapter on the digital divide).

The Net's distributed and anarchic architecture makes it a medium strongly resistant to government regulation including conventional types of censorship. Distributed peer-to-peer networks such as the ones used for the sharing of music files (KaZaA or Gnutella) are particularly difficult to control. FreeNet, for example, is a *darknet* a—Web site used to avoid Internet surveillance and censorship. It is a fully distributed network that relies on strong encryption to protect the privacy of its users as they share information and is considered to be “almost perfectly ungovernable” (Vaidhyanathan, 2004). Nonetheless, in most cases, thanks in part to certain software and hardware architectures, governments have found ways to censor this medium, often under the pretense that they must regulate access to “protect” their citizens from corrupting foreign influences located in cyberspace.

## THE FIRST AMENDMENT

Any discussion of censorship would be incomplete without understanding the scope of the right to free speech as

expressed in the First Amendment of the U.S. Constitution. That amendment simply states:

Congress shall make no law respecting the establishment of religion, or the free exercise thereof; or abridging the freedom of speech or of the press; or the right of the people peaceably to assemble, and to petition the Government for a redress of grievances.

The purpose of this amendment is to protect freedom of individual thought and expression and to encourage a robust “marketplace of ideas” that serves the common good. Free speech is also regarded as important for one’s self-fulfillment and autonomy: “the value of free expression . . . rests on its deep relationship to self-respect arising from autonomous self-determination without which the life of the spirit is meager and slavish” (Richards, 1974).

Although the right to free speech has broad scope in the United States, it is by no means absolute. Since the Constitution was written, a number of free speech principles have emerged that articulate when the government can intervene in speech issues. Those guidelines help to define the limits of protected free speech. Here is a concise overview of some of the key principles:

Courts have focused not only on what forms of speech are protected but on the means of restriction that are “constitutionally permissible;” in accordance with the over breadth, vagueness, and prior restraint doctrines courts may “invalidate restrictions on expression . . . even though the particular speech at issue might constitutionally be restricted by other means.” (Stone, Seidman, Sunstein, Tushnet 2001)

Government restrictions on the “time, place, and manner” in which speech is allowed are constitutional only if they meet these three conditions: they must be “content neutral” (that is, limit expression without regard to its content); they must leave other opportunities for speech to occur; they must be “narrowly tailored” and “serve a significant state interest.” (Fisher, 2001)

Content-based government restrictions on speech are regarded as unconstitutional unless they serve a “compelling state interest”;

Although some forms of expression have a privileged status (such as literary, artistic, and political expression), several forms of low value speech are not fully protected by the First Amendment:

- Speech that will likely induce “imminent lawless action”
- “Fighting words,” that is, insulting words apt to start a fight or a conflict of some sort
- Obscenity: speech that depicts or describes sexual conduct in a “patently offensive” way, appeals to “prurient interests,” and “taken as a whole, lacks serious literary, artistic, political, or scientific value” (*Miller v. California*, 1973).

- Child pornography
- Material harmful to minors
- Defamatory statements defined as communication that tends to harm the reputation of another so as to lower his or her esteem in the eyes of the community (Fisher, 2001; Spinello, 2002).

Commercial speech has an intermediate status. According to Justice Powell, commercial speech should be “afforded . . . a limited measure of protection, commensurate with its subordinate position in the scale of First Amendment values” (*Ohralik v. Ohio State*, 1978). Thus, such speech can be banned if it is misleading or if it is associated with illegal products.

The First Amendment protects citizens only from the government’s attempts to impose restrictions on free speech rights. According to this “state action” doctrine, the limits of the First Amendment apply to the government but not to private agents. An Internet service provider (ISP), for example, may decide to install filters to screen out pornographic content. If such a policy were mandated by the government or if the ISP were assuming “government-like powers,” it would most likely constitute “state action” and trigger First Amendment issues. Some scholars disagree with this interpretation of the First Amendment and believe that the Internet should prompt us to reconsider this “state action” philosophy. They reason that ISPs, search engines, and other intermediaries now have the means to place restrictions on speech, and yet the First Amendment would not apply to their restrictive activities. Fried (2000), however, pointed out the downside of turning to such a revisionist doctrine, despite the growing influence of the Internet and the accretion of power by ISPs:

By limiting the First Amendment to protecting citizens from government (and not from each other), the state action doctrine enlarges the sphere of unregulated discretion that individuals may exercise in what they think and say. In the name of First Amendment ‘values,’ courts could perhaps inquire whether I must grant access to my newspaper to opinions I abhor, must allow persons whose moral standards I deplore to join my expressive association, or must remain silent so that someone else gets a chance to reach my audience with a less appealing but unfamiliar message. . . . I am not convinced that whatever changes the Internet has wrought in our environment require courts to mount this particular tiger.

The Internet has surely been a major challenge for First Amendment jurisprudence. But in the United States and in other democratic countries, good faith efforts have been made to treat the Internet fairly as another medium of communication and to ensure that it enjoys the same amount of free speech protection without special privileges (see the chapter on electronic speech).

## HARMFUL FORMS OF SPEECH

The Internet has made it easier for individuals to speak with anonymity and with greater impact, and it has provided a valuable space for new virtual communities. As a result, it has become a positive force for social and political change in many countries. There is, however, a dangerous side to this proliferation of speech. The Internet is a borderless global technology that cannot be easily controlled. It sometimes delivers offensive material that can range from child pornography to racist diatribes.

The use of censorship tools is most often induced by these many forms of harmful speech that have appeared in cyberspace alongside of constructive and healthy speech. Categories of speech that have been deemed harmful by various countries and governments include pornographic or obscene speech, hate speech, virtual threats, online incitement, defamation, and even spam (or junk e-mail). While those who pioneered Internet technology have consistently asserted that the right to free expression in cyberspace should have as broad a scope as possible, the increased use of the Internet especially among more vulnerable segments of the population (such as young children) has forced some public policy makers to rethink this *laissez-faire* approach.

In the United States, the result has been a concerted effort to control pornographic forms of speech, although the definition of this type of speech is notoriously difficult to express concisely. Nonetheless, pornographic speech appears to include speech that is obscene for everyone and speech that is harmful to minors, that is, “defined to be obscene on the basis of its appeal to [children] whether or not it would be obscene to adults” (*Ginsberg v. U.S.*, 1966). The *penthouse.com* Web site would fall into the latter category whereas child pornography would be included in the former one. Islamic countries such as Saudi Arabia have also expressed grave concerns about the abundance of pornography in cyberspace, and they, too, have initiated censorship measures to block this type of expression.

Other countries such as Germany and France, however, have been more preoccupied with extirpating hate speech from Web sites viewed by their citizens. There are stringent anti-hate laws in Europe that must be followed even in cyberspace. In Germany, for example, carefully defined laws forbid the posting of Nazi propaganda or other racist and anti-Semitic material. According to the European Convention for the Protection of Human Rights, “the right to free speech does not extend to speeches that threaten, deny or even lead to the destruction of human dignity and human integrity” (Rorive, 2003).

But extremist hate sites are more commonly hosted on servers in the United States, where hate speech is protected by the First Amendment unless it rises to the level of a specific threat, or in developing countries. The Internet’s global nature makes possible this type of arbitrage opportunity, whereby individuals locate their servers in a different jurisdiction to evade certain regulations. Although some regard regulatory arbitrage as problematic, others contend that its “effects will tend to promote democratic values of openness and freedom more than they will detract from what most consider to be the modern states’ legitimate regulatory powers” (Froomkin, 1997).

One of the most pernicious and pervasive forms of speech is spam, which is most properly defined as automated unsolicited bulk e-mail. Spam is usually some form of commercial e-mail, but noncommercial enterprises can also communicate by means of bulk e-mail. However, should *all* unsolicited bulk e-mail be considered as nuisance spam mail? Given the need to respect and protect speech of public concern, this would depend on the nature of the speech, the volume of the mailings, and frequency of transmission. Regardless of how we define it, however, the economics of spam are highly attractive because the marginal cost of sending another electronic message is virtually zero. Yet spam imposes costs on the recipients and the ISPs who must deliver this mail. Users are burdened by the need to delete an endless stream of messages. Given the costs of spam, it is no surprise that organizations and ISPs seek to block it to protect their servers from a burdensome overload of unauthorized e-mail messages (see the chapter on spam and the legal counter attacks).

These various forms of harmful speech that proliferate in cyberspace represent the primary motivation for the use of censorship tools. Of course, some countries, such as China, Cuba, and Saudi Arabia, go further and seek to censor dissenting political discourse as well. In China, for example, the Chinese company QQ filters words such as “democracy” and “Falun Gong” from its instant messaging service in compliance with government regulations (Hutzler, 2004). The Chinese government has also jailed some individuals for promoting political dissent on the Web. Such actions are considered repressive and an unambiguous violation of human rights according to the standards set by international bodies such as the United Nations.

## TOOLS OF THE CENSORS

What sorts of tools do the censors have at their disposal? I have already alluded to some of these tools, but Lessig (1999) provided a framework that can answer this question more comprehensively. In the physical world, argued Lessig, we are regulated or constrained in four basic ways: laws, social or ethical norms, the market, and physical architectures. We are also constrained in cyberspace by the same four modalities of regulation: law, code (such as software applications), social norms, and the market. Laws, such as those that provide copyright and patent protection, regulate cyberspace behavior by proscribing certain activities and by imposing *ex post* sanctions for violators. According to Lessig, “law functions in two different ways: when its operation is direct, it tells individuals how to behave and threatens punishment if they deviate from that behavior; [w]hen its operation is indirect, it aims at modifying one of the other structures of constraint (95)” For example, law might dictate that car manufacturers make cars that will not start without a seatbelt fastened, and it thereby brings a significant architectural change. Markets regulate behavior in various ways—the pricing policies of ISPs will determine who can afford access to the Internet, and e-commerce Web sites come and go depending on their marketplace acceptance.

The counterpart of architectural constraint in the physical world is code: “not the code at its most basic level of

Internet exchange [the transmission control protocol/IP protocols], but the applications (both in hardware and software) that use or implement those protocols” (Lessig, 1999). They, too, constrain and control our activities. These programs are often referred to as the “architectures” of cyberspace. Code, for example, limits access to certain Web sites by demanding a username and password; encryption code is used to protect data from thieves and snoops, and software programs such as CyberPatrol filter out pornographic material from an end user’s computer. All of these “architectures” constrain behavior and have regulatory impact. According to Lessig (2004), “the code of cyberspace is itself a kind of sovereign . . . [and] thus competes with the regulatory power of local sovereigns.”

Finally, there are norms that regulate cyberspace behavior, including Internet etiquette and social customs. For example, “flaming” is considered “bad form” on the Internet, and those who do it will most likely be disciplined by other members of the Internet community. Those who misrepresent themselves in a chat room also violate those norms, and they too will be reprovved if their true identity is revealed. Just as in real space, cyberspace communities rely on shame and social stigma to enforce cultural norms.

Censorship is most effectively accomplished by the use of code and law, and sometimes by reliance on the combined forces of code and law—that is, code backed up by law. Consider the Digital Millennium Copyright Act (DMCA) of 1998, which forbids circumventing technological measures that protect copyrighted material. It also prohibits making or “trafficking in” anticircumvention devices. In this case, law and technology work together as a potent constraint to protect online digital content. The DMCA was invoked to halt the dissemination of a decryption program known as DeCSS that was written to decode encrypted DVD files. The defendants in this case were forbidden from posting this code on their Web site and from linking to other sites where the DeCSS program could be found (see the chapter on the Digital Millennium Copyright Act).

The primary theme of Lessig’s analysis for our purposes is that code creates new opportunities for the censor, who can now suppress unwelcome speech in nontransparent ways by means of software filters, firewalls, and similar mechanisms. According to Mitchell (1995), “control of code is power,” and we might add that control of code is control of content because it can structure what we see and read in cyberspace and thereby facilitate the work of the censor. Code also makes private censorship possible. Censorship can be “private” in two ways: it can be implemented in the private sector by parents or organizations (private schools and libraries, corporations, etc.) and it can be accomplished in a nonpublic or clandestine manner because users do not always know when their access to certain information is being restricted.

## SECURITY, CENSORSHIP, AND “POINTS OF CONTROL”

Thanks to the Internet, computers are connected to one another in a “single cloud-like global network” (“Securing

the Cloud,” 2002). Despite the benefits of easy connectivity, which include international commerce opportunities, greater efficiency, and remote access, there are costs as well. One such cost is the elevated risk of security breaches. Networks are vulnerable to attack and susceptible to unwanted data or intrusive activities.

The linkage of countries throughout the world to the global information infrastructure (GII) has also created many sources of friction. These countries are obviously anxious to participate in the benefits of connectivity, but they keenly recognize the costs sometimes associated with that connectivity. Countries such as Singapore and China aspire to be key players in the global economy, but they also want to protect their cultures from dehumanizing influences and antisocial Web sites. Foremost among these concerns is the need to prevent exposing users to sexually explicit content. Censorship has become a primary means of dealing with such material. In 1995, for example, the German government raided the offices of CompuServe’s German subsidiary, accusing the company of failure to block access to pornographic material in violation of German law. Countries want to protect their citizens from objectionable content, and this objective is often seen as a vital element of an overall security plan. Thus, censorship is often justified as one way of “securing” or protecting national cultures from certain forms of unwelcome content.

The primary purpose of network security is to prevent unauthorized intrusions such as hacker attacks and the diffusion of malicious code or even Internet infrastructure attacks. Malicious code includes Trojan horses, viruses, worms, and other “malware” often hidden in legitimate programs. A worm, for example, resembles a virus because it is a self-replicating program, but unlike a virus, it requires no host system to propagate. These parasitic programs can lead to destruction of data or to prolonged downtime (see the chapter on computer viruses and worms).

Firewalls are the principal means of keeping these infectious programs and other forms of malware away from computers or networks. A firewall is usually a combination of hardware and software that sits between the Internet and an internal network (see the chapter on firewall basics). Its task is to examine the stream of network traffic (and service requests) and to follow certain rules about which data are to be allowed into and out of that internal network. According to Ellis (1997), “A simple firewall may consist of a filtering router, configured to discard packets that arrive from unauthorized addresses.”

But these security tools can also be used to facilitate the goal of censorship. Firewalls represent code that can also function as digital fences, keeping out unwanted forms of speech such as sexually explicit content. Organizations can protect themselves from the Internet with proxy servers that typically reside inside a firewall between the Web browser and the true server. A proxy server can help an organization stop its users from accessing undesirable Web sites, and it can protect the internal network from being identified by the public. This “alias” keeps the network anonymous from the outside world and makes it harder for hackers to identify and attack client systems.

Thus, there is a strong temptation to use the code that has been developed to enhance security as an instrument

of censorship. The purpose is often to enforce local laws and to achieve the goal of security, broadly conceived. Some countries seek to “secure” client systems against any objectionable communication from the Internet. This may include malicious viruses, but it might also include speech considered to be harmful such as pornography. Saudi Arabia, for example, attempts to block Internet pornography at the national level as a means of “protecting” its citizens. In some Eastern or Islamic cultures the definition of “pornography” is fairly broad and includes material considered merely erotic or romantic in the West.

Organizations may be anxious to keep out viruses, but they also want to keep out pornography and spam. Spam has been classified by corporate plaintiffs in some cases as a form of “trespass to chattels,” that is, an illicit interference with one’s property (Spinello, 2003; *Intel v. Hamidi*, 1999). Many companies and ISPs seek to suppress this form of commercial speech for the sake of the viability of their systems and integrity of the network. Censors, therefore, erect “barbed wire” or digital fences on this electronic frontier that restrict the free flow of information in cyberspace as a means of protecting their internal network.

Finally, it is instructive to consider the various “points of control” where censors are most likely to exert influence (Zittrain, 2003). Data on the Internet passes from one node or computer system (“source”) to another node (“destination”) through intermediaries. A packet of data is transmitted from the source computer with the Internet protocol (IP) address of the destination computer. It usually passes through the source node’s ISP to the ISP serving the destination node which in turn delivers it to that node. According to Zittrain, the movement of data on the Internet passes through five distinct phases: the data begins at the (1) source node and passes through (2) the source ISP; “it continues through transit and/or peering through (3) the cloud, is handled by (4) the destination ISP and then arrives at (5) the destination [node] (120).” All of these represent points of transmission simultaneously represent points of control for the data that pass over this system. Censorship (or security) can take place at any of these crucial junctures.

## GOVERNMENT CENSORSHIP

Governments’ efforts to restrict Internet speech they regard as dangerous have varied greatly. Islamic countries have focused on pornography and some forms of political speech. Some liberal Western democracies, such as the United States, have sought to censor or suppress sexually explicit speech, and others, such as France and Germany, have concentrated on virulent hate speech. It is instructive to consider the concerted efforts of the United States to restrict sexually explicit speech in cyberspace by means of command and control legislation.

The United States government first sought to deal with the pervasive problem of Internet pornography with a piece of legislation called the Communications Decency Act of 1996 (CDA). This ill-fated law criminalized the “knowing” transmission over the Net of “obscene or indecent” material to anyone under the age of 18. Shortly after the CDA was signed into law, a lawsuit was immediately

filed by the American Civil Liberties Union (ACLU) and several other groups, claiming that the CDA violated the First Amendment. One year after its passage, the Supreme Court struck down the law because it interfered with the First Amendment rights of adults to access sexually explicit sites. According to the majority opinion in *Reno v. ACLU* (1997) the act “suppresses a large amount of speech that adults have a constitutional right to receive and to address to one another.” Moreover, the law’s reference to “indecent” material was considered to be unconstitutionally vague.

In October 1998, however, Congress tried again, passing the Child Online Protection Act (COPA), which was immediately challenged by the ACLU. COPA was more precisely written than the CDA. It required Web site operators to restrict access to any material deemed to be “harmful to minors.” Such material had to be obscene or meet a new federal harmful-to-minors standard with three requirements (for example, the material “depicts, describes, or represents, in a manner patently offensive with respect to minors, an actual or simulated sexual act or sexual conduct . . . or lewd exhibition of the genitals”).

The ACLU also challenged COPA and won its case in Federal District Court in Philadelphia and in the U.S. Court of Appeals for the Third Circuit. In 2002, the U.S. Supreme Court remanded the case to the Third Circuit, which again found COPA unconstitutional because it did not satisfy the First Amendment’s “least restrictive means” test. However, the case *Ashcroft v. ACLU* was appealed once again to the Supreme Court. That Court decided in 2004 to keep in place the district court’s order blocking the enforcement of COPA, but it remanded the case to the district court for yet another hearing (Greenhouse, 2004).

Despite these setbacks, Congress did not abandon its efforts to contain the spread of pornography in cyberspace. In 2000, it passed the Children’s Internet Protection Act (CIPA), which was signed into law by President Bill Clinton just before his departure from office. With CIPA, the government sought to implicitly mandate the use of filters. It hoped to rely on private surrogates, libraries, and schools to regulate speech harmful to minors. According to Lessig’s paradigm, this regulatory regime is a clever combination of code and law.

CIPA is linked to the federal government’s e-rate program, which provides an opportunity for schools and libraries to be reimbursed for the costs of connecting to the Internet or to be subsidized for other telecommunications expenses. The law mandates that computer terminals used by all library patrons (i.e., adults and children) must have filters that block Internet access to visual images that are obscene or involve any sort of child pornography. In addition, library computer terminals used by children under 17 must filter out these two categories of material plus any visual material that is harmful to minors. Public schools seeking e-funds must implement the same type of filtering scheme.

In April 2001, a group of libraries and library associations initiated a lawsuit against the government, claiming that CIPA was unconstitutional. The plaintiffs argued that filters were imprecise and “blunt” instruments, inadvertently blocking out many Web pages that did not contain

sexually explicit material. Some of the sites blocked by typical filters included those having to do with sex education, and others were related to health issues, including Columbia University's question-and-answer site. Also, as the plaintiffs pointed out, technology protection measures cannot block access to *all* the material that is obscene, child pornographic, or harmful to minors

In the summer of 2002 a federal judicial panel of the U.S. District Court for the Third Circuit struck down the law. The court concluded that sections of this law were "invalid under the First Amendment." The federal government appealed the case to the Supreme Court, and in late June 2003, that court vacated the district court's ruling and upheld CIPA. In its 6–3 decision, the Supreme Court concluded that limitations imposed by CIPA on Internet access were equivalent to limitations on access to books that librarians choose to acquire or not acquire. There was consensus that filters are inaccurate instruments for restricting the access of children to pornographic material because those filters sometimes block sites that adults have a right to see. Nonetheless, the majority of the Supreme Court concluded that First Amendment rights were not being infringed by this law, as long as adults could request that the filters be disabled, without unnecessary delay.

Other countries have taken more extreme and direct steps to protect their citizens from objectionable content. In some countries, comprehensive restrictions on Internet traffic have been imposed for social and political purposes. Saudi Arabia, China, Singapore, and a host of other countries have put into effect countrywide filtering systems by blocking content, usually at the level of the destination ISP. In Saudi Arabia, all Internet traffic is routed through a proxy server that weeds out certain Web sites based on filtering criteria determined by the state. The blocked sites included pornographic sites along with those that might offend the sensibilities of its citizens. This would include content critical of the Islamic religion or political discourse critical of the Saudi regime. Political dissent is not tolerated in Saudi Arabia, and government officials wanted to be sure that the Web would not provide a forum to foment such dissent. In addition, many other sites, "including anonymizers and translators which might themselves be easy launching pads to otherwise-blocked sites" are filtered out as well (Zittrain & Edelman, 2002).

Although China has embraced digital technology and has tried to extend Internet usage among its citizens, it seeks to keep out the "foreign 'flies'—from liberalism to democracy to pornography—that will come in with the Internet" ("Wired China," 2000). China requires ISPs to install routers capable of blocking problematic IP addresses. Thus, routers across the country have been skillfully configured to delete packets that have objectionable content. China's filtering software blocks many mass media Web sites such as those operated by the BBC, CNN, and the *Washington Post* (Zittrain & Edelman, 2003). Private companies that offer Internet access in China must abide by the same rules. All service providers and media companies operating in China must sign the Public Pledge on Self-Discipline, promising not to produce or make available information that would violate the country's censorship

laws. As a consequence, "if someone in Shanghai uses Yahoo! China to query the term 'Taiwan independence,' the search will yield no results" (Scanlon, 2003).

India, a democratic state, has also implemented Internet content filtering on a countrywide basis. The Open Net Initiative (2004) reports that Indian Ministry of Communications & Information Technology has ordered Indian Internet Service Providers to block sites such as Yahoo!Group kynhun and HinduUnity.org. The latter site was ordered blocked because it contains "inflammatory anti-Islamic material." The Open Net Initiative reported that the Indian ISPs complied with the order in a way that "result[ed] in collateral blocking of thousands of newsgroups."

Thus, the Internet is subject to various forms of censorship at the national level. The firewalls and filtering mechanisms used for this purpose are far from foolproof, but they make it much more difficult for Internet users to retrieve sought after information. They also "represent the most effective point of blockage along the path of data from faraway places into the personal computers of Internet users within those countries" (Zittrain, 2003).

## PRIVATE CENSORSHIP

Given the difficulty of regulating content on the borderless Internet at a national level (by code or law), a more decentralized approach to censoring cyberspace may be more feasible. When government action fails, the burden falls on private "regulators" such as parents, private schools, and corporations. Of course, reliance on such a decentralized mode of censorship is made possible through code, the same filtering architectures that are a surrogate for ineffectual laws.

Popular blocking programs for individual systems or local area networks (LANs) include Cyber Patrol, N2H2 Internet Filtering, Websense Enterprise, and SmartFilter. These programs generally function by relying on preset categories of objectionable speech. Categories might include Adult/Sexually Explicit, Nudity, Pornography, and so forth. Once the categories are determined, filtering companies use automated systems (such as a spider) to examine Web sites and determine candidates for each category. Thus, a bot such as a spider might visit the penthouse.com Web site and based on key words or textual data at that site classify it as "Adults Only/Pornography." For some companies, the final categorization is made without human intervention; others rely in part on human reviewers to make the final determination. If a parent installs a filtering program such as N2H2 with categories such as "Adults Only/Pornography" activated, anyone trying to access the penthouse.com site will be prevented from doing so by the software (Spinello, 2003).

In addition to private schools, and parents, corporations also assume the dubious role of private censors. Most workers have come to accept ongoing monitoring as part of the new reality for the 21st-century work environment. Companies monitor the network activities of workers through software that detects access to Web sites providing pornography, gambling, music or streaming video. For example, products such as Websense permit employers to set which Web site categories are permitted

for particular categories of employees. It blocks content and generates detailed reports on Web site visits. Or software such as MIMESweeper may be employed to monitor and restrict internal and external e-mail messages and to screen e-mail for viruses, malicious programs, or attachments that violate file size limits. MIMESweeper can also be used to review e-mail content based on key word searches, checking for objectionable content such as obscene words. Once such e-mail is detected it is prevented from being sent or delivered.

Finally, as we have seen, Internet intermediaries such as ISPs and search engines are being called on to stop the flow of objectionable content such as pornography and hate speech. ISPs have traditionally been regarded as passive conduits, unaccountable for the online activities of its customers. In some contexts, however, they might be asked to “co-regulate [harmful] content in collaboration with public authorities” (Rorive, 2003). Warner (2002) reported that “industry groups, with the help of law enforcement authorities, are succeeding in getting ISPs to take down sites that violate laws regarding . . . speech and standards of decency.” Some search engines such as Google, on the other hand, voluntarily restrict the flow of problematic information. This strategy flows from the company’s idealistic “do no evil” philosophy. According to McHugh (2003), Google “has begun filtering its own servers to block users in Germany, France, and Switzerland from accessing sites carrying material likely to be judged racist or inflammatory in each country.” Google also offers its users a version of its search engine functionality that omits sites containing “pornography and explicit sexual content.”

Many reasons are given for some of this extensive censorship, but the validity of restricting information flows is a matter of great debate. Employers worry about their liability if a worker transmits objectionable content over their network, and search engine providers may not want to abet young children searching for pornography to download. Countries such as India and Iran are also attempting to protect their cultural values. However, censorship involves collateral damage because accurate filtering is difficult to achieve. Edelman (2004) reports that Google’s SafeSearch “blocks at least tens of thousands of web pages without any sexually explicit content . . . includ[ing] sites operated by educational institutions, non-profits, news media, and national and local governments.” Filters used to block pornography have also been criticized for both overblocking nonpornographic material and underblocking (that is, failing to block such material).

In addition, there should be a clear distinction established between the activities of censorship and security. As I have argued in this chapter, censorship is suppression of content based on its nature. Fencing off users from pornographic material or virulent hate speech is not the same as protecting servers, clients, and networks from damaging viruses, denial of service attacks, or illicit acts of trespass. The purpose of digital security should be clarified as the protection against the *physical impact* of another’s conduct and not the potential ill effects of another’s expression, however odious that expression may be.

This is not always an easy line to draw, however, and so there will be some ambiguous cases, such as the blocking

of spam. Is the filtering of spam equivalent to securing servers and networks from the potential physical impairment or is it censorship? A case can surely be made that bulk e-mail transmissions are tantamount to trespass because they can be a burden on server equipment and on networks. Blocking such e-mail, however, would not be censorship as long as the intention is not to suppress a particular type of content but to protect those servers and networks from the burden of processing vast amounts of unsolicited e-mail. In the case of *CompuServe v. Cyber Promotions, Inc.* (1997), the service provider CompuServe alleged that the heavy volume of spam transmitted by Cyber Promotions was a burden on its equipment and thereby impaired that system. A federal court agreed and analogized that the transmission of unwanted spam was no different from throwing unsolicited newspapers onto someone’s property.

## CONCLUSIONS

This chapter has shown that the goal of a secure network or the protection of computer systems can lead organizations and even countries to engage in the activity of censorship, that is, the suppression of objectionable content. Some countries have relied on technical means such as software filters and proxy servers to make the Net safe for children and to protect their citizens from exposure to indecent images. Sometimes that censorship is repressive, however, because it includes valuable political speech.

This chapter has eschewed taking a position on the merits of censorship or delineating its possible parameters. Repressive forms of political censorship obviously deserve condemnation. Yet given the diversity of cultures involved in the use of the Internet and the need to be wary of cultural imperialism, it is difficult to reproach countries for blocking Internet traffic containing hate speech or what they regard as pornographic material. Suffice it to say that democratic governments like the United States prefer to suppress only the most harmful forms of speech (such as child pornography) and never political speech that is in the public interest. Other cultures, of course, do not give the same preeminence to free speech rights. The primary problem with any form of censorship is the difficulty of separating constructive speech from problematic speech. As Barlow (1996) wrote, “We cannot separate the air that chokes from the air upon which wings beat.” Efforts to make this distinction all too often lead to the suppression of legitimate forms of expression. The collateral damage associated with the use of blunt instruments such as filtering software is proof enough of that proposition.

Thanks to digital technology censorship seems to be more ubiquitous because it can be undertaken by both the public and private sectors. Censorship is triggered by content that is unwelcome for various ideological reasons. I maintain, however, that security should not be confused with censoring data based on ideology. The goal of security should not be limitations on expression for the sake of its content. Rather, the goal of digital security should be protection against the negative physical impact of another’s conduct, which can result from malicious code, hacking, or denial of service attacks. Countries and organizations may end up using security tools such as proxy

servers and firewalls for the purpose of censorship. But they should not justify censorship under the pretext of Internet security, and all citizens of cyberspace should keep this critical distinction clearly in mind.

## GLOSSARY

- Censorship** The intentional suppression or regulation of expression based on its content.
- Code** Hardware and software applications that use Internet protocols and can function as a regulatory constraint.
- Content Filtering** Software that restricts access to Internet content by scanning that content based on key word searches.
- Darknet** A Web site used to avoid Internet surveillance and censorship.
- Firewall** An electronic barrier restricting communications between two points of control on the Internet.
- Hate Speech** Any form of speech that threatens, denies, or leads to the destruction of human dignity and human rights.
- Pornography** Includes indecent and obscene sexually explicit material that appeals to the prurient interest in sex.
- Proxy Server** An Internet server that controls client computers' access to the Internet.
- Spam** Unsolicited, automated electronic mail.

## COPYRIGHT FUNDAMENTALS

### Introduction

This chapter is meant to provide readers with a fundamental understanding of the core concepts of U.S. copyright law as they apply to the digital realm; these concepts are expanded further in the chapter in this handbook, *The Digital Millennium Copyright Act*. As copyright law is complex and ever changing, this chapter should be used for informational purposes only. It should not be relied upon as a source of legal advice; instead the reader should contact a lawyer who practices in the field of copyright law to determine whether the particular issues of concern are lawful and/or appropriate given the current state of the law.

### Copyright as Intellectual Property

Intellectual property rights include trademarks, copyrights, patents, and trade secrets. These intellectual property rights share a common characteristic in that the rights granted are intangible; there is no physical embodiment of such rights that can be provided to another to transfer ownership of these rights. For example, a plastic chair is a physical asset and is personal property, whereas the method of manufacturing and assembling the chair is intellectual property. Rights in intellectual property are

secured by adherence to various legal mechanisms that have been adopted and used nationwide since the ratification of the Constitution. However, the United States was not the first country to recognize intellectual property rights, and at present the vast majority of foreign countries provide similar and complementary protection schemes.

The desire for intellectual property protection in the United States originated during the Constitutional Conventions. The Founding Fathers debated to what extent various types of monopolies should be permitted in their new nation. They decided to distance themselves from some of the practices of England, one of which was the monarchy's practice of granting valuable monopolies to produce certain well-known items throughout the British Empire. Such monopolies did not encourage the development of new technologies or provide enhanced rights to the citizenry; instead, they provided certain select citizens who were friends of the monarchy with financial windfalls by giving them protection from competition. England altered some of its long-standing monopolistic practices in 1710 when Parliament enacted the Statute of Anne. This statute was intended to limit the perpetual rights of publishers to a fixed number of years, after which other publishers could produce the work.

The Founding Fathers ultimately agreed that Congress should have the authority to promulgate legislation to

protect works and inventions. Article I, Section 8, Clause 8 of the U.S. Constitution provides that “Congress shall have Power . . . [t]o promote the Progress of Science and useful Arts, by securing for limited Times to Authors and Inventors the exclusive Right to their respective Writings and Discoveries.” This clause provided Congress with a constitutional basis for the development of federal copyright and patent law. The Founding Fathers intended these rights to spur development of new ideas and creations by providing creators with a financial incentive to make such developments. However, these rights are not without limitation in that ultimately consumers must benefit from the provision of the additional rights to the authors and inventors. The balance between the right of authors and inventors to profit and the consumers to receive a benefit as a result of the right is a key element that Congress considers when altering the scope of protection for creations and inventions.

Copyright law fits in the scheme of intellectual property rights by enabling authors to protect their particular manner of expressing an idea. Examples of works in the digital realm that are subject to copyright protection include digital photos, Web sites, and e-books. Patent law, the intellectual property scheme most similar to copyright law, protects the underlying applied idea irrespective of its expression in a particular embodiment. Examples of various inventions that are subject to patent protection include Internet shopping carts, methods of processing digital images, and microprocessor improvements.

Trademark law enables consumers to identify and distinguish the products and services offered from one source to that offered by another and protects against consumer confusion by use of a device, such as a mark. Examples of marks that are subject to trademark protection include COCA-COLA® soft drink, YAHOO!® Internet services, and EXPRESS PERSONNEL SERVICES® employment and personnel services. Trade secret law enables persons to protect information from being taken without authorization so long as access to the information is limited. Examples of information that is subject to trade secret protection include customer lists, the names of key employees, and new product development information that has not yet been made public.

Copyright law has significantly evolved since the passage of the first Congressional set of copyright laws in 1790. Congress passed substantial revisions to the Copyright Act in 1831, 1870, 1909, 1976, and 1998 to reflect technological advances and changes in the scope of protection. Copyright law continues to adapt to the changing environment of computers and the Internet and is likely to undergo further development over the coming years as a result. Nonetheless, this chapter should provide a strong basis for understanding the basic concepts of copyright law, as well as the current state of the law.

## Subject Matter of Copyright

Before the Copyright Act of 1976, copyright protection for a particular work was based on when the author first made his or her work available to the public by publishing it. Prior to publishing, the work was subject to a so-called common law copyright under the Copyright Act of 1909.

By refusing to publish, the author had unlimited rights at common law to control the work so as to prevent others from utilizing it without permission. After publishing, the common law copyright was extinguished, and the statutory copyright (i.e., under the 1909 Act) governed the copyright rights in the work to which the author was entitled. However, under the 1976 Act copyright protection begins upon fixation in a tangible form as opposed to publishing. Despite the change in law, the 1909 Act is still relevant because works that entered the public domain name before the effective date of the 1976 Act (i.e., January 1, 1978) may not be protected thereunder.

## COPYRIGHT REQUIREMENTS

### Introduction

For an author to have a valid copyright in a particular work, the work must (1) be original, (2) remain fixed in a tangible medium of expression, and (3) have involved a minimum degree of creativity. For example, if the students in a classroom each drew a representation of the St. Louis Arch on a piece of paper, each would have a copyright in their respective drawings regardless of their artistic abilities. The aforementioned requirements for having a valid copyright are explained in greater detail in the sections below.

### Originality

Copyright protection under the 1976 Act extends to original works of authorship that are fixed in a tangible medium of expression. To be protected, the creation must be an original work of the author, originating from the author claiming copyright, and not copied from another source.

There are several significant aspects of the originality requirement. Artistic merit is irrelevant to the ability to copyright the work. Without such a limitation, only works that were judged to have merit (by the Register of Copyrights) would be imbued with protection, and other such works deemed unworthy would leave the author with no such rights. This limitation would thereby encourage various types of works while discouraging others that could be unrecognized masterpieces or otherwise significant to a smaller class of people. Ultimately, appointing a person or an agency to distinguish “good works” from “bad works” is unnecessary because the public buys or supports what it likes and ignores that which it does not. As the Supreme Court stated in *Bleistein v. Donaldson Lithographing Co.* (1903),

It would be a dangerous undertaking for persons trained only to the law to constitute themselves final judges of the worth of pictorial illustrations, outside of the narrowest and most obvious limits. At the one extreme some works of genius would be sure to miss appreciation. Their very novelty would make them repulsive until the public had learned the new language in which their author spoke. It may be more than doubted, for instance, whether the etchings of Goya or the paintings of Manet would have been sure of protection when

seen for the first time. At the other end, copyright would be denied to pictures which appealed to a public less educated than the judge. Yet if they command the interest of any public, they have a commercial value—it would be bold to say that they have not an aesthetic and educational value—and the taste of any public is not to be treated with contempt. It is an ultimate fact for the moment, whatever may be our hopes for a change. That these pictures had their worth and their success is sufficiently shown by the desire to reproduce them without regard to the plaintiffs' rights.

In addition, the underlying idea of the work is not subject to copyright protection. Copyright law does not provide a monopoly on an idea (e.g., the process of formatting a digital image), but rather on the expression of that idea by a particular author (e.g., the way a programmer implements his or her process of formatting a digital image). Accordingly, two different authors could write stories about the friendship and similarities between a computer scientist who becomes a patent attorney and his friend who is an ambitious and famous rock drummer, and each author would be entitled separately to copyright protection for his or her stories.

Works must have some minimal degree of creativity to be original, such that the author must contribute something to the work for it to be entitled to a copyright. The author must demonstrate substantial creative input or variation; the work must be more than a trivial (i.e., insubstantial) variation or a mere reproduction of prior works. Thus, a painter who makes a hand-painted reproduction of a prior painter's work would not be entitled to copyright protection; however, a second painter's drawing of the same subject matter using different lighting, different materials, and a different view would be entitled to copyright protection. Works that fail to have the minimal degree of creativity are denied copyright protection.

Originality is not equivalent to the novelty requirement of patent law, as it is a lower standard in which the author must only create the work independently. The ideas and themes contained in a particular work may have appeared in earlier works, but so long as the work originates with the author, copyright protection is still available. For example, consider how many movies include police officers performing the good cop/bad cop scenario. None of these movies can claim the exclusive rights to such a scenario and limit the others' expression of the same. In contrast, a first entity can infringe a second entity's patent even if the first entity was not aware of the second entity's patent and had created invention independently. The comparison of the two standards frequently arises, because computer software was generally not considered patentable until the *State Street Bank* case as discussed in the chapter, *Patent Law*, found elsewhere in this handbook.

With respect to computer software and other works that may use both copyright and patent law for protection, a copyright is more likely to be found valid in a court case than a patent because of the types of challenges available to third parties. With copyright law, copying another's work is needed to demonstrate copyright infringement,

whereas such information is not needed in patent law. However, the scope of protection with copyright is less in that it only protects against copying and not the underlying idea. Accordingly, companies typically seek both patent and copyright protection on their computer software.

## Works of Authorship

Works of authorship define the type of "writings," as used in the Constitution, for which copyright protection is available. Congress has broadly interpreted "writings" to define these categories for works of authorship: (1) literary works; (2) musical works, including any accompanying words; (3) dramatic works, including any accompanying music; (4) pantomimes and choreographic works; (5) pictorial, graphic, and sculptural works; (6) motion pictures and other audiovisual works; (7) sound recordings; and (8) architectural works. These categories were meant by Congress to be nonexclusive so as to encompass new technologies, which include computer software and the "look and feel" of a Web site.

## Unprotectible Works

Certain types of work are not subject to copyright protection because protection of those works would prevent others from using the underlying idea. To the extent that the expression cannot be delivered in another author's form, the expression is unprotectible because the underlying idea has merged with the expression. Accordingly, if there was only one way to implement an online shopping cart system, no one could claim exclusive copyright rights to such an implementation of the system, but yet the same system could be subject to patent rights. In addition, copyright protection does not extend to ideas, procedures, processes, systems, operational methods, concepts, principles, or discoveries, but rather is limited to the manner in which the creation is expressed by the author.

Works consisting of words and short phrases, such as names, titles, and slogans; familiar symbols or designs, mere variations of typographic ornamentation, lettering or coloring; and the mere listing of ingredients or contents are not subject to copyright law. For example, a list of ingredients for chocolate chip cookie mix is unprotectible. However, a book of recipes for various kinds of chocolate chip cookies may be entitled to protection as a compilation, and a particular recipe could also be subject to trade secret protection. Certain words and short phrases may still be subject to trademark protection. For example, LET'S GET READY TO RUMBLE® is a registered service mark used by Michael Buffer to promote various boxing matches.

Works that consist entirely of public domain information are also not protectible, including standard calendars, height and weight charts, tape measures and rulers, schedules of sporting events, and lists or tables taken from public documents or other common sources. Such works fail to demonstrate the more than trivial level of creativity that is necessary for copyright protection. However, even though a map consists of public information, the generation of such a map involves substantial selection

and arrangement and is therefore eligible for copyright protection. For example, Internet users cannot utilize a map generated from Yahoo! or Mapquest.com in their Web site without properly obtaining a license from these companies by following the terms and conditions posted on their respective Web sites.

Other works that are not subject to copyright include typefaces, ideas, plans, methods, systems, or devices, as distinguished from the particular manner in which they are expressed or described in a writing. Thus, a translation of an existing work to another format or another language is ineligible for copyright protection as a work of a new author, whereas copying the underlying idea but utilizing new expression is eligible for such protection. However, the utilitarian aspects of such creations are protectible under patent law, such as a system for communicating digital information over a network.

Blank forms, such as time cards, graph paper, account books, diaries, bank checks, scorecards, address books, report forms, order forms, and the like, which are designed for recording information and do not in themselves convey information, are also not subject to copyright protection. The underlying facts and the methods of recording information are not protectible, but the textual information that accompanies the blank forms if significant enough may have enough originality and creativity to make the work subject to copyright protection.

## Fixation

Works must be fixed in a tangible medium of expression to be protected under the Copyright Act. Without the fixation requirement, it would be difficult to determine what a particular author considered to be his or her work. In addition, the Copyright Office would be unable to review and consider whether a work should be entitled to a copyright registration. Material objects that qualify as media of expression include canvas, paper, audio and video cassettes, DVDs, CDs, and computer disk drives.

Works must be embodied in a tangible form that is “sufficiently permanent or stable to permit it to be perceived, reproduced, or otherwise communicated for a period of more than transitory duration.” Accordingly, a digital image that is electronically transmitted over a computer network and is never retained in a storage medium is not subject to copyright protection. The requirement for fixation is met when the work can either be perceived directly or with the aid of a machine or other device. Unfixed works, such as extemporaneous utterances, unchoreographed dance performances, and unwritten jazz and musical performances, are all subject to common law copyright and are not covered under the federal Copyright Act because they do not meet the fixation requirement. However, when these works are recorded they may then be eligible for copyright.

## TERM OF COPYRIGHT

### Background of Term

The author and the author’s heirs enjoy a period of exclusivity in which they can reap the financial rewards from the author’s creation of the work. However, the length of

the copyright per the Constitution is only for a “limited” time. Upon expiration of the term of the copyright, the work is dedicated to the public, which is then free to use it without authorization from or compensation to the author.

### Term Under the 1909 Act

Under the 1909 Act, the duration of the copyright for published works was 28 years, with a single 28-year renewal term, for a maximum of 56 years. The duration under the 1909 Act was set with the intention that the author would be able to have exclusive rights to the work during his or her lifetime. Works that were not published were subject to common law copyright, and the authors (and the author’s heirs) could indefinitely protect the work from copying by refusing to publish the work. If the work was ultimately published, its limited period of protection was the aforementioned two terms.

### Term Under the 1976 Act

Since the adoption of the 1976 Act, works that are fixed in a medium of expression are protectible under statutory copyright, regardless of whether the work is published or unpublished. The term for such works under the 1976 Act was for the life of the author plus 50 years; for anonymous and pseudonymous works and for works made for hire the term was for 75 years from publication or 100 years from creation, whichever expired first. Accordingly, the term under the 1976 Act was meant to enable the author to have exclusive rights during his or her lifetime and for the next generation. However, the term was extended by Congress in 1988, as described below.

### Sonny Bono Copyright Term Extension Act of 1998

The passage of the Sonny Bono Copyright Term Extension Act of 1998 (the Sonny Bono Amendment) extended the terms in the 1976 Act by 20 years, not only for newly created works but also for works already subject to the previous terms. Upon passage, critics complained that the Sonny Bono Amendment’s retroactive effect would effectively prevent a plethora of works from entering the public domain name for an additional 20 years.

The Sonny Bono Amendment was challenged in a series of court decisions resulting in the 2003 Supreme Court case of *Eldred v. Ashcroft*. In this case, the petitioner asserted that the Sonny Bono Amendment was unconstitutional under the Copyright Clause because it extended the duration of the copyright for preexisting works, as opposed to only newly created works. The Court ruled that the amendment was constitutional because (1) the precise duration of a federal copyright has never been fixed at the time of the initial grant, (2) Congress has routinely applied new definitions or adjustments of the copyright term to both future works and existing works not yet in the public domain, and (3) the amendment did not create a perpetual copyright.

The effect on consumers of this ruling is that few works will enter into the public domain for the next 20 years, thereby preventing people such as Eldred from making

such works available over the Internet for free. Copyright owners assert that consumers will receive additional benefits because copyright owners are able to reap financial rewards over a longer time period. Despite the courts' allowance of the Sonny Bono Amendment to stand, unlimited extensions for preexisting works still would appear to violate the Constitutional mandate that protection for works only be awarded for a limited time.

## FORMALITIES

### Copyright Notice

The accession by the United States to the Berne Convention in 1989 removed the requirement that works must contain a notice of copyright. Works protected by copyright may now optionally contain a notice of the copyright on publicly distributed copies. When used, the Copyright Act dictates that the form of the notice comprise three elements: (1) the symbol © (the letter C in a circle), or the word "Copyright" or the abbreviation "Copr."; (2) the year of first publication of the work; and (3) the name of the owner of the copyright in the work. For example, the copyright notice used with the DVD movie, "The Usual Suspects," is © 1996 Polygram Video.

The copyright notice, if affixed, must be done so in a manner and location to provide a person with reasonable notice of the copyright. Although notice of the copyright is optional on works after the accession to the Berne Convention, its inclusion in a copyright infringement case where the defendant had access to the work effectively eliminates the defendant's innocent infringement defense as described in greater detail below. For works prior to the accession to the Berne Convention, the copyright can be lost if the notice was omitted and the omission was not properly cured. Accordingly, it behooves most authors to include copyright notices on their works. For example, the author of a particular Web site can place a suitable copyright notice at the bottom of each of the Web pages by using footers on every page.

### Registration with the Copyright Office

To have a copyright in a work, it is not a prerequisite to register the copyright with the Copyright Office. Rather, copyright is established upon fixation in a tangible medium of expression so long as the underlying work is original. Registration of a copyright for a work may occur at any time. However, registration is a prerequisite to obtaining statutory damages, putting third parties on constructive notice of the copyright registration, and having a *prima facie* presumption of validity of the copyright. Because damages are often difficult to prove in copyright infringement suit, the ability to recover statutory damages not only greatly benefits the plaintiff's case but also increases the likelihood of a favorable settlement.

The Copyright Office provides various forms to enable copyright owners to register their copyrights: form TM for nondramatic literary works, form PA for works of performing art, form SR for sound recording works, form VA for works of visual arts, and form SE for serial works, including newspapers, magazines, newsletters, annuals, and journals. All these forms are available

for free download at the Copyright Office Web site at <http://www.copyright.gov>. Each form generally is a double-sided page and often includes the option of providing instructions on additional pages. Despite the apparently simplicity of the documents, issues including authorship and ownership of the work can often confuse a layperson and cause him or her to complete these forms incorrectly. The author urges that persons seeking to register their works first consult an attorney who practices in the field of copyright law prior to filing.

## OWNERSHIP

### General Ownership

Copyright ownership provides its owner with various exclusive rights as described in greater detail below. Ownership differs from a license, as a license may only provide its user with a limited right to use a particular copy in possession of the user; for example, the usage may be for a limited time, within a set geographical area, or in a certain manner. Ownership traditionally vests with the author or jointly among a group of authors, and assignment of copyright is possible.

### Work Made for Hire

One of the fundamental issues in copyright law for companies is whether a worker is the author of a particular work that was created. Unlike patent law in which inventorship cannot be altered based on employment or agreements, authorship of a particular work may vest with another, depending on the nature of the relationship between the worker and the employer and whether an agreement governs the creation of the work. If a work is considered a *work made for hire*, the employer will be considered the actual author of the work instead of the employee who created the work. For example, the work made for hire issue frequently arises when companies hire outside developers to create a Web site or write code for a computer program on behalf of the company. When the company wants to modify the Web site or distribute the software program and the developer objects without the payment of additional fees, the company frequently learns that it did not have all rights that it had anticipated in the particular work. Companies often rely on the faulty logic that if they paid a lot of money for the work, then they must own all rights to it. However, that is not a legitimate basis for determining whether a work qualifies as a work made for hire.

A work made for hire is defined differently for employees and nonemployees (i.e., contractors). For an employee's work to be considered to be a work for hire, the work must be prepared within the scope of the employee's employment. For a nonemployee, the work must be (1) specially ordered or commissioned; (2) for use as a contribution to a collective work, a part of a motion picture or other audiovisual work, a translation, a supplementary work, a compilation, an instructional text, a test, answer material for a test, or an atlas; and (3) in a written instrument signed by the parties that states the work shall be considered a work made for hire.

With employees, the key question is whether the work is within the scope of employment. If so, the work is deemed authored by the employer, and the employer will have all exclusive rights associated with the work. If the work falls outside the scope of employment, the work is deemed authored by the employee, and the employer will simply have a license to use the particular embodiment of the work without the exclusive rights associated with the work. Under the 1909 Act, whether a worker was considered an employee was based on the traditional employment relationship. However, under the 1976 Act, the determination as to whether a worker is an employee was modified as discussed in *Cnty. for Creative Non-Violence v. Reid* (1989) below.

With nonemployees, the first issue is whether the work is specially ordered or commissioned. Thus, purchasing an “off the shelf” object at a store cannot be considered a work made for hire. The second issue is whether the work falls within the defined statutory classes, which include contributions to collective works, parts of a motion picture or other audiovisual work, translations, supplementary works, compilations, instructional texts, tests, answer material for tests, and atlases. If the work falls outside these defined classes, such as is the case with computer software, it cannot be considered a work made for hire. The third issue is whether there is a properly written agreement between the parties that the work shall be considered a work made for hire. Without such a written agreement, the work will fail to qualify as a work made for hire.

In *Cnty. for Creative Non-Violence v. Reid* (1989), the Supreme Court considered whether James Earl Reid, an artist, or the Community for Creative Non-Violence (CCNV), an organization that hired Reid to produce a sculpture, owned the copyright in a sculpture. Reid agreed to donate his services to create the sculpture, and CCNV paid for the materials. However, there was no written agreement between the parties, and copyright ownership was not discussed. When the parties disagreed on how the work should be preserved and presented, communication between the parties broke down, and a lawsuit ensued.

In this case, the Supreme Court acknowledged that the copyright in a work initially vests in the author or authors of a work, subject to the important work made for hire exception. This exception provides that “the employer or other person for whom the work was prepared is considered the author’ and owns the copyright, unless there is a written agreement to the contrary.” Because a sculpture is not specifically listed within the class of specially commissioned works included in the definition of work made for hire, the Court first considered whether an employee within the scope of employment made the sculpture.

The Court held that the author is an employee under the common law understanding of agency law. The factors that the Court considered to support this ruling include “the hiring party’s right to control the manner and means by which the product is accomplished[,]... the skill required; the source of the instrumentalities and tools; the location of the work; the duration of the relationship between the parties; whether the hiring party has the right to assign additional projects to the hired party; the extent of the hired party’s discretion over when and how long

to work; the method of payment; the hired party’s role in hiring and paying assistants; whether the work is part of the regular business of the hiring party; whether the hiring party is in business; the provision of employee benefits; and the tax treatment of the hired party.”

Despite the apparent definiteness that work made for hire may seem to provide, circumstances with workers change that could affect whether a particular worker is still considered an employee. In addition, there may be questions as to whether a particular work is within the scope of the employee’s employment. Therefore, it is always a best practice to create an employment agreement that clearly defines the scope of the employee’s employment and a fallback assignment clause that provides that works will be assigned to the employer if they fail to qualify as a work made for hire.

## RIGHTS GRANTED

### Exclusive Rights

The copyright laws of the United States grant the author of a copyrighted work certain exclusive rights in the work, including the right to (1) reproduce the copyrighted work in copies or phonorecords; (2) prepare derivative works based upon the copyright work; (3) distribute copies or phonorecords of the copyrighted work to the public; (4) publicly perform literary, musical, dramatic, and choreographic works, pantomimes, and motion pictures and other audiovisual works; (5) publicly display literary, musical, dramatic, and choreographic works, pantomimes, and pictorial, graphic and sculptural works, including individual images from a motion picture or other audiovisual work; and (6) publicly perform sound recordings by means of a digital audio transmission. Of the six rights, the first two are infringed by an act performed publicly or privately, whereas the remaining four are infringed only when occurring publicly.

The copyright owner can transfer or license these rights in full or in part to others. The language used to provide these rights to another should be unambiguous so that there is no dispute as to what rights are being transferred or licensed, and a transfer of copyright rights must be in writing to be valid. For example, a court found that a transfer of “all right, title and interest” to computer programs and software was not merely a license to use the software, but rather a transfer of the copyright embodied in the computer programs and software.

### Public Performance

Under the Copyright Act, performing a work publicly means either to (1) perform or display it at a place open to the public or at any place where a substantial number of persons outside a normal circle of a family and its social acquaintances are gathered or (2) to transmit or otherwise communicate a performance or display of the work to a place previously specified or to the public, by means of any device or process, regardless of the place and time it is received by the public. Thus, the presentation of a movie at a movie theater and a performance of a song at a music club are both considered public performances. With respect to the Internet, a Web conference between two

parties would not be considered a public performance, but a worldwide WEBEX presentation to clientele would be considered a public performance.

For-profit performances of works require a license from the copyright owner. Such performances include those for which an admission fee is charged or performances that enhance the related profit-making activity of the entity. Nonprofit performances also require a license unless the performance is exempted by the fair use doctrine or the public performance is exempted under the Copyright Act. The exempted performances include some teaching activities and religious assemblies when no admission is charged or when the profit is used for educational, religious, or charitable purposes, unless the public performance is objected to by prior written notice. Public performances occur in places that are open to the public or where a substantial number of persons outside the normal circle of family and social acquaintances are gathered.

The Copyright Act does, however, provide some limitations for certain types of performances that are not infringements of copyright. These performance include performance or display of a work by instructors or pupils in face-to-face meetings and in certain proscribed circumstances: such performances include digital transmissions between such persons, performance of a nondramatic literary or musical work or of a dramatico-musical work of a religious nature or display of a work in the course of services at a place of worship or other religious assembly, and performance of a nondramatic literary or musical work otherwise than in a transmission to the public without any purpose of direct or indirect commercial advantage and without payment of any fee in certain proscribed circumstances.

## Public Display

Public display is the copyright owner's exclusive right to show other people the copyrighted work. The receipt of a fee is irrelevant to whether a party displaying the work constitutes a public display. An example of when the copyright owner's exclusive right to display a copyrighted work publicly is violated includes when Internet users are allowed to view copyrighted images from a Web site upon the payment of a fee without a license from the owner of the copyrighted image and when preview clips consisting exclusively of scenes taken from full-length copyrighted feature films are presented on a Web site.

## Reproduction

*Phonorecords* are defined as material objects in which sounds, other than those accompanying a motion picture or other audiovisual work, are fixed by any method now known or later developed, and from which the sounds can be perceived, reproduced, or otherwise communicated, either directly or with the aid of a machine or device.

The exclusive right of reproduction allows the copyright owner to prevent others from reproducing the work in the form of a copy or phonorecord. Copies are defined broadly under the Copyright Act and include all material objects, excluding phonorecords, in which a work is fixed by any method now known or later developed and from

which the work can be perceived, reproduced or otherwise communicated, either directly or with the aid of a machine or device. Copies include downloading reproduced thumbnail and full-sized images taken from an Internet newsgroup to a user's hard drive.

## Distribution and the First Sale Doctrine

Copyright owners are provided with the exclusive right to distribute copies of phonorecords of their works, which includes posting a work on a Web site for download by Internet users. The distribution right is limited to the first transfer of ownership, because under the Copyright Act the ownership of the copyright is distinct from ownership of a material object in which the copyright is embodied per the First Sale Doctrine as described in greater detail below.

Under the *First Sale Doctrine*, the copyright owner's right to control distribution is exhausted by the first sale of each lawfully made copy. The owner of such a copy has the right of resale or transfer, and the copyright owner has no control over resale or transfer of a particular copy. Mere possession of the copyright object by rental, lease, loan, or otherwise is insufficient to trigger first sale rights. For example, as discussed in *Adobe Sys. v. One Stop Micro, Inc* (2000), a copyright owner does not forfeit the right of distribution by entering into a distribution agreement by which it licenses off-the-shelf software; the owner can therefore prevent an educational version of a software program from being resold as a full retail version.

## TYPE OF WORK

### Derivative Work

A copyright owner has the exclusive right to create or authorize the creation of a work based in part on his or her underlying work. A *derivative work* is a work based upon one or more preexisting works in which the original work is recast, transformed, or adapted. The derivative work copyright protects only new materials contributed by the author and does not affect or enlarge the scope, duration, ownership, or subsistence of any copyright protection in the preexisting material. Examples of various types of derivative works include translations, musical arrangements, dramatizations, fictionalizations, motion picture versions, sound recordings, art reproductions, abridgments, and condensations. Cases involving derivative works include copying and using specific functions from a preexisting computer software in a new software program, creating a descrambler to obtain access to otherwise protected video programming content by copying portions of the original access program, and utilizing portions of source code in a computer game to create a new computer game. In addition, a work consisting of editorial revisions, annotations, elaborations, or other modifications, which, as a whole, represent an original work of authorship, is a derivative work.

### Joint Work

A *joint work* is a work prepared by two or more authors with the intention that their contributions be merged into inseparable or interdependent parts of a unitary

whole and for which the intent to merge the work into a unitary whole must exist at the time of creation. The second author must contribute more than the suggestions of ideas and minor bits of expression, as each author's components must be independently copyrightable. The joint owners can independently exploit the work without consent of the other joint owners, but must account to the other joint owners for such exploitation. The duration of the copyright is the life of the last author to die plus 70 years.

### Composite Work

A *composite work* is a work prepared by two or more authors without the intent to merge their contributions into a unitary whole. Each part of the composite work must be licensed and terminated separately, and each part has its own copyright duration.

### Compilation

A *compilation* is a work formed by the collection and assembling of preexisting materials or of data that are selected, coordinated, or arranged in such a way that the resulting work as a whole constitutes an original work of authorship. Therefore, it is not the underlying materials or data that are protected by copyright, but rather the selection, coordination, or arrangement of the work that is entitled to a copyright. Thus, although a standard program call or database read is not subject to copyright protection, the series of such calls and reads in the context of a computer program may be subject to copyright protection for the work as a compilation.

In *Feist Publications, Inc. v. Rural Telephone Service Co., Inc.* (1991), the Supreme Court addressed whether a telephone directory was subject to copyright protection. Rural Telephone Service Company issues an annually updated telephone directory comprising both white pages and yellow pages for northwest Kansas. Feist Publications publishes telephone directories that cover a wider area. Both companies distribute their directories free of charge and compete vigorously for yellow page advertisements. Of further significance is that Rural Telephone had access to subscriber information pursuant to its monopoly and was required to issue a directory as part of its monopoly agreement; however, it refused to license the directory information to Feist Publications so that it could maintain a monopoly on yellow pages listings. Feist Publications then copied the listings without authorization from Rural Telephone and a lawsuit ensued.

In its decision, the Supreme Court balanced the tensions between the two established propositions of the law that "facts are not copyrightable [and that] . . . that compilations of facts generally are." The Court found that the facts did not meet the requisite level of originality because the "first person to find and report a particular fact has not created the fact; he or she has merely discovered its existence." The Court considered that the author of a compilation "chooses which facts to include, in what order to place them, and how to arrange the collected data so that they may be used effectively by readers." The Court then held that the copyright protection of the compilation

only extended to the components of the work that are original to the author and that others were free to copy the facts so long as any expression used to express the facts was not copied. Accordingly, regardless of the effort expended, copyright does not protect generic selection, order, or arrangement such as is used with telephone white pages.

## COPYRIGHT INFRINGEMENT

### Civil Infringement

When someone violates any one of the author's exclusive rights, the person commits *copyright infringement*. Infringement may be found for both intentional and unintentional (i.e., innocent) acts, such as subconsciously copying a song written by another. The owner of the copyright is entitled to various remedies including an injunction to stop the infringing behavior and actual or statutory damages. The statute of limitations for bringing a civil action is 3 years.

To establish infringement, a party must establish ownership of a copyright and that there was impermissible copying. Ownership of the copyright is established by presenting the registration certificate received from the Copyright Office. As for copying, infringement is proven easily when actual portions of the work are copied. However, usually infringement is shown through circumstantial evidence, such as by the combination of a substantial similarity of the copied work to the original work and access by the author to the original work.

### Willful Infringement

In *Playboy Enters. v. Webworld Inc.* (1997), defendant Webworld had implemented software that scoured Internet newsgroups for adult-oriented images and posted them on its Web site for viewing by paying customers. Playboy filed suit over images that had been taken from its magazines and posted on Webworld's Web site. The district court found in favor of Playboy on the grounds of copyright infringement, as the posted images were found to violate Playboy's exclusive rights for reproducing, distributing, and displaying the copyrighted images. In addition, the court found that Webworld had acted willfully despite its implementation of a "compliance program" because it copied the images from a newsgroup whose title "centerfolds" suggested that it might have copyrighted works in it. In addition, after receiving notice of infringement from Playboy, it continued to obtain infringing images from the same newsgroup. Accordingly, Internet users who receive notice of an accusation of copyright infringement should take the notice seriously and consult their attorney to determine what, if any, remedial actions should be taken.

### Criminal Infringement

Any person who infringes a copyright willfully may be punished criminally for up to 10 years in prison and fined. Conduct that does not give rise to civil copyright infringement (i.e., money damages) cannot give rise to criminal

infringement. The statute of limitations for the government to bring such a criminal action is 5 years.

Historically, there has been an additional requirement for criminal infringement. For an infringement to rise to a criminal level, it must be (1) for purposes of commercial advantage or private financial gain, or (2) the reproduction or distribution during any 180-day period of one or more copies or phonorecords of one or more copyrighted works must have a total retail value of more than \$1,000. However, the 1997 NET Act amended the Copyright Act to make the showing of intent to create a profit to be irrelevant.

### Compensatory and Statutory Damages

The copyright owner is entitled to recover the actual damages suffered as a result of the infringement, as well as any additional profits of the infringer. As an alternative to seeking actual damages and profits, the copyright owner can seek statutory damages in a lawsuit at any time before a final judgment is rendered. Statutory damages are awarded per work and range from \$750 to \$30,000 as the court considers just, unless there is innocent infringement or if the infringer is a nonprofit in which case the amount is reduced to \$250. Finally, statutory damages may be increased to \$150,000 if the infringement is willful.

### Vicarious Infringement

*Vicarious infringement* occurs when a defendant has the legal right and physical ability to supervise the infringing activity and has a direct financial interest in those activities. Accordingly, if vicarious infringement is found, the defendant can be liable as though he or she were the party actually committing the infringement. In a typical case involving vicarious infringement, a music club owner is found liable when he or she hires a band that performs various works and the right holders to the works are not compensated.

### Contributory Infringement

*Contributory infringement* is found when a party with knowledge of the infringing activity induces, causes, or materially contributes to the infringing conduct of another. The contribution must be more than the mere passive providing of premises, the supply of staple items of commerce, or the supply of material that can also be used for lawful activities. When contributory infringement is found, the defendant can be liable as though he or she were the party actually committing the infringement. For example, the storage on a defendant's system of infringing copies of copyrighted image files and retransmission to other servers do not constitute a direct infringement by a bulletin board system (BBS) operator of the exclusive right to reproduce the images where such copies are uploaded by an infringing user; however, those actions may be considered contributory infringement, notwithstanding defenses available to the BBS operator under the Digital Millennium Copyright Act (DMCA). The chapter in this *Handbook* on the DMCA describes more fully Congress's

response to the problems associated with transmitting digital information over global networks.

## LIMITATIONS ON EXCLUSIVE RIGHTS

### Fair Use

The exclusive rights of a copyright owner are subject to certain limitations and exceptions under which some acts that would otherwise be considered an infringement are exempted under the doctrine of *fair use*. Whether a particular use of a work is fair depends on a balancing of four factors: (1) the purpose and character of the use, including whether such use is of a commercial nature or is for nonprofit educational purposes; (2) the nature of the copyrighted work; (3) the amount and substantiality of the portion used in relation to the copyrighted work as a whole; and (4) the effect of the use upon the potential market for or value of the copyrighted work. Whether a use qualifies as fair is determined by balancing the exclusive rights of the copyright owner against the rights of another to use the copyright material in a reasonable manner without the owner's consent. For example, the copying by a professor of an article from a newspaper for in-class distribution is much more likely to be found a fair use than the commercial copying and reselling of copyrighted music.

The balancing test for fair use is fact specific and requires a case-by-case analysis. Because the finding of whether a use is fair turns on the facts of each particular case, no bright line test is available to determine whether such use will be considered fair.

The fair use doctrine thereby permits courts in limited circumstances to prevent the stifling of creativity brought about by rigid interpretation of the Copyright Act. Ultimately, this means that cases will test the bounds of whether a certain use qualifies for a fair use or whether it is an infringement. Such decisions can have a significant impact on the markets available to a certain product, such as portable digital music players.

Fair use allows certain uses of copyrighted works for such purposes as criticism, commentary, news reporting, teaching, scholarship, and research.

With respect to the first factor of the fair use test—the purpose and character of the use—courts typically are less willing to deem a use fair when it is commercial and profit seeking in nature. Yet, uses involving nonprofit educational purposes, such as copying textbooks for students, can still be found to be infringing as such use would destroy the market for the textbooks and eliminate the incentive for authors and publishers to update their works.

Courts often favorably consider the first factor of the fair use test when the use of a work is transformative, such that the use of the work adds something new; alters the original work with new expression, meaning, or message; or is otherwise for a different or further purpose than the original work.

With regard to the second factor—the nature of the copyrighted work—the law generally recognizes a greater need to disseminate factual works than creative works, and therefore a finding of fair use is more likely with a factual work. In addition, the use of published works is

more likely to qualify as a fair use because the first appearance of the artist's expression has already occurred.

For the third factor—the amount and substantiality of the portion used—it inherently makes sense that the more portions of a work that are used, whether qualitatively or quantitatively, the less likely it is that the use of such portions will be considered fair. However, taking essential parts of the original work, even when they are only a small portion of the original work, can still be found to be substantial when they are at the heart of the work. In contrast, in some cases, wholesale copying can still be considered fair use, such as copying digital images in their entirety in a reduced format for an online image search engine.

With respect to the fourth factor—the effect of the use on the market or value of the work—when the use is a commercial use, market harm is presumed and must be rebutted by the defendant. When market harm cannot be presumed, the copyright holder has the burden of proof to demonstrate the market effect. Market harm would occur when the new use of the work would become widespread, adversely affecting the market for the copyrighted work, such that it would substitute for the original. The court may also consider possible adverse effects on the potential market for derivative works.

In *Sony Corp. of America v. Universal City Studios, Inc.* (1984), the Supreme Court addressed whether the manufacture and sale of video tape recorders (VTRs) by Sony violated any copyright rights of Universal City Studios, the owner of a number of copyrights on broadcast television shows. Universal City Studios sought to find Sony liable for vicarious and contributory infringement in that Sony “sold equipment with constructive knowledge of the fact that its customers may use that equipment to make unauthorized copies of copyrighted material.” The Court applied the staple article of commerce doctrine, by which the sales of copying equipment “does not does not constitute contributory infringement if the product is widely used for legitimate, unobjectionable purposes . . . [or if] . . . it [is] . . . capable of substantial noninfringing uses.” The Court also considered whether unauthorized time-shifting was fair use.

The Court found that the predominant use of the VTRs was to time-shift programming, such that a viewer could watch a televised program at a later and more convenient time because he or she was unable to view the program when broadcast. The Court ultimately ruled that VTRs were capable of a substantial noninfringing use and that home time shifting is fair use, thereby enabling many companies to sell video tape records without concern of facing massive damages for copyright infringement.

The Ninth Circuit Court addressed whether reverse engineering was a fair use in *Sony Computer Entertainment, Inc. v. Connectix Corp.* (2000). Sony produces and markets Sony Playstation gaming units on which users play Sony PlayStation games. Connectix makes and sells a software emulator program called Virtual Game Station that enables computer owners to play Sony PlayStation games on their computers. Although the Virtual Game Station does not contain any of Sony's copyright material, in the process of producing Virtual Game Station Connectix repeatedly copied Sony's copyrighted BIOS so as

to determine how the Sony Playstations gaming units operated.

The Ninth Circuit found that “the methods by which Connectix reverse-engineered the Sony BIOS were necessary to gain access to the unprotected functional elements within the program.” The court ruled that the “copies made and used by Connectix during the course of its reverse engineering of the Sony BIOS were protected fair use, necessary to permit Connectix to make its non-infringing Virtual Game Station function with PlayStation games.” However, decisions by courts have held that such reverse engineering may still be a violation of an applicable license agreement such as where the right to reverse engineer was waived.

## Audio Home Recording Act of 1992

The Audio Home Recording Act of 1992 amended the Copyright Act to prevent the importation, manufacture, or distribution of digital audio recording devices and digital audio interface devices that did not conform to the serial copy management system (SCMS). The purpose of this Act was to prevent the making of digital copies of already copied works by most consumers and provided some recourse to copyright owners by providing them with royalty payments from the sale of digital audio records and digital audio media. Although the Act's provisions for digital audio tape recorders and associated media were not controversial, the Recording Industry Association of America's attempt to prohibit the distribution of MP3 players that did not read the SCMS code resulted in a lawsuit that ultimately decided the future availability and desirability of MP3 players in the United States.

In *Recording Indus. Ass'n of Am. v. Diamond Multimedia Sys.* (1999), the Ninth Circuit considered whether the Rio portable music player was a digital audio recording device subject to the restrictions of the Audio Home Recording Act of 1992. The court considered that with the Rio player the digital audio files had to be created on a hard drive of a personal computer, and not on the player itself. Ultimately the court found that both the Rio player and computers were not digital audio recording devices within the meaning of the act and that, even when used in combination, neither were required to recognize the SCMS code.

## File Sharing

In *A&M Records v. Napster, Inc.* (2001), the Ninth Circuit addressed, among other issues described in the DMCA chapter, whether persons who transmitted and received copyrighted digital music files over a computer network without authorization from the copyright owner were making a fair use of copyrighted music. With respect to the first factor in the fair use doctrine, the court found that the use was commercial, as the plaintiff demonstrated by showing that repeated and exploitative unauthorized copies of copyrighted works were being made to save the expense of purchasing authorized copies. The court determined that the copyrighted music was creative in nature, which cuts against a finding of fair use under the second factor. The court found that the third factor weighed against a finding of fair use because Napster

users transmitted and downloaded copyrighted music in its entirety as opposed to portions thereof. Finally, with regard to the fourth factor, the court concluded that Napster harmed the market in at least two ways: it reduced audio CD sales among college students and raised the barriers to plaintiffs' entry into the market for the digital downloading of music. Therefore, the court ruled that the users who transmitted and received copyrighted digital music files over the computer network were not making a fair use of the copyrighted music. Additional issues involving the foregoing case are discussed at length in the DMCA chapter with respect to Napster's contributory and vicarious infringement in light of the DMCA.

In addition, a Supreme Court case issued after the drafting of this chapter held that companies that were created for the purpose of facilitating copyright infringement cannot avoid being liable for infringement themselves.

## Quotations

Quotations from works can be made without consent of the author under the fair use doctrine, such as for new stories and historical analysis. However, the amount of the quotations cannot be unreasonably large and cannot destroy the marketability of the source by the copyright owner.

## Innocent Infringement

The innocent infringement defense, when invoked successfully by a defendant in a copyright infringement suit, reduces the amount of damages for which the defendant could otherwise be liable. To be successful, the defendant has the burden to prove that he or she was unaware of the copyright owner's copyright and had no reason to believe that the acts constituted copyright infringement. The copyright owner can eliminate the innocent infringer defense by marking copies or phonorecords of the copyrighted work with a copyright notice.

## CONCLUSION

Copyright law attempts to strike a balance between allowing authors to control and profit from their work while still providing the public with certain rights. Ultimately, the public benefits from copyright law because it encourages further creations and allows the public to enjoy the fruits of these creations. Copyright law will continue to face challenges with respect to computers and the Internet, and further significant changes to the law should be expected.

## GLOSSARY

**BBS** An electronic bulletin board system.

**Common law** Law that has not been enacted by a legislature, but rather has been derived and developed from judicial decisions.

**Compilation** A work formed by the collection and assembling of preexisting materials or of data that are selected, coordinated, or arranged in such a way that the resulting work as a whole constitutes an original work of authorship.

**Contributory Infringement** The knowing contribution to another's infringing activity.

**Derivative Work** A work based on one or more preexisting works where the original work is recast, transformed, or adapted.

**DMCA** The Digital Millennium Copyright Act.

**Fair Use** A use that would ordinarily violate an exclusive right, but is nonetheless found to be noninfringing and permissible.

**Infringement** Violating any of the exclusive rights of the copyright owner.

**Joint Work** A work prepared by two or more authors with the intention that their contributions be merged into inseparable or interdependent parts of a unitary whole.

**License** An authorization from the copyright owner to use one or more exclusive rights of a work; licenses are normally negotiated and recorded in a written document that includes a variety of other terms.

**Phonorecords** LPs, CDs, and cassette tapes.

**Public Performance** A performance or display at a place open to the public or at any place where there are a substantial number of persons outside a normal circle of a family and its social acquaintances, whether in person or by means of a digital transmission.

**Reverse Engineering** Determining the functional aspects of a software program by monitoring the input and output of the software program.

**RIAA** The Recording Industry Association for America ([www.riaa.org](http://www.riaa.org)).

**Statutory Law** Law that has been enacted by the legislature.

**VTR** Video tape recorders are Betamax video recorders as discussed in the Sony case, but also include standard video cassette records (VCRs).

**Work Made for Hire** A work that, despite being created by one author, is considered to be authored by another.

## INTRODUCTION

This chapter introduces the fundamental concepts of patent law, both in the United States and internationally, with some focus on software and Internet-related issues. Patents are exclusionary monopolies for a limited term, granted in exchange for inventors disclosing how to make or use their inventions. With the promise of such monopolies, inventors are encouraged to invent and thus reap the rewards made possible by the rights accorded. Competitors must either obtain a license to make or use a patented invention or discover new ways that circumvent a patented invention as defined by the patent claims.

Some have rejected the use of the word “monopoly” to describe patents. Regardless of whether one uses that term, certain rights are granted to the owner of a patent. For example, in the United States, the owner of a patent has the right to *exclude* others from making, using, selling, or offering for sale the invention in the United States, importing the invention into the United States, or importing into the United States something made by a patented process. Other countries convey similar rights for patents issued in those countries. What may not be obvious is that a patent does not grant its owner the right to make, use, sell, offer for sale, or import the patented invention. In fact, many patented inventions are improvements to existing patented work and, if made, used, or sold, would constitute infringement of the earlier patent.

## GENERAL CONSIDERATIONS

### Why Get a Patent?

There are many reasons why obtaining patent protection is beneficial, and the brief discussion presented here is not intended to be all inclusive. One reason for obtaining a patent is to protect one's intellectual property. That is, the

holder of the patent may be able to prevent competition by preventing others from taking advantage of the invention. Because of the patent, others may decide not to compete at all in the particular area or may decide to spend significant amounts of time and money developing processes or products that do not infringe on it. Alternatively, if both sides are willing, the patent holder may license all or part of the patent to another party for a fixed fee, a royalty, or some combination of the two. A license is basically an agreement between a licensor (patent holder) and licensee that the licensor will not sue the licensee for what would otherwise constitute infringement of some or all of the patent claims.

Another reason for obtaining a patent is more defensive. For example, company B may be reluctant to sue company A for infringement of company B's patent, if company B thinks that company A may countersue for infringement of company A's patents. Such a situation may result in cross-licensing between the two parties, in which each agrees not to sue the other for infringement of all or part of each other's patents.

Yet another reason for obtaining a patent, especially for start-up companies, is to attract investment. Investors like to know that intellectual property has been protected and exclusive rights are controlled, providing value in their investment. The existence of one or more patents (or even pending patent applications) may be an indication of a company's viability.

### Patent Term—How Long Does a Patent Last?

Patent protection begins on the day a patent is issued. Because of a change in law in 1994 to conform to the Uruguay Round of the General Agreement on Tariffs and Trade (GATT), when a U.S. patent expires depends on when the application was filed. Before the change in law, the term of a U.S. utility patent was 17 years from the issue

date. Now, however, any U.S. utility patents issuing from an application filed on or after June 8, 1995 are valid for 20 years from the priority date; that is, the date of the earliest application to which the application claims priority (the earliest filing date in a chain of continuation and divisional applications). Utility patents that were still in force on June 8, 1995, and applications filed before that date but still pending receive the best of both worlds (with regard to patent terms): either 17 years from the issue date or 20 years from the priority date, whichever is later. Various adjustments and extensions may be available under certain conditions, although a discussion of these conditions is beyond the scope of this chapter. The patent terms discussed above pertain to U.S. utility and plant patents. U.S. design patents expire after 14 years from the issue date.

In most other countries, a utility patent expires 20 years from the priority date.

### Types of Patents

In the United States, there are three types of patents: utility patents, design patents, and plant patents. Utility patents are the most familiar type. They may be obtained for “any new and *useful* process, machine, manufacture, or composition of matter, or any new and useful improvement thereof” (35 U.S.C. §101).

Design patents may be obtained for new, original, and ornamental designs for manufactured articles. A design patent protects the way an article looks, as depicted in the drawings. Design patents have a term of 14 years from the issue date. They may be obtained for computer-generated icons, including full-screen displays and individual icons. The U.S. Patent and Trademark Office’s (USPTO) *Manual of Patent Examining Procedure* (MPEP), section 1504.01(a) provides “Guidelines for Examination of Design Patent Applications for Computer-generated Icons” (see U.S. Design Patent D453,769 for an example of a design patent for a computer-generated icon). According to MPEP section 1504.01(a).1.A, to satisfy the manufactured article requirement, such an icon may be claimed as “a computer-generated icon shown on a computer screen, monitor, other display panel, or a portion thereof” or with similar language. The icon must also be fundamentally ornamental, rather than functional. Fonts may also be patented with design patents (for an example, see U.S. Design Patent D454,582).

The Plant Patent Act of 1930, now codified as 35 U.S.C. § 161, allows “plant patents” for plants that are reproduced asexually. Tubers, such as potatoes, are excluded (i.e., they are not patentable). To be patentable, a plant must have been found in an uncultivated state (e.g., *not* in a garden). A plant patent includes the right to exclude others from causing the plant to reproduce asexually or using, offering for sale, or selling the plant (or parts of the plant) in the United States, or importing the plant into the United States if it was asexually reproduced (see 35 U.S.C. §§ 161–164).

Despite the availability of plant patents, utility patents may also be obtained for both sexually and asexually reproduced plants (see *J.E.M. AG Supply Inc., dba Farm Advantage, Inc., et al. v. Pioneer Hi-Bred International, Inc.*,

1996). The requirements for obtaining a plant patent are more relaxed than those for obtaining a utility patent, however.

Outside the United States, many countries provide for patents that are not given full-blown examinations and that do not receive full-blown benefits. Germany, Spain, and France, for example, have “petty” (or “utility model”) patents. Australia has an “innovation” patent, and Indonesia has a “simple” patent. These patents are typically for shorter terms and may not be required to satisfy the nonobviousness standard.

## PATENT LAW IN THE UNITED STATES

### Constitutional Basis

The U.S. Constitution grants to Congress the power “to promote the Progress of . . . useful Arts, by securing for limited Times to . . . Inventors the exclusive Right to their respective . . . Discoveries” (Article I, Section 8, Clause 8). In accordance with this power, Congress has over time enacted several patent statutes. In particular, in 1952, the present patent law, codified under Title 35 of the United States Code (35 U.S.C.; available on the Web at [http://uscode.house.gov/title\\_35.htm](http://uscode.house.gov/title_35.htm)), was enacted, although it has been amended many times over the years.

### U.S. Patent & Trademark Office

Almost every country has a patent or intellectual property or industrial property office. In the United States, the USPTO (<http://www.uspto.gov>) processes patent applications and ultimately issues or grants patents. During the processing of an application (a process known as *patent prosecution*), the application is reviewed by an examiner who is familiar with the specific technology field of the invention described in the application. The examiner will reject one or more of the claims of the application if he or she feels that, when compared with prior art (existing knowledge possessed and/or information accessible by those in the subject technology field), there is nothing novel or nonobvious about the invention as claimed. The examiner may also object to the written description of the application if he or she feels that it does not satisfy the disclosure requirements of the statutes. Patent prosecution typically involves communications back and forth between the examiner and the inventor (or the inventor’s patent attorney or agent) in which the inventor or attorney clarifies how the invention is in fact novel and nonobvious in relation to the prior art and is disclosed adequately by the application.

Inventors can represent themselves before the USPTO. Alternatively, an inventor or the assignee to whom the inventor assigns ownership of an invention may use an attorney or agent registered to practice before the USPTO. Both patent attorneys and patent agents must have technical backgrounds in a science or engineering field and have taken and passed a registration examination administered by the USPTO. In addition, patent attorneys must have graduated from law school and be admitted to practice law in at least one jurisdiction, whereas patent agents are not attorneys.

## What Is Patentable?

An inventor may obtain a patent for “any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof” (35 U.S.C. §101). In a landmark U.S. Supreme Court case in which whether a live, human-made microorganism could be patented was at issue, the Supreme Court unequivocally stated that “anything under the sun that is made by man” is patentable (*Diamond v. Chakrabarty*, 1980).

What is not patentable? Generally speaking, laws of nature, physical phenomena, and abstract ideas per se are not patentable. For example, the Supreme Court stated,

“a new mineral discovered in the earth or a new plant found in the wild is not patentable. . . . Likewise, Einstein could not patent his celebrated law that  $E = mc^2$ ; nor could Newton have patented the law of gravity.” (*Diamond v. Chakrabarty*, 1980)

Of course, a practical application of some physical phenomena may be patentable. For example, although a new plant found in the wild is not patentable, its medicinal use may be. In *Diamond v. Chakrabarty* (1980), the Supreme Court clearly stated that even living things, in this case microorganisms produced by genetic engineering, are patentable. In fact, all that matters is whether the living matter is the result of human intervention.

In particular, Internet-related inventions are patentable and can be protected with method claims, apparatus claims, so-called Beauregard claims, embedded signal claims, and the like, all of which are discussed later in the chapter. Many Internet-related inventions are protected by “business method” patents.

## Business Methods

Prior to the *State Street Bank & Trust Co. v. Signature Financial Group, Inc.* (1998) decision by the Court of Appeals for the Federal Circuit (CAFC), there was some uncertainty as to whether methods of doing business were patentable. Although the invention claimed was technically a “machine” that implemented business methods, this decision is cited for confirming that indeed business methods themselves are patentable.

In the *State Street Bank* case, Signature was the assignee (owner) of U.S. Patent No. 5,193,056. The claimed invention was a system in which mutual funds pool their assets into an investment portfolio to take advantage of economies of scale in administering investments. State Street Bank had been negotiating a license with Signature Financial to use that invention. When negotiations broke down, State Street Bank sought a declaratory judgment that the patent was invalid because it described a business method. The court, however, concluded that business methods are patentable subject matter.

When is a method a business method? This is not always clear. For example, Amazon.com received a patent (U.S. Patent No. 5,960,411) for its one-click process. Although the invention has been labeled a method of doing business by some, Amazon itself has asserted that its one-click patent is not a business method patent.

The USPTO has established a classification system made up of more than 400 classes that are further divided into subclasses. Every application is assigned to a class and subclass according to the technology of the invention. In general, methods that fall into the USPTO’s Class 705 (“Data processing: financial, business practice, management, or cost/price determination”) are considered to be business methods. The first few subcategories of Class 705 include health care management; insurance; reservation, check-in, or booking display for reserved space; staff scheduling or task assignment; market analysis, demand forecasting or surveying; and so on; see <http://www.uspto.gov/web/patents/classification/USPC705/def5705.htm> for a complete list of Class 705 categories.

For those inventions that are considered to be business methods, some special rules apply both during prosecution of a business method patent application and with respect to infringement. Whereas most patent applications undergo examination by a single examiner, business method applications may be subjected to multiple reviews. Extra reviews were added in part as a response to numerous complaints made in the popular press and elsewhere that many business method patents were being issued on inventions that were not patentable.

Furthermore, accused infringers of issued business method patents have at their disposal an extra defense against the accusation that infringers of other types of patents do not have. For example, for most patents, if party A receives a patent for an invention and party B has been practicing the invention prior to issuance of the patent, party B must stop its practice or obtain a license once the patent is issued. After the *State Street* decision, however, Congress added Clause § 273 to Title 35 of the U.S. Code as part of the American Inventor’s Protection Act of 1999; this clause provides for “intervening rights” to protect parties who may not have applied for a business method patent based on the misconception that such patents were unobtainable. The details of § 273 are beyond the scope of this article, but basically it provides, in certain situations, a defense to an infringement claim for a party that was using the patented business method before the patent was issued.

## Requirements for Patentability

An invention must meet four basic requirements before it can be patented in the United States: the invention must be (1) patentable subject matter; (2) novel; (3) nonobvious in view of the current state of the art and with respect to a person knowledgeable or “of ordinary skill” in the art; and (4) useful.

Novelty is statutorily provided for in 35 U.S.C. § 102, which describes several conditions in which a patent may not be obtained: if the invention was known or used by others in the United States prior to the patent applicant’s date of invention (this could happen, for example, when two people separately invent the same invention, each unaware of the other’s activity or accomplishment) or if the invention has been patented or described in a printed publication anywhere in the world. “Printed publications” may include any information that is freely accessible via the Web, even though a Web page is not technically printed

in hard copy. It is not necessary that the publication be in English.

Even an inventor's own actions or writings can be held against him or her in rejecting the novelty claim. An inventor has 1 year in which to file a patent application in the United States if the invention was patented by the inventor or described by the inventor in a printed publication anywhere in the world or if the invention was in public use or on sale in the United States.

The prohibition against obviousness is statutorily provided for in 35 U.S.C. § 103(a), which states in essence that even if the invention is not disclosed in a single prior art document or is in use or on sale, if the difference between the invention and prior art, (including use, or sale) is obvious, a patent cannot be obtained. Examiners often reject applications based on their sense that it would be obvious to combine two or more published patents or other publications that complement each other. Of course, such a combination must be obvious to a person having ordinary skill in the art, and it must have been obvious at the time the invention was made.

Often, by the time a patent is issued, which may be 2 or 3 years after the application was filed, or even at the time when the application is filed, it may seem to be obvious in light of the prior art. However, the critical time to examine obviousness is when the invention was made. As many court decisions show, it is not always easy to cast away current knowledge and place oneself back to the time the invention was made to determine whether it was obvious. Thus, assertions as to whether an invention is obvious or not in view of the cited art can be highly subjective.

Section 35 U.S.C. § 101 requires that an invention be useful, concrete, and tangible. At least three categories of subject matter have been identified by the Supreme Court as not, by themselves, patentable: laws of nature, natural phenomena, and abstract ideas. For example, the CAFC stated in the *State Street Bank* ruling that mathematical algorithms by themselves are unpatentable because "they are merely abstract ideas constituting disembodied concepts or truths that are not 'useful.'"

Generally speaking, the requirement that an invention be useful is an extremely low bar to patentability. Nonetheless, an invention can fail the usefulness test if an applicant fails to explain adequately why the invention is useful or if an assertion of utility is not credible. For example, the invention considered in *Newman v. Quigg* (1989) was considered to be a perpetual motion machine and thus found to be inoperative (as going against the laws of thermodynamics). It therefore did not meet the usefulness standard.

In addition to these requirements, a specification is required in the patent application that includes a written description and at least one claim. The written description must describe the invention and teach enough about it in sufficient detail so as to enable "any person skilled in the art" to make or use the invention without undue experimentation. The written description must also describe the "best mode" (i.e., the best way to carry out the invention) known to the inventor, although there is no requirement to point out a specific embodiment of the invention as the best mode. The first paragraph of 35 U.S.C. § 112 discusses the requirements of the written description.

The specification must conclude with at least one claim, which is the legal statement defining the subject matter over which the patent will confer the right to exclude. Courts look to the claims when determining whether an accused party is infringing a patent. Claims are discussed in more detail later in the chapter. Finally, 35 U.S.C. § 113 sets forth the particular requirements for drawings, which must be supplied as needed to provide an understanding of the invention.

## Patent Prosecution

The process of obtaining a patent—from filing a patent application, to responding to office actions from the USPTO, to paying the issue fee—is referred to as *patent prosecution*. The first step in the patent prosecution process, other than the invention itself, is often a "prior art" search. There is no obligation on the part of an applicant to do a search, although there is an obligation to report known material information to the USPTO. Nonetheless, performing a search is often a good idea. If search results show that the invention is not novel, one can avoid a long, costly, and ultimately unsuccessful prosecution process. If the invention appears to be novel in view of the search results, often the search—by exposing those aspects that are well known or that have been described in the references uncovered in the search—will then enable the person who ultimately drafts the patent application to focus on those parts that are novel.

For example, a cursory search for U.S., Japanese, and European patents and published patent applications can be performed using, respectively, the online search facilities of the USPTO, the Japanese Patent Office (in English at [http://www.ipdl.jpo.go.jp/homepg\\_e.ipdl](http://www.ipdl.jpo.go.jp/homepg_e.ipdl)), and the European Patent Office (EPO), which also enables Japanese patent searches (<http://ep.espacenet.com>). Most patent offices in other countries have their own Web sites that can be searched. A list of these sites can be found at either the USPTO's or the EPO's Web sites. In addition, many useful documents and news items may be found on the Web using standard Web searching facilities. More extensive (and expensive) searches may be conducted using proprietary databases that may contain articles from hundreds or thousands of trade journals, professional publications, newspapers, magazines, and so on. An online search may be quite limited in scope, and when possible one should use an experienced searcher to conduct an accurate and comprehensive search.

The next step is preparing or drafting the patent application. A patent attorney or agent ordinarily prepares the application, although inventors can represent themselves before the USPTO. The application is then filed with the USPTO. Once received by the USPTO, an application is assigned an application number, and if it is not a provisional application, it will eventually be assigned to an art group consisting of examiners who are familiar with the particular field to which the application/invention pertains. Finally, the application is assigned to a specific examiner in the art group.

That examiner reviews the application in light of both the results of his or her own prior art search and any material information submitted by the applicant. Typically,

the examiner objects to one or more aspects of the application and, in an *office action*, rejects one or more of the claims based on the prior art. Or the examiner may object to unclear language in the specification or an informality in the submitted drawings. An office action is mailed to the applicant (or his or her attorney), and the applicant must reply within a certain time frame or the application will be considered abandoned.

The applicant can reply to the office action in several ways. He or she can point out the differences between the invention as claimed and the prior art cited by the examiner in the office action, emphasizing that the invention is not taught or even suggested by knowledge of the prior art. The applicant can cancel claims, amend claims for clarity, narrow claims to overcome the examiner's rejections, or even broaden claims. New claims may also be added (at least in response to a first office action). Corrections to the specification or drawings may also be made, but in any case, the applicant is never allowed to introduce new matter into the application.

The examiner often makes a subsequent office action *final*. Certain rules apply when the applicant replies to a final office action—for example, new claims cannot normally be added, and only certain amendments of a limited nature are permitted—but a final office action is not as “final” as it sounds.

If some claims are allowed in an office action, an applicant can, in the reply, cancel the rejected claims, permitting a patent to be issued with the allowed claims. A new application, called a *continuation*, can then be filed with the rejected claims. (Note that this continuation application must be filed while the parent application is pending; that is, before the parent application is issued as a patent with the allowed claims.)

Alternatively, if no claims are allowed, the applicant, in response to a final office action, may file a *Request for Continued Examination* (RCE). For the equivalent cost of filing a new application, the applicant is allowed to continue prosecution without the finality of the final office action. In older cases, those filed before May 29, 2000, the applicant may, while the first application is pending, file a continuation-type application, called a *Continued Prosecution Application* (CPA), and allow the first application to become abandoned.

During the course of prosecution, it may be desirable to file a new set of claims while allowing the original application to proceed. For example, the applicant may determine that aspects of the original application not previously claimed may be worth pursuing and may file the same specification with a different set of claims, claiming priority to the first application. This continuation application has its own filing date, but because it claims priority to the first application, it will expire (under the current statute) 20 years from the filing date of the first application (or the filing date of the earliest application in the priority chain). If new matter is added to the specification of a continuation—for example, an improvement or a new configuration—the new application is called a *continuation-in-part* (CIP). A patent issuing on a CIP application, like other utility patents, expires 20 years from the filing date of the first application to which the CIP claims priority.

In some cases, an examiner may determine that the claims of an application define two or more different inventions, each requiring its own prior art search. In this case, the examiner may issue a *restriction requirement* in which the various claims are divided into different groups, each pertaining to a different invention. The applicant is then required to select one of the groups and to cancel or amend the remaining claims. The canceled claims can be filed (while the original application is still pending) in one or more applications known as *divisional* applications. As with continuations, each divisional application has its own filing date, but each must claim priority to the parent and therefore has a term of 20 years from the filing date of the parent (or the earliest filed application in the priority chain).

Eventually, the applicant hopes, each application (including parent, continuations, CIPs, and divisionals) is allowed. For a given allowed patent application, the applicant must pay an issue fee; soon thereafter the patent is issued and is then in force. Although the term of a patent is currently 20 years from the priority date, maintenance fees must be paid at specific intervals from the date of issue or the patent will expire. These intervals are 3 years and 6 months; 7 years and 6 months; and 11 years and 6 months from the date of issue. A 6-month grace period is available for a surcharge.

## Appealing an Examiner's Decision

If the applicant is dissatisfied with the examiner's conclusions as to unpatentability, the applicant can appeal to the Board of Patent Appeals and Interferences within the USPTO. Each appeal is heard by at least three members of the board. An applicant who is unhappy with the board's decision may make a further appeal to the U.S. Court of Appeals for the Federal Circuit (CAFC). The CAFC makes a decision based only on the record from the appeal to the board. Alternatively, an unhappy applicant may file a civil suit against the Director of the USPTO in the U.S. District Court for the District of Columbia. Unlike appeals to the CAFC, new evidence may be presented in these civil suits in addition to the record from the appeal to the board.

## Publication and Provisional Rights

Applications filed on or after November 29, 2000 are published roughly 18 months from the priority date, unless the applicant specifically requests that they not be published, certifying at the same time that the invention has not been and will not be the subject of an application filed in another country. Early publication can be requested. Applications filed before November 29, 2000 but still pending as of that date are not typically published, but publication may be requested.

If a published application eventually issues as a patent, with a claim that is “substantially identical” to a claim published in the application publication, the owner of the patent may be entitled to a reasonable royalty, from the time of the publication date up to the issue date, from someone who makes, uses, offers for sale, or sells an infringing device as against that claim in the United States or who imports an infringing device into the United States and who has “actual notice” (currently a matter of some

dispute) of the published patent application. The rights to these royalties are known as *provisional rights*.

## How to Read a Patent

A patent is organized into four sections: a cover sheet, drawings, a specification, and claims. The cover sheet includes bibliographical information, a short abstract that describes the invention briefly, and usually a copy of one of the drawings considered to be representative of the invention. Drawings must be provided when necessary for understanding the invention.

The specification includes a background, a summary, a brief description of the drawings, and a detailed description of the invention. The background section describes prior art or the state of the art prior to the patented invention. The summary provides a short synopsis of the invention and often is a regurgitation of the claims in plainer language. A brief description of the drawings typically follows. Next comes a written description of one or more embodiments of the invention. As previously mentioned, the written description must enable any person skilled in the art to make and use the invention. It must also set forth the “best mode” contemplated by the inventor, although this best mode need not be pointed out as such.

In the final section, a set of claims are provided that point out and distinctly claim the protected subject matter. Each claim is written as a single sentence and typically includes a preamble, a transitional phrase, and a set of limitations. For example, claim 1 of U.S. Patent No. 6,004,596 (“Sealed crustless sandwich”) appears as follows:

I claim:

1. A sealed crustless sandwich, comprising:
  - a first bread layer having a first perimeter surface coplanar to a contact surface;
  - at least one filling of an edible food juxtaposed to said contact surface;
  - a second bread layer juxtaposed to said at least one filling opposite of said first bread layer, wherein said second bread layer includes a second perimeter surface similar to said first perimeter surface;
  - a crimped edge directly between said first perimeter surface and said second perimeter surface for sealing said at least one filling between said first bread layer and said second bread layer;
  - wherein a crust portion of said first bread layer and said second bread layer has been removed.

In this example, the *preamble* is the phrase: “A sealed crustless sandwich.” The transitional phrase is “comprising.” These elements are followed by five limitations: “a first bread layer,” “at least one filling,” “a second bread layer,” “a crimped edge,” and the condition “wherein a crust portion . . . has been removed.” For this claim to be infringed, an unauthorized party must make, use, sell or offer to sell, or import into the United States a sandwich product that satisfies every one of these limitations. It is irrelevant that another crustless sandwich may have other components not described in the claim; for example, a

cherry on top. As long as some food product meets every one of the limitations listed in claim 1, that product is said to infringe claim 1. On the other hand, if a sandwich is lacking some element, such as the crimped edge, it cannot literally infringe (but see below regarding the doctrine of equivalents).

A first claim is typically written broadly, to cover a wide range of variations. Narrower claims often follow that include the limitations of the broad claim, plus additional limitations that limit the scope of the invention recited by these narrower claims. Narrower claims are often written as dependent claims.

For example, claim 1 above is an independent claim. Claim 2 in the same patent reads as follows:

2. The sealed crustless sandwich of claim 1, wherein said crimped edge includes a plurality of spaced apart depressions for increasing a bond of said crimped edge.

Claim 2 is called a dependent claim because it *depends from* claim 1. That is, it includes all of the five limitations of claim 1, plus the further limitation that the crimped edge includes “spaced apart depressions.” For a sandwich to infringe this claim, it must meet all of the limitations of claim 1 *and* claim 2. One reason for providing additional narrower claims is that often, during litigation of a patent suit, some claims may be found to be invalid. Even though a claim may be invalidated in a court of law (for example, if a publication is presented that predates the patent’s priority date and that teaches or suggests one or more of the claims), a narrower claim with additional limitations may still be valid, even if it depends from the invalidated claim.

Another reason for providing additional narrower claims is the so-called doctrine of claim differentiation, under which “two claims of a patent are presumptively of different scope” (*Kraft Foods, Inc. v. Int’l Trading Co.*, 2000). According to this doctrine, if a dependent claim includes a narrowing definition of some limitation of a base claim, then the base claim is presumed to encompass not only the narrow definition but other embodiments as well. For example, claim 2 above may help support the proposition that claim 1 covers crustless sandwiches that do not have depressions that are spaced apart as well as crustless sandwiches that have other kinds of bonding mechanisms.

First-time readers of claims are often puzzled by their seemingly bizarre language and grammar. Sometimes this language results from the statutory requirement that claims particularly point out and distinctly claim the subject matter that the inventor or applicant regards as his or her invention. Thus, use of a definite article such as “the” is typically not allowed unless it refers to something already defined in the claim (i.e., there is an “antecedent basis” for the thing being referred to). For this reason, one often sees “a number of (things),” whereas in normal usage one would say “the number of (things).”

In addition, use of the word “or” is generally frowned upon as it leaves options open and is therefore not considered to distinctly claim an invention. Thus, one often sees in claims the following wording—“at least one of [Choice A], [Choice B], *and* [Choice C]” or “any of

[Choice A], [Choice B], and [Choice C]”—whereas in normal speech, one might say “either [Choice A], [Choice B], or [Choice C].” Similarly, instead of stating “one or more of,” claims will more often state “a plurality of” or “at least one of,” leading to even more confusing language later in the claims, such as “the at least one of.” Although such language may at first be confusing, an understanding of why these terms are used may help in reading and interpreting a claim.

Another aspect of claims that can be confusing to the layperson is that often very similar language is used in two different claims. For example, a patent typically will have a method claim and an apparatus (or system) claim that use parallel language. Remember, however, that the scope of the right to exclude may be different between a method and an apparatus or composition of matter.

A limitation in an apparatus claim may also be expressed as a means or step for performing a specified function without the recital of any specific structure. Although such a limitation is not always triggered by “means for” (also called “means-plus-function”) language and may even be triggered in the absence of such language, such claims are often added to a patent. A “means for” limitation is construed to cover the corresponding structure, material, or acts described in the specification and their equivalents (see 35 U.S.C. § 112, sixth paragraph).

In addition to the more or less standard apparatus, method, and “means-for” claims, computer- and software-related inventions are often additionally recited in so-called Beauregard claims and signal claims. As the USPTO states, a computer program is merely a set of instructions, capable of being executed but is not itself a process (see section 2106(a) of the *Manual of Patent Examining Procedure*). To be patentable, a computer-readable medium or an “article of manufacture” comprising a computer-readable or useable medium is claimed, having therein a computer program that performs some steps of a process. These types of claims have been called Beauregard claims after the inventor of one of the first patent applications to use such claims (see U.S. Patent No. 4,962,468).

Another type of claim one might encounter is the so-called propagated signal claim. Such a claim might appear as follows:

1. A computer data signal embodied in a carrier wave for [doing something], the computer data signal comprising:
  - program code for [performing a first action];
  - program code for [performing a second action]; etc.

Such claims are thought to protect against the unlicensed transmission of a computer program over a network such as the Internet or through modems. Of special concern with claims directed to client/server applications is the fact that a single party may not be performing or using all of the limitations of a claim. In other words, if a claim states actions taken by both the server and the client, which are controlled by two independent parties, then neither party can be an infringer. Therefore, it may be desirable in a patent to have one set of claims directed

to the overall invention, another set of claims directed to actions taken at the server (possibly in response to messages received from a client), and yet another set of claims directed to actions taken by a client (possibly in response to messages received from a server).

## Protecting Patent Rights

### What Rights Are Conferred on a Patentee?

A patent confers specific “exclusive” rights on the owner of a patent. That is, the owner of a patent is granted the right to exclude other parties from various acts, including making, using, offering to sell, or selling the patented invention (as set forth in the claims) within the United States or importing the patented invention into the United States. When a process is patented as opposed to an apparatus or composition of matter, the patentee is similarly granted the right to exclude others from using, offering to sell, or selling in the United States or importing into the United States any product made by the claimed process. Note that a patent does not give an owner the right to practice the invention recited in the patent; another (broader) patent may exclude the owner from practicing the invention. These rights begin when the patent is granted—that is, when the patent is issued—and last until the patent expires.

### Infringement

When someone performs one of the restricted acts described above without permission of the patent owner, the claims of the patent are said to be infringed. There are three types of infringement: direct infringement, active inducement to infringe, and contributory infringement. *Direct infringement* occurs when someone performs one of the restricted acts; that is, makes, uses, sells the invention (as set forth in at least one claim of the patent), or offers it for sale in the United States or imports it into the United States. Note that direct infringement does not require knowledge by the infringer that the invention is prohibited, nor does it require that the infringer intentionally perform the act. All that is required for direct infringement is the act.

*Active inducement to infringe* occurs when someone induces another to infringe. If there is no direct infringement, there cannot be an active inducement to infringe, no matter how hard someone tries to induce infringement. Of course, there could be other legal issues in this case.

*Contributory infringement* occurs when a component of a patented invention is sold or offered for sale in the United States or imported into the United States by a party who is aware that the component is especially made or adapted for an infringing use. As with active inducement to infringe, there cannot be any contributory infringement unless there is direct infringement by some party. Note that because use must occur within the United States, in an Internet-related patent, there may be no infringement where either a server or a client outside the United States performs some of the elements of a patent claim.

### Doctrine of Equivalents

Under the *doctrine of equivalents*, a patent claim may be infringed even if the accused device does not literally

infringe the claim, but the differences between the claims of the patent and the accused device are insubstantial. This means that the accused product can infringe a patent's claims if it performs the same function to achieve the same result in substantially the same way as the patent claim.

*Prosecution history estoppel*, however, may limit the scope of equivalents of a patent. Prosecution history estoppel applies when an applicant amends the patent claims to overcome an examiner's rejection or makes arguments during patent prosecution that help interpret the claims. After amending the claims, the applicant cannot recapture that which was given up or surrendered by narrowing the scope of the patent claim, and the applicant is estopped from claiming that he or she could not have reasonably been expected to have drafted a claim that would have literally encompassed the alleged equivalent (see *Festo Corporation v. Shoketsu Kinzoku Kogyo Kabushiki Co., Ltd.*, 2002).

### Remedies

When the owner of a patent believes another party is infringing on it, the owner typically seeks one of two things: (1) to have the accused party cease from engaging in the infringing acts and collect damages for past infringement and/or (2) to license the invention to the accused party in order to collect future royalties. An owner typically files a lawsuit seeking one or more remedies if he or she does not wish to license the invention, or if license negotiations break down, or to "persuade" the accused party to obtain a license. The patent owner can seek an injunction against the accused party, wherein the court can order a cessation of the infringing act. A court can also award monetary damages to compensate the owner for the infringement. These damages can be the patentee's lost profits due to lost sales or can be a reasonable royalty for the use of the invention and may include interest and other costs, if the court so decides. A court may increase these monetary damages up to three times where willful infringement is found. In exceptional cases, a court may award attorney fees for either party, whichever prevails.

### Defending Against an Accusation of Infringement

There are two main ways a party accused of infringement can avoid liability: the party can assert that (1) its product does not infringe the patent(s) in question or that (2) the patent in question is invalid of when forceable, based on any one of a number of reasons (i.e., lack of novelty, obviousness, incorrect inventorship, inequitable conduct, etc.). Issuance of a patent by the USPTO creates a presumption of validity of the patent. Nonetheless, a court may rule, based on the patent itself, the prosecution history of the patent application, and/or new evidence, that the patent is not valid. Generally speaking, damages cannot be obtained for infringements that occurred more than 6 years before the filing of the suit.

Independent of the statutory time frame, an infringement suit may be barred by *laches*; for example, if the patent owner deliberately delayed bringing the suit for an unreasonable time, knowing that the delay would work to the detriment of the accused infringer. In 2002, the CAFC confirmed the existence of *prosecution laches*, in which

an unreasonable delay during prosecution of the application, together with harm to the other party caused by the delay, can result in unenforceability of a patent (*Symbol Technologies, Inc. al. v. Lemelson Medical, Education & Research Foundation, Limited Partnership*, 2002).

### Court Jurisdiction in Patent Cases

Because patent law is federal law (as opposed to state law), federal courts have jurisdiction over all patent-related cases. Furthermore, although there are many federal courts of appeal, Congress, in seeking to establish a single interpretation of the patent laws, established the Court of Appeals for the Federal Circuit (CAFC) to hear all patent-related appeals (but see the discussion below of *Holmes Group, Inc.*).

Typically, a three-judge panel hears and decides an appealed case. On occasion, that decision may be appealed. One of the parties may ask for an *en banc* rehearing in which all or most of the judges from the CAFC rehear the case. If a party is not satisfied with the final ruling, it may appeal to the U.S. Supreme Court. However, very few patent cases are ever heard by the Supreme Court, typically 1 or 2 a year, if that.

One case that was heard by the Supreme Court recently was *Holmes Group, Inc. v. Vornado Air Circulation Systems, Inc.* (2002). In this case, Holmes filed a complaint seeking a declaratory judgment that its products did not infringe Vornado's *trade dress*. Trade dress is another form of protection that does not involve patents. Although the original complaint did not involve patents, Vornado filed a counterclaim alleging patent infringement. After an appeal to and decision by the CAFC, the Supreme Court heard the case.

The Supreme Court ruled that the CAFC does not have jurisdiction over a case that involves questions of patent law where the party bringing the suit did not, in its complaint, assert any patent law issues. Thus, although the CAFC was created in part to form a uniform interpretation of patent law across the country, where the original complaint does not assert any patent law issues, the CAFC may not have jurisdiction, even where patent issues are later asserted in a counterclaim.

### Provisional Applications

A provisional application must have a written description and drawings sufficient to teach the invention to one skilled in the art. However, a provisional application is not examined and thus will never issue into a patent. No claims are required, although it may be preferable to include some claims for reasons beyond the scope of this article. A provisional application is relatively inexpensive to file and provides a priority date for any application filed within a year claiming the benefit of the provisional application, as to the matter disclosed in the provisional application. Note, however, that a provisional application is automatically abandoned 1 year from its filing date, unless it is converted into a nonprovisional application within that time. To receive the benefit of the filing date, within a year either a provisional application must be converted to a nonprovisional application, or more commonly a nonprovisional application must be

filed. Although a provisional application establishes a priority date, the 20-year term of an issued patent claiming the benefit of the provisional application begins on the filing date of the first nonprovisional application in the priority chain.

## NON-U.S. PATENTS

### General Information

Patents are, of course, available outside the United States. One may file a first application almost anywhere in the world and follow up with applications in other countries within 1 year of filing the first application, maintaining the first application's filing date as a priority date.

As the USPTO's *Manual of Patent Examining Procedure* (MPEP) states, the right to rely on a foreign application is known as the *right of priority* in international patent law. The right of priority originated in a multilateral treaty of 1883, known as the Paris Convention for the Protection of Industrial Property, or more simply as the Paris Convention. The treaty is administered by the World Intellectual Property Organization (WIPO) at Geneva, Switzerland.

In addition to filing in individual countries, applications can be made in several regional areas, including the European Patent Convention (EPC; <http://www.european-patent-office.org/index.en.php>), the African Intellectual Property Organization (OAPI; <http://www.oapi.wipo.net>) made up of French-speaking African countries, the African Regional Industrial Property Organization (ARIPO; <http://www.aripo.wipo.net>) comprising English-speaking African countries, and the Eurasian Patent Organization (EAPO), (<http://www.eapo.org/>) which includes former republics of the Union of Soviet Socialist Republics.

For protection in EPC member countries, an application is filed at the European Patent Office (EPO) in Munich, Germany, designating some or all EPC member countries. Only one application needs to be filed and prosecuted to obtain coverage for any or all of the member countries. The application can be filed and prosecuted in English up to the point of issuance. A separate national patent is issued for each selected country, and each patent is subject to the patent laws of the country in which it is issued (and could ultimately be invalidated in some countries but not others). A separate European Community Patent may become available in the next few years, wherein an application filed under this regime would issue as a single community-wide patent, subject to a single jurisdiction with regard to various legal claims.

### Patent Cooperation Treaty

Yet another alternative is to file an application according to the Patent Cooperation Treaty (PCT; see <http://www.wipo.int/pct/en/>). A PCT application serves as an application in each country that is designated. The process begins when an applicant from a member country files a PCT application in a designated receiving office (such as the USPTO). This begins the "international stage." The application is published approximately 18 months after the priority date. A search is performed and a search report sent to the applicant.

PCT procedures have undergone significant changes as recently as January 2004. For applications filed before January 1, 2004, at the request (i.e., a "Chapter II Demand") of the applicant, a preliminary examination may be performed and a written opinion is issued. This is similar to patent prosecution in the United States. However, the applicant typically has only one opportunity to respond to the written opinion and to amend the claims. Ultimately, an International Preliminary Examination Report is issued. Thirty months (31 months for some countries) from the priority date, or 20 months for some countries if the preliminary examination has not been requested, the application must enter the "national stage" in those countries or regions in which protection is sought. Prosecution of the application then continues independently in each country or region until the patent is granted.

For applications filed on or after January 1, 2004, the search authority issues, in addition to the search report, a written opinion, whether or not requested by the application in a Chapter II demand. Except in a very few countries, the national stage may be entered at 30 months regardless of whether a Chapter II Demand was made. If a Chapter II Demand is not made, the written opinion is transformed into a Chapter I "international preliminary report on patentability." For these applications, a Chapter II Demand must be made by the later of 22 months from the priority date or 3 months from the international search report.

Applications filed prior to January 1, 2004 had to designate, at filing, those countries or regions from which the applicant might later elect to enter into the national stage. Although many applicants often designated all countries just to be safe (after paying for a certain number of designated countries, the rest were free), for applications filed on or after January 1, 2004, all countries and regions are designated automatically unless expressly excluded.

Filing patent applications in multiple jurisdictions can be very expensive. To keep costs down, applicants typically file only in those jurisdictions where the invention is likely to be used most frequently and where meaningful enforcement can be achieved. A PCT application enables an applicant, for a relatively low cost, to delay for up to 30 months (31 months in some cases) both the designation of particular countries or regional jurisdictions and the costs of entering in those countries and regions.

### Other Considerations

Although many procedures and rights are similar in various countries and regions, there are differences, some of which may be somewhat significant. It is not the intent of this chapter to cover the particulars of the patent laws and procedures of every nation. The number of countries is too numerous, and laws and procedures are always changing. Nevertheless, it is instructive to discuss some details to give an idea of the subtle and not-so-subtle differences among countries or regional organizations. Thus, although this section does not provide a comprehensive comparison of patent procedures and rights throughout the world, it offers an instructive examination of several different aspects employed around the world.

Although novelty, nonobviousness, and usefulness form the cornerstone in obtaining a U.S. patent for an invention, in most of the rest of the world, the requirements are stated differently. For example, a claim in a PCT application must be novel, involve an “inventive step,” and be “industrially applicable.”

A few countries, such as Australia, Canada, Colombia, and the United States, provide a 1-year grace period after publication of a document describing an invention during which an application for the invention may be filed. In most other countries, such a disclosure before the filing of an application is an absolute bar to obtaining a patent.

Another difference is that in the United States, when two inventors claim to have invented the invention independently, the patent is awarded to the first to invent (with some caveats). Of course, the precise instance of invention may be difficult to discern and to prove, leading to a complicated procedure known as an interference proceedings. The rest of the world follows a “first-to-file” policy, in which a patent for an invention is awarded to the first applicant to file, regardless of who invented it first.

In the United States, a computer program is patentable if it produces a “useful, concrete, and tangible result,” as specified in the State Street ruling. However, in many foreign countries, software per se is explicitly barred from being patentable. Nonetheless, “thousands of patents for computer-implemented inventions have been granted by the European Patent Office (EPO) and by national patent offices,” according to the Commission of the European Communities (2002).

Another notable difference is that in the United States the applicants must be the inventors (though they can assign their rights), whereas in other countries, applicants may be either the inventor or the assignee, which can be an individual or a corporation.

In the United States, examination of a patent application by an examiner is automatic. However, in many other countries, examination must be requested within some time period from the filing date. For example, in Japan, the examination must be requested within 3 years for patent applications filed on or after October 1, 2001. For applications filed before October 1, 2001, the request must be made within 7 years. In Canada, a request for examination must be filed within 5 years.

Before filing a foreign application, a foreign filing license is required for any invention *invented* in the United States, even by a non-U.S. citizen. Filing a “foreign” application without a foreign filing license could lead to invalidation or unenforceability of a patent. Italy similar requirements, although many other countries do not.

Patent prosecution procedures for the EPO are governed by the European Patent Convention (EPC; see <http://www.european-patent-office.org/legal/epc/index.html>). There are currently 31 member countries of the EPO and 5 “extension” countries that are expected to become members. About 18 months after the priority date, an application is published or “laid open” to public inspection. A prior art search is performed and a search report is generated, in which an examiner may cite references that show that certain claims are either not novel or do not have an inventive step (i.e., the claims are obvious in view of the prior art). The search report is typically

published along with the application. (If the application was originally filed as a PCT application and the search report was performed by the EPO, then a second search is not performed.) Within 6 months of the search report, the applicant must file a request for examination.

In the United States, during patent prosecution, claims can usually be broadened or new broader claims added in an amendment. It is usually sufficient that the narrower (prebroadening) claims are supported in the specification. In the EPO, in contrast, claims typically cannot be broadened unless the claimed (broader) invention is specifically described in the specification.

EPO applications can be very expensive as the number of claims exceeds 10. Typically only one of each type of independent claim (e.g., apparatus, method) is allowed.

## Types of Patent Applications

In foreign countries, the term “divisional” application covers both divisional applications and continuations. If the parent application is an innovation patent, a divisional application can be filed as either an innovation patent or as a standard patent. Australia provides for “patents of addition” for improvements and modifications to an invention (somewhat akin to U.S. CIPs) and for divisionals.

Some countries have equivalents to U.S. provisional applications. For example, in Great Britain and Canada, one can file an “informal” application without claims. Such an informal application acts, as does a U.S. provisional application, to preserve the priority date. However, the informal application is not provisional in that claims must be added within 1 year to formalize the application. Australia, in contrast, provides for a “provisional” application that must be followed within 12 months by either a “complete” or international (PCT) application. New Zealand also provides for a provisional application, with 12 months to file a regular application or up to 15 months with a 3-month extension.

## Time Limits in Patent Prosecution

In both the EPO and USPTO, there is no time limit to the prosecution process, and prosecution can theoretically last for a very long time. Certain countries, however, do impose limits. For example, Great Britain requires that an application be put in order within 4-1/2 years of the priority date. At most, a 1-month extension is available. This process includes the PCT international stage and the EPO prosecution if any.

## Employed Inventor Laws and Shoprights

In the United States, absent agreement otherwise, an employer has a nonexclusive, nontransferable right to use an employee’s patented invention for its own use if the employee used the employer’s materials or facility to develop the invention. Such rights are known as *shoprights*. Conversely, some countries, such as Germany and Japan, have “employed inventor laws.” Under such laws, if an employer fails to file an application for an invention within a certain time frame, the employee can file an application in his or her own name. To protect themselves in such cases, employers may file petty patents.

## Provisional Rights

Though not necessarily called by that term, many countries provide the equivalent of U.S. provisional rights. For example, in Canada, after the granting of a patent, a patentee may be entitled to reasonable compensation for infringement occurring in Canada as of the date the application was laid open.

## Compulsory Licenses and U.S. March-in Rights

According to 35 U.S.C. § 203 (*march-in rights*), a federal agency that has funded development of an invention to which a small business or nonprofit organization has acquired patent rights has the right to require a contractor, an assignee, or exclusive licensee of the invention to grant a license in any field of use.

In the United States, state and federal governments and their agencies are immune from certain types of suits for infringement under the doctrine of sovereign immunity. Essentially, states may be enjoined, but not sued for damages. The federal government may be sued for a “reasonable royalty” before the U.S. Court of Federal Claims pursuant to its limited waiver of sovereignty embodied in 28 U.S.C. § 1498. Most other countries apply at least some form of sovereign immunity.

In many foreign countries, a patented invention must be manufactured or otherwise worked or exploited in that country within a certain period, typically 3 years, or the patent could be invalidated; alternatively, a compulsory license may be granted. In Canada, a compulsory license may be granted to remedy certain abuses of patent rights. Such abuses, which are beyond the scope of this article, cannot be considered until 3 years after the grant.

## CONCLUSION

Patents can be valuable assets for any business, large or small, or they can be a waste of money. In return for disclosing the invention, the patentee is granted a limited term (typically 20 years from filing) in which the competition cannot use the patented device or method. The competition therefore must research and develop noninfringing alternatives, a process that could be costly, timely, and in some cases, even futile, therein giving the patentee a substantial advantage. Alternatively, the patentee may choose to license the patented technology in return for a royalty or some other consideration. A patent does not give the owner the right to practice the invention.

## GLOSSARY

**Claim** The part of a patent that defines the actual intellectual property protected by the patent; that is, the inventive subject matter protected by the patent.

**Dependent Claim** A patent claim that incorporates by reference the limitations of another patent claim. Such a claim typically begins with language such as, “The device of Claim X, further comprising . . .,” which has the effect of incorporating by reference the limitations of Claim X.

**Doctrine of Claim Differentiation** A doctrine under which claims of a patent are presumptively of different

scope, so that if a dependent claim includes a narrowing definition of some limitation of a base claim, then the base claim is presumed to encompass not only the narrow definition but other embodiments as well.

**Doctrine of Equivalents** A doctrine by which, even if a device or process does not exactly match every limitation of a patent’s claim, the device may still infringe the patent if the differences are, to a “person of ordinary skill in the art,” insubstantial (as determined by a judge or jury during an infringement hearing).

**Element** Although “element” and “limitation” are sometimes used interchangeably, the term “element” is used more frequently by the courts to refer to aspects of an allegedly infringing device or method. In an infringement case, the elements of the alleged infringing device or method are compared with the claim limitations of the patent allegedly being infringed. Note, however, that the U.S. statute (35 U.S.C. § 112) refers to both an “element in a claim” (sixth paragraph) and “limitations of [a] claim” (fourth and fifth paragraphs).

**Independent claim** A patent claim that does not incorporate any other patent claim by reference.

**Infringement** When a device or method has all of the limitations of a claim (which may be interpreted differently under the patent laws of individual countries), the device or method is said to infringe the claim. Various remedies may be available to the owner of the infringed patent.

**Laches** An equitable principle whereby a party is estopped (not allowed) from bringing a lawsuit after an unreasonable or unexplained delay that has had a detrimental effect on the party being sued.

**Limitation** A claim limitation is a part of a claim that defines a particular aspect of the invention (i.e., an aspect of the invention that must be practiced if the invention is to be infringed). Every claim has at least one limitation, and most claims have two or more limitations.

**Means plus function** A particular claim limitation may be written in “means plus function” language, wherein the limitation is recited as a means or a step for performing a specified function, without reciting the particular structure, material, or acts, which are thus construed to be those described in the specification (and equivalents). “Means plus function” claim limitations are specifically authorized by U.S. statute. In some countries, “omnibus” claims serve a similar purpose.

**Nonobvious** One of the basic requirements in obtaining a patent is that the invention be nonobvious to one of ordinary skill in the particular art concerned, in view of the known (prior) art.

**Novelty** One of the basic requirements in obtaining a patent is that the invention be novel. Legally, in the United States, this means that a claim may be barred if any of the conditions stated in 35 U.S.C. § 102 hold true; that is, a description has been published anywhere in the world, the invention has been sold or offered for sale or otherwise placed in the public domain, etc. Similar conditions apply in other countries; however, certain grace periods apply in some countries for certain types of prior disclosure.

**Patent** A grant that gives the holder of a patent certain rights to exclude others from practicing, (i.e.,

making), using, selling, offering for sale, importing, etc., a claimed invention, in the country in which the patent has been granted and for the term during which the patent is valid.

**PCT** The Patent Cooperation Treaty under which an applicant of a member country can file a single international patent application that may designate one, many, or all of the member countries. The PCT does not provide for the granting of patents; that occurs at the “national stage.”

**Prior art** The accumulated knowledge of those skilled in the particular art concerned, which can bar issuance of a patent if the claims are not novel or nonobvious in view of the prior art.

**Prosecution** The process of obtaining a patent, from the filing of an application to the issuance of the patent (or abandonment of the application).

**Prosecution laches** An equitable principle in which unreasonable delay during prosecution of a patent application, together with harm to another party caused by the delay, can result in unenforceability of the issued patent.

**Provisional application** A particular type of patent application that is never examined but serves to provide a priority date for a future, nonprovisional application, subject to the requirement that the provisional application describes the invention fully.

**Provisional rights** The rights of a patent owner to a reasonable royalty for an infringing device or method, covering the period between publication of a patent application and the granting of the patent with substantially identical claims as those in the published application.

**Right of priority** The right to rely on another application.

**U.S. Patent and Trademark Office (USPTO)** The U.S. governmental agency authorized to issue patents, as well as to register trademarks (see Trademark Law in this handbook).

## INTRODUCTION

Trademark law is a fascinating subject for many people, in part because most everybody in our society understands and appreciates the power of popular trademarks, such as Lexus, Pokemon, Yahoo!, and Safeway. Trademarks are such an integral part of our language and culture that we all have a vested interest in their protection. Because trademarks are all about meaning, trademark disputes are a kind of spectator sport: they involve popular cultural icons and turn on questions such as whether the average person is likely to be confused if a trademark is used improperly. So in many respects, everybody gets to have an opinion on trademark issues, and that opinion more often than not counts for something in the final calculus of trademark disputes.

In this chapter, we will look at the fundamental ideas that underlie the protection of trademarks and we will look at ways in which trademarks can be infringed and protected. Once that groundwork has been laid, we will then look at how these fundamentals have been applied to the unique and significant disputes that have arisen in the Internet context. In many respects, trademark law has been turned upside down by the Internet, so we will look at how the principles of trademark law are being applied in today's Internet-oriented business environment.

## TRADEMARK DEFINED

*Merriam-Webster's Dictionary of Law* defines **trademark** as "a mark that is used by a manufacturer or merchant to identify the origin or ownership of goods and to distinguish them from others and the use of which is protected by law."

In practice, a trademark is any word (Sun), name (Calvin Klein), symbol (golden arches), device (the Energizer Bunny), slogan ("Fly the Friendly Skies"),

package design (Coca-Cola bottle), colors (FedEx purple and orange), sounds (the five tone Intel Corporation sound) or any combination thereof that identifies and distinguishes a specific product or service from others in the marketplace.

As trademark law has evolved, the field has become an important subset of the larger category known as **intellectual property** law. As the name implies, intellectual property law (which also includes patent, copyright, and trade secret law) treats these rights as a kind of property right, protecting the rights of owners to exploit the property for their own benefit while prohibiting unauthorized use by others. But unlike real estate or personal property law, intellectual property law concerns ownership of intangible things such as ideas, words, and meanings, rather than physical things.

The legal protections afforded by trademark law also extend to the related concepts of **service marks** and **trade dress**. Service marks differ from trademarks in that they are marks used to identify a particular service, or to distinguish the provider of a service, rather than a tangible product. For example, the name of a consulting firm, or the name of a proprietary analytical process used by that consulting firm, might be more properly identified as a service mark. Trade dress is the overall image of a product, composed of the nonfunctional elements of its design, packaging, or labeling. This could include specific colors or color combinations, a distinctive package shape, or specific symbols or design elements.

Many people confuse trademark with copyright. Copyright is a person's exclusive right to benefit from the reproduction or adaptation of an original work of authorship, such as a literary, artistic, or musical work. Trademark differs from copyright in that trademark law does not prohibit the reproduction or adaptation of the creative products of an author. Rather trademark law seeks to prevent confusion over words or other characteristics used to uniquely identify the source or quality of a

product or service. For example, Paul Simon's 1973 song "Kodachrome" refers to a trademark owned by Eastman Kodak Company even though Simon holds the copyright on his work.

The relative strength of a particular trademark depends upon where it falls within a range of five categories: fanciful, arbitrary, suggestive, descriptive, or generic. The greatest protection comes for fanciful marks consisting of invented words like Xerox, Kodak, or TiVo. The next strongest protection comes for arbitrary marks, which are commonplace words used in a manner that is unrelated to their dictionary meaning, such as Apple for computers or Shell for gasoline. Suggestive marks are familiar words or phrases that are used in an inventive way to "suggest" what their product or service really consists of, such as Home Box Office for a movie channel or Mail Boxes Etc. for a postal services franchise. The least protection comes for descriptive marks which do little more than describe the characteristics or contents of the product, such as the publication *Automotive Industry News*, or *Cellphone Center* for a cellular telephone retailer. Finally, generic names, which merely state what the product or service is, cannot function as trademarks. Some marks, such as aspirin, linoleum, escalator, or nylon, were once trademarks but became generic because the trademark holder failed to police unauthorized use.

## FEDERAL TRADEMARK LAW

For trademarks used in interstate commerce, U.S. law provides protection under the Trademark Act of 1946, known more commonly as the **Lanham Act**. The Lanham Act also created a registration process for trademarks, and legal and procedural incentives for trademarks to be registered with the U.S. Patent and Trademark Office (USPTO). Many States within the U.S. also afford trademarks protections under their State's laws.

The Lanham Act provides a functional definition of what is eligible to be registered as a trademark. Potentially anything can be registered as a trademark if it functions among consumers to distinguish a specific product from other products in the marketplace. The Lanham Act does, however, prohibit certain marks, including anything immoral, deceptive, scandalous, disparaging towards an institution or national symbol, falsely suggests a connection to a person, consisting of a flag or other governmental insignia, using a name or portrait of a deceased President of the United States during the life of his widow without her consent, and numerous other limitations. Once registered, a mark may also be cancelled if it has become generic, has been abandoned, was obtained through fraud, or is otherwise prohibited by the aforementioned conditions.

One important limitation on registration comes when the mark is part of the product's functionality. An aspect of the product may meet the definition of a trademark and may even be recognized as a trademark by consumers, but it cannot be registered if it is essentially a functional aspect of the product. For example, a company might sell a computer monitor that has a unique shape that is immediately recognizable to the public and distinguishes the monitor from the products of competitors. Under the functional definition of a trademark, the unique shape

may be registered. However, if the shape is actually a functional aspect of the product, for example the shape is responsible for improved resolution, the shape cannot be registered as a trademark. (In such a case, though, the manufacturer may be able to seek patent protection for the unique design.)

The USPTO registers trademarks and service marks that are used in interstate commerce. Trademarks need not be registered for an owner to enforce his or her rights in court, however federal registration provides numerous legal benefits to a trademark owner at a reasonable expense. For example, once a mark is registered, the registration establishes the validity of the registrant's claims of ownership and places the world on constructive notice that the owner has exclusive rights to use the mark in commerce. If the holder of a registered trademark establishes infringement under the Lanham Act, they can not only enjoin any misuse of a mark, but they may also be able to recover statutory damages and in some cases, attorneys' fees.

Federal registration on the principal register gives nationwide protection from infringement, while common law protects the mark only in the specific geographical area in which the mark is used in commerce; and state law protects the mark only within the state where the mark is registered. Thus, another benefit of federal registration is the establishment of rights across a larger geographical area than under common law and state law.

In fact, the scope of protection for a federally registered mark is usually broader than under common law or state law. For example, under common law and many state trademark registration statutes, trademark protections may be restricted to those specific products or services for which the mark has explicitly been used, while federal law allows a mark to be protected even when used in conjunction with a wider array of related products or services, such as a family of services offered under an umbrella trademark. Finally, the Lanham Act provides legal remedies that go beyond those available at common law including, for example, treble damages against a "willful" infringer, as well as reimbursement of attorney fees in exceptional cases. It is important to note, however, that unlike many areas in which federal law supercedes state law, state and federal trademark law often co-exist well and aggrieved parties can frequently bring legal actions using both state and federal law to equal effect.

The Lanham Act's protections flow equally to trademarks and service marks. Trade dress is also protected by the Lanham Act, provided it is not a functional part of the product and is distinctive, has acquired secondary meaning as being uniquely associated with the product, and there is a likelihood of confusion on the part of the consumer if a competing product were to possess similar trade dress.

## Trademark Registration

First, it is important to note that there are legal protections under trademark law for marks that have not been registered with the USPTO. Section 43(a) of the Lanham Act permits legal action against anyone who falsely makes use of a trademark word, name, or symbol in a manner that is likely to cause confusion or misrepresents the

nature or origins of the product or service. This protection is not predicated on the registration of a mark with the USPTO. In addition, as noted elsewhere in this article, state laws may also provide protections as well. However, the Lanham Act, and many state laws, provide significant incentives for registration, giving additional remedies and rights to those who have availed themselves of the registration process.

For those who do choose the registration route, the USPTO maintains two types of trademark registries, the Principal Register and the Supplemental Register. The Principal Register is where a “registered trademark” is registered. There are three ways a trademark or service mark may be registered with the USPTO. The first method, called an “in use” application, is for an applicant who is already using a mark in commerce. The second method is an “intent to use” application, for marks that are not yet in use, but which the applicant is preparing to use. The third method is based upon certain international agreements, by which applicants outside the United States can file an application based upon applications or registrations in another country.

The Supplemental Register is where marks that are descriptive in nature but have not yet established secondary meaning are maintained. Marks on the Supplemental Register can use the ® symbol, and if the mark is continuously used and unchallenged for five years, the holder may file another application and claim such use presumptively establishes secondary meaning under Section 2(f) of the Lanham Act, and thereby move the mark onto the Principal Register.

The registration process itself is relatively straightforward. The application documents must be filed by the owner of the mark, usually through the services of an attorney concentrating in trademark law. (For brevity we will focus only on an “in use” application and will not further discuss the “intent to use” application.) The application contains information about the individual or corporation who owns the mark, an exact representation of the mark (in text or in image form) as well as several specimens of the mark in actual use, information about the date of first use and date of first use in commerce of the mark, a description of the goods or services used in conjunction with the mark, and the “classification” of the goods or services according to a standardized list of 42 pre-defined classifications. Some goods and services may be registered in multiple classes, with the application fees increasing accordingly.

Once received, the USPTO makes an initial review of the application to determine if the application contains all the information necessary to be considered “filed.” If the application is complete, a “filing date” is issued along with a serial number and sent to the applicant. Several months after filing, an examiner at the USPTO reviews the application in more detail, researches the information provided, and makes a determination as to whether the mark should be registered. If it cannot be registered, the examiner will issue a notice called an “office action” which explains the grounds for refusal, including any deficiencies in the application itself. In some cases, only minor adjustments might be necessary in order to permit registration and sometimes the application can be corrected over the phone. Applicants have six months to respond to

an office action or else the application will be considered abandoned. If the applicant cannot overcome the examiner’s objections, a final office action is issued, at which point the applicant may appeal to the Trademark Trial and Appeal Board. Should the applicant be unsuccessful there, they may appeal that decision to federal court.

If there are no objections to the application, or the applicant overcomes the objections, the examiner will approve the mark for publication in the Official Gazette, a weekly publication of the USPTO. The applicant is notified of the date of publication through an official Notice of Publication.

Anyone who believes the registration harms them or is otherwise in violation of the Lanham Act has 30 days from publication to file an opposition to the registration or seek an extension of time to do so. At this point the administrative proceeding is *inter partes* (meaning between two parties, in contrast to an *ex parte* proceeding before the examiner only) and is known as an “opposition.” The opposition proceeding determines the validity of the objections. If no objection is received, the mark will be registered. After the registration is issued, anyone who believes they have been harmed by the registration may begin a “cancellation proceeding,” which is similar to an opposition proceeding except that it takes place after registration. In an opposition, the applicant bears the ultimate burden of establishing registerability; in a cancellation, the party seeking the cancellation bears the burden of proving the registration was improvidently issued. Opposition and cancellation proceedings are held in a formal, trial-like hearing before the Trademark Trial and Appeal Board, a division of the USPTO.

A mark will be registered only after it has been published and the opposition period has expired. Once registered, federal trademark registrations run for ten years, with renewal terms lasting ten years. Between the fifth and sixth year, however, the registrant must file an affidavit to confirm the mark is still in use. If that affidavit is not filed, the registration is cancelled. Thus, a trademark must remain in use or its registration may be cancelled, but if a mark is in continual use and that use is properly demonstrated as required by law, the registration could remain effective forever.

After five years, the owner of a registered mark may request that the mark be deemed “incontestable.” Under the Lanham Act, incontestability means that certain legal avenues of challenging the mark—such as a claim that the mark is not distinctive, lacks secondary meaning, is confusingly similar to another mark, or the mark is purely functional—are no longer available. The term “incontestable” is somewhat misleading in that there remain certain circumstances in which the mark may be challenged and have the registration cancelled, such as an assertion that the mark was improperly registered in the first instance.

### The Differences Between ®, ™ and ℠

Once registered, the registration symbol, ®, may be used. It is considered trademark misuse to display the registration symbol at any point before the USPTO issues the final registration notice to the applicant. In contrast, anyone who wishes to claim rights in a mark may use

the <sup>TM</sup>(trademark) or <sup>SM</sup> (service mark) designation alongside the mark. Use of <sup>TM</sup> or <sup>SM</sup> alerts the public to the claim of ownership and exclusive use. It is not necessary to have a registration, or even a pending application, to make use of these designations, and consequently the claim may or may not have any validity. In short, use of <sup>TM</sup> or <sup>SM</sup> tells the world that you are prepared to put up a fight.

## STATE STATUTES AND COMMON LAW

Many states also have trademark registration statutes that allow registration of marks used in intrastate commerce, using procedures that function similarly to the USPTO process defined by the Lanham Act. In addition, all states protect unregistered trademarks under some combination of state statute and common law. For the sake of brevity, this section will not detail trademark protections in all fifty US states.

In most states, the common law recognizes ownership of a trademark. Ownership under common law is most often established by demonstrating when the mark was first used in commerce, but unlike federal law, common law protections extend only to those areas or markets in which the mark is actually used. In contrast, federal registration of a trademark gives a basis under federal law for a suit for infringement, in addition to any common law claims that might be available. While it is possible to protect one's rights using only common law or state statutory protections, the benefits that flow from federal registration make it highly desirable.

## INFRINGEMENT AND DILUTION

There are two main rights that trademark owners will assert: **infringement** and **dilution**. Infringement of a trademark usually involves the use of the mark in a way that is so similar to the owner's usage that the average purchaser will likely be deceived, will mistake the infringing goods for the original, or will likely experience confusion. Dilution is a lessening of the value of a trademark caused by an unauthorized use of the mark, regardless of whether any actual confusion, deception, or mistake occurred.

### Infringement

Under the Lanham Act the standard for determining whether a mark is infringing is whether there is a "likelihood of confusion" over the mark in a particular usage context. More specifically, infringement comes when a consumer is likely to be confused over the source, sponsorship, or approval of the goods bearing the mark.

In deciding whether consumers are likely to be confused, courts have previously looked at a number of factors, including:

- Similarity between the two marks (such as any visual, phonetic, or contextual similarities);
- Similarity of the goods or services being offered;
- Proximity of the goods in a typical retail setting;
- Strength of the plaintiff's mark as exemplified by how well known the mark is to the public at large;
- Evidence of any actual confusion by consumers;

- Evidence of the defendant's intent in using the mark;
- Likely level of care employed by consumer in the purchase of that type of product; and,
- Likely growth or expansion of the product lines.

Of these eight factors, the first two are arguably the most important. For example, using an identical mark on an identical product is a clear case of infringement, such as a company other than Ford manufacturing a midsize automobile and calling it a Taurus. Similarly, calling the vehicle a Taurius would run into problems. (This use of similarly spelled names is of particular concern in the Internet domain name context, which will be discussed in a later section.)

But mere similarity is not always determinative of infringement. For example, it is possible to find Delta Faucets just a few aisles away from Delta power tools at your local home improvement store. While made by different companies, the similarity in trademark does not constitute infringement because consumers are not very likely to mistake a belt sander for a shower head.

### Dilution

To further clarify the distinction between normal trademark infringement and dilution, in 1995 Congress amended the Lanham Act by passing the Federal Trademark Dilution Act (FTDA). This legislation expanded protections granted to famous and distinctive trademarks under the Lanham Act. Unlike infringement, dilution does not require evidence of a likelihood of confusion. Instead, the plaintiff must demonstrate that their mark is "famous," that it is being used in commerce by another party, and that the use causes the dilution of the "distinctive quality" of the mark.

The FTDA says that in determining whether a mark is "famous," a court may look at factors including the length of time a mark has been used, how widely and in what geographic areas it has been advertised, how recognizable the mark is to the public, and other factors. Highly distinctive long-used and well known marks, such as Coca-Cola or Kodak are examples of famous marks. Once a plaintiff establishes the fame of a mark, the owner can seek an injunction against further use of the mark in a manner that dilutes the distinctive qualities of that mark.

There are two types of dilution of a mark: **blurring** and **tarnishment**.

**Blurring.** Blurring is the weakening of a mark through its identification with dissimilar goods. For example, marketing Kleenex brand refrigerators would not likely confuse someone looking for bathroom tissue to accidentally purchase a refrigerator, however the use of the trademark would dilute the marks distinctiveness as representing personal care paper products.

**Tarnishment.** Tarnishment is the use of a mark in an unflattering light, through associating it with either inferior or distasteful products. For example, in the case *Toys 'R' Us v. Akkaoui*, 40 USPQ.2d 1836 (N.D. Cal. 1996), the toy retailer brought a successful tarnishment claim against a pornographic web site "adultsrus.com."

## Other Trademark Claims

Although dilution claims and infringement claims based upon likelihood of confusion are the two most common trademark-related causes of action, there are a number of other bases for bringing suits. Many states have enacted unfair competition laws that prohibit a range of activities known as **passing off**, **contributory passing off**, **reverse passing off**, and **misappropriation**.

**Passing off.** Passing off occurs when a defendant attempts to “pass off” their product as if it were the mark owner’s product. For example, affixing a Dell nameplate to computers actually made in someone’s basement would constitute passing off.

**Contributory passing off.** Contributory passing off occurs when a defendant induces a retailer to pass off a product. For example, bribing a computer store to sell computers with a fake Dell nameplate would be contributory passing off.

**Reverse passing off.** Reverse passing off takes place when someone tries to market someone else’s product as their own. If a computer store purchased Dell computers, replaced the nameplate with its own store brand nameplate, and attempted to sell the computers, they would have engaged in reverse passing off.

**Misappropriation.** Misappropriation, a privacy-related tort, is traditionally defined as using the name or likeness of someone for an unauthorized purpose, such as claiming a commercial endorsement by publishing someone’s image (or even that of a look-alike impersonator) in an advertisement. In the trademark context, using a mark without authorization can violate federal and state law prohibitions on certain unfair trade practices, including the unauthorized use of marks in inappropriate ways.

## Parody and Fair Use

Aside from challenging the validity of a trademark claim or attacking the elements of the infringement claim, defendants in trademark infringement or dilution cases can also claim two affirmative defenses: parody and fair use.

**Parody.** Certain uses of a trademark for purposes of humor, satire, or social commentary, may be permissible if they are not very closely tied to commercial use. The theory underlying the protection of parody is that artistic and social commentary are valuable contributions to the society, therefore some deference to the First Amendment’s protection of these types of speech is in order, even when balance against the detriment to a trademark owner. The protections vary, however. For example, in the highly amusing case of *Hormel Foods Corp. v. Jim Henson Productions*, 73 F.3d 497 (2d Cir. 1996), the use of a pig-like character named “Spa’am” in a Muppet movie was found not to violate Hormel’s rights in the trademark “SPAM.” However, in *Coca-Cola Co. v. Gemini Rising, Inc.*, 346 F. Supp. 1183 (E.D.N.Y. 1972), the printing of posters with a stylized slogan and logo reading “Enjoy Cocaine” were

found to violate the rights of Coca-Cola in the stylized slogan and logo “Enjoy Coca-Cola.”

**Fair Use.** Fair use occurs when the public benefit of allowing the use is perceived to override any perceived harm to the trademark owner. For example, in the case *Zatarains, Inc. v. Oak Grove Smokehouse, Inc.*, 698 F.2d 786 (5th Cir. 1983), the defendant’s use of “fish fry” to describe a batter coating for fish was not an infringement of the plaintiff’s mark “Fish-Fri.” The court held that fair use prevents a trademark owner from monopolizing a descriptive word or phrase to the exclusion of anyone else who seeks merely to accurately describe their goods. The defense of fair use is only available, however, when the mark at issue is descriptive, and then, only where the descriptive term is used descriptively. Federal trademark statute also contains a right to fair use limited to usage in comparative advertising.

## POLICING TRADEMARK ON THE INTERNET

Along with the tremendous growth in the usage of the Internet for both commercial and personal use, there has been a similar expansion in the number of trademark-related disputes involving the Internet. In a later section we will discuss the complex legal issues arising from trademark disputes over Internet domain names. But first there are a number of trademark issues that arise just from the very nature of the Internet as a facilitator of ubiquitous information sharing and access.

Perhaps the most important reason behind the growing amount of trademark-related litigation is that uncovering instances of trademark violations can be as simple as typing your trademark into an Internet search engine. Just a decade ago, a trademark owner in Maine might have no idea that his trademark might be in use by someone in Oregon. But with the ability to quickly and cheaply search the Internet, trademark owners are quickly able to perform searches that might have been impossible—or just impossibly costly—a few years ago.

The ability to so easily discover trademark infringement, both intentional and unintentional, has catapulted trademark law into one of the most active areas of litigation in the Internet arena. But the nature of trademark law itself has also added to the litigation explosion. As noted above, failure to properly police a mark can result in it becoming generic, and thus unprotected. Therefore, the same ease with which a trademark owner might uncover infringement may require that a trademark owner keep policing the Internet routinely and bring enforcement actions: If an infringement is known—or could be discovered through basic due diligence—and goes unchallenged, the trademark owner could lose control of its mark.

The requirement of constant policing of trademarks has, however, caused the unfortunate side effect of a growing number of heavy-handed actions against inexperienced web users, and still more enforcement actions that are brought in cases where a finding of infringement or dilution is highly unlikely. In many of these cases, well-intentioned individuals have been bullied by corporations

over trademarks appearing on personal web pages. In some cases that have received significant media attention, sites created by fans of rock groups, automobiles, and movie stars have been threatened by the very entities that the sites were set up by their creators to honor.

## Meta Tags

In recent years, several disputes have arisen over the use of trademarks in **meta tags** on Internet web pages. Web pages on the Internet are coded using a type of programming language called Hyper Text Markup Language, or HTML. The codes that are embedded in HTML documents, called tags, tell the browser how to display the information contained on the page, such as when to display words in bold, when to change fonts or font sizes, how to align tables, or where to place images. Web page designers can also include meta tags, which are special tags that contain information about the contents of the web page. Meta tags are used by search engines to find and rank pages so that more relevant search findings are displayed before less relevant ones.

In one of the first lawsuits over meta tags, *Oppedahl & Larson v. Advanced Concepts, et al.*, Civ. No. 97-CV-1592 (D.C. Colo., 1997), a Colorado law firm discovered that the defendants had put the law partners' names, "oppedahl" and "larson," in meta tags on several web pages. This was presumably done in hopes that searches for the respected law firm's name would gain more attention for the defendants' web pages. Suing under both the Lanham Act and the Federal Trademark Dilution Act, as well as state and common law unfair trade practice actions, the law firm won a permanent injunction against any further use of their names in meta tags on the defendants' web sites. Since that case, a number of other disputes have tested the extent to which trademarks may be used in meta tags and have largely resulted in prohibitions against uses by entities seeking to enhance site traffic by using the marks of competitors.

One of the issues that has arisen in meta tag disputes is the concept of "initial interest confusion." Initial interest confusion occurs when the use of another's trademark is done so in a manner reasonably calculated to capture initial consumer attention, even though no actual sale is finally completed as a result of the confusion. The case of *Brookfield Communications, Inc., v. West Coast Entertainment Corp.*, 174 F.3d 1036 (9th Cir. 1999), illustrates the issue. Brookfield operated a web site, MovieBuff.com, containing a movie database. West Coast, a video retailer, used the term "moviebuff" in meta tags on its web site. A court held that West Coast's use of term in meta tags led to "initial interest confusion," in which search engine users looking for MovieBuff.com's site might visit West Coast's site and stop looking for MovieBuff.com, even though there might never be any confusion over sponsorship of the two sites.

Not all cases in which meta tags were at issue have resulted in a ban on their use. For example, in the case of *Playboy Enterprises, Inc. v. Terri Welles*, 162 F.3d 1169 (9th Cir. 2002), a model who had posed as a Playboy Playmate of the Month was permitted to use "Playboy" and "Playmate" as meta tags for her web site. But new uses

have created more confusion in this area. For example, in late 2003 and early 2004, several courts issued diverging opinions on the usage of trademarks to trigger various advertising "pop-up" advertisements and targeted advertisements keyed to trademarks appearing in search engines. Many of these cases are ongoing at the time this article is being written, and it is likely that confusion will continue until higher courts weigh in.

## Deep Linking

Fundamental to the functioning of web pages on the Internet is the concept of a link. A link, short for hyperlink, is a tag coded within a web page that turns a piece of text (or in some cases an image) into a pointer to another document or page. Clicking on that link will typically cause the browser to follow the link and open the new page. While a simple link to the homepage of a web site will not typically run into trademark issues, some sites choose to create links to pages many levels down within a site. For example, instead of linking to the home page of a manufacturer, a web site designer might choose to create a link that goes directly to a page displaying one of the manufacturer's products. This practice is called **deep linking**.

Some site owners object to deep linking because it allows visitors to quickly bypass other contents of a web site, including advertisements, which they would normally see if they had to navigate step-by-step through the contents of a site. In several court cases, plaintiffs have charged that deep linking deprives them of the full benefits of having visitors explore their site, and have argued a variety of copyright, trademarks, and unfair competition claims. Proponents of deep linking counter that deep links are no different than footnotes or bibliographies, permitting readers to jump quickly to precise information. There are few clear court decisions on the trademark implications of deep linking, however many of the suits have focused on evidence of a defendant's bad faith, such as any appearance that the deep linking is intended to take unfair advantage of the other site's content, which will cut strongly in favor of the plaintiff.

In a related issue, there have been numerous disputes over the practice of "framing" Internet content. Framing is a technique in which content from one site is displayed within a "frame" appearing on another unrelated site. The use of framing often makes it appear that the content is owned or otherwise presented by an entity other than its actual owner or authorized user. Most disputes regarding framing have centered on copyright implications of unauthorized framing of content, however trademark issues also arise when there might be confusion as to the source of the content or its relationship to advertisements and other affiliations which might be suggested by the way in which the framed material appears.

## DOMAIN NAMES

With the explosive growth of the Internet, both in its importance to global commerce and in the effect it has had on all aspects of our society, the importance of the domain names used on the Internet cannot be understated. The academic and non-commercial roots of the Internet

caused many of its key functions, such as the Domain Name System, to be designed without some important safeguards. For example, domain names could then—and in many cases can still—be registered by anyone willing to pay the registration fee. In the early days of the Internet this fact caused something of a “land grab” mentality in which speculators rushed to purchase the rights to domain names that were expected to become valuable. Indeed, the domain name *WallStreet.com*, registered for under \$100, was reportedly sold for over \$1 Million (Bicknell, 1999).

Unfortunately however, some speculators also rushed in and purchased domain names that were identical (or in some cases merely similar) to valuable brand names. These so-called “cybersquatters” sought to gain financially by occupying the “virtual” real estate of someone else’s trademark translated into a domain name. Because a domain name has become such an important part of a company’s marketing identity, trademark owners have been forced to wage legal battles to retake control of their trademarks in cyberspace. Cybersquatting is discussed in detail in a later section, but it may be useful to look first at how domain names work and why they have become a trademark law battleground.

## Domain Name System Basics

Generally speaking, each computer connected to the Internet requires a unique address, called an Internet Protocol (“IP”) address, in order to distinguish it from all the other computers on the Internet. When computers communicate across the Internet, they use IP addresses in order to ensure that when a user on a particular computer requests data from another computer, the data gets delivered to the right place.

IP addresses are not very friendly to human eyes. Looking something like “192.168.27.145,” it was quickly determined that it would be easier to assign names to stand in for those numbers, because many humans find it easier to remember names than to remember numbers. Thus, the designers of the early Internet developed the Domain Name System (“DNS”) to permit the reliable association of names with IP addresses. As a result, with the help of DNS, when you tell your web browser that you want to check out the latest news at *CNN.com*, it is able to correctly direct your query to 64.236.16.116, which is one of the many web servers that answer to the busy *CNN.com* domain name.

Domain names, and their underlying numbers, are controlled by the Internet Corporation for Assigned Names and Numbers (“ICANN”). ICANN controls not only the allocation of IP addresses and the network of domain name registrars who control all domain names, but also delegate operation of the Root Servers. The Root Servers, the heart of the Domain Name System, are a collection of servers operated around the globe that manage all requests for information about the top level domains (“TLDs”). TLDs are simply a means of organizing domain names into broad categories.

As of this writing, there are 14 generic TLDs in which entities or individuals can register secondary domains, in some cases subject to certain restrictions. They include:

- .com for commercial sites
- .net for networks
- .org for non-profit organizations
- .gov for U.S. federal government sites
- .edu for educational institutions
- .int for entities created by international treaties
- .mil for U.S. military sites
- .biz for businesses
- .info for general use
- .name for personal use by individuals
- .pro for professional fields such as lawyers and accountants (this TLD was still inactive as of February 2003)
- .aero for the aerospace industry
- .coop for cooperatives
- .museum for museums

There are also over 200 country code TLDs (ccTLD), based upon the two-letter country codes for the worlds recognized nations. Examples include:

- .us for the United States
- .uk for the United Kingdom
- .ca for Canada
- .mx for Mexico
- .de for Germany
- .jp for Japan

When you enter a domain name into your browser (for purposes of this example we will use *www.example.com*) here is—in theory—how the Domain Name System works to assure you get to the web site you want:

- Your browser communicates your request for *www.example.com*, via your Internet connection, to the Domain Name Servers designated for your use by your Internet service provider.
- Your service provider’s Domain Name Servers in turn ask the upstream DNS servers (and if necessary, eventually, the Root Servers) to search their database for the IP address of the Domain Name Servers that are authoritative for the TLD “com.”
- Your query is then passed to the Domain Name Servers for “com,” which then search their database for the IP address of the Domain Name Servers that are authoritative for the second-level domain “example” within the top level domain “com.”
- Your query is then passed to the Domain Name Servers for “example.com,” which then searches their database for the IP address of the server that answers to the sub-domain “www” within that second-level domain.
- Once it locates the correct IP address, it tells your web browser what IP address to connect to, whereupon that server recognizes your request for a web page and transmits the appropriate data back to your computer.

This is “in theory” because in reality, this process can be simpler, or more complex, depending upon how your ISP chooses to manage its DNS requests. For example,

some ISPs keeps a record of previous DNS requests in a “cache” file so that it can better manage time lag and server load issues by serving up IP addresses that it trusts are probably still correct since the looking them up a few hours earlier.

## Domain Name Registration

The first challenge in registering a domain name is to identify a domain name that is suitable for your needs. Depending on the intended use of the domain name, there are many considerations, beginning with the choice of TLD that best suits your vision for your domain. Once you have decided on the TLD, you may have a choice of registrars delegated by ICANN to manage the process of domain name registration. For example, as of this writing there are several hundred ICANN-accredited registrars, not counting the designated registrars for all the country code TLDs.

Once you have selected a registrar, you will communicate to them what second-level domain you wish to register. In most cases, they will check their records and determine whether the domain name requested is already registered, or might have previously been reserved. Presumably you will have checked to see if there is a web site already operating at the domain name you have selected, however the absence of an active site is not determinative, as it is possible for a domain name to be registered, but not in active use.

If the second-level domain name you desire has not been previously registered, you will likely be given the choice of registering it. Upon providing contact and billing information, and paying the registrar’s fee of course, you will also be asked to provide the IP addresses of a primary and a secondary Domain Name Server for your domain. While some registrars offer you the option of also hosting the domain on their own servers, you may need to have previously arranged with an ISP to establish the technical details necessary for operating DNS, web, and email services for your newly-chosen domain name. If you have set up these services in advance, however, then it is possible to have your new domain fully functional within just a matter of minutes or hours after completing the registration process.

## Internet Domain Disputes

Far and away the greatest amount of trademark-related controversy on the Internet concerns use of domain names. Because of both the value of trademarks themselves, and the value of memorable domain names for maximizing the marketing and sales power of online operations, using popular trademarks as domain names has been an important issue for businesses beginning to make use of the Internet. Much to their consternation however, many companies have attempted to register domain names related to their company name or their trademarks only to discover that someone else has already registered those domain names.

In the course of many legal disputes over domain names, some consensus among the courts has developed. Most courts have applied trademark law in much the same fashion as they would in any other trademark dispute. For

example, marks are assessed for the extent to which they are fanciful, arbitrary, suggestive, descriptive or generic. Disputes have also been judged on whether there is evidence of bad faith on the part of either party. In the Oppedahl & Larson case discussed above, there was no reasonable basis for the defendant to be making use of “Oppedahl” and “Larson” other than their desire to garner traffic attracted by someone else’s mark.

The most common method of using a trademark in a domain name is the verbatim use of the mark in conjunction with the TLD, such as Pepsi.com. But a related form of trademark infringement comes in dilution through the registration of similar domains, or domains containing misspellings or common typographical errors. Disputes over domains such as “amazom.com” (instead of amazon.com), gateway20000.com (instead of gateway2000.com), and micros0ft.com (microsoft.com with the second letter “o” replaced with a zero), have almost uniformly resulted in court decisions or settlements transferring domain ownership to the aggrieved party. These and other cases of infringement have resulted in a new area of law—and even of legislation—focused on resolving trademark-related domain name disputes.

## Cybersquatting

In the mid-1990s, Dennis Toeppen registered some 250 domain names that were either similar or identical to popular trademarks, including deltaairlines.com, eddiebauer.com, neiman-marcus.com, northwairlines.com, and yankeestadium.com. In two cases considered pivotal among domain name trademark disputes, *Intermatic Incorporated v. Toeppen*, 947 F.Supp. 1227 (N.D. Ill. 1996), and *Panavision Int’l, L.P. v. Toeppen*, 945 F. Supp. 1296 (C. D. Cal., 1996), the plaintiffs successfully forced Toeppen to relinquish control of the domains intermatic.com and panavision.com, respectively.

The Panavision case in particular illustrates how many of the cybersquatting disputes play out. In 1995, Toeppen registered the domain name www.panavision.com and created a web site that contained photographs taken around the city of Pana, Illinois. When contacted by Panavision, a maker of motion picture cameras and photographic equipment, Toeppen offered to sell the domain name for \$13,000. Panavision declined and brought suit under the Federal Trademark Dilution Act.

As discussed in an earlier section, the FTDA requires plaintiffs to demonstrate that their mark is “famous” and that the defendant is using a mark in commerce in a fashion that could cause dilution of the mark’s distinctiveness. While Toeppen claimed that his use of the mark was non-commercial, the court held that having offered the domain name for sale indicated that he intended that the domain name itself be a commercial offering.

In the Intermatic case, Toeppen originally operated a web page at the intermatic.com address which described a piece of software he claimed to be developing called “Intermatic,” later replacing it with information about Champaign-Urbana, Illinois, the community in which Toeppen lived. The Intermatic court held that despite these non-commercial uses, the registration of the domain name itself was dilutive of Intermatic’s mark.

## Anticybersquatting Consumer Protection Act

As the problem of cybersquatting grew throughout the 1990s, Congress responded in 1999 by enacting the Anti-cybersquatting Consumer Protection Act (“ACPA”), which amended the Lanham Act to include protections specific to Internet domain names. One change from past practice under the Federal Trademark Dilution Act, however, was the ACPA’s removal of the requirement that the mark be used in commerce. This greatly expanded plaintiffs’ ability to take control over domain names that had merely been registered but were not actually in use.

The ACPA states that cybersquatting occurs when the person registering a domain name containing a trademark “has a bad faith intent to profit from that mark” and “registers, traffics in, or uses” a domain name that is “identical or confusingly similar to or dilutive of that mark.” The Act includes nine factors that courts may take into consideration when determining the existence of bad faith intent:

- the trademark or other intellectual property rights of the person, if any, in the domain name;
- the extent to which the domain name consists of the legal name of the person or a name that is otherwise commonly used to identify that person;
- the person’s prior use, if any, of the domain name in connection with the bona fide offering of any goods or services;
- the person’s bona fide non-commercial or fair use of the mark in a site accessible under the domain name;
- the person’s intent to divert consumers from the mark owner’s online location to a site accessible under the domain name that could harm the goodwill represented by the mark, either for commercial gain or with the intent to tarnish or disparage the mark, by creating a likelihood of confusion as to the source, sponsorship, affiliation, or endorsement of the site;
- the person’s offer to transfer, sell, or otherwise assign the domain name to the mark owner or any third party for financial gain without having used, or having an intent to use, the domain name in the bona fide offering of any goods or services, or the person’s prior conduct indicating a pattern of such conduct;
- the person’s provision of material and misleading false contact information when applying for the registration of the domain name, the person’s intentional failure to maintain accurate contact information, or the person’s prior conduct indicating a pattern of such conduct;
- the person’s registration or acquisition of multiple domain names which the person knows are identical or confusingly similar to marks of others that are distinctive at the time of registration of such domain names, or dilutive of famous marks of others that are famous at the time of registration of such domain names, without regard to the goods or services of the parties; and,
- the extent to which the mark incorporated in the person’s domain name registration is or is not distinctive and famous.

The Act then indicates that bad faith cannot be found if the defendant “believed and had reasonable grounds to

believe that the use of the domain name was a fair use or otherwise lawful.”

The recent dispute over the domain name Nissan.com gives some insight into how courts are applying the ACPA and other aspects of traditional trademark law analyses. The domain name is at the center of a dispute between Nissan Motor Co., Ltd., a popular car manufacturer, and Nissan Computer Corporation, a small business in North Carolina operated by Mr. Uzi Nissan. In *Nissan Motor Co., Ltd v. Nissan Computer Corp.*, 61 U.S.P.Q.2d 1839 (C.D. Cal., 2002), the court noted that the defendant registered the domain in 1994 and has been operating his firm under the Nissan name since 1985. While the court found that the initial registration of the domain name was not in bad faith, the court did take issue with several aspects of Mr. Nissan’s behavior, including his initial response to Nissan Motors complaint: an offer to sell the domain name for several million dollars. More recently, the court ordered Mr. Nissan to cease any commercial activities involving the site when it was discovered that Mr. Nissan was advertising automotive-related products on the site, despite his business being unrelated to automobiles. (Officialspin. com, 2002)

One of the innovative aspects of the ACPA is the way it deals with jurisdictional matters. Traditionally, legal disputes have always been subject to jurisdictional boundaries and national borders, and either the physical presence of the parties within those boundaries or evidence of the parties’ contacts with the jurisdiction. Recognizing that in many cases cybersquatters go to some lengths to hide their identity or their location, the ACPA permits the trademark owner to take action against the domain name itself, rather than the domain owner personally. This permits aggrieved parties to locate the registrar and, although the registrar itself cannot be held liable for an infringing domain it permitted to be registered, the domain name itself can be attacked.

## ICANN Domain Name Dispute Process

While the ACPA’s jurisdictional elements have simplified matters somewhat for trademark owners with domains that have been registered within the United States, the global nature of the Internet has required a less geocentric dispute resolution process. To that end, ICANN as developed a Uniform Domain Name Dispute Resolution Policy (“UDRP”) the provisions of which are in many respects similar to those of ACPA.

The UDRP process relies upon third-party, private dispute resolution mechanisms rather than the more expensive prospect of litigation in a court of law. For trademark owners who are seeking a quicker and cheaper resolution of domain disputes, the UDRP route has proven to be extremely popular, even though no monetary damages or injunctions are available. Indeed, the only remedies available under the UDRP are the cancellation or transfer of the domain name. Thus, for instance where the injury to the trademark owner is more serious, traditional litigation may yet be necessary.

The World Intellectual Property Organization (“WIPO”) has attempted to define cybersquatting, and to establish guidelines for dispute resolution. In a 1999 report on the

Management of Internet Names and Addresses, the WIPO delegates discuss at great length the phenomenon of registering trademarks as domain names with the intent of profiting from the ownership, either by capitalizing on traffic brought in through the confusion, or by selling the domain to the trademark owner. In the end, WIPO's recommendations are very similar to those contained in the ICANN UDRP and the ACPA.

The UDRP, WIPO's recommendations, and the operations (and even the very existence) of ICANN are currently the subject of tremendous international debate. While the details of these arguments are too lengthy for inclusion in this brief article, many web sites (including ICANNWatch.org and UDRPinfo.com) chronicle the legal, technical, and political arguments over this emerging field.

## CONCLUSION

As the Internet becomes an even more critical channel for businesses to reach out to consumers, the value of a well leveraged trademark has never been higher. At the same time, the pressures on trademark owners from infringing activities is requiring them to be ever more vigilant in their policing and prosecution of violators. In response to these pressures, courts and lawmakers have expanded and clarified traditional trademark protections, adding greatly to the remedies available to trademark owners who feel their rights have been violated. In this chapter we have covered the fundamentals of trademark law, and seen them applied to the unique new situations presented by Internet technologies. While the trademark space will continue to evolve, it is clear that the value of trademarks is as well recognized as ever in the history of commerce.

If there is one conclusion to be drawn, it is that trademark is a very complex field of law and procedure, requiring expert guidance in order to provide maximum opportunity and protection. While this article may provide readers with a general overview of many current issues in trademark law, it is not a substitute for qualified legal counsel. As has been noted repeatedly throughout this article, successful use of trademark law depends upon many detailed analyses, procedural hurdles, and requires a significant commitment of time and resources in order to take full advantage. Trademark law provides robust protections to those who, with assistance from talented counsel, seek to protect their goods and services in the marketplace.

## GLOSSARY

**Blurring** A type of dilution in which the distinctiveness of a mark is weakened through its identification with dissimilar goods.

**Deep linking** Creating a web page link that is tied directly to a document deep within the page hierarchy of a web site, rather than simply linking to the main home page of the site.

**Dilution** A lessening of the value of a famous trademark caused by an unauthorized use of the mark, regardless of whether any actual confusion, deception, or mistake occurred.

**Distinctiveness** The ability of a mark to distinguish the goods and services of the mark from the goods and services of another.

**Domain Name** An alphanumeric electronic address on the Internet.

**Famous Trademark** A court-determined trademark designation under 35 USC §1125(c).

**Lanham Act** Also known as the Trademark Act of 1946, it created a set of federal rules for governing the process of registering trademarks and established certain nationwide legal protections for trademark

**Likelihood of Confusion** The test of trademark infringement under the Lanham Act. A likelihood of confusion exists if a substantial number of reasonably prudent consumers are likely to be confused as to the source of the goods or services.

**Infringement** Use of a trademark in a way that is so similar to the owner's usage that an average consumer will be deceived, will mistake the infringing good for the original, or will experience confusion over the nature or origin of the product.

**Initial Interest Confusion** The use of another's trademark in a manner reasonably calculated to capture initial consumer attention, even though no actual sale is finally completed as a result of the confusion.

**Intellectual property** The concept of legal recognitions for property rights in intangible things such as ideas and intellectual creations.

**Meta tags** Hidden codes embedded in web pages that contain keywords related to the contents of a particular page, designed to only be seen by search engines.

**Secondary meaning** An association that has developed in the public's mind between the mark or trade dress of a product and owner of the mark or product.

**Service mark** A mark that is used to identify a service or the provider of a service rather than a tangible product, such as the name of a consulting firm, or the name of a proprietary analytical process used by that consulting firm.

**Tarnishment** A type of dilution in which the mark is used in an unflattering light, such as by associating it with inferior or distasteful products or services.

**Trademark** A mark that is used by a manufacturer or merchant to identify the origin or ownership of goods and to distinguish them from others and the use of which is protected by law.

**Trade dress** The overall image of a product, composed of the nonfunctional elements of its design, packaging, or labeling, including specific colors or color combinations, a distinctive package shape, or specific symbols or design elements.

**U.S. Patent and Trademark Office (USPTO)** The federal agency charged with managing the nationwide issuance of patents and registration of trademarks.

## INTRODUCTION

The global organization of networked computers that we call the Internet has given contracts a new role and dimension. Contracts have become the very building blocks of electronic commerce. Not only do they perform an essential function as the purveyors of software and content licenses, but they also provide the core infrastructure for the exchange of informational products in networked markets. In fact, one of the five key principles of the *A Framework for Global Electronic Commerce* (White House, 1997) relies on the establishment of a legal environment based on a contractual model of law. In a renaissance of freedom of contract, licensors are charged with the freedom to order contractual relationships as they see fit to market their products online and, in so doing, advance the growth of the new economy. One of the clearest indications of the new economic trajectory may be seen in the significant returns of the software sector. The actual and estimated return of the combined hardware, software, and services sectors was \$536.8 billion for the U.S. economy during 2003 (U.S. Department of Commerce, 2003).

Since the idea of open-architecture networking was first introduced in 1972, the Internet has revolutionized the communications world in an unparalleled manner.

Whether we are talking about selling intangible or tangible goods, the Internet has dramatically changed not only business–customer relations but also the way in which products are distributed and exchanged. Computer networks make possible new vertical and horizontal business relationships between producers, users, consumers (P2P), and suppliers (B2B). In response, Internet business models, whether virtual or clicks-and-mortar, are assuming an increasing variety of forms, including the following: brokerage, advertising, intermediary, merchant, manufacturer, affiliate, community, subscription, and utility (Afuah & Tucci, 2000). Moreover, the supply of goods and services directly between supplier and consumer has given rise in turn to new classes of business intermediaries. From the business communities of aggregators to the online auctions, all rely on contracts to provide stable online trading markets, a trading venue defined by clear rules, industrywide pricing, and open market information for buyers. eBay.com, for example, was among the first successful sites to provide a framework where consumers could trade a wide variety of goods and services with each other (consumer-to-consumer, C2C) and with business (consumer-to-business, C2B).

Arguably, we might think of shrink-, click-, or browsewrap agreements as a new kind of *lex mercatoria*

or merchant-designed law to facilitate the online exchange of goods and services in consumer markets. In contrast to traditional contracts, there is a far greater degree of uncertainty as to online contracts' validity and enforceability, particularly in the areas of jurisdiction, contract formation, identification of the terms and statutory issues relating to signature, and other evidentiary requirements. For example, vendors and merchants question how an offer should be made and acceptance given. Buyers are concerned that one false click might result in their being ensnared into entering a binding contract.

Through a combination of mercantile custom, common law, and legislative developments, the classic principles of contract law are being adapted and supplemented to accommodate the needs of electronic commerce. The aim of this chapter is to provide the reader with an overview of the law relating to the formation and validity of electronic contracts and to offer some recommendations concerning the measures that might be taken to create an enforceable electronic contract. The first part of this chapter describes the problems pertaining to contracting online, including the maintenance of security of electronic transactions and the integrity of electronic documents. The next part considers the legal framework for electronic contracting, notably with respect to the provision of standards and procedures for electronic signature. The next section examines the enforceability of clickwrap and browserwrap licenses that the software industry has pioneered to facilitate online transactions of its products and to give additional security to its intellectual property. In a medium where it is all too easy to include unduly harsh terms, this section also discusses the doctrine of unconscionability, which may subsequently render a contract unenforceable, and how to guard against such a contingency. The chapter then discusses the vexed question of contractual restrictions in end user license agreements, including limitations on the fair use of software, the means of dispute resolution, and the forum in which licensees can bring suit. The next section examines the problems that have arisen with respect to the licensing of digital information and sales law, particularly warranties concerning the fitness and merchantability of informational goods, such as software. The chapter then considers the developments that have taken place with respect to consumer rights online, in particular the ability of consumers to enjoy the legal protection offered by their home states. The chapter concludes with some tips and suggestions for contractors as to how, given the current state of the law, they might best offset the risks of contracting online. Although this chapter generally deals with contractual issues associated with the security of online commerce, other security-related considerations that also affect the validity of online contracts are beyond its scope and are covered in other parts of this handbook: network security (Volume I, Part 2: Infrastructure for the Internet, Computer Networks and Secure Information Transfer), protocol standards (Volume I, Part 3: Standards and Protocols for Secure Information Transfer), and security management (Volume II, Part 3: Foundations of Information, Computer, and Network Security).

## MAINTAINING THE SECURITY OF ELECTRONIC TRANSACTIONS

### Problems Concerning the Authenticity and Integrity of Electronic Documents

Authenticity is concerned with the source or origin of a document or message ([Fed. R. Evid. 901]). Integrity is concerned with the accuracy and completeness of the communication. In a paper-based world, a contracting party can rely on numerous indicators of trust to ensure the authenticity and integrity of a document. These indicators include using paper, perhaps with a letterhead or watermarks, or other indicia of trust, to which the message is attached and not easily altered; handwritten ink signatures; sealed envelopes for delivery via a trusted third party, such as the postal service or a courier service; or personal interaction between the parties. However, with electronic documents and electronic communications conducted remotely over the Internet, none of these indicia of trust is possible. To all intents, a communication in binary code can be copied and modified easily without discovery. In addition, although a handwritten signature can be readily verified to authenticate the identity of the signer and the source of a document, online there is an additional risk that the party contracting may not be who they claim or that the substance of the communications used to form an agreement may be subject to alteration.

### Party Authentication and Message Integrity

Moving transactions to an electronic environment has two important consequences. First, in many cases it may be difficult to know when one can rely on the authenticity and integrity of an electronic message. Authentication issues, although rare in the real world, become increasingly important in the virtual world (see the chapter in this handbook, Anonymity and Identity on the Internet). On the Internet, how do we decide whether Jane Doe is who she says she is? Those decisions that involve entering into contracts, shipping products, making payments, or otherwise incurring financial risk are difficult to make when relying on an electronic message. Second, in the event of legal action, this lack of reliability can make it extremely difficult to prove the validity of the contract in court. For example as an evidentiary matter, if the defendant denies making the "signature" that is attached to an electronic document, it may be impossible for the plaintiff to prove the authenticity of that electronic signature, in the absence of additional evidence (e.g., *U.S. v. Eisenberg*, 1986; *U.S. v. Grande*, 1980).

The concern regarding integrity arises from the fact that electronic documents are easily altered in a manner that is not detectable. Further, because every copy of an electronic document is a perfect reproduction, the original of an electronic document does not exist. How then are we to know whether the document the recipient received is the same as the document that the sender sent? How do we know whether the document has been altered either in transmission or storage?

If users are to have trust in the electronic medium, recipients of electronic messages must be confident of

the communication's accuracy (Smedinghoff, 2002). The question of integrity is critical when it comes to the negotiation and formation of contracts online, the licensing of digital content, the making of electronic payments, and the verification of the authenticity of these transactions at a later date. For example, a contractor who wants to receive tenders from bidders online must be able to verify that the messages containing the bids have not been altered. In that situation, the use of cryptographic algorithms, accompanied by digital signatures, is the best means of detecting any alteration in an electronic document.

If the commercial world is to benefit from the advantages of online contracts, both buyers and sellers need to be assured that online contracts are secure insofar as the identity of the parties and the certainty of the terms are concerned. The Statute of Frauds, which requires that certain contracts, such as those dealing with transfers of land, be in writing, was designed to overcome the problem of fraud with respect to oral contracts. Although the principle is still a sound one, to condition the enforceability of an online contract on a requirement for pen-and-paper writing would present a barrier to the effective use of the electronic medium (Prefatory Note to the Uniform Electronic Transactions Act, 7a, Part I, U.L.A. 17 (supp. 2000)).

## THE LEGAL FRAMEWORK FOR ELECTRONIC CONTRACTING

### United Nations Model Law on Electronic Commerce

With a view to removing barriers to electronic transactions, the United Nations Commission on International Trade Law (UNCITRAL) Model Law on Electronic Commerce of 1996:

- establishes rules and norms that validate and recognize contracts formed through electronic means
- sets default rules for contract formation and governance of electronic contract performance
- defines the characteristics of a valid electronic writing and an original document
- provides for the acceptability of electronic signatures for legal and commercial purposes
- supports the admission of computer evidence in courts and arbitration proceedings

### U.S. Laws Covering Electronic Transactions

These principles were implemented in the United States in 1999, when the National Council of Commissioners on Uniform State Laws (NCCUSL) approved the Uniform Electronic Transactions Act (UETA), 7A, Part I, U.L.A. 17 (Supp. 2000), which facilitates the use of electronic documents and electronic signatures. As of June 2004, 46 states have enacted the UETA (see <http://www.ncsl.org/>). In addition, the Uniform Computer Information Transactions Act (UCITA), also approved by NCCUSL in 1999, among its substantive provisions on electronic contracts, includes articles validating electronic transactions for the "licensing" of computer data (National Conference

of Commissioners on Uniform State Laws, 2001b). Concerned at the slowness and lack of consistency with which UETA was being adopted by state legislatures, in 2000 Congress stepped in to enact the Electronic Signatures in Global and National Commerce Act (E-SIGN; Pub. L. No. 106-229, 114 Stat. 464 (2000)).

Finally, Article 2 of the Uniform Commercial Code (UCC), which has governed the sale of goods since its promulgation in 1951, has recently been amended to accommodate electronic commerce and to reflect the development of business practices, changes in other law, and interpretive difficulties of practical significance (National Conference of Commissioners on Uniform State Laws, 2002). Adopted on May 13, 2003 by the NCCUSL and the American Law Institute (ALI), the amended Article 2, section 2-108(4) is intended to modify, limit, and supercede E-SIGN. In addition to the potential difficulties of application concerning its interface with E-SIGN, amended Article 2 (Sales) is not a revolution in sales law. The provisions of amended Article 2 include substitution of the word "record" for "writing" throughout amended UCC Article 2 and the adoption of new language concerning contract formation in amended UCC 2-204, 2-211, 2-212, and 2-213. In states that do not adopt amendments to UCC Article 2, E-SIGN (or UETA to the extent that it preempts E-SIGN) will apply to transactions subject to Article 2. In states that do adopt amended UCC Article 2, E-SIGN will not govern transactions subject to Article 2.

### Formation and Validation of Electronic Contracts

As a matter of general principle, there is no requirement that the parties to a contract must indicate their consent to be bound by signature. In fact, the law provides that a contract for sale of goods may be made in any manner sufficient to show agreement, including conduct by both parties that recognizes the existence of such a contract (UCC § 2-204). Similarly, E-SIGN provides that "a contract . . . may not be denied legal effect, validity, or enforceability solely because an electronic signature or electronic record was used in its formation" (§ 101(a)(2)). In addition, UETA provides that "a contract may not be denied legal effect or enforceability solely because an electronic record was used in its formation" (§ 7(b)). Finally, the UNCITRAL Model Law on Electronic Commerce is even more explicit in providing that "an offer and the acceptance of an offer may be expressed by means of data messages" and "where a data message is used in the formation of a contract, that contract shall not be denied validity or enforceability on the sole ground that a data message was used for that purpose" (Article 11(1)).

As a general rule, offers to contract may be made orally, in writing, or by conduct. There is no reason in principle therefore why an offer that is electronically transmitted should be any less effective than a written one. The problem is largely one of evidence. Questions may arise concerning the reliability of electronic communications, which may make it more difficult to introduce evidence in court. To be valid, an offer must communicate to the person receiving it that, once the offer is accepted, a contract is created. An offer may be accepted "in any manner and

by any medium reasonable in the circumstances” (UCC 2-206(1)(a)). Online offers may be accepted by e-mail or other form of electronic message, by electronic agent, and by conduct, such as clicking on a button or downloading content. Thus, if an offer is made by e-mail, one should be able to accept it by the same means unless the offer states otherwise (Restatement (Second) of Contracts § 65).

Although, generally speaking, an acceptance does not necessarily have to be sent the same way as the offer (*Market Development Corp. v. Flame-Glo Ltd.*, 1990), UETA provides that an electronic record is considered received only when it enters a computer system “that the recipient has designated or uses for the purpose of receiving electronic records of the type sent” (§15(b)(1)). Consequently, if the parties have regularly corresponded in the past by e-mail, an e-mail acceptance sent to the offerer’s e-mail address will presumably be effective. The purpose of the UETA requirement is to assure that recipients can designate the e-mail address or system to be used in a particular transaction in the event the parties have multiple e-mail addresses.

### When Is an Electronic Record Sent or Received?

Issues surrounding the timing of electronic records may be essential for resolving questions as to whether a binding contract has been created, as in the case where the offeror sets a deadline for acceptance. In addition, electronic transmissions may pose similar problems to cases where the offer and acceptance were exchanged by fax or other means of communication in which the interaction is not immediate. In the case where a message is sent from one computer system to another, UETA provides that the time at which an electronic record is considered to have been sent is the time that the record “enters an information processing system outside the control of the sender”; in the case where a message is sent from one person to another on the same system, such as where both parties are using the same Internet service provider, it is the time that the record “enters a region of the information processing system designated or used by the recipient which is under the control of the recipient” (§ 15(3)). An electronic record is considered to have been sent as of that time, provided that it is addressed properly to an information-processing system that the recipient has designated or uses for the purpose of receiving electronic records and from which the recipient is able to retrieve the electronic record, and provided further that it is in a form capable of being processed by that system (UETA § 15(a)(1) and 15(a)(2)).

Conversely, UETA provides that an electronic record is considered received by the intended recipient when it enters an information processing system that the recipient has designated or uses for the purpose of receiving electronic records of the type sent and from which the recipient is able to retrieve the electronic record, and is in a form capable of being processed by that system (§ 15(b)). It is also important to note that an electronic record is considered received even if no individual is aware of its receipt. That is, as with the postal service, once the message is delivered, it makes no difference whether the addressee actually opens it.

### Automated Transactions

Can a computer be said to have entered into a contract? Generally speaking, it may do so, depending on the circumstances. Certainly, a computer is capable of generating an offer. Inventory systems for example, are designed to calculate when supplies are low and automatically generate an electronic purchase order to the vendor. By analogy, case law indicates the validity of such contracts (*State Farm Mutual Auto. Ins. Co v. Bockhorst*, 1972). The law accepts that the computer operates in accordance with the information and directions supplied by its programmers. Similarly, a computer-generated acceptance, as distinct from a mere acknowledgment of receipt, may serve to create a binding contract (*Corinthian Pharmaceutical Systems v. Lederle Labs*, 1989). Accordingly, an electronic data interchange (EDI) message, such as a purchase order acknowledgment, would be considered an appropriate acceptance.

With respect to the related question of the enforceability of contracts formed via electronic agents, both E-SIGN and UETA expressly recognize the validity of such contracts. An electronic agent is defined as a computer program or other automated means used to initiate an action or respond to electronic records or performances in whole or in part without review or action by an individual at the time of the action or response (E-SIGN § 106(3); UETA § (2)(6)).

E-SIGN provides that a contract or other record relating to a transaction may not be denied legal effect, validity, or enforceability solely because its formation, creation, or delivery involved the action of one or more electronic agents so long as the action of any such electronic agent is legally attributable to the person to be bound (§ 101(h)). Similarly, UETA recognizes that a contract may be formed by the interaction of electronic agents of the parties, even if no individual was aware of or reviewed the electronic agent’s actions or the resulting terms and agreements (§ 14(1)). In addition, UETA recognizes that a contract may be formed by the interaction of an electronic agent and an individual (§ 14(2)). Likewise, UCITA provides for the making of contracts by means of an “electronic agent” (s.102) and provides for the validation of electronic contracts to the extent that it validates contracts made by “electronic agents” or preprogrammed computer programs (ss. 107 and 206).

### Notice and Consent Requirements

Because electronic contracts involve additional risks when compared with traditional transactions, both E-SIGN and UETA expressly require that the parties agree to enter into their transaction electronically before it will be considered enforceable. Conversely, as there is no obligation on the parties to do so, they are entitled to refuse to enter into the transaction in electronic form (E-SIGN, 15 U.S.C. § 7001(b)(2); UETA § 5(a)). As to the question whether the parties have “agreed to conduct transactions by electronic means” (UETA § 5(b); E-SIGN, 15 U.S.C. § 7001 (c)), their agreement may be either express or implied and is to be objectively determined from the surrounding circumstances, including the parties’ conduct (UETA § 5(b)). Although some state enactments of

UETA—for example, that of California—require such consent to be in electronic form in order to provide greater certainty, in other states consent may be implied from conduct. For example, in the event one party launches a Web site that is capable of entering into electronic transactions and the other party accesses that Web site and proceeds to enter into an electronic contract with the first party, there is a strong inference that the parties have implicitly agreed to conduct business electronically.

### E-SIGN's Consumer Consent Provisions

Whereas the provisions of UETA concerning consent to transact electronically apply equally to commercial and consumer transactions, E-SIGN contains special requirements for businesses that want to use electronic records or signatures in consumer transactions. It requires businesses to obtain from consumers electronic consent or confirmation to receive information electronically that is required by law to be in writing. This would be the case for example, with laws requiring written disclosure of interest rate charges in consumer loan transactions. The act went into effect in October 2000 (15 U.S.C. § 7001(c)). Section 101(c)(1) of the act provides that information required by law to be in writing can be made available electronically to a consumer only if he or she affirmatively consents to receive the information electronically and the business clearly and conspicuously discloses specified information to the consumer before obtaining his or her consent. Moreover, Section 101(c)(1)(C)(ii) states that a consumer's consent to receive electronic records is valid only if the consumer "consents electronically or confirms his or her consent electronically, in a manner that reasonably demonstrates that the consumer can access information in the electronic form that will be used to provide the information that is the subject of the consent." Presumably, the obligation to "reasonably demonstrate" ability to access the information may be met if the consumer merely states in an electronic message that he or she can access the electronic records in the specified formats or otherwise acknowledges or responds affirmatively to an electronic query that asks whether the consumer can access the electronic record (Federal Trade Commission, 2001; Consumer Consent Provision in Section 101(C)(1)(c)(ii)).

### Signature Requirements

The requirement that the parties sign their transaction has three purposes: (1) the signature serves as an expression of intent, (2) it may be required by law, and (3) it may be necessary for the security of the transaction. With respect to the first purpose, a signature provides *prima facie* evidence of the signer's intent with respect to the document signed. Of course, the nature of the signer's intent varies with the transaction and in most cases can be determined only by looking at the surrounding circumstances in which the signature was made. For example, a signature may indicate an intent to be bound to the terms of a contract, the approval of a request by an employee or person designate for funding of a project, authorization to a bank to transfer funds, or simply that the contents of a document have been made known and that the other party has had an opportunity for review.

Concerning the second purpose, a signature is often the means employed to satisfy a law that requires the fact of signature before the document will be considered legally binding. The Statute of Frauds is probably the best known of the numerous federal and state statutes that require certain types of transactions, such as the sale of land or contracts for the sale of goods in excess of the stipulated monetary limit (Amended Article 2 (Sales), 2002, increases the threshold amount to \$5,000), to be documented in writing and to be signed. In this regard, the increasing weight that courts tend to be placing on e-mail communications and electronic signatures should put buyers on their guard. Prospective buyers should ask themselves whether they are willing to be contractually bound by offers that are made by e-mail, because the e-mail sender's act of typing his or her name at the bottom of the e-mail may be sufficient to manifest intention to authenticate the transmission for Statute of Frauds purposes. The copy of the e-mail in question submitted as evidence of an intention to contract has been held sufficient for the purpose. In the case of *Rosenfeld v. Zerneck* (2004), for example, the plaintiffs had e-mailed the defendant, confirming their offer to purchase the defendant's home for \$3.5 million. The defendant accepted the offer via e-mail. The typed signature at the bottom of the defendant's e-mail was held to satisfy the requirement that a "writing be subscribed under New York State's general Statute of Frauds" (General Obligations Law § 5-701), for the New York legislature had amended that provision to allow for the subscription of electronically transmitted memoranda.

Finally, a signature often functions as a means of security, in the sense that it can be used either to authenticate a document, notably for the purposes of identifying the source of the document, or to ensure the integrity of the document to the extent that it has not been altered by an unauthorized source. It is for this reason, for example, that parties to a multipage contract sometimes initial each page of the contract. In the electronic environment, certain types of signatures (e.g., cryptographically created digital signatures) can play an important role in verifying the integrity of the entire document.

### Definition of Electronic Signature

Traditionally, the law has allowed any symbol (e.g., the notorious "x"), that is made with the intent to sign a document to qualify as a legally valid signature. Hence, the definition of "signed" in the Uniform Commercial Code includes "any symbol" as long as it is "executed or adopted by a party with present intention to authenticate a writing" (Article 1, § 1-201(39) (1999)). The law is chiefly concerned with the signer's "intention to authenticate" the document by affixing her signature and thereby indicating her intention to be legally bound.

Both E-SIGN and UETA extend the traditional approach of the law to the concept of an electronic signature. To be enforceable, they require that an electronic signature meet the following three criteria (E-SIGN, 15 U.S.C. § 7006(5) and UETA § 2(8)):

1. be a sound, symbol, or process.
2. be attached to or logically associated with an electronic record. This requires that the parties implement

an electronic recordkeeping process that is capable of providing evidence that a specific signature was applied to or used in connection with a specific document. The easiest way to comply with this requirement is to have the signature incorporated as part of the electronic record that is stored.

3. be made with the intent to sign the electronic record to the end that the signature relates to a specific document and to evidence the signer's intent with respect to that document.

The European Union (EU) Electronic Signature Directive uses a similar definition of an electronic signature. Under the directive, an electronic signature must also meet three criteria: (1) be data in electronic form, (2) be attached to or logically associated with other electronic data, and (3) serve as a method of authentication (Electronic Signature Directive, Article 2(1) AA). For the majority of transactions electronic signatures that meet these requirements will be considered legally enforceable as substitutes for handwritten signatures (UETA §§ 2(8) and 7(d); E-SIGN, 15 U.S.C. § 7001(a) and 7006(5)).

### Methods of "Signing" an Electronic Record

The definition of an electronic signature acknowledges that there are a variety of methods by which an electronic record may be signed. Although an electronic signature, by its nature, must be represented digitally—that is, in binary code—it can take many forms and can be created using a variety of different technologies. Well-known examples of electronic signatures that satisfy E-SIGN and UETA include the following:

- a name typed at the end of an e-mail message by the sender (*Shattuck v. Klotzbach*, 2001)
- a digitized image of a handwritten signature that is attached to an electronic document
- a PIN number that identifies the sender to the recipient
- a unique biometrics-based identifier, such as a fingerprint
- a mouse click as illustrated by the ubiquitous "I accept" button
- a "digital signature" created through the use of public key cryptography

### "Digital Signatures" Created by Public Key Cryptography

There is a considerable difference, however, between an electronic signature that merely satisfies the requirements of E-SIGN and UETA and a trusted, certified electronic signature. As we have noted, when transactions are automated and carried out remotely, using digital technology that can easily alter the record, it becomes critical to have a means of ensuring the identity of the parties and the integrity of the document. Merely clicking on an "I accept" button or typing a name on an e-mail message offers no evidence as to the authenticity of the signature.

Because most legally recognized electronic signatures provide only a weak level of authentication, they have to

be accompanied by certification procedures. Parties who wish to conduct their business by electronic means would be well advised to use the services of one of the many certification authorities. VeriSign, Baltimore Technologies, RSA Security, and Pretty Good Privacy are some of the companies that offer digital signature technologies and certification services. A digital signature is the sequence of bits that is created by running an electronic message through a one-way hash function to create a unique digest (or "fingerprint") of the message and then using public key encryption to encrypt the resulting message digest with the sender's private key.

Encryption technology through public key infrastructures (PKI) is employed to enhance security. Public key cryptography employs an algorithm using two different but mathematically related cryptographic keys: one for creating a digital signature or transforming data into a seemingly unintelligible form and the other key for verifying a digital signature or returning the message to its original form (American Bar Association Section of Science and Technology Electronic Commerce Division Information Security Committee. Digital Signature Guidelines. August 1, 1996. Available at: <http://www.abanet.org/scitech/ec/isc/dsgfree.html>.) Such digital signatures allow the sender of a document or a message to encrypt that message or document with a unique, private key. The message recipient is then able to decrypt the document using a related public key.

Most governments have undertaken initiatives to promote the use of digital signature and encryption technology in the public and private sector. In contrast with E-SIGN, the EU Directive for example provides a comprehensive regulatory framework. It envisions the growth of a complex network of competing and complementary PKIs providing electronic certificates to customers that, in turn, can be used by these customers to sign documents electronically.

### Record Accessibility Requirements

Another key requirement for the enforceability of electronic transactions is that the documents that comprise the transaction should be communicated in a form that can be retained and reproduced accurately by the receiving party. E-SIGN legislation provides that the legal effect, validity, or enforceability of an electronic record "may be denied if such electronic record is not in a form that is capable of being retained and accurately reproduced for later reference by all parties or persons who are entitled to retain the contract or other record" (15 U.S.C. § 7001(e)). Similarly, UETA provides that "if a sender inhibits the ability of a recipient to store or print an electronic record, the electronic record is not enforceable against the recipient" (§ 8(c)).

That is not to say that this requirement limits electronic transactions to those parties that possess the technical capability for downloading or printing documents. Rather, the focus is on the form of the document as communicated by the sender and essentially requires that the sender do nothing to inhibit the ability of the recipient to download, store, or print the applicable record. The fact that the recipient may choose to use a device without such capabilities, such as a PDA or other handheld device without a

print capability, should not affect the enforceability of the transaction. On the other hand, such provisions clearly call into question the form of clickwrap agreement typically used on many Web sites in which the agreement is displayed in a separate window from which it cannot be downloaded or printed.

### Record Retention Requirements

An essential element for the enforceability of all transactions is record keeping. In the event of a dispute, it is necessary to produce reliable evidence documenting the terms of the transaction and the agreement made by the parties. For electronic transactions, this issue raises questions as to whether the keeping of electronic records is sufficient to satisfy the applicable statutes, regulations, or evidentiary rules and, if so, what requirements must be met for acceptable electronic records. Both E-SIGN and UETA address this issue directly and impose similar requirements. In essence, storage of an electronic record will satisfy legal record retention requirements if the stored copy of the electronic record meets the following two criteria:

1. accurately reflects the information set forth in the record (E-SIGN, 15 U.S.C. § 7001(d)(2); UETA § 12(b))
2. remains accessible for later reference to all persons who are entitled to access by law, for the period required by the relevant statute and in a form that is capable of being accurately reproduced for later reference, whether by transmission, printing, or otherwise (UETA § 12(a); E-SIGN, 15 U.S.C. § 7001(d))

With respect to evidentiary rules, both E-SIGN and UETA also provide that if a rule of evidence or other rule of law requires a record relating to a transaction to be provided or retained in its original form, this obligation is satisfied by meeting the accuracy and accessibility requirements listed above (E-SIGN 15 U.S.C. § 7001(d)(3); UETA § 12(d)). These provisions also make clear that records can be kept in electronic-only form. Furthermore, they provide considerable flexibility to the parties in terms of how they store the records, when and whether they wish to store the records on new media, and how to meet applicable evidentiary requirements.

## ENFORCEABILITY OF ONLINE CONTRACTS

### Characterizing Shrink-, Click-, and Browsewrap Agreements

Clickwrap agreements may be seen as analogous to shrinkwrap agreements, the original character and form of which are generally attributed to software producers and their desire to find a satisfactory method of distributing software held on CDs or diskettes and sold in packaged form. Likewise, clickwrap agreements are online contracts that invite users to scroll through their terms and conditions before manifesting their assent to contract by clicking on a button that states "I accept" or "I agree." A third form of online contract that is rapidly gaining favor because of its user friendliness is the browsewrap agreement. In this form of agreement, a notice is simply

placed on the Web page informing users that they are subject to a license agreement, which is available for online viewing at any time.

The enforceability of clickwrap and browsewrap agreements and the security of the intellectual property they purport to protect are of critical importance, in view of the fact that such agreements have become the common means of exchange for consumer goods in networked markets worldwide. Although the intention to contract might be signaled by the user's clicking on the "I accept" button, the validity and hence the security of clickwrap agreements are by no means as easily assured. Intention is but one of the essential elements necessary to the formation of a legally binding contract. As a matter of general principle, the law also requires one party, usually the seller, to make an offer setting out the terms of the proposed contract to another party, the buyer. A valid contract is formed when an unequivocal acceptance of the offer is communicated to the offeror or seller.

### Manifesting Assent to Clickwrap and Browsewrap Agreements

If a clickwrap or browsewrap agreement is implemented properly, it should operate to create a valid and binding online contract between buyer and seller. Both E-SIGN and UETA explain that the "process" of clicking a mouse can qualify as a signature if the other applicable requirements are also present. As the Reporter's note to UETA explains, "this definition includes as an electronic signature the standard webpage click-through process. For example, when a person orders goods or services through a vendor's web site, the person will be required to provide information as part of a process which will result in receipt of the goods or services. When the customer ultimately gets to the last step and clicks 'I agree,' the person has adopted the process and has done so with the intent to associate the person with all the record of that process" (§ 2, comment 7). More broadly, with respect to the formation of such contracts, the courts are guided by the principles of sales law as contained in Article 2-204 of the UCC (Uniform Commercial Code), which states that "a contract for sale of goods may be made in any manner sufficient to show agreement, including conduct by both parties which recognizes the existence of such a contract."

The classic case on the validity of such contracts is *ProCD v. Zeidenberg* (1996), where the Seventh Circuit held that software shrinkwrap license agreements are a valid form of contracting under Wisconsin's version of the Uniform Commercial Code. In ringing affirmation of the recent trend to also uphold clickwrap contracts, the federal district court of Minnesota in *I-Sys Inc. v. Softwares Inc.* (2004) rejected an argument that clickwrap acceptance of a software license under protest did not bind the defendants. According to the terms of the license, installation and use of the software with the license attached constituted acceptance of the 1995 and 1998 license terms. The 1995 and 1998 licenses were shrinkwrap agreements, meaning that a file was installed together with the software containing a license document instructing users that by using the software they were accepting the license terms. Subsequently, in 2001 software updates were distributed by means of a clickwrap license that

required users to accept the terms by clicking through a series of screens before they could access the software. Plaintiff software developers contended that, by not returning the software with a 1995 or 1998 license and by clicking through the 2001 license, the defendants had accepted the terms of the license and were bound by it. The defendant software distributors argued that they were unaware of the 1995 and 1998 licenses and only “accepted” the 2001 license under protest because they needed the updated software that came with it. The court rejected the defendants’ argument that they did not truly “accept” the license terms, but clicked through only because they needed the software to upgrade earlier, unsatisfactory versions. It found that references to the licenses in invoices and in the software development agreements gave the defendants sufficient notice of them.

Until recently, the enforceability of browsewrap agreements, in which the terms and conditions are typically posted on the Web site by way of a hyperlink, had been in some doubt. Courts had generally been reluctant to enforce the terms of an agreement that lacks any formal indication that the user has read and agreed to the terms of the contract (*Pollstar v. Gigmania Ltd.*, 2000; *Ticketmaster Corp. v. Tickets.com, Inc.*, 2000). However, in a landmark decision affirming the enforceability of browsewrap licenses, the U.S. Court of Appeal for the Second Circuit found Verio Inc., having accepted the plaintiff’s terms of use, to be in breach of contract (*Register.com Inc v Verio Inc.*, 2004). Register.com derived its authority to act as a registry for the issuance of domain names from a standard form agreement with the Internet Corporation for Assigned Names and Numbers (ICANN), a nonprofit corporation established by the U.S. government to administer the domain name system. Under the agreement with ICANN, Register was required to maintain a publicly available ‘WHOIS’ database of registrants’ contact information and was not to impose restrictions on the use of this data, except in relation to mass solicitations by e-mail or spamming. Register established a WHOIS database, which it updated on a daily basis, and provided a free public inquiry service for the information contained therein. Register’s responses to WHOIS queries were captioned by a legend stating that by submitting a query, the user agreed not to use the data to conduct mass solicitations of business by e-mail, direct mail, or telephone. Contrary to the terms of use, Verio developed an automated software program or robot to access the WHOIS database and compile substantial lists of new domain name registrants whom Verio then proceeded to bombard with unsolicited marketing by e-mail, direct mail, and telephone. Register demanded that Verio cease the practice, but Verio complied only in part—ceasing the e-mail solicitations but continuing to promote its services by direct mail and telephone.

When Register brought suit for breach of contract, Verio argued that because they had not received adequate notice, they could not be said to have consented to the restrictive terms and were therefore not contractually bound to comply with them. In this case notice of the restrictive conditions did not appear until after Verio had submitted the query and received the WHOIS data. Contrary to the Ticketmaster case, the Court of Appeals found that online contracts do not always require formal

acceptance by the offeree. Rejecting the need for a requirement that users click an “I agree” icon, the Court of Appeals drew on the general principles of contract law to find that the terms of use in Register’s browsewrap agreement, combined with Verio Inc.’s conduct in repeatedly utilizing the WHOIS database, constituted a valid offer and acceptance, thereby resulting in a legally enforceable contract with Verio. Of course, had Verio’s utilization of the database been irregular or occasional, it might not have been deemed to have accepted Register’s terms of use. In the event, however, the Court upheld the preliminary injunction enjoining Verio Inc. from either utilizing a search robot to obtain information from the plaintiff’s database or utilizing information derived from it for mass solicitation.

The Court of Appeals distinguished the facts in Register.com from its former decision in *Specht v. Netscape Communications* (2002). In that case the question for the court was whether plaintiffs were bound by an arbitration clause in the agreement. The Second Circuit held that under the terms of the license agreement to which plaintiffs agreed, governing their use of Netscape’s browser, they were under no obligation to arbitrate the claims they raised in the litigation. The software in question could be downloaded from a page on defendant Netscape’s Web site by clicking on a button that said “download.” When plaintiffs proceeded to initiate installation of the Communicator, they were automatically shown a scrollable text of that program’s license agreement and were not permitted to complete the installation until they had clicked on a “Yes” button to indicate that they accepted all the license terms. However, the terms of the license agreement were not contained on this Web page, and the only notice users received of the license agreement was found on a portion of the Web page below the download button. Typically, this notice appeared “below the fold” and was not on that portion of the page that first appeared on the user’s screen when he or she proceeded to download the program. This notice informed users that their use of the software would be governed by the terms of a license agreement, which could be seen by clicking on a link provided on the Web page. Once the program was downloaded, the user received no further notice of either the license agreement or its terms. The Second Circuit Court of Appeals found that the plaintiffs were not bound by the terms of the license agreement because they had neither had reasonable notice of the restrictive terms nor had they adequately manifested their assent to be bound by them.

### Notice of Unusual or Onerous Terms

Although the general trend at both the legislative and judicial spheres is, in principle, to endorse the validity of clickwrap contracts, that does not mean that the contract is necessarily enforceable. Case law reveals that problems can arise in two areas in particular: the form of assent and the reasonableness of the contractual terms. The legal problems associated with such agreements concern the conditions for the formation of a valid contract and the identification of contractual terms. A contract’s terms and conditions are fixed at the moment the contract is formed. Contractual provisions will form part of the agreement

only if the other party has reasonable notice of them before agreeing to contract.

Reasonable notice for unusual and onerous provisions requires greater time than does reasonable notice for normal provisions. This is a particularly significant issue since the clickwrap license is commonly used to unilaterally set out the sellers' terms to the purchaser. Thus the standard software license tends to include a conspicuous notice of title retention in the seller, restrictions on transfer and modification, prohibition of reverse engineering, limited copying provisions, and a forum selection or arbitration clause.

In *Forest v. Verizon Communications Inc.* (2002), the question was whether a forum selection clause mandating that claims be brought in a particular jurisdiction should be applied to a class action suit involving plaintiffs' attempts to register for and use Verizon's broadband service. The subscribers argued that Verizon had not provided sufficient notice of the forum selection clause or its consequences. To become broadband subscribers, users had to agree to all the terms of the agreement, including the forum selection clause. The clause was found in the final part of the agreement, which was available for viewing in a scroll box; however, the box was only large enough to enable users to view a small portion of the document at any time. Users were on notice to "read the following agreement carefully." The contract was entered into by the subscriber clicking an "Accept" button below the scroll box. The District of Columbia Court of Appeals found that users were provided with adequate notice of the forum selection clause, stating that "the general rule is that absent fraud or mistake, one who signs a contract is bound by a contract which he has an opportunity to read whether he does so or not." The court noted that in reading through the agreement before it was accepted, users would have inevitably discovered the forum selection clause. Nevertheless, it pointed out that the use of a "scroll box" that displays only part of the agreement at any one time is detrimental to the provision of adequate notice (see also *Caspi v. Microsoft Network*, 1999; *CompuServe, Inc v. Patterson*, 1996; *I Lan Systems v. Netscout Service Level Corp.*, 2002, concerning the incorporation of a clause limiting liability).

Similarly in the earlier case of *Hill v. Gateway 2000, Inc.* (7th Cir. Jan. 6, 1997), the Seventh Circuit Court of Appeals held that the "accept-or-return" agreement was effective, stating "competent adults are bound by such documents, read or unread." Although it is not necessary for the buyer to have read the agreement to be bound by it, clearly failure to read the terms can result in substantial loss. Thus, in *M.A. Mortenson Co., Inc. v. Timberline Software Corp.* (2000), the plaintiff sought recovery of \$1.95 million, based on an alleged software malfunction that resulted in a project bid of \$1.95 million lower than intended. The court followed the reasoning of *ProCD* and *Hill* to find that Mortenson's use of the software constituted its assent to the agreement, including the license terms.

### Contracts Voidable for Unconscionability

The enforceability of contracts generally may be affected by particularly onerous or unconscionable terms in

standard consumer contracts. The common law of contract has traditionally been able to provide relief when one party is so clearly incapable of looking after his or her interests; in other words, that to enforce the contract would be unconscionable or against all conscience. This principle is codified in Section 2-302 of the UCC, which provides that where a court finds the contract or any clause of the contract to have been unconscionable at the time it was made the court may refuse to enforce the contract, or it may enforce the remainder of the contract without the unconscionable clause, or it may so limit the application of any unconscionable clause as to avoid any unconscionable result. The courts do not set aside private bargains lightly, and the test of unconscionability is notoriously difficult to satisfy. The terms of an unconscionable transaction must suggest that one party took unfair advantage of the party with the disability. Thus, offering to buy a Picasso drawing at a rock-bottom price from a 92-year-old impecunious widow who is unaware of its true market value would be *prima facie* unconscionable.

Nonetheless, in a medium where it is all too easy to create unrealistically one-sided commercial contracts, drafters of online contracts should bear in mind the doctrine of unconscionability to ensure that particularly onerous or unusual (and potentially "unfair") terms are brought to the attention of the persons with whom they are contracting with or risk a court later determining such contracts to be unenforceable. Moreover, even if incorporated properly into a contract, certain terms, such as unreasonable exclusion clauses or limitations of liability, may nevertheless not be enforced against buyers who agreed to a contract of adhesion or standard form contract.

Almost all unconscionability cases have elements of both procedural and substantive unconscionability. Procedural unconscionability involves the manner and process by which the terms become part of the contract. For example, these practices are unconscionable: the use of incomprehensible or legalistic fine-print standard form contract provisions; binding the buyer to additional written terms after the contract is signed; switching contract documents at the last moment to include non-negotiated, one-sided terms; and pressuring the client to sign a contract before reading it. Substantive unconscionability involves the terms of the contract themselves that are unreasonably, unacceptably, or unfairly harsh and against good conscience. Potentially unconscionable clauses would include those authorizing venue or jurisdiction in distant forums, disclaimer of warranties, and limitations or waiver of remedy clauses.

The following case is illustrative: in *Comb v. PayPal, Inc.*, (ND Cal. 2002), plaintiffs successfully claimed that even if they had concluded the user agreement, this agreement, and in particular its arbitration clause, was unconscionable. The court held that PayPal's user agreement was a contract of adhesion, and hence procedurally unconscionable, because it was a form agreement drawn by PayPal, a party of superior bargaining power, and offered to its customers on a take-it-or-leave-it basis. The court also found that the user agreement and its arbitration provisions were substantively unconscionable. In reaching

this conclusion, the court pointed to several provisions contained in the agreement, including the following:

- PayPal could amend the agreement at any time without notice to users, and these amendments would be binding on them.
- PayPal could freeze all of the funds in a customer's account pending its resolution of any dispute.
- The arbitration provisions mandated arbitration pursuant to the commercial rules of the American Arbitration Association (AAA), which was cost prohibitive, in light of evidence that such a procedure would cost \$5,000, whereas the average PayPal transaction was \$55.
- The arbitration provision required all arbitrations to proceed in Santa Clara County, California, where PayPal was headquartered, whereas PayPal's customers resided throughout the United States.
- The arbitration provision prohibited joinder of claims among individuals, requiring each instead to proceed individually.

Taken as a whole, these provisions rendered the user agreement and its arbitration provisions unconscionable. The court accordingly denied PayPal's motion to compel arbitration.

## CONTRACTUAL RESTRICTIONS ON THE USE OF SOFTWARE

### Copyright Preemption, Fair Use, and Reverse Engineering

It is common practice among software companies to study competitors' products in order to improve their own offerings. In this context, the legality of *reverse engineering*, a procedure that generally involves converting machine code back to source code, was recently called into question after the U.S. Supreme Court denied leave to appeal in *Bowers v. Baystate Technologies Inc.* (2003). The Supreme Court's denial of Baystate's petition tends to implicitly affirm the decision of the Federal Court of Appeals that private parties can indeed contract to prohibit the reverse engineering of their intellectual property. A divided Appeals Court found that the federal Copyright Act does not preempt state contract law that allows parties to impose a ban on reverse engineering.

In this controversial case, Harold Bowers had obtained patent and copyright protection for computer-aided design (CAD) software that he distributed under a shrinkwrap licensing agreement that prohibited reverse engineering. Baystate then developed a competing product, which incorporated features of Bowers' software. Bowers alleged Baystate had not only infringed his copyright but also breached the end use license agreement (EULA) by reverse engineering his software in order to modify its own competing software package. For its part, defendant Baystate claimed that it had only evaluated a competitor's product in order to improve its CAD software and that it had not violated encrypted source code. Moreover, Baystate argued that federal copyright law preempts terms that limit the use of copyrighted materials.

Copyright law permits fair use of the work in the form of clean room reverse engineering. Section 117 of the Copyright Act permits an owner of a computer program to make an adaptation of that program provided that the adaptation is either "created as an essential step in the utilization of the computer program in conjunction with a machine" (§§ 117(1)) or "is for archival purpose only" (§§ 117(2)). The Court of Appeals found that federal copyright law does not preempt the terms of the contract and upheld the shrinkwrap license. Its decision of January 2003 upheld the decision of the lower court in awarding the plaintiff US\$5.27 million for breach of contract and patent infringement.

Nonetheless, contractual prohibitions on reverse engineering remain controversial (Reichman, 1999). In Bower's case the Appeal Court was split, the dissenting judge finding that with respect to nonnegotiated contracts such as shrinkwrap licenses, the contract claim was indeed preempted by federal copyright law. Judge Anthony Dyk chose to follow the decision of the Fifth Circuit in *Vault Corp. v. Quaid Software Ltd.* (1988). He took the view that restrictions on reverse engineering represented the thin end of the wedge. If today software developers were permitted to eliminate the fair use defense, then tomorrow they could also restrict a purchaser from asserting the "first sale" defense, embodied in 17 U.S.C. § 109(a) or any other of the protections Congress has afforded the public in the Copyright Act.

In the case cited, Quaid reverse engineered Vault's program in order to create its own program, called RAMKEY, which disabled PROLOK's copy protection. In the course of writing RAMKEY, Quaid loaded the PROLOK program into its computer memory. The court rejected Vault's claim of copyright infringement. The plaintiff's principal claim was founded in Louisiana law. Quaid breached its license agreement by decompiling or disassembling Vault's program in violation of the Louisiana state licensing law that permits a software producer to impose a number of contractual terms upon software purchasers when the license agreement accompanies the producer's software (La.Rev.Stat. Ann. §§ 51:1963 & 1965). Enforceable terms include the prohibition of (1) any copying of the program for any purpose and (2) modifying and/or adapting the program in any way, including adaptation by reverse engineering, decompilation, or disassembly (La.Rev.Stat. Ann. §§ 51:1964).

Although the restrictions in Vault's license agreement were consistent with the state statute and *prima facie* enforceable under Louisiana's License Act, the District Court found that it conflicted with several areas of federal copyright law. First, although the License Act authorizes a total prohibition on copying, the Copyright Act allows archival copies and copies made as an essential step in the utilization of a computer program (17 U.S.C. §§ 117). Second, although the License Act authorizes a perpetual bar against copying, the Copyright Act grants protection against unauthorized copying only for the life of the author plus (then) 50 years (17 U.S.C. §§ 302(a)). Third, although the License Act places no restrictions on programs that may be protected, under the Copyright Act, only "original works of authorship" can be protected (17 U.S.C. §§ 102. Vault, 655 F.Supp. at 762-63).

With respect to the questions of the preemption of federal law based on section 301 of the Copyright Act, the Federal Appeals Court found that the provision in Louisiana's License Act, which permits a software producer to prohibit the adaptation of its licensed computer program by decompilation or disassembly, conflicts with the rights of computer program owners under §§ 117 and clearly "touches upon an area" of federal copyright law. Because Louisiana's License Act "touched upon the area" of federal copyright law, its provisions were pre-empted or superseded by the fair use provisions of the Federal Copyright Act. As a result Vault's efforts to prohibit this activity under Louisiana law was illegal. This finding was consistent with the Supremacy Clause of the U.S. Constitution and its role in precluding any state laws that conflict with expressed federal policy in fields where the federal government exercises substantial control (*Bonito Boats, Inc. v. Thunder Craft Boats, Inc.*, 1989; *Kewanee Oil Co. v. Bicron Corp.*, 1974).

To allow software vendors unilaterally and without restriction to impose terms that prohibit reverse engineering is inimical to the free flow of ideas and information and would frustrate the policy of encouraging the creation of innovative and interoperable software products. Yet, how can small software developers stay in business if larger companies can simply reverse engineer the product before they have been able to recover their investment? Software vendors and content providers rely on contracts to reinforce their intellectual property rights in the digital environment where the risk of unauthorized reproduction and distribution is so much greater. Bower's company, HLB Technology, epitomized the small to medium-sized enterprise driven out of the market by big business. The defendant had not only incorporated features of Bower's product but, having acquired the company with which Bower's held a distribution agreement, it also proceeded to repudiate the contract.

The problematic state of the relationship between copyright and contract is a reflection of the difficulty the licensor has in monitoring licensee use of software and in distinguishing between licensees likely to breach terms of the license essential to the protection of valuable intellectual property (Nimmer, 1998). In the earlier case of *ProCD* the Court of Appeals for the Seventh Circuit also dealt with the preemption issue as to whether federal copyright law disallowed enforcement of the contractual restrictions on use of informational content. The question for the court in *ProCD* was whether the buyer's promise not to make commercial use of the uncopyrightable data in the plaintiff's directory interfered with the balance drawn in the Copyright Act. Previously in *Feist Publications v. Rural Telephone Service Co.* (1991), the U.S. Supreme Court had ruled that the unoriginal compilation of data, such as white pages listings in telephone directories, was unprotectable by copyright law. The Supreme Court's decision seemed to regard such information, once published, as being in the public domain and therefore able to be appropriated freely. A mass-market license term prohibiting the redistribution of telephone listings was ostensibly contrary to the Supreme Court's ruling.

Hence in *ProCD v. Zeidenberg* the defendant argued that the Copyright Act preempts the enforcement of such

contracts. The appellate court, however, disagreed. Judge Easterbrook, writing for the majority, found no problem of preemption once he differentiated between contractual rights that are good against the parties to the agreement only, and property rights that are good against the world. Because there was an "extra element" of agreement, the state contract claim was not "equivalent" to a copyright claim. Hence, federal policy did not preempt enforcement of the contractual restrictions.

The issue remains a live one. The migration of software distribution systems to networked environments poses both new risks and new possibilities of risk management for licensors. To the extent that access controls can be placed on software and brought within the Digital Millennium Copyright Act framework (1998), the large corporate licensors have been successful in gaining new tools for controlling the volume of infringing activities. As a matter of technical self-help, the ability to monitor the use of software is also increasing and provides licensors not only with more information about potentially infringing activities but also with the necessary foundation for new pricing models.

## SALE OF GOODS LAW AND DIGITAL INFORMATION TRANSACTIONS

### Is a Computer Information Product a "Good" or a "License"?

Case law shows that contracts for the transfer of intangible property test the very limits of established law concerning the sale of goods. As a threshold matter, its application is problematic because the product involved is a transaction of "goods," as defined in UCC Article 2 to mean "all things (including specially manufactured goods) which are movable at the time of identification to the contract for sale." To distinguish between transfers that consist largely of intangible as opposed to tangible property, proposed amendments to the Uniform Commercial Code (UCC) in Article 2, section 2-103 (2003), state that the term "goods" expressly excludes "information." However, neither Revised Article 2 nor Revised Article 1 defines the term "information" (National Conference of Commissioners on Uniform State Laws, 2001a, 2002), The Official Comment to § 2-103 declares, "This article does not directly apply to an electronic transfer of information, such as the transaction in *Specht v. Netscape* (2002)."

Revised Article 9 clarifies that software is ordinarily not a good and is a "general intangible" except in some limited cases of embedded software. Consequently, although Article 2 would not apply directly to a download of software or digital content, the sale of "smart goods" such as an automobile would be covered fully by Article 2, even though it incorporates many computer programs. In the case of *Specht*, the Second Circuit Court of Appeals observed that downloadable software "is scarcely a tangible good." It chose instead to base its decision on the common law of contracts of California and the Restatement (Second) of Contracts, as it declined to enforce the terms of a license concerning mandatory arbitration that appeared below the "Download" button on a portion of the

Web page that was not visible on most visitors' screens until they scrolled to the bottom of the page.

Whether and to what extent Revised Article 2 applies to a transaction that includes both goods and information are to be determined from all the facts and circumstances. In effect, the amendments to Article 2 leave the courts to sort out in individual cases the UCC's application to computer and software licensing transactions. Generally speaking, with respect to the question whether an online transaction should be characterized as a "sale" or a "license," courts have been accustomed to looking at the totality of the circumstances of the transaction, including such factors as whether a single copy or multiple copies are transferred, whether the transaction involves the physical movement of goods, how the payment is structured, the duration of the agreement, who retains title to the copy for purposes of loss, and the tax treatment of the transaction (*Applied Info. Mgmt. Co. v. Icart*, 1997). In allowing the common law to develop an appropriate body of principles for informational transactions online, the Uniform Computer Information Transactions Act (UCITA), promulgated expressly with the aim of bringing uniformity and certainty to the rules that apply to software transactions, is likely to play its most influential role to date. In view of the problems that may be associated with characterizing software as goods or services, business and software vendors would be well advised to address this distinction expressly in the terms of the contract.

### Warranties as to Fitness and Merchantability

Sales and consumer law traditionally protects the buyer's legitimate expectation that the goods will be of merchantable quality (UCC 2-314: implied warranties of merchantability) and fit for the purpose for which they were bought (UCC 2-315: fitness for a particular known purpose). Additionally, revised Article 2 would considerably expand the risk of liability for breach of the warranty of good title. Current law makes sellers liable if they actually do not have "good title"; Revised Article 2-312 creates liability any time that a third party makes a "colorable claim" to title.

In the information economy, however, the problem the law has to confront is that software vendors and content providers, by typically characterizing the transaction as a license to use the software or content and not a sale as such, thereby purport to preclude the application of the UCC's implied warranties. Should the licensor wish to disclaim all implied warranties in a mass-market license, it is sufficient to state the following: "except for express warranties stated in this contract, if any, this information is being provided with all faults, and the entire risk as to satisfactory quality, performance, accuracy, and effort is with the user, or words of similar import." In addition, under current law licensors appear to have the advantage where computer viruses are concerned—that is, destructive computer instructions designed to damage or destroy intangibles—insofar as the principal basis for liability is a warranty of merchantability, which is routinely disclaimed in both negotiated and mass-market licenses. Thus, in *Specht* for example, the terms of the

communicator license agreement included a complete disclaimer of warranties ("as is"), an entire-risk clause, and a limitation of liability clause for consequential and other damages. Again, in *Mortenson Company, Inc. v. Timberline Software Corporation* (2000), Timberline's license agreement provided the usual warranty disclaimers, together with a disclaimer for damages or liability. When the plaintiff nonetheless brought suit for breach of express and implied warranties, alleging the software was defective, Timberline moved for summary judgment, arguing the limitation on consequential damages in the licensing agreement barred Mortenson's recovery. Moreover, Revised Article 2 tends to sanction this practice by purporting to exclude informational products from the scope of the UCC.

### Warranties for Informational Products under UCITA

The Uniform Computer Information Transactions Act (UCITA, formerly UCC Draft Article 2B), is founded upon the conceptual framework for commercial transactions in Article 2 of the UCC, which regulates the sale of goods. UCITA creates a standard framework of rules applicable to software and other computer information licensing transactions. "Information" includes computer programs, "computer information" means information in electronic form, and "computer information transaction" includes license agreements (§ 102(35), (10), and (12)).

UCITA contains several innovative provisions drafted to accommodate issues unique to transactions in information. These provisions address such controversial questions as the validity of adhesion contracts, warranties for information products, problems associated with breach, and the remedies for breach. Other issues addressed by the provisions are express warranties (s. 402) and implied warranties of quiet enjoyment and noninfringement, merchantability and quality of the computer program's informational content, licensee's purpose, and system integration (ss. 403-5).

Although UCITA contains implied warranties that reflect those found in sales law, these warranties have been adjusted and expanded to meet the unique character of information products. For example, merchantability for mass-market licenses consists of five minimum performance standards, including the contract description, fitness for the ordinary purposes, and the functionality of a computer program (ss. 403-5). The warranty that the goods will be fit for purchaser's purpose is the same as in sales law if the transaction is to deliver a product; however, UCITA creates a standard to distinguish this warranty from a services contract. Although sales law has no implied warranty that services will give a result consistent with the transferee's purpose, UCITA warrants that the services will not fail of the purpose because of a lack of effort. Again, where necessary, UCITA extends the nature and scope of implied warranties, as in the case of the warranty that the system components will work in integration (s. 405).

In sum, warranties for informational products are still at a formative stage. Although two states have enacted UCITA (Maryland and Virginia), five states (Iowa, West

Virginia, New York, Oregon, and Ohio) have enacted anti-UCITA “bomb shelter” legislation that would protect their residents from the application of UCITA in a transaction subject to the laws of states that have enacted it. Given the extent of the controversy, UCITA was significantly amended by NCCUSL in 2002 in response to substantive recommendations made by a Working Group on UCITA appointed by the American Bar Association. Absent statutory provisions, it is likely that courts will base their decision-making on the common law of contracts and the Restatement (Second) of Contracts as the case of *Specht* illustrates. Consequently, taking account of the problematic state of warranties for fitness, for purpose, and for merchantability of software and content, buyers would be well advised to seek warranties from the supplier wherever possible and to the extent feasible to ensure that the software will operate under certain conditions and that it will have the functionality the business needs.

## CONSUMER PROTECTION ONLINE

### Caveat Emptor

As consumer groups have argued, under the terms of UCITA it is relatively easy for the licensor to eliminate any warranty or representation in mass-market licenses. In fact, because of the strength and concentration of the software and content industries, there has been international interest in ensuring that consumers have adequate redress against defective products (Evans, 1999). The Organization for Economic Cooperation and Development (OECD) *Guidelines for Consumer Protection in the Context of Electronic Commerce* (1999) are designed to help ensure that consumers are no less protected when shopping online than they are when they buy from local stores or order from catalogues. By setting out the core characteristics of effective consumer protection for online business-to-consumer transactions, the guidelines are intended to help eliminate some of the uncertainties that both consumers and businesses encounter when buying and selling online. The guidelines reflect existing legal protection available to consumers in more traditional forms of commerce; encourage private sector initiatives that include participation by consumer representatives; and emphasize the need for cooperation among governments, businesses, and consumers. Their aim is to encourage fair business, advertising, and marketing practices; clear information about an online business's identity, the goods or services it offers, and the terms and conditions of any transaction; a transparent process for the confirmation of transactions; secure payment mechanisms; fair, timely, and affordable dispute resolution and redress; privacy protection; and consumer and business education.

### Choice of Law

Although the ability to market and sell products and services from a single site to an unlimited geographic market is one of the advantages of electronic commerce, it also poses a major challenge for consumer protection online (*American Libraries Ass'n. v. Pataki*, 1997). When transactions cross the jurisdictional boundaries defining

legal communities, there must be a workable method of coordinating the rights and liabilities of the parties. Fair, timely, and affordable dispute resolution is not possible if consumers are unable to benefit from the protection they have come to expect. One of the key issues for policymakers is developing a practicable and reasonably predictable set of rules to determine which jurisdiction's laws will apply to consumer contracts and which courts will have the authority to adjudicate and enforce disputes. UETA and, to a lesser extent E-SIGN provide little guidance with respect to these issues. UETA provides, as a default rule, that an electronic record is deemed to be sent from the sender's place of business and to be received at the recipient's place of business (§ 15(d)) or residence (§ 15(d).) UCITA, which allows the choice of any U.S. forum (including a foreign one) for the convenience of the producer, is criticized for allowing a too flexible choice of law and forum in mass-market transactions to the detriment of consumer interests.

Insofar as the sale of goods (as distinct from information), is concerned, Revised Section 1-301 of the UCC represents a significant rethinking of the choice of law issues addressed in current UCC Section 1-105. Current law allows the parties to the transaction to designate a jurisdiction whose law is to govern, if the transaction bears a “reasonable relation” to that jurisdiction. Revised Article 1 deviates from this unified approach by providing different rules for consumer transactions than for “business to business” transactions. Revised Article 1 requires no such relationship between the transaction and the chosen jurisdiction, unless one of the parties to the agreement is a consumer. It proposes a choice of law rule that would afford greater autonomy to each party, but with certain safeguards to protect consumer interests. On the one hand, Revised Article 1-301 purports to allow vendors the ability to choose the law of any state to apply to their contracts. On the other hand, Revised Article 1-301(2) provides that a choice of law agreement cannot alter the applicability of a consumer protection law of the state in which the consumer habitually resides. Thus, if ComCo has its headquarters in New York, I am a resident of California, and I purchase a microwave oven from a ComCo store in Ohio, then a provision in the sales agreement subjecting all disputes to the law of Texas would not be binding because I am a consumer. However, if Comco purchased the microwave for resale from Panacook, located in North Carolina, and had it shipped directly to the California store, then a provision in the Comco-Panacook agreement subjecting all disputes to Texas law would be binding because neither party is a consumer.

Needless to say, the proposed choice of law rule has given rise to controversy concerning the scope of party autonomy on the part of both business and consumer interests (National Association of Manufacturers, 2004). Many businesses find the notion that they should be expected to comply with the various regulatory regimes in which consumers happen to be located expensive and unrealistic (Americans for Fair Electronic Commerce Transactions, 2004; National Conference of Commissioners on Uniform State Laws, 2001a). The revision is sufficiently problematic that none of the small number of states that have enacted Revised Article 1 to date has enacted Section

R1-301 as drafted. Virginia's version of Revised Article 1 (effective July 1, 2003) rejects the uniform version's choice of law provision, opting to retain the basis of former Section 1-105, which requires some reasonable relation between the state whose law the parties choose by agreement and the transaction the parties choose to subject to that law. In view of the novelty and potentially problematic nature of consumer contracts online, revised UCC Article 2 gives the courts the right to overrule the statute in contracts involving consumers. Hence, Revised § 2-108(1)(b) is subordinate to any judicial decision "that establishes a different rule for consumers."

## BEST PRACTICE FOR ONLINE CONTRACTS

The foregoing review of statute and case law has provided some pertinent indications as to how online vendors, in particular software vendors and content providers, might utilize clickwrap agreements to protect their rights and promote consumer confidence. In the absence of national standards and given the sometimes divergent decisions of the courts respecting these issues, online business should keep in mind three general criteria with regard to the enforceability of clickwrap and browsewrap agreements:

1. Agreements that are clear and conspicuous and require some proof of acceptance by the user are more likely to be enforced by the courts.
2. Browsewrap and clickwrap agreements potentially face challenges on two separate grounds: procedural challenges based on the manner in which the mutual assent is made and substantive challenges as to the terms of the agreement itself. Thus, even if the agreement is enforceable overall, particular terms might not be enforceable.
3. The enforcement of clickwrap and browsewrap agreements is likely to differ depending on the law in the jurisdiction where the contract is construed.

Consequently, when drafting an online agreement on behalf of the vendor, best practice involves two chief points:

1. To increase the site's chances of having any such agreement enforced against site visitors, the agreement should be set up so as to create a "contract." This means that, in addition to the issues about validity of consideration, there must be an offer that is set forth in the respective agreement, terms of service and, for the issues related to this chapter, a valid "acceptance" of the terms of that offer. Hence, there must be prominently displayed on the site, preferably on the home page, a link to the respective agreement in large, bold type. This link must take the visitor to the agreement, and there must be a mechanism whereby the visitor affirmatively clicks on an "I accept" button, having been given an opportunity to review the terms and conditions, before being able to proceed through the site. This latter procedure—blocking access to the site until there is an affirmative response from the visitor—is what the courts seem most likely to look for in determining

whether there has been a valid acceptance. Equally, vendors should make sure that the buyer has the opportunity to reject the transaction upon review of the terms.

2. Vendors should make sure warranty disclaimers and limitations of damages are conspicuous by placing them in a large, bolded font and making sure that the purchaser does not have to scroll down to see them. Equally, it is not advisable to place additional terms where they can only be viewed through a "disclaimer" link or at another location on the Web site.

In summary, by ensuring that the terms and conditions are readily accessible, that the purchaser has certain clear rights upon receipt and review of these provisions, and not least by keeping records to prove assent, vendors can minimize the possibility that a court may conclude that they are unenforceable.

Even if best practice is followed, it is still possible that a purchaser may dispute his or her consent to terms and conditions that appear in a shrinkwrap or clickwrap agreement. In such an event, in an attempt to bring the dispute settlement into familiar home territory, consider adding an arbitration clause. Alternatively, an agreement might attempt to invoke laws more favorable to software and content providers, such as those of California, or to have recourse in a choice of law clause to the law of those states where UCITA applies such as Virginia.

Given the unsettled state of the law, whether you are an individual user or in a business, software licenses may need more careful attention than simply clicking "I accept." Falling into the clickwrap trap can leave buyers vulnerable to costly upfront fees and products that are not fit for the intended purpose. Those in business would be well advised to protect their company's intellectual property by taking the time to negotiate all software licenses, even those involving off-the-shelf software. Readers now cognizant of the uncertain state of the law, who take the time to read the entire clickwrap agreement, may well decide they want to buy on very different terms!

## CONCLUSION

The law relating to the enforceability of contracts online is still in its formative stages. Early legislative intervention in the form of electronic signature legislation has largely accomplished two goals: first, it has removed the initial barriers to e-commerce, and second, it has promoted the uptake of electronic commerce by helping establish the "trust" and the "predictability" needed by the parties if they are to enter into contracts online. Likewise, the courts have followed suit in seeking to validate the clickwrap and browsewrap agreements used by vendors to distribute their goods online. Yet, now that in the United States alone there are 46 enactments of electronic signature legislation, not to mention the national variations that exist worldwide, the very predictability that governments are seeking to establish is at risk. Consequently, with the aim of continued harmonization, the United Nations Commission on International Trade Law (UNCITRAL) is constructing a *Draft Convention On [International] Contracts Concluded Or Evidenced By Data Messages* (2002). It

includes provisions dealing with the substantive rights and obligations of the parties in the context of contract formation by electronic means.

In sum, the continued development of electronic commerce depends on how problems are resolved relating to the formation and enforceability of contracts online. Rules regarding offer and acceptance, place of formation, and certainty of terms are still not perfectly transferable to the online environment. As far as the individual parties are concerned, those who contract autonomously and in the course of an ongoing business relationship can simply agree to the particular rules that are to govern their transactions. However, where standard form, mass market contracts are concerned, given the failure of UCITA to gain widespread acceptance, it remains largely up to the courts to adapt the law of contract to the online environment.

## GLOSSARY

**Assent/Consent** In law, the active acquiescence or silent compliance by a person legally capable of consenting (see age of consent). It may be evidenced by words or acts or by silence when silence implies concurrence. Actual or implied consent is necessarily an element of every contract and every agreement. In criminal charges, the consent of the party injured (if not obtained by fraud or duress) is a defense for the accused, unless a third party or the state is injured.

**Browsewrap license** A “browsewrap agreement” appears on a web site, but does not require the user to take any action to express consent. The terms of the agreement are displayed to users only if they click on the hyperlink that brings up the “terms and conditions” page.

**Clickwrap License** A window containing the terms of a clickwrap agreement commonly appears on the downloading, installation, or first use of a software application. The user is asked to click either “I agree” or “I do not agree.” If the user does not agree, the process is terminated.

**Contract** For a contract to be valid, both parties must indicate that they agree to its terms. This is accomplished when one party submits an offer that the other accepts within a reasonable time or a stipulated period. If the terms of the acceptance vary from those of the offer, that “acceptance” legally constitutes a counteroffer; the original offering party may then accept it or reject it. At any time before acceptance, the offer may be rescinded on notice unless the offering party is bound by a separate option contract not to withdraw.

**Copyright** A property right by an author in an original work that has been fixed in a tangible medium, including literary, musical, artistic, photographic, or film works. The holder of a copyright has the exclusive right to reproduce, distribute, perform, and display the work.

**Electronic Contract** An electronic contract is an agreement created and “signed” in electronic form—in other words, no paper or other hard copies are used.

**Electronic Signature** An electronic sound, symbol, or process attached to or logically associated with a

contract or other record and executed or adopted by a person with the intent to sign the record.

**Fair Use** An exception under the U.S. Copyright Act that allows one who does not own a copyright to make “fair use” of the copyrighted work for such purposes as criticism, comment, news reporting, teaching, scholarship, or research without being liable for copyright infringement.

**Internet** The international computer network linking together thousands of individual networks at military and government agencies, educational institutions, nonprofit organizations, industrial and financial corporations of all sizes, and commercial enterprises (called gateways or service providers) that enable individuals to access the network.

**Law Merchant** (or *Lex Mercatoria*). Originally a body of rules and principles relating to merchants and mercantile transactions, developed by merchants themselves for the purpose of regulating their dealings. The law merchant owed its origin to the fact that the civil law was not sufficiently responsive to the growing demands of commerce, as well as to the fact that trade in medieval times was in the hands of those who might be termed cosmopolitan merchants, who wanted a prompt and effective jurisdiction.

**License** Licensing is a branch of the law of contracts. The contract is a specific form of agreement and strictly speaking embodies a license; that is, a permission from an owner of a right given to another to use part of that right. The other side of the contract is the obligation assumed by the receiver of the permission (i.e., the licensee) in return for the permission.

**Online** The state in which a computer is connected to another computer or server via a network; in other words, a computer communicating with another computer.

## INTRODUCTION

The Internet is fundamentally a mechanism for communication. By lowering the costs of copying and distributing information, it created a revolution in electronic speech. That in turn led to a host of issues stemming from the new methods of reaching an audience. Suddenly, old equilibriums and economics between speaker and listener were disrupted. One famous aphorism stated, "The Net interprets censorship as damage, and routes around it." This was then rebutted by the question, "What if censorship is in the router?"

The conflict between social and technological constraints is a key part of the evolution of electronic speech. It is conceivable that speakers and listeners could route around censorship laws by using various electronic networks. However, a router, a device that connects different networks (facilitating speech), may contain within it technological censorship programs that do not permit certain types of speech to either be made or received. Thus, contrary to purely utopian or dystopian views, there is no inevitable outcome in terms of a freer or more constrained ability to speak or be heard.

These new speech issues can be viewed as aspects of information or signal processing or as previous problems in new contexts. The positive results of gains in speech ability have been matched by potentially negative effects stemming from those gains in speech ability.

## SOCIAL SIGNAL PROCESSING

There is a saying, "If a tree falls in the forest, and nobody hears it, does it make a sound?" If someone writes an article, and nobody reads it, has the author communicated anything? Or, how does one get heard over the noise? The idea of free speech coexists with an understanding that usually there is no guarantee of listeners. Thus, there is an imbalance between those seeking to speak and those who wish to hear. This differential leads to specific patterns of modulating the exchange between writers and readers. By

an analogy with the issues of electronic signal processing communications, this might be thought of as social signal processing, with comparable structural issues. Many vocabulary terms, such as broadcasting, channel, communication, filtering, noise, receiver, transmitter, and so on, have applicability in overlapping contexts.

## Commons Models

The commons model is a common model of interaction, similar to the idea of a "speaker's corner" in a public park. In this configuration, every speaker communicates with every listener in a collective, many-to-many arrangement. The writers individually send their messages to a system that then by default distributes it to every other member of the system. In the simplest form, each member has equal access to every other member. Usenet newsgroups or open mailing lists follow this model: "Usenet is a worldwide distributed discussion system. It consists of a set of 'newsgroups' with names that are classified hierarchically by subject. 'Articles' or 'messages' are 'posted' to these newsgroups by people on computers with the appropriate software... [T]hese articles... are then broadcast to other interconnected computer systems via a wide variety of networks" (Spafford, 1993).

This system does not scale well as the number of writers increases. As more messages compete for the fixed amount of reading time available, the expected utility of each message often decreases. Moreover, a well-known hazard is that a few participants can engage in a protracted series of exchanges that generate objections from other members, as Nagel (1996) points out, "Discomfort with diversity (the number of messages increases dramatically; not every thread is fascinating to every reader; people start complaining about the signal-to-noise ratio; person 1 threatens to quit if *other* people don't limit discussion to person 1's pet topic; person 2 agrees with person 1; person 3 tells 1 and 2 to lighten up; more bandwidth is wasted complaining about off-topic threads than is used for the threads themselves; everyone gets annoyed)."

These stresses on the commons system lead to ad hoc methods of managing list conduct. Participants viewed as deviating from group norms may be admonished by others, with varying degrees of politeness and subsequent success (it can be said that personal attacks are a form of governance of open mailing lists). Readers are often advised to shun problematic writers by simply ignoring them or automatically deleting their messages via sorting software known as “killfiles” (Phillips, 1995).

However, these methods of speech management often fail, at least from the viewpoint of those practicing them. Personal attacks on recalcitrant writers may just not work. Not everyone wants to maintain killfiles or uses a message-reading system that supports such features. Moreover, messages may be distributed in a collected digest form, which is not amenable to killfiles as a solution.

This tragedy of the commons leads to a search for a more tightly controlled environment.

### Moderator Models

In the moderated model of electronic speech, a few selected authorities exercise value judgments on the contributions. These individuals read every message submitted and perform an editorial function of selecting contributions for approval, possibly even adding additional explanatory material. Often the authority is a single person due to the proprietary nature of the group or list or the moderator’s interest (McKeon, 1997).

There are 280+ moderated groups in the 8 Usenet hierarchies, mostly in comp., soc., sci., and rec.; and about 80+ in alt.\*

Some parallel models for moderation are:

- a refereed scientific journal;
- publication with a small subscriber base and an unpaid editor;
- restaurant with a polite but determined doorman.

This arrangement almost always produces results: the selected material is overall of much higher quality than that in the commons model. However, that higher quality comes at several costs. The editor may have notable biases and prejudices or may even use the position to engage in personal attacks, to which the target cannot reply to the same audience. Submitters may feel discouraged if they have devoted time to composing a message only to have it rejected.

There is typically no direct payment for the editor. So the return for the effort may only be from professional service (such as building a record for tenure committees), prestige, self-promotion, or influence. The time demands of sorting through the material can be burdensome. Delays in approving messages can make a fast-moving discussion impossible or result in messages being old news when finally distributed.

The scaling limit here is the number of messages that can be processed effectively by the selecting authority or authorities. To alleviate some of the workload, automated assistance has been developed to try to handle some of the most common cases programmatically. A notable example is the software program, Secure Team-based Usenet

Moderation Program (STUMP). This software has such features as the ability to create a list of contributors who will have contributions immediately accepted, another list for immediate denial, and management of evaluation of the rest (Chudov, 2004). Yet, substantial human effort is still necessary.

Given the demands on a single person or even a small group of people, the editorial burdens have led to explorations of more elaborate ways to distribute the workload.

### Distributed Models

A distributed model seeks to address the evaluation issues by spreading the necessary work among as large a group as possible. Web discussion forums, such as the sites <http://slashdot.org/> or <http://www.kuro5hin.org/>, are popular examples of this model. These community sites have thousands of members, many of whom write small comments about an article. To select comments of greater value (according to varying definitions of value), there is a system of rating the comments, and the ratings work is spread among the site members themselves.

This distributed system can scale to numbers of comments previously unmanageable by earlier methods. However, the problems scale up as well. A highly rated comment may be popular, but not accurate, whereas a low-rated comment may be accurate but not popular. Methods are needed to prevent small groups from “gaming” the system. The site administrators themselves may put a thumb on the scales in the ratings, using their authority to override results of the group selection (Jobi, 2002). Even when unfair moderating is not taking place, lack of accountability in the process may lead to a perception of unfairness, or inversely, abusive moderating can be given a cloak of plausible deniability.

Engineering and tuning these distributed evaluation systems (as well as examining their often complex unintended consequences) are currently fertile areas of research, as Lampe and Resnick (2004) note:

Closer analysis, however, revealed that it often takes a long time for especially good comments to be identified. We also found that incorrect moderations were often not reversed, and that later comments, comments not at top-level, and comments with low starting scores, did not get the same treatment from moderators as other comments did. These findings highlight tensions among timeliness, accuracy, limiting the influence of individual moderators, and minimizing the effort required of individual moderators. We believe any system of distributed moderation will eventually have to make tradeoffs among these goals.

Thus, the tradeoffs required in community moderation can subtly define the overall feel and utility of the community. It is important to distinguish between “reader-fair” versus “writer-fair” results. An outcome which is “reader-fair” is one where all highly rated comments are worth reading. An outcome which is “writer-fair” is one where all comments that are worth reading are highly rated. While

a system which was perfectly writer fair would then be reader fair, it's possible to have an overall reader fair result along with many individual cases which are not writer fair. Reader fair globally is not the same as writer fair locally. A site's economic survival may depend on achieving a large measure of reader fairness, but individual contributors may be more concerned with writer fairness (especially for their own comments). Too many writer unfair outcomes would eventually produce reader unfairness. However, it may be entirely viable for a community to have a maltreated minority as long as there is a satisfied majority. In this way, distributed systems generate problems familiar to any analysis of social governance.

## Power Laws

With the expansion of the Internet and the availability of simple Web site publishing tools, there has been a concomitant growth of small-scale electronic speech outlets—first e-mail, then mailing lists, then newsgroups, and then Web sites. As of this writing, much interest has been generated around Web-hosted chronologically updated pages that are updated frequently, known as *blogs* (from the word “Web-logs”).

Initially, the rise of the Internet as a means of distribution of electronic speech was often greeted with great optimism because of its prospects for equality. “The world of computer communications, however, has turned out to be the great equalizer. Suddenly anyone can become a publisher, reporter, or editorialist. What's more, each of us has as good a chance of being heard as anyone else in the electronic community” (Godwin, 1993).

Yet, it is a fallacy to assume that production equals audience. The empirical experience has been virtually the opposite, as Perseus (2003) points out:

Nanoaudiences are the logical outcome of continued growth in blogs. Assume for a moment that one day 100 million people regularly read blogs and that they each read 50 other peoples' blogs. That translates into 5 billion subscriptions ( $50 * 100$  million). Now assume on that same day there are 20 million active bloggers. That translates into 250 readers per blog ( $5 \text{ billion} / 20 \text{ million}$ )—far smaller audiences than any traditional one-to-many communication method. And this is just an average; in practice many blogs have no more than two dozen readers.

More simply, everyone cannot have a million readers. Just because of time constraints, there will only be available a very few high readership ecological niches. Or, more broadly, only a relatively small number of high-influence positions can exist, if influence is defined nontrivially.

The words “equality” or “democracy” have two different, somewhat contradictory meanings. They can signify that all participants have equal power (“one person, one vote”), or they each may have an abstractly equal chance of achieving vastly unequal power (“anyone can be President”). Electronic speech often promises the former in theory and delivers the latter in practice.

There are solid mathematical reasons for extreme inequalities. One extensively discussed phenomenon is the

power-law distribution. Shirky (2003) writes, “In systems where many people are free to choose between many options, a small subset of the whole will get a disproportionate amount of traffic (or attention, or income), even if no members of the system actively work towards such an outcome. This has nothing to do with moral weakness, selling out, or any other psychological explanation. The very act of choosing, spread widely enough and freely enough, creates a power-law distribution.”

Power-law distribution formalizes the pyramids of influence concept, in which there are a few powerful members at the top and many much less influential participants below. The counterintuitive nature of this result, of replicating the influence structures present in older media, often comes as a disappointment to almost everyone involved. Note, however, that there is some variation as to the magnitude of the effect within specialties: “NEC researchers discovered that the degree of ‘rich get richer’ or ‘winners take all’ behavior varies in different categories and may be significantly less than previously thought. A new model has been developed which can be used to predict and analyze competition and diversity in different communities on the Web” (Pennock, Flake, Lawrence, Glover, & Giles, 2002).

The gulf between initial estimation and the realities of implementation has an intriguing similarity to the difficulties of effective computational parallel processing. Ideally, if one processor can do one unit of work,  $N$  processors working in parallel should do  $N$  units of work. Yet, scaling the computational work is known to be extremely complex in practice because of coordination limits. Similarly,  $N$  voices of electronic speech often simply thrash at each other, producing nothing but the equivalent of process contention.

Whatever the gross equivalences, there will always be deep functional distinctions among one horse, a dozen dogs, a hundred cats, and a million ants.

## INEQUALITY AND PUBLIC POLICY

The structural inequalities described above have profound implications for political speech, as Hindman, Tsioutsouluklis, and Johnson (2003) point out:

Claims about the Web and politics have commonly confounded two different things: retrievability and visibility, the large universe of pages that could theoretically be accessed versus those that citizens are most likely to encounter. While the governing assumption of much previous work has been that retrievability would translate inexorably into visibility, we cast doubt on that claim . . . . Online political communities on the Web thus seem to function as “winners take all” networks, a fact that would seem to have widespread implications for politics in the digital age.

Rather than democracy, the natural organization of Web communities in electronic speech apparently tends to a form of oligarchy. As some sites become more well known, they capture the attention of the population,

becoming a common reference for the group. Less well-known sites are then less able to compete for share, receive less attention, and thus have (all other factors being equal) correspondingly diminishing influence. This effect inverts the naive conception of electronic speech as a level playing field. Instead, it has a few kings of the hill.

Journalist A. J. Liebling famously observed “Freedom of the press is guaranteed only to those who own one.” And although electronic speech has naively been hailed as everyone owning a press, as has been noted above, inequality of audience can span a difference of many orders of magnitude: “it is clear that in some ways the Web functions quite similarly to traditional media. Yes, almost anyone can put up a political Web site. But our research suggests that this is usually the online equivalent of hosting a talk show on public access television at 3:30 in the morning” (Hindman et al., 2003).

If one assumes this inequality is at least worthy of examination, the question then arises as to potential methods of redress. The general issue of imbalances of distribution of communication ability has been addressed by various laws and court decisions. In the United States, the case *Miami Herald v. Tornillo* (1974) overturned a “right of reply” law applied to newspapers (FindLaw, 2004):

The Court was unanimous in holding void under the First Amendment a state law that granted a political candidate a right to equal space to answer criticism and attacks on his record by a newspaper. Granting that the number of newspapers had declined over the years, that ownership had become concentrated, and that new entries were prohibitively expensive, the Court agreed with proponents of the law that the problem of newspaper responsibility was a great one. But press responsibility, while desirable, “is not mandated by the Constitution,” while freedom is. The compulsion exerted by government on a newspaper to print that which it would not otherwise print, “a compulsion to publish that which “reason” tells them should not be published,” runs afoul of the free press clause.

When discussing electronic speech, there is often confusion regarding legal ideas of regulation that apply to broadcast television or radio, based on the inaccurate lumping together of all media that have any association with electronic equipment. These legal ideas of representation include such concepts as the (obsolete) “fairness doctrine” or “indecentcy.” When electronic speech is transmitted through wireless networks, there may be an attempt to invoke government control of the public airwaves. However, again in the United States, the Supreme Court concluded, in *Reno v. ACLU* (1997), there is “no basis for qualifying the level of First Amendment scrutiny that should be applied to this medium.” That is, electronic speech is more like a print publication than a radio show.

Other countries have different approaches. As of the writing of this chapter, the Council of Europe (2004) has received extensive commentary on a draft recommendation addressing issues of “the right of reply in the new

media environment.” Principle 1 of this draft document states, “The right of reply, and in particular the principles of Resolution (74) 26, should apply not only to the press, radio and television, but also to professional on-line media.”

An idea that new media will intrinsically cure inequality is merely a restatement of the hope of a technological solution to a social problem.

## SPEECH-RESTRICTING ARCHITECTURES

The action of a large number of people who want to speak necessarily generates an opposite reaction from those who do not want them to be heard (see the chapter, Internet Censorship, in this *Handbook*). The battle between speakers and censors has profound implications for Internet architecture (Lessig, 1999).

One difficulty in this area is the overloading of the word “filter.” This word has at least three different meanings:

1. Prohibition—An authority forbids another person to read the content.
2. Killfiling—The reader wishes not to read the content.
3. Personalization—The reader wants to affirmatively obtain selected content.

Confusion over these varying meanings can lead to mixing ideas primarily associated with one meaning with another. Prohibition of content assumes a willing reader attempting to seek out that material and an external directive to forbid it.

It should be emphasized that debates over the justifications for electronic speech restrictions need to distinguish between arguments over values and arguments over implications. What content a government can prohibit from its citizens is a statement of values. That the method of prohibition works equally well on any kind of content is a statement of implications. Moreover, if a method works for parents with regard to teenagers in America, it will certainly work for a government against citizens in China. Inversely, if the effects of electronic speech are such that citizens can escape the control of government in China, then teenagers will be able to avoid the control of parents in America.

### Private Blacklists

The most common speech-restricting architecture is the compilation by a private entity of *blacklists* of prohibited sites and key words, or alternately *whitelists* of permitted sites. Although this practice is often termed “filtering,” the possibility of confusion with other applications of the word makes the alternate, more precise term “censorware” a better choice for these programs. Moreover, a filter is associated with removing toxic material that the user does not wish to have. These speech restrictions pertain to a third party, an authority controlling what another person is permitted to read.

The essential mechanism of the restriction is conceptually simple (Finkelstein & Tien, 2001). Every time a reader wishes to connect to any electronic speech, the request is examined programmatically against the lists of

sites and/or key words. The system may be configured in a manner that whatever is not explicitly permitted is forbidden (whitelisting) or whatever is not explicitly forbidden is permitted (blacklisting). Depending on whether or not the request is considered acceptable, the reader is then either allowed or prohibited from obtaining the content.

Given this framework, the checking of acceptable speech requests can be done at any level of detail. Entire sites can be uniformly prohibited, or the restrictions can be on partial portions of Web sites (directories) or specific items (file). Alternately, any content that has a particular pattern in its name can be prohibited (e.g.).

Although the most common area of blacklisting is sexual material, the principle is general, and a product usually has a collection of blacklists, which cover various subjects that are to be forbidden. Some other typical forbidden topics are drug-oriented material or music-trading sites.

Virtually all private blacklists are encrypted and considered as highly secret intellectual property of the censorware company (the exceptions to this rule have a very small market share). Decrypting the blacklist can subject an investigator to a lawsuit on the grounds of violating copyright, trade secret, breach of shrinkwrap license contract, and more. The right to circumvent the encryption of censorware blacklists has also been one of the few exemptions granted, for a limited time, to the anti-circumvention prohibition of the Digital Millennium Copyright Act.

## Government Blacklists

Given the simplicity and straightforwardness of the blacklist system, it translates naturally into an application of direct government censorship. In this implementation, the government simply commands all Internet service providers (ISPs) in the country to attempt to suppress the speech by disallowing network connections to any of the sites on the blacklist. In the case of undemocratic regimes, this is straightforward (Edelman & Zittrain, 2003).

However, for democratic countries, attempts at direct prohibition are problematic. In the United States, one contentious instance has been a Pennsylvania law where, according to the Center for Democracy and Technology (2003), "The law provides that the state Attorney General or any country district attorney can unilaterally apply to a local judge for an order declaring certain Internet content may be child pornography, and requiring any ISP serving Pennsylvania citizens to block the content."

In the United States, measures taken to implement such speech restrictions involve such issues of law as prior restraint and acceptable burdens to enforce such a law. Because some sites may share Internet protocol address locations with other sites (virtual hosting), denying access to a targeted site might also deny access to the speech of many innocent sites.

In the United Kingdom, the Internet Watch Foundation (IWF) has begun providing a small blacklist of various prohibited, highly illegal sites (IWF, 2004): "One of the services the IWF offers its members is access to a database of child abuse website URLs so they can help protect children and the public from inadvertent exposure to abusive

images of children online. These URLs are for websites which contain child abuse images and are collated from the reports we receive via our [I]nternet hotline."

Other governments may try to follow this lead.

## Government Classification Bureaus Applied to the Internet

In contrast to blacklists, a classification or labeling approach typically leads to proposing a speech-suppression architecture that is optimized to the complex needs of encoding government law and social customs. Such an approach relies on the existence of elaborate databases maintained either implicitly or explicitly by force of law and then may layer exemptions, special treatment, or elaborate joins on top of those databases. There is even a research area of specification languages devoted to expressing censorship policy, much like the computer language Fortran is devoted to mathematical calculations and Java to object-oriented modeling. For example, consider the following fragment of the PICSRules specification (Evans, Feather, Hopman, Presler-Marshall, & Resnick, 1997).

```
11 Policy (RejectByURL ("http://*www.badnews.com:*/*"
    "http://*@www.worsenews.com:*/*"
    "*://*@18.0.0.0!8:*/*))
```

```
12 Policy (AcceptByURL "http://*rated-g.org/movies*")
```

...

```
11 Reject any HTTP URLs from the www.badnews.com
    and www.worsenews.com hosts, and all URLs that
    specify a host whose ip address has 18 as its first eight
    bits (these are the addresses corresponding to mit.edu).
```

```
12 Accept URLs whose domain names end in rated-g.org
    and whose pathnames begin "movies", but only if no
    username or port number is specified. For example
    "http://www.mystuff.rated-g.org/movies/hello" would
    be accepted, but neither "http://joe@www.mystuff.
    rated-g.org/movies/hello" nor "http://www.mystuff.
    rated-g.org:8009/movies/hello" would be accepted
    at this point in the rule processing (although they
    might be accepted by one of the subsequent policy
    statements).
```

Although such specifications were popular at the start of the growth of the Internet in the mid-1990s, maintaining the labeling database in any distributed form has proved to be less efficient than simple private blacklists. The primary interest in this area at the time of this writing seems to be in the European Union. These systems are theoretically a method for potentially resolving the cultural conflicts of member states over the problems of electronic speech and worldwide interconnection, in terms of the potential to subvert local censorship regulations.

Yet, even though they have not been implemented widely, such systems are already present in prototype form, complete with sample code for demonstration products. Too often the concept is naively reinvented by people unfamiliar with the state of the art as it has been developed. For example, the Internet Content Rating Association (ICRA) advocates a system with several

rating descriptors, which are arguably both elaborate and confusing (ICRA, 2004):

Nudity and sexual material, Erections and female genitals in details, Male genitals, Female genitals, Female breasts, Bare buttocks, Explicit sexual acts, Obscured or implied sexual acts, Visible sexual touching, Passionate kissing, None of the above.

Context: this material... appears in an artistic context and is suitable for young children, appears in an educational context and is suitable for young children, appears in a medical context and is suitable for young children.

Note that the concerns of certain Islamic states, where censorship may be applied even to the clothed depiction of the female anatomy, are not addressed by this framework. Further, same-sex interactions and opposite-sex interactions seem to have the same rating, a decision that may be contentious.

Moreover, determining what is “passionate,” “artistic,” and “suitable for young children” is left as an exercise for the reader. Determining such ratings accurately for a Web site that publishes hundreds of pages every day, some perhaps generated by site members without editorial control, is left as another exercise for the reader.

### Third-Party Sites

The extensive relaying and copying aspects of many electronic speech systems produce an architectural effect that has profound implications for attempts at control. It is not enough merely to suppress the speaker or to direct paths of speech distribution. All indirect distribution paths must be cut as well.

Ordinarily, little attention is given to the architecture of connection between a speaker and a listener. In public speaking, the connection is via sound waves, leading to the problem of the “Heckler’s Veto.” That is, physically, a heckler injects competing sound waves into the communications channel, creating channel noise that overrides the intended signal. For publication, censorship is designed to prevent the speaker from generating the message in the first place and then others from further spreading that message.

However, for networked speech, there are sites that act upon other sites. These third-party sites provide services on speech, such as archiving material from other sites (“The Internet Archive”), keeping a local copy that may be more accessible than the original (Google cache), or providing privacy and anonymity by stripping personally identifying details from the connection (Finkelstein, 2002). By providing these services, these sites thus constitute a loophole in any system of speech suppression. That is, a reader might be able to obtain prohibited content by connecting to one of these sites and using it as a relay to reach the contraband content. Even scanning the packets at the reader’s point of origin might not help, as the connection could be encrypted. Mere compression of content in transport, often done for efficiency as opposed to secrecy, can frustrate packet monitoring. This issue has

now been acknowledged by various censorware companies themselves (N2H2, 2003).

### Loopholes

Sites filtered because they open a loophole that can be exploited to access pages which would otherwise be filtered out from your service. Unless this category is selected, the system’s Internet Content Filtering protection can be compromised.

Examples:

<http://www.kaza.com>

[www.triangleboy.com](http://www.triangleboy.com)

<http://www.google.com/search?q=cache>

In particular, the need to prohibit access to privacy and anonymity sites sets up a profound conflict between social expectations which are common, at least in Western society, and requirements of law enforcement within the system. While there are many contexts where a person is made aware that his or her actions may be subject to monitoring by authorities, it is yet a further step to prohibit conduct which might impede that monitoring.

## SPEECH-RESTRICTION THEORIES: CONTROL RIGHTS VERSUS TOXIC MATERIAL

Participants in debates about the architectural restriction of electronic speech sometimes approach the topic using different conceptual frameworks. Unexamined incompatibilities in the theoretical grounding of the restrictions can lead to significant problems with their implications. For example, lawyers and policy analysts are often concerned with the right of control in an environment and determining the chain of authority via control of property:

The burden should be on the filterer to justify the denial of another person’s access. The most plausible justifications for restricting access are that the third party owns the computer or that the third party has a relation of legitimate authority over the user. For privately-owned computers, the brute fact of ownership may often be a good enough reason, although a relation of legitimate authority will often also be present. Thus parents may restrict their children’s use of their computers. . . . Private employers may restrict employees’ use based on ownership of the computer and legitimate relations of authority and workplace control. Nevertheless, restricting employee access may involve technological surveillance and invasions of privacy. These are separate questions that must not be overlooked (Balkin, Noveck, & Roosevelt, 1999).

So the focus here may be said to be control rights. However, discussing the issue of parents restricting their children in terms of relationship or computer ownership can

obscure the possible rationale used by the parents themselves. In a competing framework, the primary considerations are potential exposure to speech that is regarded as harmful and its conjectured negative effects. In this system, the focus may be said to be on toxic material. These theories can be seen, for example, in one court case where a mother sued a public library in an attempt to force it to restrict the speech available on its computers: "Parents in the community generally do not know that the library allows children to view obscene and pornographic material on library computers and believe that the library is a "safe" place where children will not be harmed by library resources. . . . Children such as Brandon P. who view obscenity and pornography on the library's computers can and have sustained emotional and psychological damage in addition to damage to their nervous systems. It is highly likely that such damage will occur given the library's policy" (Millen, *Kathleen R. v. City of Livermore*, 1998).

According to this viewpoint, the harmful result would presumptively be the same no matter who owned the computer. Indeed, an implication here is that the untoward effect would be identical if the material was viewed as a side effect of someone else obtaining it, even if that other reader had a legal right to acquire it:

How I train my children and what moral values I impart to them doesn't do much good if they're simply walking by a computer in the reference area while an adult male is accessing hard-core pornography, which has been a very common occurrence at our library. What gives the library or anyone else that right, especially in a public institution, to take away the innocence of my child? We get frequent phone calls from distraught parents . . . who are being responsible parents with their children in the library and suddenly being exposed to the most vile material (Thornburgh & Lin, 2002).

Alternately, the presumed toxicity of the speech can be deemed a type of environmental effect, a kind of pollution, where the influence is considered a civil rights violation. One library's policy viewed the issue of restriction of speech in terms of sexual harassment (Loudoun County Public Library, 1997):

Title VII of the Civil Rights Act prohibits sex discrimination. Library pornography can create a sexually-hostile environment for patrons or staff. Pornographic internet displays may intimidate patrons or staff, denying them equal access to public facilities. Such displays would transform the library environment from one of reading and scholarship to one which invites unwelcome sexual advances and sexual harassment. Permitting pornographic displays may constitute unlawful sex discrimination in violation of Title VII of the Civil Rights Act. This policy seeks to prevent internet sexual harassment.

Note that this rationale has no factor regarding the age of the reader. That is, minors and adults are not differentiated in terms of basis for the restriction.

Thus, for best results, policy debate participants should carefully examine the ideology they are using in their own approaches and be aware of possible conflicts with those who hold other theories. A parent who believes the toxic material theory is unlikely to be sympathetic to a lawyer's argument about the limits of government authority (under the First Amendment of the U.S. Constitution) to restrict speech in a public library. On the other hand, civil libertarians, who try to accommodate public concern about children and sexual material by focusing on speech restrictions that are permissible at home under the control rights theory, could find their conceded restrictions extended far past the proposed initial domain when government authorities focus on the material itself. These are fundamental differences in viewpoint that are not amenable to simple resolution.

## UNINTENDED CONSEQUENCES

Given the expansive reach of electronic speech, undesired effects that once were limited to wreaking a small amount of possible damage now have much greater possible effects. Negative results from hostile use and archiving of one's speech are well known throughout history. However, the increased potential for positive applications comes with a similar gain in the potential for negative applications.

### Search Engine

The ability to easily research decades-old statements, formerly a problem mostly for long-term politicians and such, has been democratized. That is, although opposition research previously required significant expense and so limited the application to targets worth that cost, the commodification of information has greatly lowered the threshold for performing an investigation. With large databases of indexed writing, especially of the small-scale electronic publishing discussed earlier, comes the ability to readily locate perhaps embarrassing or untoward content created by a person. As one old cartoon depicted it (Farley, 1996), "Suddenly, just as Paul was about to clinch the job interview, he received a visit from the Ghost of Usenet Postings Past."

As the amount of available speech increases, the applications of a search become more widespread. Romantic dates, academic applications, business partners can be cheaply, and perhaps unreliably, researched in this manner. Often this is termed "Googling" a person, after the most popular way of conducting this research, with the Google search engine. Such searches have become a matter of ethical debate:

The Internet is transforming the idea of privacy. The formerly clear distinction between public and private information is no longer either/or but more or less. While the price of a neighbor's condo may be a matter of public record, it's a very different kind of public if it's posted on the Internet than if it's stored in a dusty filing room open only during business hours. This distinction does not concern the information itself but the

ease of retrieving it. . . . With this change comes a paradoxical ethical shift where laziness, or limiting yourself to insouciant Googling, is more honorable than perseverance, as in hauling yourself down to the municipal archives, say (Cohen, 2002).

As noted, the very ease with which research can be accomplished requires rethinking the ethics to be applied to it.

### E-mail Embarrassment

Complementing the issues of being able to pull speech from archives is the speech hazard that exists in which speech that was not intended to be distributed extensively can be disseminated widely to an audience far beyond expectations. The most well-known examples are those that have a sexual appeal. The <http://snopes.com> Urban Legends site has verified several examples of this effect:

Don't send messages describing your sexual exploits from your employer's e-mail system (especially if you work for a staid professional firm), no matter how much you trust the recipients. One invocation of the 'forward' command by any of the recipients is all it takes to start a chain reaction that will send your e-mail on its way to thousands of e-voyeurs, land your name (accompanied by an embarrassingly graphic story) in the newspapers, and possibly get you fired from your job (Mikkelson & Mikkelson, 2001).

Of course, the forwarding of interesting documents has occurred since copying existed. What is notable is the increased ease of the communication. The overall effect is that items that would otherwise be of minor interest can achieve more renown. In one case, a long letter from a journalist describing a World Economic Forum conference eventually appeared on a popular community discussion site. This conflicts with some social expectations that have been developed previously, leading to what has been called "accidental privacy spills":

In crudely mechanistic terms, going from paper to bits lowers the cost of copying and forwarding. It takes a pretty important letter to be worth the bother of Xeroxing, stamping, and mailing, but even an infinitesimally small benefit is worth the minimal cost of clicking on the forward button and typing in a few addresses. People who wouldn't have forwarded a letter will forward an email—and they'll forward it to more people (Grimmelmann, 2003).

So practical expectations of privacy, which formerly existed from different thresholds of information flow, now need to be reconsidered.

### Spam

Spam (unsolicited bulk e-mail) is an extensive topic in itself (see the *Handbook* chapter, Spam and the Legal

Counter Attacks). However, in some ways spam is an electronic speech problem and a classic unintended consequence. If electronic speech becomes very cheap, then there is an economic incentive to indulge in mass solicitations. The financial basis is that by shifting the costs of processing the solicitation onto the receiver, a mass of unwilling listeners can be ignored and profit made from a very few interested targets. From this perspective, the problem of spam is created because it is too easy to speak to other people, spawning electronic sales efforts that are the equivalent of doorbell-ringing of whole cities at once.

This mass solicitation then creates an interest in the idea of a right NOT to listen or in what permissions, implicit or explicit, must be present before an attempt to contact another person is acceptable (especially to make a sales pitch). The idea of being able to speak by default, unless told otherwise, in all contexts, quickly yields an unworkable implication of being required to opt out of an endless stream of individual product advertisements. Yet, requiring too strict a permission system risks criminalizing casual, though arguably commercial, contacts.

Anti-spam efforts can become electronic speech issues in and of themselves. One common system is to create a blacklist of Internet addresses, which might be of addresses that send spam, or Web sites devoted to products advertised in spam, or much more aggressively, sites that are deemed to be "spam-support" under some criteria. Even further, some blacklists go into the realm of a secondary boycott, containing addresses that have no connection to spamming whatsoever, except that they share ISP service with an ISP that has spammers. Note that the extensive blacklisting in this secondary boycott case differs from overbroad censorware blacklisting, in that the expansive spam blacklisting is not an error, but a deliberate and intentional pressure tactic.

The spam blacklists efforts are often defended as electronic speech themselves, as an opinion for the purposes of association. For example, one spam blacklist organization, the Spam Prevention Early Warning System (SPEWS), compares itself to the *Consumer Reports* magazine (SPEWS, 2004).

Q10: Isn't SPEWS censorship?

A10: No, SPEWS is a list of areas of the Internet that some people do not wish to communicate with. Think of it as one group's *Consumer Reports* review of portions of the billions of Internet addresses. These are the ones SPEWS members have a poor opinion of. SPEWS is not anti-commerce and fully supports the USA's First Amendment and other nations' free speech protections. In fact, the USA's Supreme Court agrees with the SPEWS view. The creators of SPEWS are its main users and who it was designed for; if others decide to also use its data, they are exercising their own rights. No one is forced to use SPEWS.

In this framework, the argument regarding the use of the blacklist is over issues of causality and responsibility of speech. After all, in the case of the crime of blackmail, a blackmailer is only providing information to the community, and ideally the information used for the blackmail is completely truthful. All other community members who

use the data provided by the blackmailer are then exercising their own rights. The moral dispute is not resolvable by an appeal to speech rights.

## CONCLUSION

Many of the issues arising from electronic speech are generated by the effects of more efficient information exchanges. However, this gain is independent of the assumed social value of the speech. A change that spreads politics also spreads pornography. An improved ability to research product reviews goes hand in hand with an improved ability to research people's history. An inexpensive way to connect with long-lost relatives is also a cheap way for many new best friends to send solicitations. The copyright status of any particular message is generally completely irrelevant to its technical ease of propagation.

Moreover, increasing speech production, while listening ability remains relatively unchanged, causes a need for techniques to better allocate the finite span of attention. This then creates new environments for monopolization and marginalization of speech distribution. It's all a matter of implications, rather than values. The bits don't know why they shouldn't flow.

## GLOSSARY

**Blacklist** A list of items intended to be stigmatized or marginalized.

**Blog** A frequently updated, reverse-chronologically ordered set of Web pages, often written by one person (though it can be a group effort). Also termed Weblog or Web-log.

**Censorware** Software designed and optimized for use by an authority to prevent another person from sending or receiving information.

**Moderation** A system for selecting among speech based on imputed value.

**Power Law** Also known as Zipfian distribution, an arrangement where the occurrence of each element in a ranking of elements falls off with an exponential frequency.

**Spam** Unsolicited bulk mail, typically commercial in nature.

## INTRODUCTION

Paper tape, floppy disk, CD-ROM, and now the Internet: whatever the medium in which software has been provided as technology has progressed, pirates have found ways to copy it illicitly. The software industry regards piracy as a major problem. In recent years, an estimated 35% of all copies of packaged PC software applications installed worldwide were pirated, having a retail value of some US \$30 billion annually. If all software categories were included, this total would be even larger. Illicit copying of software has existed for a long time, and the new modes of copying enabled by the Internet have made it much harder for the software industry to combat it.

## MODES OF SOFTWARE PIRACY

Software piracy is any copying of software in contravention of its license. One of the biggest obstacles to reducing piracy is the widespread ignorance of what actions constitute piracy. Here are some ways that piracy can occur:

- downloading proprietary software from an unauthorized Internet bulletin board or Web site or directly from another user via a peer-to-peer file-sharing program
- purchasing counterfeit software in a store or at an Internet Web site or auction
- borrowing the medium containing an application purchased by an employer for use at one's place of work and installing it on a personal computer at home
- borrowing a program from a friend, co-worker, or a library and installing it on one's own computer
- selling or giving away an old version of a program after receiving an upgrade
- leaving an installed program on an old computer after installing it on a new computer without purchasing a new copy of the program
- installing more copies of a program on the computers in an enterprise than the license allows or installing it on a server for use over a local area network if this is not permitted by the license

Note that it is always permissible to make a copy of software for backup or archival purposes, but any such copy must be destroyed if the user no longer can legitimately use the program. In addition, users may sell or give away programs they legitimately own to someone else, provided they do not retain their copies. For instance, users can leave installed software on old machines that they sell or give away if they purchase new computers with new software preinstalled.

The term "piracy" has long been used to mean acts of infringement of copyright. Thus, it was natural to adopt the term to include the illicit copying of software, even before the application of copyright law to software was clarified fully. However, piracy is a broad term encompassing many diverse forms of infringement, only some of which are listed above. Each of these forms has its own legal and ethical ramifications, as well as distinct perceptions by its practitioners. One important distinction is between copying for private use only or end-user piracy, and copying for sale. Many people consider copying for personal use to be either acceptable or having only minor ethical significance, whereas most recognize copying for sale as both unethical and illegal. Another distinction is between small-scale and large-scale piracy. Although each act of small-scale piracy is relatively minor, the aggregate effect is quite large. In fact, small-scale copying for personal or corporate use is said to be the most widespread form in practice, accounting for over half the total value of pirated software (Software and Information Industry Association, 2000). The growth of the Internet as a medium for exchange of software has greatly facilitated this form of piracy.

## End-User Piracy

Small-scale piracy mainly takes the form of *softlifting*, which means unauthorized copying by individuals for their own personal use. Softlifting can be done in a wide variety of ways. Probably the most common method is to borrow the installation media from a friend or co-worker. Or instead of borrowing the original media, one might obtain an unauthorized or "bootleg" copy. Sharing

of software over the Internet is also common. Before the advent of the World Wide Web, individuals often posted software on Usenet newsgroups or on bulletin board systems. Today, there are thousands of Web sites that post “warez,” contraband software, for download. More recently, peer-to-peer systems have been developed that allow individuals to share software with each other directly.

Renting software and not uninstalling it after use was once a fairly common mode of softlifting. For this reason, the unauthorized renting of software was made illegal in the United States in 1990. Web sites offering software rental can still be found on the Internet, but it does not seem that this is a prevalent mode of softlifting today. The law permits libraries to lend software, provided that the package contains a clear copyright notice. Quite likely these loans are often used for softlifting.

Closely related to softlifting is *softloading* or the installation of a legitimately purchased program onto more machines than for which the software is licensed. It can also involve the installation of the software onto a server for use by multiple client machines in a local area network. Softloading usually occurs in a corporate setting, which can be a business, a nonprofit institution such as a university or hospital, or a government agency. It can occur inadvertently, if the information technology staff does not keep proper records of licenses and the number of installed copies of each software application.

### Commercial Piracy

Bootlegging is the reproduction of pirated software for sale. Frequently this software is a cracked version of a commercial product, but it may also be an illicit duplicate of a legitimately acquired copy. Bootlegging is called counterfeiting if it is done in such a way as to make the product appear to be authentic, so that it can be sold for a price that is comparable to the normal retail price. Counterfeiters take care to duplicate the appearance of the media, the packaging, and even the documentation as closely as possible. In some cases, the purchaser may be unaware that the product is not genuine and will be unpleasantly surprised to find it is not entitled to support, such as upgrades from the manufacturer. Or there may be telltale indications that the software is not legitimate, such as poorly reproduced artwork, misplaced logos, misspellings, or a missing authenticity hologram. In other cases, the bootleggers make no attempt to conceal the pirated status of the product, and it is sold for an extremely low price. Often, a number of bootleg applications with a market value of hundreds of dollars are bundled together on a single CD that may sell for \$20 or less.

Bootlegging is the easiest form of piracy for software producers to combat, provided there is support from the authorities in the host country. This is because bootlegging resembles most closely traditional forms of copyright or patent infringement, for which legal remedies are well established. Furthermore, the offender is often identified readily, and a lawsuit is likely to yield a substantial return in the form of damages and penalties. However, it must be recognized that in many countries, especially in Eastern Europe and Asia, enforcement is lax and bootleggers often sell their wares quite openly.

Original equipment manufacturers (OEMs) produce personal computers that are typically sold fully loaded with an operating system and a suite of applications. The OEMs typically enter into licensing agreements with the software producers to authorize the installation of this software. However, OEMs or hardware dealers sometimes illegally load software onto more machines than authorized, or they may load software that was not included in the license agreement as a way of making the computers more attractive for sale. This practice is called *hard-disk loading*. *Unbundling* is the sale of OEM-version software items separately from the computer system for which they are authorized. *Mischanneling* is the diversion of specially discounted software, intended for academic institutions, government agencies, and other high-volume customers, for sale to others who do not qualify for these discounts.

### MOTIVATIONS FOR SOFTWARE PIRACY

Why does an individual choose to pirate software? Conversely, if obtaining an illicit copy of a software application is so easy and cheap, why does anyone purchase the legitimate article? Probably the reader can think of several likely motivations on either side, but a number of studies have been done in an effort to provide well-founded answers to these questions (see, for instance, Cheng, Sims, & Teegen, 1997; Peace, Galletta, & Thong, 2003; Simpson, Banerjee, & Simpson, 1994; Taylor & Shim, 1993). These studies are not always directly comparable, because they take different approaches and use different models of softlifting attitudes and intentions. They also vary in the ways they validate the measures used and control for various biases. Despite these differences in methodology, the results of these studies are generally consistent, supporting their overall validity.

Of course, studies of this nature inevitably have some limitations. For instance, most are based on surveys of students and business executives. Although these groups are important in the softlifting scene, they may not be representative of softlifters generally. In addition, the studies do not measure piracy activity directly. Rather, they measure perceptions and motivations—subjective factors that nonetheless should be significant predictors of behavior. It is also possible that some of the reasons given by the survey participants may be rationalizations, rather than true motives. So long as these limitations are kept in mind when interpreting the results, the studies can still provide useful guidance toward identifying measures that could affect softlifting behavior.

Probably the most important reasons for softlifting identified by these studies are economic: the software is seen as overpriced, or the individuals cannot afford it. Another commonly given reason is the desire to try out the software before buying it or to use it for only a short time. Reasons for purchasing software, in contrast, include the perception that it will be useful for schoolwork or on the job, and the expectation that it will be used frequently. Another motive for purchasing is the availability of user manuals and technical support. A significant finding of the studies is that the perception of softlifting as unethical, illegal, or against school or company policy has little effect

on the decision to softlift. However, a perception that softlifting is acceptable and prevalent among one's peers increases the likelihood of softlifting.

Other studies have tried to identify cultural and socioeconomic indicators that are predictors of software piracy rates (see, for instance, Depken & Simmons, 2004; Husted, 2000; Marron & Steel, 2000; Ronkainen & Guerrero-Cusumano, 2001). These studies have the advantage of using software industry estimates of piracy rates, rather than relying on self-reporting in surveys, which is not as reliable an indicator of actual behavior. However, these studies perforce use data at the level of whole nations and so necessarily average out the differences among individuals or among regions within a given country. It should be noted that the piracy data on which these studies are based include only business software. However, because there is probably a strong correlation between business and personal copying of software in each country, the results should be applicable to rates of individual softlifting as well. These studies found that lower piracy rates are associated with higher levels of economic development (per capita gross domestic product [GDP] or income), with greater disparities in income within a country (implying a smaller middle class), and with stronger institutions to enforce contracts and protect property from expropriation. They also found that individualist cultures—those that value individual rights and ownership—have lower piracy rates than more collectivist ones that put greater value on mutual help and sharing.

These results are reasonable. Higher levels of economic development mean that individuals and businesses are more able to pay for software. In countries with greater income inequalities, the lower classes are unable or barely able to afford computers at all, and so most technology purchasing is done by the wealthy who can easily afford to pay for it. It is the members of the middle class, often struggling to make ends meet, who are the most likely to seek to cut costs by pirating software.

### Alternative Views of Softlifting

Economic factors alone are not able to explain the disparities among nations with respect to the acceptability of unauthorized copying (Depken & Simmons, 2004; Kini, Ramakrishna, & Vijayaraman, 2004). For instance, Hong Kong's per capita GDP is one of the highest in the world, yet its software piracy rate is nearly twice that of Switzerland. Strong institutional protection of property and contract rights is primarily a feature of Western cultures that emphasize individualism and competition. Other cultures, particularly those of southern and eastern Asia, have a different tradition that deemphasizes rights of individual ownership in favor of the duties of cooperation and sharing of the fruits of one's creativity for the benefit of society. Anti-American sentiment or local nationalism could also be significant factors favoring piracy in some countries.

The reader should keep in mind that, although the Western paradigm of copyright protection is the basis for the laws governing the dissemination of most software, such protection is a particular legal framework corresponding to a particular era and society and is not

a universal ethical norm. The use of the term "piracy" in this chapter should not be taken to imply that all unauthorized copying is unethical or that those who practice it are behaving immorally. In many countries, the imposition of copyright protection for software is seen as an effort by the West to strengthen and maintain its dominance in technology. Even in countries where such protection is provided by law, this legal framework often must compete in the moral sphere with strongly held traditional values of community and solidarity, which may lead individuals to judge that it is ethical to copy software in some circumstances.

### Hackers and Crackers

There is another category of individuals whose motivations need to be examined: the *warez doodz*. In the typology of Loper (2000), these are hackers who specialize in trading pirated software. Like other types of hackers, they are fascinated with learning the inner workings of software systems and reject conventional norms regarding ownership of intellectual property when it is in electronic form. Some warez doodz are "crackers," highly skilled programmers who can analyze and neutralize sophisticated software copy protection mechanisms. Many are relatively unskilled and are limited to following the instructions of others to crack or distribute software. Some warez doodz engage in this activity for profit, but very often they do not, nor do they need or use the software themselves. Instead, they are motivated by the intellectual challenge involved, the feeling of power and control, and the desire to enhance their reputation (McCandless, 1997). Rehn (2004) has pointed out the similarities between the "warez scene" and classical gift economies or potlatch rituals, phenomena that are normally associated only with archaic communities.

### Implications of the Studies

The findings of all the studies cited above carry some implications for software publishers' efforts to reduce the rates of software piracy. First, it seems that educational programs aimed at increasing individuals' awareness of the illegality of softlifting or persuading them to regard it as unethical are of only limited effectiveness. The studies show, perhaps surprisingly, that simple awareness of the illicitness of softlifting has little effect on behavior. Technical copy protection mechanisms (discussed in a later section) can deter casual copying, but cannot stop all piracy. They are inevitably defeated by clever crackers who enjoy the challenge they present. In contrast, perceived consequences, in terms of benefits as well as penalties, are important factors in most individuals' decisions whether or not to softlift. The studies indicate that increasing the likelihood of being caught and punished would deter softlifters. However, it is impractical to prosecute individual softlifters, and in addition, an overly aggressive enforcement program could backfire by creating an adverse public reaction.

Hence, although a gently applied "stick" consisting of user education and relatively unobtrusive technical copy-protection measures, such as product activation, can be of some use, software publishers will obtain more

effective results with a “carrot” by making their products more affordable through attractive pricing options (perhaps charging different prices for different categories of customers) while enhancing the perceived value of their products by providing user manuals, technical support, and inexpensive upgrades. The studies cited above show that, if individuals value the software for its usefulness and value the support provided by the vendor, they will be more willing to pay for it. In fact, many software makers are already using some or all of these options to good effect.

The validity of these arguments is confirmed by the observation that the Linux operating system and its accompanying utility and application software from the GNU organization and elsewhere are sold successfully by a number of vendors, even though the software is all legally obtainable for free over the Internet. These vendors succeed in charging money for the software because they provide valuable support services, including documentation and help lines. Firms that depend on computer systems for their daily operations willingly pay for such support because they want to have someone to turn to for help when something fails.

### Organizations that Combat Software Piracy

There are two main trade organizations that represent the software industry in its efforts to counter the illicit traffic in software. The Business Software Alliance (BSA; <http://www.bsa.org>) is an international organization representing major software and e-commerce developers. Its membership includes such flagship companies as Microsoft, Apple, and Adobe. Founded in 1988, its mission is to educate computer users about copyrights, to lobby for intellectual property legislation, and to combat software piracy. The Software and Information Industry Association (SIIA; <http://www.sii.net>) is a coalition of software and electronic content producers. It was formed in 1999 from the merger of the Software Publishers Association (SPA; founded in 1984) and the Information Industry Association (IIA). Its membership includes some members of BSA, but also includes many smaller software and information technology companies. Its mission is to promote the interests of the software and digital information industry, to provide knowledge resources to member companies, and to fight software piracy. SIIA still uses the name SPA for its anti-piracy arm.

## SCOPE AND IMPACT OF PIRACY

### Estimated Piracy Rates

Estimating the extent of software piracy is not a simple task. Obviously, many of the transactions whereby people obtain illicit copies of software are conducted in secrecy, and Internet warez sites do not usually keep careful records of downloads. Consequently any estimates of piracy rates must be indirect. One of the most widely cited estimates of piracy rates and of the economic impact of piracy has been produced by the International Planning and Research Corporation (IPR) and later by the International Data Corporation (IDC), which are specialized consulting firms. These studies, referred to hereafter as “the

BSA studies,” have been commissioned annually since 1994 by the BSA and SIIA.

The basic quantity estimated in the BSA studies is the annual piracy rate, calculated by dividing the number of illicit copies of software applications newly installed each year by the total number of copies installed in the same year. Thus, a piracy rate of zero would mean that all software was acquired legitimately, whereas a piracy rate of 100% would mean that all software was pirated. The BSA studies estimate the piracy rate globally, as well as on a regional and country-by-country basis (Business Software Alliance, 2005). Up until 2002, the BSA studies considered only business software applications. Beginning in 2003, the studies have encompassed all packaged PC software, including operating systems and typical home-use applications, such as recreational, educational, and personal finance software. Therefore the piracy rates calculated from 1994 through 2002 cannot be directly compared to those for 2003 and later, although they show considerable similarity.

For the first 6 years of the studies, the global piracy rate showed a slow but steady decline from about 50% in 1994 to 36% in 1999. This trend was probably due to several factors, including the efforts made by the software industry and national governments to educate the public about copyright laws and to enforce those laws. In addition, during that time, U.S. software companies made efforts to increase their presence in overseas markets, including providing better user support, while software prices generally declined. These developments made the option of purchasing software legitimately more attractive in those countries. After 1999, the global piracy rate increased slightly, fluctuating near 40% with no clear trend evident. This increase may be due to the increased competitive pressures during a period of slower economic growth, which led businesses to be more willing to pirate software to cut costs. If this explanation is correct, then we may expect to see piracy rates resume their decline once worldwide economic conditions improve. The global piracy rates for 2003 and 2004, based on the expanded set of categories of software, were 36% and 35% respectively, too small a difference to infer a trend at this time.

The BSA studies also estimate the retail “dollar losses” due to software piracy, calculated by multiplying the number of pirated copies by the average market price of a copy. (This is a simplistic calculation, but it provides a rough measure of the amount, as distinct from the proportion, of pirated software.) The global dollar losses showed little variation over the first 9 years of the BSA studies, varying between a low of US \$11 billion and a high of US \$13 billion, with no overall trend. The reason for the low degree of variation in this quantity is that the growth of the software market during this period has been accompanied by decreases in both the piracy rate and the price of software. These figures increased substantially, to about US \$30 billion annually, in 2003 and 2004 due to the larger number of categories of software included.

Regional and country-by-country piracy data from the BSA studies are not analyzed in detail here for reasons of space, but a few broad patterns are noted. North America, with a rate of 22% in 2004, has had the lowest piracy rate of any region for every year of the study. Western

Europe regularly comes in second, with a rate of 35% in 2004. Despite their relatively low piracy rates, these two regions have some of the highest dollar losses. This seeming paradox is explained by the fact that these two regions are the largest consumers of software. Eastern Europe, with a piracy rate for 2004 of 71%, has consistently had the highest rate of any region. The other regions have intermediate piracy rates; in 2004, their rates were as follows: Asia/Pacific, 53%; Latin America, 66%; and Middle East/Africa, 58%. The largest dollar loss among these regions is found in Asia/Pacific, where a substantial piracy rate is combined with a large consumption of software, resulting in a dollar loss that is comparable to that for Europe or North America.

With the exception of Eastern Europe, all of the countries with piracy rates over 70% are Third World countries. In most of these countries there is little indigenous software production, and so for them piracy has a net economic benefit without adversely affecting their own local industry. In this regard it is noteworthy that India, which has become a major player in the software industry, reduced its piracy rate significantly from 79% in 1994 to a low of 61% in 1999. The rate has, however, climbed again, to 74% in 2004, erasing much of this gain. China's piracy rate, meanwhile, has remained very high, only declining from 97% in 1994 to 90% in 2004. China was seeking membership in the World Trade Organization during much of this period and was consequently under pressure to improve its protection of intellectual property rights, but its efforts in this direction have evidently had little effect. An alternative interpretation could be that enforcement efforts succeeded to some extent, but were offset by increases in piracy as China's economy grew very rapidly and became more open in this period.

As mentioned, Eastern Europe has consistently had the highest piracy rate of the six regions of the BSA studies. However, if we exclude Russia and most other countries of the former Soviet Union, the rest of the Eastern European countries (including the Baltic States) have made substantial progress recently, reducing their software piracy rates by at least 15 percentage points during the period from 1994 to 2002. However, their current piracy rates still have room for improvement, ranging from a high of 74% (Romania) to a low of 41% (the Czech Republic) and averaging about 53%. The large reductions in piracy rates in these countries probably reflect the emergence of free-market economies, a process that is normally accompanied by increased protection of intellectual property (Software and Information Industry Association, 2000). This transition has apparently not happened in the countries of the former Soviet Union, which had a combined piracy rate of 87% in 2004.

### Methodology of the Study

To calculate the piracy rate for a given country or region, the analyst needs to determine the number of pirated copies and the number of legitimately purchased copies of software applications installed in that region. The BSA has access to proprietary sales information from the BSA member companies, and so the figures for legitimate software sales are obtained readily. The number of pirated

copies is inferred as the difference between this number and the "demand" for software (i.e., the number of application programs that one would expect to be loaded onto the computers in use). The BSA uses hardware sales data to determine the number of new machines sold each year. To obtain an estimate of the number of machines currently in use, a correction is applied for turnover as older machines are taken out of service and replaced by new ones. From this figure the demand is calculated based on the average number of application programs that would normally be installed on each computer. The BSA studies' calculation of demand takes into account differences between new and replacement machines, between home and business computers, and among the various categories of software, as well as different levels of technological development in different regions.

Freeware and shareware are taken into account in the study by estimating the demand for this type of software and assuming it is fulfilled completely. Freeware is software that its producer makes available free of charge, and shareware is software that is distributed for free with a request that users who like it should send the author a contribution. Because there are no sales records for these applications, supply is difficult to measure, but this uncertainty has little impact on the study's conclusions because freeware and shareware currently represent an insignificant fraction of the packaged PC software market.

Despite all of the uncertainties involved, the BSA piracy estimates are probably the best obtainable under the circumstances. Marron and Steel (2000) performed a regression of the BSA estimated piracy rates on an independently estimated measure of patent protection in various countries and found a strong correlation, as would be expected. This test gives some confidence in the basic validity of the BSA data. In addition, because the BSA uses a consistent methodology globally and from year to year (except for the above-mentioned expansion of software categories beginning in 2003), trends and inter-regional comparisons should be reasonably reliable.

### Financial Impact of Piracy

The most recent BSA calculations of lost revenue include all packaged (as opposed to custom or in-house developed) PC software applications. Therefore, the roughly US \$30 billion in estimated annual losses probably represents the majority of the revenue losses experienced by the industry.

Of course, calling these revenues "losses" implicitly assumes that all software now pirated would be purchased through legitimate channels at current prices if all piracy were stopped. However, it is likely that, if piracy were somehow made impossible, some users who currently pirate software would choose not to purchase the software at all. In addition, very probably prices would change in such an altered market. Thus, it is more precise to refer to this quantity as the "market value" of the pirated software.

More realistic economic models have been developed to consider the overall effect of illicit copying on software producers' revenues. Slive and Bernhardt (1998), among others, describe how, in some situations, piracy of a software product can actually increase the total profits of its

manufacturer through what economists call *network externalities*. In essence, the value of a particular software product is increased by having a large community of users. For instance, the users enjoy the convenience of being able to interchange files in the format used by the application. They may also invest considerable time in learning to use the application and can then move more easily to a new employer where the same software is in use than to one that uses some other product. In this context, piracy can be viewed as a form of price discrimination (the practice of charging different prices to different customers) in which the software is effectively sold at zero price to some customers. The resulting increase in the size of the user community enhances the value of the software, leading to increased sales and possibly also allowing the vendor to charge higher prices to those customers who will pay.

A key element of network externalities is the existence of two distinct populations of users. Home users generally place less value on software than businesses do and are less likely to be willing to pay for it. Businesses value the software more and are also likely to pay for it for the sake of reliability and support. Businesses and other organizations are also targeted more easily by anti-piracy campaigns. Hence, the software companies may find it in their best interest to turn a blind eye to home-use softlifting, knowing that it is helping them build market share that pays dividends in the more lucrative business market.

For small firms attempting to enter the software market, it is unlikely that the positive network effects of piracy will be sufficiently strong to compensate for the revenue losses. This is especially the case for non-U.S. software producers. They have an inherent advantage in their home countries in producing certain types of applications, such as manufacturing, banking, and financial software, areas that are the most dependent on local laws and business practices. However, this advantage is defeated if they are forced to compete against extremely low-cost pirated copies of software produced in the United States (Price-waterhouseCoopers, 1999).

## MECHANISMS FOR PROTECTION OF SOFTWARE

Softlifting has been going on ever since there was anything to softlift. The very first consumer application produced by Microsoft was a Basic language interpreter for the Altair microcomputer that appeared in 1975. A paper tape containing a demo version of the interpreter was stolen, and soon the demo was circulating widely among the Altair user community. Subsequent software products have fared no better. Industry efforts at education and persuasion have met with only limited success. Consequently, the industry turned to legal and technical measures to protect its interests.

### Legal Protection Mechanisms

#### Goals of Legal Protection Mechanisms

Historically, one can identify three main distinct philosophical frameworks on which theories of intellectual property rights have been based. The natural rights view, prominent in European legal theory, finds a right of

ownership to arise from the investment of one's labor in the creation of the product. Another viewpoint considers information to be a public good, which cannot be owned by anyone. This view has prevailed in socialist systems, which reserved the creation and control of intellectual goods to the state. Third, the utilitarian view considers intellectual property as one element of an economic balance sheet that is to be optimized for the maximum benefit to society (Maskus, 2000). This viewpoint has predominated in the United States and has guided the formulation of its legal mechanisms of copyrights and patents.

The basic tradeoff involved in intellectual property rights laws is between stimulating innovation and creation of new inventions and creative works, on the one hand, and allowing access to and utilization of those inventions and works, on the other. This tradeoff is complex, depending on such factors as the state of development of creative industries in the country, its market structure, the educational level of its citizens, and so forth. Finding the right balance becomes even more problematic on a global scale among a diversity of interacting countries with widely different levels of economic development. For a thorough discussion of this topic, see Maskus (2000). Here we simply observe that the essential element of copyright and patent mechanisms is the granting to the creator of a work a temporary monopoly on its production and sale. This permits the owner of the monopoly to charge a price substantially above the marginal cost of reproducing the work (which is often quite low) so as to recover the costs of development, and it also provides an incentive for innovation. The monopoly protection is made contingent on the publication of the idea or its expression, so that others can build on the idea in further creative works.

Some have argued that existing legal conceptions of intellectual property are not adequate for dealing with software (Davis, Samuelson, Kapor, & Reichman, 1996). Copyright laws have traditionally been applied only to writings and other forms of expression that are not industrially useful, whereas patents were applied only to useful ideas and inventions. Yet, software is precisely a useful object that happens to be expressed as a writing. The application of copyright protection to software can also be criticized because of the very long term of protection, usually at least 50 years. For software such a long period is effectively infinite because a program will be completely useless after that time. Furthermore, the manner in which software is published, as binary code that is meant to be read only by machines while the source code is treated as a trade secret, effectively does not amount to disclosure in the traditional sense. Thus, others are unable to build on or improve upon the works, which is contrary to the aim of fostering innovation. For such reasons as these, many observers consider copyright to be overly protectionist of the interests of the software makers. Notwithstanding these objections, the existing legal framework has been adapted to deal with software by a process of relatively narrowly focused changes to existing legislation accompanied by court decisions to establish precedents, just as happened with earlier technological innovations, such as audio and video recorders.

Still, it should be kept in mind that this legal framework is only one of several possible solutions to the problem

of ensuring for society an abundant supply of creative works. It is a solution that is situated within the Western tradition of protection for intellectual property. Other solutions, such as state support for software producers or a system of shared royalty payments funded by hardware or media sales, can be imagined. The *open source* software movement promotes an alternative mode of software production in which widely dispersed programmers contribute to the development of an application, the source code of which is freely available. However, to date none of these alternatives has provided a viable mechanism for funding the work at the levels that would be required to support the current software establishment.

In what follows, the discussion of legal issues is mainly in terms of U.S. law. This is reasonable because most software is produced in the United States, and various international treaties have established a legal climate that is substantially the same in most countries. These treaties include the Berne Convention for the Protection of Literary and Artistic Works, the Universal Copyright Convention, and the General Agreement on Tariffs and Trade (GATT) accord on Trade-Related Aspects of Intellectual Property Rights (TRIPs; see, for instance, *Harvard Law Review*, 2003, for a discussion of these developments.)

### Software Copyright and Licensing

Because a program must be copied from a distribution medium to a computer's hard drive to be installed, and then copied again from the hard drive to the working memory (RAM) to run, copyright in principle gives the software maker almost complete control over the use of its product. According to this view, the customer does not purchase the software, but only pays for a license to use it, under whatever terms the maker chooses to dictate. Exceeding the scope of the license grant is thus tantamount to a violation of copyright, though whether this is always an act of piracy is debatable. In practice, the strictness of this view is tempered by market pressures and by the recognition in law that the customer is entitled to certain basic rights. For instance, licenses that disclaim any liability for defects in the software are generally considered to be unenforceable (Kaner & Pels, 1998). In addition, the making of legitimate backup copies of software is explicitly permitted by U.S. copyright law (17 USC 117) and the European Software Directive (Section 5(b)). Today, most packaged software carries a notice on the outside of the package saying that the purchaser indicates acceptance of the license by the act of opening the package. However, because the license is inside the shrinkwrapped package, there is no way the customer can read it first in order to decide whether to accept it. In the United States and elsewhere, court cases such as *ProCD vs. Zeidenberg* (1996) have generally upheld the enforceability of these shrinkwrap licenses, provided that the terms of the license fall within ordinary expectations, but the question is still controversial among legal scholars.

### Fair Use

One legal question that should be addressed is whether individual copying of software for personal use might fit within the parameters of the fair use doctrine, which permits the duplication of copyrighted material under some

conditions. A determination of fair use must consider four factors: (1) the purpose or character of the use (whether commercial or productive); (2) the nature of the use (whether one is primarily availing oneself of the uncopyrightable factual content of the work or of its expression); (3) the substantiality of the use (whether the work is copied in its entirety or only in part); and (4) the effect of the action on the market for the work. Hornik (1994) argues persuasively that softlifting fails to meet these four criteria for fair use:

1. Although the software is not being copied for sale and even though it may be used in ways that benefit the rest of society (the main aim of fair use), it is also likely to be used directly or indirectly for financial gain.
2. What the softlifter is primarily interested in is the "expression" of the software; that is, its embodiment in code.
3. In softlifting, the entire work is duplicated.
4. Although some softlifters would choose not to buy the software if the choice were to pay or to do without, the practice probably decreases sales at least to some extent.

Hence, a fair use defense of softlifting as it is typically practiced would probably not stand up in court.

### Enforcement Efforts

One area in which the software industry has had some success in improving compliance with licensing and copyright laws has been in pressing its case against corporate softloaders. On behalf of their member companies, BSA and SIIA have undertaken programs of voluntary audits of large firms, inspecting their computers to determine whether software has been loaded onto them in violation of license agreements. When the organization receives a reliable report (usually from an employee of the firm) that softloading is occurring, the firm is sent a letter giving it a choice of permitting the audit or being sued for infringement. Most firms choose the audit to avoid the adverse publicity that a lawsuit would entail. They may also have favorable software licensing arrangements that would be at risk if they failed to cooperate. If the audit reveals violations, the firm must destroy the infringing software, purchase replacements for it, and pay a fine. In return, the firm is released from all further legal claims for prior acts of infringement.

Stopping bootlegging, on the other hand, requires different measures. As discussed above, the development of an indigenous software industry is a key element for gaining the strong support of local governments for the enforcement of intellectual property laws. Even so, the U.S. dominance of the software industry means that, for most other countries, enforcement of laws protecting software nearly always imposes a net cost on their economies. Hence, efforts to increase compliance with these laws have involved tying them to other aspects of trade relations (Shadlen, Schrank, & Kurtz, 2003).

Internet piracy presents greater obstacles to legal enforcement. Suppose someone downloads a software package that has been illicitly placed on a Web site. A software producer that wishes to bring suit to redress this action

faces several practical difficulties (Christensen, 1997). First it must decide whom to sue: the downloader, the intermediary (the service provider hosting the Web site), or the person who uploaded the software in the first place. Next it must decide where to sue: because each of the three parties involved in the action could be located in a different country, the choice of an appropriate venue can be complicated. Finally, assuming the prosecution is successful, the software producer must attempt to recover damages.

Prosecution of an individual downloader is difficult in all of these respects. Web sites usually do not maintain logs of download activity for very long. Even with access to these logs, it can be difficult to identify the downloader, and savvy pirates can masquerade as different users. The downloader may be located in a foreign country that may have weaker intellectual property laws than those in the software producer's home country. Although suit may be brought against foreign nationals in a domestic court, enforcement of the judgment can be difficult. Finally, the amount of damages that can be assessed for a single count of softlifting may not cover the costs of litigation, and the guilty party may not have the means to pay the damages anyway.

In the United States, the 1997 No Electronic Theft (NET) Act addressed this last issue by increasing civil penalties and for the first time providing for criminal penalties for copyright infringement that is not for financial gain, provided the value of the stolen works is at least \$1,000. These measures have made it more likely that an action against an individual softlifter could result in significant penalties, including jail time. Recently some high-profile actions have been brought against particularly flagrant softlifters in hopes of making examples of a few in order to deter others. However, because of the difficulties, as well as for public relations reasons, software companies have historically tended to avoid legal action against individual softlifters.

A more suitable target for legal action may be the uploader. A single upload can be responsible for thousands of downloads, so the damages that can be claimed can be quite large. Furthermore, if the uploader acted for profit, the penalties are even greater. However, many uploaders post software on warez sites simply for the enjoyment of sharing with others and thumbing their noses at powerful software companies. Identification of the uploader can also be difficult, for the same reasons as with downloaders. Finally, even if the legal action is successful, an individual uploader may not have the means to pay the penalties, and the software company would have to be satisfied with a moral victory.

Prosecution of the online service provider (OSP) used as an intermediary for software piracy may be a viable option. The term "OSP" is used here to distinguish such a provider from an Internet service provider (ISP) that merely provides a connection to the Internet. OSPs operate the computers on which reside bulletin board systems (BBSs), Web pages, newsgroups, and chat rooms, all of which can be used to exchange pirated software. Courts have held OSPs responsible for the copyright infringement activities of their customers under the notions of contributory or vicarious liability (Hayes, 2002).

Contributory liability is applicable if the OSP knew about the infringing activity and encouraged or facilitated it. Vicarious liability can apply if the OSP controlled the means to commit infringements, even if it did not monitor or encourage the infringing activity itself, so long as it benefited financially from it. In response to the threat of legal action, many OSPs now publicize and enforce strict policies against infringing activities by their users, although undoubtedly much pirating activity still goes undetected.

Prosecution of the OSP has several practical advantages from the point of view of the software maker: the OSP is an established firm that can be identified easily, the amount of damages that can be sought is large, and in the event of a successful suit the OSP is likely to have the resources to pay the judgment.

A recent development that makes prosecution of the intermediary harder is peer-to-peer (P2P) file sharing. The novel idea behind a P2P service is that the files to be downloaded do not reside on a central server, but on the computers belonging to the users of the service. The central server, if there is one, only acts as a go-between by maintaining lists of what files the users have made available for download by others. Once a user has located a particular file on another user's machine, the file is exchanged directly from one machine to the other without any further involvement on the part of the server. P2P file sharing was pioneered by Napster, which was originally designed to allow users to share music files in MP3 format. Napster's free service was shut down following a lawsuit brought by the music industry (*A&M Records, Inc., et al. vs. Napster, Inc.*, 2002). The success of this suit hinged on the fact that Napster maintained lists of available titles on a central server and thus participated actively in the process of file sharing, although it did not store any music files itself. Successors to Napster, such as KaZaA and Morpheus, have adopted more decentralized structures that are less susceptible to legal action. However, suits have been brought against them; see *Metro-Goldwyn-Mayer Studios, Inc. et al., vs. Grokster, Ltd.* (2003). These newer services also provide facilities for sharing other types of files in addition to MP3s, including software.

## Technical Protection Mechanisms

Because legal protections alone have not sufficed, software makers have devised various technical mechanisms to prevent the unauthorized copying of their products. The most commonly used protection mechanisms rely on a special key code that must be entered by the user during the installation process. Typically this key code is provided along with the installation medium in each software package. Key codes do not prevent softloading, because there is nothing to prevent the user from installing the same software on multiple machines. However, the user can at least be limited to using the software on one machine at a time by means of a key disk or a dongle. A key disk is a special diskette or CD, provided along with the software, which must be inserted into the disk drive during operation of the application program. The program queries the key disk from time to time to verify the user's authorization. For the key disk to be effective, of course, it must be difficult to copy by the means at a typical user's disposal.

A drawback of key disks is that they prevent the disk drive from being used for other purposes while the application is in use. A related alternative is the dongle, a device that attaches to the parallel, serial, or USB port of the computer. As with a key disk, the application queries the dongle as it runs. Dongles are relatively expensive, typically adding \$20 to \$30 to the cost of an application, so they are only practical for high-end software.

Media-limited installations are a way to prevent soft-loading. In these schemes, the installation program counts how many times the application has been installed and refuses to exceed the limit. This method requires the installation medium or at least a component of it to be writeable. In addition, for the protection to be effective, the medium must be difficult to copy by standard means.

Such mechanisms as key disks and media-limited installations were suitable during the 1980s when most software was distributed on floppy disks. As applications grew in size and distribution on CDs became the norm, these methods became less appropriate. In addition, any copy-protection scheme that would prevent legitimate uses, such as making archival backup copies or reinstalling the software after a hardware failure, irritated customers. Because of the consumer backlash against copy protection, by the early 1990s, relatively few packaged software applications that were being sold included any protection other than an installation key code.

Protection measures that rely on special hardware, whether key disk, uncopyable medium, or dongle, are not well suited to today's environment in which much of the software is distributed via the Internet. Often, the software can be downloaded freely, but contains a "time bomb" that will deactivate it after a trial period, such as 30 days. Before that period expires, the customer must register and pay for the software, obtaining a key code that renders the installation permanent.

Unfortunately for the software producers, all of the methods that they have invented to deter the unauthorized use of their products can be cracked or circumvented. Copy-protection schemes suffice to keep the average user, who has no knowledge of the inner workings of software, honest. It is virtually impossible to devise a scheme that a skilled and dedicated cracker cannot defeat.

Cracking a program typically involves reverse engineering the binary code, taking it apart to find where the key code is checked or the dongle is interrogated, and bypassing or disabling these sections. If the protection scheme involves cryptography, this only adds to the challenge. Cryptography is the science of scrambling the contents of a file in such a way that it can be unscrambled only by using a secret, randomly chosen key. It is a practical impossibility to crack a well-designed modern cryptographic system by sheer guesswork, even using the fastest available computers. However, a fundamental problem facing any cryptographic copy-protection method is that the software itself must contain a decryption routine including the key, which a clever cracker can in principle discover no matter how well it is hidden.

### Recent Developments

The battle against online piracy is no longer the province of the software producers alone. The entertainment media industry is getting involved because of the increasingly

digital nature of their products. Their lobbying efforts in the United States bore fruit in the 1998 adoption of the Digital Millennium Copyright Act (DMCA), which greatly strengthened the copyright protection of digital information. Perhaps the most controversial aspect of the DMCA is its prohibition of all acts of circumvention of copy-protection mechanisms. Critics argue that these provisions of the law have primarily been used to silence those who disclose weaknesses in these mechanisms, rather than to stop copyright pirates.

Hollywood has also lobbied for new legislation that would require copy-protection mechanisms to be embedded in every digital device and in all pieces of software that will be produced in the future. The new measures being advocated go even farther than the software industry wishes. Some of the proposed protection mechanisms will interfere with the legitimate duplication of software by OEMs and may prevent computer users from performing legitimate tasks. It is not clear at this time where these efforts will lead, but it is unlikely that they will be any more successful than previous measures in stopping piracy completely.

## CONCLUSION

Piracy costs the software industry billions of dollars annually in lost revenues. The precise cost cannot be ascertained, because there are many economic factors that would change if the illicit copying could somehow be stopped entirely. Softlifting and softloading probably account for the largest proportion of the activity, and the Internet is an increasingly important medium for the exchange of "warez."

Technical means of enforcing copy protection can always be defeated. Veterans of the struggle against crackers recognize that, at best, copy protection only slows pirates down and puts some obstacles in the softlifters' path, so that enough people will purchase the product for it to be profitable. Furthermore, copy protection, if it is too intrusive, annoys customers and can even backfire by spurring more circumvention efforts. Consequently, most software producers have decided not to rely solely on technical means, but to undertake a campaign of user education, coupled with high-profile legal action, to try to persuade customers to obey the laws protecting software. These efforts have borne fruit, reflected in a slow but steady decline in piracy rates in most countries. The biggest reductions in piracy rates have occurred in countries that have been making the transition to free-market economies and developing their own indigenous software industries. Although software piracy will probably never be eliminated completely, there are good reasons to hope that in coming years it will decline to levels that are tolerable for the software industry.

## GLOSSARY

**Crack** As a verb, to circumvent technical measures intended to prevent the unlicensed operation of a program. As a noun, a program that has been cracked so that it can be used by unauthorized users.

**Dongle** A specialized hardware device that attaches to a computer's parallel, serial, or USB port and that is

queried by a program during operation to verify the user's authorization to use the program.

**Hard-disk loading** The installation of unauthorized software on computers being prepared for sale by original equipment manufacturers or other computer vendors.

**Mischanneling** The selling of software intended for academic, government, or other special categories of customers to those who do not belong to the intended group.

**Softlifting** The unauthorized copying of software by an end user for his or her own use, rather than for sale.

**Softloading** The copying of software by an end user onto more machines than permitted by the license, or the unauthorized loading of software onto a server for use by client machines in a local area network.

**Unbundling** The selling of software that is licensed only to be sold as part of a package as a separate item.

**Warez** Slang term for pirated software, usually referring to items made available on the Internet.

## INTRODUCTION: SECURITY RISKS AND OTHER CHALLENGES OF INTERNET GAMBLING

The U.S. General Accounting Office has defined Internet gambling as “any activity that takes place via the Internet and that includes placing a bet or wager” (U.S. General Accounting Office, 2002, p. 1). Many types of gambling activity take place online, including casino-style games (like blackjack, poker, or roulette), pari-mutuel wagering (such as wagering on horse races, dog races, or jai alai), lotteries, sports wagering, and bingo. Nonexistent before the mid-1990s, Internet gambling is now easily available to anyone with access to a computer hooked up to the Internet. As Internet gambling has become more widespread, it poses security and privacy risks for an increasing number of people. The next section of this chapter describes the phenomenal growth of Internet gambling.

Gambling has always been a financially hazardous activity, but gambling online may increase the dangers. Some gambling Web sites have serious security problems. They may close down without paying out winnings, use software to unfairly manipulate outcomes so bettors cannot win, or commit identity theft. Some online gambling operations have been vehicles for money laundering by criminals or terrorists. Gambling online may also imperil the privacy of personal information. Some unscrupulous Internet gambling operations may sell or steal personal data, which may end up in the hands of spammers or criminal entities. Online bettors often have little effective legal recourse against illegal or offshore gambling operations. As with other forms of e-commerce, nefarious third parties pose added security risks, such as hackers diverting online gambling payments. Online casinos may also be at risk of loss from cheaters who break into computer systems or interfere with random number generators. The third section of this chapter discusses these security and privacy problems in more detail.

From a regulator’s perspective, Internet gambling poses difficult challenges. Some regulators advocate the wholesale prohibition of Internet gambling, not just because of security and privacy problems but also because of the risk of other social harms, including organized crime, money laundering, global terrorism, fraud, pathological or addictive gambling, and underage gambling. Another concern is that offshore Internet gambling causes economic harm to local communities by drawing away customers, jobs, tax revenues, and profits from local land-based casinos.

Others contend that the prohibition of Internet gambling is neither necessary nor effective. Some believe that a type of more limited regulation will be sufficient to avert the dangers associated with Internet gambling. One argument that is often cited against prohibition is that a wholesale ban on Internet gambling is effectively impossible because some gambling operators are unscrupulous, do not respect the law or other forms of regulation, are based offshore beyond the reach of regulators, and can use fast-developing technologies to evade any regulation that may be imposed. The fourth section considers this debate over the regulation of Internet gambling in greater depth.

As a result of social and moral concerns, including fears of security and privacy abuses, some jurisdictions prohibit online gambling. For example, the current position of the U.S. government is that offshore operators who offer online gambling services to U.S. residents violate federal law. Other jurisdictions, such as Antigua and Barbuda, have embraced Internet gambling on the theory that it will boost their local economies by creating jobs, especially for young people who might otherwise turn to crime. The fifth section surveys the current regulatory landscape for online gambling, showing its complexity, variation, and uncertainty.

Applying the law to Internet gambling activities involves difficult issues. Gambling laws enacted before the

advent of online gambling raise problems of interpretation. Technology is moving so swiftly in this area that even laws that specifically address online gambling may still be difficult to apply to technologies that did not exist when they were enacted. Another complexity is that even jurisdictions that clearly permit some types of Internet gambling may prohibit others or may limit some gambling activity to their own residents. Moreover, even when a server hosting a gambling Web site is located in a jurisdiction that has legalized Internet gambling, it may not be legal for that gambling operation to accept bets from a computer located in a jurisdiction that prohibits Internet gambling.

Jurisdictional rules often impose significant limitations on the ability to enforce domestic gambling laws directly against offshore online gambling operators. As a result, some American federal and state authorities have chosen to pursue some offshore gambling operations indirectly by pressuring financial institutions to block credit card and other payments relating to Internet gambling. In turn, some online gamblers have increased this pressure on financial institutions by claiming that their unpaid credit card debts cannot be legally enforced as a matter of public policy. In response to these developments, many American banks that issue credit cards have implemented policies to block Internet gambling transactions. This move has in turn sparked conflict among World Trade Organization members over its trade and development ramifications.

Internet gambling raises two central problems for regulation of the Internet generally. The first is the proper relationship between law and technology as sources of

regulation. The second is whether one jurisdiction's regulatory regime can legitimately affect online activity by people who are physically outside that jurisdiction's borders. Other difficult issues involving these problems are spam, online infringement of intellectual property rights, and the spread of computer viruses around the world (see these chapters in this *Handbook*: Hackers, Crackers, and Computer Criminals; Developments in Global Law Enforcement; Spam and the Legal Counter Attacks; and Cybercrime and the U.S. Criminal Justice System.

## PHENOMENAL GROWTH OF INTERNET GAMBLING

Although reported statistics vary somewhat, observers generally agree that the online gambling industry has exploded since its start in the early 1990s. According to a major U.S. government study, the number of Internet gamblers doubled between 1997 and 1998, increasing from 6.9 million to 14.5 million (National Gambling Impact Study Commission [NGISC], 1999). One prominent online gambling analyst, Christiansen Capital Advisors, has reported that global online gambling industry revenue grew by more than 42% between 2002 and 2003, to over \$US 5.6 billion (CCA, 2003). It has estimated that global revenue from online gambling will increase to over \$18 billion by 2010 (Figure 1).

Although a definitive tally of Internet gambling sites is not currently available, one widely quoted estimate provided by a U.S. Department of Justice official (Internet gambling, 2003) stated that by the end of 2003 there would be around 1,800 casino-style online gambling sites.

Figure 1: Estimated Global Revenue from Online Gambling. From Christiansen Capital Advisors (2004).

The growth of Internet gambling parallels a similar trend in gambling generally, which has recently been increasing significantly in the United States. The American Gaming Association has reported that from 1992 to 2002 gross gambling revenue (GGR) more than doubled from all forms of gaming, including casinos, lotteries, parimutuel wagering, legal bookmaking, charitable gaming and bingo, Indian reservations, and card rooms. Over this decade, GGR increased from \$US 30.4 billion to \$US 68.7 billion. Christiansen Capital Advisors reported that GGR increased to over 72.8 billion in 2003 (CCA, 2003).

Many online gambling operations use software developed by gaming software providers, such as Microgaming, CryptoLogic, Playtech, or Odds on Gaming. Some of these software providers own and operate their own online gambling operations. Others just license their software to third-party casinos. Security and privacy are significant issues for all types of online gambling operations.

## SECURITY AND PRIVACY ISSUES FOR INTERNET GAMBLING

Opponents of online gambling (Internet gambling, 2003; Kindt & Joy, 2002) contend that it spawns crime and is increasingly being used to further organized crime. There are certainly very serious security and privacy problems associated with some online gambling operations. Criminal acts associated with Internet gambling include identity theft, fraud, extortion, money laundering, and cheating. Some online gambling operations fail to protect the privacy of players' financial and other personal data, which may violate the law of some jurisdictions. Even where the disclosure of such data is not itself illegal, it may put players at risk of being defrauded if that information is provided to criminal enterprises or individuals.

### Security Problems

The NGISC Final Report (1999) warns that unscrupulous Internet gambling operators can easily close down at will, and they do so frequently, pocketing payments made to them without paying out winnings. Many bettors who have provided online gambling sites with credit card or bank account information have suffered identity theft or have been defrauded, either by the online gambling operator or by a third-party hacker.

Another danger for those wagering on Internet gambling sites is dishonest software. For example, a rigged software-based random number generator can be used to cheat players. When rogue gambling operations or hackers are based offshore, they are often beyond the reach of regulatory bodies, leaving bettors unprotected from fraud. Concerns about fraud are a major reason for recent attempts by U.S. authorities to block the financial transactions used to pay for Internet gambling transactions (see below).

Even if an online gambling site is legitimate, players may still be at risk for a type of identity theft known as "black-holing" (Germain, 2004). Criminals hijack a gambling Web site, causing those who attempt to link to the hijacked site to be redirected without their knowledge to another, apparently identical site run by the hijackers.

When visitors log in to the fake site, the hijackers collect their user IDs and passwords. The thieves then redirect visitors to the real gambling site so that they will believe that they never left it. Another risk for players at legal online gambling sites is the possible lack of adequate reserves to pay out winnings (Cabot, 2004).

Online bettors are not the only ones who may suffer harm from security violations. Criminals have also targeted online gambling operations. Cyberextortionists have sent online gambling operators e-mails threatening distributed denial of service (DDOS) attacks if they fail to accede to demands for payment (Germain, 2004). The amounts demanded by such cyberprotection rackets are typically small, designed to ensure that the threatened sites can afford to pay them. Although some gambling sites, such as the large British betting chain William Hill, have refused to accede to such threats (Leyden, 2004), many other sites have chosen to comply, rather than risk serious harm to their businesses. For example, BetWWTs.com, a sportsbook licensed by the Government of Antigua and Barbuda, paid \$30,000 to hackers who had attacked its site (Swartz, 2004). Because online gambling sites rely on transactions with customers every few seconds, just a few hours offline during a popular betting event like the Superbowl could strike a devastating financial blow. Some gambling sites have gone out of business after DDOS attacks (Swartz, 2004).

One study (U.S. GAO, 2002) reports that many American law enforcement officers are seriously worried about the potential of Internet gambling to foster money laundering in an age of global terrorism, because of the anonymity of the Internet, the availability of encryption, and remote access. Officials at many U.S. government agencies have frequently voiced concern about links between online gambling and organized crime. One Department of Justice official (Internet gambling, 2003) has pointed out that offshore online gambling operations are attractive to money launderers, because their location is effectively beyond the reach of American regulators. Other features that attract criminals are the high volume and speed of Internet gambling transactions, as well as the difficulty in tracing anonymous gambling transactions.

Along with the security problems of identity theft, extortion, and money laundering, online gambling operations also face the problem of cheating by players. This is a common problem for land-based casinos as well. As depicted in the television drama *Las Vegas*, bricks-and-mortar gambling businesses often use overhead cameras to survey an entire casino for cheaters. Such businesses may even employ facial recognition technology in an effort to match players with known cheaters. The anonymity of the Internet makes the pursuit of cheaters an even greater challenge for online gambling operations. No existing technology can provide absolute protection against cheating.

Nor is there yet any completely effective technological means to secure gambling sites against hacking or identity theft. Many online gambling sites use encryption technologies, such as the Secure Sockets Layer (SSL) protocol to protect personal information and credit card numbers from being viewed as they travel across the Internet. A variety of other measures have been deployed to

combat hackers and intruders, including firewalls, hardware and software detection units, monitoring by humans and custom-designed monitoring scripts, and filtering technologies designed to identify and block attack packets. Many sites also take precautions against hardware failure or data loss, including using power backups and emergency generators, tape backups, offsite storage for backups, network monitoring, and hardware redundancy. But none of these security technologies can provide an absolute bar to intruders or identity thieves. Clever hackers have always found ways to evade new security technologies as quickly as they are developed. The arms race between security technology and intruder technology is likely to continue for the foreseeable future.

## Privacy Violations

An issue that is closely related to security is personal privacy. Some online gambling operations have sold or provided personal and financial data to other entities, which have included telemarketers, spammers, and fraudulent businesses. Privacy laws vary considerably among jurisdictions and often fail to protect many kinds of personal information (see these chapters in this *Handbook*: Anonymity and Identity on the Internet and Privacy Law and the Internet).

Some online gambling sites have posted privacy policies specifying the circumstances and extent to which the site may sell or transfer customers' personal data to third parties. Any such policy should be read carefully before providing any personal information to a site. Unfortunately, the mere existence of a privacy policy is no guarantee that it will be followed. If a site violates its own privacy policy, its operators may be liable for unfair or deceptive practices, depending on applicable laws (see Privacy Law and the Internet in this *Handbook*).

## Protecting Yourself from Security and Privacy Violations

Although some online gambling sites are honest and legitimate, it is often very difficult to know which particular sites are trustworthy. Anyone wishing to gamble online should thoroughly investigate an online gambling site before placing any bets. The Web site should provide information on the operator, the jurisdiction where the operation is licensed, the rules and guidelines governing it, and its cash policies. Players should test the validity of a site's contact information by trying out its customer support and checking the validity of its contact information before playing. Of course, security risks may still exist, such as the risk of a site closing down and disappearing before paying out winnings. Players should therefore be careful not to wager more than they can afford to lose.

Some online gambling sites have received the seal of approval of respected self-regulatory gambling watchdog organizations, such as the Gambling Commission (<http://www.gamblingcommission.com>), which conducts random remote audits throughout the year to ensure the fairness, integrity, and randomness of the casino's software, as well as to confirm that the casino follows its own posted rules, is truthful in advertising its payout

odds and percentages, honors wagers even if there is a power failure, has sufficient cash reserves to pay winners, handles players' disputes swiftly and accurately, maintains thorough logs of player transactions, and has customer service representatives available to discuss players' accounts. Other respected gambling watchdogs are the Canadian-based Interactive Gaming Council (IGC; <http://www.igcouncil.org/>) and the United Kingdom-based E-Commerce and Online Game Regulation (eCOGRA; <http://www.ecogra.org>). Even if a gambling Web site displays the seal of approval of one of these watchdog organizations, it is a good idea to confirm that the site is actually included in the list of members on the watchdog organization's Web site.

A useful American resource for victims of online fraud is the Internet Fraud Complaint Center (IFCC), a partnership between the FBI and the National White Collar Crime Center. The IFCC's mission is to address fraud committed over the Internet. Complaints can be filed at its Web site at <http://www.ifccfbi.gov>. The U.S. Federal Trade Commission also has a Web site at <http://www.ftc.gov> with which complaints of fraud, identity theft, or privacy violations can be lodged. If a fraudulent Internet gambling Web site is based in another country, victims should find and contact the appropriate regulatory or law enforcement agency for the country where the gambling operation is based. However, there is no guarantee that doing so will prove effective. Even if the appropriate body can be found, it can provide players with little assistance if the offending Web site has closed down or disappeared or if the governing law provides no recourse.

## DEBATE OVER PROHIBITION OR REGULATION

There is considerable disagreement over whether Internet gambling should be prohibited or regulated. Supporters of prohibition point not only to the security and privacy problems discussed above but also contend that online gambling leads to a host of other social, moral, and economic harms. Although some opponents of prohibition agree that Internet gambling is associated with serious dangers, they believe that some more limited system of regulation will be effective to combat them. Others oppose prohibition on the basis that online gambling has social benefits and is consistent with American constitutional values. Still another point of view is that wholesale prohibition of online gambling is effectively unenforceable. This section considers this debate in more detail.

### The Case for Prohibition of Internet Gambling

Many commentators, such as Kindt and Joy (2002), support the prohibition of Internet gambling because of its social, moral, and financial dangers, including security and privacy violations, fraud, pathological and underage gambling, bankruptcy, crime, and economic harm to local communities. One major government study on the social and economic impact of gambling in the United States recommended that the U.S. federal government

should prohibit all online gambling that is not already authorized in the United States or between gamblers in the United States and offshore operations (NGISC, 1999). It also concluded that states should not allow the expansion of home gambling. The same study also supported the enactment of state and federal law to prohibit wire transfers to Internet gambling operations and to bar the collection of credit card debts arising from Internet gambling. It also called on the U.S. government to "take steps to encourage or enable foreign governments not to harbor Internet gambling organizations that prey on US citizens" (pp. 5–12).

One frequently voiced concern about Internet gambling is the need to protect consumers from fraudulent online gambling operations (see above). Critics of Internet gambling, such as Kindt and Joy (2002) and Schwartz (1999), fear that it causes gambling addictions leading to the squandering of family assets and bankruptcies. The NGISC (1999) reported that online gambling is likely to be especially attractive to pathological gamblers because of the instant gratification it provides, as well as the privacy, ease, convenience and 24-hour availability of gambling from home. A 2002 University of Connecticut study categorized 74% of the online gamers surveyed as pathological or problematic gamblers (Ladd & Petry, 2002). The American Psychiatric Association has issued a mental health advisory on Internet gambling, which states: "Internet gambling, unlike many other forms of gambling activity, is a solitary activity, which makes it even more dangerous: people can gamble uninterrupted and undetected for unlimited periods of time" (p. 1).

Another social concern is that Web sites facilitate gambling by underage children, who may use their parents' credit cards to gamble, thereby causing financial problems for their families. The NGISC (1999) reported that the anonymity of the Internet permits underage children to gamble online and that most gambling Web sites rely on users to provide their real age, without requiring any independent verification. A recent survey found that 7% of adolescents had gambled online, a significant rise over previous studies that reported that only 1% to 2.7% of adolescents had gambled online (Annenberg Public Policy Center, 2003). There is evidence of increased gambling addictions among young people as Internet access spreads rapidly across the globe and most online gambling sites continue to lack effective age verification controls (Kindt & Joy, 2002). A 2002 Federal Trade Commission survey of 100 Internet gambling sites found that most were easy for children to access, lacked adequate or any warnings for minors about the laws prohibiting underage gambling, and did not have any effective way to prohibit access by minors. The same survey also reported that children were exposed to ads for online gambling sites on other Web sites (Federal Trade Commission, 2002).

Additionally, some advocates for prohibitions on virtual casino gambling, such as Craig (1998), fear that Internet gambling causes economic harm to local communities. Craig argues that offshore casinos are likely to draw bettors away from local casinos, harming jobs and profits and reducing tax revenue. According to Craig, online casinos based on local servers are unlikely to create many new jobs, except for a handful of computer programmers.

## The Case Against Prohibition: A More Limited Regulatory Approach

Some commentators, such as Friedrich (2003) and Loscalzo and Shapiro (2000), oppose the wholesale prohibition of Internet gambling while agreeing with prohibitionists that Internet gambling poses some serious social and moral dangers. These opponents of prohibition argue that the better course is some more limited regulation of online gambling. A variety of regulatory regimes have been proposed, ranging from industry self-regulation to several types of governmental regulation.

Proponents of regulation do not always agree on which social and moral dangers are valid concerns for online gambling. For example, Loscalzo and Shapiro (2000) agree that fraud and addiction are serious concerns, but dispute the argument that children's use of parental credit cards for Internet gambling is likely to result in family bankruptcies. They point out that there are liability limits for the unauthorized use of credit cards and contracts with minors are likely to be voidable and unenforceable.

Other supporters of more limited regulation argue that prohibition will not work. Friedrich (2003) believes that gambling is now so widespread in American society that attempts to wipe out online gambling will be as ineffective as the constitutional prohibition of alcohol was against drinking in 1920s America. According to this view, the unintended consequence of the wholesale prohibition of Internet gambling is likely to be more illegal gambling and related unlawful activity. A similar argument, made by Loscalzo and Shapiro (2000) and by Kelly (2001), is that such prohibition will encourage online gambling operations to move offshore, putting them beyond the reach of U.S. regulators.

If a society elects to regulate rather than prohibit Internet gambling, it must decide what type of regulatory regime to adopt. One commentator (Craig, 1998) enumerates several approaches short of prohibition that policymakers can take to regulate Internet gambling. These include (1) a "decriminalization" model, which tolerates Internet gambling regardless of whether the current law on the books prohibits it; (2) a "gambler protection" model, which permits some Internet gambling while attempting to ensure that online gambling operations provide fair and honest gambling services and keep criminal elements out of gaming; and (3) a "government protection" model, under which a government sponsors certain forms of gambling to generate revenue for a local community. Craig advocates the application of different regulatory models to different types of Internet gambling. He supports decriminalization of online sports gambling, a government protection model for online lotteries, and a gambler protection model for pari-mutuel wagering. Craig also argues for the prohibition of virtual casino gambling, on the basis that its social cost outweighs its social gain.

## The Case Against Prohibition: A Market-Based Approach

In his list of regulatory models, Craig (1998) also includes a nongovernmental approach. This libertarian "government-neutral" model would allow the market to

determine the extent of Internet gambling. Some opponents of prohibition favor this model. For example, Bell (1999) contends that legalization of Internet gambling is inevitable. Echoing the classic cyberlibertarian position famously trumpeted by John Perry Barlow in his 1996 manifesto, "A Declaration of the Independence of Cyberspace," Bell argues that effective prohibition of Internet gambling is impossible. According to Bell, the architecture of the Internet provides the technological means to evade laws prohibiting Internet gambling. Moreover, the global nature of the Internet makes purely domestic prohibitions on Internet gambling ineffectual in stopping online gambling activity. Jurisdictional and sovereignty rules limit the ability of national authorities to regulate or control offshore gambling activity. According to this view, it is pointless to enact unenforceable laws prohibiting online gambling.

Moreover, Bell argues that legalizing Internet gambling is socially beneficial. He believes that Americans enjoy gambling and will fight to continue to gamble online. According to Bell, the right to gamble is enshrined in fundamental rights and values guaranteed by the Founding Fathers, including the right to dispose of one's property as one wishes and the inalienable right to the pursuit of happiness. Another benefit, in Bell's view, is that online gambling operations will spur the development of better software and networking technology, which can be used to benefit e-commerce more broadly. He also contends that gambling at home provides a more "wholesome environment" (1999, p. 11) than that of real-world casinos. Although Bell opposes wholesale prohibition, he does not argue against all regulation, but suggests that, to be effective, it will be sufficient for such regulation to be minimal.

One possible market-based approach is industry self-regulation. As noted above, there are several watchdog organizations with the mission of furthering self-regulation of the Internet gambling industry, generally by setting standards for online gambling operations. For example, the IGC has a code of conduct requiring its members to, *inter alia*, ensure compliance with applicable laws and regulations, maintain accountability and proper record-keeping, ensure truth in advertising, prohibit access by minors, control compulsive gamblers, ensure adequate financing for prize payouts, assure customer privacy, and deter fraud. The IGC also has drafted Responsible Gaming Guidelines, which attempt to deal more specifically with the problems of addicted gamblers and underage gamblers. Some online gambling watchdogs also test, through the use of audits or other means, that their members actually adhere to their standards (see above). For example, the Gambling Commission conducts random ongoing audits on its members and also obtains information on its members through player feedback, independent research, phone interviews, and insider news and tips.

As Loscalzo and Shapiro (2000) point out, a self-regulatory model must rely heavily on the market policing itself. Such a model would not bar unregulated operations from offering online gambling services, but assumes that the market will operate to support only trustworthy and responsible operations.

The debate over whether Internet gambling should be prohibited or regulated continues. There is disagreement

both over what the proper extent of regulation should be and the extent to which current law regulates or prohibits online gambling.

## CURRENT REGULATION OF INTERNET GAMBLING

Both in the United States and worldwide, the application of the law to the relatively new phenomenon of Internet gambling varies widely and is accompanied by great uncertainty. This section broadly surveys the current state of the law in this area and also considers other kinds of regulation of Internet gambling.

### Legal Regulation of Internet Gambling in the United States

Americans are heavily involved in online gaming and generate between 50% and 70% of online gaming revenues (U.S. GAO, 2002). Whether American players are violating U.S. federal and/or state law is a complex question because there is a patchwork of different laws regulating gambling, and most of these do not specifically address online gambling.

#### Federal Law

Although under the U.S. Constitution, the regulation of gambling is primarily left to state law, the Commerce Clause permits the federal government to regulate gambling that affects interstate commerce. Most Internet gambling can thus be federally regulated as long as bets are placed and received in different states or between a state and a foreign country (Gottfried, 2004).

There has been ongoing debate over whether U.S. federal law prohibits Internet gambling. Most commentators agree that federal law bans online sports betting (Miller & Claussen, 2004); the legality of casino gambling under federal law is subject to greater dispute. The Bush Administration has often repeated the assertion made in a January 2004 letter sent by the U.S. Department of Justice to the Chair of the Virgin Islands Casino Control Commission that existing federal law prohibits all types of Internet gambling, including casino-style gambling (Kelly, Mignin, & Saxman, 2004). According to this view, if an offshore gambling site accepts bets from customers in the United States, it would violate various federal laws, including the federal Wire Wager Act (Wire Act).

The Wire Act was enacted during the Kennedy Administration at a time long before the existence of online gambling. This statute, part of a series of antiracketeering laws designed to combat organized crime, specifically prohibits a person "engaged in the business of betting or wagering" from knowingly using "a wire communication facility for the transmission in interstate or foreign commerce of bets or wagers or information assisting in the placing of bets or wagers on any sporting event or contest, or for the transmission of a wire communication which entitles the recipient to receive money or credit as a result of bets or wagers, or for information assisting in the placing of bets or wagers" (Wire Act §1084(a)).

The U.S. Department of Justice has prosecuted several Internet gambling operators under the Wire Act. Some

courts have found the Wire Act applicable to Internet gambling. For example, in 2000, a New York federal court convicted Jay Cohen, an American citizen, of Wire Act violations arising from his operation of a lucrative offshore Internet sports betting operation, World Sports Exchange (WSEX). Though WSEX was based in Antigua, its advertising targeted U.S. residents. Cohen voluntarily returned to the United States to fight the charges against him, though his business associates continued to operate WSEX in Antigua beyond the reach of American regulators.

Cohen unsuccessfully argued that the Wire Act's safe harbor in §1084(b) applied to Internet gambling. The safe harbor exempts transmissions from liability where (1) betting is legal in both the place of origin and the destination of the transmission and (2) the transmission is limited to mere information that assists in the placing of bets, as opposed to including the bets themselves. The U.S. Court of Appeals for the Second Circuit upheld Cohen's conviction on appeal, finding that betting was indisputably illegal in New York, and the U.S. Supreme Court refused to review this decision (*United States v. Cohen* (2001/2002)).

Cohen was sentenced to a 21-month prison term. He served 17 months at a federal minimum-security prison camp in Las Vegas and then a brief period at a halfway house in Oakland, CA before being released in May 2004 on probation for two years (Free Jay Cohen!, 2004). Cohen has continued to fight against his conviction, both by posting his views on a Web site (<http://www.freejaycohen.com>) and appealing the dismissal, by a New York federal district court, of his habeas corpus petition to vacate his conviction and sentence (Aronovitz & Schopper, 2004). This appeal was unsuccessful (*Cohen v. U.S.*, 2005).

Another successful Wire Act prosecution was brought in January 2000 by the U.S. Attorney's Office for the Eastern District of Missouri against the owners of Paradise Casino, an offshore sportsbook based in Curacao (U.S. Department of Justice, 2001). The owners, Marc Meghrouni and Scott Shaver, were also charged with tax fraud, and their casino was charged with money laundering. Each of these defendants entered guilty pleas to all of the charges against them and agreed to forfeit a million-dollar condominium and a 1995 Lamborghini.

The Department of Justice's view that the Wire Act prohibits all types of online gambling is controversial. A different interpretation of this law is that it applies only to Internet sports betting and not to other types of online gambling. In the only reported ruling on this issue to date, a federal appellate court in New Orleans agreed with this narrower interpretation. In November 2002, in *In Re Mastercard International Inc. Internet Gambling Litigation*, the U.S. Court of Appeals for the Fifth Circuit endorsed a federal trial court's holding that the Wire Act's statutory language clearly applies only to online gambling on sporting events or contests and not to casino-style Internet gambling. As a result, the Fifth Circuit upheld the trial court's dismissal of the complaint in the lawsuit, a class action brought under racketeering laws by Internet gamblers seeking to avoid credit card debts incurred at online casinos.

Another open question, on which courts have been divided, is whether the Wire Act covers gambling activity

in which information assisting bets or wagers is received but not actually sent. For example, in *United States v. Stonehouse* (1971), the U.S. Court of Appeals for the Seventh Circuit held that the Wire Act did not apply to a situation in which the defendant used a Western Union ticker tape machine only to *receive* interstate communications that assisted in the placing of bets, because the machine did not permit him to *send* such information. Other courts have disagreed with this approach. For example, the U.S. Court of Appeals for the Eighth Circuit found, in *United States v. Reeder* (1980), that the word "transmission" in the statute covered both the sending and receiving of wagering information and thus applied to the defendant's interstate telephone calls to an out-of-state sports information service. No court has yet ruled on this issue in the context of Internet gambling.

The Wire Act's requirement that a defendant be "engaged in the business of betting or wagering" (§1084(a)) appears to exclude individual casual gamblers. Courts considering the meaning of this phrase have supported this interpretation. For example, in *United States v. Baborian* (1981), the U.S. District Court for the District of Rhode Island held that Congress did not intend for social bettors to be subject to prosecution under the Wire Act, regardless of how sophisticated an individual bettor might be or how large the amount of money being wagered. In keeping with this approach, federal prosecutors have not pursued individual players for merely placing bets online.

However, Wire Act prosecutions relating to Internet gambling have not been limited to the operators of online casinos and sportsbooks. Prosecutors have also targeted online payment services for processing gambling payments. For example, the U.S. Attorney's office for the Eastern District of Missouri accused the online payment service PayPal of violating the Wire Act and the Patriot Act for processing gambling payments to offshore gambling casinos and sportsbooks between October 2001 and November 2002 (U.S. Department of Justice, 2003a). The Patriot Act, enacted in 2001, strengthens existing federal money laundering laws and prohibits money-transmitting businesses in interstate or foreign commerce from transmitting either funds derived from criminal offenses or funds intended to promote or support unlawful activity (18 U.S.C. §1960). In the PayPal case, the prosecution sought a settlement from eBay, which acquired PayPal in 2002, including payment of all earnings derived from Internet gambling over the 9-month period. In July 2003, eBay agreed to pay the U.S. Attorney's Office a settlement of \$10 million and to undergo a corporate compliance program. eBay has now ceased the processing of gambling payments.

Other federal laws may apply to Internet gambling, including the Racketeer Influenced and Corrupt Organizations Act (RICO), the Travel Act, the Wagering Paraphernalia Act of 1961, and the Illegal Gambling Business Act. The RICO Act imposes both civil and criminal penalties for receiving and using or investing income from "a pattern of racketeering activity," including illegal gambling as well as the collection of unlawful debt, such as a debt incurred in connection with unlawful gambling activity (18 U.S.C. §1962(a)).

Federal prosecutions have been brought successfully under racketeering laws against Internet gambling operations and operators. For example, an Internet sportsbook based offshore on the island of Curacao in the Netherlands Antilles, Gold Medal Sports, pleaded guilty to racketeering in December 2001 in a federal district court in Madison, WI (U.S. Department of Justice, 2001). Gold Medal Sports agreed to cease operating and to forfeit criminal earnings of more than \$3 million. The two primary owners of Gold Medal Sports also pleaded guilty to violating the Wire Act and filing false tax returns. They were each sentenced to 5 years in prison and paid fines of \$100,000 each, as well as back taxes cumulatively amounting to over \$1.4 million (U.S. Department of Justice, 2002). Five others involved in Gold Medal Sports, including two accountants and two attorneys, were also indicted on federal charges. Three pleaded guilty, and one became a fugitive from justice. The fifth was later convicted at trial (Thompson, 2003).

Internet gambling operations have also been prosecuted for violations of the federal Travel Act, which criminalizes interstate travel or use of the mail or any facility with intent to distribute the proceeds of illegal gambling activity, to commit any crime of violence to further such activity, or to otherwise promote or carry on such activity. In *People v. World Interactive Gaming Corporation* (1999), a New York state trial court found that the operator of an Internet casino that offered online gambling to New York residents was guilty of violating both the Travel Act and the Wire Act. Because the defendants knowingly violated New York's antigambling laws, they had conducted "unlawful activity" under the Travel Act. The defendant, a Delaware corporation that operated an online casino based in Antigua, was enjoined from conducting business in New York and also had to pay restitution, penalties, and damages.

Another indictment involving Travel Act violations arising out of Internet gambling activities was announced in October 2003 by the U.S. Attorney's Office for the Northern District of California (U.S. Department of Justice, 2003b). Four individuals and two businesses controlled by them were indicted on various conspiracy, money laundering, and Travel Act charges. According to the indictment, the defendants allegedly formed one of the companies, Gold Chips Technologies, to develop Internet gaming software for virtual casinos.

Some Internet gambling transactions may be subject to the Wagering Paraphernalia Act, which prohibits anyone except common carriers from knowingly carrying or sending "in interstate or foreign commerce any record, paraphernalia, ticket, certificate, bills, slip, token, paper, writing, or other device used or to be used, or adapted, devised or designed for use in (a) bookmaking; or (b) wagering pools with respect to a sporting event; or (c) in a numbers, policy, bolita, or similar game" (18 U.S.C. §1953(a)). Violators are subject to fines or imprisonment for up to 5 years. Although the Wagering Paraphernalia Act contains an exception for "the transportation of betting materials to be used in the placing of bets or wagers on a sporting event into a State in which such betting is legal" (18 U.S.C. §1953(b)), this provision has been found to be inapplicable to the transportation of lottery tickets to a foreign country where betting is legal (*United*

*States v. Baker*, 1966). Although the Wagering Paraphernalia Act was subsequently amended to add a specific exception for such activity, it may still prohibit many other types of offshore Internet gambling transactions. It was held to be violated in *People v. World Interactive Gaming Corporation* (1999), in which records of gambling activity were sent from Antigua to New York and computers used for gambling were sent from New York to Antigua. Some commentators, such as Schwartz (1999), have contended that the Wagering Paraphernalia Act, the Travel Act, and the Wire Act should all be interpreted broadly to apply to online gambling because of the common purpose underlying all these statutes, namely to prohibit the use of interstate commerce for immoral or illegal purposes.

The Illegal Gambling Business Act prohibits illegal gambling businesses. An illegal gambling business is defined as a gambling business that violates the local law where it is conducted; involves at least five people in its conduct, financing, management, supervision, direction, or ownership; and has been in substantially continuous operation for more than 30 days or has a gross revenue of at least \$2,000 in any single day (18 U.S.C. § 1955(b)(1)).

Another federal statute that is relevant to Internet gambling is the Indian Gaming Regulatory Act (IGRA). IGRA permits some gambling on Indian reservations, providing that certain types of games are subject to the agreement of a tribal-state compact. IGRA could apply to Internet gambling if it takes place on tribal lands. The Eighth Circuit considered this issue when the Missouri Attorney General sought to bar the Coeur d'Alene Indian Tribe (the Tribe) in Idaho from accepting money from Missouri residents using home computers to play an Internet lottery run by the Tribe under an IGRA compact with Idaho. The Tribe claimed that IGRA preempted Idaho from regulating the lottery. In *Missouri ex rel Nixon v. Coeur D'Alene Tribe* (1999), the Eighth Circuit ruled that the federal district court had erred in its finding that IGRA completely preempted the field of Internet gaming, and it instructed the federal district court to determine whether the lottery was on Indian lands. Only if it would IGRA completely preempt the state's right to regulate or prohibit the lottery. The U.S. Supreme Court denied certiorari (1999). The case was eventually settled without clearly resolving this issue.

The Tribe has shut down its Internet lottery, but it may not be offline forever. A recent Ninth Circuit decision may have provided the Tribe with a ray of hope for its online lottery. This case arose out of a dispute over interstate toll-free phone service, which the Tribe had sought to obtain for the lottery from various services, including AT&T. When, under pressure from various state attorneys general, AT&T refused to provide toll-free telephone service for the lottery, the Tribe successfully sued in Coeur d'Alene Tribal Court to force AT&T to do so. AT&T then filed suit in federal district court in Idaho, arguing that the Tribal Court lacked jurisdiction. The district court ruled that, although the lottery's administration occurred on tribal lands, because some lottery participants were buying their tickets when off the Tribe's reservation IGRA did not govern the lottery, and thus the Tribal Court's ruling was erroneous as a matter of law. This ruling mooted AT&T's

jurisdictional challenge. However, the district court also granted AT&T declaratory relief, ruling that the telephone company was not required to provide toll-free telephone service from any state that notified AT&T that the lottery violated that state's law. On appeal, the Ninth Circuit ruled in *AT&T v. Coeur d'Alene Tribe* (2002) that the tribal court did lack jurisdiction, but AT&T was not the proper challenger. Because the National Indian Gaming Commission had approved the Tribe's lottery, the states should have filed the action. AT&T decided not to petition the Supreme Court for review, but left it to the states to mount further legal challenges to the lottery. At the time of this writing, the states have not yet acted and the Tribe has not yet restarted the lottery.

Another federal statute, the Interstate Horseracing Act (IHA) has been viewed by some, including the World Trade Organization's Dispute Settlement Body, as permitting the extension of some legal gambling operations to the online environment. Congress enacted the IHA to regulate interstate pari-mutuel wagering on horse races. In pari-mutuel wagering, the bets are pooled. The winning bettors take approximately 80% of the pool, and the remainder goes to the jockeys, racetrack owners, and the state government licensing the horserace. The IHA prohibits interstate off-track wagers except where certain consents have been obtained, including from the host racing association, the host racing commission, the off-track racing commission, and, in most circumstances, all racetracks operating within 60 miles of where the wager is accepted. The statute defines an "interstate off-track wager" as a "legal wager placed or accepted in one State with respect to the outcome of a horserace taking place in another State and includes pari-mutuel wagers, where lawful in each State involved, placed or transmitted by an individual in one State via telephone or other electronic media and accepted by an off-track betting system in the same or another State, as well as the combination of any pari-mutuel wagering pools" (15 U.S.C. §3002).

This language, which was amended in 2000 over objections by the U.S. Department of Justice, appears to permit wagering on horses over the Internet, subject to the required consents. Although the Department of Justice stated in 2000 that it considered the offering of bets on horses over the Internet to violate the Wire Act regardless of this amendment (Bishop, 2000-2001), at the time of this writing no state-licensed horse racing tracks have been prosecuted for conducting Internet betting.

Excluding horse racing, dog racing, and jai alai, most sports betting is now prohibited by the federal Professional and Amateur Sports Protection Act of 1992 (PASPA). This law prohibits the establishment of state-sponsored gambling operations for betting or wagering on amateur and professional sports. However, PASPA contains some exceptions for certain preexisting legal sports wagering, including Nevada's state sports pools and Oregon's sports lottery, as well as exemptions for horseracing, dog racing, and jai alai. PASPA's opponents included the Department of Justice, which considered the law to intrude excessively on states' rights (Senate Report, 1991). A contrary position was offered by the National Gambling Impact Study Committee, which criticized PASPA for not being strong enough (NGISC, 1999). The NGISC recommended that state exemptions should be removed

entirely for collegiate and amateur sporting events. Some commentators, such as Cabot and Faiss (2002), have criticized PASPA for its ineffectiveness in deterring sports gambling, which is widespread and broadly socially accepted and amounts to a significant proportion of Internet gambling.

This brief survey of federal law relating to Internet gambling has sought to show its complexity and lack of clarity. Even if the Justice Department is correct in its contention that federal law clearly prohibits online gambling, there would still be jurisdictional and enforcement barriers to suing offshore gambling operations successfully. In recognition of these barriers, most recent federal enforcement efforts against offshore Internet gambling have targeted such operations indirectly by pursuing companies that service offshore gambling operations, including advertisers, consultants, and Web portals.

In 2003, the Department of Justice launched an initiative, spearheaded by the U.S. Attorney's Office for the Eastern District of Missouri, against broadcasters and other media outlets, warning them that running ads for online casinos and offshore sportsbooks amounted to "aiding and abetting" violations of federal law for which they would risk prosecution (Walters, 2004). Since then, federal law enforcement officials have continued to take even more aggressive action against advertisers and promoters of online gambling operations. Their efforts have included the use of investigative subpoenas seeking information and documents about media companies' ties to offshore gambling operations, as well the seizure of millions of dollars from one media company, Discovery Communications (Discovery), which had placed television ads for an offshore gambling operation, Costa-Rican-based Tropical Paradise (Richtel, 2004). Tropical Paradise later sued Discovery for breach of contract. The case was dismissed without prejudice in June 2004.

This latest federal enforcement effort has had significant results. Major search engines Google and Yahoo, as well as broadcasters Infinity Broadcasting and Clear Channel Communications, have stopped taking the placement of ads for online gambling operations (Richtel). Nevertheless, the First Amendment's protection for commercial speech makes the Justice Department's "aiding and abetting" argument legally controversial. The U.S. Supreme Court recently held in *Greater New Orleans Broadcasting Association, Inc. v. United States* (1999) that the government's ability to regulate gambling is not necessarily coextensive with its ability to regulate the advertising and marketing of gambling, but the precise extent of constitutional protection for online gambling advertising has not yet been resolved definitively by the courts (Walters, 2004).

The operator of several portal websites on online gambling, Casino City, Inc. (Casino City) attacked the Justice Department's enforcement actions by filing suit in August 2004 in the United States District Court for the Middle District of Louisiana, seeking a declaratory judgment that it has a constitutional right, under the First Amendment, to sell and run advertising for online gambling operations based in jurisdictions that have legalized such activity (*Casino City v. United States Dep't of Justice* (2004)). In February 2005, the court dismissed the case on the basis that Casino City lacked standing, finding that Casino

City's self-described conduct could not amount to aiding and abetting federal law, and that Casino City was subject to no credible threat of prosecution. Additionally, the court found that Casino City had not established a valid right under the First Amendment, which did not guarantee the right to advertise unlawful activity. Casino City's appeal against this ruling is currently pending. Advertising for online gambling thus remains yet another area of uncertainty for the applicability of existing federal law to online gambling activities.

### Proposed Federal Legislation

None of the existing federal laws discussed above specifically addresses the legality of Internet gambling. Since 1995, several bills have been introduced to more clearly prohibit or regulate Internet gambling. None of these has yet been enacted into law. In June 2003, the House of Representatives did pass one piece of proposed legislation, the Unlawful Internet Gambling Funding Prohibition Act, sponsored by Representative Spencer Bachus, an Alabama Republican. This bill sought to choke off the financial transactions, including credit card payments and electronic fund transfers, used by Americans to pay for Internet gambling at offshore casinos. This proposed law, gave federal regulators 6 months to draft regulations to restrict such financial transactions. The bill provided that these restrictions must be "reasonably designed to identify and prevent" such transactions (H.R. 2143, §3(a) (2003)). Transactions with lawful state-sponsored gambling operations, including horse racing, dog racing, and lotteries, were exempted.

In July 2003 the Senate Banking Committee voted to report an amended form of a somewhat similar legislative proposal, the Unlawful Internet Gambling Prohibition Act of 2003 (S. 627), to the Senate for consideration. Senator Jon Kyl, an Arizona Republican, originally introduced this bill. Like its House of Representatives counterpart, S. 627 would prohibit gambling businesses from accepting credit cards or other bank instruments in connection with Internet gambling (S. 627 §3 (2003)), though it differed from the Bachus bill by including criminal sanctions and eliminating the exemption for state online lotteries. Congress never had to reconcile the two bills because the full Senate never acted on S. 627. Even though these particular legislative proposals have not been enacted, many observers believe that federal legislation specifically regulating Internet gambling legislation is now likely. However, there is little agreement on when this will happen or the form it will take.

### State Law

The Constitution leaves the regulation of gambling largely to the states through the exercise of their police power. In *United States v. Edge Broadcasting* (1993), the U.S. Supreme Court stated: "While lotteries have existed in this country since its founding, States have long viewed them as a hazard to their citizens and to the public interest, and have long engaged in legislative efforts to control this form of gambling" (p. 421). Another U.S. Supreme Court decision, *Greater New Orleans Broadcasting Association, Inc. v. United States* (1999), stated "[t]hat Congress has generally exempted state-run lotteries and casinos from

federal gambling legislation reflects a decision to defer to, and even promote, differing gambling policies in different States" (p. 187).

Each state can decide whether to allow any gambling within its borders and, if so, which kind of gambling operations to permit. Although there is considerable variation in the extent to which different states regulate gambling, most states license or permit at least some forms of gambling. Only two states, Utah and Hawaii, entirely prohibit gambling.

The gambling laws of most states do not specifically address online gambling. One state, Nevada, has passed legislation that would legalize Internet gambling, but implementation is currently stalled due to the hostility of certain U.S. federal authorities to the law, including the Justice Department (Kelly, Mignin, & Saxman, 2004). An American territory, the Virgin Islands, has also enacted legislation to legalize Internet gambling, but federal authorities consider it to violate federal law (Kelly et al.). Several states, including Illinois, South Dakota, Nevada, Louisiana, and Oregon, have passed laws specifically prohibiting Internet gambling. Many of these state laws have carve-outs for existing forms of legal gambling. For example, the Illinois law contains exceptions for, *inter alia*, state-licensed pari-mutuel wagering, certain games of bingo, Illinois-sponsored state lotteries, certain raffles, certain riverboat gambling, and certain charitable games (720 Ill. Comp. Stat. Ann. 5/28-1(b)(2005)). South Dakota's prohibition on Internet gambling is not applicable to the South Dakota lottery (S.D. Codified Laws §22-25A-15 (2004)). Louisiana's prohibition on Internet gambling is inapplicable to, *inter alia*, certain riverboat gambling, certain pari-mutuel wagering, certain charitable gaming, and Louisiana state-licensed lotteries (Louisiana Revised Statutes 14: 90.3 (F) (2005)).

Perhaps oddly, the states that have enacted specific Internet gambling prohibitions have not actively enforced them. This may be attributable to constitutional hurdles posed by the "dormant Commerce Clause," which bars a state statute from applying to commerce taking place entirely outside the state's borders, even if the commerce has effects within the state (Kelly, Mignin, & Saxman, 2004). However, other states that lack specific prohibitions for Internet gambling have launched enforcement efforts against online gambling.

The attorneys general of several states, including Florida, Indiana, Kansas, Louisiana, and Texas, have issued opinions that Internet gambling is generally illegal under state law, with few exceptions (Kelly, Mignin, & Saxman, 2004). The attorneys general of other states, including Arizona and Colorado, have sought to regulate online gambling by requesting media entities not to broadcast advertising for it (Kelly et al.). Some state attorneys general have prosecuted gambling operations that have permitted residents of their states to bet on the Internet.

New York Attorney General Eliot Spitzer has been particularly aggressive in enforcing New York's antigambling laws. All types of gambling except pari-mutuel wagering and the state lottery are illegal in New York (*United States v. Cohen*, 2001), and there have been successful prosecutions of online gambling operators in New York state and federal courts, including the Wire Act prosecution discussed above against Jay Cohen, the American operator

of an Internet casino based in Antigua that took bets from residents of New York. No doubt aware of how difficult it is to prosecute offshore enterprises, Spitzer has taken action successfully against financial institutions in an effort to block the payments used for online wagering.

Spitzer launched an investigation of Citibank's Internet gambling transaction policy and threatened the credit card giant with civil or criminal actions for advancing or profiting from illegal gambling activity. In response, Citibank agreed to introduce a policy, lasting for 5 years, to block transactions coded by Visa and Mastercard that indicate that a customer has engaged in online gambling (Attorney General of the State of New York Internet Bureau, 2002a). Apparently fearing investigations by other states' attorneys general, Citibank agreed to block transactions for customers in all 50 states. Another Spitzer investigation led to a 2002 agreement with online payment service PayPal, under which PayPal agreed not to process payments by PayPal's New York members for online gambling transactions prohibited by New York law (Attorney General of the State of New York Internet Bureau, 2002b). As noted above, PayPal was subsequently acquired by eBay, which has terminated the processing of online gambling payments.

Other state attorneys general have also been active in pursuing those they believe to be operating unlawful Internet gambling enterprises. For example, in 2001, then New Jersey Attorney General John Farmer brought several civil lawsuits against various operators of offshore Internet casinos and sports betting operations, as well as suppliers, such as Cryptologic, a gaming software developer. In 2002, two of these lawsuits were settled on terms that included the agreement of the online betting operations not to accept bets from people located in New Jersey and that of the suppliers to use their best efforts to prevent their customers or licensees from accepting online bets from people in New Jersey (Kelly et al., 2004; New Jersey Office of Attorney General, 2002).

Missouri Attorney General Jay Nixon, also an active opponent of online gambling brought the first successful prosecution of an Internet gambling operation in 1998, obtaining guilty pleas from a Pennsylvania business, Interactive Gaming & Communications (IGC), as well as from its president, Michael Simone, for violating Missouri law by accepting gambling wagers over the Internet from a Missouri resident. Both Simone and IGC pleaded guilty. As part of Simone's plea, he agreed to pay a \$2,500 fine. IGC agreed to pay a \$5,000 fine, as well as a \$20,000 payment for the costs of the prosecution (Missouri Attorney General's Office, 1998).

In 1995, then Minnesota Attorney General Hubert Humphrey III filed a lawsuit for injunctive relief under Minnesota consumer protection law against Granite Gate Resorts, Inc., a Nevada corporation that provided online advertising for a planned Internet sports wagering service, WagerNet, which was to be run out of Belize. Humphrey alleged that Granite Gate's advertising in Minnesota that Internet gambling was lawful amounted to deceptive trade practices, consumer fraud, and false advertising. Ruling on Granite Gate's challenge to the Minnesota court's jurisdiction, a Minnesota state trial court judge refused to dismiss the case. The Court of Appeals of Minnesota

subsequently affirmed the trial court's decision, finding that, Granite Gate had sufficient contacts with Minnesota that the lawsuit did not offend due process by reason of its Internet advertising directed to a nationwide market, including Minnesota residents, as well as its solicitation of Minnesota residents. An equally divided Supreme Court of Minnesota later affirmed the decision of the Court of Appeals (*State by Humphrey v. Granite Gate Resorts*, 1998). The case was settled in 1999 (Kelly et al., 2004).

Attorneys general from Missouri and Wisconsin have also taken action to stop Indian tribes from offering Internet gambling to residents of their states. As discussed above, when the Idaho Coeur d'Alene tribe set up a national Internet lottery, the Attorney General of Missouri filed suit in 1998 to stop this service being offered to Missouri residents. Later, then Wisconsin Attorney General Jim Doyle, also sued to block the lottery, claiming it violated Wisconsin law. The U.S. District Court for the District of Wisconsin ruled that Wisconsin could not regulate Internet gambling by Indian tribes because of their sovereign immunity (Kelly, 2000). However, the contractor hired by the technology company to operate its online lottery, Unistar Entertainment, was not protected by sovereign immunity. The Wisconsin lottery case was later settled. Other lawsuits brought by the state of Wisconsin against online gambling operations have also ended with settlements (Kelly, 2000).

## Targeting Gambling Payments

State attorneys general have not been the only ones to target Internet gambling payments, as discussed above. Some online gamblers have sought to prevent collection on their Internet gambling debts by claiming that credit card companies and card-issuing banks have facilitated illegal gambling. One example is a California state court case, *Providian National Bank v. Haines* (1998). The defendant, Cynthia Haines, used credit cards to rack up \$70,000 in Internet gambling charges, but did not pay her credit card bills. When one of the banks that had issued Haines with a credit card, Providian National Bank (Providian), sued her, she counterclaimed that Providian's efforts to recoup the debt violated California law because online gambling transactions were illegal, unfair, and unenforceable. She also added claims against Visa and MasterCard, alleging that they had acted unlawfully in allowing her to use her credit card for illegal Internet gambling. Both MasterCard and Visa eventually settled with Haines (Anastasio, 2001).

Under the settlements, Haines did not have to pay back her debts herself. The online gambling sites would cover the payments with the card-issuing banks, and Visa agreed to pay the banks, including paying Providian the almost \$5,000 that Haines had accrued using a Providian-sponsored card (Macavinta, 1999). The settlements also required MasterCard to implement a new policy that required gambling sites accepting its cards to post notices that Internet gambling was illegal in some jurisdictions (Anastasio, 2001). These gambling sites also had to ask gamblers where they were located. Visa agreed to send its cardholders nationwide notices stating that Internet gambling was illegal in some jurisdictions and that their

credit cards could only be used for legal transactions (Macavinta, 1999).

Some courts have been hostile to Internet gamblers who have attempted to evade their gambling debts. For example, in 1999, the U.S. District Court for the Western District of Wisconsin dismissed a class action lawsuit brought by an Internet gambler, Ari Jubelirer, against MasterCard and MBNA America Bank seeking a declaratory judgment that the defendants had violated federal racketeering law by paying credit card charges to illegal gambling operators (*Jubelirer v. Mastercard International, Inc.*, 1999). Jubelirer sought to prevent collection of his \$20 online gambling loss, as well as a \$4.95 processing fee. Ordering Jubelirer's complaint dismissed for disclosing no viable cause of action, District Judge John C. Shabaz wrote, "However broadly worded, the RICO statute is not to be applied to 'situations absurdly remote from the concerns of the statute's framers'" (p. 1053 [citation omitted]).

Despite the outcome in *Jubelirer*, after the *Haines* settlement many credit card companies remain concerned about lawsuits founded on claims that they are facilitating unlawful gambling activity. They are also worried about fraudulent charges. The full-service credit card companies, American Express Company and Discover Financial Services, have instituted policies prohibiting the use of their cards for Internet gambling and have also implemented procedures designed to ensure that Internet gambling operations do not become merchants for their credit cards (U.S. GAO, 2002). Both of the major credit card associations, Visa and MasterCard, now have policies and a coding system that allow members to deny authorization for Internet gambling transactions, although they do not require members to do so (U.S. GAO, 2002). The voluntary nature of these policies may be attributable to the fact that many of these association's members are located in areas of the world where Internet gambling is legal.

Member banks that are authorized to issue credit cards often attempt to block Internet gambling transactions, sometimes using third-party processors to assist them. These banks are waging a continuous battle with Internet gambling sites, some of which attempt to disguise gambling transactions or to mask where payments are going through the use of online payment providers like NETeller. Many of the largest American member banks that issue credit cards, as well as most small community bank issuers, have started to block online gambling transactions (U.S. GAO, 2002). These banks include Bank of America, Fleet, Direct Merchants Bank, MBNA, Chase Manhattan Bank, and Citibank. American acquiring banks that are members of credit card associations try not to acquire Internet gambling operations as merchants, although some non-U.S. acquiring banks do not attempt to restrict such operations from becoming merchants (U.S. GAO, 2002).

### Regulation of Internet Gambling in the Rest of the World

The discretionary nature of the credit card associations' Internet gambling policies is the result of wide variation in the regulation of Internet gambling around the world. In contrast to the prohibitionist stance of the U.S. federal government, around 75 jurisdictions have legalized vari-

ous types of online gambling (Schneider, 2004). Antigua and Barbuda, Belgium, Belize, Dominica, Gibraltar, Isle of Man, Liechtenstein, the Netherlands Antilles, and dozens of other jurisdictions currently permit some type of Internet gambling, although a detailed discussion of their laws is outside the scope of this relatively brief overview.

Worldwide regulatory approaches to online gaming include a prohibitionist model, a gambler protection model, and a government protection model (Cabot, 2004). As discussed above, the U.S. Justice Department takes a prohibitionist stance toward online gambling, although there is debate over the extent to which federal law actually prohibits online gambling. The theory underlying the gambler protection model of regulation is that gambling cannot be effectively prohibited, even if it is a potentially harmful activity (Cabot). Governments regulating on this basis issue gambling licenses subject to restrictions designed to protect against the social harms discussed above, such as security violations, problem gambling, underage gambling, and the use of gambling operations to launder money. An example is Antigua and Barbuda's Gaming Regulations of 2001 (Antigua and Barbuda, 2003). A third type of regulation, the government protection model, permits at least some online gambling because of its economic and social benefits, such as generating tax revenues, contributing to charities, and promoting employment (Cabot). An example of this type of regulation is the online lottery sponsored by the government of Liechtenstein at <http://www.interlotto.li/>.

Some less developed countries have legalized online gambling as a means to stimulate economic development by generating government revenue in license fees and taxes and increasing employment. In 1999 the small Caribbean nation of Antigua and Barbuda, with a population of less than 100,000, had 119 licensed online "remote access" gambling operators employing approximately 3,000 citizens and generating approximately 10% of its gross domestic product (Antigua and Barbuda, 2003).

However, between 1999 and 2003 there was a considerable reduction in the number of Antiguan-based online gambling operations, decreasing by more than three-quarters to 28, and also a very significant drop in number of their employees, from around 3,000 to fewer than 500. The Government of Antigua and Barbuda has charged that a "material factor" in this decrease is the "increasingly aggressive" action that the U.S. has taken against offshore gambling operations that it views as unlawful (Antigua and Barbuda, 2003, pp. 1-2).

This decline in Antiguan online gaming operations has generated an international trade conflict. In 2003, the Government of Antigua and Barbuda submitted a dispute to the World Trade Association (WTO), contending that existing and proposed American federal and state laws prohibiting cross-border Internet gambling, as well as executive and judicial acts taken against offshore gambling operations, put the United States in violation of its treaty obligations under the WTO's General Agreement on Trade in Services (GATS), including its market access and national treatment commitments, because the United States measures treated foreign suppliers of cross-border gambling services less favorably than domestic providers

of gambling services. Antigua's position was that the fundamental issue is international development, specifically the development of global e-commerce, which the United States pledged to foster at a 2001 WTO ministerial conference in Doha, Qatar (Directorate of Offshore Gambling, 2003; Doha Declaration, 2001; Sanders, 2003).

Antiguan officials argued that the online casino industry helps provide much-needed employment to Antigua's young people, helping deter them from turning to unlawful means of livelihood, such as the drug trade. They also argued that concerns about crime and money laundering are unfounded because the online casino industry in Antigua and Barbuda is tightly regulated and supervised by the government (Antigua and Barbuda, 2003). Although, as noted above, the extent to which U.S. federal law, as well as state law, bars cross-border Internet gambling is a complex and uncertain question, Antigua argued that the United States conceded that it has measures that totally prohibit cross-border Internet gambling services from Antigua. In support of this argument, Antigua relied, *inter alia*, on various U.S. government statements that it is always illegal for foreign operators to provide cross-border Internet gambling services anywhere in the United States.

In response, the United States criticized Antigua's characterization of American federal and state law as cumulatively amounting to a complete prohibition of cross-border Internet gambling, contending that Antigua had not satisfied the burden it bore as complainant to establish a *prima facie* case that some specific regulatory measure is not consistent with U.S. obligations under GATS. Additionally, the United States denied that cross-border gambling services are within its commitments under GATS and argued that even if they were, Antigua had not proved that any U.S. measure is inconsistent with its GATS obligations. In support of the latter argument, the United States argued that remote online gambling poses serious financial and social dangers, such as crime, money laundering, and problem or addictive gambling (United States, 2003).

In July 2003, the Dispute Settlement Body of the WTO agreed to establish a dispute resolution panel (WTO, 2003). In the spring of 2004, the WTO panel assigned to this case issued a confidential report on the dispute (Georgi, Vlaeminck, & Alberda, 2004). Although this report was not immediately made publicly available, it was widely reported to be in favor of Antigua's position, and the United States immediately stated its intention to appeal to the WTO's Appellate Body (Georgi et al., 2004).

In late June 2004, the WTO panel agreed to a suspension of the dispute until August 23, 2004, giving the parties time to attempt to resolve the dispute through negotiations (WTO, 2004a). The panel subsequently agreed to two additional extensions, the first until early October 2004 and the second until mid-November 2004 (WTO, 2004b, WTO, 2004c). Antigua requested the resumption of the proceedings in November 2004, and the United States did not object.

The WTO panel made its report public on November 2004 (WTO, 2004d). The panel found that the United States had made specific commitments under GATS with regard to gambling and betting services and, rejecting the argument that Antigua had failed to make out a *prima*

*facie* case that specific U.S. measures violated these obligations, also found that certain U.S. federal and state laws, including the federal Wire Act, Travel Act, and Illegal Gambling Business Act, as well as the Louisiana and South Dakota prohibitions on Internet gambling, amounted to GATS violations. The panel also found that the United States had not been able to establish that the laws were justified under an exception in GATS permitting WTO members to adopt measures necessary to protect public morals or maintain public order, because the United States had failed to consult with Antigua before imposing its prohibitions on the cross-border supply of gambling and betting services. The panel additionally found that Antigua had failed to show that these U.S. measures were not administered in a reasonable, objective and impartial manner in violation of other provisions in GATS.

The United States appealed to the Appellate Body in January 2005 (WTO, 2005a). Antigua also appealed on some issues. In April 2005, the Appellate Body circulated its report (WTO, 2005b; WTO, 2005c).

Both sides' appellate arguments had mixed success in the Appellate Body's 145-page report. The Appellate Body rejected the United States' argument that Antigua had failed to sufficiently identify particular federal measures that it alleged to be in violation of GATS, finding that Antigua had made out a *prima facie* case of inconsistency for the Travel Act, the Wire Act, and the Illegal Gambling Business Act. But the Appellate Body found that Antigua had not done so for the state laws reviewed by the panel.

The Appellate Body also rejected the contention of the United States that it had not excluded gambling and betting services from its commitments under GATS. Nevertheless, the Appellate Body agreed with the United States that it could restrict gambling if it was necessary to protect public morals or maintain public order. The Appellate Body found that the United States had succeeded in showing that there was a connection between Internet gambling and danger to the American public, but it rejected the claim that remote gambling was linked to organized crime. It disagreed with the panel's finding that the United States had failed to show that the three statutes were necessary based on the lack of consultation with Antigua. As a result, the Appellate Body concluded that it was legitimate for the United States federal government to legislate the prohibitions in the Travel Act, the Wire Act, and the Illegal Gambling Business Act to protect American residents, provided that such laws did not discriminate against foreign businesses. But the Appellate Body also found that the United States had failed to establish that the prohibitions in the three statutes were applied equally to both domestic and foreign suppliers of gambling services. Another federal statute, the Interstate Horseracing Act, appeared, on its face, to exempt certain domestic suppliers from the prohibitions under the three federal statutes on the provision of remote pari-mutuel betting on horseracing. The Appellate Body did not find it necessary to rule on whether the IHA in fact had this discriminatory effect.

The Appellate Body's report recommended that the Dispute Settlement Body request the United States to bring its laws into conformity with its obligations under GATS. On April 25, 2005, the Dispute Settlement Body adopted the Appellate Body's report (WTO, 2005d). In May 2005,

the United States stated that it would require a reasonable period of time to comply with the Dispute Settlement Body's recommendations and rulings, but could not agree with Antigua on what a reasonable period would be (WTO, 2005e) Antigua requested that this dispute be resolved through binding arbitration under WTO dispute settlement rules by July 19, 2005.

The rulings and recommendations of the WTO Dispute Settlement Body have no immediate effect on U.S. law, which can be changed only by Congress. The current administration is unlikely to support legislation to permit foreign gambling operators to provide services to U.S. residents. But the horseracing lobby is likely to oppose legislation to ban all online gambling on horseracing. Rather than amending its law, the United States could opt to pay compensation or be subject to trade sanctions by Antigua and Barbuda (Georgi, Valemminck, & Alberda, 2004). Such sanctions might, ironically, inflict less harm on the United States than the small Caribbean nation.

However until this international trade law dispute is ultimately resolved, its existence demonstrates that Internet gambling has become a significant trade and development issue. It also highlights the global aspect of the controversy over online gambling. Because the Internet lacks geographical borders, the regulatory systems adopted by one jurisdiction to control online activity are likely to have significant effects elsewhere in the world. This makes the effective regulation of Internet gambling even more of a challenge than for offline forms of gambling.

## CONCLUSION: THE FUTURE OF INTERNET GAMBLING

The future of the Internet gambling industry and how it will be regulated are uncertain. Some recent events seem to be harbingers of a future decline for the industry, such as the decision by some major financial institutions not to get involved with online gambling, as well as the recent crackdown by U.S. federal authorities on some media companies for placing advertisements for Internet gambling operations. Other recent technological developments, including alternate payment systems and wireless gambling systems, seem to point in the opposite direction.

The recent actions taken by American credit card-issuing banks to block Internet gambling transactions did put serious financial pressure on some online gambling operations. During 2001 and 2002, many online gambling operations experienced a decline in revenues by up to 70 or 80%, and some smaller operations did not survive this downturn (Cabot & Balestra, 2004). However, the industry as a whole is continuing to experience growth. Many commentators believe that the future of the online gambling industry will depend on the success of alternate digital payment systems, such as e-cash or smart cards. If such new types of payment systems become widespread, a perverse long-term effect of Internet gambling regulation by U.S. federal and state authorities may be an increase in the fraud and money laundering that such regulation is designed to prevent, because the greater anonymity of e-cash and similar alternate payment systems makes it more difficult to trace payments.

New wireless hand-held gambling technology is being developed, which seems likely to foster the growth of the industry by allowing players to make wagers anywhere they happen to be, whether in the street, at the bank, at the post office, in a café, in a store, or elsewhere. Wireless wagering devices are already used quite widely in Asia, where over 100,000 Hong Kong bettors own them, but they have been slower to reach the American market (Finley, 2004). However, in 2004, the online horseracing wagering company Youbet introduced a wireless subscription wagering service for American consumers in many states using certain pocket PC phones. This service was developed by Digital Orchard, which maintains a Youbet Anywhere website at <http://products.digitalorchid.com/youbet/>. There are plans to add live video streaming to enable customers to watch and bet on races as they are being run, no matter where those customers may be (Finley, 2004).

Across the globe, the law is having great difficulty in keeping pace with technological development. As discussed above, many gambling laws were drafted so long ago that they do not make any specific provision for online gambling. Even as new laws are drafted that deal with online gambling specifically, digital gambling technologies are evolving so rapidly that these new laws may be obsolete in many respects by the time they are enacted. This situation poses a serious challenge to the rule of law. The law must find a way to function effectively in this climate of technological change if it is to retain its central importance in society. If the law permits technology to trump its regulatory effect, it will lose its power to affect human behavior and ultimately to shape a just society. How the law should deal with this problem is one of the central problems of our Internet age.

A second central problem that is implicated by Internet gambling is whether one jurisdiction's regulatory regime can legitimately affect online activity by people who are physically outside that jurisdiction's borders. The WTO dispute between Antigua and the United States exemplifies this difficult problem.

Regulators confronting the security and privacy problems of Internet gambling must bear both of these central problems in mind when seeking to craft a regulatory framework for Internet gambling. This has already proved to be a very difficult challenge, and there is little likelihood that the immediate future will see an end to the many conflicts over gambling online.

## ACKNOWLEDGMENTS

The author would like to express her gratitude to Stan McCoy, Assistant General Counsel, Office of the U.S. Trade Representative, and Kay C. Georgi, a partner in the Washington D.C. office of Coudert Brothers LLP, for providing expert advice on the international trade dispute between Antigua and the United States.

## GLOSSARY

**Black-holing** The hijacking of a gambling Web site.

**Casino** A place where games of chance are played.

**Cyberlibertarian** An ideology of regulation for cyberspace that frowns on any intervention by national

governments and encourages the free flow of information over the Internet.

**Distributed denial of service (DDOS) attack** The flooding of computer servers with packets of data by malicious Web users, who are typically exploiting the vulnerability of insufficiently secured computers. The goal of a DDOS attack is to shut down targeted systems and to deny legitimate users the ability to access and use these systems.

**Extortion** Blackmail, or an offense that includes the illegal taking of money by anyone who employs threats or other illegal use of fear or coercion; commonly punishable as a felony.

**Fraud** A knowing misrepresentation made with the intent of causing another to detrimentally rely on it; can be punishable as a crime.

**Internet gambling** Gambling in which the Internet is used to place bets or wagers. Many courts require three elements—a prize, consideration, and chance—for an activity to be considered gambling.

**Jurisdiction** The legal authority of a court to hear and decide a case; the geographical area over which a court has authority to decide cases.

**Money laundering** The process whereby criminals conceal illicitly acquired funds by converting them into seemingly legitimate income.

**Pari-mutuel gambling** A form of gambling in which the gambler bets against other gamblers, not the house (as in casino gambling); frequently offered at certain sporting events, including horse and dog racing; often state regulated and legally available in many places where most or all other forms of gambling are illegal.

**Pathological gambling** The inability over a period of time to control or resist the compulsion to gamble, despite what may be serious negative consequences of this behavior.

**Random number generator** A software program that determines the outcome of online casino games by using algorithms to generate sequences of numbers that are indistinguishable from random coin flips or dice throws. A random number generator that is not rigged or biased should produce numbers that are unpredictable and not correlated with each other. Random number generators pose a difficult problem for computer science because computers cannot generate truly random numbers but only numbers that appear to be random.

**Regulation** The act of controlling or directing through the use of rules or standards.

**Secure sockets layer protocol (SSL)** A security protocol developed by Netscape for transmitting private data over the Internet, providing data encryption, server authentication, message integrity, and optional client authentication for a TCP/IP connection. Major Web browsers, including Internet Explorer, support SSL.

**Sovereignty** The principle that a state exercises power over its territory, system of government, and population.

**Underage gambling** Gambling by children or teenagers. It is illegal in many jurisdictions; although the age limit varies, it is often 18 or 21.

**World Trade Organization (WTO)** An international organization that regulates trade and tariffs between nations. Most nations have ratified the WTO's trade agreements that set rules for international commerce.

## INTRODUCTION

In 1998, citing the United States’ obligations under World Intellectual Property Organization (WIPO) copyright treaties, Congress passed the Digital Millennium Copyright Act (DMCA). The DMCA is a wide-ranging addition to copyright-related law, encompassing such topics as take-down procedures in copyright infringement disputes and safe-harbor defenses for Internet service providers (ISPs). This chapter focuses on the aspects of the DMCA that have particular relevance to research by academics and professionals: the portions that define offenses such as “circumvention” or “trafficking.”

## BASICS AND CRITICAL PROVISIONS

The DMCA is structured as a set of prohibitions, followed by various qualifications and exemptions to those prohibitions. The initial provisions are very broad and far reaching. It is a matter of much controversy whether subsequent interpretations and legal holdings will sufficiently constrain the scope of what constitutes a violation. The law in this area is very unsettled, with new cases being argued regularly. Significant judicial opinions are expected for years to come, and in response to those rulings, various legislative modifications and amendments will be proposed. Although it is always good practice to check for the most recent work, the subject matter in this instance is evolving particularly rapidly.

### Circumvention

The first provision of this type is §1201(a)(1), defining circumvention violations. It reads:

- (a) Violations Regarding Circumvention of Technological Measures.—(1)(A) No person shall circumvent a technological measure that effectively controls access to a work protected under this title.

Circumvention is a new offense, one created by the DMCA. It is not copyright infringement, which is an infraction

against a different set of rights, most commonly the making of copies in violation of copyright law. Rather, the §1201(a)(1) circumvention offense itself is obtaining unauthorized access to copyrighted material (“work protected under this title”). This new offense can be confusing to those who have formed their idea of copyright law from earlier incarnations. One common reaction is to repeat the defenses to infringement, such as fair use. However, circumvention is not infringement so the defenses that apply to infringement do not apply to circumvention. Indeed, this difference in defenses is one of the most significant aspects of the DMCA.

It should be stressed that *access* is not necessarily *copying*. Obtaining unauthorized access may involve nothing more than viewing encrypted video on an operating system that does not have a licensed (authorized) decryption player. Inversely, copying is not necessarily access. Encrypted copyrighted material can be reproduced while still encrypted. However, often these two actions are necessarily intertwined.

### Technological Measure and “Effectively Controls Access”

The DMCA goes on to define the terms used in the circumvention offense as follows:

- (A) to “circumvent a technological measure” means to descramble a scrambled work, to decrypt an encrypted work, or otherwise to avoid, bypass, remove, deactivate, or impair a technological measure, without the authority of the copyright owner; and
- (B) a technological measure “effectively controls access to a work” if the measure, in the ordinary course of its operation, requires the application of information, or a process or a treatment, with the authority of the copyright owner, to gain access to the work.

It is important to take note of the phrase, “effectively controls access.” This is often misunderstood by scientists or

engineers as meaning that a measure successfully controls access, implying perhaps a necessity to use strong cryptography. No such requirement is present. In fact, the access control can be very weak in technological terms. Possibly the best analogy is the phrase used to characterize the criminal offense, “breaking and entering.” This offense does not require anything to be damaged physically, which is one ordinary sense of the word “breaking.” Even opening a closed door would qualify. That the open door is not a broken object, in the English sense of the word, is irrelevant. The argument that “effectively controls access” has a paradoxical meaning has been both attempted repeatedly in court and strongly ruled incorrect by judges.

The judicial failure of “effectively” as a limiting argument cannot be overemphasized. Technologists often reinvent and propose that interpretation. To give one important rejection, in *Universal City Studios Inc. v. Reimerdes* (2000), the trial court wrote at length regarding how the definition cannot be viewed as self-defeating:

Finally, the interpretation of the phrase “effectively controls access” offered by defendants at trial—viz., that the use of the word “effectively” means that the statute protects only successful or efficacious technological means of controlling access—would gut the statute if it were adopted. If a technological means of access control is circumvented, it is, in common parlance, ineffective. Yet defendants’ construction, if adopted, would limit the application of the statute to access control measures that thwart circumvention, but withhold protection for those measures that can be circumvented. In other words, defendants would have the Court construe the statute to offer protection where none is needed but to withhold protection precisely where protection is essential. The Court declines to do so. Accordingly, the Court holds that CSS effectively controls access to plaintiffs’ copyrighted works.

When the case was appealed, *Universal City Studios Inc. v. Corley* (2001), the appeals court accepted the above reasoning regarding what constitutes effectiveness. In *321 Studios v. Metro Goldwyn Mayer et al.* (2004), the trial court rejected a challenge to the concept of effective control stemming from widespread availability:

321, in a footnote, questions whether CSS is an effective control or protection of DVDs, since the CSS access keys are widely available on the internet. However, this is equivalent to a claim that, since it is easy to find skeleton keys on the black market, a deadbolt is not an effective lock to a door.

Further, in the case *RealNetworks, Inc. v. Streambox, Inc.* (2000), merely setting a bit flag (called there a “Copy Switch”) was held by the district court to qualify as effective protection when combined with an authentication scheme:

8. In conjunction with the Secret Handshake, the Copy Switch is a “technological measure” that effectively protects the right of a copyright owner to control the unauthorized copying of its work. See 17 U.S.C. §1201(b)(2)(B) (measure “effectively protects” right of copyright holder if it “prevents, restricts or otherwise limits the exercise of a right of a copyright owner”); . . . To access a RealMedia file distributed by a RealServer, a user must use a RealPlayer. The RealPlayer reads the Copy Switch in the file. If the Copy Switch in the file is turned off, the RealPlayer will not permit the user to record a copy as the file is streamed. Thus, the Copy Switch may restrict others from exercising a copyright holder’s exclusive right to copy its work.

A password has been also been ruled to meet the standard of an effective technological measure. However, the unauthorized use of a password has been held *not* to be circumvention within the meaning of the DMCA, in a district court case, *I.M.S. Information Management Systems, LTD. v. Berkshire Information Systems, Inc.* (2004):

Defendant is alleged to have accessed plaintiff’s [password] protected website without plaintiff’s authorization. Defendant did not surmount or puncture or evade any technological measure to do so; instead, it used a password intentionally issued by plaintiff to another entity. As an analogy to Universal Studios, the password defendant used to enter plaintiff’s webservice was the DVD player, not the DeCSS decryption code, or some alternate avenue of access not sponsored by the copyright owner (like a skeleton key, or neutralizing device). Plaintiff, however, did not authorize defendant to utilize the DVD player. Plaintiff authorized someone else to use the DVD player, and defendant borrowed it without plaintiff’s permission. Whatever the impropriety of defendant’s conduct, the DMCA and the anti-circumvention provision at issue do not target this sort of activity.

In sum, the standard is legal, not cryptographic. The key element is not the computational strength of a cipher or any type of certification to an industry standard or best practices procedure. Rather, only a minimal effort is needed. Just meeting a simple test concerning the procedure by which access to the work is obtained will trigger the application of the law.

## Trafficking

Building on the prohibition of circumvention itself, a second provision, §1201(a)(2), forbids various types of trafficking:

- (2) No person shall manufacture, import, offer to the public, provide, or otherwise traffic in any technology, product, service, device, component, or part thereof, that—

And then the law sets out a qualifying test, which is important to understand in terms of implications:

- (A) is primarily designed or produced for the purpose of circumventing a technological measure that effectively controls access to a work protected under this title;
- (B) has only limited commercially significant purpose or use other than to circumvent a technological measure that effectively controls access to a work protected under this title; or
- (C) is marketed by that person or another acting in concert with that person with that person's knowledge for use in circumventing a technological measure that effectively controls access to a work protected under this title.

As circumvention is different from infringement, trafficking is different from circumvention. One need not do any circumvention oneself in order to violate the trafficking provision, and no infringement need be done in either case. Trafficking provisions concern tools and are sometimes analogized to laws against burglary tools. This analogy has problems though, as many burglary tools are often legal in and of themselves, with related offenses requiring an intent to commit burglary.

Although trafficking is often discussed in terms of devices, the text of the law specifically forbids "any technology." This has been held to encompass the source code of computer programs (*Universal v. Reimerdes*, 2000, footnote 135). A very controversial question is whether it also extends to academic research papers (Liu, 2003).

The test to qualify as a circumvention tool addresses certain frequent objections to the concept of prohibited devices. For example, a general-purpose debugging program would not qualify because it is not "primarily designed" for circumvention, nor does it have "only limited commercially significant purpose or use" except for circumvention.

Closely related to §1201(a)(2) is another trafficking provision, §1201(b)(1). Although §1201(a)(2) is concerned with a technological measure that effectively protects "access," §1201(b)(1) addresses trafficking regarding "a right of a copyright owner." Except for this change, the language of §1201(b)(1) is otherwise parallel to that of §1201(a)(2).

## Fair Use Implications

As has been discussed above, the offenses defined by the DMCA are distinct from the concept of copyright infringement. These differences, particularly fair use rights, are mentioned in a provision of the DMCA, §1201(c), which begins:

- (c) Other Rights, Etc., Not Affected.
  - (1) Nothing in this section shall affect rights, remedies, limitations, or defenses to copyright infringement, including fair use, under this title.

This is an especially subtle statement, going to the heart of the debates over the meaning of fair use. The logical

problem is an interpretation that, as a legal matter, because the DMCA offenses are not copyright infringement, by definition defenses to copyright infringement such as fair use are not affected. This view holds that if a prohibition against circumvention of access controls makes impossible any unauthorized use at all, that does not affect the ability to argue fair use as a defense to copyright infringement. More simply, if a copy could be made, fair use could be argued as a defense to copyright infringement. However, the fact that the copy might not be able to be made in the first place, without violating access controls, is deemed irrelevant.

One way to think of this problem is as a conflict about whether fair use is a reflection of a substantive right, grounded in the First Amendment, or merely one particular defense to one specific part of copyright law having to do with infringement. The legal results so far have supported the latter viewpoint. In the case *Universal v. Corley* (2001), the court stated:

We know of no authority for the proposition that fair use, as protected by the Copyright Act, much less the Constitution, guarantees copying by the optimum method or in the identical format of the original. Although the Appellants insisted at oral argument that they should not be relegated to a "horse and buggy" technique in making fair use of DVD movies, [Footnote 36] the DMCA does not impose even an arguable limitation on the opportunity to make a variety of traditional fair uses of DVD movies, such as commenting on their content, quoting excerpts from their screenplays, and even recording portions of the video images and sounds on film or tape by pointing a camera, a camcorder, or a microphone at a monitor as it displays the DVD movie. The fact that the resulting copy will not be as perfect or as manipulable as a digital copy obtained by having direct access to the DVD movie in its digital form, provides no basis for a claim of unconstitutional limitation of fair use.

The court concluded: "Fair use has never been held to be a guarantee of access to copyrighted material in order to copy it by the fair user's preferred technique or in the format of the original."

The footnote 36 in the passage above is notable in itself:

36. In their supplemental papers, the Appellants contend, rather hyperbolically, that a prohibition on using copying machines to assist in making fair use of texts could not validly be upheld by the availability of "monks to scribe the relevant passages."

These interpretations are another instance where the legal reasoning strikes many technologists as paradoxical if not incomprehensible. One might ask, in what sense can a right be said to exist, if the means to exercise it are heavily constrained? The judicial resolution of this quandary, via strict theoretical partitioning of the concepts, invites

repeated challenges because of the practical connections. Yet, so far, all rulings on this issue have been consistently along the above lines. For example, in *321 Studios v. MGM* (2004),

This Court agrees with this analysis in Corley: [“optimum method” conclusions repeated]  
The fact that the resulting copy will not be as perfect or as manipulable as a digital copy obtained by having direct access to the DVD movie in its digital form, provides no basis for a claim of unconstitutional limitation of fair use.

These rulings all demonstrate how complex and counter-intuitive are the fair use issues in view of the DMCA's constraints on access and copying tools.

## MAJOR EXEMPTIONS

Despite not having a general defense for fair use, the DMCA does exempt various activities. These exemptions are notably restrictive and narrow, but some are worthy of discussion for academic or scientific applications.

### Reverse Engineering

The §1201(f) provision contains a limited right to engage in circumvention (§1201(a)(1)) for the purpose of reverse engineering, specifying the qualifications as follows:

(f) Reverse Engineering.—(1) Notwithstanding the provisions of subsection (a)(1)(A), a person who has lawfully obtained the right to use a copy of a computer program may circumvent a technological measure that effectively controls access to a particular portion of that program for the sole purpose of identifying and analyzing those elements of the program that are necessary to achieve interoperability of an independently created computer program with other programs, and that have not previously been readily available to the person engaging in the circumvention, to the extent any such acts of identification and analysis do not constitute infringement under this title.

The most important portions of this provision are the “sole purpose” aspect and the clause “to the extent . . . not constitute infringement.” These narrow the range of the defense considerably in practice. It is critical to keep in mind that these determinations may be affected by the court's view of the overall value of the activity and of the character of the defendants. In *Universal v. Reimerdes* (2000), the court ruled very unfavorably on the “sole purpose” aspect of this provision, with notable comments:

Finally, it is important to recognize that even the creators of DeCSS cannot credibly maintain that the “sole” purpose of DeCSS was to create a Linux

DVD player. DeCSS concededly was developed on and runs under Windows—a far more widely used operating system. The developers of DeCSS therefore knew that DeCSS could be used to decrypt and play DVD movies on Windows as well as Linux machines. They knew also that the decrypted files could be copied like any other unprotected computer file. Moreover, the Court does not credit Mr. Johansen's testimony that he created DeCSS solely for the purpose of building a Linux player. Mr. Johansen is a very talented young man and a member of a well known hacker group who viewed “cracking” CSS as an end in itself and a means of demonstrating his talent and who fully expected that the use of DeCSS would not be confined to Linux machines. Hence, the Court finds that Mr. Johansen and the others who actually did develop DeCSS did not do so solely for the purpose of making a Linux DVD player if, indeed, developing a Linux-based DVD player was among their purposes.

Accordingly, the reverse engineering exception to the DMCA has no application here.

Yet, the ability to conduct reverse engineering is deeply affected by the development of tools to aid in the process. The exemption addresses that trafficking prohibitions by providing a limited ability to make and communicate such tools. As §1201(f) goes on to state,

- (2) Notwithstanding the provisions of subsections (a)(2) and (b), a person may develop and employ technological means to circumvent a technological measure, or to circumvent protection afforded by a technological measure, in order to enable the identification and analysis under paragraph (1), or for the purpose of enabling interoperability of an independently created computer program with other programs, if such means are necessary to achieve such interoperability, to the extent that doing so does not constitute infringement under this title.
- (3) The information acquired through the acts permitted under paragraph (1), and the means permitted under paragraph (2), may be made available to others if the person referred to in paragraph (1) or (2), as the case may be, provides such information or means solely for the purpose of enabling interoperability of an independently created computer program with other programs, and to the extent that doing so does not constitute infringement under this title or violate applicable law other than this section.

Note though, that the permissions are again constrained by the qualifiers as to “solely for the purpose” and “not constitute infringement.” It is especially important to observe that although §1201(f)(1) permits a person to circumvent, and §1201(f)(2) allows them to develop tools, §1201(f)(3) restricts distribution of the fruits of these efforts to apply only to the person who has done them in the first place. Therefore, against what would be a prevailing

conception, third-party republication is not within this exemption. Again, in *Universal v. Reimerdes* (2000), Judge Kaplan said: “First, Section 1201(f)(3) permits information acquired through reverse engineering to be made available to others only by the person who acquired the information. But these defendants did not do any reverse engineering. They simply took DeCSS off someone else’s web site and posted it on their own.”

Judge Kaplan went on to say, “Defendants would be in no stronger position even if they had authored DeCSS. The right to make the information available extends only to dissemination “solely for the purpose” of achieving interoperability as defined in the statute. It does not apply to public dissemination of means of circumvention, as the legislative history confirms. [footnote 151] These defendants, however, did not post DeCSS ‘solely’ to achieve interoperability with Linux or anything else.”

In a different case, (*Lexmark International Inc. v. Static Control Components, Inc.*, 2003) the district court said quite bluntly: “Sections 1201(f)(2) and (3) of the DMCA are not broad exceptions that can be employed to excuse any behavior that makes some device “interoperable” with some other device.” However, a successful appeal resulted in a more robust view, where the appeals court opinion stated “the statute is silent about the degree to which the “technological means” must be necessary, if indeed they must be necessary at all, for interoperability.”

## Encryption Research

The exemption of most interest to the academic reader is certainly the §1201(g) provision, which provides a DMCA framework for “permissible acts of encryption research.” It lays out a complex series of definitions and tests that must be met to qualify for the exemptions. The term “encryption research” is defined as

- o (1) Definitions.—For purposes of this subsection—
  - (A) the term “encryption research” means activities necessary to identify and analyze flaws and vulnerabilities of encryption technologies applied to copyrighted works, if these activities are conducted to advance the state of knowledge in the field of encryption technology or to assist in the development of encryption products; and
  - (B) the term “encryption technology” means the scrambling and descrambling of information using mathematical formulas or algorithms.

Note the clause requiring activities to be “conducted to advance the state of knowledge.” It provides fertile ground for argument over what qualifies as proper research. Although much security research is conducted within an unquestioned academic context, not all such activity is necessarily sympathetic to the courts or public opinion.

The text of the exemption specifies further conditions— that one must have “lawfully obtained the encrypted copy,” have “made a good faith effort to obtain authorization before the circumvention,” and not otherwise have violated any laws. Then it enumerates complicated

qualifying conditions. These conditions warrant detailed study, as they are most relevant to avoiding being the target of litigation:

- o (3) Factors in determining exemption.—In determining whether a person qualifies for the exemption under paragraph (2), the factors to be considered shall include—
  - + (A) whether the information derived from the encryption research was disseminated, and if so, whether it was disseminated in a manner reasonably calculated to advance the state of knowledge or development of encryption technology, versus whether it was disseminated in a manner that facilitates infringement under this title or a violation of applicable law other than this section, including a violation of privacy or breach of security;
  - + (B) whether the person is engaged in a legitimate course of study, is employed, or is appropriately trained or experienced, in the field of encryption technology; and
  - (C) whether the person provides the copyright owner of the work to which the technological measure is applied with notice of the findings and documentation of the research, and the time when such notice is provided.

This might be seen as an attempt to codify a distinction between “black hats” and “white hats” (crackers versus scientists) in terms of research. Yet, given the arguments over practices and methods of disclosure of security vulnerabilities, there is certain to be ample room for debate over who will be protected under the above criteria.

## CRIMINAL PROVISIONS

Although copyright law is commonly thought of in terms of monetary damages and civil lawsuits, there has always been a criminal law component. The DMCA criminal offenses are at §1204:

Sec. 1204.—Criminal offenses and penalties

(a) In General.—

Any person who violates section 1201 or 1202 willfully and for purposes of commercial advantage or private financial gain—

(1) shall be fined not more than \$500,000 or imprisoned for not more than 5 years, or both, for the first offense; and

(2) shall be fined not more than \$1,000,000 or imprisoned for not more than 10 years, or both, for any subsequent offense.

Note all violations of section 1201 are included, encompassing §1201(a)(1) circumvention offenses and §1201(a)(2) and §1201(b)(1) trafficking offenses.

The critical element in the above provisions is “for purposes of commercial advantage or private financial gain.” Satisfying this provision turns out to be much easier than one might think. In particular, it does not require any money to be exchanged, contrary to intuitive expectations. In a comparable copyright law provision (No Electronic

Theft Act, 1997), the US Department of Justice sample language for jury instructions regarding this element is that “the Government need not prove that the defendant actually received a profit from the infringement. The Government need only show that the defendant acted with the hope or expectation of some commercial advantage or financial gain.”

The Department Of Justice Criminal Resource Manual (1997a, b) states clearly, “Emphasis should be placed on the word ‘purpose,’ because it is not necessary to prove that any profit was realized.” Later in the document, the manual stresses with emphasis that the key word in the requirement is “*purpose*” (emphasis in original): “Evidence of discrete monetary transactions (i.e., the selling of infringing goods for a particular price) provides the clearest evidence of financial gain, but such direct evidence should not be a prerequisite to prosecution. Such a stringent requirement would ignore the plain wording of the statute, which requires only the showing of commercial or financial *purpose*.”

The overall requirement seems to be construed broadly (bartering, being an employee, etc.), encompassing “expressed or implied intent of the parties.” This aspect of being an employee was seen very specifically in the *United States v. Elcom Ltd.* (2002) “Sklyarov” case, discussed below.

## EXEMPTION PROCESS— ANTICIRCUMVENTION RULEMAKING

Section 1201(a)(1)(C) of the DMCA provides a process by which users of a “class of works” can apply for an exemption from the §1201(a)(1) circumvention prohibitions. These exemptions specifically do not apply to any trafficking prohibitions. This process takes place every 3 years, starting from 2000. All exemptions last for only one 3-year cycle and must be reargued from the start at every rulemaking.

Note these exemptions do not affect any other laws that might be used against a researcher. In particular, copyright infringement, trade secret law, and shrinkwrap license prohibitions against reverse engineering are all potential legal problems (Copyright Office, 2003).

Although this process does have an effect, it also has notable limitations. As outlined in the “Statement of the Librarian of Congress Relating to Section 1201 Rulemaking” (Billington, 2003; see Library of Congress, 2003)

It is important to understand the purposes of this rulemaking, as stated in the law, and the role I have in it. The rulemaking is not a broad evaluation of the successes or failures of the DMCA. The purpose of the proceeding is to determine whether current technologies that control access to copyrighted works are diminishing the ability of individuals to use works in lawful, non-infringing ways. The DMCA does not forbid the act of circumventing copy controls, and therefore this rulemaking proceeding is not about technologies that control copying. Some of the

people who participated in the rulemaking did not understand that and made proposals based on their dissatisfaction with copy controls. Other participants sought exemptions that would permit them to circumvent access controls on all works when they are engaging in particular non-infringing uses of those works. The law does not give me that power. . . .

Despite these restrictions, the anticircumvention rulemaking is one of the few avenues where researchers can attempt to ameliorate the effects of the DMCA in even the smallest way. Participation does not require a law degree, being part of a lobbyist organization, or access to Congressional legislative staff. As stated in the “Recommendation of the Register of Copyrights” (Peters, 2003) regarding one particular exemption (censorware): “The Register’s recommendation in favor of this exemption is based primarily on the evidence introduced in the comments and testimony by one person, Seth Finkelstein, a nonlawyer participating on his own behalf.”

It is possible for a researcher to be heard (Finkelstein, 2002, 2003).

## Classes of Works Exempted (2003)

At the time of the writing of this chapter, the 2003 rulemaking process had recently been completed. The following exemptions were granted:

- (1) Compilations consisting of lists of Internet locations blocked by commercially marketed filtering software applications that are intended to prevent access to domains, websites or portions of websites, but not including lists of [spam or viruses].
- (2) Computer programs protected by dongles that prevent access due to malfunction or damage and which are obsolete.
- (3) Computer programs and video games distributed in formats that have become obsolete and which require the original media or hardware as a condition of access.
- (4) Literary works distributed in ebook format when all existing ebook editions of the work . . . contain access controls that prevent the enabling of the ebook’s read-aloud function and that prevent the enabling of screen readers to render the text into a specialized format.

However, these exemptions did not come close to covering all the various areas of research that have been affected by the DMCA.

## MAJOR CASES

Much of the meaning of the DMCA is being shaped by judicial interpretation. This is an ongoing process, as various questions are considered and ruled on. The law may change, and the reader must keep that in mind. The material below is accurate as of mid-2004.

**Universal City Studios, Inc. v. Reimerdes (DeCSS)**

The most significant case of litigation under the DMCA is arguably *Universal City Studios, Inc. v. Reimerdes*, aka the DeCSS case. Many movie and TV shows available on DVD format disks are encrypted with a process known as content scramble system (CSS). This encryption restricts the material to access only on authorized DVD players, which are licensed to decrypt the content. Notably, commercial-grade bit-for-bit copying of the DVD disks can proceed whether or not the content is encrypted with CSS. However, it is of little use to exchange the encrypted data over file-sharing networks. Moreover, tying viewing the DVD video to licensed players enforces a geographical market segmentation scheme known as “region coding.” Each DVD can have a region assigned to it, which makes it viewable only on players that are coded to the corresponding region.

DeCSS is a program that decrypts the CSS encryption. The unencrypted files can then be viewed on unlicensed players and exchanged over networks, and region coding becomes irrelevant. Making the DeCSS program available quickly led to lawsuits. One lawsuit branch involved trade secret law (*DVD-CCA v. Bunner* and *DVD-CCA v. Pavlovich*, California DeCSS cases), and is not discussed here. The *Universal v. Reimerdes* case (New York DeCSS case, later appealed as *Universal v. Corley*, has become the leading law on the DMCA. These are two different phases of the same case. At the trial level, in district court, Reimerdes was the main defendant. Later, after an adverse decision, Corley appealed to the U.S. Court of Appeals for the Second Circuit, which decided that case.

Contrary to many newspaper reports, it is not accurate that a 15-year-old Norwegian teenager (Jon Johansen) broke the encryption code. Perhaps the best account of the origin of DeCSS can be found in the testimony of Jon Johansen during the trial (Johansen, 2000, p. 619).

Q. Who wrote DeCSS?

A. I and two other people wrote DeCSS.

...

Q. Mr. Johansen, what did you do next towards making DeCSS?

A. We agreed that the person who I met would reverse engineer a DVD player in order to obtain the CSS algorithm and keys.

....

Q. Thank you very much. Now, you testified on direct that a German person, I think, had reverse-engineered the Xing DVD player, is that correct?

A. Yes, that is correct.

Q. And that person goes by the nick Ham?

A. Yes, that's correct.

Q. And it's Ham who wrote the source code that performed the authentication function in DeCSS, is that correct?

A. No, that is not correct. He did not write the authentication code. He wrote the decryption code.

...

Q. And it was Ham's reverse engineering of the Xing DVD player that revealed the CSS encryption algorithm, am I right?

A. Yes, that's correct.

Q. Reverse engineering by Ham took place in or about September 1999?

A. Yes, I believe it was late in September of 1999.

Q. And you testified that it was this revelation of the CSS encryption algorithm and not any weakness in the CSS cipher that allowed MORE to create DeCSS, is that correct?

A. Yes, that's correct.

Q. You obtained the decryption portions of the DeCSS source code from Ham, correct?

A. Yes, that's correct.

Q. You then compiled the source code and created the executable?

A. Well, in the form I received it, it was not compatible.

The actual writer of the DeCSS decryption code remains anonymous to this day. Given that Jon Johansen was criminally prosecuted in Norway for his role in the creation of the DeCSS code, the consequences for the programmer behind the decryption would certainly be severe.

Johansen was tried on charges related to a Norwegian law concerning data security and was acquitted. However, Norwegian law allowed the prosecutor to appeal the case. Johansen was then retried and reacquitted.

However, the litigation in the U.S. case was not concerned with creation of a program, but rather with its distribution. At issue was the right to publish the decrypting programs, not liability for their production. As software involves speech issues, several constitutional principles were at stake. However, the eventual court ruling went completely against publication rights (*Universal v. Reimerdes*, 2000).

The District Court, Kaplan, J., held that [sic]: (1) posting decryption software violated DMCA provision prohibiting trafficking in technology that circumvented measures controlling access to copyrighted works; (2) posting hyperlinks to other web-sites offering decryption software violated DMCA; (3) DMCA anti-trafficking provision was content-neutral as applied to computer program; (4) DMCA did not violate First Amendment as applied to defendants and decryption software; (5) defendants failed to establish anti-trafficking provision was overly broad on grounds that it prevented noninfringing fair use of movies; (6) application of anti-trafficking provision to enjoin defendants from hyper-linking to other web-sites offering decryption software did not violate First Amendment; and (7) plaintiffs were entitled to injunction enjoining defendants from posting decryption software or hyperlinking to other web-sites that made software available.

As the leading case authority on the DMCA, this decision has been cited repeatedly for the manner in which it interprets the various controversies.

### United States v. Elcom (Dmitry Sklyarov, eBooks)

Many people believe that DMCA criminal sanctions will be applied only to large-scale commercial copyright infringers. The case of Dmitry Sklyarov, the first programmer to be arrested and face criminal charges under the DMCA, shows that the reach of the law is much further than assumed. Dmitry Sklyarov was a Ph.D. student at the Bauman Moscow State Technical University. Working for the Russian company ElcomSoft, he developed software (Advanced eBook Processor; AEBPR) to decrypt the encrypted eBook format developed and marketed by the document technology platform company, Adobe Systems.

While attending a conference in the United States, Sklyarov was arrested for violating DMCA provision §1201(b)(1), under a theory of trafficking in copy-control circumvention tools. Contrary to the popular conception, he was not arrested for anything he said at the conference itself. Rather, his appearance there presented an opportunity for the United States to exercise jurisdiction. The facts that the AEBPR program itself was sold commercially and he had been listed at one time as the copyright owner were taken to be sufficient for criminal liability (*U.S. v. Sklyarov Criminal Complaint*, 2001).

Notably, it was not necessary for any actual infringement to have taken place. A ban on merely selling a circumvention tool itself (which fell under the DMCA's standards) was ruled to be a reasonable prohibition (*U.S. v. Elcom*, 2002, aka *Elcomsoft*):

Pirates and other infringers require tools in order to bypass the technological measures that protect against unlawful copying. Thus, targeting the tool sellers is a reasoned, and reasonably tailored, approach to "remedying the evil" targeted by Congress. In addition, because tools that circumvent copyright protection measures for the purpose of allowing fair use can also be used to enable infringement, it is reasonably necessary to ban the sale of all circumvention tools in order to achieve the objectives of preventing widespread copyright infringement and electronic piracy in digital media.

The arrest of a programmer at a conference caused widespread public concern, especially within the security and cryptography communities. Protest rallies were held, and the case attracted interest that publicized problematic aspects of the DMCA. Eventually the charges were dropped against Sklyarov in return for his testimony against his employer. Finally, ElcomSoft was acquitted in a jury trial (Bowman, 2002). There has been extensive argument regarding what implications should be drawn from both the initial prosecution and the subsequent acquittal (Liu, 2003).

### 321 Studios v. MGM

321 Studios makes and sells programs called DVD Copy Plus and DVD-X COPY. These programs are marketed for the purpose of making a personal, archival backup copy of content on a DVD, even of CSS-encrypted content, such as a commercial movie. 321 Studios sought a declaratory judgment that, in distributing these programs, it was not in violation of the DMCA. It was opposed by members of the Motion Picture Association of America (MPAA).

The eventual ruling thoroughly rejected the claims of 321, on summary judgment (i.e., ruling that simply as a matter of a law, 321 was in violation of the DMCA). The court found prior cases—*Universal v. Reimerdes* (2000), *Universal v. Corley* (2001), *United States v. Elcom* (2002)—"dispositive on many of the same issues" of fair use and application of the DMCA: "This Court finds, as did both the Corley and Elcom courts, that legal downstream use of the copyrighted material by customers is not a defense to the software manufacturer's violation of the provisions of §1201 (b)(1)."

Though the case was appealed, 321 Studios was driven out of business by legal costs from being the target of many lawsuits (Cowley, 2004).

### Felten et al. v. RIAA

Princeton University Computer Science professor Edward Felten is a researcher in the field of information security. His research group participated in a challenge by the Secure Digital Music Initiative (SDMI) to evaluate vulnerabilities in digital watermarking systems for music files. When the group (Felten, Scott Craver, Bede Liu, Min Wu, Dan Wallach, Ben Swartzlander, Drew Dean, and Adam Stubblefield) planned to present a paper detailing its research results showing weaknesses in the various technologies, Professor Felten was threatened with legal liability by the Recording Industry Association of America and the SDMI, on the grounds of violating a "click-through agreement" and the DMCA (Oppenheim, 2001):

In addition, because the public disclosure of your research would be outside the limited authorization of the Agreement, you could be subject to enforcement actions under federal law, including the DMCA. The Agreement specifically preserves any rights that proponents of the technology being attacked may have "under any applicable law including, without limitation, the U.S. Digital Millennium Copyright Act, for any acts not expressly authorized by this Agreement." The Agreement simply does not "expressly authorize" participants to disclose information and research developed through participating in the Public Challenge and thus such disclosure could be the subject of a DMCA action.

Although later statements from the RIAA and SDMI denied there was a legal threat, a "declaratory judgment" suit was brought against them to establish that such scientific research would not be chilled by the fear of litigation. However, the court was not convinced that there was an actual case or controversy qualifying for a legal

opinion. The paper in question had been published after the issue was publicized widely, and further judicial action was ruled premature.

This case is notable for the implication that the reach of the DMCA extends to “information and research,” at least to the extent of generating a formal letter regarding legal action from organizations that object to the dissemination of the material.

## EXAMPLE CONTROVERSY— MEDIAMAX CD3

Although not a legal case, this widely publicized conflict between a company and a graduate student is additionally instructive regarding what academic researchers may face and how the issues can be phrased.

SunnComm is a company that manufactures a copy-restriction system for CD music, MediaMax CD3. John Alex Halderman was a Princeton Ph.D. student studying computer security with, interestingly enough, Edward Felten as his advisor. Halderman published a report, “Analysis of the MediaMax CD3 Copy-Prevention System,” detailing vulnerabilities of SunnComm’s technology. SunnComm reacted with nationally publicized threats to sue on various grounds, including the DMCA (SunnComm, 2003a; Vance, 2003).

Although SunnComm was widely reported to be angered that its copy-control technology could be disabled by the use of the shift key (Borland, 2003), deeper examination indicates that the most contentious issue was publishing details of its MediaMax drivers (Halderman, 2003):

Next, follow these additional steps to disable MediaMax:

1. Select the SbcPHid driver from the Device Manager list and click “Properties” from the Action Menu.
2. Click the Driver tab and click the Stop button to disable the driver.
3. Set the Startup Type to “Disabled” using the dropdown list.

A little-noted part of the SunnComm press release explained the basis under which SunnComm considered it had grounds for a lawsuit under the DMCA (SunnComm, 2003a):

In addition, SunnComm believes that Mr. Halderman has violated the Digital Millennium Copyright Act (DMCA) by disclosing unpublished MediaMax management files placed on a users computer after user approval is granted. Once the file is found and deleted according to the instructions given in the Princeton grad students report, the MediaMax copy management system can be bypassed resulting in the copyrighted protected music being converted or misappropriated for potentially unauthorized and/or illegal use. SunnComm intends to refer this possible felony to authorities having jurisdiction over these matters because: 1. The author admits that he

disabled the driver in order to make an unprotected copy of the discs contents, and 2. SunnComm believes that the authors report was disseminated in a manner which facilitates infringement in violation of the DMCA or other applicable law.

One commentator in a discussion forum, who claimed to be a SunnComm employee, put the issue as follows (AfterDawn.com, 2003):

Just out of complete curiosity, do you guys \*really\* think that the shift key/autorun issue was what the problem was about?

...do you guys \*really\* believe..and i mean \*\*really\*\* believe that the shift key ‘escaped’ notice, going thru the various dev cycles, testing 3rd party testing etc etc??? \*especially\* if the autorun feature was going to be used???

Just a little FYI for all .. the issue was about disclosing file names, locations and circumvention directions, which, if i read the DMCA correctly could be construed as a possible violation..

...

were we \*ever\* gonna sue over the shift key? jeez .. are you guys serious? that makes us laugh every time we see it, in big bold headline stories, such as at the top of this one..

btw, he didn’t get sued, we decided not to go after him, and not because of the shift key, but because ultimately, the media’s ‘spin’ would eventually become bigger (and badder) than the actual initial problem....

Translated from the informal phrasing, the commentator argues that SunnComm considered charging Halderman with violating the §1201(a)(2) trafficking provisions, under the theory that the details in his paper constituted *technology* for circumvention (not that the shift key was a circumvention device). Likely a §1201(a)(1) circumvention access violation was intended as well.

Although these theories are expansive, it is notable how the language of the press release is directed toward countering the §1201(g) research exemption. The “disseminated in a manner which facilitates infringement” phrasing is a direct reference to the §1201(g)(3)(A) factor “in determining if a person qualifies for the exemption” for performing “permissible acts of encryption research.” Further, other parts of the press release seem aimed to delegitimize Halderman with regard to the §1201(g)(3)(B) “legitimate course of study” factor. It is possible to see an attack on the §1201(g)(3)(C) “notice” factor too. If this construction was intended, SunnComm had designed its press release to set the terms of public debate in a way that would nullify Halderman’s obvious defenses.

SunnComm (2003b) quickly retracted its legal threats in the wake of an enormous amount of bad publicity. However, all researchers cannot count on having such favorable publicity.

## CODE AS SPEECH

Consider the following text (Winstein & Horowitz, 2001)

```
s"$=\,2048;while(<>){G=29;R=142;if((@a=unqT="C",,.)
[20]&48){D=89;:=unqb24,qT,@b=map{ord qb8,unqb8,
qT,^$a[-D]}@INC;s/...$/1$/;Q=unqV,qb25,;H=73;O=$b[4]<<9
|256|b[3];Q=Q>>8^(P=(E=255)&(Q>>12^Q>>4^Q/8^Q))<<17,
O=O>>8^(E&(F=(S=O>>14&7^O)^S*8^S<<6))<<9,:=
(map{U=.%16orE^=R^=110&(S=(unqT,"\xb\ntd\xbz\x14d")
[_/16%8]);E^=(72,@z=(64,72,G^=12*(U-2?0:S&17)),
H^=.%64?12:0,@z[_%8])(16..271)[_]^(D>>=8)+P+(~F&E)
for@a[128..$#a]}print+qT,@a';s/[D-HO-U_]^\$/&/g;s/q/
pack+g;eval
```

Above is a series of symbols that form a program in the computer language Perl. In this sentence, the words are a series of symbols that convey meaning in the language English. Though more people are familiar with the latter than the former, can there be said to be an intrinsic, or practically sustainable, distinction? As noted in one legal brief (Tyre, 2001): “If ‘\$plain\_text = \$file\_key ^ \$xor\_block’ seems unapproachable, consider what those not trained in the language of legal citation would make of ‘111 F.Supp.2d 294, 326 (S.D.N.Y. 2000).’ Each is meaningless to those unfamiliar with the language; but each is more precise and compact for those who do understand than would be an English narrative equivalent.”

As a further example, consider the following different explanations of a simple cipher:

The ROT13 algorithm explained (“Caesar Cipher”):

- 1) The decryption algorithm for ROT13 is to take the range of letters from a-z, and for those twenty-six letters, replace the first thirteen of them with the range of letters from n-z and the second thirteen of them with the range of letters from a-m
- 2) To un-ROT13, do a tr/a-z/n-za-m/ over each character in the file
- 3) perl -pe ‘tr/a-z/n-za-m/’ < infile > outfile

Where was the line crossed, from “speech” to “code”?

The potential narrative equivalence between English and computer language will undoubtedly be a subject of much contentious litigation over the boundaries of permissible expression (Touretzky, 2000). Possible disputes are foreshadowed in *Universal v. Reimerdes* (2000) where the court remarked

During the trial, Professor Touretzky of Carnegie Mellon University, as noted above, convincingly demonstrated that computer source and object code convey the same ideas as various other modes of expression, including spoken language descriptions of the algorithm embodied in the code. . . . He drew from this the conclusion that the preliminary injunction irrationally distinguished between the code, which was enjoined,

and other modes of expression that convey the same idea, which were not, id., although of course he had no reason to be aware that the injunction drew that line only because that was the limit of the relief plaintiffs sought. With commendable candor, he readily admitted that the implication of his view that the spoken language and computer code versions were substantially similar was not necessarily that the preliminary injunction was too broad; rather, the logic of his position was that it was either too broad or too narrow. . . . Once again, the question of a substantially broader injunction need not be addressed here, as plaintiffs have not sought broader relief.

Arguably, that “broader relief” would have been requested by SunnComm versus Halderman had the controversy proceeded to a lawsuit as threatened. Strategic considerations on this matter may have been one reason for the withdrawal by SunnComm.

However, because new languages and ways of expressing computational concepts are continually being invented, the exact reach of the DMCA will remain unclear for the foreseeable future. The DeCSS algorithm has even been expressed in Haiku format poetry (Schoen, 2004).

## HOW NOT TO GET SUED UNDER THE DMCA

Given the potential for the DMCA to chill cryptography and security research, many professionals are concerned with what they can do to reduce their risk of prosecution. Dmitry Sklyarov’s arrest and criminal charges show that the problem is not in the realm of fantasy.

Surveying the behavior of plaintiffs in many DMCA cases, the critical variable seems to be the perception of the character of the defendant. Although a corporation might have the legal ability to bring DMCA charges against a university professor, any prospect of setting an unfavorable legal precedent with a sympathetic defendant results in the withdrawal of threats. Conversely, an unsympathetic defendant appears not to do well in the judicial process (Bowman, 2001): “As soon as the judge says ‘hacker,’ you know you’ve lost,” University of Minnesota law Professor Dan Burk said. “There is an attempt to paint defendants as unsympathetic, low-priority, on the fringe—to make it seem like nobody respectable is going to be harmed except for weird hacker types.”

In view of this, the best practice is arguably to have as much professional and institutional backing as is possible. Consulting staff counsel, if available, can help with specific situations.

Keeping in mind the text of the §1201(g) exemption, preliminary notification of parties adversely affected by the research should not be done casually or without prior legal consultation. The fact that such notification is an element of a DMCA defense means it will affect how a court views any potential case. Pragmatically, it presents an opportunity for one to be the target of a legal threat aimed at chilling the presentation of results. This topic is extensively covered in Liu’s “The DMCA and the Regulation

of Scientific Research” (2003), and the interested reader should consult that paper for further discussion.

## CONCLUSION

The DMCA has profoundly unsettled the delicate balance that existed earlier in copyright law. Advances in technology, which have vastly increased the ability to make copies, have been in direct conflict with the imperative of copyright-concerning controls on content. The compromises of fair use and ability to produce and market technology if the technology has substantial noninfringing use may be irreconcilable in practice with the offenses of circumvention itself and the broad prohibitions against trafficking in circumvention technology. Moreover, the interpretation of contraband technology to encompass computer programs (even source code), and hence perhaps technical speech itself, greatly extends the reach of copyright-related regulation. Potentially the effects could lead to a chilling effect on academic research.

Various proposals have been made to ameliorate the negative effects of the DMCA. However, there is a fundamental clash between the needs of copyright owners to suppress information regarding copy-controlling encryption algorithms and the needs of the free exchange of methodology and validation of results for any research. This clash may ultimately be unsolvable.

## GLOSSARY

**1201(a)(1)** The DMCA provision prohibiting the act of *circumvention* of a *technological protection measure* that effectively controls *access* to a copyrighted work.

**1201(a)(2)** The DMCA provision prohibiting trafficking in “any technology, product, service, device, component” for *circumvention* of a *technological protection measure* that effectively controls *access* to a copyrighted work.

**1201(b)(2)** The DMCA provision prohibiting trafficking in “any technology, product, service, device, component” for *circumvention* of a *technological protection measure* that effectively protects a right of a copyright owner (usage controls).

**Circumvention** To “descramble... decrypt..., or otherwise to avoid, bypass, remove, deactivate, or impair a technological measure, without the authority of the copyright owner.” This is legally and conceptually distinct from *infringement*. Note that circumvention encompasses much more than decryption.

**CSS** Content scramble system, an encryption algorithm used to control access to content on DVD format disks. Although CSS does not affect commercial-grade duplication of a DVD, it prevents meaningful consumer copying and peer-to-peer file sharing.

**DeCSS** A program that decrypts the CSS encryption created by a team of three programmers (not, as commonly believed, the work of one teenager). Lawsuits concerning DeCSS have been the most prominent DMCA litigation.

**Effectively** A legal standard for content restriction. A technological protection measure “effectively controls access” if it, “in the ordinary course of its

operation, requires the application of information, or a process or a treatment, with the authority of the copyright owner, to gain access to the work.” A technological protection measure “effectively protects a right of a copyright owner” if it “in the ordinary course of its operation, prevents, restricts, or otherwise limits the exercise of a right of a copyright owner.”

**Fair Use** In law, a defense against copyright infringement, allowing legal use of copyrighted material for such purposes as criticism, comment, news reporting, teaching, scholarship, or research. More philosophically, a safety valve for resolving the conflicts between copyright’s restrictions on the use of speech and the U.S. Constitution’s First Amendment provision concerning freedom of speech.

**Infringement** A violation of any of certain exclusive rights granted by copyright law. Some examples of these rights are reproduction, making of derivative works, performance, and display. This is legally and conceptually distinct from *circumvention*. Fair use is one defense against infringement.

**Reverse Engineering** In legal terms, “to study or analyze (a device, as a microchip for computers) in order to learn details of design, construction, and operation, perhaps to produce a copy or an improved version.” (see *Bowers v. Baystate Technologies Inc.*, 2002)

**Trafficking** To “manufacture, import, offer to the public, or otherwise traffic in any technology, product, service, device, component, or part thereof” that violates the relevant DMCA provision. It is important to note that devices are just one part of this term, as it also encompasses the very broad idea of technology (which is extended to computer program source code).

Types of Evidence	461	Cross References	465
Rules of Evidence	461	Further Reading	465

## INTRODUCTION

Computer and system security professionals traditionally deal with issues of technology, but may be called upon to investigate when security is breached and to support forensic investigations and legal proceedings. Conversely, members of the legal profession are increasingly called upon to bring cases based upon, and present in court, information obtained from computer, network, and other technical systems.

To both groups, let me point out that this chapter is an overview and not an encyclopedia itself. Subfields of forensic science can produce very fat books, and the law produces entire libraries. Technical experts are not going to find details of file system internals here, nor are lawyers going to find case law.

## LEGAL SYSTEMS

In dealing with legal issues, we have an immediate problem in that different countries not only have distinct laws but possibly even diverse legal systems. There are different approaches to what constitutes law and legal proceedings, and these will have an impact in regard to what constitutes evidence permissible in court.

Those from Britain, the Commonwealth countries, and the United States will be most familiar with the *common law* system, based on the presumption of laws that uphold the common good, from an originating charter document and case law precedents laid down over the years. (Common law is also the system under which a suspected criminal is presumed to be “innocent until proven guilty.”) In some of those countries there are specific laws that would make, for example, malicious software illegal. In Canada, a relevant section of the Criminal Code states that anyone “who, without authorization, modifies data, or causes data to be modified” is guilty of an offense, which would seem to cover it nicely. However, most common law systems also have provisions against mischief or vandalism, so malicious software could probably be prosecuted even in the absence of a specific law. (Successful prosecution is quite another matter, the requirements for which this chapter covers at length.) Common law systems have, in fact, two different standards of legal evidence and proof, which are described below.

Most other countries have *code law* or *civil law* systems. Under these systems, an activity is not illegal unless there is a specific law against it. (In access control terms, everything is permitted unless it is forbidden.) Therefore, under such systems, it may be perfectly legal to write and distribute malicious software (or break into computer systems, or sell pirated copies of copyright-protected software) simply because there are no laws prohibiting such activities: the lawmakers haven’t caught up with the times. (“Black hat” who break into computer systems, need not think they can get off freely by moving to such countries: if they travel in or to a country where the activity is illegal, they can be prosecuted there and sometimes even extradited.)

Common law and code law systems are not the only types of legal systems. There are religious legal systems, and you may also encounter systems based on socialist theories of social and economic structures. Of these additional systems, possibly the most important, in terms of evidence, are the religious systems.

The religious legal systems that most people will have heard about are probably the systems of *Shariah*, or Islamic law. These systems are generally stated to be based on the holy book of Islam, the Koran or Qu’ran. In broad outline this statement is true, but with certain provisos. Possibly the most important aspect of religious legal systems is that the clergy hold very special rights and powers. Although this is true of all religious legal systems, it has been amply demonstrated recently in a variety of Islamic jurisdictions. Koranic scholars have noted that the Taliban regime in Afghanistan upheld a variety of laws (dealing, for example, with the cutting of beards and the position of women in society) that had little or no basis in Islamic religious writings. Under religious systems, therefore, the clergy may also have extraordinary powers of determining what may constitute evidence.

## Differences within Common Law

Just to make the situation even more obscure (given lawyers, what else did you expect?), beware of confusing the two different uses of the term “civil.” Common law and code (civil) law are two different types of legal systems. Under the common law system, there are criminal cases, tort (or civil) cases, and regulatory cases, governed

by different types of law. Criminal cases involve criminal laws and possibly jail time. Civil cases involve some form of tort, or injury (which only has to be a hurt—it does not have to be a wound) to someone. Once again, under the common law system, even if you cannot, for some reason, prosecute someone as a criminal for writing malicious software, if you can prove that what he or she did hurt you in some way (cost you money, lost you something, or even just got people to make fun of you) then you can launch a civil action, or lawsuit, against that person. You cannot put that person in jail, but you may be able to get some money. (Well, you can get a decision that he or she owes you something. Collecting actual money may be an entirely different issue, indeed.)

There is an additional point to be made about the difference between civil and criminal cases under common law systems, and it is directly relevant to forensic studies and digital evidence. The test of evidence and proof is not the same in the two types of cases. A criminal case must be proven “beyond a reasonable doubt.” If a case can be made, and accepted by reasonable people, that the events in question could have occurred without illegal activity on the part of the accused, then the case must fail. Civil cases only require that a decision be made on the balance of the probabilities. The most famous example of this difference was in the trials surrounding the death of Nicole Simpson. The trial for murder was a criminal case, and the defense raised sufficient doubt of guilt that O. J. Simpson was found to be not guilty. The case for wrongful death was a civil case, and O. J. Simpson was found, in regard to the same event and on the basis of the same evidence, to be guilty. (It is interesting to note that DNA evidence, a technical and at that time novel form of identification, played a large part in that trial.) Thus, evidence for a criminal trial must be presented much more carefully than for civil cases.

## Jurisdiction

When dealing with information and telecommunications systems, jurisdictional issues may play a role; that is, determining who has the right to try the case and under what system of law. For example, if a Canadian, living in Canada, started a business writing malware that was created and distributed from a machine in the United States and that malware affected someone in Britain, it is possible that the person responsible for creating the malicious software could be prosecuted in any or all of the three countries. A greater problem arises when the activity could be legal in one jurisdiction, but is against the law in another. This has become a major issue recently in regard to privacy. For example, the European Union has a set of directives in regard to privacy. One of the principles is that personally identifiable information about European citizens cannot be transferred by a third party to a jurisdiction where similar protections do not apply. Because the United States has no consistent privacy regulation on a federal level, special arrangements must be made by American companies to safeguard data relating to European customers.

Jurisdictional issues can be extremely complex, and everyone involved in Internet activities should be aware of the potential problems. Courts are increasingly willing to

allow cases to proceed even if the activities of an individual or site are intended for a specific area and are legal in that locale, simply because they are available on the Internet and may be illegal elsewhere.

A similar, but unrelated concept is that of venue, the particular place where the trial is conducted. In many cases a great deal of effort and maneuvering are done to ensure that a trial proceeds at a specific location, either for the convenience of one side or to increase the cost and difficulty, in relation to attendance and the production of witnesses, for the other.

## Digital Court

In discussing the law and issues of evidence with regard to technology, the topic of the *digital court* will likely arise. Unfortunately, this term is used in a variety of ways. To the general public, the term probably evokes the idea of courts that may act entirely within the realm of cyberspace, possibly being held as an activity on a Web site. Although this may be an end goal for this concept, the current reality tends to be more limited.

In general, courts now use a number of technologies. Most courts now accept the practice of remote depositions or testimony, with examinations being made by types of teleconference or videoconference. Some specialty courts, with limitations on the size or importance of disputes, may conduct most or all activities, including motions and judgments, by e-mail messages and/or file attachments. (A recent study in the Canadian province of British Columbia, for example, demonstrated that cryptographically robust digital signatures of land title documents precluded a common form of mortgage fraud.)

Another use of the term “digital court” arises in relation to legal training. There are companies that provide simulated courts, using a variety of technologies, furnishing the ability to “play out” cases and then examine the activities and results.

At present, the term “digital court” is used most frequently in regard to court reporting. More and more courts are dispensing with fully trained and experienced court stenographers who can provide a real-time transcript of the proceedings. Such reporters require a significant amount of education and experience, and increasing demands on the court system are placing such activities out of reach. Therefore, technology is being used in a variety of ways to reduce the need for real-time transcripts. In some cases, the verbal activity in the court is recorded as sound files, and a stenographer creates a transcript later. In others, the sound file is recorded, but no transcript is made if the case is not appealed.

Returning to the broadest definition of the term as a full court conducted entirely online, this activity is currently problematic and will require much greater study before it is to be realized. The activities of a court are highly complex, and the greatest probity and confidentiality must be maintained. Note that even in such a simple matter as an election, the use of fully digital technology is far from being universally accepted. A number of issues of security, availability, authentication, confidentiality, and acceptability must be dealt with before a fully digital court can be realized.

## EVIDENCE

Simply by including the word “forensic” along with “computer” (or “digital,” “network,” or “software”), we have indicated that we are primarily concerned with evidence. That being the case, we need to know what items the law and the courts consider to be evidence.

### Types of Evidence

Many types of evidence can be offered in court. The most common forms are direct, real, documentary, and demonstrative evidence.

Direct evidence is the normal statement from a witness that we are all familiar with from television dramas. Knowledge is obtained from any of the witness’s five senses and is, in itself, proof or disproof of a fact. Direct evidence is called to prove a specific act or occurrence. Because direct evidence relates to a person, digital evidence is not involved.

Real evidence, also known as associative or physical evidence, is made up of tangible objects. Physical evidence includes such things as tools used in the crime, fruits of the crime (possession of stolen goods or even a suddenly acquired pile of cash), or possibly perishable evidence that we may be able to reproduce. Often the purpose of the physical evidence is to link the suspect to the scene of the crime. It is this evidence that has material existence and can be presented to the view of the court and jury for consideration. Digital evidence is unlikely to be real evidence, although certain pieces of computer hardware may be real evidence.

Documentary evidence is material presented to the court in the form of business records, manuals, printouts, and so forth. Much of the evidence submitted in a computer crime case—and almost everything that can be considered digital evidence—is documentary, and there are special considerations for this type of material that are described below.

Finally, demonstrative evidence is evidence used to aid the jury. It may be in the form of a model, experiment, chart, or an illustration offered as proof. It should be noted that demonstrative evidence is being used more often to aid the court and the jury, especially in the form of simulation and animation. In regard to computer, network, software, or digital forensics, there will be increasing significant requirements for demonstrative evidence as the courts come to accept the process as reliable. Explanations of how software forensics works, how information is laid down on disks or tape, how characteristics are obtained and analyzed, and the reliability of the procedures (including error rates) are all forms of demonstrative evidence.

There are many mathematical algorithms used in linguistic or software forensic analysis that must either be stipulated or proven to the court to be completely accurate. It is generally more difficult to admit a simulation as evidence because of the substantive nature of the process. Simulations must make a great many assumptions about what is important in the real world, and it is unlikely that the opponent in litigation would allow such assumptions to go unchallenged.

Computer animation, in contrast, is simply a computer-generated sequence, illustrating an expert’s opinion. (This chapter discusses, in more depth, the requirements for expert testimony in later sections.) Animation does not predict future events, but merely supports the testimony of an expert witness through the use of demonstrations. An animation of a hard disk spinning while the read/write heads are reading data can help the court or jury understand how a disk drive works. There are no mathematical algorithms that must be proven. The key to having animation admitted as evidence is a strong expert witness. It is very important to understand the difference between these two types of evidence because it affects the standard of admissibility (discussed in the next section).

### Rules of Evidence

The specific rules of evidence may vary among jurisdictions, but some principles are fairly standard. Some are common sense, whereas others are not quite as obvious and may direct specific actions that must be taken in regard to the collection, preparation, and presentation of exhibits.

First of all, evidence must be *relevant*. Although the assessments that are done on hardware or software may be technically interesting, the court will not want to hear about results unless the data have a bearing on the matter at hand. The fact that a given program uses a particular programming trick is not necessarily evidence. In contrast, the fact that the trick is used in this program, and only in programs written by one particular author, *is* evidence. Analysis of software can provide information about what a program does, what it was intended to do, and possibly who wrote it, but generally to turn this information into evidence, there needs to be additional data (possibly about the programming environment). On the other hand, a comparative analysis of the code of two programs can probably provide evidence of whether one copied from another and which came first.

Another concept in evidence is what is called a *foundation of admissibility*. This is somewhat more technical and deals with the reliability or acceptability of the evidence as something upon which the court can base a decision. It partly relates to specific procedures for what is called the chain of evidence or chain of custody and also the matter of expert testimony, both of which are examined below.

Any information presented as evidence should have been obtained by legal means. The results of illegal searches or surveillance will not (with some provisos) be accepted in court. Some recent laws may have interesting ramifications in this regard. The U.S. Digital Millennium Copyright Act holds that it is illegal to break into any technology intended to protect copyrighted material. Programmers are held to have copyright on the programs that they produce. Therefore, if the programmer even does a simple self-encryption on the program code, it may be illegal to do a decryption in order to analyze the software.

### Hearsay and Business Documents

An additional factor in the admissibility of evidence is the concept of *hearsay*. As a witness in court, you may be

asked to say what you did or witnessed directly. Except in very unusual circumstances, you will not be asked and will not be allowed to say what someone else told you that he or she did or saw. This “second-hand” testimony is called hearsay and is pretty much automatically suspect. If the court is to accept evidence other than directly from the source, there has to be corroborating testimony.

Business documents are all considered to be, in some sense, hearsay. This is because they are all, in a way, information about a transaction, rather than direct evidence of a transaction. This characterization is particularly true in relation to electronic data. When presenting printouts or other representations of digital information, there must be testimony about how the information is stored and handled, whether there are regular procedures for doing so, whether there was any kind of departure from regular procedures in this particular instance, what protections are in place to ensure the integrity of the data, who has access and the ability to change the data, and so forth.

Whether related to a business or not, all computer and digital records are regarded as hearsay in this light. In a sense, this point is going to lie at the heart of every examination of digital evidence. In addition, digital evidence is suspect because of the ease with which it can be created, destroyed, or altered.

### Digital Frailty and the Chain of Evidence

Digital information is extremely fragile. A change of a single bit in a megabyte file can radically alter its implications, meaning, or outcomes. Although operating systems generally track changes to some extent, even if only the last time a file was changed, it is quite possible to alter data without leaving any trace that a modification has been made or indicating by whom. Therefore, it is vitally important, in terms of admissibility, to be able to prove that the analyst has not made any changes to the system while studying it. This is so important that the G-8 nations commissioned an initiative for a set of proposed international principles for computer evidence. The standards state that actions taken in seizing digital evidence should not change the evidence, that any person accessing the evidence should be forensically competent, and that all actions in regard to the evidence should be documented fully.

Of course, not every single-bit change to a massive file has any significance. In fact, there are situations in which identical files are stored in different ways, without any meaningful change having taken place at all. For example, text files in DOS and Windows systems are stored with two characters (a carriage return and a line feed) at the end of every line. UNIX file systems store text files with only a single character indicating the end of the line. Therefore, for identical text files stored on different file systems the hash value, digest, or digital signature would detect a difference (because they are designed to indicate a variation even in a single bit) and declare the files to be different. Thus, computer forensics must sometimes deal with the issue of *canonicalization*, which ensures that the digital material being marked to determine changes is limited to those sections where changes are relevant. Obviously, the concept of canonicalization itself needs to be presented carefully in court, if relevant, to ensure that the significance and reliability of the procedure are understood.

An important concept in the presentation of any physical evidence is the chain of custody. The court will need to know who had access to the evidence and what they did to it. The court will also need to know that nobody other than the people listed could have had access to the material. If there is any possibility that the evidence might have been tampered with, even if there is no specific reason to suspect that something was done to the items in question, then there is a reasonable doubt that the evidence actually does support what we assert.

Remember also the point about competence in regard to the handling of data. Even without the G-8 standards, the existence of an incompetent person in the chain of custody could raise doubts about the validity of the results obtained in any testing. In the case of a criminal case, this fact could be sufficient to cause the case to fail.

In the case of digital and electronic data, the identification and preservation of the information are absolutely vital. Digital data are fragile and can be modified easily; once modified, there is almost no way to determine that a change was made, when the change was made, and who made it. Therefore, the establishment of an iron-clad chain of custody is crucial.

The chain of custody for computer, network, or software forensics uses procedures very similar to those for other forms of electronic evidence. There will have to be identification and preservation of the original system. Either the computer itself or the electronic media will need to be labeled and secured. Access to these original items must be restricted. (In some special circumstances, of course, the material to be studied will be available only in the memory of the computer, and therefore the original physical representation cannot be preserved. In that case, the procedures involved in recovering the material and maintaining it thereafter must be documented.)

The original material should not be studied, because the tools used to study the files can also be used to modify them. Therefore, printouts and/or message digest calculations should be created as soon as possible to be able to demonstrate that the data studied or presented are the same as the original. In most cases, it is a good idea to have a videotape of the original procedures of seizing and recovering the computer. Rather ironically, any videotaping should be analog, not digital to avoid the suggestion that the digital video was itself edited or modified.

### Providing Expert Testimony

For the foreseeable future, digital forensics is going to be an arcane art that is presented in court, if at all, by an expert. Therefore, the rules governing expert witnesses are also germane to this discussion.

Despite the aphorism attributed to Mark Twain that an expert is simply some guy from out of town, it is not necessarily possible to walk into court and simply state that you are an expert in a field. The court will decide (or the other side will challenge) whether you have sufficient education and training, experience, or skill to support your conclusions and whether there is a “reasonable basis” for the conclusions you reach. If you are not an expert, you can present the uninterpreted results of your analysis. However, masses of unexplained data are likely

to be judged irrelevant to the case. If you do obtain the status of an expert witness, then you are also able to present your opinion about what the results mean.

Assessment of expertise in cases involving information technology has been and continues to be difficult. Unlike other professions such as medicine, civil engineering, or accounting, there is no organized, licensed professional college, organization, institute, or other body involved in the regulation, censure, and discrimination of specific expertise. (Or, at least, no universally recognized one—As the old joke has it, the nice thing about computer standards is that there are so many of them.) Given the novelty of the field of software forensics, the requirements for education and training are likely to be even more problematic. After all, there is no certificate, diploma, or degree program in software forensics, although there are some courses available in the data recovery procedures of computer forensics. Some individuals are working on various aspects of the field, but academic research in isolated areas is unlikely to be accepted as sufficient training, at least not in and of itself.

The expert need not have complete knowledge about the field in question, need not be certain, and need not be unbiased: the expert must only be able to aid the jury in resolving a relevant issue. Although the level of expertise may affect the weight accorded to the expert's opinion, it does not affect admissibility. It has been held that the court cannot exclude testimony simply because the trial court does not deem the proposed expert to be the best qualified or because the proposed expert does not have the specialization the court considers most appropriate.

Again, experience is going to be difficult to assess in the immediate future. Experience as a low-level programmer analyzing and debugging code is likely to be a help, but not necessarily sufficient. Academic research on plagiarism and the similarity of code between programs could be relevant. Virus researchers, who are used to finding identifiable patterns in programs (as well as specific functions), could have an advantage. However, the experience of a specific software forensic practitioner will probably have to be matched with the particular case being pursued.

Skill is an interesting concept and is not necessarily simply related to training or experience. A peer group may very well adjudge an individual as being particularly skilled, even though there is little or no difference in training or experience between the skilled person and his or her colleagues. Therefore, we may be faced with the situation of bringing testimony, of one type or another, attesting to the skill of the expert being brought before the court. A demonstrated success rate may be said to be a measure of skill, but even this is going to be a rather subjective criterion because definitions of success will vary.

Of the different factors that make up the assessment as to whether or not a witness is expert, probably one that deserves a lot of attention is that of reasonable basis. It is not enough that we, as experts, can see a conclusion or finding. An expert's opinion must be reliable; that is, based on valid reasoning and reliable methodology, as opposed to subjective belief or unsupported speculation. If an expert opinion is based on speculation or conjecture, it may be stricken. An expert witness must be able to explain the reasoning leading to that conclusion at least to a judge

and possibly to members of a jury, who probably do not have any kind of technical background.

Software forensic evidence is likely to rely on statistical methods. Presentation of the evidence, therefore, will need to be accompanied by clear explanations not only of how the characteristics were determined but also of why they are important. The court must make an assessment as to whether the reasoning or methodology underlying the testimony is scientifically valid. To do so, the court should consider whether a method consists of a testable hypothesis, whether the method has been subject to peer review, the known or potential rate of error, the existence and maintenance of standards controlling the technique's operation, whether the method is generally accepted, the relationship of the technique to methods that have been established to be reliable, the qualifications of the expert witness testifying based on the methodology, and the non-judicial uses of the method. All of these factors should be addressed in presenting expert testimony in court.

In the United States there is case law, known as the Daubert decision, which states that judges must decide not only whether a witness is truly expert but also on what the expert may testify about. This restriction of testimony on the part of the judge has become known as the *gatekeeper function*. In American courts an expert witness may find that restrictions are placed on the testimony that can be delivered. The court, even after having decided that a witness is an expert, may limit the areas of expertise that are acceptable.

An expert witness may play several roles in a case. First, there is the consulting expert who provides advice and information to counsel well in advance of the trial itself. At the time of the trial, the court's expert gives supposedly unbiased explanations to the court (usually the judge) about specialized technical matters bearing on the case. Then there is the testifying expert, which is the role most people think of in regard to expert witnesses. The testifying expert explains findings, discoveries, and their implications. However, the discoveries may be such that they could only be seen or made by the expert. In that case, the expert witness also functions as a witness to fact. It is important to ensure that the expert knows and does not confuse which of these roles he or she is being asked to undertake. The expert may, in fact, be asked to fulfill more than one of these roles in the course of the proceedings, and in such a situation maintaining the division between roles is vital. The function the expert is being asked to undertake will shape the work to be done and will possibly restrict the testimony that can be given.

In normal testimony, witnesses are only allowed to tell what they saw, heard, or in some way know to be a fact. Witnesses are not permitted to infer or extrapolate beyond direct observation. In contrast, experts are allowed to draw conclusions and even present opinions. This extension of the testimony of the professional is not unrestricted and is therefore more open to challenge by the opposing side.

One very common source of tension in obtaining and presenting technical testimony is the significant difference in mindset between the technical and legal worlds. Computer work generally involves finding an answer to a problem: if the code works, background study and

documented analysis are generally irrelevant. The legal profession, on the other hand, depends absolutely upon advance preparation, and an answer is almost useless unless the reasoning, background, and process are not only chronicled but also obtained properly and legally. Both the legal counsel and the technical expert have to work to see the other's point of view. Lawyers, accustomed to carting around trunks full of papers for even the simplest case, will have to be prepared for the assumption that "it works" is sufficient proof. Techies will need to overcome their deep-seated aversion to any and all forms of documentation and shed the automatic assumption that all users are incapable of understanding technical concepts.

## ETHICS

The topic of ethics is a very difficult one, and a complete discussion is beyond the scope of this chapter. Discussions of ethics, particularly in regard to information technology, tend to fail to provide useful direction. This deficiency is due in large measure to a breakdown in communication: the parties to such debates seldom agree even on the most basic definition of what ethics actually are. Some see ethics as fundamental guiding principles, whereas others assume that they are legalistic codes of conduct. Few can even agree on whether ethical standards are absolute or relative. This chapter does not pursue this deliberation, but rather addresses some related topics that are more directly relevant to digital forensics.

## Disclosure

The concept of disclosure—how much information to provide about a potential security weakness—has become a major issue in security circles in recent years. In the early days of computer security work, a majority of practitioners came from a military or related background, with its strong emphasis on confidentiality. Thus, it was automatically assumed that limiting information was a good thing. Because nobody knew much about computers then, keeping the details quiet did provide a limitation on the number of people who could even attempt to penetrate systems. Later, this position became known as security by obscurity, or SBO.

Obscurity has now been found wanting. In the same way that writers cannot edit their own text (trust me on this), security planners and administrators are often blind to the faults in their own protective systems. Without some outside analysis of a setup or product, flaws can go undetected for years. In such a situation, the first time the existence of a problem becomes apparent is when someone uses it. The attackers and black hat will find weaknesses, even if nobody talks about them. The only people that obscurity keeps in the dark are those charged with protecting the systems.

Some experts advocate full disclosure. This means that anyone who discovers a security loophole should immediately publish all details in full, including instructions on how to use the vulnerability. However, because full disclosure requires that everyone be alert to every security warning that comes along, no matter how minor, most

people are more comfortable with some level of partial disclosure. Partial disclosure usually involves limits, such as informing the publisher of a product problem before alerting the general public, to give the vendor time to come up with some way to fix the problem. Sometimes the information given to the public may be restricted to the existence of the issue, as well as suggestions about safety measures. Partial disclosure is not standardized in any way, and the definition of what it entails may vary from person to person.

The virus research community has frequently been accused of practicing a form of security by obscurity. Legitimate researchers refuse to distribute virus code unless they know that the person making the request is qualified and that the requester abides by the same code of conduct and will not give out copies of the software. This position may seem untenable in these days of e-mail viruses, when virus code may be obtained almost as easily as spam messages. The virus research community, however, believes that establishing a flexible line on distribution would be too complex and would inevitably lead to increased distribution and therefore chooses to err on the side of caution.

## Black Hat Motivations as a Defense

Because some of these contentions may be used as a defense in court, it is important to examine the commonly presented justifications for the activities of the black hat community (system penetration, software piracy, virus writing, etc.) as arguments relating to the activity of digital forensics. Regardless of how we may consider them from an ethical standpoint, we may need to defend against them as legal debates.

One of the most frequently attempted justifications of black hat activity of all kinds is that it is protected under the concept of freedom of speech. The free speech defense may be an extremely strong one, particularly in nations under common law systems, where some form of freedom of expression is often a constitutional right. So far the courts still appear to be divided on the issue of whether or not computer code counts as "speech." A more reliable approach to dealing with the free speech argument is to examine the restrictions on freedom of speech, which restrict the right to create harm with speech. There are generally laws and precedents against slander, hate speech, and even shouting "fire" in crowded theaters.

Many individuals who practice system violation activity rationalize that they are following in the detective footsteps of the old-time hackers (system experts), who explored and discovered the capabilities of early computing devices. In many cases there is honest disagreement among individuals in regard to the legality of attempts to break into security systems for the purpose of strengthening those same systems. Some individuals who seem to have sincerely wanted to publicize security weaknesses, or offer their services as consultants, have found themselves facing criminal charges. There are two points to make in this regard. One is to ensure that the activity you are examining is malicious in intent. The other is to be very sure that, when investigating a system, you have permission to do so.

## CONCLUSION

In today's interconnected computing environment, you may be faced with a variety of legal systems. Although you cannot know all the relevant laws around the globe, a general overview of the types of legal systems you may encounter can be helpful.

The digital forensic investigator is involved in collecting, analyzing, and presenting evidence. Note that there are very definite rules in regard to the collection and treatment of evidence. In particular, note the chain of custody concept that is so vital in the traditional data recovery side of computer forensics.

As a specialist in computer, network, or software forensics, you may be required to act as an expert witness in one or more roles. Be aware of the special demands and responsibilities of that function.

A number of issues will bear on your activities in the legal arena. Although the law and ethics are not identical, it is probably necessary to examine all activities from an ethical perspective while the legislation and precedents relating to software are being worked out.

## GLOSSARY

Relevant terms may also be found in the security glossary at <http://victoria.tc.ca/techrev/secgloss.htm> or <http://sun.soci.niu.edu/~rslade/secgloss.htm>

**Acceptable use policy (AUP)** A written policy outlining the usage that may or may not be made of computing or network resources. Previously this applied primarily to institutions (such as universities) providing access to systems such as the Internet. Although not as widely used currently, AUPs should still be part of a company's security policy.

**Accountability** The property that enables activities on a system to be traced to individuals (or entities) who may then be held responsible for their actions.

**Black hat** Communities or individuals who either attempt to break into computer systems without prior authorization or who explore security primarily from an attack perspective. The term originates from old American Western genre movies where the "good guys" always wore white hats and the "bad guys" always wore black.

**Computer forensics** Originally the full means of obtaining legal evidence from computers and computer use, computer forensics is now apparently limited to the recovery of data from computers and computer media. Computer forensics has therefore become only one part of digital forensics.

**Digital forensics** Sometimes known as digital forensic research or digital forensic science, this has recently become the umbrella term for all forms of research and analysis of computers and computer use directed at obtaining evidence of intrusion, attack, or wrongdoing. The First Digital Forensic Research Workshop defined digital forensic science as "[t]he use of scientifically derived and proven methods toward the preservation, collection, validation, identification, analysis, interpretation, documentation and presentation of digital evidence derived from digital sources for the purpose of

facilitating or furthering the reconstruction of events found to be criminal, or helping to anticipate unauthorized actions shown to be disruptive to planned operations." Three major fields of digital forensics are computer forensics, forensic programming (or software forensics), and network forensics.

**Forensic programming** Originally from the field of computer virus research, forensic programming involves the analysis of code for evidence of intent, program identity, or authorship. Outside the field of virus research, forensic programming is often referred to as code analysis, although code analysis may be limited to analysis of source code, whereas forensic programming frequently deals with object code when object code is the only evidence available. It is one of the major divisions of digital forensics.

**Hacker** Originally the term meant one who was skilled in the use of computer systems, particularly if that skill was acquired in an exploratory manner. Later, the term evolved to be applied to someone, skilled or unskilled, who breaks into security systems. Actually, you can determine people's level of technical expertise by how they use the term. Someone who uses hacker as meaning expert is someone who really does advanced technical work. Someone who uses hacker as a bad guy may have a technical background of some type or hold a technical job, but usually is nowhere near the "cutting edge."

**Incident** An occurrence that has been assessed as having an adverse effect on the security or performance of a system. Note that this definition is somewhat vague, particularly in regard to the level of assessment. Those from a law enforcement background tend to see incidents in terms of attacks with (potentially) identifiable intruders. Those from a systems administration or support background tend to see an incident as any anomaly in the system that might affect performance or service.

**Incident response** The reaction, generally by a pre-designated team, to a detrimental incident. Currently, the incident response literature is primarily concerned with the collection and preservation of evidence in a manner appropriate for presentation in a court of law.

**Network forensics** The collection and analysis of evidence of intrusion or malfeasance from network activity and data. It is closely related to intrusion detection systems and one of the major divisions of digital forensics.

## INTRODUCTION

Encryption is the procedure of rendering a message into a concealed form so that it is decipherable exclusively by a particular recipient or recipients. The message in its original state is known as a *plaintext* (or *cleartext*); in its encrypted form, it is known as a *ciphertext*. Historically, the aim of encryption has been to enable two parties to exchange messages confidentially, even in the presence of an eavesdropper capable of intercepting most or all of their communications. The use of encryption has been confined chiefly to diplomatic and military circles in the past, but its scope in everyday life has broadened enormously in recent years. Thanks to the rise of the Internet, it is estimated that over half a billion personal computers are equipped today with strong encryption capabilities in their Web browsing software. This includes nearly every new computer sold today.

Active users of the Internet employ encryption on a regular basis. When accepting credit card information or processing other financial transactions, most Web servers initiate encryption sessions with clients. The form of encryption used to support sessions of this kind on the Web is very strong—so strong that it is generally believed to be effectively unbreakable by even the most powerful computers. In most browsers, the appearance of an icon representing a closed padlock on the bottom of the screen indicates the use of encryption in a protocol known as SSL (Secure Sockets Layer). By clicking on this padlock, a user can learn detailed information about the encryption session, much of which is explained in further depth in this chapter. Encryption also plays an important role in most important industrial communications systems, of course, such as networks used for banking transactions.

For the reader interested in a cursory introduction to encryption, without much of the detail provided in this chapter, it is possible to read the following sections as a more-or-less self-contained exposition: Some Basics, Symmetric-Key Encryption Today, the opening paragraphs of Public-Key Cryptography, The RSA Cryptosystem, and How Public-Key Encryption Is Used.

## Some Basics

The science of constructing encryption algorithms and related systems is known as *cryptography*. That of analyzing and attempting to find weaknesses in encryption algorithms is called *cryptanalysis*. Together, the two complementary sciences are known as *cryptology*. Cryptologists like to explain their ideas in terms of a small troupe of fictional characters. Traditionally, Alice and Bob are the names assigned to the fictional parties wishing to exchange confidential messages with one another. The hypothetical eavesdropper on their communication is called Eve. We follow this nomenclature in our explanations in this chapter.

An encryption algorithm is considered to be secure when Eve cannot feasibly distinguish between the encryptions of two different plaintexts. This should hold even in cases where Eve has the ability to manipulate the messages transmitted between Alice and Bob in various ways. For example, suppose that Eve can cause Alice to generate and reveal ciphertexts  $A$  and  $B$  computed on messages  $X$  and  $Y$  in a random order. Eve should nonetheless be unable to tell whether  $A$  is an encryption of  $X$  or of  $Y$ .

The operational basis of an encryption algorithm, or cipher, is a piece of information known as a key. A key serves as input to the encryption process that Alice and Bob have agreed to use. The encryption process consists of a series of instructions on how Alice, for instance, should convert a plaintext into a ciphertext. The key serves as a parameter guiding the instructions. The reverse process, whereby Bob converts a ciphertext back into a plaintext, is also guided by a key, one that may or may not be the same as Alice's. The security of traditional ciphers, that is, the privacy of the messages they encrypt, depends on a shared key that is kept secret. For example, in one form of folklore encryption, Alice and Bob each have copies of the same edition of a particular novel. They share the identity of this novel as a secret between them. Alice encrypts a plaintext by finding a random example of each letter of her message in the novel. She writes down the page, line, and ordinal position of each of these letters in turn. The result of this process constitutes the ciphertext. Bob, of course, can reverse the process and obtain the original

plaintext by referring to his copy of the shared novel. In this case, the novel itself serves as a key—one that is quite long, of course, running as it usually does to hundreds of pages. In the forms of cryptography used on computers today, the key is much shorter, typically the equivalent in length of several words or sentences.

## A Brief Historical Note

An exciting subject of study in its own right, the history of cryptology is also intimately associated with the birth of the digital computer. During World War II, the efforts of British signals intelligence to break the German Enigma cipher led to the development of mechanical devices known as “bombes,” so called because of the ticking sounds they made in testing possible cipher keys. The “bombes” and the later generation of Colossus machines arising from these efforts were important precursors of the modern computer. Moreover, the man overseeing the immensely successful Enigma break was Alan Turing, a progenitor of the field of computer science.

## SYMMETRIC-KEY ENCRYPTION: INTRODUCTION

When Alice and Bob make use of the same key for encryption and decryption, as in our example above involving the novel, this is referred to as symmetric or symmetric-key encryption. Figure 1 gives a basic operational schematic of symmetric-key encryption.

Let us consider another folklore cipher, in which each letter of a message is replaced with another letter according to a fixed set of random, predetermined assignments. For example, the message, “MEET ME UNDER THE BRIDGE” might be encrypted as follows:

ZKKO ZK BWIKQ OPK UQMIFK.

This form of encryption is known as a substitution cipher. It is in fact quite easy for a skilled cryptanalyst—or even just a good puzzle solver—to break. Edgar Allen Poe, for instance, challenged readers of a newspaper in 1839 to submit English-language ciphertexts produced by letter substitution. He published the plaintexts of many such challenge ciphertexts in subsequent numbers of the

**Figure 1:** (Symmetric-key encryption): Bob wishes to transmit plaintext message  $m$  securely to Alice over a channel subject to eavesdropping. He encrypts it under shared symmetric key  $k$  to obtain ciphertext  $c$ , and transmits  $c$ . Eavesdropper Eve learns the ciphertext  $c$ , but should not learn  $m$  if the cipher is constructed and used properly.

newspaper. Knowing, for example, that ‘e’ is the most common letter in the English language, one would be tempted—quite correctly—to identify the letter ‘K’, which appears most frequently in the above ciphertext, with the letter ‘E’ in the plaintext. More sophisticated cryptanalytic techniques for attacking substitution ciphers focus on the frequency statistics not just for single letters, but also for letter pairs and triples.

Knowing that their cipher is subject to cryptanalytic attacks of this kind, Alice and Bob might be tempted to use a different, perhaps more complex, cipher and to hide from Eve not just their key but also the workings of the cipher. This is equivalent in effect to making the choice of the cipher a part of the key itself. An important principle enunciated by the 19th-century cryptologist Kerckhoffs discourages this approach. Adhered to by contemporary cryptologists, this principle may be stated as follows: The security of a cipher should reside in the key alone, not in the secrecy of the process of encryption. The motivations behind Kerckhoffs’s principle are several. First, widespread use of a good cipher requires that its workings be divulged in some form. Even if a cipher is disseminated only through software, for example, the underlying instructions can be reverse-engineered. Thus, it is fair to assume that an attacker can learn the mechanics of the cipher. Moreover, despite the oft-demonstrated inventiveness of the cryptographic community, there is time enough to devise and refine only a limited number of basic techniques for strong new ciphers. A poorly designed cipher, even when its workings are hidden from view, is vulnerable to attack by means of an arsenal of analytic techniques refined by the cryptanalytic community over many years. These techniques are roughly analogous in spirit to the idea that leads to the discovery of the letter ‘E’ in the example ciphertext above, but rely on more sophisticated forms of statistical analysis.

The basic unit of information in the computer and the fundamental unit for the encoding of digital messages is not the letter, but the bit. For this reason, contemporary symmetric-key ciphers operate through the manipulation of bits rather than lexicographic units. One of the earliest ciphers designed from this perspective is known as the one-time pad. Invented during World War I, the one-time pad is also of interest as the only cipher whose security is provable in the strictest mathematical sense. Formal understanding of its properties emerged in 1948–1949, with the publication of seminal work by Claude Shannon. (The security analysis of other ciphers, as we shall explain, has a strong, but less complete or rigorous mathematical basis.)

A one-time pad is a key shared by Alice and Bob consisting of a perfectly random string of bits as long as the message that Alice wishes to transmit to Bob. To encrypt her message, Alice aligns the pad with the message so that there is a one-to-one correspondence between the bits in both. Where the pad contains a ‘1’, Alice flips the corresponding bit in her plaintext. She leaves the other bits of the plaintext unchanged. This simple process yields the ciphertext. As may be proven mathematically—and perhaps grasped intuitively—this ciphertext is indistinguishable to Eve from a completely random string. Indeed, from her perspective, it is a completely random string. This is to say

that Eve can learn no information at all from the ciphertext, no matter how powerful her cryptanalytic capabilities. Apart from its requirement of perfect randomness, though, the one-time pad carries another strong caveat. The term *one-time* refers to the fact that if Alice uses the same key to encrypt more than one message, she loses the security properties of the cipher. This makes the one-time pad impractical for most purposes, as it requires that Alice and Bob generate, exchange, and store many random bits in advance of their communications. Nonetheless, the one-time pad has seen practical use. For example, the “hot-line” established between the United States and Soviet Union in the wake of the Cuban missile crisis employed a one-time pad system to ensure confidentiality, with tapes containing random keying material exchanged via the embassies of the two countries.

### Symmetric-Key Encryption Today

The symmetric-key ciphers in common use today are designed to employ relatively short keys, typically 128 bits in length. Moreover, these ciphers retain their security properties even when individual keys are used to encrypt many messages over long periods of time. Indeed, a well-designed symmetric-key cipher should permit only one effective avenue of attack, described by cryptographers as exhaustive search or brute force. By this, it is meant that an attacker familiar with the cipher makes random guesses at the key until successful. If Eve wishes to mount a brute force attack against a ciphertext sent by Alice to Bob, she will repeatedly guess their shared key and try to decrypt the message until she obtains the correct plaintext.

Given use of a 128-bit-long key, Eve will on average have to make well more than a trillion trillion guesses before she is successful! This is more, for example, than the total number of atoms composing all of the human beings in the world. The most powerful computers available today could not be expected to mount a successful brute force attack against a well-designed cipher employing a key of this length, even over the course of many years. It should be observed that the difficulty of breaking a key doubles for every additional bit in length. Thus, for instance, a 128-bit key is not twice as hard to break as a 64-bit key, but over a million trillion times harder.

The first widely embraced cipher employing the strong design principles in use today was the Data Encryption Standard or DES (pronounced “dehz”). Developed at IBM, the DES cipher was published as a federal standard in 1976 by what is now the National Institute of Standards (NIST) of the United States government. DES and security-enhanced variants are still widely deployed, particularly in the banking industry. DES employs a 56-bit key, operating on a basic unit of encryption consisting of a 64-bit block. This is to say that to encrypt a long message using DES, Alice first subdivides the message into 64-bit (i.e., eight-byte) blocks, each of which she enciphers individually. Ciphers that operate in this fashion are referred to as block ciphers.

Brute force attack on a 56-bit key requires substantial computational effort, very likely beyond the reach of most organizations at the time of invention of DES. Today,

however, such capability is attainable with networks of ordinary workstations. This was first demonstrated in 1997 when a successful attack was mounted against a DES-encrypted ciphertext by a network of thousands of computers over the course of 39 days, and subsequently duplicated by a single, special-purpose computer in less than a day. (It should be noted that even today, DES is still not easy to break without considerable resources.) Earlier concerns about the strength of DES had already prompted many organizations to employ a strengthened version involving application of DES operations not once but three times to each input block, and typically using two distinct DES keys. Known as triple-DES, this enhanced version offers considerably stronger security than DES, with what may be viewed as an effective key strength of up to 112 bits.

With DES in its basic form approaching the end of its serviceable lifetime, the cryptographic community began in 1999 to lend its efforts to the development of a new standard cipher to serve as a successor. The Advanced Encryption Standard or AES (pronounced letter by letter) emerged as the result of an open competition conducted by NIST. After a period of rigorous scrutiny by the research community and government agencies, a cipher known as Rijndael (of which one recognized pronunciation is “Rhine dahl”) was selected as the AES. Designed by two Belgian researchers, Joan Daemen and Vincent Rijmen, the AES promises to see widespread deployment in the United States and internationally in coming years. Rijndael is a block cipher designed to accommodate key lengths of 128, 196, or 256 bits and operate on data blocks of 128, 196, or 256 bits in any of the nine possible combinations. Rijndael, like many contemporary symmetric-key ciphers, is capable of very fast encryption—substantially faster than triple-DES. On a Pentium III running at 1 GHz, implementations of AES with 128-bit keys are capable of achieving an encryption speed of 50 MB/s. The code sizes for such implementations can be less than 1 kB. The size of a basic ciphertext yielded by AES, as with any block cipher, is roughly the size of the plaintext. A little extra space—less than the block size—may also be needed to accommodate added randomness and the fact the plaintext generally cannot be divided into data blocks of exactly the right size. See the NIST AES Web site for further information and links (National Institute of Standards and Technology, 2005).

Another symmetric-key cipher deserving discussion is RC4. In contrast to the block ciphers described above, RC4 is known as a stream cipher. It does not operate by encrypting individual blocks of data. Rather, the only input to RC4 is a key, typically 128 bits in length. The output of this cipher is a string of random-looking bits. This string may be made as long as desired by the user. To encrypt a message for Bob, Alice inputs a shared key to RC4 and generates a string as long as the message. Although not a one-time pad, this string is used by Alice to encrypt the message in exactly the same manner as a one-time pad, i.e., using the same system of bit alignment and flipping. Additionally, the output string of RC4 for a particular key has the “one-time” restriction, which is to say that the string can be safely used for encryption only once. The fact that RC4 can generate a string of arbitrary length,

however, means that different portions of the string can be used for different messages. Also, encipherment under RC4 is naturally capable of yielding a ciphertext identical in length to the plaintext.

This said, the output string of RC4 on a given key is not in fact a one-time pad, because it is not fully random. This may be seen in the fact that Alice and Bob know the process that generated the string, because they know their shared input key to RC4. In particular, they can write down a short set of instructions describing to someone else how to generate exactly the same output string from RC4. If  $k$  denotes their shared key, these instructions would simply say, "Give the key  $k$  as input to RC4." They could not do this in the case of a truly random string. Suppose, for instance, that Alice and Bob generated a shared random string, i.e., a one-time pad, by flipping a coin many times. If they gave the instructions "flip a coin" to Carol, it is almost certain that Carol, in following the same instructions, would generate a very different-looking string. Obviously, though, RC4 is much more convenient for Alice and Bob to use than a one-time pad, because it only requires of them that they share a key of, say, 128 bits in length. For all intents and purposes, this is true no matter how long the messages they wish to encrypt.

The security of the RC4 cipher comes from the fact that from the perspective of Eve, who does not know the key, the output of RC4 is indistinguishable from a one-time pad. This is to say that if Alice were to give an RC4 output string to Eve (rather than using it for encipherment), and were also to give Eve a truly random string of the same length, Eve would not be able to tell the difference. Thus, as far as Eve is concerned, when Alice and Bob encrypt their messages using RC4, they might as well be using a one-time pad. This, at any rate, is a rough expression of the conclusion that cryptanalysts have arrived at after many years of statistical study of the RC4 cipher. They express this belief by describing the output of RC4 as being pseudorandom. Strong block ciphers like AES are also believed to possess this property of pseudorandomness, but in a different form.

RC4 is of particular interest because it is one of the most commonly used ciphers in the world and included in the software in nearly every new PC sold today. It is generally a component of the SSL encryption system used for secure credit-card transactions on the Internet. In other words, the closed padlock on a browser screen mentioned earlier in this chapter indicates that the RC4 cipher is being used. RC4 was designed by Ronald L. Rivest, one of the co-inventors of the RSA cryptosystem, which we discuss later in this chapter. The letters "RC" stand for "Ron's Code," and the number '4' denotes Rivest's fourth cipher design. The design principal for RC4, like that of most symmetric ciphers, is a delicate sequencing of a few very basic mathematical instructions. In RC4, the operations are the swapping of integer elements in a small array representing a permutation and addition of small integers (in fact, modular addition, an operation explained later in this chapter). Others of Rivest's suite of cipher designs are also in common use, namely RC2, which forms the basis of many e-mail encryption programs, and also RC5. In addition to DES, triple-DES, AES, and the RC series,

there are a number of other popular ciphers used in various systems today. These include IDEA, CAST-128, and Blowfish, to name just a few.

## More on the Security of Symmetric-Key Encryption

As already explained, cryptologists know of a truly complete mathematical proof of security only for the one-time pad. For DES, triple-DES, AES, RC4, and kindred ciphers, cryptographers have no such security proofs. Strong proof for these ciphers is not possible at present; belief in their security, however, rests on fairly well-explored (if heuristic) mathematical foundations.

Shortly after the publication of DES, two cryptologists named Eli Biham and Adi Shamir developed a technique called differential cryptanalysis. Roughly speaking, differential cryptanalysis involves statistical analysis of a cipher based on the way particular bits change (or do not change) in output ciphertexts when bits in certain positions are flipped in input plaintexts. The technique of differential cryptanalysis helped to confirm the strength of DES and to inform the design of later ciphers. (Some time after the academic development of differential cryptanalysis, it was publicly revealed that the technique had already been familiar to the government intelligence community and had indeed helped guide the design of DES.) Subsequently developed cryptanalytic techniques have further enhanced the collection of tools available to the cryptanalyst, influencing new cipher designs in the process.

We have thus far been describing Eve as an inert eavesdropper, attempting to decipher the messages sent between Alice to Bob by harvesting and analyzing the ciphertexts they exchange. In fact, cryptologists also consider a range of ways in which Eve might try to tamper with or otherwise influence what messages Alice and Bob exchange in the hope of learning additional information. For example, if Alice encrypts all of her e-mail, then Eve might send a note containing a petition to Alice and ask Alice to forward it to her friends. If Alice sends the petition to Bob while Eve is eavesdropping, then Eve learns a ciphertext for which she herself has selected the corresponding plaintext. In other words, Eve is able to perform active experimentation on the cipher. If Alice and Bob use a cipher that is poorly designed, then Eve may be able to gain information about their key in this way or about messages they have exchanged with one another. This type of attack is known as a chosen-plaintext attack. It is an example of one of the types of attack against which cryptographers must ensure that their cipher designs are resistant.

Even if a cipher is well designed, it must still be used with great care. Consider another example. Suppose that Alice and Bob always use a strong block cipher such as AES with a random 128-bit key to encrypt their communications. They perform encryption simply by dividing their messages into blocks and encrypting each block individually under their key. But suppose further that Eve knows that Alice and Bob exchange stock tips, and that these regularly take the form of simple buy and sell orders. Eve might then pass some stock tips to Alice, such as "Buy ABC, Inc." and "Sell DEF Corp.," and suggest that these be

forwarded to Bob. If Eve eavesdrops while these stock tips are forwarded, then she learns what the corresponding ciphertexts look like. Thus, if Alice later sends the message “Buy ABC, Inc.” to Bob, Eve will be able to recognize the ciphertext and identify the corresponding buy or sell order. In other words, even though Alice and Bob are using a very strong cipher, Eve will be able to identify (and, effectively, to decrypt) any of a small set of target messages!

The way that Alice and Bob use a block cipher is known as a mode of operation. The naïve example we just described is known as electronic code book (ECB) mode, a form whose use is avoided today in part because of the problem we have just described. To prevent Eve from learning what particular ciphertexts look like, Alice may adopt a mode of operation that involves the introduction of random bits into the message. One popular mode of operation today is known as cipher-block-chaining (CBC) mode. In this system, Alice divides her plaintext into blocks and inserts some freshly generated random bits at the beginning to serve as the first block. Alice then employs a principle of “chaining” in which the encryption of one block is affected by the encryption of the previous one, thereby causing the randomness in the first block to propagate through the ciphertext. Although the architectural motivations behind this mode are somewhat complex, its basic impact on message privacy is easy to understand. The fact that Alice introduces randomness into her ciphertexts means that the same plaintext is not encrypted twice the same way, and thus that Eve cannot trick Alice so as to recognize the stock tips or other plaintexts that Alice encrypts. Other modes of encryption aim at formally achieving additional security aims like message authentication. In particular, they enable Alice and Bob to ensure that the origin of messages is legitimate, and that the messages do not include spurious insertions or modifications made by Eve.

## Encryption and Passwords

Symmetric-key ciphers are used not only to protect communications but also commonly to protect files against unauthorized access. Many users rely on encryption software to protect files on their hard drives against exposure to hackers or to protect sensitive data in case of laptop theft. For these purposes, it is common for the user to employ a password. The encryption software converts this password into a key for use with a standard symmetric-key cipher such as AES. Because users typically employ passwords consisting of or closely related to words in their native languages, there is generally less randomness in the key generated by a password than in a randomly generated symmetric key. One well-known means for a hacker to attack password-encrypted files in a particular encryption system, therefore, is to compile a large lexicon of common passwords. The hacker converts each entry in the lexicon into a symmetric key in the same manner as the encryption system and then uses each such key in a brute force attack against individual users employing that system. This is known as a dictionary attack. One way to reduce vulnerability to dictionary attacks is to use salt. This is a random string of bits generated for each password individually and combined with the password in the generation of a

symmetric key. The use of salt renders dictionary attacks more difficult, as it effectively forces an attacker to recompile the base lexicon for each target password. It should be understood nevertheless that salt is a limited countermeasure and does not compensate for poor selection of passwords.

Passwords are, of course, also the most common way for users to authenticate when logging into accounts over the Internet. In this context, however, the password is typically not used as an encryption key. Instead, the server to which the user is attempting to connect checks processed password information against a database entry for the requested account.

## PUBLIC-KEY CRYPTOGRAPHY

Many years of research have led to the widespread deployment of strong symmetric-key ciphers capable of high encryption speeds. One might be tempted to believe that the basic problem of private communications has been solved and that the science of cryptology has run its course. Even if a symmetric-key cipher is unbreakable, however, there remains a fundamental problem. We have assumed in our discussion that Alice and Bob share knowledge of a secret key. The question is: How do they obtain this key to begin with?

If Alice and Bob can meet face to face, in the absence of the eavesdropper Eve, then they may generate their shared key by repeatedly flipping a coin, or Alice may simply hand Bob a key written on a piece of paper or stored on a floppy disk. What if Alice and Bob wish to communicate privately over the Internet, however, without ever meeting? Alternatively, what if a commercial site on the Web wishes to enable any customer, new or old, to submit an order and credit card number securely from anywhere in the world? The administrator of the Web site cannot possibly hope to communicate keys in private to all customers before they log in. To simplify the formidable difficulties that secure key distribution can pose, cryptographers have devised a form of mathematical magic known as public-key encryption or cryptography (also known as asymmetric-key cryptography, in contrast to symmetric-key cryptography). Using public-key cryptography, Alice and Bob can send each other encrypted messages securely, even if they have never met and even if Eve has eavesdropped on all of their communications!

In a public-key cryptosystem, Alice possesses not one, but two keys. The first is known as her public key. Alice makes this key known to everyone; she may publish it on her Web page, in Internet directories, or in any other public place. Her second, mathematically related key is known as a private key. Alice keeps this key secret. She does not divulge it to anyone else, even people she wishes to communicate with privately. Together, the public key and private key are referred to as a key pair. Bob sends a private message to Alice by performing a computation using her public key and perhaps a private key of his own as well.

Public-key cryptography is a powerful tool—indeed, one whose feasibility may at first seem counterintuitive. Even if Eve knows Alice and Bob’s public keys, it is possible for Alice and Bob to communicate privately using

public-key cryptography. Moreover, with public-key cryptography, not only Bob but Carol or any other party can achieve private communication with Alice over a public communication medium such as the Internet.

## Diffie–Hellman Key Exchange

Public-key encryption was the brainchild of Ralph Merkle, who in 1974 conceived a plausible, but somewhat impractical, initial scheme. The idea saw its first practical form in 1976 in a seminal article by Whitfield Diffie and Martin Hellman entitled “New Directions in Cryptography.” Diffie and Hellman proposed a system in which Alice can combine her private key with the public key of Bob, and vice versa, such that each of them obtains the same secret key. Eve cannot figure out this secret key, even with knowledge of the public keys of both Alice and Bob. This system has come to be known as Diffie–Hellman key exchange, abbreviated D–H.

Diffie–Hellman exploits a form of mathematics known as modular arithmetic. Modular arithmetic is a way of restricting the outcome of basic mathematical operations to a set of integers with an upper bound. It is familiar to many schoolchildren as “clock arithmetic.” Consider a clock on military time, by which hours are measured only in the range from zero to 23, with zero corresponding to midnight and 23 to 11 o’clock at night. In this system, an advance of 25 hours on 3 o’clock brings us not to 28 o’clock, for example, but full circle to 4 o’clock (because  $25 + 3 = 28$  and  $28 - 24 = 4$ ). Similarly, an advance of 55 hours on 1 o’clock brings us to 8 o’clock (because  $55 + 1 = 56$  and  $56 - (2 \times 24) = 8$ ). In this case, the number 24, an upper bound on operations involving the measurement of hours, is referred to as a modulus. When a calculation involving hours on a clock yields a large number, we subtract the number 24 until we obtain an integer between 0 and 23, a process known as modular reduction. This idea can be extended to moduli of different sizes. For example, in the modulus 10, the sum of 5 and 7 would not be 12, which is larger than 10, but 2, because modular reduction yields  $12 - 10 = 2$ . We say that an arithmetic operation is modular when modular reduction is applied to its result. For example, modular multiplication is simply ordinary multiplication followed by modular reduction. We write  $\text{mod } p$  to denote reduction under modulus  $p$ . Thus, for example, it is easily seen that  $3 \times 4 \text{ mod } 10 = 2$ .

Diffie and Hellman proposed a public-key cryptosystem based on modular multiplication or, more precisely, on modular exponentiation, i.e., the repeated application of modular multiplication. Their scheme depends for its security on the use of a modulus that is a very large number. In the systems used today, the modulus is typically an integer that is 1024 bits in length, i.e., a little more than 300 decimal digits. It is also generally prime, which is to say that apart from the number 1, it is not divisible by any smaller integers. There are some additional, technical restrictions on the form of the modulus that we do not explore here.

The security of D–H is based on the following idea. Suppose that  $p$  is a large modulus and  $g$  is an integer less than  $p$  (again, with some additional technical restrictions). Suppose that Alice selects a random integer  $a$ , also

less than  $p$ . She then computes the integer  $y = g^a \text{ mod } p$  and gives the integers  $p$ ,  $g$ , and  $y$  to Eve. It is believed by cryptologists that with this information alone, it is infeasible for Eve to figure out the value  $a$ . The task of figuring out  $a$  is known as the discrete logarithm problem, one that has been the subject of many years of study by mathematicians and cryptographers. Although the security of D–H is not directly based on the discrete logarithm problem, it is very closely related.

In D–H, the values  $p$  and  $g$  are standard, public values. They may be conveyed in some widely distributed piece of software, such as a browser. Alice selects a random integer  $a$  less than  $p$  as her private key and computes  $y_{\text{Alice}} = g^a \text{ mod } p$  as her public key, i.e., the key that she publishes. Bob similarly selects a random integer  $b$ , also less than  $p$ , as his own private key and computes  $y_{\text{Bob}} = g^b \text{ mod } p$  as his public key. Using her secret key  $a$ , Alice can take the public key  $y_{\text{Bob}}$  and compute a value  $k = (y_{\text{Bob}})^a \text{ mod } p$ . Bob, similarly, can compute exactly the same value  $k$  using  $y_{\text{Alice}}$  in combination with his own private key  $b$ . In particular, it is also the case that  $k = (y_{\text{Alice}})^b \text{ mod } p$  (thanks to the commutative properties of modular exponentiation). Eve, however, cannot figure out the secret  $k$ . This, at least, is the belief of cryptologists, based on the idea that Eve knows neither of the private keys  $a$  or  $b$  and on the difficulty of the discrete logarithm problem. Thus, if Alice and Bob employ the secret  $k$  as the basis for private communication using a symmetric-key cipher such as AES, Eve will be unable to eavesdrop successfully on their communications. This is a capsule summary of the idea behind the Diffie–Hellman cryptosystem. There are other details involved in making D–H a secure, workable system, which we gloss over in this description. We also note in passing that an attractive feature of D–H is the fact that variants may be implemented over algebraic structures known as elliptic curves. This results in more compact key lengths and faster running times.

D–H is used, among other places, in some versions of PGP (Pretty Good Privacy), a popular piece of encryption software used to secure Internet communications such as e-mail and available as freeware in some versions.

## The RSA Cryptosystem

A year after the publication of Diffie and Hellman’s key exchange system, three faculty members at MIT proposed a new public-key cryptosystem. This cryptosystem is called RSA after its three inventors, Ronald Rivest, Adi Shamir, and Leonard Adleman. RSA is now the most widely deployed cryptosystem in the world (see RSA Laboratories, 2005).

Use of the RSA cryptosystem for encryption is very similar to that of D–H. One superficial difference is that in the RSA cryptosystem, Bob can send an encrypted message to Alice without having a public key of his own. In particular, Bob can encrypt a message directly under Alice’s public key in such a way that Alice can decrypt the ciphertext using her private key. Figure 2 diagrams this operation of RSA and similar public-key encryption schemes. (Much the same functionality can be achieved with D–H by having Bob generate a temporary key pair on the fly and using this as the basis for encryption of a message for Alice.)

**Figure 2:** Public-key encryption (e.g., RSA). Alice generates for herself a private key  $SK_A$  and corresponding public key  $PK_A$ . Suppose then that Bob wishes to transmit plaintext message  $m$  securely to Alice over a channel subject to eavesdropping. Bob encrypts  $m$  under public key  $PK_A$  to obtain ciphertext  $c$ , which he transmits to Alice. Eavesdropper Eve learns the ciphertext  $c$  and may also learn  $PK_A$ , as it is a public value. If the public-key encryption algorithm is well constructed and properly used, however, Eve should be unable to learn  $m$ .

There are two rather more important differences between the two cryptosystems. The first lies in the speed of their respective operations. In RSA, encryption is a very fast operation; it generally requires less computational effort than a D–H key exchange. Decryption, however, is several times slower for RSA than key exchange in D–H. Another important difference between the two is a feature present in RSA. RSA can also be used to perform digital signing, an operation not covered in this chapter, but of central importance in cryptography. Digital signing achieves the goal of authenticating messages, i.e., proving their origin, rather than concealing their contents.

The RSA system employs modular arithmetic, the same type of mathematical basis as for Diffie–Hellman key exchange. In D–H, the modulus is a published value that may be used by any party to construct his or her key pair. In RSA, however, every party uses a different modulus, published as part of his or her public key. Thus, if Bob wishes to encrypt a message for Alice, he uses a modulus  $N_{\text{Alice}}$  unique to the public key of Alice; if he wants to encrypt a message for Carol, he uses a different modulus,  $N_{\text{Carol}}$ . The reason for the use of different moduli is the fact that the value of the modulus in the RSA cryptosystem relates directly to that of the private key.

A modulus  $N$  in the RSA cryptosystem has a special form. It is the product of two large prime integers, generally denoted by  $p$  and  $q$ . In other words,  $N = p \times q$ . The pair of primes  $p$  and  $q$  are treated as private values in the RSA cryptosystem; they are used to compute the private key for the modulus  $N$ . Thus the security of RSA is related very closely to the difficulty of determining the secret primes  $p$  and  $q$  given knowledge of the modulus  $N$ . This is known as the problem of factoring and is believed to be extremely difficult when  $p$  and  $q$  are large. In typical systems today,  $p$  and  $q$  are chosen to be primes of about 512 bits in length, so that  $N$  is an integer of about 1024 bits, the same length as generally selected for a Diffie–Hellman modulus. Factoring is the only effective method known for attacking RSA when the cryptosystem is used properly.

Among its many other uses, the RSA cryptosystem (along with RC4) is used as the basis for SSL, the

encryption system in most Web browsers today, and also in some versions of PGP (Pretty Good Privacy) software.

## More Technical Detail on RSA

We now describe in more mathematical detail how the RSA cryptosystem works. Unable as we are to delve further into the underlying mathematics, we provide only prescriptive formulae, without explaining the rationale behind them. For further information, the reader is directed to a good textbook (e.g., Menezes, van Oorschot, & Vanstone, 1996).

To compute her public key, Alice selects two random primes,  $p_{\text{Alice}}$  and  $q_{\text{Alice}}$ , both of roughly equal length in bits, e.g., 512 bits long. The product

$$N_{\text{Alice}} = p_{\text{Alice}} \times q_{\text{Alice}}$$

is the modulus used by Alice in her public key. She also selects a small odd integer  $e_{\text{Alice}}$ ; generally, this value is more or less standardized in a given system, the integer 65535 being a common choice. An additional restriction on  $e_{\text{Alice}}$  is that it must not have a factor in common with  $p_{\text{Alice}} - 1$  or  $q_{\text{Alice}} - 1$ , a criterion considered in the selection of primes. Together, the pair of values  $(e_{\text{Alice}}, N_{\text{Alice}})$  constitutes Alice’s public key. Her private key is computed as follows. Let  $\Phi(N_{\text{Alice}}) = (p_{\text{Alice}} - 1) \times (q_{\text{Alice}} - 1)$ . Alice computes her private key, generally denoted by  $d_{\text{Alice}}$ , in such a way that  $e_{\text{Alice}} d_{\text{Alice}} = 1 \pmod{\Phi(N_{\text{Alice}})}$ . The bit-length of the private key  $d_{\text{Alice}}$  here is typically quite close to that of  $N_{\text{Alice}}$ .

A message in the RSA cryptosystem consists of a positive integer  $m$  less than  $N_{\text{Alice}}$ . To encrypt  $m$ , Bob computes the ciphertext

$$c = m^{e_{\text{Alice}}} \pmod{N_{\text{Alice}}}.$$

As a technical restriction required to achieve good security, the plaintext  $m$  is formatted so as to be about equal in length to the modulus, resulting in a ciphertext that is similarly so. To decrypt the ciphertext, Alice applies her private key and computes the following:

$$m = c^{d_{\text{Alice}}} \pmod{N_{\text{Alice}}}.$$

## An Example

Let us consider a small example to provide some flavor of how the RSA cryptosystem works. For illustrative purposes, we consider integers much smaller than those needed for true, secure use of RSA. Suppose that  $p_{\text{Alice}}$  and  $q_{\text{Alice}}$  are 5 and 11, respectively. Then  $N_{\text{Alice}} = 5 \times 11 = 55$ . Observe that  $e_{\text{Alice}} = 3$  does not divide  $p_{\text{Alice}} - 1$  or  $q_{\text{Alice}} - 1$ . Thus, Alice can use  $(e_{\text{Alice}}, N_{\text{Alice}}) = (3, 55)$  as her public key. A valid private key for Alice is  $d_{\text{Alice}} = 27$ , because  $\Phi(N_{\text{Alice}}) = (p_{\text{Alice}} - 1) \times (q_{\text{Alice}} - 1) = (5 - 1) \times (11 - 1) = 40$  and  $e_{\text{Alice}} \times 27 = 81 = 1 \pmod{40}$ .

To encrypt the message  $m = 7$ , Bob computes the ciphertext  $c = 7^3 \pmod{55} = 343 \pmod{55} = 13$ . Alice decrypts the ciphertext  $c = 13$  by computing  $13^{27} \pmod{55}$ . Using a pocket calculator, the reader can easily verify that the result of this decryption operation is indeed the original plaintext  $m = 7$ .

The security of RSA requires some special, technical restrictions on the value of  $m$ . In fact, as the RSA cryptosystem is generally employed, the message  $m$  is itself the key for a symmetric-key cryptosystem such as AES, and is specially formatted prior to encryption. Public-key cryptosystems are generally used in conjunction with symmetric-key cryptosystems, as we discuss below.

With a 1024-bit RSA modulus, a Pentium III running at 1 GHz can perform roughly 40 RSA decryption operations per second, and about 600 encryption operations per second under the public exponent  $e = 65535$ . (These speeds, of course, depend critically on the particular software implementation.)

As explained above, the security of the RSA cryptosystem is closely related to the difficulty of factoring the product of two large primes. Security guidelines for RSA thus depend on advances in the factoring problem made by researchers, as well as the cost and availability of computing power to a potential attacker. According to guidelines issued in 2003 by NIST, 1024-bit RSA moduli may be used to secure data whose privacy needs to be assured until the year 2015. For more sensitive data, a 2048-bit RSA modulus is recommended instead. Although there is substantial debate and uncertainty among cryptographers as to the exact ongoing security level afforded by RSA, there is general agreement as to the rough accuracy of these predictive guidelines. To avoid a common misconception, it should be emphasized that the mathematical basis for the RSA cryptosystem means that the recommended modulus lengths, and thus the public and private keys, are substantially longer than the 128- to 256-bit key lengths prescribed for symmetric-key ciphers.

## How Public-Key Encryption Is Used

Encryption of a large quantity of data is generally much slower using a public-key cryptosystem than using a symmetric-key cipher. On the other hand, public-key encryption offers an elegant approach to the problem of distributing keys that is unavailable in symmetric-key ciphers. It is common in practice, therefore, to combine the two types of encryption systems to obtain the best properties of both. This is achieved by use of a simple principle known as enveloping. Enveloping involves use of a public-key cryptosystem such as RSA as a vehicle for transporting a secret key, which is itself then used for encryption with a symmetric-key cipher. To send a megabyte-long file to Alice, for example, Bob might select a random 128-bit RC4 key  $k$  and encrypt the file under  $k$ . He would then send this ciphertext of the file to Alice, along with an RSA encryption of  $k$  under Alice's public key. In effect, enveloping is a way of making a public-key cryptosystem faster. Enveloping yields much the same data flows as in Figure 2. The only difference is that a symmetric key  $k$  is encrypted rather than an ordinary plaintext  $m$ ; in addition to the public-key ciphertext  $c$ , Bob also transmits a symmetric-key ciphertext  $c'$ , namely the message  $m$  encrypted under  $k$  using a symmetric-key cipher.

As with symmetric-key ciphers, cryptologists aim to design public-key cryptosystems to withstand a wide range of possible attacks, including some very strong ones in which Eve can persuade Alice to decrypt a range of ciphertexts that Eve herself selects. Like symmetric-key block

ciphers, when used in a naïve manner, RSA has a limitation in that encryption of the same plaintext always yields the same ciphertext; it also has the additional weakness of leaking some bits of a plaintext. Prior to encryption under RSA, therefore, it is common practice to subject a message to a special type of formatting that involves the addition of random bits. Loosely speaking, this incorporation of randomness serves much the same purpose as in the case of cipher-block chaining for symmetric-key block ciphers, as described above. Other aspects of the formatting process permit the RSA cryptosystem to withstand other forms of attack, and to do so with guarantees that are subject to rigorous mathematical justification.

Most public-key encryption systems have an additional advantage over symmetric-key systems in that they permit a flexible approach to distributed storage of the private key, known as secret sharing. This is a way of mathematically splitting a private key into a number of elements known as shares. To achieve a decryption operation, each of these shares may be applied individually to a ciphertext, without the need to assemble the shares themselves in a single place. Thus, a cryptosystem can be set up so that compromise of any one share does not expose the full decryption key itself. For example, Alice can divide her private key into, say, three shares, keeping one for herself and giving one each to her friends Bob and Carol. To decrypt a ciphertext, Alice can ask Bob and Carol to apply their shares and to send her the result. Alice can then complete the decryption with her own share, without Bob or Carol seeing the resulting plaintext. If an attacker breaks into Alice's computer and obtains her share, the attacker will still be unable to decrypt ciphertexts directed to Alice (without also obtaining the assistance of Bob and Carol). The system can even be set up so that decryption is possible given particular sets of shares. Thus, for example, Alice might be able to achieve decryption of her ciphertexts even if Bob or Carol is on vacation.

Despite its great flexibility, public-key cryptography does not directly address all of the challenges of key distribution. For example, we have said that Alice can safely disseminate her public key as widely as she likes, publishing it in Internet directories and so forth. But when Bob obtains a copy of Alice's public key, how does he really know it belongs to Alice and is not, for example, a spurious key published by Eve to entrap him? To solve problems of this kind, we appeal to a public-key infrastructure (PKI), as explained in detail in the chapter on that topic. Another issue worth mentioning—and a pitfall for many system designers—is the problem of finding an appropriate source of randomness for generating keys. Good generation of random bits is the cornerstone of cryptographic security and requires careful attention.

A final problem that encryption alone does not solve is that of message integrity. When Bob sends a message to Alice encrypted using, for example, RC4, he may be reasonably well assured of the privacy of his communication if he uses the cipher correctly. When Alice receives his message, however, how does she know that Eve has not tampered with the message en route, by changing a few bits or words? Indeed, how does she even know that Bob is the one who sent the message? For this type of assurance, some additional cryptographic apparatus is required in the form of a message authentication code or a

digital signature. These are techniques for applying a key to a message to obtain an unforgeable “fingerprint” that shows evidence of any tampering.

## CONCLUSION: FURTHER READING

The reader interested in more detailed treatment of the topics discussed here need go no further than this encyclopedia. Subsequent chapters offer details on symmetric-key cryptography, including the ciphers DES and AES, on public-key cryptography, and also on more advanced topics such as hash functions, elliptic curves, and identity-based cryptography. This encyclopedia also contains chapters on the selection and management of cryptographic keys, as well as the design of cryptographic protocols, that is, systems that build on encryption techniques to achieve complex aims such as electronic voting and digital rights management (DRM).

Two broad and accessible introductory books on the field of cryptology are *Applied Cryptography*, by Bruce Schneier (2002a), and the online compendium *Frequently Asked Questions About Today's Cryptography* (RSA Laboratories, 2005). A more detailed technical treatment of cryptographic techniques and concepts, along with an extensive bibliography, may be found in the excellent *Handbook of Applied Cryptography*, by Alfred J. Menezes, Paul C. van Oorschot, and Scott A. Vanstone (Menezes et al., 1996). Detailed information on the AES algorithm (Rijndael) is available in *The Design of Rijndael*, by Joan Daeman and Vincent Rijmen (2002).

Readers interested in the practical application of cryptography in real-world systems may wish to consult *Network Security: Private Communication in a Public World*, by Charles Kaufman, Radia Perlman, and Mike Speciner (2002), and *Cryptography and Network Security: Principles and Practice*, by William Stallings (2002). For a more comprehensive view of security engineering, an excellent work is Ross Anderson's *Security Engineering: A Guide to Building Dependable Distributed Systems* (2002). Of similar interest is Bruce Schneier's *Secrets and Lies* (Schneier, 2002b), which offers some caveats regarding the limitations of cryptography and other security tools.

A good introductory textbook of a more academic flavor is *Cryptography: Theory and Practice*, by Douglas Stinson (2002). For information on the foundational mathematics and theory of cryptology, an important work is *Foundations of Cryptography: Basic Tools*, an evolving series of volumes by Oded Goldreich (2000, 2004); a second volume, entitled *Foundations of Cryptography: Basic Applications* (2004), is forthcoming in 2004. For a historical overview of cryptology, the classic text is *The Codebreakers*, by David Kahn (1996). More up-to-date, although less exhaustive, is *The Science of Secrecy from Ancient Egypt to Quantum Cryptography*, by Simon Singh (2000).

The use and export of products containing strong cryptographic algorithms were at one time strongly restricted by regulations of the United States government and other nations. The United States government dramatically relaxed its restrictions in 2000, however, as did many other nations at around the same time. Some countries, such as China, still retain strong regulations around both domestic use and import and export of cryptographically

enabled products. Although regulations treating the use of cryptography are in frequent flux, readers may refer to the Electronic Privacy Information Center (2005) for historical and some current information on this topic.

Cryptologists continue to devote effort to the development of new symmetric ciphers and public-key cryptosystems, as well as the improvement of existing ones. Although encryption is the fountainhead of contemporary cryptology, it is by no means the only focus of the field. As is the case with many branches of science, cutting-edge inventions in cryptology often lie dormant for years or decades before their widespread use. The scope of cryptologic research today extends beyond the problems of message privacy and integrity to the goal of achieving fair play in electronic environments in a much broader sense. Secure electronic voting, online privacy protection, and digital rights management are just a few of the many areas where researchers in cryptography have made strides in recent years. At the frontiers of cryptology are ideas involving the use of quantum mechanics and even DNA for attacking ciphers. Many cryptologists are members of the International Association for Cryptologic Research (IACR), whose home page (IACR, 2005) lists publications and conferences devoted to advanced current research in cryptography and cryptanalysis.

## GLOSSARY

**AES** The Advanced Encryption Standard, a symmetric-key cipher known as Rijndael, serving as successor to DES.

**Asymmetric** In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and D-H are examples of asymmetric systems. *Asymmetric* is synonymous with *public-key*.

**Ciphertext** The data conveying an encrypted message.

**Cryptanalysis** The science of analyzing weaknesses in cryptographic systems.

**Cryptography** The science of constructing mathematical systems for securing data.

**Cryptology** The combination of the complementary sciences of cryptography and cryptanalysis.

**Cryptosystem** A complete system of encryption and decryption, typically used to describe a public-key cryptographic system.

**Decryption** The process of obtaining a readable message (a *plaintext*) from an encrypted transformation of the message (a *ciphertext*).

**DES** The Data Encryption Standard, an existing form of symmetric cipher in wide use today, often in a strengthened variant known as triple DES.

**Diffie-Hellman (D-H)** A public-key cryptosystem used to exchange a secret (symmetric) key.

**Encryption** The process of rendering a message (a *plaintext*) into a data string (a *ciphertext*) with the aim of transmitting it privately in a potentially hostile environment.

**Enveloping** A method for using a symmetric-key cipher in combination with a public-key cryptosystem to exploit simultaneously the advantages of the two respective systems.

**Key** A short data string parameterizing the operations within a cipher or cryptosystem, and whose distribution determines relationships of privacy and integrity among communicating parties.

**Key pair** The combination of a public and private key.

**Plaintext** A message in readable form, prior to encryption or subsequent to successful decryption.

**Private Key** In an asymmetric or public-key cryptosystem, the key that a communicating party holds privately and uses for decryption or completion of a key exchange.

**Public Key** In an asymmetric or public-key cryptosystem, the key that a communicating party disseminates publicly. In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and D-H are examples of public-key systems. *Public-key* is synonymous with *asymmetric*.

**RC4** A symmetric-key cipher of the type known as a stream cipher. Used widely in the SSL (secure sockets layer) protocol.

**RSA** A public-key cryptosystem in very wide use today, as in the SSL (secure sockets layer) protocol. RSA can also be used to create and verify digital signatures.

**Symmetric** A type of cryptographic system in which communicating parties employ shared secret keys. The term is also used to refer to the keys employed in such a system.

## INTRODUCTION

*Symmetric key* encryption schemes (also variously known as *secret key*, *private key*, or *shared key* encryption schemes for reasons that will become clear in a moment) allow users who have previously agreed on a shared, secret key to ensure the secrecy of their communication. A prototypical example might be two soldiers who wish to communicate securely while they are in the battlefield. Before heading to the battlefield (say, while they are together on base), these two soldiers can generate and share a random key  $k$ , which they will keep secret from everyone else. Later, when they are in the battlefield, these soldiers can use the common key  $k$  they have shared to communicate securely. In particular, when one soldier (the “sender”) wishes to send a message  $M$  (sometimes also called the *plaintext*) to the other (the “receiver”), she will *encrypt*  $M$  using some symmetric key encryption scheme and the shared key  $k$ ; this results in a *ciphertext*  $C$ , which is transmitted to the receiver. When the receiver obtains  $C$ , he will *decrypt* it—again using the key  $k$ —to recover the original message  $M$ . Roughly speaking (and we will see more formal definitions later), a “good” encryption scheme satisfies the property that any passive eavesdropper who observes the transmitted ciphertext  $C$  learns nothing about the underlying message  $M$  (i.e., the secrecy of  $M$  is ensured).

A number of quick observations are in order. First, because both parties hold the same key that is used for both encryption and decryption, either party can send messages securely to the other party; there is thus no fundamental distinction between which party is the “sender” and which is the “receiver” (as either party may take on either role), and this motivates the terminology “symmetric key” encryption. Because the same key is used for both encryption and decryption, however, it is clearly crucial that the shared key be kept *completely secret* from any potential adversary or eavesdropper who might try to recover  $M$  from the observed ciphertext  $C$ . Less obvious, but still a consequence of the above, is that the shared key must be

chosen *completely at random*; otherwise, an eavesdropper can “guess” partial information about the key with high probability and then potentially learn some information about the underlying message  $M$ .

## Symmetric Key Encryption Versus Public Key Encryption

It is instructive to compare symmetric key encryption to public key encryption and to discuss briefly the relative advantages of each. (The reader is referred to the Chapter “Key Management” for further discussion of public key algorithms.) In the public key setting, a potential receiver first generates a pair of keys ( $PK, SK$ ):  $PK$  represents a public key that is widely disseminated, whereas  $SK$  is a secret key that is kept private by the receiver. To send a message  $M$  to this receiver, a sender encrypts  $M$  using  $PK$  to generate a ciphertext  $C$ , which is then transmitted to the receiver. The receiver decrypts  $C$  using  $SK$  to recover the intended message  $M$ .

A clear difference is that public key encryption is inherently *asymmetric*: the keys used by the sender and receiver are different, and thus secret communication can occur in one direction only. (This can be addressed in any of a number of ways, but the point is that a single invocation of a standard public key encryption scheme forces a distinction between one user who will act as a receiver and other users who will act as senders.) Furthermore,  $PK$  is not kept secret from a potential eavesdropping adversary—the message remains indecipherable to an eavesdropper who obtains  $C$  even if this adversary also knows  $PK$ . A summary of the differences between symmetric key and public key encryption is given in Table 1.

It may appear at first glance that public key encryption has a clear advantage over symmetric key encryption in that it does not require any secret distribution of keys prior to communication. More generally, any public key encryption scheme can be used as a symmetric key encryption scheme by simply having parties share (secretly) both  $PK$  and  $SK$ . However, symmetric key encryption has

**Table 1** Summary of Differences Between Symmetric and Public Key Encryption.

Symmetric Key	Public Key
Key $k$ shared by both parties	Key $PK$ known by sender; key $SK$ known by receiver
$k$ used for encryption/decryption	$PK$ used for encryption; $SK$ used for decryption
Secrecy of $k$ essential for security	Encryption “secure” even though $PK$ not secret

at least two primary advantages as compared to public key encryption:

1. Perhaps most importantly, symmetric key encryption is roughly 2–3 orders of magnitude faster than public key encryption (it is difficult to give an exact comparison because the exact efficiency advantage depends on a number of implementation details). In fact, symmetric key encryption is essentially always used in practice in the public key setting to yield improved efficiency for the (public key) encryption of bulk data; this is discussed further under “Hybrid Encryption.” A thorough understanding of symmetric key encryption is therefore crucial to fully appreciate how encryption (of either type) is implemented in practice.
2. Symmetric key encryption provides a simple and immediate way to establish a secure “point-to-point” channel between two parties. In particular, in addition to ensuring secrecy a symmetric key scheme potentially allows each party to ensure that the communications it receives indeed originate from the other party (as discussed briefly under “Stronger Definitions of Security”). Such functionality is somewhat more difficult to achieve in the public key setting.

In contrast, public key encryption does offer the following advantages:

- We have already mentioned that public key encryption solves (to some extent) the *key distribution problem* in that the communicating parties do not need to secretly share a key in advance of their communication. Thus, public key encryption is potentially more powerful in that it allows two parties to communicate secretly even if *all* communication between them is monitored.
- Consider the scenario in which it is desired to establish secure channels between every pair of users in a network of size  $n$ . Using symmetric key techniques, this will require a total of  $\binom{n}{2} = O(n^2)$  keys (one for each pair of parties). If public key cryptography is used, however, this can be reduced to a total of only  $n$  keys.

Because the focus of this chapter is on the symmetric key setting, “encryption scheme” will be used to refer to a symmetric key encryption scheme unless explicitly stated otherwise.

## Basic Notation and Definitions

The above discussion has been relatively informal and in particular has not included a careful and formal definition of what it means for a symmetric key encryption scheme

to be “secure.” Before we turn to this problem in the sections that follow, we first introduce some basic definitions.

Let  $\{0, 1\}^\ell$  denote the set of binary strings of length  $\ell$ .

**Definition 1** A symmetric key encryption scheme is defined by a key space  $\mathcal{K}$ , a message space  $\mathcal{M}$  with  $|\mathcal{M}| > 1$ , and two (efficient) algorithms: the encryption algorithm  $\mathcal{E}$  and the decryption algorithm  $\mathcal{D}$ . The latter have the following functionality:

- The encryption algorithm  $\mathcal{E}$  takes as input a key  $k \in \mathcal{K}$  and a message  $M \in \mathcal{M}$  and outputs a ciphertext  $C$ ; this is denoted by  $C \leftarrow \mathcal{E}_k(M)$ .
- The decryption algorithm  $\mathcal{D}$  takes as input a key  $k \in \mathcal{K}$  and a ciphertext  $C$  and outputs a message  $M \in \mathcal{M}$ . We write this as  $M := \mathcal{D}_k(C)$ .

We require that for all  $k \in \mathcal{K}$  and all  $M \in \mathcal{M}$  we have  $\mathcal{D}_k(\mathcal{E}_k(M)) = M$ .

Note that the above definition describes only the semantics of symmetric key encryption; it does not say anything about security.

Following the above notation, a symmetric key encryption scheme is utilized as follows: First, a key  $k$  is chosen uniformly at random from the key space  $\mathcal{K}$  and shared by two parties. When one of these parties wants to send a plaintext message  $M \in \mathcal{M}$  to the other party, this party computes  $C \leftarrow \mathcal{E}_k(M)$  and transmits  $C$ . Upon receiving  $C$ , the second party recovers the initial message by computing  $M := \mathcal{D}_k(C)$ . As expected, because they use the same key  $k$ , the message recovered by the second party is the one intended by the first party.

A few remarks about the above definition are in order:

- Except for some “classical” encryption schemes and their weaknesses we make the simplifying assumption that the key space  $\mathcal{K}$  consists of all binary strings of some fixed length; that is,  $\mathcal{K} = \{0, 1\}^s$  for some  $s$ .
- In an effort to simplify more formal definitions (see, e.g., Bellare, Desai, Jorikii, & Rogaway, 1997; Goldreich, 2004; Katz & Yung, 2000), we do not define what it means for  $\mathcal{E}$  and  $\mathcal{D}$  to be “efficient.” A number of other simplifications were also made, but the interested reader is referred to the listed references for more details.
- We have used the notation  $C \leftarrow \mathcal{E}_k(M)$  to represent the fact that the encryption algorithm may be randomized (see further discussion under “A Stronger Notion of Security”) and thus running  $\mathcal{E}_k(M)$  multiple times may yield a different ciphertext each time. In contrast, we assume the decryption algorithm is deterministic without much loss of generality.

## SOME “CLASSICAL” ENCRYPTION SCHEMES AND THEIR WEAKNESSES

It is instructive to begin with some examples of “classical” symmetric key encryption schemes, both to get a feel for how symmetric key encryption works as well as to see why constructing a “secure” encryption scheme is harder than it might first appear. In the descriptions that follow, we consider the alphabet  $\Sigma$  consisting of all capital English letters (i.e.,  $\Sigma = \{A, \dots, Z\}$ ) and the message space will be all strings over this alphabet. We also use the fact that we can map letters in  $\Sigma$  in the natural way (i.e.,  $A = 0, B = 1, \dots$ ) to the numbers from 0 through 25, inclusive. The *shift cipher* is about the simplest scheme one might consider. In this scheme, the key is an arbitrary letter chosen from  $\Sigma$ . To encrypt a message  $M = \sigma_1 \dots \sigma_n$ , where each  $\sigma_i \in \Sigma$ , we simply “add” the key to each letter of the message, working modulo  $|\Sigma| = 26$  (so that, for example,  $Z + B = A$ ). To decrypt, we simply reverse the process and subtract the key from each letter of the ciphertext. As an example, using this scheme to encrypt the message “HELP” with the key “D” gives the ciphertext “KHOS” and it is clear that decryption of this ciphertext using the same key will recover the original message.

It is not very difficult to see that the security provided by the shift cipher is quite weak. An adversary, faced with a ciphertext corresponding to some unknown message, can simply try decrypting this ciphertext using all possible values of the secret key. Because there are only 26 possible keys, this will not take exceedingly long. Furthermore, it is likely (especially for longer messages) that only one key will decrypt the ciphertext to a meaningful message (for instance, this is the case for the ciphertext “KHOS” considered above), in which case the adversary can determine with reasonable likelihood the message that was sent.

This type of attack—in which an adversary tries decrypting a ciphertext using all (or many) possible keys—is called an *exhaustive key-search attack*. Obviously, one way for a symmetric key scheme to be secure against such an attack is for the key space to be large enough so that searching through all keys is infeasible. A larger key space, however, is not enough to guarantee security of a scheme. To see this, consider the *substitution cipher* in which the key is an arbitrary permutation of  $\Sigma$ . A permutation of  $\Sigma$  can be given by simply listing the elements of  $\Sigma$  in two rows, once in the “regular” order and once in an arbitrary order, for example:

$$\begin{array}{cccc} A & B & C & \dots & Z \\ F & T & Z & \dots & X \end{array}$$

If the above represents a permutation  $\pi$ , then we have  $\pi(A) = F, \pi(B) = T$ , and so on. We can also compute the inverse mapping  $\pi^{-1}$ ; for example,  $\pi^{-1}(X) = Z$ . In this scheme, encryption of a message  $M = \sigma_1 \dots \sigma_n$  using a key  $\pi$  results in the ciphertext  $C = \pi(\sigma_1) \dots \pi(\sigma_n)$ . Decryption of a ciphertext  $C = \sigma'_1 \dots \sigma'_n$  using key  $\pi$  is performed as one might expect by simply computing the message  $M = \pi^{-1}(\sigma'_1) \dots \pi^{-1}(\sigma'_n)$ .

The number of permutations of  $\Sigma$  is  $26!$  and so the key space of the substitution cipher is clearly much larger than the key space of the shift cipher. (Although it would not

be difficult for a modern computer to search through  $26!$  keys, it would be difficult to search through this many keys by hand.) Nevertheless, the substitution cipher is not very secure; indeed, the substitution cipher is used for making puzzle “cryptograms” in newspapers! In particular, one feature of this encryption scheme is that it preserves letter frequencies; that is, if a given letter  $x$  occurs some fraction of the time in the plaintext message, then there will be some letter  $\pi(x)$  that occurs with the same frequency in the ciphertext. When the plaintext is reasonably long, this begins to “leak” information about the key and the message. For example, it is well-known that in normal English text the letter  $E$  occurs more often than any other letter. So, an adversary might guess that the letter occurring most often in the ciphertext corresponds to the plaintext letter  $E$ . Using additional information about English letter frequencies, as well as frequencies of digrams (consecutive letters) and trigrams (three consecutive letters), the adversary can gradually learn information about the message without the need to exhaustively search through all possible keys.

## “PERFECT” SECURITY AND ITS LIMITATIONS

The brief discussion of some classical cryptosystems in the previous section generates the following observations and questions, which we hope will serve as motivation for the remainder of this chapter. First, *designing good cryptographic algorithms is hard*; for this reason, one should avoid designing “home-brew” cryptographic algorithms without having first developed the requisite expertise in cryptography. Moreover, the attacks described in the previous section raise another concern: *how does one identify when an encryption scheme is secure?* This is a fundamental question, as, clearly, it is undesirable to deploy an encryption scheme that might be broken by an adversary more clever than the designer of the scheme. This hints at a more basic question: *what does it mean for a scheme to be secure?* (Alternately, how do we know that the substitution cipher, say, does not qualify as a “secure” scheme?) Before we delve into the design of “secure schemes,” we first more carefully study different definitions of what it might mean for a scheme to be “secure.” It is important to stress here that a number of different security definitions are possible, and so—in general—saying that a scheme is “secure” is meaningless unless one also specifies the definition with respect to which security holds.

The most basic goal of an encryption scheme is to preserve the secrecy of  $M$  in the presence of an eavesdropping adversary who learns  $C = \mathcal{E}_k(M)$  (but does not know  $k$ !). We stress that the adversary is assumed to know the full details of the encryption scheme used (i.e., the adversary knows the encryption algorithm  $\mathcal{E}$  being used by the parties); the only information the adversary does *not* know is the secret key  $k$ . Indeed, following Kerckhoffs’s rule (Kerckhoffs, 1883), a “good” encryption scheme should be secure even under this assumption; furthermore, designing a scheme to be secure “only” when the details of the scheme are not revealed to an adversary usually results in a weak scheme that is soon broken.

It remains only to formally specify what “preserving the secrecy of  $M$ ” means. One, perhaps natural, possibility is to require that an eavesdropping adversary who observes  $C$  cannot determine the message  $M$ . However, this definition is easily seen to be too weak because an encryption scheme that completely reveals, say, the first half of  $M$  (but that “securely encrypts” its second half) would potentially meet this definition. Of course, when the first half of the message is the critical half such an encryption scheme is useless! Additionally, it is unclear what this definition requires in the case of small message spaces (or, equivalently, large message spaces but where the adversary has some *a priori* knowledge about what messages are likely to be sent). For the message space  $\mathcal{M} = \{\text{“yes”}, \text{“no”}\}$ , for example, an adversary who simply guesses which message was encrypted will be correct half the time!

A much stronger definition of secrecy—termed *perfect secrecy*—was proposed by Shannon (Shannon, 1949) and forms the starting point for more modern definitions. Informally, a symmetric key encryption scheme achieves perfect secrecy if an eavesdropping adversary who observes the ciphertext  $C$  learns *no information whatsoever* about the communicated message  $M$  (note that this rules out schemes such as the one described earlier which leak the first half of  $M$ ). In particular, even if the adversary knows in advance that the message is one of two possibilities (say, “yes” or “no” as above), the adversary does not learn which of these is the actual message upon observing  $C$ .

Because the original definition (Shannon, 1949). Is somewhat complex, we omit the details here. However, the following, simpler definition—which considers exactly the case in which the adversary “knows” that the message is one of two possibilities—can be shown to be equivalent to the original definition.

**Definition 2** An encryption scheme  $(\mathcal{E}, \mathcal{D})$  over key space  $\mathcal{K}$  and message space  $\mathcal{M}$  achieves perfect secrecy if for all  $M_1, M_2 \in \mathcal{M}$  and all eavesdropping adversaries  $A$ , the probability (over choice of key  $k \in \mathcal{K}$ ) that  $A$  guesses “ $M_1$ ” when it observes an encryption of  $M_1$  is equal to the probability that  $A$  guesses “ $M_1$ ” when it observes an encryption of  $M_2$ .

That is, no eavesdropper  $A$  can distinguish between the case that  $M_1$  is encrypted and the case that  $M_2$  is encrypted, even when  $A$  knows that the message must be one of these possibilities.

## Achieving Perfect Secrecy

Perfect secrecy can be achieved by the so-called *one-time pad* encryption scheme (Vernam, 1926), which is defined as follows. Let the message space  $\mathcal{M}$  be identified with  $\{0, 1\}^\ell$  (i.e., the set of all binary strings of length  $\ell$ ) for an arbitrary  $\ell > 0$ . The key space  $\mathcal{K}$  is identical to the message space. To encrypt an  $\ell$ -bit message  $M \in \mathcal{M}$  using an  $\ell$ -bit key  $k \in \mathcal{K}$ , the sender computes  $C := M \oplus k$ , where  $\oplus$  denotes the bitwise exclusive-or (xor) operation (i.e., the  $i$ th bit of  $C$  is equal to the xor of the  $i$ th bits of  $M$  and  $k$ ). To decrypt ciphertext  $C$ , the receiver computes  $M := C \oplus k$ . Note that this indeed recovers the original message because

$$C \oplus k = (M \oplus k) \oplus k = M \oplus (k \oplus k) = M,$$

where we use the fact that any string xor’ed with itself gives the all-zero string.

To prove that this scheme achieves perfect secrecy we need only observe that, over random choice of  $k \in \{0, 1\}^\ell$ , the ciphertext  $C$  is a uniformly distributed,  $\ell$ -bit string regardless of the message being encrypted. In other words, for *any*  $M \in \mathcal{M}$  the ciphertext  $C$  is uniformly distributed when  $k$  is chosen uniformly at random from  $\mathcal{K}$ . (As proof, let  $\Pr_{k \in \{0, 1\}^\ell}[C = \hat{C} | M]$  denote the probability, over choice of  $k$ , that the ciphertext  $C$  is equal to some arbitrary, fixed  $\ell$ -bit string  $\hat{C}$  when  $C$  is an encryption of  $M$ . Then for any  $\hat{C}, M$  we have  $\Pr_{k \in \{0, 1\}^\ell}[C = \hat{C} | M] = \Pr_{k \in \{0, 1\}^\ell}[k = M \oplus \hat{C}]$ , and this last expression is equal to  $1/2^\ell$  because  $k$  is uniformly distributed.) Because the (distribution of the) observed ciphertext  $C$  is independent of the message  $M$  being encrypted, the ciphertext reveals no information whatsoever about  $M$  and hence Definition 2 is satisfied for any algorithm  $A$ . A formal proof follows easily from this somewhat informal argument.

## Limitations of Perfect Secrecy

The one-time pad encryption scheme, though it achieves perfect secrecy, does have a number of limitations. First, the shared key  $k$  is as long as the message  $M$ . In addition to being inefficient, this also requires the length of the message (or at least an upper bound on the message length) to be known in advance at the time the key is generated and shared. Furthermore, the one-time pad encryption scheme is *completely insecure* when it is used to encrypt more than one message using the same key (hence the name “one-time” pad): if an adversary intercepts  $C_1 = M_1 \oplus k$  and  $C_2 = M_2 \oplus k$ , then the adversary can compute  $C_1 \oplus C_2$ , which is equal to  $M_1 \oplus M_2$ . Given this information, the adversary can then learn partial information about the two encrypted messages (and, in particular, learn the bit positions where  $M_1$  and  $M_2$  differ). Even worse, if the adversary happens to know  $M_1$  (say, because of some *a priori* information) it can then derive the key by computing  $k = C_1 \oplus M_1$  and then decrypt any messages sent in the future using the same key. This latter attack extends similarly even if the adversary knows only partial information about  $M_1$  (in which case it may then learn corresponding partial information about  $M_2$ ).

Unfortunately, the following theorem shows that the above limitations are inherent (Shannon, 1949):

**Theorem 1** Any encryption scheme achieving perfect secrecy requires the key space  $\mathcal{K}$  to be at least as large as the message space  $\mathcal{M}$ . In particular, if keys and messages all have some fixed length then the key must be at least as long as the total length of all encrypted messages.

Without giving a formal proof, we discuss the intuition which is quite straightforward. Consider the case of an encryption scheme with key space  $\{0, 1\}^{\ell_1}$  and message space  $\{0, 1\}^{\ell_2}$  with  $\ell_2 > \ell_1$  and focus on the encryption of a single message. In this case, before observing the ciphertext an adversary may have no information about which message is being sent and thus all  $2^{\ell_2}$  messages are possible. After observing a ciphertext, however, an adversary can compute  $M := \mathcal{D}_k(C)$  for all  $k \in \mathcal{K}$  and thus narrow down the

space of possible messages to only  $2^{\ell_1} < 2^{\ell_2}$  possibilities. This means that the adversary has learned some information about the message, in contradiction of the stringent requirements of perfect secrecy.

We also remark that “perfect *secrecy*” does not imply “perfect *security*”! In particular, as discussed above, the one-time pad encryption scheme is *not* secure in the sense of Definition 5, below, which refers to secrecy following the encryption of multiple plaintext messages. Finally, the one-time pad encryption scheme is not at all secure with respect to even stronger definitions of security such as those briefly mentioned under “stronger definitions of security.”

To summarize: we have introduced the notion of perfect secrecy, shown that the one-time pad encryption scheme achieves this notion, and then proved that this scheme is, in fact, optimal as far as perfect secrecy is concerned. Does this end our discussion of symmetric key encryption? Not by a long shot. Perfect secrecy is, on the one hand, too weak in that it does not ensure secrecy when multiple messages are encrypted (with the same key) and does not satisfy stronger notions of security such as those considered under “stronger definitions of security.” On the other hand, perfect secrecy is too strong in that it requires secrecy even against *all* adversaries (and, in particular, even adversaries having arbitrarily high computational power), which is simply not necessary in practice. Indeed, we will see that by (slightly) relaxing the definition it is possible to circumvent the limitations outlined above. This is fortunate because the limitations of the one-time pad—especially the restriction that it is secure only when used to encrypt a single message—make it undesirable for use in almost all practical situations.

## COMPUTATIONAL NOTIONS OF SECURITY

As discussed in the previous section, one of the drawbacks of the notion of perfect secrecy is that it requires secrecy to hold even against “all-powerful” adversaries having unbounded computational power and running for an unlimited amount of time. Here, we explore so-called *computational* notions of security that focus on ensuring security “only” against adversaries having some (reasonable) bound on their computational power and/or running time. First, let us establish some notation by reconsidering Definition 2. Fixing an encryption scheme and considering any particular eavesdropper  $A$ , let  $\Pr_{k \in \mathcal{K}}[A(\mathcal{E}_k(M)) = 1]$  denote the probability (over random choice of key  $k$ ) that  $A$  outputs “1” when it observes an encryption of the message  $M$ . Viewing an output of “1” as a “guess” that the encrypted message was  $M_1$ , we may rewrite Definition 2 as follows:

An encryption scheme over message space  $\mathcal{M}$  is perfectly secure if for all  $M_1, M_2 \in \mathcal{M}$  and for all adversaries  $A$  we have the following:

$$\Pr_{k \in \mathcal{K}}[A(\mathcal{E}_k(M_1)) = 1] - \Pr_{k \in \mathcal{K}}[A(\mathcal{E}_k(M_2)) = 1] = 0.$$

Note that this definition protects against *all* adversaries and ensures that all such adversaries learn *absolutely*

*nothing* about the message. In practice, however, it may well be sufficient to protect “only” against adversaries *running in some bounded amount of time* and to allow such adversaries to (potentially) learn at most a *very small amount* of information about the encrypted message (or to learn some information about the message but only with very small probability). Modifying the definition of perfect secrecy in this way, we obtain the following definition of computational secrecy:

**Definition 3** An encryption scheme over message space  $\mathcal{M}$  is  $(t, \varepsilon)$  computationally secret if for all equal-length messages  $M_1, M_2 \in \mathcal{M}$  and all eavesdropping adversaries  $A$  running in time at most  $t$  we have the following:

$$|\Pr_{k \in \mathcal{K}}[A(\mathcal{E}_k(M_1)) = 1] - \Pr_{k \in \mathcal{K}}[A(\mathcal{E}_k(M_2)) = 1]| \leq \varepsilon,$$

where the probabilities are over random choice of  $k \in \mathcal{K}$ , as well as any randomness used by  $A$ .

We remark that the requirement that  $M_1$  and  $M_2$  are equal-length messages is essential, because an encryption scheme cannot, in general (and is not, in general, intended to), hide information about the length of the encrypted message. We stress that the adversary  $A$  may potentially be randomized (as long as it does not run in time longer than  $t$ ). Indeed, this will be the case for all definitions of security considered in this chapter, even if not explicitly stated. (We remark that for the case of Definition 2 we may assume without loss of generality that the adversary is deterministic because there are no limitations there on the amount of time the adversary may run and hence randomization does not provide any additional benefit to an adversary.) Note that  $(\infty, 0)$  computational secrecy is equivalent to perfect secrecy.

The definition above allows for any choice of  $t, \varepsilon$ , and ultimately the desired level of secrecy—or, equivalently, the desired setting of these parameters—will depend on the application, the security requirements of the communicating parties, and the assumed abilities of any potential adversaries trying to learn information about the communicated message. Typical choices in practice might be  $t = 1000$  years,  $\varepsilon = 2^{-80}$  so that (informally) an eavesdropper would not learn anything about the encrypted message with probability better than  $2^{-80}$  even after trying for 1000 years.

### Beating the One-Time Pad

We show now how one of the limitations of the one-time pad—namely the restriction that the key must be as long as the message—can be overcome when computational secrecy is allowed. First, we introduce the notion of a *pseudorandom generator* (PRG) (Blum & Micali, 1984; Yao, 1982). Informally, a PRG is a deterministic function that expands a short, random “seed” into a longer, “random-looking” (i.e., pseudorandom) output. What does it mean for the output of a PRG to “look random”? This is defined in a manner analogous to the definition of computational secrecy, above, by requiring that no time-bounded adversary can distinguish the output of the PRG from a random string. We stress here that the adversary is not

limited to any particular set of statistical tests—the only “restriction” is that the adversary is not allowed to run “too long.” This important difference is what differentiates *cryptographic* PRGs (Blum & Micali, 1984; Yao, 1982), from PRGs used in noncryptographic contexts (see Knuth, 1997); the latter should never be used when the former are called for.

We now present the formal definition:

**Definition 4** Let  $G$  be an efficient, deterministic algorithm that takes an  $\ell_1$ -bit string as input and returns an  $\ell_2$ -bit string as output, with  $\ell_2 > \ell_1$ . We say  $G$  is a  $(t, \varepsilon)$  secure PRG if for all algorithms  $A$  running in time at most  $t$  we have the following:

$$|\Pr_{x \in \{0,1\}^{\ell_1}} [A(G(x)) = 1] - \Pr_{y \in \{0,1\}^{\ell_2}} [A(y) = 1]| \leq \varepsilon.$$

In words, no adversary  $A$  running in time at most  $t$  can distinguish between the output string  $G(x)$  (for randomly chosen input  $x$ ) and a random  $\ell_2$ -bit string  $y$  with probability better than  $\varepsilon$ . We remark that any PRG can be “broken” (namely its output can be distinguished from random) by simply performing an exhaustive search for the input string  $x$ . Thus (informally), at a minimum it must be the case that exhaustive search through all  $2^{\ell_1}$  possible input strings cannot be performed in time  $t$ .

Pseudorandom generators may be constructed based on a number of widely believed assumptions (Blum, Blum, & Shub, 1986; Blum & Micali, 1984; Goldreich & Levin, 1989; Håstad, Impagliazzo, Levin, & Luby, 1999; Yao, 1982). Stream ciphers, used extensively in practice, can be viewed as a generalization of PRGs and are discussed further under “block ciphers and stream ciphers” and “modes of encryption.”

The existence of a PRG  $G : \{0, 1\}^{\ell_1} \rightarrow \{0, 1\}^{\ell_2}$  suggests the following natural modification of the one-time pad encryption scheme: the shared key  $k$  is a randomly chosen string of length  $\ell_1$ . To encrypt a message  $M \in \{0, 1\}^{\ell_2}$ , the sender computes  $s := G(k)$  and then forms the ciphertext  $C := M \oplus s$ . To decrypt this ciphertext, the receiver computes  $s := G(k)$  and then  $M := C \oplus s$ . It is not hard to see that this correctly recovers the original message. Note further that this scheme indeed improves upon the one-time pad encryption scheme in that the key length  $\ell_1$  is less than the message length  $\ell_2$ .

What can we say about the security of this scheme? Arguing informally, the security of  $G$  implies that the string  $s = G(k)$  computed by the sender during the process of encryption is pseudorandom and hence indistinguishable from a random string of length  $\ell_2$  for any adversary running in time at most  $t$ . Thus, from the point of view of any eavesdropping adversary (running in time at most  $t$ ), an execution of the above encryption scheme is indistinguishable from an execution of the one-time pad encryption scheme. Perfect secrecy of the one-time pad thus implies computational secrecy of the above encryption scheme. More formally:

**Theorem 2** If  $G$  is a  $(t, \varepsilon)$  secure PRG, then the encryption scheme described above is  $(t, 2\varepsilon)$  computationally secret.

## A Stronger Notion of Security

Although the above scheme does allow for a key that is shorter than the message, it still suffers from another drawback of the one-time pad encryption scheme in that it is secure only when used to encrypt a single message. Indeed, the same attacks shown previously for the case of the one-time pad apply here as well: for example, observing two ciphertexts  $C_1 = M_1 \oplus G(k)$  and  $C_2 = M_2 \oplus G(k)$  still allows an adversary to compute  $C_1 \oplus C_2 = M_1 \oplus M_2$  and hence to learn partial information about the two messages. Also, if an adversary sees  $C = M \oplus G(k)$  for a known message  $M$  then the adversary can compute  $G(k)$  (but not the key  $k$ !) and then decrypt any ciphertexts intercepted in the future.

This discussion of various attacks motivates the following taxonomy of possible methods by which an adversary might try to learn information about an encrypted message (or messages):

**Ciphertext-only attacks:** Here, an adversary has observed a sequence of ciphertexts  $C_1 = \mathcal{E}_k(M_1), C_2 = \mathcal{E}_k(M_2), \dots$  encrypted with respect to the same key. In such a scenario, the adversary may try to learn information about the sequence of messages (say, whether  $M_1 = M_2$ ) even if it cannot learn information about any particular message.

**Known-plaintext attacks:** Here, an adversary observes a sequence of ciphertexts  $C_1, C_2, \dots$  (again encrypted with respect to the same underlying key  $k$ ) and may additionally *know* that  $C_1$  is an encryption of  $M_1$ , and so on (say, because it has some *a priori* information about the messages). Then, it obtains a ciphertext  $C = \mathcal{E}_k(M)$  for an unknown message  $M$  (more generally, it may obtain a sequence of ciphertexts as in the case of a ciphertext-only attack) and then tries to learn information about  $M$ .

**Chosen-plaintext attacks:** Stronger than the above is an attack in which the adversary obtains ciphertexts  $C_1 = \mathcal{E}_k(M_1), \mathcal{E}_k(M_2), \dots$  for messages  $M_1, M_2, \dots$  of the adversary’s *choice*. This might occur, for example, if the adversary is an “insider” (mistakenly trusted by the sender and receiver) who has some influence over the messages sent by the parties. Then, as above, the adversary might obtain a ciphertext  $C = \mathcal{E}_k(M)$  for an unknown message  $M$  (more generally, it may obtain a sequence of ciphertexts as in the case of a ciphertext-only attack) and then try to learn information about  $M$ .

The above attacks are certainly plausible in many practical situations, and one would therefore like to design an encryption scheme that is secure even in the face of such attacks. As has already been noted, however, neither the one-time pad encryption scheme nor the modified encryption scheme discussed in the previous section is secure against any of the above attacks. In fact, neither Definition 2 nor Definition 3 takes into account any of the above attacks, and thus a revised definition of security is needed.

It is possible to capture all the above attacks in an elegant way by imagining a mental experiment in which an adversary is given access to an *encryption oracle*  $\mathcal{E}_k(\cdot)$ . As the notation implies, this “oracle” represents a means by

which the adversary can obtain encryptions of any message(s) of its choice; namely the adversary submits message  $M$  to this oracle and receives in return a corresponding ciphertext  $C := \mathcal{E}_k(M)$ . We stress that the adversary is allowed to access this oracle as many times as it likes, subject to the bound on its total running time. Definition 3 may then be modified as follows:

**Definition 5** *An encryption scheme over message space  $\mathcal{M}$  is  $(t, \varepsilon)$  secure against chosen-plaintext attacks if for all equal-length messages  $M_1, M_2 \in \mathcal{M}$  and all eavesdropping adversaries  $A$  running in time at most  $t$  we have the following:*

$$|\Pr_{k \in \mathcal{K}}[A^{\mathcal{E}_k(\cdot)}(\mathcal{E}_k(M_1)) = 1] - \Pr_{k \in \mathcal{K}}[A^{\mathcal{E}_k(\cdot)}(\mathcal{E}_k(M_2)) = 1]| \leq \varepsilon,$$

where the probabilities are over random choice of  $k \in \mathcal{K}$ , as well as any randomness used by  $A$ . Note that the same key  $k$  used by the encryption oracle is also used to encrypt the unknown message  $M_1/M_2$ .

It follows directly from the definition that an encryption scheme satisfying the above does indeed ensure security against chosen-plaintext attacks in the informal sense discussed at the beginning of this section (when  $A$  then observes the encryption of a single unknown message  $M_1/M_2$ ). Moreover, it can be shown (Bellare et al., 1997) that the above definition also implies security when  $A$  observes a sequence of ciphertexts corresponding to the encryption of a sequence of unknown messages; that is, the definition ensures security against ciphertext-only attacks as well (and also ensures security against the more general version of the chosen-plaintext attack in which the adversary observes a sequence of ciphertexts for unknown messages). We now make a simple—but extremely important—observation regarding the above definition:

**Lemma 3** *No deterministic encryption scheme is secure against chosen-plaintext attacks.*

*Proof.* Let  $(\mathcal{E}, \mathcal{D})$  be a deterministic encryption scheme, let  $M_1, M_2 \in \mathcal{M}$  be arbitrary distinct messages of the same length, and consider an adversary  $A$  who does the following: it submits  $M_1$  to its encryption oracle to obtain  $C_1$  and then submits  $M_2$  to its encryption oracle to obtain  $C_2$ . It then observes a ciphertext  $C$  and has to decide whether  $C$  represents an encryption of  $M_1$  or  $M_2$ . If  $C = C_1$  then  $A$  outputs “1”, whereas if  $C = C_2$  then  $A$  outputs “2.”

Note that we must have  $C_1 \neq C_2$  because otherwise the receiver would be unable to decrypt correctly. Furthermore, because  $\mathcal{E}$  is deterministic it must be the case that either  $C = C_1$  (if and only if  $C$  is an encryption of  $M_1$ ) or  $C = C_2$  (if and only if  $C$  is an encryption of  $M_2$ ). Thus,

$$\begin{aligned} |\Pr_{k \in \mathcal{K}}[A^{\mathcal{E}_k(\cdot)}(\mathcal{E}_k(M_1)) = 1] - \Pr_{k \in \mathcal{K}}[A^{\mathcal{E}_k(\cdot)}(\mathcal{E}_k(M_2)) = 1]| \\ = 1 - 0 = 1, \end{aligned}$$

which means that the scheme is not very secure (in the sense of Definition 5).

Although the above may seem a bit contrived (in the sense that rarely does a real-life adversary have full access

to an encryption oracle in this way), it does point to an important practical limitation of deterministic encryption schemes: they reveal when the same message is encrypted more than once. Because it may often be desirable to keep even this information secret, deterministic encryption schemes are not recommended for use in practice.

## Pseudorandom Functions and Security Against Chosen-Plaintext Attacks

Before showing a randomized encryption scheme that is secure against chosen-plaintext attacks, we first introduce the notion of a *pseudorandom function* (Goldreich, Goldwasser, & Micali, 1985). This primitive—which may be viewed as a more powerful generalization of a pseudorandom generator—is an efficiently computable, keyed function that “acts like a random function” from the perspective of anyone not knowing the key. In more detail, let  $F: \{0, 1\}^s \times \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  represent an efficiently computable, keyed function where for any  $k \in \{0, 1\}^s$  we let  $F_k: \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  denote the function  $F(k, \cdot)$  (we set the input and outputs lengths of  $F_k$  equal for convenience only; this is not essential). Informally,  $F$  is a pseudorandom function if the function  $F_k$  “looks like” a random function to any adversary who can observe the input/output behavior of  $F_k$  but does not know the value of the key  $k$ . This is formalized by giving an adversary access to some (imaginary) “black box” which contains either a completely random function (mapping  $\{0, 1\}^\ell$  to  $\{0, 1\}^\ell$ ), or an instance of  $F_k$  for a randomly chosen  $k$ . The adversary can “probe” this black box by submitting inputs of its choice and receiving the corresponding outputs. We say  $F$  is pseudorandom if no time-bounded adversary can distinguish between the two cases. Formally:

**Definition 6** *Let  $F$  be as above, and let  $\text{Rand}^{\ell \rightarrow \ell}$  denote the set of all functions mapping  $\{0, 1\}^\ell$  to  $\{0, 1\}^\ell$ . We say  $F$  is a  $(t, \varepsilon)$  secure pseudorandom function if for all algorithms  $A$  running in time at most  $t$  we have the following:*

$$|\Pr_{k \in \{0, 1\}^s}[A^{F_k(\cdot)} = 1] - \Pr_{f \in \text{Rand}^{\ell \rightarrow \ell}}[A^{f(\cdot)} = 1]| \leq \varepsilon.$$

*In other words,  $A$  cannot distinguish between the case when it is given oracle access to  $F_k$  (for randomly chosen  $k \in \{0, 1\}^s$ ) and the case when it is given oracle access to a completely random function  $f$ .*

Pseudorandom functions may be constructed based on a any pseudorandom generator (Goldreich, Goldwasser, & Micali, 1986) and hence from any of a number of standard cryptographic assumptions. In practice, highly efficient *block ciphers* are assumed to be good pseudorandom functions; these are discussed further under “block ciphers and stream ciphers.”

With the above definition in mind, we now show a simple encryption scheme secure in the sense of Definition 5 (Goldreich, Goldwasser, & Micali, 1985). The shared key  $k$  is a randomly chosen string of length  $s$ , and the message space  $\mathcal{M}$  is  $\{0, 1\}^\ell$ . To encrypt a message  $M \in \{0, 1\}^\ell$ , the sender chooses a random  $r \in \{0, 1\}^\ell$  and then sends the

following ciphertext:

$$\langle r, F_k(r) \oplus M \rangle.$$

Decryption proceeds in the obvious way: given a ciphertext  $\langle r, C \rangle$  the receiver recovers  $M$  by computing  $C \oplus F_k(r)$ .

Arguing informally about the security of this scheme, we may observe the following: because  $F$  is pseudorandom and an eavesdropper does not know the shared key  $k$ , use of the function  $F_k$  is indistinguishable from the use of a truly random function  $f$  as far as any adversary running in time at most  $t$  is concerned. We may thus analyze the security of the scheme assuming a truly random function  $f$  is used, and the adversary is given a ciphertext  $\langle r, f(r) \oplus M \rangle$  for which  $M \in \{M_1, M_2\}$ . Letting  $\langle r_1, C_1 \rangle, \dots, \langle r_n, C_n \rangle$  denote the ciphertexts the adversary has received in return from the encryption oracle, there are two cases to consider:

1. If  $r \notin \{r_1, \dots, r_n\}$ , then because  $f$  is a truly random function the value of  $f(r)$  is completely random and hence the observed ciphertext is encrypted essentially as in the one-time pad scheme. Thus, in this case  $A$  learns nothing about the encrypted message.
2. If  $r \in \{r_1, \dots, r_n\}$ , then  $A$  learns the value of  $f(r)$  from one of the responses it received from its encryption oracle and hence can tell whether  $M_1$  or  $M_2$  was encrypted. (For example: assume  $r = r_i$ . Then if  $M_i$  is the  $i$ th message that  $A$  submitted to its encryption oracle,  $A$  learns that  $f(r) = f(r_i) = C_i \oplus M_i$ .) Because all the  $r_i$ 's are chosen at random, however, the probability that this occurs is at most  $n/2^\ell$ , which is small when  $\ell$  is reasonably large.

Because  $n \leq t$  (where  $t$  is the running time of  $A$ ), we obtain the following theorem.

**Theorem 4** *If  $F$  is a  $(t, \varepsilon)$  secure pseudorandom function, then the encryption scheme described above is  $(\mathcal{O}(t), \mathcal{O}(\varepsilon + t/2^\ell))$  secure against chosen-plaintext attacks.*

The above scheme immediately extends to allow encryption of arbitrarily long messages: given a message  $M \in \{0, 1\}^n$ , simply break it into a sequence of  $n$  blocks, each of length  $\ell$ , and then encrypt each block using the above scheme (with independent choices of  $r$  each time). It follows from the definition of security against chosen-plaintext attacks that this too is secure in the sense of Definition 5.

## SYMMETRIC KEY ENCRYPTION IN PRACTICE

### Block Ciphers and Stream Ciphers

As mentioned briefly earlier, a pseudorandom function may be constructed based on quite general cryptographic assumptions (Goldreich, Goldwasser, & Micali, 1986). Yet what makes the notion of pseudorandom functions especially useful in practice is the existence of *block ciphers*: very efficient keyed functions that seem to be pseudorandom for all practical purposes. In fact, block ciphers satisfy the following even stronger property: they are efficiently invertible keyed *permutations*. That is, if  $F$ :

$\{0, 1\}^s \times \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  is a block cipher, then for all keys  $k \in \{0, 1\}^s$  the function  $F_k$  is a permutation over  $\{0, 1\}^\ell$ ; furthermore, given  $k$  it is possible to efficiently compute  $F_k^{-1}$ . (Definition 6 may be appropriately modified in this case so that the comparison is now between  $F_k$  for random  $k$  and a truly random permutation  $f$ .) In addition, block ciphers are typically assumed to satisfy a stronger security property than that of Definition 6 in which the adversary is given access either to both  $F_k$  and  $F_k^{-1}$  or to both  $f$  and  $f^{-1}$  (where  $f$  now represents a random permutation as discussed earlier) and *still* cannot distinguish between these two cases.

Two popular and widely used block ciphers are the data encryption standard (DES) (Federal Information Processing Standards Publication 46, 1977) and the advanced encryption standard (AES) (Daemen & Rijmen, 2002). (These algorithms are covered in more detail in the Chapters “Hashes and Message Digests” and “Number Theory for Information Security,” respectively). Triple-DES (which uses two or three independent DES keys and applies DES three times) may be viewed as a block cipher as well.

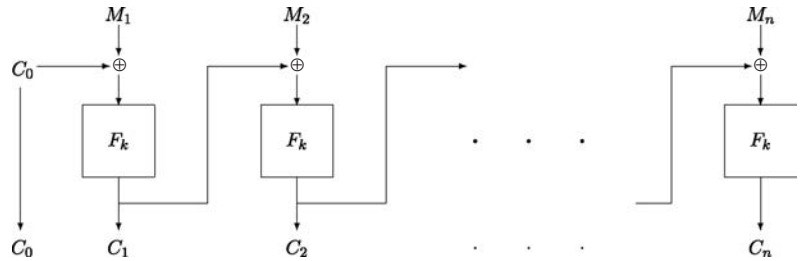

Though block ciphers are already quite efficient, when efficiency is at a premium a *stream cipher* is sometimes used. Perhaps the best way to view a stream cipher is as a pseudorandom function mapping a fixed-length input to an arbitrarily long output. The best-known stream cipher is RC4. This algorithm was designed by RSA Security and has never been publicly released by this company. Nevertheless, a purported description of the RC4 algorithm was posted anonymously to a newsgroup in 1994. See RC4 (2004) or Scheier (1995, Section 17.1) for further details.

### Modes of Encryption

A stream cipher enables efficient instantiation of the encryption scheme discussed under “Pseudorandom Functions and Security Against Chosen-Plaintext Attacks”: to encrypt an arbitrary length message  $M$  using a stream cipher  $F$  and key  $k$ , simply choose a random  $r$  and then compute the ciphertext  $\langle r, F_k(r) \oplus M \rangle$ . The only difference between this scheme and the one discussed under “Pseudorandom Functions and Security Against Chosen-Plaintext Attacks” is that now  $M$  may be arbitrarily long since the output of a stream cipher  $F$  is no longer a short, fixed length but is instead arbitrarily long.

In contrast, block ciphers operate only on short, fixed-length blocks. To encrypt arbitrary length messages using a block cipher a *mode of encryption* must be used. We have already seen that the scheme discussed under “Pseudorandom Functions and Security Against Chosen-Plaintext Attacks” may be used to encrypt arbitrary length messages using a block cipher; however, this results in a ciphertext that is twice as long as the message being encrypted and it is natural to wonder whether better efficiency is possible. In fact, three efficient modes of encryption secure against chosen-plaintext attacks were introduced as part of the DES standard (Federal Information Processing Standards publication 81, 1980): *cipher-block chaining* (CBC) mode, *cipher feedback* (CFB) mode, and *output feedback* (OFB) mode (a fourth mode of encryption discussed in the standard—*electronic codebook* (ECB)

**Figure 1:** CBC mode encryption of message  $M = M_1, \dots, M_n$  using key  $k$  and block cipher  $F$ . The initialization vector  $C_0$  is chosen at random, and the output ciphertext is  $C = C_0, C_1, \dots, C_n$ .

mode—is deterministic and thus not secure in the sense of Definition 5). Many other modes of encryption have since been proposed and offer some advantages; however, these are outside the scope of this survey.

In the descriptions that follow, we assume a block cipher  $F$  operating on  $\ell$ -bit blocks and view the plaintext message  $M$  as a sequence of  $\ell$ -bit blocks  $M_1, \dots, M_n$  (we assume for simplicity that the length of  $M$  is a multiple of  $\ell$ ). In CBC mode, the sender constructs the ciphertext as follows (see Figure 1):

Choose  $C_0 \in \{0, 1\}^\ell$  at random  
 For  $i = 1$  to  $n$ :  
 $C_i := F_k(M_i \oplus C_{i-1})$   
 Output  $\langle C_0, C_1, \dots, C_n \rangle$

The block  $C_0$  is known as the *initialization vector* and is chosen at random each time encryption is performed. Decryption of ciphertext  $\langle C_0, \dots, C_n \rangle$  is done by reversing the above steps:

For  $i = 1$  to  $n$ :  
 $M_i := F_k^{-1}(C_i) \oplus C_{i-1}$   
 Output  $M_1, \dots, M_n$

(Note that decryption requires  $F$  to be efficiently invertible.) As mentioned above, it is known that CBC mode is secure in the sense of Definition 5 (Bellare et al., 1997). Note that the ciphertext is only  $\ell$  bits longer than the message, a substantial improvement over the simple scheme discussed under “Pseudorandom Functions and Security Against Chosen-Plaintext Attacks.” This feature will be shared by all the modes of encryption described here.

OFB mode can be viewed as a method for building a stream cipher out of a block cipher. Here, the sender computes the ciphertext in the following manner:

Choose  $C'_0 \in \{0, 1\}^\ell$  at random  
 Set  $C_0 = C'_0$

For  $i = 1$  to  $n$ :  
 $C'_i := F_k(C'_{i-1})$   
 $C_i := C'_i \oplus M_i$   
 Output  $\langle C_0, C_1, \dots, C_n \rangle$

The initialization vector  $C'_0 = C_0$  is used as a seed to generate a pseudorandom sequence  $C'_1, \dots, C'_n$ , which is then xor’ed with the message. In this way, OFB mode may be viewed as defining a stream cipher  $G_k(C'_0) = F_k(C'_0)F_k^2(C'_0) \dots F_k^i(C'_0)$  and then using this to encrypt as discussed earlier in this section. Decryption of ciphertext  $\langle C_0, \dots, C_n \rangle$  is done as follows:

Set  $C'_0 = C_0$   
 For  $i = 1$  to  $n$ :  
 $C'_i := F_k(C'_{i-1})$   
 $M_i := C_i \oplus C'_i$   
 Output  $M_1, \dots, M_n$

We remark that OFB mode does not require that  $F$  be efficiently invertible or even a permutation.

CFB mode also generates a pseudorandom sequence which is xor’ed with the message, but this sequence now depends on the message itself and so CFB mode cannot be viewed as a “pure” stream cipher. Here, the sender generates the ciphertext as follows (see Figure 2):

Choose  $C_0 \in \{0, 1\}^\ell$  at random  
 For  $i = 1$  to  $n$ :  
 $C'_i := F_k(C_{i-1})$   
 $C_i := C'_i \oplus M_i$   
 Output  $\langle C_0, C_1, \dots, C_n \rangle$

Decryption is done by reversing the above:

For  $i = 1$  to  $n$ :  
 $C'_i := F_k(C_{i-1})$   
 $M_i := C_i \oplus C'_i$   
 Output  $M_1, \dots, M_n$

**Figure 2:** CFB mode encryption of message  $M = M_1, \dots, M_n$  using key  $k$  and block cipher  $F$ . The initialization vector  $C_0$  is chosen at random, and the output ciphertext is  $C = C_0, C_1, \dots, C_n$ .

As in the case of OFB mode, CFB mode does not require that  $F$  be efficiently invertible or a permutation.

## Hybrid Encryption

Throughout this chapter, we have assumed that the communicating parties share a secret key in advance of their communication. If this were the only instance in which symmetric key encryption could be used, its applicability would be rather limited. However, symmetric key encryption is used extensively in the public key setting as well, via a technique called *hybrid encryption*. Here, a public key encryption scheme is used to encrypt a randomly chosen symmetric key  $k$  that is then itself used—in conjunction with a symmetric key encryption scheme—for encryption of bulk data. In more detail, assume a receiver has generated keys  $(PK, SK)$  for some public key encryption scheme in which encryption is denoted by  $\mathcal{E}$ ; let  $\mathcal{E}'$  denote a symmetric key encryption scheme with key space  $\mathcal{K}$ . A sender who knows  $PK$  can encrypt a long message  $M$  by choosing a random key  $k \in \mathcal{K}$ , encrypting  $k$  using  $PK$  (and the public key encryption algorithm  $\mathcal{E}$ ) to generate  $C \leftarrow \mathcal{E}_{PK}(k)$  and then encrypting  $M$  using  $k$  and the symmetric key scheme to generate  $C' \leftarrow \mathcal{E}'_k(M)$ . The ciphertext transmitted to the receiver is simply  $(C, C')$ . Decryption can be done in the obvious way by reversing these steps: to recover the message, the receiver first recovers  $k$  using  $SK$  and then recovers  $M$  using  $k$ . Note that this achieves the functionality of public key encryption with the asymptotic efficiency of symmetric key encryption (i.e., when long-enough messages are encrypted). Furthermore, it can be shown that this construction is secure against chosen-plaintext attacks (under an appropriate analog of Definition 5 for the public key setting) as long as the underlying symmetric key and public key schemes are secure against chosen-plaintext attacks.

## Stronger Definitions of Security

A notion of security that is stronger than that of Definition 5 is that of security against *chosen-ciphertext attacks*. Informally, such attacks correspond to scenarios in which an adversary may be able to obtain (partial) information about plaintexts corresponding to ciphertexts constructed by the adversary. More formally, Definition 5 is augmented by additionally giving the adversary access to a *decryption oracle*  $\mathcal{D}_k(\cdot)$  that returns the decryption of any ciphertext(s) of the adversary's choice. (To make the definition nontrivial, the adversary is disallowed from submitting its input ciphertext—that is, the ciphertext  $C$  for which the adversary is trying to decide whether  $C$  corresponds to an encryption of  $M_1$  or  $M_2$ —to the decryption oracle.) See Katz and Yung (2000b) for further details. Although such an attack may seem contrived, protecting against chosen-ciphertext attacks is crucial when encryption schemes are used as primitives within higher level protocols (e.g., authentication protocols), and this notion of security is now required of all modern-day encryption schemes. It is not hard to see that none of the encryption schemes discussed in this chapter is secure against chosen-ciphertext attacks, but further discussion of this issue (including descriptions of schemes that are secure against chosen-ciphertext attacks) is outside the scope of this survey.

More generally, one often wants to achieve secrecy in combination with *integrity* (that is, to prevent an adversary from undetectably modifying the messages sent between the two communicating parties). A crucial point is that, generally speaking, *encryption alone does not guarantee integrity*; in particular, an encryption scheme secure in the sense of Definition 5 does not necessarily (and, in fact, usually does not) provide any integrity whatsoever. This is evident from, for example, OFB mode encryption as discussed under “Modes of Encryption”: it is not hard to see that an adversary can modify the ciphertext at will and the receiver will always decrypt any ciphertext as some valid message. Even worse, an adversary can potentially modify the ciphertext in such a way that it has a predictable effect on the underlying message *even though the adversary does not necessarily learn what that underlying message is*. Consider again the case of OFB mode encryption, for example, and assume an adversary observes a ciphertext  $C_0, C_1, C_2$  (where these are a sequence of  $\ell$ -bit blocks) that is an encryption of some unknown message  $M = M_1, M_2$ . If the adversary sets  $C'_2 = C_2 \oplus 1^\ell$  and forwards  $C_0, C_1, C'_2$  to the receiver, the receiver will recover a message  $M_1, M'_2$  in which all the bits in the second message block have been flipped (i.e.,  $M'_2 = M_2 \oplus 1^\ell$ )! This may be problematic in itself or may lead to other security problems (see, e.g., Katz & Schneier, 2000).

If one desires both secrecy and integrity, an *authenticated encryption scheme* must be used (Bellare & Namprepre, 2000; Katz & Yung, 2000a). Interestingly, an authenticated encryption scheme is automatically secure against chosen-ciphertext attacks (Bellare & Namprepre, 2000; Katz & Yung, 2000a). Recently, there have been a number of constructions of authenticated encryption schemes (see Black, 2005); these, however, are outside the scope of this survey.

## FURTHER INFORMATION

Further information about symmetric key encryption, written in a manner that is accessible to nonspecialists, is available in books by Schneier (1995) and Ferguson and Schneier (2003). The *Handbook of Applied Cryptography* (Menezes, van Oorschot, & Vanstone, 2001) also contains detailed coverage of many aspects of symmetric key encryption. For further information about classical symmetric key encryption schemes and additional weaknesses of such schemes, the reader may consult the textbook by Stinson (2002). More advanced presentations of some of the material covered here are available in Stinson's book (2002), the online notes by Goldwasser and Bellare (2001) or Bellare and Rogaway (2003), and the second volume of Goldreich's graduate-level textbook (Goldreich, 2004).

The notion of computational security for encryption derives from the work of Goldwasser and Micali (1984) who first rigorously defined the notion for the case of public key encryption. Subsequent work concerning definitions of security for symmetric key encryption includes (Bellare et al., 1997; Katz & Yung, 2000b). Goldreich's first volume (Goldreich, 2001) contains much more information about pseudorandom generators and pseudorandom functions.

## GLOSSARY

- Block Cipher** A highly efficient keyed permutation operating on short blocks that is assumed to act as a pseudorandom permutation.
- Ciphertext** The “garbled” output that results from encrypting a message.
- Decryption** Application of a keyed procedure to a ciphertext to recover the underlying message.
- Encryption** Application of a keyed procedure to a message with the intent of making the message unreadable to anyone who does not know the corresponding key enabling decryption.
- Plaintext** Another word for the message, or data, to be communicated.
- Pseudorandom Function** A keyed function whose input/output characteristics for a randomly generated key cannot be distinguished from a truly random function by anyone who does not know the underlying key.
- Pseudorandom Generator** A deterministic function which expands a short “seed” to a longer, “random-looking” string.
- Public Key Encryption Scheme** An encryption scheme in which the keys used for encryption and decryption are different and that is “secure” (in some appropriate sense) even if the encryption key is known.
- Stream Cipher** A highly efficient keyed function that maps a short input to an arbitrary-length pseudorandom string.
- Symmetric Key Encryption Scheme** An encryption scheme in which the same key is used both for encryption and decryption.

## INTRODUCTION

The Data Encryption Standard (DES) is a widely deployed secret key encryption method standardized by the U.S. National Bureau of Standards in 1977. This chapter describes the method in detail, explains how it is used to encrypt long messages, and how it is used with multiple keys for better security.

## HISTORY

DES was originally developed by an IBM team formed in the early 1970s in response to customer requests for a method to secure data. IBM submitted DES to the National Bureau of Standards, which published it as a standard in 1977. One of the members of the IBM team, Horst Feistel, had come up with the basic structure on which DES is built, and he and fellow teammate Don Coppersmith created the Lucifer cipher, the direct ancestor of DES. The U.S. National Security Agency provided guidance toward the final form of DES.

## OVERVIEW

DES (see Figure 1) uses a 56-bit key to transform a block of 64 bits (called the plaintext) into another block of 64 bits (called the ciphertext). DES starts by rearranging (permuting) the bits of the plaintext. It then transforms the 64-bit block resulting from this initial permutation in a sequence of 16 identical rounds, each round using a different 48-bit round key derived from the 56-bit DES key. After the last round, it swaps the two 32-bit halves of the transformed block. Finally, it permutes the bits to produce the ciphertext. The final permutation is the inverse of the initial permutation; that is, if you started with a block of 64 bits and performed the initial permutation immediately followed by the final permutation (or vice versa), you would end up with what you started with.

This transformation from plaintext to ciphertext is called DES encryption. The inverse transformation, DES

decryption, uses the same 56-bit key to transform the ciphertext into the plaintext. It turns out that DES decryption is identical to DES encryption but with the 48-bit round keys applied in reverse order.

## PERMUTATIONS

The initial permutation can be specified as a sequence of 64 numbers that are the input bit numbers:

```
58 50 42 34 26 18 10 2
60 52 44 36 28 20 12 4
62 54 46 38 30 22 14 6
64 56 48 40 32 24 16 8
57 49 41 33 25 17 9 1
59 51 43 35 27 19 11 3
61 53 45 37 29 21 13 5
63 55 47 39 31 23 15 7
```

So, the first input bit (bit 1) gets moved to position 40, the second input bit (bit 2) to position 8, and so on (see Figure 2). Similarly, the final permutation is as follows:

```
40 8 48 16 56 24 64 32
39 7 47 15 55 23 63 31
38 6 46 14 54 22 62 30
37 5 45 13 53 21 61 29
36 4 44 12 52 20 60 28
35 3 43 11 51 19 59 27
34 2 42 10 50 18 58 26
33 1 41 9 49 17 57 25
```

## KEY DISTRIBUTION/PER-ROUND KEYS

The 56-bit DES key is the source for the sixteen 48-bit round keys (also known as subkeys). DES key bits are numbered from 1 through 64, where bits 8, 16, 24, 32, 40, 48, 56, and 64 are not actually bits from the 56-bit key but rather the odd parity of the preceding 7 bits.

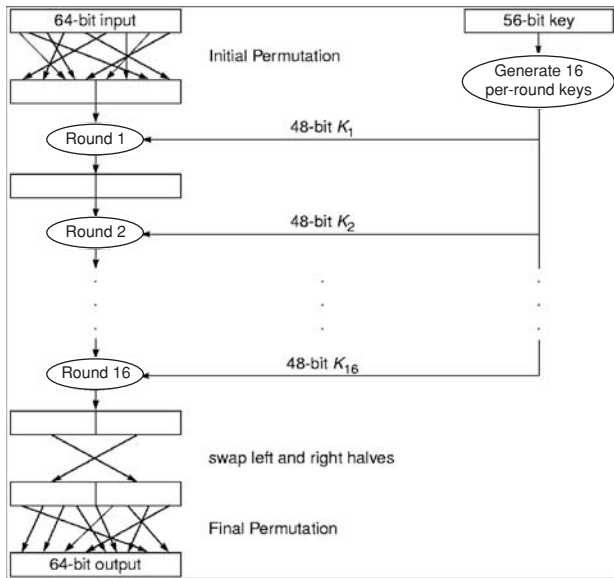

Figure 1: Basic structure of DES.

These parity bits are numbered but not used (other than for error detection when all 64 bits are transmitted).

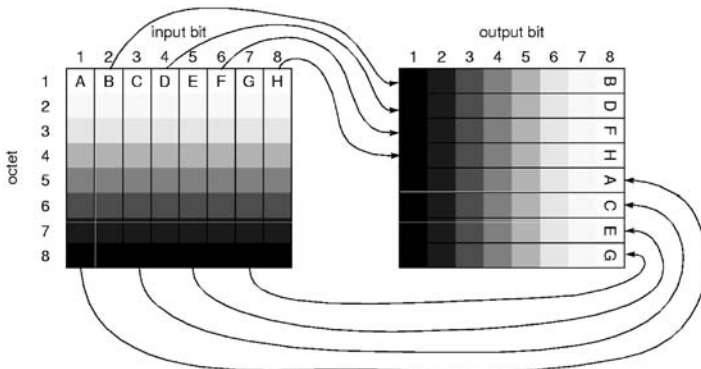

First, the 56 bits of the key are permuted (see Figure 3) into two 28-bit halves, called  $C_0$  and  $D_0$ :

$C_0$								$D_0$							
57	49	41	33	25	17	9		63	55	47	39	31	23	15	
1	58	50	42	34	26	18		7	62	54	46	38	30	22	
10	2	59	51	43	35	27		14	6	61	53	45	37	29	
19	11	3	60	52	44	36		21	13	5	28	20	12	4	

Next, the round keys  $K_n$  are generated in 16 rounds. First each of  $C_{n-1}$  and  $D_{n-1}$  are rotated left to get  $C_n$  and  $D_n$ . In rounds 1, 2, 9, and 16, it is a single-bit rotate; that is, the bits are shifted left one position and the bit falling off the left end ends up at the right end. In the other rounds, it is a two-bit rotate. Twenty-four of the 28 bits of  $C_n$  (where the bits of  $C_n$  are numbered 1 through 28) are permuted to get the left half of  $K_n$  using the following permutation:

14 17 11 24 1 5 3 28 15 6 21 10 23 19 12 4 26 8 16 7 27 20 13 2,

and 24 of the 28 bits of  $D_n$  (where the bits of  $D_n$  are numbered 29 through 56) are permuted to get the right half of

$K_n$  using the following permutation:

41 52 31 37 47 55 30 40 51 45 33 48 44 49 39 56 34 53 46 42 50 36 29 32.

This key distribution process contributes to the *diffusion* of the key.

### A ROUND

(See Figure 4.) Round  $n$  takes its 64-bit input block considered as a 32-bit left half  $L_n$  and a 32-bit right half  $R_n$ , and, using the round key  $K_n$ , transforms these into two 32-bit halves  $L_{n+1}$  and  $R_{n+1}$  that are concatenated to produce its 64-bit output block.  $L_{n+1}$  is just  $R_n$ , whereas  $R_{n+1}$  is the bitwise exclusive or ( $\oplus$ ) of  $L_n$  and a function of  $K_n$  and  $R_n$ . This function is the “mangler function,” which we describe in the next section.

Note that if you feed round  $n$  its own output with the halves swapped (i.e.,  $R_{n+1}|L_{n+1}$ ), it produces its own input with the halves swapped, namely  $R_n|L_n$ . If you look at the structure of DES, what was a mysterious swapping of halves after the last round now makes complete sense, because it means that DES decryption is identical to DES encryption but with the round keys applied in reverse order. A cipher with this structure is known as a Feistel cipher.

### THE MANGLER FUNCTION

The mangler function is the crucial part of DES algorithm. It is responsible for hiding the data by mixing it with the key. So the mangler function provides much of DES’s *confusion*. It is also a source of *diffusion* that is amplified by successive rounds.

The mangler function produces a 32-bit result  $V$  from two input values: a 48-bit round key  $K$  and a 32-bit value  $R$ . First, it expands  $R$  to 48 bits (see Figure 5). Then it performs a bitwise exclusive or ( $\oplus$ ) of  $K$  with the expanded  $R$  to get a value  $X$ . Then, it breaks up  $X$  into eight 6-bit chunks  $X_i$  and looks up  $X_i$  in a substitution table called S-box  $i$ , which produces a 4-bit result. Finally, the eight 4-bit results are concatenated into a 32-bit quantity whose bits are permuted to get  $V$ , the output of the mangler function. This permutation is as follows:

16 7 20 21 29 12 28 17 1 15 23 26 5 18 31 10 2 8 24 14 32 27 3 9 19 13 30 6 22 11 4 25.

The expansion of  $R$  to 48 bits is done by breaking  $R$  into eight 4-bit chunks and then expanding each of those chunks to 6 bits by taking the adjacent bit on each side the

Figure 2: Initial permutation of data block (reverse the arrows for final permutation).

Figure 3: Initial permutation of key.

chunk and pasting them onto the chunk. For this process, the leftmost and rightmost bits of  $R$  are considered adjacent. The resulting 6-bit chunks are concatenated. (This expansion also goes by the name *expansion permutation*, although it is not a permutation at all.)

As described previously, each 6-bit chunk of  $X$  is turned into a 4-bit chunk using its associated S-box, and the resulting 4-bit chunks are concatenated into a 32-bit quantity. Numbering the bits of  $X$  from left to right as 1 through 48, and the bits of the 32-bit quantity as 1 through 32, the S-box lookup tables are shown in Figures 6–13.

The S-boxes were carefully crafted to make DES resistant to differential cryptanalysis. They are the only nonlinear portion of DES algorithm. [A function  $f$  transforming one fixed-length chunk of bits to another (of possibly different length) is linear if  $f(a \oplus b) = f(a) \oplus f(b) \oplus f(0)$  for all  $a$  and  $b$ . For example, one of the simplest linear functions is the parity function that is 0 if its argument has an even number of 1s and is 1 otherwise.]

This completes the description of DES algorithm.

### WEAK AND SEMI-WEAK KEYS

There are 16 DES keys with properties that make them suspect, and so their use is discouraged. These are the keys that have each of  $C_0$  and  $D_0$  being one of four values: all ones, all zeroes, alternating ones and zeroes, and alternating zeroes and ones. The weak keys have each of  $C_0$  and  $D_0$  being all ones or all zeroes; they are their own inverses in that encryption and decryption are identical. The remaining 12 possibilities are semi-weak keys; each is the inverse of one of the others in that encryption by one is identical to decryption by the other.

Whether weak and semiweak keys are actually less secure is not particularly important. Once particular values of a key are pointed out, they are likely to be tried first when attempting cryptanalysis. This is why it's probably also not a good idea to use keys with small numeric values. To avoid such “distinguished key” attacks, keys should have approximately equal numbers of 0s and 1s. Almost all potential keys are of this form anyway.

### TRIPLE DES (3DES OR TDEA)

When DES was designed, its 56-bit key was at best barely good enough to keep data secure. These days, 56 bits is not nearly enough, and so TDEA (Triple Data Encryption Algorithm) was standardized. TDEA uses three successive DES operations, each with its own key, to encrypt a block. The first and third are DES encryptions, whereas the middle is a DES decryption. The main reason for this “EDE” scheme is so that a TDEA engine can emulate a DES engine by using the same DES key for all three operations. TDEA is often used with only two distinct keys, where the two DES encryptions use the same key, but it should be used with three distinct keys for maximum security. There is a known attack (although not a practical one) that suggests that TDEA with only two distinct keys is much less secure than would be expected from its 112-bit total key size.

As should be obvious, decrypting a TDEA-encrypted block also involves three successive DES operations. Here, the first and third are decryptions, whereas the middle is an encryption, with the keys being the same as those used for the TDEA encryption, but used in reverse order.

## MODES OF OPERATION: ENCRYPTING LONG SEQUENCES OF DATA

To encrypt a long sequence of data, a block encryption algorithm must break up the data into blocks with a block size specific to the encryption algorithm. In the case of DES, the data is broken into 64-bit blocks. Although each block could be encrypted with a different key, in practice a single key is used. The problem with just encrypting each block with the same key is that the same plaintext block is always encrypted into the same ciphertext block, which might help a forger or cryptanalyst.

We describe several techniques for encrypting long sequences of plaintext: electronic codebook (ECB), cipher block chaining (CBC), output feedback mode (OFB), cipher feedback mode (CFB), and counter mode (CTR). ECB, CBC, OFB, and CFB, when used with TDEA, are called TECB, TCBC, TOFB, and TCFB. TCBC-I, TOFB-I, and TCFB-P, where *I* stands for “interleaved” and *P* stands for “pipelined,” are modifications specified by ANSI to take advantage of the availability of multiple (actually three) encryption engines.

### Electronic Codebook (ECB)

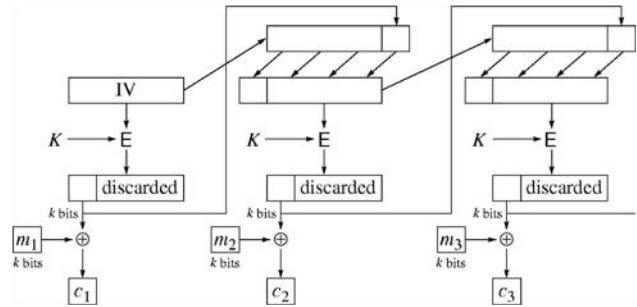

This is the technique we just described: each block of plaintext is encrypted independently with the same key. (See Figure 14).

### Cipher Block Chaining (CBC)

In this technique, each block of plaintext is  $\oplus$ ed with another quantity before being encrypted. The first block is  $\oplus$ ed with something called an initialization vector (IV), which must be known to the decrypter. It is normally a random number selected by the encrypter and kept with the ciphertext so that it is known to the decrypter. Each plaintext block after the first is  $\oplus$ ed with the ciphertext of the previous block before being encrypted. (See Figure 15).

**Figure 15:** CBC. For decryption, just reverse the vertical arrows and replace encrypt (E) with decrypt (D).

**Figure 16:** *k*-Bit OFB. For decryption, just reverse the arrows at  $m_1$  and  $c_1$ .

### Output Feedback Mode (OFB)

In this technique, the data to be encrypted is broken up into chunks of a size *k* less than or equal to the encryption algorithm’s blocksize. The plaintext is not actually encrypted, but merely  $\oplus$ ed with a pseudorandom stream of *k*-bit chunks generated by repeated application of the encryption algorithm, starting with a *k*-bit initialization vector. Thus OFB encryption and decryption are identical operations.

To start the generation of the pseudorandom stream, the IV, padded on the left with zeroes, is written to a blocksize-length shift register. Then the following is repeated: the shift register contents are passed to the encryption engine. The leftmost *k* bits of the encrypted result form the next chunk of the pseudorandom stream and are also shifted into the shift register from the right. (See Figure 16).

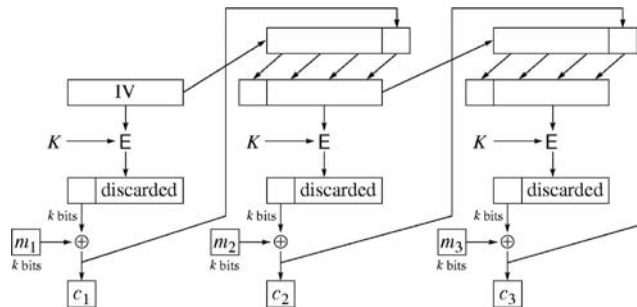

A serious weakness of OFB is that someone who knows the plaintext associated with a given ciphertext can forge any same-length (or shorter) message by  $\oplus$ ing the ciphertext with the known plaintext  $\oplus$ ed with the forged plaintext.

### Cipher Feedback Mode (CFB)

CFB is similar to OFB. The only difference is the *k*-bit value that is shifted into the shift register. For CFB, it is the just-generated chunk of ciphertext, which is the  $\oplus$  of the newly-generated pseudorandom stream chunk with the current plaintext chunk. (See Figure 17).

### Counter Mode (CTR)

Counter mode generates a pseudorandom stream of chunks from an initialization vector by successively

**Figure 17:** *k*-Bit CFB. For decryption, just reverse the arrows at  $m_1$  and  $c_1$ .

Figure 18: CTR.

encrypting  $IV, IV+1, IV+2, \dots$  (see Figure 18). These chunks are  $\oplus$ ed with the plaintext chunks to form the ciphertext chunks. Thus CTR encryption and decryption are identical operations. CTR has the same weakness as OFB.

## CRYPTANALYSIS

Various ideas have been used in an attempt to “break” DES, that is, to decrypt DES-encrypted data without knowing the key. What this really means is figuring out the key based on knowing the ciphertext and having some knowledge of the plaintext. At the very least, one has to be able to recognize when something is plaintext. Some of the techniques require much more knowledge, such as having a large number of plaintext–ciphertext pairs using the key or knowing the ciphertext associated with some carefully chosen plaintext. We mention exhaustive search, and differential and linear cryptanalysis in the following sections. Of these, the only really practical attack at present is exhaustive search, and it is the main reason that TDEA has replaced DES.

### Exhaustive Search

The idea of exhaustive search is to try each possible key in turn until the correct key is discovered. On average, one has to try half of the  $2^{56}$  keys (i.e.,  $2^{55}$  keys) before finding the correct one.

### Differential Cryptanalysis

The idea of differential cryptanalysis is to correlate  $p \oplus q$  with  $c \oplus d$ , where  $p, c$  and  $q, d$  are each plaintext–ciphertext pairs. This technique can be used to crack a DES key with about  $2^{47}$  known plaintext–ciphertext pairs.

### Linear Cryptanalysis

The idea of linear cryptanalysis is to look at linear relations between plaintext bits, ciphertext bits, and key bits. A linear relation just means that the  $\oplus$  of the selected bits is zero (or one). This technique can be used to crack a DES key with about  $2^{43}$  plaintext–ciphertext pairs.

## SUMMARY

DES is the first commercial encryption scheme standardized by the U.S. government. It is a block encryption scheme with 64-bit blocks and 56-bit keys. It has been in use for over a quarter of a century and has withstood the test of time. Although it is not considered secure in its 56-bit key incarnation, it can be combined with itself in

TDEA to provide 112- or 168-bit key encryption. Although this seems to still be secure, a new block encryption algorithm called AES (Advanced Encryption Standard) has been standardized by the U.S. National Institute of Standards and Technology, which uses 128-bit blocks and 128-, 192-, or 256-bit keys and can be implemented much more efficiently in software than DES.

## GLOSSARY

**Bitwise Exclusive Or ( $\oplus$ )** A function that takes two equal-length chunks of bits (the arguments) and produces another equal-length chunk of bits (the result) where a result bit is 0 when the corresponding two argument bits are equal and is 1 when they differ. Note that  $\oplus$  has a number of interesting properties: it is commutative [ $a \oplus b = b \oplus a$ ] and associative [ $a \oplus (b \oplus c) = (a \oplus b) \oplus c$ ]; if 0 represents bitwise 0,  $a \oplus a = 0$  and  $a \oplus 0 = a$ ; as a consequence of these properties, if  $a \oplus b = c$ , then  $a = b \oplus c$  and  $b = c \oplus a$ .

**Block Encryption** An encryption method that transforms a fixed-length block of plaintext into an equal-length block of ciphertext.

**Ciphertext** The result of encrypting the plaintext.

**Confusion** A property of a good block encryption technique where changing any subset of key and plaintext bits has a complex effect on the ciphertext.

**Diffusion** A property of a good block encryption technique where a single bit of the key or the plaintext affects many bits of the ciphertext.

**Feistel Cipher** A block encryption technique with a structure similar to DES: The plaintext block (after an initial permutation) is split into two halves, and then a sequence of identical rounds is performed where the right half becomes the new left half while the right half and the round key are combined by a mangler function [see below] whose result is then  $\oplus$ ed with the left half to produce the new right half. The halves from the final round are then swapped (and the inverse of the initial permutation is performed) to produce the ciphertext block. In a Feistel cipher, the only difference between encryption and decryption is the order in which the round keys are applied.

**Key Distribution** Within a block encryption algorithm with multiple rounds, the method by which the round keys are derived from the encryption key.

**Mangler Function** In a Feistel cipher, the part of the algorithm that provides the confusion. The mangler function, considered as a round key-dependent function of the right half, is not normally reversible.

**Permutation** A technique in which the bits in a chunk are rearranged according to a specific rule. In this chapter, we define a given permutation by a sequence of source bit numbers. So, for example, 3 1 2 would define the permutation that moves bit 3 to position 1, bit 1 to position 2, and bit 2 to position 3.

**Plaintext** The actual data to be encrypted.

**Round** In many block encryption techniques, a part of the algorithm that is repeated many times, with the output of one round used as the input to the next. Usually, a second input to a round is the round key, derived from the encryption key and often different for each

round. Rounds are repeated to provide sufficient diffusion and confusion.

**S-Box** The part of an encryption algorithm such as DES that performs substitution.

**Secret Key Encryption** A method of encryption in which a single value (called a key) is used by both the encryption and decryption algorithms to map plaintext to ciphertext and ciphertext to plaintext, respectively.

**Substitution** A technique in which a chunk of bits is replaced by a different chunk of bits according to a specific rule. Also called table lookup.

**Symmetric Encryption** Another name for secret key encryption. The word *symmetric* refers to the fact that the same secret value (the key) is used for both encryption and decryption.

## HISTORY OF THE ADVANCED ENCRYPTION STANDARD PROCESS

In July 1977, the United States National Bureau of Standards (NBS, whose name was later changed to the National Institute of Standards and Technology, or NIST), promulgated Federal Information Processing Standard (FIPS) 46, the Data Encryption Standard, or DES, for ensuring secure communication, primarily with regard to financial transactions conducted electronically (NIST, 1999). DES had a rather controversial start; from the very beginning there were critics who pointed out that the technical capability for breaking DES was not entirely beyond 1980s technology. Diffie and Hellman argued in 1977 that by about 1987 a machine capable of an essentially brute-force attack on DES would cost only about \$200,000 (Diffie, 1977). Indeed, DES was broken, using an approach similar to and at a cost similar to the projections of Diffie and Hellman, but not until 1998. A careful analysis of the nature of DES and its successors can be found in Landau (2000a, 2000b).

In part because of concerns about security, many of those using DES by the 1990s were using “Triple-DES,” encrypting three times instead of just once. It was clear to NIST by the mid-1990s that a new encryption standard was necessary. To this end, a competition was announced in January 1997.

A number of NIST criteria were outlined in advance. The goal was a cryptosystem that was at least as secure as Triple-DES that was in moderately wide use, but a cryptosystem that was much more efficient than Triple-DES. The Rijndael/AES algorithm, for example, is strongly byte-oriented, making it clean and efficient in a high-level language on a standard processor but also relatively straightforward to implement on the kind of minimal-capability processor as might be found on a smart card. The NIST specification was for a block length of 128 bits and for key lengths of 128, 192, and 256 bits.

Finally, there were stringent standards set regarding intellectual property issues, in that NIST intended AES to

be an open standard without encumbrances from patents or other claimed proprietary content.

A series of three conferences were held on proposals for AES, on 20–22 August 1998 in Ventura, California (NIST, 1998a; Roback, 1999), on 22–23 March 1999 in Rome, Italy (NIST, 1998b), and on 13–14 April 2000 in New York City (NIST, 2000a).

There were fifteen submissions that were accepted by NIST for the first round of the evaluation. These are (from Daemen and Rijmen, 2001) presented in Table 1.

In August 1999, the list of fifteen candidates was reduced to five—MARS, RC6, Rijndael, Serpent, and Twofish. An analysis of the study of the finalists can be found in Nechvatal et al. (2000), and summary can be found in Stallings (2003). The initial three criteria of security, cost, and implementation characteristics were modified somewhat during the evaluation process. Although security remained the primary concern, the analysis of the proposed algorithms resulted in a refinement of the other two criteria. The cost criteria included both software efficiency and the cost, both in general silicon area and in memory required, of a hardware implementation. Implementation characteristics included the specifics of implementation in silicon, in field programmable gate arrays, on general purpose processors with a high degree of instruction-level parallelism. Also considered were the flexibility of the algorithm to accommodate parameters outside the original requirements of AES (in case attacks on the original algorithm were discovered).

Finally, the selection of Rijndael as the AES was announced in a press release on 2 October 2000 and followed by the publication of FIPS 197 on 26 November 2001 (NIST, 2001). The security of all the finalists had been judged to be adequate. In general, the choice of Rijndael can be traced to the simplicity of the operations it requires and the byte orientation of those operations. These led to relatively high execution efficiency both in software and hardware, although the extensive use of memory tables results in a relatively large silicon area among the finalist

**Table 1** The Original AES Candidates

Cryptosystem	Submitter(s)
CAST-256	Entrust (Canada)
Crypton	Future Systems (KR)
DEAL	Outerbridge and Knudsen (U.S.A. and Denmark)
DFC	ENS-CNRS (France)
E2	NTT (Japan)
Frog	TecApro (CR)
HPC	Schroepel (U.S.A.)
LOKI97	Brown et al. (Australia)
Magenta	Deutsche Telekom (Germany)
MARS	IBM (U.S.A.)
RC6	RSA (U.S.A.)
Rijndael	Daemen and Rijmen (Belgium)
SAFER+	Cylink (U.S.A.)
Serpent	Anderson, Biham, Knudsen (UK, Israel, Denmark)
Twofish	Counterpane (U.S.A.)

algorithms. Finally, Rijndael as proposed incorporated the variations in key and block size beyond the original specifications for AES that would be needed in a flexible algorithm.

## References

The best overall reference for AES as it has been adopted is probably the book by the AES inventors, Joan Daemen and Vincent Rijmen (2001). We have relied heavily on this reference in our description of AES. A NIST Web site points to its standards information on cryptographic matters (2003a); this Web site contains pages specifically on AES, the FIPS, and the process by which the standard was adopted (2001, 2003b). A number of additional Web sites contain links to articles describing implementations as well as attacks (Courtois, 2004).

## AES and Rijndael

The original cipher proposed by Daemen and Rijmen was named Rijndael as a word created from the surnames of the authors. As is pointed out in their book (2001), the only difference between the the original Rijndael algorithm and the AES algorithm as selected is that the Rijndael algorithm can be used with a number of block lengths and a number of key lengths, but the AES, as a standard, fixes the block length at 128 bits and the key lengths at 128, 192, or 256 bits.

The only other distinction to be noted is in the labeling of the transformations of AES. We follow the labeling of the FIPS and of the inventors' book (Daemen & Rijmen, 2001) and not that of the original submission of Rijndael to the AES competition. For example, the original submission referred to a `ByteSub` and a `ShiftRows` transformation, and the FIPS now refers to `SubBytes` and `ShiftRows`.

## BACKGROUND MATHEMATICAL CONCEPTS

### Galois Field Arithmetic

The AES makes extensive use of arithmetic in the *finite field*, or *Galois field*,  $GF(2^8)$  of  $2^8 = 256$  elements. A background in finite field arithmetic can be found in Chapter 110 of these volumes. We do not attempt here to cover the theory of finite fields, but we do describe the computational structure of these fields as that structure is needed to understand AES.

For pedagogical purposes, we consider first  $GF(2^3)$ , a finite field of eight elements. Such a field can be realized using modular polynomial arithmetic and the primitive irreducible polynomial  $x^3 + x + 1$ . Consider the eight polynomials in an indeterminate  $x$  of degree less than or equal to 2 and with coefficients either 0 or 1:

$$GF(2^3) = \{0, 1, x, x + 1, x^2, x^2 + 1, x^2 + x, x^2 + x + 1\}.$$

We create a finite field of these eight polynomials by providing them with an *addition* operation as follows:

$$(a_2x^2 + a_1x + a_0) + (b_2x^2 + b_1x + b_0) = (a_2 \text{ XOR } b_2)x^2 + (a_1 \text{ XOR } b_1)x + (a_0 \text{ XOR } b_0)$$

and a *modular multiplication* operation as follows:

$$\begin{aligned} (a_2x^2 + a_1x + a_0) * (b_2x^2 + b_1x + b_0) &\equiv (a_2 \text{ AND } b_2)x^4 \\ &\times [(a_1 \text{ AND } b_2) \text{ XOR } (a_2 \text{ AND } b_1)]x^3 \\ &+ [(a_0 \text{ AND } b_2) \text{ XOR } (a_1 \text{ AND } b_1) \text{ XOR } (a_2 \text{ AND } b_0)]x^2 \\ &+ [(a_0 \text{ AND } b_1) \text{ XOR } (a_1 \text{ AND } b_0)]x \\ &+ (a_0 \text{ AND } b_0) + \\ &\equiv c_4x^4 + c_3x^3 + c_2x^2 + c_1x + c_0 \pmod{x^3 + x + 1}. \end{aligned}$$

The arithmetic modulo the polynomial  $x^3 + x + 1$  proceeds as if we had the following equation:

$$0 = x^3 + x + 1.$$

If this were true, and once we have defined addition as above as a coefficient-wise XOR operation, we can add  $x^3$  to both sides of the equation to get the following:

$$x^3 = x^3 + x^3 + 1 + x = (1 \text{ XOR } 1)x^3 + x + 1 = x + 1.$$

We use this identity recursively if necessary to reduce the degree of a polynomial by two with every application. The modular reduction of the product polynomial above thus becomes the following:

$$\begin{aligned} c_4x^4 + c_3x^3 + c_2x^2 + c_1x + c_0 \\ &\equiv c_4(x^2 + x) + c_3(x + 1) + c_2x^2 + c_1x + c_0 \\ &\equiv (c_2 \text{ AND } c_4)x^2 + (c_1 \text{ AND } c_3 \text{ AND } c_4)x \\ &+ (c_0 \text{ AND } c_3) \pmod{x^2 + x + 1} \end{aligned}$$

+	0	1	$x$	$x + 1$	$x^2$	$x^2 + 1$	$x^2 + x$
0	0	1	$x$	$x + 1$	$x^2$	$x^2 + 1$	$x^2 + x$
1	1	0	$x + 1$	$x$	$x^2 + 1$	$x^2$	$x^2 + x + 1$
$x$	$x$	$x + 1$	0	1	$x^2 + x$	$x^2 + x + 1$	$x^2$
$x + 1$	$x + 1$	$x$	1	0	$x^2 + x + 1$	$x^2 + x$	$x^2 + 1$
$x^2$	$x^2$	$x^2 + 1$	$x^2 + x$	$x^2 + x + 1$	0	1	$x$
$x^2 + 1$	$x^2 + 1$	$x^2$	$x^2 + x + 1$	$x^2 + x$	1	0	$x + 1$
$x^2 + x$	$x^2 + x$	$x^2 + x + 1$	$x^2$	$x^2 + 1$	$x$	$x + 1$	0
$x^2 + x + 1$	$x^2 + x + 1$	$x^2 + x$	$x^2 + 1$	$x^2$	$x + 1$	$x$	1

Figure 1: Addition table for  $GF(2^3)$  arithmetic.

Thus, for example, we define the product of  $x^2 + x + 1$  and  $x^2 + x$  to be the following:

$$\begin{aligned}
 (x^2 + x + 1) * (x^2 + x) &\equiv x^4 + x^3 + x^2 + x^3 + x^2 + x \\
 &\equiv x^4 + (1 \text{ AND } 1)x^3 + (1 \text{ AND } 1)x^2 + x \\
 &\equiv x^4 + x \equiv x(x + 1) + x \equiv x^2 + x + x \\
 &\equiv x^2 + (1 \text{ AND } 1)x \equiv x^2 \pmod{x^3 + x + 1}. \quad (1)
 \end{aligned}$$

The reader can verify that the addition and multiplication tables for this arithmetic are given in Figures 1 and 2.

We observe that the following conditions for this arithmetic to make  $GF(2^8)$  into a field are true:

- The addition and multiplication are commutative. That is, for all  $p, q \in GF(2^3)$  we have the following:

$$p + q = q + p \quad \text{and} \quad p * q = q * p.$$

- There is an additive identity, namely the polynomial 0, such that

$$0 + p = p + 0 = p$$

holds for all  $p \in GF(2^3)$ .

- For every  $p \in GF(2^3)$ , there is an additive inverse, which we shall write  $-p$ , such that

$$p + (-p) = (-p) + p = 0.$$

We note that the additive inverse of a polynomial  $p$  is in fact  $p$  itself. This follows from the use of the coefficient-wise XOR for polynomial addition in this field.

- There is a multiplicative identity, namely the polynomial 1, such that

$$1 * p = p * 1 = p$$

holds for all  $p \in GF(2^3)$ .

*	1	$x$	$x + 1$	$x^2$	$x^2 + 1$	$x^2 + x$	$x^2 + x + 1$
1	1	$x$	$x + 1$	$x^2$	$x^2 + 1$	$x^2 + x$	$x^2 + x + 1$
$x$	$x$	$x^2$	$x^2 + x$	$x + 1$	1	$x^2 + x + 1$	$x^2 + 1$
$x + 1$	$x + 1$	$x^2 + x$	$x^2 + 1$	$x^2 + x + 1$	$x^2$	1	$x$
$x^2$	$x^2$	$x + 1$	$x^2 + x + 1$	$x^2 + x$	$x$	$x^2 + 1$	1
$x^2 + 1$	$x^2 + 1$	1	$x^2$	$x$	$x^2 + x + 1$	$x + 1$	$x^2 + x$
$x^2 + x$	$x^2 + x$	$x^2 + x + 1$	1	$x^2 + 1$	$x + 1$	$x$	$x^2$
$x^2 + x + 1$	$x^2 + x + 1$	$x^2 + 1$	$x$	1	$x^2 + x$	$x^2$	$x + 1$

Figure 2: Multiplication table for  $GF(2^3)$  arithmetic.

- For every  $p \in GF(2^3)$ , there is a multiplicative inverse, which we shall write  $p^{-1}$ , such that

$$p * p^{-1} = p^{-1} * p = 1.$$

- Multiplication distributes over addition.
- The seven nonzero polynomials of  $GF(2^3)$  can be generated as the powers of a single polynomial, which for this field can be taken to be  $x$ , so that the set of powers

$$\{x^i \pmod{x^2 + x + 1} \mid 1 \leq i \leq 7\}$$

is the full set of seven distinct nonzero polynomials of  $GF(2^3)$ . (This fact is crucial to doing fast arithmetic for AES.)

### The Galois Field $GF(2^8)$ and AES

The above example used a polynomial of degree three to create a finite field of  $2^3 = 8$  elements. For AES, we use the following polynomial:

$$m(x) = x^8 + x^4 + x^3 + x + 1$$

of degree eight and thus create a finite field of  $2^8 = 256$  elements. Except for the level of tedium in computing the addition and multiplication tables, the arithmetic is entirely similar.

What we now note is that we can dispense with the polynomial notation and view the polynomials simply as bit strings, with the 8-bit byte that is the bit string  $b_7b_6b_5b_4b_3b_2b_1b_0$  being used as a shorthand notation for the degree-seven polynomial

$$b_7x^7 + b_6x^6 + b_5x^5 + b_4x^4 + b_3x^3 + b_2x^2 + b_1x^1 + b_0x^0$$

that is an element of the finite field of 256 elements defined by  $m(x)$ .

The AES makes extensive use of the fact that bit strings can be taken a byte at a time and interpreted in this way as coefficients of polynomials. What is crucial to the performance of AES is that the fact that the nonzero polynomials can be generated as powers of a single polynomial [ $x$  in the case of the example above, and  $x + 1$  in the case of the field defined by  $m(x)$ ]. This permits us to use the powers of the generator to create a table of logarithms and do multiplication in the Galois field by table lookup. In the case of our example (1) above, we have the following:

$$111 \leftrightarrow x^2 + x + 1 \equiv x^5 \pmod{x^3 + x + 1}$$

and

$$110 \leftrightarrow x^2 + x \equiv x^4 \pmod{x^3 + x + 1}$$

so the product is as follows:

$$(x^2 + x + 1) * (x^2 + x) \equiv x^5 * x^4 \equiv x^9 \equiv x^2 \pmod{x^3 + x + 1} \leftrightarrow 100,$$

because we know that  $x^7 \equiv 1 \pmod{x^3 + x + 1}$ .

### More Polynomial Arithmetic

As part of the encryption and decryption processes, AES uses groups of four bytes to define polynomials  $f(X)$  of degree three in an indeterminate  $X$ ; each byte is taken to define an element of  $GF(2^8)$  that is one of the coefficients of  $f(X)$ . The AES process then does arithmetic on these polynomials modulo the polynomial  $X^4 + 1$ . We write these polynomials as follows:

$$a_3 \odot X^3 + a_2 \odot X^2 + a_1 \odot X + a_0$$

and write the coefficients  $a_i$  in hexadecimal notation, so a specific coefficient  $a_3 = x^5 + x^3 + 1 \leftrightarrow 00101001$  would be written as 29.

Although there is a mathematical basis for these operations, from a computational point of view we can regard this almost as a positional notation for the arithmetic. Because  $X^4 \equiv 1 \pmod{X^4 + 1}$ , multiplication of a polynomial  $f(X)$  by  $b \odot X$  modulo  $X^4 + 1$  is really a coefficientwise multiplication by  $b$  in  $GF(2^8)$  and a left circular shift of the coefficients as follows:

$$\begin{aligned} (b \odot X) \cdot (a_3 \odot X^3 + a_2 \odot X^2 + a_1 \odot X + a_0) \\ \equiv (b * a_2) \odot X^3 + (b * a_1) \odot X^2 \\ + (b * a_0) \odot X + (b * a_3) \pmod{X^4 + 1} \end{aligned}$$

where the multiplication  $*$  of the coefficients takes place in  $GF(2^8)$ . It is in part to recognize this purely formal nature of these polynomials that we use the  $\odot$  symbol for multiplication by the coefficients.

## THE ADVANCED ENCRYPTION STANDARD ALGORITHM

This section closely follows the descriptions of Daemen and Rijmen (2001) and of the FIPS (NIST, 2001).

$p_0$	$p_4$	$p_8$	$p_{12}$
$p_1$	$p_5$	$p_9$	$p_{13}$
$p_2$	$p_6$	$p_{10}$	$p_{14}$
$p_3$	$p_7$	$p_{11}$	$p_{15}$

Figure 3: Byte-by-byte view of the 128 bits of a plaintext block.

The AES is a *key-alternating iterated block cipher*. A *block cipher* is a cipher in which bits are enciphered in blocks. That is, the *plaintext* is broken into equal-sized blocks, and each block is passed through an encipherment process to produce a block of *ciphertext*. In the case of AES, blocks are fixed at 128 bits. An *iterated block cipher* is one in which a fixed encipherment process, usually called a *round*, is applied a number of times to the block of bits. Finally, by *key alternating* we mean that the cipher key is XORed to the *state* (the running version of the block of input bits) alternately with the application of the round transformation.

The input to AES is the *plaintext*, a sequence of blocks of 128 bits each of the message to be encrypted, and the *key*, a block of  $K = 128, 192,$  or  $256$  bits, with the size an option of the user. The blocks of plaintext are encrypted using the key to produce a *ciphertext* of blocks of bits of 128 bits each. AES is a *symmetric* cipher, in that the ciphertext produced by plaintext and key is converted back to plaintext using the same key.

Viewed simplistically, AES is almost (but not quite) an outer loop of  $N_r$  iterations, each called a *round*, of bit transformations and an inner set of four stages of transformations per round. The current pattern of bits as input to or output from one of these transformations is referred to as the *state*.

The AES plaintext is 128 bits long. AES is strongly byte oriented; if we view the stream of bytes of both plaintext and key as being numbered in increasing order

$$p_0 p_1 \dots p_{15}$$

and

$$k_0 k_1 \dots k_{K/8},$$

then the bytes of both plaintext and key are usually viewed as a two-dimensional array in column-major order, shown for the plaintext in Figure 3; the key can be represented similarly.

A key would be arranged in a similar pattern of four rows and  $K/32 = 4, 6,$  or  $8$  columns, respectively, for the key lengths of  $K = 128, 192,$  or  $256$  bits.

### The Outer Structure of the Rounds

The outer structure of AES is shown in Figure 4. For key lengths of  $K = 128, 192,$  and  $256$  bits, we use  $N_r = 10, 12,$  and  $14$  round transformations, respectively. (Note that the initial specification of Rijndael, as opposed to the adopted version for AES, permits various key lengths and plaintext block lengths and has a specification for  $N_r$  that varies accordingly. What we describe here is AES and not the more general Rijndael.)

```
Rijndael(State, CipherKey)
{
    KeyExpansion(CipherKey, ExpandedKey);
    AddRoundKey(State, ExpandedKey[0]);
    for (i = 1; i < Nr; i++)
        Round(State, ExpandedKey[i]);
    FinalRound(State, ExpandedKey[Nr]);
}
```

**Figure 4:** Outer transformation loop of AES.

The input key is first expanded with the `KeyExpansion` function to produce a key that is  $N_r + 1$  times its original size. The expanded key is then taken in blocks of  $K$  bits at a time. One block is added to the state prior to the round iterations,  $N_r - 1$  blocks are added in at the end of each of the rounds in the loop, and the final block is added in at the end of the `FinalRound` transformation. The rounds themselves are shown in Figure 5.

**SubBytes**

**Encryption**

The `SubBytes` step is nonlinear. Indeed, it is the only nonlinear step in AES. Each individual byte  $a = a_7a_6a_5a_4a_3a_2a_1a_0$  (written as a string of bits) of the state is subjected (at least conceptually) to a two-stage transformation

$$a \rightarrow a^{-1} \text{ in } GF(2^8) \rightarrow f(a^{-1})$$

where  $y = f(x)$  is the transformation of Figure 6 and the  $GF(2^8)$  arithmetic is defined above.

**Decryption**

For decryption, the inverse operation to `SubBytes`, called `InvSubBytes`, is accomplished with the function  $f^{-1}$  of Figure 7 followed by a byte inversion in  $GF(2^8)$ .

**The  $S_{RD}$  function**

A crucial feature of AES is that its predilection for computation on bytes makes for efficient implementation. Although the `SubBytes` operation is conceptually a Galois field inversion followed by an affine transformation, these two can be combined and implemented with a 256-long table lookup, which is referred to later as the function

```
Round(State, ExpandedKey[i])
{
    SubBytes(State);
    ShiftRows(State);
    MixColumns(State);
    AddRoundKey(State, ExpandedKey[i]);
}

FinalRound(State, ExpandedKey[Nr])
{
    SubBytes(State);
    ShiftRows(State);
    AddRoundKey(State, ExpandedKey[Nr]);
}
```

**Figure 5:** Round transformations of AES.

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 1 \end{pmatrix} \times \begin{pmatrix} x_7 \\ x_6 \\ x_5 \\ x_4 \\ x_3 \\ x_2 \\ x_1 \\ x_0 \end{pmatrix} \oplus \begin{pmatrix} 0 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \\ 1 \\ 1 \end{pmatrix} = \begin{pmatrix} y_7 \\ y_6 \\ y_5 \\ y_4 \\ y_3 \\ y_2 \\ y_1 \\ y_0 \end{pmatrix}$$

**Figure 6:** The function  $f(x)$  in `SubBytes`.

$S_{RD}$ . For example, the byte 73 in hexadecimal represents the polynomial in  $GF(2^8)$  whose inverse is represented by the byte 85. Computing  $f(85)$ , we get 8F, which would be stored in the  $73_{16}$  location of the lookup table.

For high level language code or for implementation on any standard processor, this is almost certainly the most efficient approach, because the intraword bit manipulations of Galois inversion and the affine transformation are not supported by CPU instructions. For hardware implementations, implementation of the actual arithmetic is not out of the question, as discussed.

**ShiftRows**

**Encryption**

The second stage of the inner loop of AES is the `ShiftRows` operation. In this stage, the bytes of the four rows of the state are circularly shifted left. Row 0 of the state is not shifted; row 1 is shifted left one byte, row 2 shifted two bytes, and row 3 shifted left circularly by three bytes. A graphical tableau for `ShiftRows` is as shown in Figure 8.

**Decryption**

In decryption, the inverse of the `ShiftRows` step, referred to as `InvShiftRows`, is simply the appropriate right circular shift of the bytes of the state.

**MixColumns**

**Encryption**

In the `SubBytes` stage, The bits  $b_7b_6b_5b_4b_3b_2b_1b_0$  of a byte were viewed as coefficients of a polynomial  $b_7x^7 + b_6x^6 + b_5x^5 + b_4x^4 + b_3x^3 + b_2x^2 + b_1x^1 + b_0$  that represented an element of the finite field  $GF(2^8)$ , and this element was inverted in  $GF(2^8)$ . In the `MixColumns` stage, we carry that representation one step further. The four bytes of a column in the state are each viewed as elements of  $GF(2^8)$  that are now coefficients of a cubic polynomial. For example, a column of state (with bytes written as two hexadecimal digits)

$$\begin{pmatrix} 0 & 1 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \end{pmatrix} \times \begin{pmatrix} y_7 \\ y_6 \\ y_5 \\ y_4 \\ y_3 \\ y_2 \\ y_1 \\ y_0 \end{pmatrix} \oplus \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} x_7 \\ x_6 \\ x_5 \\ x_4 \\ x_3 \\ x_2 \\ x_1 \\ x_0 \end{pmatrix}$$

would be taken to represent the polynomial

$$1F \odot X^3 + 3D \odot X^2 + 5B \odot X + 79$$

with, for example, the last coefficient  $79 = 0111\ 1001$  being taken to mean the polynomial

$$0 \times x^7 + 1 \times x^6 + 1 \times x^5 + 1 \times x^4 + 1 \times x^3 \\ + 0 \times x^2 + 0 \times x^1 + 1 \times x^0$$

as an element of  $GF(2^8)$ .

The columns of the state, viewed as polynomials in  $X$  with coefficients in  $GF(2^8)$ , are multiplied by the following:

$$c(X) = 03 \odot X^3 + 01 \odot X^2 + 01 \odot X + 02$$

modulo  $X^4 + 1$ . The polynomial  $c(X)$  is invertible modulo  $X^4 + 1$ , with inverse

$$d(X) = c^{-1}(X) = 0B \odot X^3 + 0D \odot X^2 + 09 \odot X + 0E.$$

Because this is more complicated than most of the stages of AES, we will go into somewhat more detail. Assume we have the following column of state:

$a_3$
$a_2$
$a_1$
$a_0$

The multiplication of MixColumns is as follows:

$$(a_3 \odot X^3 + a_2 \odot X^2 + a_1 \odot X + a_0) \\ \times (03 \odot X^3 + 01 \odot X^2 + 01 \odot X + 02),$$

which is rewritten as follows:

$$X^6 \cdot ( \quad \quad \quad 03 \odot a_3) \\ X^5 \cdot ( \quad \quad 03 \odot a_2 \quad +01 \odot a_3) \\ X^4 \cdot ( \quad +03 \odot a_1 \quad +01 \odot a_2 \quad +01 \odot a_3) \\ X^3 \cdot (03 \odot a_0 \quad +01 \odot a_1 \quad +01 \odot a_2 \quad +02 \odot a_3) \\ X^2 \cdot (01 \odot a_0 \quad +01 \odot a_1 \quad +02 \odot a_2 \quad ) \\ X^1 \cdot (01 \odot a_0 \quad +02 \odot a_1 \quad ) \\ X^0 \cdot (02 \odot a_0 \quad )$$

and which reduces to the following:

$$X^5 \cdot ( \quad \quad \quad 03 \odot a_2 \quad +01 \odot a_3) \\ X^4 \cdot ( \quad +03 \odot a_1 \quad +01 \odot a_2 \quad +01 \odot a_3) \\ X^3 \cdot (03 \odot a_0 \quad +01 \odot a_1 \quad +01 \odot a_2 \quad +02 \odot a_3) \\ \equiv X^2 \cdot (01 \odot a_0 \quad +01 \odot a_1 \quad +02 \odot a_2 \quad +03 \odot a_3) \\ X^1 \cdot (01 \odot a_0 \quad +02 \odot a_1 \quad ) \\ X^0 \cdot (02 \odot a_0 \quad )$$

and then to

$$X^4 \cdot ( \quad +03 \odot a_1 \quad +01 \odot a_2 \quad +01 \odot a_3) \\ X^3 \cdot (03 \odot a_0 \quad +01 \odot a_1 \quad +01 \odot a_2 \quad +02 \odot a_3) \\ \equiv X^2 \cdot (01 \odot a_0 \quad +01 \odot a_1 \quad +02 \odot a_2 \quad +03 \odot a_3) \\ X^1 \cdot (01 \odot a_0 \quad +02 \odot a_1 \quad +03 \odot a_2 \quad +01 \odot a_3) \\ X^0 \cdot (02 \odot a_0 \quad )$$

and finally to

$$X^3 \cdot (03 \odot a_0 \quad +01 \odot a_1 \quad +01 \odot a_2 \quad +02 \odot a_3) \\ X^2 \cdot (01 \odot a_0 \quad +01 \odot a_1 \quad +02 \odot a_2 \quad +03 \odot a_3) \\ \equiv X^1 \cdot (01 \odot a_0 \quad +02 \odot a_1 \quad +03 \odot a_2 \quad +01 \odot a_3) \\ X^0 \cdot (02 \odot a_0 \quad +03 \odot a_1 \quad +01 \odot a_2 \quad +01 \odot a_3),$$

where the reduction is done modulo  $X^4 + 1$ .

The entire operation on columns of the state can thus be done as a matrix multiplication in  $GF(2^8)$ :

$$\begin{pmatrix} b_3 \\ b_2 \\ b_1 \\ b_0 \end{pmatrix} = \begin{pmatrix} 03 & 01 & 01 & 02 \\ 01 & 01 & 02 & 03 \\ 01 & 02 & 03 & 01 \\ 02 & 03 & 01 & 01 \end{pmatrix} \begin{pmatrix} a_3 \\ a_2 \\ a_1 \\ a_0 \end{pmatrix}$$

### Decryption

The inverse to MixColumns, called InvMixColumns, is a multiplication of the columns by the inverse  $d(X)$ , all taken modulo  $X^4 + 1$ . As above, the operation can be condensed into a matrix operation on the columns of state as follows:

$$\begin{pmatrix} a_3 \\ a_2 \\ a_1 \\ a_0 \end{pmatrix} = \begin{pmatrix} 0E & 0B & 0D & 09 \\ 09 & 0E & 0B & 0D \\ 0D & 09 & 0E & 0B \\ 0B & 0D & 09 & 0E \end{pmatrix} \begin{pmatrix} b_3 \\ b_2 \\ b_1 \\ b_0 \end{pmatrix}$$

### Key Addition

The key addition step is labeled AddRoundKey. Because this is an XOR of bits of the expanded key with the state, the AddRoundKey step is its own inverse. The key addition is displayed in Figure 9.

### Key Schedule

The key addition steps require significant numbers of bits of key. These bits are obtained from the initial key by an expansion process. Care must be taken, of course, when expanding an input key because the resulting key bits can

Figure 9: AddRoundkey operating on the 128 bits of a plaintext block.

contain no more inherent randomness than is present in the initial key prior to the deterministic expansion.

With 10, 12, or 14 rounds in AES, the algorithm will need  $128 \times 11 = 1408$ ,  $128 \times 13 = 1664$ , or  $128 \times 15 = 1920$  bits of key to perform the AddRoundKey step. One 128-bit block of key is used prior to the iteration of the rounds, and then additional 128-bit blocks are used for each iteration within the rounds. The key bits are obtained via an ExpandedKey function that is applied to the initial key value.

For a version of AES with  $N_r$  rounds, the expanded key should be viewed as a two-dimensional array of four rows and  $4 \times (N_r + 1)$  columns, which we subscript as  $W[0..3][0..4 \times (N_r + 1)]$ . If we set  $N_k$  to 4, 6, or 8 according as the key length is 128, 192, or 256 bits, then the first  $4 \times N_k$  block receives the original key in column-major order as in Figure 10, and the key is then expanded by the application of the recursive function detailed below. Columns of bytes of key are produced recursively:

1. If the column subscript  $j \geq N_k$  is neither 0 modulo  $N_k$  nor 4 modulo  $N_k$  for  $N_k = 8$ , then we have the following:

$$\begin{bmatrix} W[0][j] \\ W[1][j] \\ W[2][j] \\ W[3][j] \end{bmatrix} = \begin{bmatrix} W[0][j - N_k] \\ W[1][j - N_k] \\ W[2][j - N_k] \\ W[3][j - N_k] \end{bmatrix} \oplus \begin{bmatrix} W[0][j - 1] \\ W[1][j - 1] \\ W[2][j - 1] \\ W[3][j - 1] \end{bmatrix}$$

```

KeyExpansion(byte K[4][Nk], byte W[4][Nb*(Nr+1)])
{
  for(j = 0; j < Nk; j++)
  {
    for(i = 0; i < 4; i++)
    {
      W[i][j] = K[i][j];
    }
  }

  for(j = Nk; j < Nb*(Nr+1); j++) /* expansion loop on columns */
  {
    if(0 == j mod Nk) /* if-then for bytes down columns */
    {
      W[0][j] = W[0][j-Nk] XOR S[W[1][j-1]] XOR RC[j/Nk];
      for(i = 1; i < 4 i++)
      {
        W[i][j] = W[i][j-Nk] XOR S[W[i+1 mod 4][j-1]];
      }
    }
    else
    {
      for(i = 0; i < 4 i++)
      {
        W[i][j] = W[i][j-Nk] XOR W[i][j-1];
      }
    }
  } /* end if-then down columns */
} /* end expansion loop on columns */
} /* end KeyExpansion */

```

Figure 10: Key expansion for 128- or 192-bit keys.

2. If  $N_k = 8$  (256-bit keys) and the column subscript  $j$  is 4 modulo 8, then we XOR the  $(j - N_k)$ -th column not with the  $(j - 1)$ -st column but with the bits obtained by first applying  $S_{RD}$  to that column. That is, we have the bit operations below. In this,  $S_{RD}$  is the combined  $GF(2^8)$  and affine transformation used in SubBytes.

$$\begin{bmatrix} W[0][j] \\ W[1][j] \\ W[2][j] \\ W[3][j] \end{bmatrix} = \begin{bmatrix} W[0][j - N_k] \\ W[1][j - N_k] \\ W[2][j - N_k] \\ W[3][j - N_k] \end{bmatrix} \oplus \begin{bmatrix} S_{RD}(W[0][j - 1]) \\ S_{RD}(W[1][j - 1]) \\ S_{RD}(W[2][j - 1]) \\ S_{RD}(W[3][j - 1]) \end{bmatrix}$$

3. If the column subscript  $i$  is 0 modulo  $N_k$ , then we have the bit operations below. In addition to the  $S_{RD}$  operation, we have a circular shift down of the bytes of column  $j - 1$  before the application of  $S_{RD}$  and the XOR in byte 0 of a round constant  $RC$ , where

$$\begin{bmatrix} W[0][j] \\ W[1][j] \\ W[2][j] \\ W[3][j] \end{bmatrix} = \begin{bmatrix} W[0][j - N_k] \\ W[1][j - N_k] \\ W[2][j - N_k] \\ W[3][j - N_k] \end{bmatrix} \oplus \begin{bmatrix} S_{RD}(W[1][j - 1]) \oplus RC[j/N_k] \\ S_{RD}(W[2][j - 1]) \\ S_{RD}(W[3][j - 1]) \\ S_{RD}(W[0][j - 1]) \end{bmatrix}$$

$$RC[1] = x^0 \quad \text{that is, } 01$$

$$RC[2] = x^1 \quad \text{that is, } 02$$

...

$$RC[j] = x^{j-1} \quad \text{in } GF(2^8).$$

The ExpandedKey[i] value as used in the pseudocode description of the algorithm refers to columns  $N_b \times i$  through  $N_b \times (i + 1) - 1$  when viewed as columns or bytes  $4 \times N_b \times i$  through  $4 \times N_b \times (i + 1) - 1$  taken in column-major order. Thus, key bits are extracted from the ExpandedKey in blocks of 128 bits at a time, but the key bits are generated column by column as needed, not necessarily in blocks of 128 bits.

Specifically, for key lengths of 128 or 192 bits, the ExpandedKey is created with the function of Figure 10. For key lengths of 256 bits, the ExpandedKey is created with the function of Figure 11.

## IMPLEMENTATION ISSUES

The AES was designed so that it would perform well on a range of processors, including smart cards with small 8-bit processors, fast standard processors, and even on special purpose hardware. Because the functions of AES are bit manipulations, and because many of these functions are not provided in the instruction set architecture (ISA) of a standard processor, some accommodation for the bit-processing must be made in an implementation on

```

KeyExpansion(byte K[4][Nk], byte W[4][Nb*(Nr+1)])
{
  for(j = 0; j < Nk; j++)
  {
    for(i = 0; i < 4; i++)
    {
      W[i][j] = K[i][j];
    }
  }

  for(j = Nk; j < Nb*(Nr+1); j++) /* expansion loop on columns */
  {
    if(0 == j mod Nk) /* if-then for bytes down columns */
    {
      W[0][j] = W[0][j-Nk] XOR S[W[1][j-1]] XOR RC[j/Nk];
      for(i = 1; i < 4 i++)
      {
        W[i][j] = W[i][j-Nk] XOR S[W[i+1 mod 4][j-1]];
      }
    }
    else if(4 == j mod Nk)
    {
      for(i = 0; i < 4 i++)
      {
        W[i][j] = W[i][j-Nk] XOR S[W[i][j-1]];
      }
    }
    else
    {
      for(i = 0; i < 4 i++)
      {
        W[i][j] = W[i][j-Nk] XOR W[i][j-1];
      }
    }
  } /* end if-then down columns */
} /* end expansion loop on columns */
} /* end KeyExpansion */

```

Figure 11: Key expansion for 256-bit keys.

a standard processor. Conversely, AES has been designed so that these tweaks are relatively straightforward and so that high performance can be achieved even on relatively low-performance processors.

Just to review the operations necessary, we summarize the operations to be performed:

1. **SubBytes**: Mathematically, the computation in `SubBytes` includes the  $GF(2^8)$  arithmetic followed by the affine transformation  $f(x)$ . Computationally, this can all be done by table lookup in a 256-long table and is referred to as the  $S_{RD}$  (or sometimes just  $S$ ) function.
2. **ShiftRows**: This consists entirely of byte-oriented memory moves of the array of state.
3. **MixColumns**: Mathematically, the `MixColumns` operation involves modular polynomial operations using polynomials in  $X$  whose coefficients are elements of  $GF(2^8)$ . Computationally, the polynomial arithmetic is just byte moves in memory following arithmetic on the coefficients in  $GF(2^8)$ . In the case of encryption, the coefficient arithmetic is very easy because one needs only to multiply coefficients by 1,  $x$ , and  $x + 1$ . In the case of decryption, the multipliers are more complicated and the arithmetic is thus harder to implement in hardware. In the case of a software implementation, neither is a complicated operation because the multiplication is usually done with a table lookup.
4. **AddRoundKey**: This operation is simply an XOR of the key for the round and the state.

5. **KeyExpansion**: Most of the key expansion operations are XORs. The other operation is the application of the  $S_{RD}$  function from `SubBytes`.

## Software Implementations

The primary points of concern for any software implementation clearly are three computations:

1. The  $GF(2^8)$  arithmetic appearing in several places.
2. The byte-oriented finite field operations in `MixColumns`.
3. The issue of memory storage and/or access for the expanded key bits.

Because AES operates entirely on bytes, we can ignore the XOR operations and the byte movements of the `ShiftRows` step; there are no operations here that are not well supported by the ISA of a standard processor.

We have already pointed out that the combined `SubBytes` operation can be done by table lookup with the  $S_{RD}$  function. If not for this, then at other points in the computation one will need to be able to do arithmetic in  $GF(2^8)$ . Fortunately, this can be done with fixed arithmetic steps and does not need complex loops with decisions. The polynomial modulus is as follows:

$$m(x) = x^8 + x^4 + x^3 + x + 1,$$

so we have the following:

$$\begin{aligned}
 x \cdot \sum_{i=0}^7 a_i x^i &= \sum_{i=0}^7 a_i x^{i+1} \\
 &\equiv a_6 x^7 + a_5 x^6 + a_4 x^5 + (a_3 \oplus a_7) x^4 + (a_2 \oplus a_7) x^3 \\
 &\quad + a_1 x^2 + (a_0 \oplus a_7) x^1 + a_7 \pmod{m(x)}.
 \end{aligned}$$

The modulus  $m(x)$  is a nine-bit pattern  $1|00011011$ . Multiplication of the eight-bit pattern  $a_7 a_6 a_5 a_4 a_3 a_2 a_1 a_0$  produces the nine-bit pattern  $a_7 | a_6 a_5 a_4 a_3 a_2 a_1 a_0 0$ , so in the case that  $a_7 = 1$  we XOR the right-hand eight bits with a mask  $00011011$  to perform the reduction modulo  $m(x)$ . In software, this can be implemented as a shift left that is possibly followed by an XOR with a mask  $00011011$ . Multiplication by any element of  $GF(2^8)$  can be accomplished by breaking that element down into its powers of  $x$  (in effect, by using the usual recursive doubling approach), so that the fundamental operation of multiplication by  $x$  (a.k.a.  $02$ ) is sufficient as a kernel.

One of the reasons for the choice of the polynomial  $c(x)$  was that the coefficients  $01$ ,  $02$ , and  $03$  allow for multiplication as a simple operation. Multiplication by  $01$  is in fact not multiplication; multiplication by  $02$  is the operation defined above, and multiplication by  $03$  is multiplication by  $02$  followed by an XOR. Unfortunately, the coefficients  $09$ ,  $0B$ , and  $0D$ , and  $0E$  of the `InvMixColumns` step are not inherently so simple, if only because the nontrivial entries are more dense and the number of 1-bits greater, making for more bit operations required for the  $GF(2^8)$  operation.

Fortunately, as pointed out by Daemen and Rijmen (2001), P. Barreto has observed that the `InvMixColumn` multiplication is separable into two matrix products

as follows:

$$\begin{pmatrix} 0E & 0B & 0D & 09 \\ 09 & 0E & 0B & 0D \\ 0D & 09 & 0E & 0B \\ 0B & 0D & 09 & 0E \end{pmatrix} = \begin{pmatrix} 02 & 03 & 01 & 01 \\ 01 & 02 & 03 & 01 \\ 01 & 01 & 02 & 03 \\ 03 & 01 & 01 & 02 \end{pmatrix} \times \begin{pmatrix} 05 & 00 & 04 & 00 \\ 00 & 05 & 00 & 04 \\ 04 & 00 & 05 & 00 \\ 04 & 04 & 00 & 05 \end{pmatrix}$$

This permits the `InvMixColumns` to be implemented with the following preprocessing step followed by the same multiplication as used in `MixColumns`.

On 32-bit or larger processor platforms, the same intraword operations can be implemented as on 8-bit platforms, but the longer wordlength can be an advantage in that one can handle four-byte columns in a single step.

Software for AES is relatively straightforward to implement, and use of the software features mentioned above mitigates substantially any complexities because of ISA shortcomings. As part of the original AES competition and selection process, it was necessary for reference code for each algorithm to be submitted. Reference code by P. Barreto and V. Rijmen appears in Daemen and Rijmen (2001) and totals fewer than 350 lines of C, including four major tables for lookup of the  $GF(2^8)$  arithmetic. Two other versions of reference code can be found at Daemen and Rijmen (2004).

Several authors have reported the processing rate of software implementations of AES. Timings are notoriously quick to become obsolete, and timings are often difficult to compare. Lipmaa reports (2004) 260 cycles (1.437 Gbits/s) for encryption and 257 cycles (1.453 Gbits/s) for decryption, with assembly language programs on a 3.05-MHz Pentium 4 processor and 319 cycles (0.861 Gbits/s) and 344 cycles (0.798 Gbits/s) for encryption and decryption, respectively, with C programs (gcc 3.0.2) on a 2.25-MHz Athlon processor. Other implementations are reported at between 226 and 376 cycles on lesser processors, with the faster implementations being in assembly language and the slower implementations in C or C++. Gladman reports (1999, 2000) similar timings.

It is worth pointing out that the speed of AES in software is somewhat, but not significantly, slower than either DES or triple-DES (Sanchez-Avila, 2001).

## Hardware Implementations

The AES was designed so that it might be suitable for smart-card and similar applications. Thus, although software implementations are of interest, the various hardware or programmable-logic implementations of AES are of interest, and in addition to speed, issues of silicon resources and attendant power consumption become relevant. Many of the hardware implementations were done prior to the adoption of Rijndael as the AES, and the articles were published in the AES conference proceedings (NIST, 2000a). A number of these articles provide a comparative analysis of the five finalist algorithms. Some comparisons have also been published in other journals or conferences (Dandalis, 2000).

Hardware implementations of AES have been quite varied, in part because of the varied many different uses to which AES could be put. Many of these implementations

have been specific ASICs or ASIC designs; some have been architectural specifications for a processor that would support AES computations in a “native” mode (Kuo, 2001; Satoh, 2003; Sklavos, 2002). A large number of implementations have been made on field programmable gate arrays (FPGAs) (Chodowicz, 2001, 2003; Fischer, 2001; Gaj, 2001; Jarvinen, 2003; Kancharla, 2003; McLoone, 2001; Standaert, 2003; Weaver, 2002). Some work also continues on algorithmic means by which processing could be sped up under the assumption that one has, in hardware, substantial flexibility in how the bits are manipulated; among these studies are some on the best way by which the Galois Field arithmetic can be supported in hardware (Rudra, 2001).

Finally, there are corporate offerings of AES cores. Companies such as Helion or North Pole Engineering offer a range of AES cores, from tiny ASIC designs to large ASIC designs or FPGA implementations, with a throughput range of tens of megabits per second to claimed best-case rates in the tens of gigabits per second (Helion, 2004; North Pole, 2003).

Hardware implementations, although varied, can generally be said to address one or more of the following questions:

1. If one were designing an ASIC for AES, what design would yield the absolutely the fastest throughput?
2. If one were designing an ASIC for AES, what design would yield the the fastest throughput and use no more hardware than might be available on a smart card?
3. If one were designing an ASIC for AES, what design would yield the the fastest throughput and use no more hardware than might be available on a network interface card?
4. If one were implementing AES on reconfigurable hardware (FPGAs), what design would yield the absolutely the fastest throughput?
5. If one were implementing AES on reconfigurable hardware, what design would yield the the fastest throughput and use no more hardware than might be available on a smart card?
6. If one were implementing AES on reconfigurable hardware, what design would yield the the fastest throughput and use no more hardware than might be available on a network interface card?

The FPGA-based implementations add another dimension to the definition of “best” in that they permit designing an implementation with the look and feel of an ASIC, but they must be placed on specific commercial chips. Where software implementations are constrained by the ISA of the processor, the FPGA implementations are constrained by the size and nature of the FPGA resources. In most instances, the eventual constraint on throughput is not on the AES core but on the bandwidth through the device of which the FPGA is a part (Rudra, 2001).

Further, on either ASICs or FPGAs, there are methods either for improving performance or for decreasing size by rearranging the steps of the algorithm. If hardware size is not an issue, then the iterative loop of the rounds can be unrolled to pipeline the rounds themselves. This should

permit increased throughput, at the cost of a latency that will not be noticed in steady state, but which will require hardware for each individual round instead of a single hardware module used repeatedly.

One effect of the loop unrolling is that the number of lookup tables might increase dramatically, because one would prefer to keep the tables physically close to the logic that uses the stored values. To avoid the hardware cost of the  $GF(2^8)$  lookup tables, one can perform the arithmetic in hardware; one comparison (Kancharla, 2003) showed a very dramatic decrease in hardware utilization and an increase in speed when this change was made to a design. An additional benefit is that memory access is inherently going to be sequential, working against the parallelism of hardware, and the on-chip memory resources of FPGAs is not sufficient to provide for all the tables needed in a fully unrolled AES design.

Even if the outer loop of rounds cannot be fully unrolled, there is also the possibility in hardware for combining the flow of processing inside the rounds. In general, the larger the hardware circuit to be synthesized by design tools, the more efficient and higher performing the circuit will be (until the circuit is so large that the tools can no longer function properly). Larger designs provide more opportunity for synthesis tools to extract parallelism. Also, breaking a large design into modules often requires signals that must propagate from one module to another to be registered both on output and on input; if multiple modules are synthesized together, then such signals can be dealt without the artificial modularization.

## SECURITY—THE FUTURE OF THE ADVANCED ENCRYPTION STANDARD

The primary reason for existence of a cryptographic algorithm is to maintain *confidentiality* of data, that is, to prevent disclosure of data to unauthorized parties. In its simplest application, a user would encrypt a data file so that it could be transmitted “in the clear” without fear that the contents could be read by someone not possessing the key. Conscious user action to encrypt the data can provide the security required, although in a corporate setting the data transmission software could be configured to make this transparent. Either way, the data need only be encrypted and decrypted once per transmission in this end-to-end method, and the management of keys is simplest of all the scenarios because keys need only be distributed to users.

A more complicated setting would exist if the goal were to encrypt the data payloads of individual packets after the transmission process has begun, and if the process of decryption and reencryption were to take place at every link along the path from sender to receiver. Because the number of packets and the number of links would normally each be much larger than the number of files transmitted, and because the process would now have to be completely transparent to the users involved, this situation requires a much higher speed of encryption and decryption. This also requires a much different standard for the integrity of the key distribution process because all the link-to-link connections must be provided with keys.

Regardless of the application, the fundamental question to be addressed with regard to any cryptographic algorithm is, “Is it secure?” The initial attempts at cryptanalysis, done as part of the AES evaluation process, are detailed in the NIST report (Nechvatal et al., 2000). There has been subsequent work attacking AES, and one summary of some of these attacks can be found at Courtois (2004). Courtois and Pieprzyk have shown (2002) that AES can be written as an overdefined system of multivariate quadratic equations and an attack developed on that basis; this approach has also been used by Murphy and Robshaw (2002). As of this writing and according to Courtois, no one has so far shown that this approach will not work, but no one has so far demonstrated by example that it does work.

Courtois is clearly skeptical about AES. In response to the NESSIE (New European Schemes for Signatures, Integrity and Encryption) press release (2003) that states that no weakness has been found in AES (or in 16 other algorithms submitted to the European competition), Courtois argue, “This is simply not true and such a recommendation could have serious consequences.” Much more positive, or at least less skeptical, about the status of AES is Landau (2004), who writes, “The cryptography community is a rather contentious lot, but it has been virtually unanimous in its praise of NIST’s AES effort and the choice of Rijndael as the Advanced Encryption Standard. This is high praise indeed.”

Despite the complaints of Courtois, then, the future of AES seems assured. The NIST Web site (2000b), in the response to a frequently asked question, says that AES “has the potential to remain secure well beyond twenty years.” It seems likely, then, that AES will continue to be an approved algorithm for U.S. government use for many years to come.

## INTRODUCTION

Modern asymmetric cryptology started with the invention of digital signatures (see Chapter 176, Digital Signatures and Electronic Signatures) in the mid-1970s, when Diffie and Hellman described properties of suitable mathematical mechanisms. Very shortly later Rivest, Shamir, and Adleman made this idea concrete by introducing their famous RSA scheme (see Chapter 111, Public Key Algorithms). Signing and verification in this scheme uses modular exponentiation, which is useful because of its algebraic properties. Conversely, modular exponentiation is relatively slow when applied to the bit sizes needed for RSA to be secure.

To implement digital signature schemes, in practice one needs an additional cryptographic primitive, a so-called (cryptographic) hash function. A hash algorithm computes an output (or hash value), which is a short string of fixed length—say  $n$  bits—as a function of the input (message), a bit string of arbitrary length.

In a digital signature scheme, when Alice wishes to sign a message, she hashes the message, signs the hash value with her *private key*, and sends both the message together with the signed hash value to Bob. To verify the signature, Bob also hashes the message (using the same hash function). Conversely, he recovers the hash value of the signed message from the signature using Alice's *public key*. Then he checks whether the two hash values are equal; if they are, the signature is valid (see Figure 1). (The latter applies to schemes such as RSA, whereas the verification in schemes like the NIST standard Digital Signature Standard (DSS); [Federal Information Processing Standard, 186-2, 2000] is a bit different. But a hash function is involved here in the same way.)

The reasons for using a hash function are (1) to save computation time (hash algorithms are significantly faster than asymmetric mechanisms—to be more precise, a hash function not meeting this requirement would be practically useless for real applications) and (2) to save

storage space and time for sending (signing without hashing would, at a minimum, double the size of a message).

Hash functions are nowadays also used in various cryptographic applications. For example, if one needs to preserve the integrity of a long message that is being sent, one can simply compute the hash value of the message and send it in addition to the message. Then, if one is able to preserve the integrity of this much shorter hash value, the receiver can check the integrity of the received message by simply computing the hash value of the received message and comparing it with the received hash value. Hash functions are also used in other cryptographic protocols such as, for example, protocols for payment or for broadcast authentication (see also Chapter 114, Cryptographic Protocols).

This chapter begins with general definitions and remarks. Then we describe some approaches to designing hash functions, and we give a description of general attacks, especially the birthday attack, followed by the main principle of *iterated compression* and the *Merkle–Damgård theorem*.

Almost all hash functions that appear today in practical applications are either in some sense derivatives of the hash function MD4, introduced by Ron Rivest, or in a minor part built from a block cipher by some general method. Therefore, in this chapter we focus on these classes of hash functions. We first present the compression functions of the most important MD4-type hash functions. Then we describe some techniques that were used to attack some of these functions and give an overview of the current status of these hash functions. Finally, we describe the general methods that can be used to construct hash functions from block ciphers and the most important construction of a message authentication code.

## Definitions

In general, a hash function is a function that meets two requirements: (1) it is easily computable and (2) it

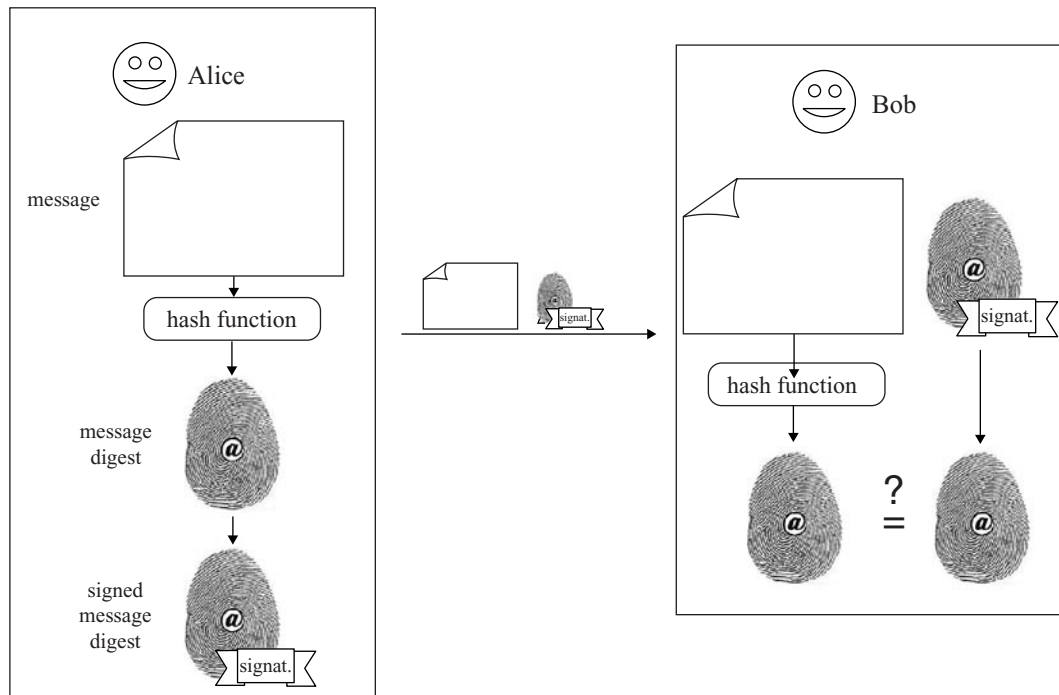

Figure 1: Hashing in a digital signature scheme.

compresses the input to some shorter output (hence the name).

Hash functions are also used in a noncryptographic framework, especially in connection with searching. In this context, a hash function is used to map the key of an object to a memory address at which the object is stored. For these kinds of hash functions it is desirable that collisions (i.e., keys with the same hash value occur very rarely). See Knuth's standard textbook [29] (1998) for more details and examples on this kind of hashing.

In this chapter, we deal with *cryptographic* hash functions. For a cryptographic hash function, the need to avoid collisions is much stricter; it has to be *collision resistant*.

**Definition 1** A hash function  $h$  is called **collision resistant** if it is computationally infeasible to find a collision, that is, a pair of two different messages  $X$  and  $X'$  with  $h(X) = h(X')$ .

Of course the *existence* of collisions is unavoidable. Because of the compression, on average there are very many preimages to one hash value (i.e., very many messages which map to this hash value). The point is that in fact two such messages cannot be *found*. The reason for this requirement is that Eve could take advantage of a collision as follows (see Figure 2): suppose Eve would be able to produce two messages,  $X$  and  $X'$ , that are mapped to the same hash value and whose contents differ significantly, for example, two contracts about buying something but with very different prices. Then Alice might be willing to sign  $X$ , which seems to be quite cheap to her. So Eve asks Alice for her digital signature on this contract and what she receives is not only a valid signature for  $X$  but also

for  $X'$ . The signature for  $X$  is also valid for  $X'$ , because the verification process only refers to the (common) hash value of  $X$  and  $X'$ . This means, Eve can replace  $X$  by  $X'$  and claim that Alice signed  $X'$ .

Therefore it makes sense to require that security of a hash function means collision resistance.

Hash functions also occur as components in various other cryptographic applications (e.g., protection of pass phrases) where usually much weaker cryptological requirements are sufficient, namely *preimage resistance* and *second preimage resistance*.

**Definition 2** A hash function  $h$  is called

- **preimage resistant** if, given a hash value  $V$ , it is computationally infeasible to find a message  $X$  with  $h(X) = V$
- **second preimage resistant** if, given a message  $Y$ , it is computationally infeasible to find a message  $X \neq Y$  with  $h(X) = h(Y)$ .

If both conditions (preimage resistance and second preimage resistance) are satisfied, then we say that  $h$  is *one-way*. If onewayness is violated, then the cryptographic defect is made even dramatically worse than in the case of a simple violation of collision resistance: Eve does not depend on the cooperation of Alice. If she obtains any message signed by Alice, then she will be able to replace it with a different message.

Let us take a look at some relationships between these properties of hash functions.

**Theorem 1** If  $h$  is a collision resistant hash function, then it is also second preimage resistant.

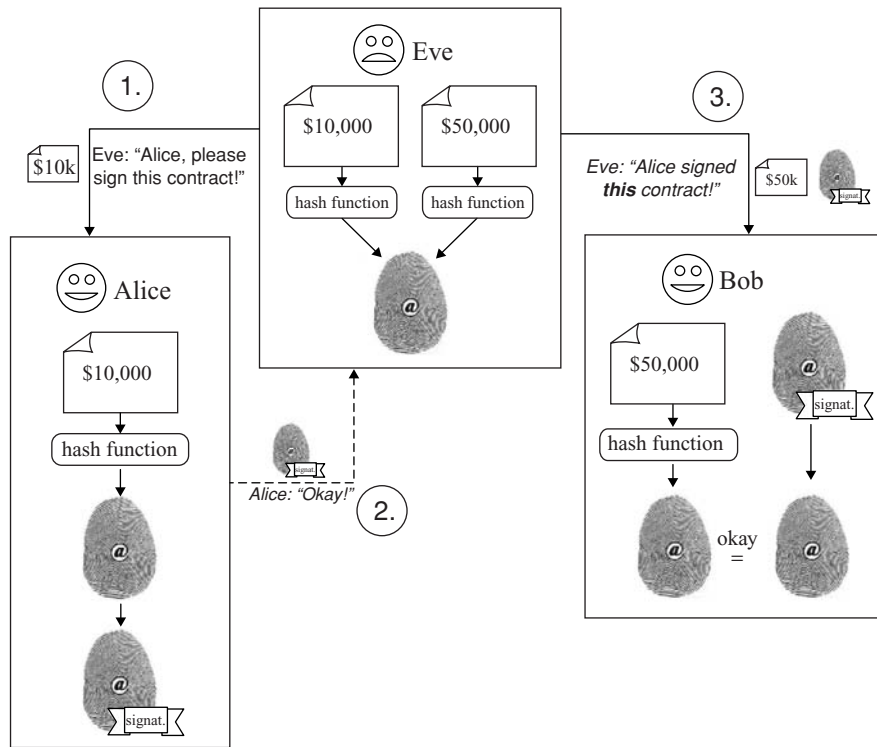

Figure 2: Forging a signature with a noncollision resistant hash function.

This is quite obvious, given the definitions above. Intuitively it seems to be quite clear as well that second preimage resistance implies preimage resistance: If we would be able to find preimages for given hash values than it seems to be clear intuitively that given some message  $Y$  with hash value  $h(Y)$  it is possible to compute some preimage  $X$  that produces the same hash value. For common hash functions with a lot of compression this conclusion should be true, but formally there is some problem with this argument. It is not clear that the messages  $X$  and  $Y$  are different. This means that formally we can present a function that is second preimage resistant but not preimage resistant.

### Example 1

The identity function is obviously not preimage resistant, but as there is only one preimage to each image, it is impossible to find a second message with the same hash value as any other message. Thus the identity function is second preimage resistant as well as collision resistant.

But if we ignore such “pathological” examples of hash functions that do not behave like a random function (what a good hash function should do), then, in fact, collision resistance implies preimage resistance and second preimage resistance.

We must admit that the above notions of collision resistance and onewayness are pragmatic and not formal mathematical definitions. In particular, the question What does *computationally infeasible* mean precisely? depends very much on the context being considered. For

example, computationally feasible may mean in polynomial time (asymptotically) or simple requiring less than some specified bound of computing time or space (e.g.,  $2^{80}$  steps).

It is possible to make these definitions more precise by introducing suitable formalisms, but often these definitions are not very useful in practice for the concrete hash functions we can construct today.

## DESIGNING HASH FUNCTIONS

The design of hash functions is certainly one of the most difficult problems in cryptography. The difficulty is to find a design that is simultaneously fast and cryptographically strong. To be more precise, one needs to find an appropriate balance between performance and a complexity, which is estimated to be sufficient for collision resistance.

The first decision to make when designing a hash function is to choose the size of the hash values. Of course, for reasons of efficiency, it is desirable to make it as small as possible, but, conversely, it must be sufficiently large that the hash function can be considered collision resistant and (second) preimage resistant.

As mentioned earlier, these terms depend on the context in which the function is considered. But in the community it is well established that in the general case an attack needing at least  $2^{80}$  steps can be considered computationally infeasible, today. To decide whether a certain hash function is secure in this context, one should be aware of possible general attacks on hash functions. The most important of these attacks is the Birthday attack.

## Birthday Attack

The term *birthday attack* stems from the so-called birthday paradox. Strictly speaking this is not a true paradox but simply a surprising fact.

**Fact 1 (Birthday Paradox)** *In a group of 23 persons, the probability that 2 of them share the same birthday is greater than 50%.*

At first glance, the number of people required for this probability is surprisingly low. However, it can be confirmed as follows: For two persons, the chance that they share the same birthday is  $1/365$  (we are simplifying a little by ignoring leap years and other irregularities). Thus, the probability that they have different birthdays is  $1 - 1/365 = 364/365$ . Given that the first two persons have different birthdays, there are 363 “possible birthdays” left for a third person such that all three of them have different birthdays (i.e., the chance for this to happen is  $364/365 \times 363/365$ ). A fourth person adds another factor of  $362/365$  to this probability and so on. This argument shows that, for  $k$  people, the probability that they all have different birthdays is as follows:

$$\frac{364}{365} \times \frac{363}{365} \cdots \frac{366-k}{365} = \prod_{i=0}^{k-1} \frac{365-i}{365}.$$

Hence, the probability that two of these  $k$  people share the same birthday is as follows:

$$1 - \prod_{i=0}^{k-1} \frac{365-i}{365}.$$

Computing these values for 22 and 23 people, respectively, shows that the corresponding probabilities are approximately 47.6 and 50.7%, respectively (i.e., 23 is the smallest number of people for which the probability of two people in a group of  $k$  people having the same birthday is greater than 50%).

Another approach of understanding why the *birthday paradox* is not as surprising as it seems at first glance, is the following argument: The number of possible pairs of persons (and therefore possible instances of having the same birthday) is as follows:

$$\binom{23}{2} = \frac{23 \times 22}{1 \times 2} = 253$$

in this case. Considering the fact that the probability for each of these pairs for being composed of two persons sharing the same birthday is  $1/365$ , this result seems much less surprising.

In fact, for 30 people the probability of two of these people sharing the same birthday is greater than 70%, and, for more than 60 people, one can be almost sure, because then the probability is greater than 99%.

We give a precise analysis for a more general form of the paradox, stating the following:

**Theorem 2 (Generalized Birthday Paradox)** *Given a set of  $t$  pairwise distinct elements ( $t \geq 10$ ), the probability that in a sample of size  $k > 1.2\sqrt{t}$  (drawn with repetition) there are two equal elements is greater than  $\frac{1}{2}$ .*

*Proof.*

Let  $P$  be the probability that all  $k$  chosen elements are distinct. Then by analogy with the above argument, this probability is as follows:

$$P = \prod_{i=0}^{k-1} \frac{t-i}{t} = \prod_{i=0}^{k-1} \left(1 - \frac{i}{t}\right) = \frac{t!}{t^k(t-k)!}.$$

This is because, after drawing  $i$  elements, there are  $t-i$  (of  $t$ ) elements that can be drawn without producing two equal elements. Because  $e^x \geq x+1$ , for all  $x$ , it holds that (with  $x = -\frac{i}{t}$ )

$$P \leq \prod_{i=0}^{k-1} e^{-\frac{i}{t}} = e^{-\sum_{i=0}^{k-1} \frac{i}{t}} = e^{-\frac{1}{t} \binom{k-1}{2}} = e^{-\frac{k(k-1)}{2t}}.$$

For  $k > 1.2\sqrt{t}$  and thus  $k > \frac{1}{2}(1 + \sqrt{1 + 8t \log 2})$  (for  $t \geq 10$ ), it follows that

$$e^{-\frac{k(k-1)}{2t}} < e^{-\frac{\frac{1}{2}(\sqrt{1+8t \log 2}+1) \frac{1}{2}(\sqrt{1+8t \log 2}-1)}{2t}} = e^{-\frac{1}{4} \frac{(1+8t \log 2-1)}{2t}} = e^{-\log 2} = \frac{1}{2}$$

and thus  $P < \frac{1}{2}$ , which means that the probability  $1 - P$  that there are two equal elements is greater than  $\frac{1}{2}$ .

For cryptographic applications, it is more convenient to consider the following corollary:

**Corollary 1 (Generalized Birthday Paradox; “Collision Version”)**

*Suppose that  $F : \mathcal{X} \rightarrow \mathcal{Y}$  is a random function where  $\mathcal{Y}$  is a set of  $t$  values. Then one can expect to find a collision after about  $\sqrt{t}$  evaluations of  $F$ .*

It is interesting to notice that the number of evaluations mentioned in the corollary is some kind of “worst case” (for the attacker): If there was some bias in the considered function, that is, it is more probable that some value  $Y_1$  is hit than some other value  $Y_2$ , then the expected number of required evaluations would decrease. For example, consider the extreme case that all the values from  $\mathcal{X}$  are mapped to only one value in  $\mathcal{Y}$ . Then a collision will be found after evaluating  $F$  exactly twice, independent of the size of  $\mathcal{Y}$ .

Thus it is an important requirement for a hash function that it maps to all possible hash values with (nearly) the same probability.

An  $n$ -bit hash function can take on  $2^n$  values. Thus after computation of hash values of about  $2^{n/2} = \sqrt{2^n}$  messages we expect to find a collision.

Important research is addressing the problem of how to implement, practically, a collision search using the birthday paradox or variants of it. There are two questions that arise when implementing such an attack in practice: (1) Is it possible to construct a collision between *meaningful* messages? and (2) How can one actually *find* the collision (without having to do about  $2^n$  comparisons)?

The answer to the first question is “yes”; the idea (Yuval, 1979) is the following: starting from two messages,

$X_1$  and  $X_2$ , whose hash values one wishes to collide, one produces about  $2^{n/2}$  variants of each of these messages, having the same content. This seems to be impractical, but can be done easily by finding  $n/2$  independent positions, in which the actual code of the text can be changed, without changing its contents, for example, by using synonymous expressions, exchanging tabs for spaces (or vice versa), adding some blank lines and so on. Then, by a reasoning very similar to that of the birthday paradox, there is a good chance that there are two messages,  $X'_1$  (a variant of  $X_1$ ) and  $X'_2$  (a variant of  $X_2$ ), that generate the same hash value.

But the second question still holds: how to actually *find* those messages. Clearly, it is not a good idea to compare the hash values of all  $X_1$  variants with those of all  $X_2$  variants, as then about  $2^n$  comparisons would be required. Yuval's answer to this is to first compute the hash values of all  $X_1$  variants and to store them in some data structure, allowing inserting and finding elements in constant time. This is possible in practice, for example, using a "hash table" (see [29], Kunth, 1998 not to be confused with cryptographic hashing that is the subject of this chapter). With such a data structure it is possible [in time  $O(2^{n/2})$ ] to check for all  $X_2$  variants whether there is an  $X_1$  variant with the same hash value.

The problem here is that the hash values of  $2^{n/2}$  variants of  $X_1$  need to be stored. Usually practical bounds on space are much stricter than on computing time, that is, if  $n$  is that large that a computing time of  $2^{n/2}$  can only be considered *just* feasible, then the required storage space is too large to be feasible. For example, currently, a computing time of  $2^{64}$  steps may be considered feasible by using extreme parallelization, but a required memory of  $2^{64}$  bytes ( $= 2^{34}$  GB  $\approx 17$  billion GB) is far beyond our current capabilities.

However, the required space can be reduced to "almost nothing," using an idea primarily known from Pollard's  $\rho$ -method for factorizing integers. Generally, this method works with a function  $f$  mapping some set onto itself and looks at sequences that are recursively defined by the following:

$$h_i := f(h_{i-1}).$$

As long as the set on which this function is defined, is finite, at some point this sequence will run into a loop, that is, there are natural numbers  $m, p$  with  $h_m = h_{m+p}$ . From that moment on the sequence behaves periodically, that is,

$$h_{m+l} = h_{m+l+kp}$$

for all  $l, k \geq 0$ . This is the reason for calling this method the  $\rho$ -method (see Figure 3).

In the following, let  $m$  be the minimal number with  $h_m = h_{m+p}$ . Then additionally (and most important), as long as  $m > 1$ , this also gives a collision: As  $m$  is defined to be minimal with  $h_m = h_{m+p}$ , we have the following:

$$h_{m-1} \neq h_{m-1+p},$$

but

$$f(h_{m-1}) = h_m = h_{m+p} = f(h_{m-1+p}).$$

Figure 3: The  $\rho$  in Pollard's  $\rho$ -method.

To apply this method to find collisions in hash functions, the function  $f$  is defined on the set of all the hash values of all variants of  $X_1$  and  $X_2$  in the following way: It first maps an arbitrary hash value to one of the variants and then computes the hash value of this message. For usual hash functions we can assume that they behave (nearly) randomly and thus also this mapping  $f$  can be assumed to be a (nearly) random function. Hence, it is very probable that the cycles we find for this function, have  $m > 1$  and thus directly lead to a collision.

The crucial observation (Floyd) is, that one needs to store only very few values to detect such cycles: Start with the pair  $(h_1, h_2)$  and iteratively compute the pairs  $(h_i, h_{2i})$  until one finds a pair with  $h_i = h_{2i}$ . If  $p$  and  $m$  from above are minimal, the first time such a pair occurs is, when  $i = p(\lfloor \frac{m}{p} \rfloor + 1)$  (i.e., for some  $m \leq i \leq m + p$ ). From the generalized birthday paradox we can expect  $m + p$  to be of order  $O(2^{n/2})$ , which means we essentially need to compute  $O(2^{n/2})$  hash values to find a collision, but we must store only the current pair of hash values. For more details on implementation issues in connection with collision searching (see, e.g., van Oorschot & Wiener, 1999).

### Meet-in-the-Middle Attack

Another kind of attack similar to the birthday attack is the "meet-in-the-middle" attack. This method does not attack collision resistance, but (second) preimage resistance, and is able to find (second) preimages in a time similar to that of the birthday attack.

However, it is not as general as the birthday attack because it cannot be applied to arbitrary hash functions but only to a certain class of "weak" hash functions: if one can fix some inner point in the computation of the hash value where some intermediate value is computed, such that the second part of the computation can be reversed (i.e., one can compute backward from the hash value to the intermediate value) and the inputs determining the computations in the two parts can be chosen independently, then the hash function is subject to a meet-in-the-middle attack.

The attack works as follows (very similar to Yuval's birthday attack): suppose the intermediate value has bit size  $n$ . Then generate  $2^{n/2}$  initial parts (or "first halves") of messages  $X_1$  (or, rather, as in the birthday attack, variants

of some initial part of some fixed message) that can serve as input for the first part of the computation and generate  $2^{n/2}$  endings (or “second halves”) of messages  $X_2$  for the second part of the computation. Then one obtains two sets of intermediate values, one set by computing from the beginning using the  $X_1$ 's as inputs and one set by computing backward from some fixed hash value to the intermediate value using the  $X_2$ 's as inputs. Similar to the argument used for the birthday attack after computing this many intermediate values one can expect to find a collision (i.e., one initial part  $X_1$  and one ending  $X_2$  that produces the same intermediate value). At this point, the concatenation of these two message parts gives a message whose hash value is the desired one.

Because such intermediate values in the computation usually have the same bit length as the hash value, this shows that, with an effort similar to that of finding collisions with the birthday attack (second) preimages can be computed (as long as the hash function is subject to this kind of attack). Note that the conclusion is *not* that computing preimages is as easy as finding collisions but that when designing a hash function, one has to ensure that the design is not subject to this kind of attack.

In general, these attacks show that, to prevent an attacker from finding collisions using a birthday attack,  $n$  should be large enough such that computing  $2^{n/2}$  hash values is computationally infeasible. As mentioned earlier, today  $n = 160$  is still considered to be sufficient, but recognizing the rapid increases in computing power suggests that one should consider using a larger value of  $n$  even today.

## Hashing by Iterated Compression

All the hash functions we described in the rest of this chapter follow a certain design principle proposed by Merkle and Damgård (1990). The basic idea is that hashing, like encryption, should be done blockwise. The Merkle–Damgård principle defines how a hash function  $h$  with  $n$ -bit hash values can be built up from a compression function  $f$ —loosely speaking, a “small hash function.” We assume that the computation of  $f$  is initialized by  $n$ -bit vectors, that  $f$  compresses input blocks of fixed size, say  $r$  bits, and returns  $n$ -bit outputs. (In particular, we have  $n = 128$  and  $r = 512$  for MD4 and MD5.) In the following, we denote the compression function  $f$  initialized with the value  $IV$  (initial value) by  $f_{IV}$ .

To be able to apply the Merkle–Damgård principle, we first must pad the message such that its length is a multiple of  $r$ . This can be done in different ways, for example, by simply appending some zeroes, but this would allow some special attacks (see, for example, Menezes, van Oorschot, & Vanstone, 1996, Remark 9.32). To avoid these attacks, it is necessary to at least append some block to the message during the padding that contains the binary representation of its original bit length.

Suppose that, after appropriate padding, a given message  $M$  is split into a sequence of  $s$  blocks of length  $r$  as follows:

$$M = M^{(1)}M^{(2)} \dots M^{(s)}.$$

**Figure 4:** Merkle–Damgård principle, hashing by iterated compression.

The hashing process is initialized with some fixed  $n$ -bit initial value  $IV^*$ , which is a part of the specification of the hash algorithm. The hash value of  $M$  is then computed by an iterative application of  $f$ , where the  $M^{(i)}$  are taken as inputs and each output of  $f$  is the initial value for the next application of  $f$  as follows:

$$H_0 := IV^*,$$

$$H_i := f_{H_{i-1}}(M^{(i)}), \quad i = 1, \dots, s.$$

The hash value of  $M$  is defined to be the last output of the compression function  $f$  as follows:

$$h(M) := H_s.$$

Clearly, this general design principle can easily fall victim to a meet-in-the-middle attack, if the compression function is poorly designed: a meet-in-the-middle attack can be initiated if the compression function is invertible, in the sense that the initial value  $IV$  can be easily computed from the input message block  $M^{(i)}$  and the output  $f_{IV}(M^{(i)})$ . Then one can simply choose some point between any two applications of the compression function as the collision point, and the corresponding intermediate hash value as the intermediate value needed in the meet-in-the-middle attack. This means, when designing a hash function using the Merkle–Damgård principle, it is important to avoid such poorly behaved compression functions. In many practical designs, this problem is solved by including some “feed-forward.” This means at the end of the computation the  $IV$  used at the beginning of the computation is used again such that when computing backwards one would have to know the result in advance.

Using this common design principle, the hash functions considered in this chapter mainly differ in the compression function they use (in addition to different choices for some parameters). But before we can move on to the description of these different compression functions under Compression in MD4-like hash functions, we first need to discuss in more detail the term *collision*, in the context of the compression function (“Collisions and Pseudocollisions of the Compression Function”), and the relationship between collision resistance and the discrete log problem (Collision Resistance and the Discrete Log Problem).

## Collisions and Pseudocollisions of the Compression Function

Suppose we have an iterated hash function  $h$  based on a compression function  $f$ . As the output  $f_{IV}(M^{(i)})$  of the compression function actually has two inputs or at least depends on two parameters, the input message block  $M^{(i)}$  and the initial value  $IV$ , we need to clarify the term *collision*.

A *collision* of the compression function consists of one initial value  $IV$  and two different inputs  $X$  and  $X'$  such that

$$f_{IV}(X) = f_{IV}(X').$$

It is important to observe that an attack leading to collisions of the compression function is already very close to collisions for the hash function. What remains is to extend the attack in a way that it is possible to prescribe the initial value above as the initial value  $IV^*$  of the hash algorithm.

Loosely speaking, we can state that collisions of the compression function are (instances of) collisions of the hash function with a wrong initial value.

Conversely, we use the more general term *pseudocollision* of the compression function if two initial values  $IV, IV'$  and inputs  $X, X'$  are given such that

$$f_{IV}(X) = f_{IV'}(X') \quad \text{and} \quad (IV, X) \neq (IV', X').$$

Thus we allow different initial values here.

The fundamental theoretical result of the Merkle–Damgård construction (hashing by iterated compression) is as follows:

**Theorem 3 (Merkle–Damgård Theorem)** *If the compression function  $f$  is pseudocollision resistant, then the derived hash function  $h$  is collision resistant.*

For a proof of this theorem, see Section 10 of Buchmann, 2002.

Unfortunately, we cannot apply this theorem to verify the collision resistance of MD4-like hash functions, either in the positive or in the negative sense. Finding pseudocollisions of  $f$  with different initial value does not necessarily imply any hint how to find collisions of  $h$ . (We do not have the converse of the Merkle–Damgård theorem.) Conversely, for the reasons discussed above, our present knowledge does not allow us to construct a practical compression function with provable pseudocollision resistance.

In contrast, collisions of the compression function are already close to hash collisions, only the initial value is wrong. Hence, to avoid misinterpretations of cryptanalytic results it is very important to distinguish between collisions and pseudocollisions of the compression function. (*Caution*: some authors call a collision what we call a pseudocollision; see, for instance, den Boer & Bosselaers, 1994).

## Collision Resistance and the Discrete Log Problem

For mathematical terms used in this section, we refer to Chapter 110, Number Theory for Information Security.

Suppose we have a finite cyclic group  $G$  generated by an element  $a$  as follows:

$$G = \{a^x : x = 0, 1, 2, \dots, t - 1\},$$

where  $t$  is the order of  $G$  (i.e.,  $G$  has  $t$  elements). Then the discrete log problem (DLP, see Chapter 111, Public-Key Algorithms) means that, given random  $b \in G$ , we have to find the integer  $x$ , smaller than the order  $t$  of  $G$ , such that

$$a^x = b.$$

Note that if  $a^y = b$  for any integer  $y$ , then we get  $x$  as the remainder of  $y$  modulo  $t$ .

DLP looks like a preimage problem, for which we would need about  $t$  computations of  $a^x$  to match  $b$ . But DLP can be transformed into a collision-finding problem and can therefore be solved much more efficiently. The reason is that the mapping  $x \mapsto a^x$  has a very special property, the “homomorphic” equation:

$$a^{x_1} a^{x_2} = a^{x_1 + x_2}.$$

In fact, we define the functions  $E(x) = a^x$  and  $F(x) = (a^x b)^{-1}$  for  $x = 0, 1, \dots, t - 1$ . By a collision of  $E$  and  $F$ , we understand a pair of integers  $x_1, x_2$ , such that  $E(x_1) = F(x_2)$ . Such a collision leads to the solution  $x = x_1 - x_2 \pmod t$  of  $a^x = b$ :

$$a^{x_1 - x_2} = E(x_1)F(x_2)^{-1}b = b.$$

Note that, conversely, if we have a solution of  $a^x = b$ , then  $x$  and 0 form a collision of  $E$  and  $F$ . After computing only about  $\sqrt{t}$  many values of  $E$  and  $F$ , we have a good chance of finding a collision (see “Birthday Attack”). This connection between the DLP and collision detection makes it plausible that, for the following hash function by Chaum, van Heijst, and Pfitzmann, it is possible to show its collision resistance as long as the DLP is believed to be a hard problem:

**Definition 3 (Chaum–van Heijst–Pfitzmann hash function)** *Suppose  $q$  is a large prime,  $p = 2q + 1$  is also prime and  $a, b$  are primitive elements of  $\mathbb{Z}_p$ , the ring of integers modulo  $p$ . Then the hash function*

$$h : \{0, \dots, q - 1\}^2 \rightarrow \mathbb{Z}_p^x$$

is defined as

$$h(x_1, x_2) = a^{x_1} b^{x_2} \pmod p.$$

**Remark.** Note that  $h$  is not a hash function in the proper sense because it can be applied only to messages of bit length  $\leq 2\lceil \log_2 q \rceil$ , whereas (in principle) a hash function has to be defined for arbitrarily long messages.

**Theorem 4** *The above Chaum–van Heijst–Pfitzmann hash function  $h$  is collision resistant if and only if the DLP is solvable in the cyclic group  $G = \mathbb{Z}_p \setminus \{0\}$  of integers modulo  $p$ , under multiplication.*

For the easy proof of this theorem, we refer to Section 7.4 of the standard cryptography book of Douglas Stinson (1995).

However, the Chaum–van Heijst–Pfitzmann hash function, like RSA, is based on modular arithmetic. Thus it does not meet our requirement of being fast. It remains a significant open challenge to find fast hash functions for which we can prove security, in the sense of collision resistance, relative to a mathematical problem that is believed to be hard.

As long as a solution to this problem is elusive, we must rely on ad hoc designs for practical hash functions. And here it can cause a pitfall to develop a design that allows us to derive a “provable security” in the sense that, for example, all hash values occur with about the same probability. Conversely, from the theoretical point of view it would be nice to have such a property. But experience has shown that we run the risk that the internal structure of such a design that allows us to prove a certain restricted aspect of security could, conversely, turn out to cause other weaknesses. As long as our theoretical knowledge is as limited, as it is today, we believe that, for practical applications, it is better to follow another approach—loosely speaking, trial and error. Proposals are discussed in the cryptographic community. Their analyzes lead to (partial) attacks, and in this way we obtain more insight into how to avoid the observed weaknesses. The survivors of this cryptographical evolution are the candidates for future standards. The design of practical block ciphers, in particular, the competition of candidates for the AES block cipher, is another example of this procedure.

## COMPRESSION IN MD4-LIKE HASH FUNCTIONS

The compression functions described in this section have many things in common. They use word sizes of  $w$  bits ( $w \in \{32, 64\}$ ) and operate on  $4 \leq r \leq 8$  registers that are initialized with an IV (or intermediate hash value) of  $r \times w = n$  bits. Then they are modified in 48–80 steps, using some function that depends on the 512 or 1024 bits of the message input. The output of  $n$  bits then consists of the final state of the registers, usually after adding the initial value again to include some “feed-forward” (see end of “Hashing by Iterated Compression”). Details on the parameters for certain hash functions can be found in Table 1. A survey of these functions is given in Figure 5.

The description of the compression functions can be split into two parts, the *message expansion*, in which the message is expanded to some longer bit string, which is then used as input to the second part, the *step operations* (compare Figure 6).

### Message Expansion

In the message expansion part, the current message block  $M^{(i)}$  used as input to the compression function is first split

into (usually 16) words  $M_i$ . Then, from these  $M_i$ , some values  $W_i$  are computed, which are later used in the step operation to update the registers.

The compression functions considered here use two different kinds of message expansions to compute the  $W_i$  from the  $M_i$ , a “roundwise permutation,” or some recursive definition.

### Roundwise Permutation

Roundwise permutation means that we have some number of rounds (usually 3–5) consisting of as many steps as we have message words  $M_i$  (usually 16). Then, in every round, each of the message words is used once, that is, for each round  $k$ , we have a permutation  $\sigma_k$  such that  $W_{16k+i} = M_{\sigma_k(i)}$ .

This kind of message expansion is used in (extended) MD4, MD5, HAVAL, and the RIPEMD variants. Two concrete examples of such permutations are given in Tables 2 and 3.

These tables show that the permutations used are chosen to have “regular irregularities.” For example, in the MD5 expansion, the index used in each round is increased by some fixed number (1 in the first round, 5 in the second, and then 3 and 7). These numbers are chosen such that they do not have common divisors, which means that there are only few other patterns in these sequences. There is no real, obvious reason for doing this, but heuristically it seems to be better, that is, harder, to attack if the message blocks are mixed well.

In the RIPEMD family, this is done in an even more systematic way. We describe it here, using the example of RIPEMD-160: first a permutation  $\rho$  is defined as in Table 4 and another permutation  $\pi$  is defined by setting  $\pi(i) = 9i + 5 \pmod{16}$ . Table 5 gives the order of the message words.

These permutations were chosen such that there are as few patterns as possible and message words that are close in the left half are at least seven positions apart in the right half, not only within each round, but also between different rounds.

### Recursive Message Expansion

Message expansion by recursive definition means that after choosing some starting values (usually  $W_i = M_i, i = 1, \dots, 16$ ) the following  $W_i$  are computed recursively from the preceding  $W_i$ . This kind of message expansion has the advantage that (nearly) all the  $W_i$  depend on (nearly) all the  $M_i$ , meaning that if just one of the words of the message is changed, most of the steps in the second phase of the computation are affected. This clearly makes it much harder to control what is happening. This kind of message expansion is typical for the hash functions of the SHA family. In SHA-0, the following recursive definition is used (for notation see Table 6):

$$W_i = W_{i-3} \oplus W_{i-8} \oplus W_{i-14} \oplus W_{i-16}, \quad i \in \{17, \dots, 80\}.$$

But there is a flaw in this definition: the  $k$ -th bit of each word  $W_i$  is influenced only by the  $k$ -th bits of the preceding  $W_i$ . This means that this expansion causes much less diffusion than desirable. For example, the revised version SHA-1 uses the following message expansion that

**Table 1** Parameters of Some Hash Functions

	Word Size (in bit)	Registers	Output Length (in bit)	Steps	Reference
MD4	32	4	$4 \times 32 = 128$	$3 \times 16 = 48$	Rivest (1991, 1992a)
Ext. MD4	32	$2 \times 4$	$8 \times 32 = 256$	$2 \times 48$	Rivest (1991)
MD5	32	4	$4 \times 32 = 128$	$4 \times 16 = 64$	Rivest (1992b)
HAVAL	32	8	128, 160, 192, 224, 256	$3 \times 32, 4 \times 32,$ $5 \times 32$	Vaudenay (1995)
RIPEND-0 <sup>(*)</sup>	32	$2 \times 4$	$4 \times 32 = 128$	$2 \times 48$	RIPE Consortium (1995)
RIPMED-128	32	$2 \times 4$	$4 \times 32 = 128$	$2 \times 64$	Dobbertin et al. (1996)
RIPMED-160	32	$2 \times 5$	$4 \times 32 = 160$	$2 \times 80$	Dobbertin et al. (1996)
RIPMED-256	32	$2 \times 4$	$8 \times 32 = 256$	$2 \times 64$	Bosselaers Dobbertin et al. (1996)
RIPMED-320	32	$2 \times 5$	$10 \times 32 = 320$	$2 \times 80$	Bosselaers Dobbertin et al. (1996)
SHA-0 <sup>(*)</sup>	32	5	$5 \times 32 = 160$	80	Federal Information Processing Standard (FIPS) 180 (1993)
SHA-1	32	5	$5 \times 32 = 160$	80	Federal Information Processing Standard (FIPS) 180-2 (2002)
SHA-224	32	8	$7 \times 32 = 224$	64	Federal Information Processing Standard (FIPS)180-2 (2002)
SHA-256	32	8	$8 \times 32 = 256$	64	Federal Information Processing Standard (FIPS) 180-2 (2002)
SHA-384	64	8	$6 \times 64 = 384$	80	Federal Information Processing Standard (FIPS) 180-2 (2002)
SHA-512	64	8	$8 \times 64 = 512$	80	Federal Information Processing Standard (FIPS) 180-2 (2002)

Note: The functions marked by an asterisk have originally been proposed without the “-0” extension. This was added later to avoid confusion.

**Table 2** Indices  $j$  with  $W_{16r+i} = M_j$  in the MD4 Message Expansion

$r$	$i$	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0		0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
1		0	4	8	12	1	5	9	13	2	6	10	14	3	7	11	15
2		0	8	4	12	2	10	6	14	1	9	5	13	3	11	7	15

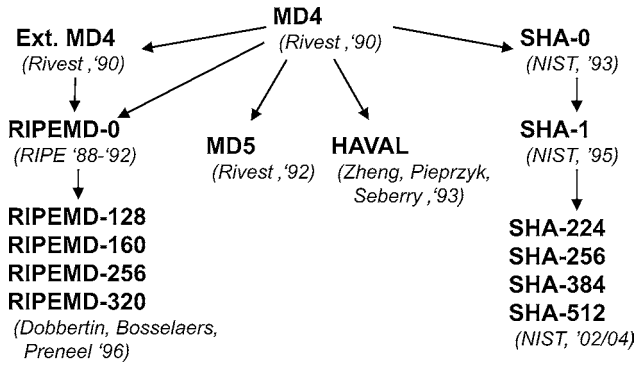

Figure 5: The MD4 family of hash functions.

achieves much more diffusion:

$$W_i = (W_{i-3} \oplus W_{i-8} \oplus W_{i-14} \oplus W_{i-16}) \lll 1, \quad i \in \{17, \dots, 80\}.$$

This means the message expansion of SHA-0 was just supplemented with a rotation by one bit, which causes the bits of these values to be mixed much more than before. In the later SHA versions, NIST decided to mix even more by using not only  $\oplus$  and bit rotations but also bit shifts and modular additions in the message expansion. SHA-256 (and thus also SHA-224, which mainly consists in applying SHA-256 and ignoring 32 output bits) uses the following expansion rule:

$$W_i = \sigma(W_{i-2}) + W_{i-7} + \sigma_0(W_{i-15}) + W_{i-16},$$

where

$$\begin{aligned} \sigma_0(x) &:= (x \ggg 7) \oplus (x \ggg 18) \oplus (x \gg 3), \\ \sigma_1(x) &:= (x \ggg 17) \oplus (x \ggg 19) \oplus (x \gg 10). \end{aligned}$$

Hence, the message expansion is no longer linear. The message expansion of SHA-512 (and SHA-384) is similar but uses 64-bit words and some adjusted  $\sigma_0$  and  $\sigma_1$ .

### Step Operation

The single steps in the compression process of all hash functions of the MD4-family are based on the following operations on words, where a word is a 32-bit (or in some cases 64-bit) quantity:

- Bitwise Boolean operations

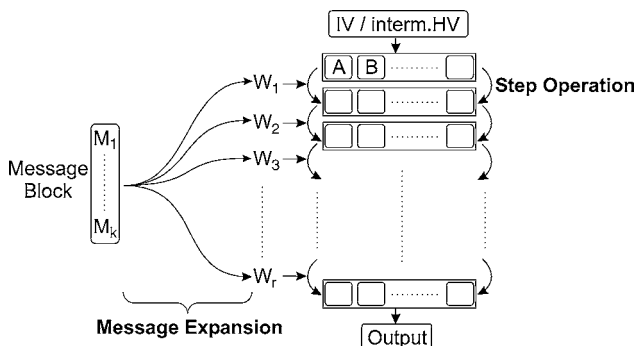

Figure 6: Interaction between message expansion and step operations.

- Addition modulo  $2^{32}$  (or  $2^{64}$ , respectively)
- Bit shifts and rotations

(For the notation of these operations see Table 6.)

These operations have been chosen, because they can be computed very rapidly on modern computer architectures and because the mixing of Boolean functions and addition is believed to be cryptographically strong.

As described earlier, the most distinctive differences between the compression functions described here lie in the different step operations, which describe how the chaining registers are updated. They have in common, that only one or two of the registers are updated in each step, using some function that is a mixture of the basic operations described above.

In the following, we describe some of the important features of each step operation. For details on the definitions of the complete hash functions, consider the references given in Table 1.

### MD4

As an example, we take a closer look at the MD4 compression function to illustrate its internal structure. The 512-bit input  $M^{(j)}$  and 128-bit initial value  $IV$  are split into words. The compression process operates on four word registers (chaining registers)  $A, B, C, D$ , which are initialized with  $IV$ . The compression algorithm has three rounds each consisting of 16 steps (i.e., in total 48 steps) in which the  $W_i$  resulting from the message expansion (see Table 2) are applied.

In every step, one of the chaining registers is updated. A typical step operation of the compression in MD4 is as follows:

$$A := (A + \Phi_i(B, C, D) + W_i + K_i) \lll s_i,$$

where  $\Phi_i$  is a round-dependent, bitwise defined Boolean function,  $K_i$  is a step-dependent constant, and the rotation amount  $s_i$  is also step dependent. The Boolean functions used in MD4 are as follows:

$$\begin{aligned} \Phi_i(X, Y, Z) &:= \text{ITE}(X, Y, Z) := XY \vee \bar{X}Z, & 1 \leq i \leq 16, \\ \Phi_i(X, Y, Z) &:= \text{MAJ}(X, Y, Z) := XY \vee XZ \vee YZ, & 17 \leq i \leq 32, \\ \Phi_i(X, Y, Z) &:= X \oplus Y \oplus Z, & 33 \leq i \leq 48. \end{aligned}$$

They were chosen, as they have some important properties supporting an “avalanche effect” (this means that small differences in the registers are mapped to large differences after only a few steps). For example, these functions are balanced. Further, if the bits of  $X, Y$ , and  $Z$  are independent and unbiased, then also each output bit will be independent and unbiased, and last, changing one bit of the inputs changes the output in exactly half of the possible cases.

After processing the three rounds, the compression value is obtained by wordwise addition (modulo  $2^{32}$ ) of  $IV$  to the chaining registers.

### MD5

The design of MD5 is quite similar to that of MD4. In addition to the ITE and the XOR function used in MD4, also the following two Boolean functions are used in MD5,

**Table 3** Indices  $j$  with  $W_{16r+i} = M_j$  in the MD5 Message Expansion

$r$	$i$	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0		0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
1		1	6	11	0	5	10	15	4	9	14	3	8	13	2	7	12
2		5	8	11	14	1	4	7	10	13	0	3	6	9	12	15	2
3		0	7	14	5	12	3	10	1	8	15	6	13	4	11	2	9

which have similar properties:

$$\begin{aligned}\Phi(X, Y, Z) &= XZ \vee Y\bar{Z} = \text{ITE}(Z, X, Y), \\ \Phi(X, Y, Z) &= Y \oplus (X \vee \bar{Z}).\end{aligned}$$

The step operation itself is very similar to that of MD4 with one primary difference: after the rotation, one of the registers is added to get the new register value:

$$A := B + ((A + \Phi_i(B, C, D) + W_i + K_i) \lll s_i).$$

For a visualization of this step operation, see Figure 7.

### RIPEMD-128/-160/-256/-320

The most important difference in the compression functions of the RIPEMD functions is that the message is processed in two parallel lines. That means we have two sets of 4 (in RIPEMD-128/256) or 5 (in RIPEMD-160/320) registers, which are initialized with the same IVs and updated using the same step operation, but with different constants, different amounts of rotations and, most important—as seen above—different message schedules. After processing the full number of rounds, in the end the results of both lines are then combined together with the IV to produce the output.

The step operation in RIPEMD-128/-256 is the same as in MD4, and in RIPEMD-160/-320, a very similar function

$$A := ((A + \Phi_i(B, C, D) + W_i + K_i \lll s_i) + E$$

is used, in which, at the end, the value of the additional (fifth) register is added to the result. Additionally, in RIPEMD-160/-320, another register is updated in each step, namely  $C := C \lll 10$ . Of course, these functions, although appearing to be identical or similar to those above (for MD4/MD5), are different in the sense that in some of the steps they use other Boolean functions  $\Phi$  and other constants for each step. For details on this, see Dobbertin, Bosselaers, and Preneel (1996).

The larger-sized functions RIPEMD-256 and RIPEMD-320 differ from their smaller brothers mainly at the end. Apart from some additional interaction between the two parallel lines, the only difference is, that in the end in RIPEMD-128/-160 the values of the register are added to-

gether, whereas in RIPEMD-256/-320, the values are just concatenated to produce a longer output. For details on this, see Bosselaers and Dobbertin et. al. (1996).

### SHA-0/1

In SHA-1 (and also formerly in SHA-0), the step operation is very similar to those above, just that the shift now uses a fixed value and operates only on one register instead of some intermediate result:

$$A := (A \lll 5) + \Phi_i(B, C, D) + E + W_i + K_i.$$

The  $\Phi_i$  are some of those also used in MD4 and MD5 (see above) and again (as in RIPEMD-160) one additional register is updated in each step by rotating it, in this case by 30 bits. For a visualization of this step operation, see Figure 7.

### SHA-224 and SHA-256

First of all, for these two hash functions notice that they are nearly identical or rather that SHA-224 is merely a shortened SHA-256. To compute a SHA-224 hash value, one performs exactly the same steps as for a SHA-256 hash value, but simply using another IV, and in the end, one truncates the output by using only the leftmost 224 bits. This is done to offer a bigger variety of standardized sizes of hash values because hash functions are usually only a building block in some bigger cryptographical protocol and often the size of the hash value is determined by the surrounding protocol.

For these two functions, the complexity of the step operation is increased by using two mechanisms, by using more (eight) registers, and by using a more complex step function. In each step, first two auxiliary values are computed as

$$\begin{aligned}T_1 &:= H + ((E \ggg 6) \oplus (E \ggg 11) \oplus (E \ggg 25)) \\ &\quad + \text{ITE}(E, F, G) + W_i + K_i, \\ T_2 &:= ((A \ggg 2) \oplus (A \ggg 13) \oplus (A \ggg 22)) \\ &\quad + \text{MAJ}(A, B, C),\end{aligned}$$

and then two of the registers are updated with  $E = D + T_1$  and  $A = T_1 + T_2$ . Here it is interesting to note that all 64 steps of the compression function use the same Boolean

**Table 4** Permutation Used in the Message Expansion of RIPEMD-160

$i$	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
$\rho(i)$	7	4	13	1	10	6	15	3	12	0	9	5	2	14	11	8

**Table 5** Permutations Used in the Message Expansion of RIPEMD-160

Line	Round 1	Round 2	Round 3	Round 4	Round 5
left	$id$	$\rho$	$\rho^2$	$\rho^3$	$\rho^4$
right	$\pi$	$\rho\pi$	$\rho^2\pi$	$\rho^3\pi$	$\rho^4\pi$

function and differ only in the constant  $K_i$  and the message block  $W_i$ .

A consequence of this new, more complex, step operation is that it is slightly slower to compute than the ones described earlier, but it should also be much harder to cryptanalyze.

**SHA-384 and SHA-512**

The situation with SHA-384 and SHA-512 is similar to that of SHA-224 and SHA-256: SHA-384 is merely a shortened version of SHA-512 with a different IV. As mentioned above, these two functions use 64-bit words instead of the common 32-bit words so as to take advantage of modern 64-bit computer architectures. Apart from this, the step operation is nearly the same as in SHA-256 with just some constants adjusted to the larger word size.

**HAVAL**

HAVAL is a very interesting design. In general it uses the same structure as all the other functions here in the MD4 family, but there are also some important differences. Apparently, the most important difference is that, instead of the commonly used Boolean functions with three input variables as in all the other MD4-family hash functions, HAVAL uses Boolean functions with seven input variables. They are constructed in a very special way (which was first described in Seberry & Zhang, 1992), such that they have a number of properties, which are believed to make them cryptographically strong. These are, for example, the properties mentioned above for the three variable functions (e.g., balancedness) but also having high nonlinearity and being linearly inequivalent. For details on this, see Section 3 of (Vaudenay 1995) the original description of HAVAL.

Another difference in HAVAL is that the user can adjust the security level by choosing between different numbers (3, 4, or 5) of passes and thus can make a trade-off between efficiency and security.

**Table 6** Notation

$a \vee b$	Bitwise or of the variables $a$ and $b$
$\bar{a}$	Bitwise negation of the variable $a$
$a \ll b$	Leftwise shift of variable $a$ over $b$ positions
$a \gg b$	Rightwise shift of variable $a$ over $b$ positions
$a \lll b$	Leftwise rotation of variable $a$ over $b$ positions
$a \ggg b$	Rightwise rotation of variable $a$ over $b$ positions
$+$	Modular addition (the modulus is usually $2^{32}$ )
$\oplus$	Exclusive-or

**Figure 7:** Step operations of MD5 (left) and SHA-0/1 (right).

**Performance**

It is difficult to measure the performance of hash functions objectively because it depends very much on actual implementations and on the platforms on which they are implemented. In this section, we try to give a rough overview at least of the relative performance of some hash functions by presenting two tables with performance data on two different platforms: Table 7 of Bosselaers shows the performance of some of the older members of the MD4-family on an old 90-MHz Pentium (for details see Bosselaers). Table 8 shows the performance of some of the newer hash functions on a 2.1-GHz Pentium 4, as they are implemented in the Crypto++ library (see Crypto++ 5.2.1 Benchmarks).

**ATTACKS ON MD4-LIKE HASH FUNCTIONS**

In what follows, we describe the status of the analysis of the MD4-like hash functions described above.

The first analyses of MD4 and MD5 were made by Merkle (unpublished), den Boer and Bosselaers (1992, 1993) and Vaudenay 1995. Then the second author developed a new general technique to attack MD4-like hash functions and applied it to RIPEMD-0, MD4, Extended MD4 and MD5 in a series of papers (1996–1998; Dobbertin 1995, 1996a, 1996b, 1997, 1998a). Later this technique was used by Kasselmann & Penzhorn (Kasselmann & Penzhorn 2000) to attack a reduced version of Haval and by van Rompay, Biryukov, Preneel, and Vandewalle (2003) to break the smallest full version of HAVAL (3 rounds, 128 bit output).

In 1998, Chabaud and Joux used a different method to show how SHA-0 could be broken theoretically. This was later extended by Biham and Chen (2004), who produced near-collisions of SHA-0 and collisions of reduced

**Table 7** Performance of Some Hash Functions on a 90-MHz Pentium (See Bosselaers)

Hash function	Performance (in megabytes per second)
MD4	23.90
MD5	17.09
RIPEMD-0	12.00
RIPEMD-128	9.73
SHA-1	6.88
RIPEMD-160	5.68

**Table 8** Performance of Some Hash Functions on a 2.1-GHz Pentium 4 (See Crypto++ 5.2.1 Benchmarks)

Hash function	Performance (in megabytes per second)
MD5	216.67
HAVAL(3 rounds)	108.54
HAVAL (4 rounds)	69.28
SHA-1	67.98
HAVAL(5 rounds)	67.44
RIPEMD-160	52.60
SHA-256	44.46
SHA-512	11.39

versions of SHA-1 with it. Joux, Carribault, Jalby, and Lemuet (2004) then used this extension to produce real collisions of SHA-0.

Also in 2004 Wang, Feng, Lai, & Yu refined and extended some of these techniques to produce real collisions for MD4, MD5, RIPEMD-0, and HAVAL (3 round, 128 bit).

In this section, we first give a survey of the most important techniques used in these attacks and try to classify them in a common scheme. After that we describe the status of the hash functions that we described earlier.

## General Attack Methods

In this section, we give a survey of the most important aspects of the techniques used in current cryptanalyses to find collisions for hash functions. For a more detailed analysis of these techniques, see Daum (2005).

All the current techniques have in common that they can be divided into at least two parts. In the first part, the general “attack strategy,” a so-called difference pattern is chosen or determined. Usually in this part many steps are done by hand and are of a more theoretical nature. In contrast, the second part, in which the actual collisions are determined, usually requires a lot of time-consuming computations. The techniques used here include “brute force”-like searches but also more sophisticated algorithms.

### Difference Patterns

All the methods described in this section are attacks on the collision resistance of a hash function. This means we are looking for two messages,  $X$  and  $X'$ , that produce the same hash value. Therefore, we have to correlate the computations that are done when computing the hash value of  $X$  and the computations for the hash value of  $X'$ . A *difference pattern* is a sequence of differences, where each difference corresponds to one step in these computations. Each of the difference values is defined as a difference of a value from the computation for  $X$  and the corresponding value from the computation for  $X'$ .

We have to distinguish between *input differences*, which means differences in the messages, or rather in the values  $W_i$  after the message expansion, and *output differences*, that is, differences appearing in the register values after applying the step operations. Another important distinction is that between *modular differences*, that is, differences with respect to integer addition, usually

modulo  $2^n$  (where  $n$  is the register size in bits), and  $\oplus$  differences.

Usually one tries to choose the input differences in a way such that the output differences behave in some special way. Clearly, the most important goal in doing so is that the last output differences, which correspond to the output value of the compression function, are zero differences because that is what constitutes a collision. But generally more restrictions than this have to be imposed to find actual collisions in the end, and this is where the methods used in the attacks differ significantly.

In some sense, it is more natural to consider modular differences because most of the basic operations from which the step operations are built are modular additions. Especially the last operations applied in each step, which have the directest influence on the differences are modular additions. But one cannot analyze the function completely by considering only modular additions, because there are also operations which are not compatible with this kind of difference and it is not possible to deduce  $\oplus$ -differences directly from the modular differences.

Conversely, it is also not possible to analyze these functions completely by considering only  $\oplus$  differences. Usually, when using mainly  $\oplus$ -differences, the operations that are not compatible with this kind of differences are approximated by other functions that are compatible. Then the algebraic structure of a vectorspace can be used and it is quite easy to analyze this approximative function with linear algebra techniques. However, one has the problem to transfer the results for the approximation to the real function.

### Inner Collisions

The method used in Dobbertin (1995, 1996a, 1996b, 1997, 1998a) to attack RIPEMD-0, MD4, and MD5 uses a concept called “inner collisions” that consists of a very simple input difference pattern and only little restrictive output difference pattern. We describe the basic ideas of this technique using the example of the attack on MD5.

The method uses mainly modular differences and the following simple input difference pattern: we assume for the colliding message pair  $X, X'$  that all words coincide, with one exception, say  $X_{i_0}$  and  $X'_{i_0}$ :

$$X'_{i_0} = X_{i_0} + \Delta,$$

where  $\Delta$  is some small value; in the actual attack it is chosen to be 1. This implies, because of the message expansion by roundwise permutation, that only four of the  $W_i$  (in the MD5 attack for  $i \in \{15, 26, 36, 51\}$ ) and the corresponding step operations differ when processing  $X'$ , in contrast to processing  $X$ . Thus, in the first 14 steps, exactly the same step operations are used to update the same register values, meaning that, initially, it suffices to start with step 15 in the cryptanalysis. Similarly, the last 13 steps (52–64) are the same, implying that finding a collision after 64 steps is equivalent to finding a collision after step 51. In other words, from this input difference pattern we can conclude that the output difference pattern has zeroes at the first 14 and at the last 13 steps. This situation is illustrated in the left diagram in Figure 8.

This limits the avalanche effect from taking effect over 64 rounds to only 37 rounds. To limit it even more, in this

**Figure 8:** Overview of the attack on the compression function of MD5.

technique one restricts the desired collisions even more, by requiring that, during the processing of the two messages, so-called inner collisions appear. That means that, not only after step 51 but also after step 26, we require the contents of the registers to be equal when processing  $X$  and  $X'$ , respectively. This leads to a situation (as shown on the right-hand side of Figure 8) where in steps 27 to 35 exactly the same things are happening (the output difference pattern has zeroes in these steps), meaning that the avalanche effect only takes place in two quite short ranges of 12 and 16 steps.

**Inner Almost-Collisions**

Another important approach used in this technique is to look for “inner almost-collisions” some steps before the required inner collisions.

The general problem with the approach of considering mainly differences of values (and not the values themselves) is that the difference propagation is not deterministic. That means, given differences for the register values and for the input value for one certain step, the difference of the values in the register, which is updated in this step, is, in general, not uniquely determined. It also depends on the actual values in the registers and not only on their differences.

However, for “small” differences, this behavior is quite predictable, meaning that the probabilities for certain output differences are significantly higher than for all the others. Here “small” does not mean the size of the actual integer value of the modular difference, nor the hamming weight of its binary representation, but mainly having a short signed representation. That means the difference can be written as a sum of very few values of the form  $\pm 2^i$  (for details on this, see Daum, (2005)).

Thus, if the output difference is quite small after some step—and this is what is called an “inner almost-collision”—there is a difference pattern for the next steps that is fulfilled with high probability for random register values. Therefore, the idea is to perform some kind of differential attack (modulo  $2^{32}$ ) on the steps immediately before the inner collisions to decide which differences in the registers are the most likely to lead to the desired inner collision.

**Elementary Collisions**

Chabaud and Joux (1998) use a different approach to dealing with this “nondeterministic difference propagation.” They use only  $\oplus$  differences, but the propagation of these differences in the actual step operation is as little deterministic as described earlier for the modular differences.

Thus their idea was to consider approximations of the step operations by some operation that has a deterministic difference propagation. Therefore, they replaced every nonlinear (with respect to the  $\oplus$  operation) operation by some linear operation. For example, instead of the modular addition of two values they used the  $\oplus$  sum of these values, which is the same as ignoring carry bits during the modular addition. As this results in a linear function the difference behavior of this approximative function, can be analyzed using linear algebra techniques.

The crucial idea then was to consider elementary collisions (or *local collisions* as they were called in Chabaud & Joux, 1998) of this approximative function, that is, collision appearing after as few steps as possible. Therefore, they defined *perturbations* and corresponding *corrective patterns*. Making a perturbation simply means to change one bit in the input difference pattern at some arbitrary step. The corresponding corrective pattern than consists of some bits in the steps following the perturbed step, which lead to a collision in the approximated function after as few steps as possible.

For example, in SHA-0 the step operation is given by the following:

$$A := (A \lll 5) + \Phi_i(B, C, D) + E + W_i + K_i,$$

which can be approximated by the following:

$$A := (A \lll 5) \oplus (B \oplus C \oplus D) \oplus E \oplus W_i \oplus K_i.$$

This means, if we decide to change the  $k$ -th bit of  $W_i$ , then also the  $k$ -th bit of the updated register  $A$  is changed. In the next step, the values in the registers are changed cyclically, that is,  $B$  inherits the value and thus also the difference from register  $A$ . But before that, the new value of register  $A$  is computed by the formula above (with  $i + 1$  instead of  $i$ ) and to avoid another nonzero difference in this register, we have to change the  $(k + 5)$ -th bit of  $W_{i+1}$ , because the register  $A$  is rotated by 5 bits before being used. Thus the  $(k + 5)$ -th bit of step  $i + 1$  is the first correction bit of the corrective pattern.

By analogous considerations, it can be determined which bits have to be changed in next four steps to avoid nonzero differences. Then, after six steps, this leads to a collision in the approximated function, a so-called elementary collision. It is called elementary, as it can be shown by arguments about the dimensions of the corresponding subspaces that all the collisions of the approximated function can be written as sums of these elementary collisions. Thus it is quite easy with methods from linear algebra to find such input difference patterns that lead to output difference patterns corresponding to a collision of the approximated function.

However, there are two drawbacks with this approach. First, the chosen input difference pattern, consisting of perturbations and corresponding corrective patterns,

must be consistent with the message expansion. That is, one must be able to find messages (or rather message differences), which, after the expansion, result in the wanted input difference pattern. For SHA-0 (where this method was used) this is quite simple, because the message expansion itself is linear. Thus this requirement resulted simply in some additional linear conditions. To apply this method on hash functions with a nonlinear message expansion, one would have to use an approximation again.

The other problem is that, so far, the input difference pattern determined in this way only leads to output difference patterns corresponding to a collision if the approximated function is applied. If this should also be the case for the actual (nonlinear) step operations and thus result in a collision of the actual hash function, various additional conditions have to be met.

This leads directly to the second part of these attacks: how to find the actual collisions after having decided the difference patterns.

### Randomized Searches

Usually the additional conditions mentioned above can be assumed to be (nearly) independent conditions, which are fulfilled for random messages with some probability. This probability can be deduced from a detailed view at the approximation. Thus the first, but quite naive, way of searching for collisions would simply be to produce random messages, apply the chosen input difference pattern, and hope that all the additional conditions are met such that the message results in a collision.

Usually the probabilities deduced from the additional conditions are so small that this approach is computationally infeasible. But there is some refinement, used in Chabaud and Joux (1998), that makes this approach much more feasible: One starts, as before by choosing random messages and applying the input difference pattern, but first only the additional conditions for the first 15 steps (in which the first 15 of 16 message words are used) are considered. After having found a message producing the intended output difference pattern in the first 15 steps, one changes only the 16th message word for a while. This does not change the output difference pattern for the first 15 steps but produces a nearly random behavior for the remaining steps. Thus mainly the probability for these remaining steps is of importance for the overall complexity of this attack.

Chabaud and Joux (1998) describe a difference pattern that is fulfilled (in this sense) with a probability of  $2^{-61}$ , which means their attack has a complexity of about  $2^{61}$ .

### Neutral Bits

Biham and Chen (2004a) refined this approach even more by looking for *neutral bits*.

Their idea is to increase this range of steps for which one tries to assure in advance (before the main part of randomized search) that the output difference pattern is as intended. Clearly, if one looks at more than 15 steps, it is no longer possible to change some message word arbitrarily without having to fear that the output difference pattern has changed. But this is where the *neutral bits* come into play. A bit of some message is called neutral if changing it does not prevent the message from fulfilling the intended

output difference pattern for the chosen range of steps. One can also try to combine these neutral bits to larger sets of bits that often also have this property.

Biham and Chen observed that if many of such sets of neutral bits are combined, changing any subset of these bits does not change the output difference pattern with a quite high probability. Thus this technique can be used to produce a large amount of messages that fulfill the intended output difference pattern in advance for some more steps than 15, as in the technique used by Chabaud and Joux.

The more steps one tries to tick off in this way in advance, the fewer neutral bits will be found and thus the fewer messages can be produced. But increasing the number of steps will also increase the probability of success for the remaining steps. Thus it is crucial for this approach to find a suitable number of steps for which the probability of success and the number of producible messages are fitting.

### Solving Systems of Equations

In the attacks used in Dobbertin (1995, 1996a, 1996b, 1997, 1998a), in which the difference pattern was chosen using the concept of *inner collisions* (see above), the second part of finding actual colliding messages is quite different from what we just described for the attacks by Chabaud/Joux and Biham/Chen.

In these attacks, we have to distinguish among three different kinds of (ranges of) steps. First, we have the areas in which the output difference is intended to be always zero. In the example of the MD5 attack (see Figure 8) this is the case for steps 1 to 14, 27 to 35, and 52 to 64. For the remaining steps (in which there is some nonzero output difference), we have to distinguish between areas with arbitrary differences and those with small differences, where the concept of *inner almost-collisions* (see above) is used.

The last mentioned areas (those with the inner almost-collisions) are dealt with in a way very similar to what we described earlier in the attack of Chabaud and Joux. As the output difference for these steps is fulfilled with a quite high probability for random register values, we simply need to produce a large amount of messages fulfilling the output difference pattern for the other areas and then with a high probability we will find one leading to a collision.

Thus the attack is reduced to mainly two computational parts: a part for finding inner collisions and a part for connecting them. Finding inner collisions means to find actual register values for the steps with nonzero output differences that can be achieved by some pair of messages and the chosen input difference, of course, taking into account the message expansion.

To achieve this, in this method the inner collisions are described by using systems of equations derived from the equations that describe the step operation. These equations usually include  $\oplus$ , modular additions, bitwise defined functions, and bit rotations simultaneously. As these operations are not very convenient to handle mathematically, it is not an easy matter to solve them efficiently, and very sophisticated methods have to be used to find solutions. Some examples of such techniques can be found in Dobbertin (1996a, 1997, 1998a). Refinements of these

algorithms that can also be used to represent the sets of solutions of these systems of equations are described in Daum.

After having found such inner collisions, the last part of the attack is to connect them. This means that one has to find the paths (corresponding to actual register values), which are identical for  $X$  and  $X'$ , between the (end of the) first inner collision and the point where the two paths drift apart again (compare the right-hand side of Figure 8). Additionally (at least to find a collision of the hash function and not only of the compression function), one also has to find a connection between the right initial value  $IV^*$  and the state at which the paths drift apart for the first time (which is in step 15 in MD5). Finding these connections again comes down to solving equations similar to those above used for finding inner collisions.

## Status of Different Hash Functions

### MD4: Three Rounds Are Not Enough

The most successful analytic result for MD4 is a collision consisting of two contracts as presented in Figure 9 (see “Alf swindles Ann”; Dobbertin, 1995). Here the asterisks represent 20 “random” bytes, which form a header. These two contracts generate the same MD4 hash value. Moreover, if the third round in the compression function of MD4 is cancelled, then it is shown in Dobbertin (1998b) how preimages can be constructed. This result brings even the onewayness of MD4 into question.

Another way of producing collisions for MD4 was found by Wang et al. (2004). They succeeded in producing collisions for MD4 with a complexity (after some precomputation) of only 4–64 runs of MD4. Despite these rather devastating analyses, it does not mean that the MD4 design principle is compromised. The moral is simple: three rounds in the compression function are not enough.

### Extended MD4 and RIPEMD-0: Too Much Symmetry

The compression of Extended MD4 consists of two instances of a modified MD4 compression that run in parallel, with some interaction. Therefore, Extended MD4 compression has 6 rounds ( $2 \times 3$ ), but despite this, it is surprisingly weak. The reason for this weakness, which led, in 1996, to finding collisions of the compression function (Section 8 in Dobbertin, 1998a) can be clearly identified: the two parallel lines in the compression are too similar.

```

*****
CONTRACT

At the price of $176,495 Alf Blowfish
sells his house to Ann Bonidea ...

*****
CONTRACT

At the price of $276,495 Alf Blowfish
sells his house to Ann Bonidea ...

```

**Figure 9:** Two contracts producing the same MD4 hash value.

The ordering in which the words are applied in the single steps is identical. This allows an attack on both lines simultaneously, in parallel.

The 1993 design of RIPEMD (which we now call RIPEMD-0, to distinguish it from the newer RIPEMD versions) is modeled after Extended MD4, and unfortunately it inherited the same design defect. Thus, the second author was able to find attacks on two-round reductions of RIPEMD-0 (Dobbertin, H. [1997]). Later Wang et al. (2004) were even able to produce real collisions for the full ( $2 \times 3$ -round) RIPEMD-0. In this attack, they also extensively use the strong symmetry in RIPEMD-0 by using the same differential patterns for both strings of RIPEMD-0.

### MD5: Four Rounds Are Not Enough for Collision Resistance

As seen above, MD5 is a slightly modified version of MD4 with a four-round compression. In 1993, den Boer and Bosselaers (1994) found pseudocollisions for the compression function of MD5 with different initial values but common input. This result implies that the Merkle-Damgård theorem (Theorem 3), which derives the security of a hash function from its underlying compression function, cannot be invoked for MD5. This finding of pseudocollisions shows that the compression function, considered as a cryptographic primitive of its own, has a weakness. But, as already discussed above, the pseudocollisions alone do not lead us closer to collisions of the hash function.

In 1996, the second author (Dobbertin, 1996b) constructed collisions of the MD5 compression function, that is, MD5 collisions with a wrong initial value. This came close enough to collisions of MD5 (compare “Collisions and Pseudocollisions of the Compression Functions”) to suggest that MD5 should no longer be used in applications such as signature schemes, where a collision-resistant hash function is required. Nevertheless, it was still used (or at least allowed to be used) in many applications.

In 2004, Wang et al. succeeded in producing real collisions for the full MD5 hash function. The new idea in their approach was to look for a collision after processing not one but two blocks of the message. This means they have the freedom to choose two difference patterns. They used this freedom by using two different difference patterns with the property that the resulting differences at the end of these patterns are additively inverse modulo  $2^{32}$ . Then a combination of these two patterns leads to a collision because after applying the second difference pattern the initial value of this application of the compression function (and thus the resulting difference of the first pattern) is added again, nullifying the difference in the registers.

Although this attack clearly shows that MD5 is not collision resistant, it tells us nothing about the onewayness of MD5. The attack (as all the methods described under “General Attack Methods”) directly aims at producing collisions and cannot be modified (at least in some obvious way) to compute preimages. Thus, using MD5 as a oneway function (as it done most of the time nowadays) can still be considered secure.

### SHA-0: Too Much Linearity

The most remarkable design idea in SHA, which is essentially different from the design of all former MD4-like hash functions, is the recursive expansion of the sequence of input words for the compression, instead of multiple applications of input words in different rounds.

As mentioned under “Message Expansion,” there was a flaw in the message expansion of SHA and this flaw caused NIST/NSA to replace SHA (later usually referenced as SHA-0) by SHA-1 in FIPS 180-1, which is now included in Federal Information Processing Standard 180-2 (2002). Details of this “flaw” found by the NSA were never published.

But, in 1998, Chabaud and Joux found an attack (see “General Attack Methods”) on SHA-0 with an effort of about  $2^{61}$ , which is not practical, but requires essentially less effort than the birthday attack. With their method of *neutral bits* Biham and Chen (2004) succeeded in actually finding collisions for SHA-0 variants with 65 and 82 steps, respectively (instead of 80 steps). Joux et al. (2004) then adopted this technique and used it to find an attack having a complexity of “only” about  $2^{51}$ , which led—with the help of a supercomputer—to actual collisions of SHA-0.

### HAVAL: Using Seven-Bit Inputs in the Boolean Functions Does Not Help Much

In 2000, using the technique of inner collisions (see “General Attack Methods”), Kasselmann and Penzhorn (2000) cryptanalyzed a reduced version of three round HAVAL. Actually, they were able to find a collision for the last two out of three rounds of HAVAL.

Later, in 2003, van Rompay et al. described an algorithm that is able to produce collisions for the full three-round HAVAL with the apparently small complexity of about  $2^{29}$  computations of the compression function of HAVAL. This attack is another example of the application of the technique of inner almost-collisions.

Then, in 2004, Wang et al. presented a technique (similar to the one which they applied also to MD4, MD5, etc.), which makes it possible to produce collisions for 3-round HAVAL with an effort of only about  $2^6$  computations of the compression function.

Thus, at least the small-sized versions of HAVAL are not collision resistant, and these results bring the collision resistance even of the larger-sized HAVAL versions into question as the attacks seem to be extendable to some degree.

### SHA-1

In SHA-1, the revised version of SHA, the message expansion includes an additional rotation by one bit in each step of the recursion. This causes a significant increase in the diffusion of this hash function. But despite this additional security, Biham and Chen (2004b) succeeded in finding collisions for at least a strongly reduced variant of SHA-1 with 43 instead of 80 rounds. But although 43 rounds is a surprisingly large number of rounds, this is far from being a threat for the full SHA-1 as it is supposed to be used.

Thus, from what we know today, SHA-1 should still be considered as collision-resistant hash function.

### RIPEMD-128/-160/-256/-320

The design of RIPEMD-128/-160/-256/-320 is based directly on RIPEMD-0 (and thus on Extended MD4, the 256-bit extension of MD4). However, conclusions from the results of analyses on these functions were taken into account (how to choose, or not to choose, certain parameters), and the number of rounds is extended from 3 to 4 and 5, respectively (for each of two parallel lines). That is, there are 128 and 160 steps, respectively.

So far, no attacks requiring less effort than the birthday attack are known on these hash functions.

### SHA-224/-256/-384/-512

In the recently published new versions SHA-256 and SHA-512 (and thus also in the shortened versions SHA-224 and SHA-384), the effect of diffusion is increased by using a yet more complex design, for example, by using even a nonlinear message expansion.

Thus, so far, no attacks requiring less effort than the birthday attack are known on these hash functions.

## BUILDING HASH FUNCTIONS FROM BLOCK CIPHERS

Comparing the common design of hash functions, as presented under “Hashing by Iterated Compression”, with the different operation modes of block ciphers (see Chapter 106, Secret Key Cryptography) shows that there are many similarities. Thus, it is not surprising, that there have been many proposals on how to construct hash functions from block ciphers. Another reason for considering this topic is that there are many block ciphers whose security is well analyzed and well established, and the hope might be that it is possible to use this to construct secure hash functions.

All the common designs for building hash functions based on block ciphers use the principle of iterated compression (see “Hashing by Iterated Compression”) and differ only in the way in which the compression function is built from the block cipher. To construct a hash function with an output length of  $n$  bits, one typically uses a block cipher with a block length of  $b$  bits, where  $b$  divides  $n$ . In most cases, the ratio  $\frac{n}{b}$  is either 1 (*single-length* constructions, considered under “Single-Length Constructions”) or 2 (*double-length* constructions, considered under “Double-Length Constructions”). Usually larger ratios are not used, as they would also lead to a larger number of calls of the encryption function of the block cipher and thus to a worse performance.

Actually, this number of calls to the encryption function during one call of the compression function is an important characteristic of such a design because it is a direct indicator for the performance of the design. If the encryption function is called  $s$  times during one call of the compression function, then the *rate* of this construction is defined to be  $\frac{1}{s}$ .

There are two reasons why in practice mostly dedicated hash functions (as in presented in the previous sections) and not hash functions based on block ciphers are used: first, despite being based on *well-analyzed* block ciphers, there are no proofs showing that the constructed

**Figure 10:** Typical single-length constructions of block cipher-based hash functions.

functions are secure *in practice* as hash functions and, second, usually the dedicated designs of hash functions are more efficient than the ones based on block ciphers.

### Single-Length Constructions

There are three schemes that have all been proposed in the 1980s and can be considered the main examples of secure single-length constructions of hash functions from block ciphers. These are the Davies–Meyer, Matyas–Meyer–Oseas, and the Miyaguchi–Preneel constructions (see Figure 10).

If  $E_k(m)$  stands for the encryption of the message  $m$  by applying the chosen block cipher using the key  $k$ , then the output of the compression function  $f$  following the Davies–Meyer scheme can be written as follows:

$$f_{H_{i-1}}(M^{(i)}) := E_{M^{(i)}}(H_{i-1}) \oplus H_{i-1}.$$

Having a close look at the designs of the dedicated hash functions described earlier shows that many of these hash functions were designed having the Davies–Meyer scheme in mind. The internal design of many dedicated compression functions, as described under “Hashing by Iterated Compression” is very similar to the design of a block cipher using a message block  $M^{(i)}$  as a key and the intermediate hash value  $H_{i-1}$  as the message to be encrypted. The idea of later adding the intermediate hash value  $H_{i-1}$  again (as in the Davies–Meyer construction) is exactly what is done in many dedicated designs to include some “feed-forward” (compare “Hashing by Iterated Compression”).

As can be seen in Figure 10, the other schemes are quite similar. The compression function in the Matyas–Meyer–Oseas scheme can be written as follows:

$$f_{H_{i-1}}(M^{(i)}) := E_{g(H_{i-1})}(M^{(i)}) \oplus M^{(i)},$$

and the compression function in the Miyaguchi–Preneel scheme is defined to be the following:

$$f_{H_{i-1}}(M^{(i)}) := E_{g(H_{i-1})}(M^{(i)}) \oplus M^{(i)} \oplus H_{i-1}.$$

In both cases,  $g$  stands for a function, which maps  $n$ -bit inputs to suitable keys for the encryption function and may be the identity function, if this is suitable.

Apparently, all these designs are very similar or rather can be written as follows:

$$f_{H_{i-1}}(M^{(i)}) := E_a(b) \oplus c,$$

with  $a, b, c \in \{H_{i-1}, M^{(i)}, H_{i-1} \oplus M^{(i)}\}$  Preneel, Govaerts, and Vandewalle (1994) analyzed a more general construction, where  $a, b, c, \in \{vH_{i-1}, M^{(i)}, H_{i-1} \oplus M^{(i)}\}$  and  $v$  simply stands for some fixed value. They examined which of these constructions led to secure hash functions and found out that all but 12 of the 64 possible constructions cannot be considered secure and are subject to more or less severe attacks. The 12 constructions left over—to which also the three constructions described above belong—can be summarized to be of the following form:

$$f_{H_{i-1}}(M^{(i)}) := E_k(m) \oplus m[\oplus k],$$

where  $k, m \in \{H_{i-1}, M^{(i)}, H_{i-1} \oplus M^{(i)}\}$ ,  $k \neq m$ , and the final addition of  $k$  is meant to be optional.

Although presented attacks for the weak constructions of this family, later Black, Rogaway, and Shrimpton (2002) analyzed these constructions again, focusing on proofs. They present proofs for all the 12 constructions mentioned above showing that these are secure at least in the black-box model (see Shannon 1949). This means that these proofs show only the absence of attacks on these schemes treating the block cipher as a black box, but they say nothing about possible attacks on these constructions that use some structural properties of the used block cipher. Additionally, they were able to figure out eight further constructions of the type defined above, which are probably (in the black-box model) as collision resistant as the first 12 functions, only their security as oneway functions is not as good. At this point, it is important to note that these proofs are only proofs in the black-box model, which is not “realistic” but an idealized model making it possible to prove anything. For a more detailed discussion, see Black et al. (2002).

The advantage of the single-length constructions is clearly their performance. Their speed is determined by the speed of the used block cipher and modern block ciphers usually come close to the efficiency of modern dedicated hash functions. The problem is that there are hardly any block ciphers providing a block length sufficiently large to guarantee collision resistance. One would need a block cipher with a block length of at least 160 bits and many common modern block ciphers usually provide only 128 bits if not only 64 bits.

### Double-Length Constructions

If one wants to construct a secure hash function based on a block cipher with a relatively small block length, one has to use double-length constructions. There are two widely used designs of such constructions, MDC-2 and MDC-4. They were designed by Brachtl et al. (1990) originally based on DES, and MDC-2 is part of the ISO/IEC standard 10118-2.

**MDC-2**

MDC-2 mainly consists of two parallel instances of the Matyas–Meyer–Oseas scheme with some additional interaction. It was originally designed to be used with DES, but it can be based on any block cipher with a block length of  $b$  bits, providing a hash value of  $2b$  bits length. The message to be hashed is split into blocks of length  $b$  each. One of these message blocks  $M^{(i)}$  together with two chaining variables  $H_{i-1}^L$  and  $H_{i-1}^R$  are used as inputs for the compression function, which is computed as follows: Apply the Matyas–Meyer–Oseas twice, each time using one of the chaining variables together with the message block as inputs and split the respective outputs into two halves:

$$E_{g(H_{i-1}^L)}(M^{(i)}) \oplus M^{(i)} =: A \parallel B,$$

$$E_{g(H_{i-1}^R)}(M^{(i)}) \oplus M^{(i)} =: C \parallel D,$$

where  $A, B, C, D$  are each of length  $\frac{b}{2}$  bits. Then mix these values by switching the right parts to compute the new values for the chaining variables as follows:

$$H_i^L := A \parallel D,$$

$$H_i^R := C \parallel B.$$

This compression function is illustrated in Figure 11.

**MDC-4**

MDC-4 is designed to be mainly a “double MDC-2,” a concatenation of two applications of MDC2. Therefore we need, as before, two chaining variables  $H_{i-1}^L$  and  $H_{i-1}^R$  and split the message into blocks of  $b$  bits each. Additionally, we need two auxiliary chaining variables  $\tilde{H}_i^L$  and  $\tilde{H}_i^R$ , which are in a first step computed exactly as the original chaining variables in MDC-2:

$$A \parallel B := E_{g(H_{i-1}^L)}(M^{(i)}) \oplus M^{(i)},$$

$$C \parallel D := E_{g(H_{i-1}^R)}(M^{(i)}) \oplus M^{(i)},$$

$$\tilde{H}_i^L := A \parallel D,$$

$$\tilde{H}_i^R := C \parallel B.$$

Then in the second application of MDC-2 the auxiliary chaining variables are used instead of the original chaining variables, and the original chaining variables take the

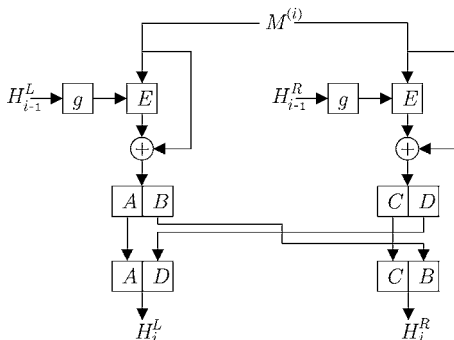

Figure 11: Construction of MDC-2.

place of the message block:

$$A \parallel B := E_{g(H_{i-1}^L)}(\tilde{H}_{i-1}^R) \oplus H_{i-1}^R,$$

$$C \parallel D := E_{g(H_{i-1}^R)}(\tilde{H}_{i-1}^L) \oplus H_{i-1}^L,$$

$$H_i^L := A \parallel D,$$

$$H_i^R := C \parallel B.$$

This design is illustrated in Figure 12.

**MESSAGE AUTHENTICATION CODES**

A message authentication code (MAC) can be shortly described as a keyed hash function. This means it is a family of hash functions  $h_k$ , that is indexed by some key  $k$ . For each evaluation, depending on the key  $k$ , one function is chosen to produce the message digest  $h_k(X)$  corresponding to the message  $X$  and the key  $k$ .

Comparing it with other cryptographical primitives, another way of describing a MAC would be to call it a “symmetric digital signature.” Clearly, it is not possible to use MACs to sign contracts: if one is able to check the signature, one has to know the key and this means one could have signed it oneself. But, if two parties agreed on a secret key, they can use a MAC to authenticate messages to each other by signing the message with the key they agreed on.

The requirements for a MAC to be useful, are similar to those proposed for hash functions earlier with the addition that the dependance of the key has to fulfill some properties: Clearly, MACs should be efficiently computable and should also compress messages of arbitrary length to fixed length message digests. Additionally, MACs should have the property that given a message  $X$  it should be difficult to compute  $h_k(X)$  without knowing the key  $k$ . This is formalized in the property of *computation resistance*: A MAC is called *computation resistant* if, given an arbitrary number of pairs  $[X_i, h_k(X_i)]$

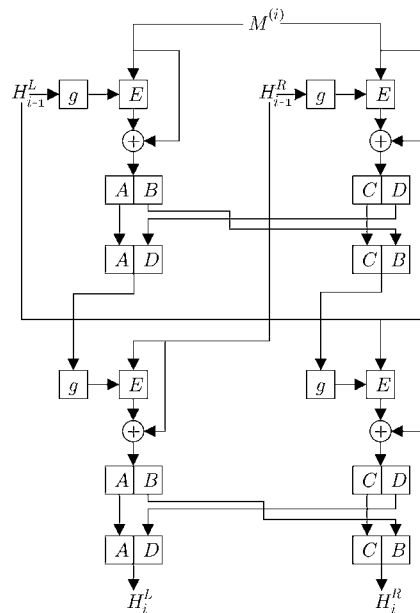

Figure 12: Construction of MDC-4.

of messages and corresponding message digests, it is computationally infeasible to compute  $h_k(X')$  for any new  $X' \neq X_i$ .

MACs are used to authenticate messages, that is, to guarantee the origin and the integrity of a message. Therefore, they are useful in various cryptographic protocols. For details on applications of MACs, see Chapter 114 (Cryptographic Protocols) and Chapter 176 (Digital Signatures and Electronic Signatures).

In this chapter, we concentrate on the technical construction of MACs. There are several possible constructions for MACs, for example, several ways of constructing MACs from block ciphers or also dedicated designs. We focus here on a very important construction, which is used most often in practice and which can be carried out on some arbitrary hash function, the HMAC.

## HMAC

The HMAC was proposed by Bellare, Canetti, and Krawczyk (1996b); a short introduction can be found in Bellare, Canetti, and Krawczyk (1996a).

The basic idea of the HMAC is to use some arbitrary hash function as a black box and build a MAC from it. As should be clear from the previous sections, hash functions do not use any kind of key, so the main question in the HMAC construction should be how to provide a hash function with a key.

The first, naive idea would be to simply prepend or append the key to the message and then hash the extended message  $X\|k$  (or  $k\|X$  respectively). This construction would fulfill the requirement of being a family of hash functions, which is efficiently computable. But it is not computation resistant, as there are many simple attacks on these constructions, such as birthday-style attacks or extension attacks (for details, see Example 9.64, 9.65 in Menezes et al., 1996).

Thus Bellare et al. decided to do a more sophisticated, nested construction: in the HMAC the key is used twice and it works as follows (as illustrated in Figure 13): let  $X$  be the message and  $k$  the key, which should be no longer than 64 bytes. If it is shorter, it is padded by appending

zeroes. Further, let

$$\begin{aligned} \text{ipad} &= 0 \times 36 \text{ repeated } 64 \text{ times,} \\ \text{opad} &= 0 \times 5c \text{ repeated } 64 \text{ times,} \end{aligned}$$

be two bit strings used to mask the key.

Start with prepending  $k \oplus \text{ipad}$  to the message and compute the hash value  $h((k \oplus \text{ipad})\|X)$  of this extended message by applying the chosen hash function  $h$ . Then prepend the bit string  $k \oplus \text{opad}$  to this computed hash value and once again apply the hash function to compute the final output as follows:

$$h_k(X) = h((k \oplus \text{opad}) \| h((k \oplus \text{ipad}) \| X)).$$

At first glance, the complexity of this construction seems to be twice the complexity of the used hash function  $h$  because it is applied two times. But especially for quite long messages it is only marginally more complex than computing the simple hash value of the message, as the “message” used as input for the second application of  $h$  is very short, only about two blocks.

The most interesting aspect of this construction is, that it is provably secure, given some reasonable assumptions. In fact, what Bellare et al. (1996b) show is that, if it is possible for an attacker to break the HMAC construction, then this attacker would be able (with the same effort) to do one of two things: (1) find collisions in the hash function, even for a random or secret IV or (2) compute the output of the compression function even without knowing the IV.

It is very reasonable to assume that this is not possible for any hash function in practical use, or, in other words, a hash function failing to meet this requirements should also not be used in other cryptographical applications.

The HMAC construction was originally designed to be used with MD5 and is nowadays usually used in conjunction with SHA-1. It is a standard in many cryptographical protocols.

## CONCLUSION

We can clearly state that the functions MD4, Extended MD4, RIPEMD-0, SHA-0, and MD5 are broken and must not be used in practical applications where security depends on the collision resistance.

We emphasize that the hash function RIPEMD-128 was designed only as a plug-in for RIPEMD-0. However, hash functions with 128-bit values are becoming more and more susceptible to the birthday attack in the near future. Some years ago, Van Oorschot and Wiener calculated that at a cost of \$10 million one could build a “birthday attack” machine that could find MD5 collisions in about a month. As a result of Moore’s law, we can suppose that today such a machine could be build for much less money and perhaps even be capable of finding the collisions faster.

The status of SHA-1 is not that clear. From what we know today, SHA-1 should still be considered collision resistant and therefore there is no need to replace it at the moment wherever it is used. But for future applications, it seems to be a better idea to use other hash functions, as it

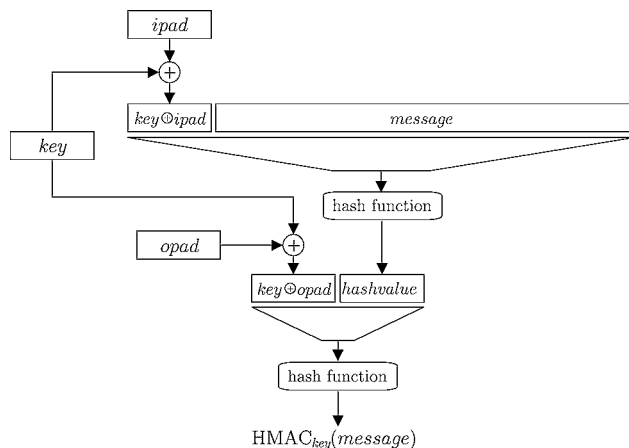

Figure 13: HMAC construction.

is difficult to estimate for how long SHA-1 will stay secure. One of the challenges presented to the crypto community in the crypto competition *Mystery Twister* is to find a collision for a 60-round SHA-1 version (see *Mystery Twister*, 2005).

Summarizing, we can recommend RIPEMD-160/-256/-320 and the new SHA versions SHA-224/-256/-384/-512 as collision resistant (and therefore oneway) hash functions. If merely a oneway hash function is needed, we also recommend MD5 because it is very fast.

## GLOSSARY

**Birthday Attack** An attack that makes use of the *birthday paradox*; that is, it uses the fact that for collision problems one needs a surprisingly low number of attempts to find a collision by brute force.

**Collision** A pair of two messages producing the same hash value.

**Collision Resistant Function** A function for which it is computationally infeasible to find a *collision*.

**Compression Function** A function that compresses inputs of some fixed length to outputs of some smaller length; usually used as the main building block of a *hash function*.

**Hash Function** A function that compresses arbitrary long messages to a hash value or *message digest* of a fixed size.

**MAC** A “keyed hash function” or “symmetric digital signature” usually used to authenticate messages.

**MD4/MD5** Two hash functions proposed by Ronald Rivest in 1990 and 1992, respectively. Archetype for a whole class of hash functions.

**Message Digest** Also called “digital fingerprint”; hash value of a message allowing in practice a unique identification of a message.

**Oneway Function** A function that is *preimage resistant* and *second preimage resistant*.

**Preimage Resistant Function** A function for which it is computationally infeasible to find a message mapping to a previously given value.

**Pseudocollision** A pair of two input pairs  $(IV, X)$ ,  $(IV', X')$  for a compression function mapping to the same output value. In contrast, for a real *collision* of a compression function we additionally require  $IV = IV'$ .

**RIPEMD** A family of hash functions based on the function RIPEMD-0. This function was proposed by the RIPE Consortium and originally simply called RIPEMD. Attacks on this function led to refinements and the definitions of the other, repaired versions RIPEMD-128/-160/-256/-320 in.

**Second Preimage Resistant Function** A function, for which it is computationally infeasible, given one message, to find another message mapping to the same value.

**SHA** A family of hash functions designed and proposed by NIST in the Secure Hash Standard. The first function of this family was originally simply called SHA (Secure Hash Algorithm) and is now usually referenced as SHA-0. This function was replaced as a standard bei SHA-1 in 1995, and in 2002/2004 the new and

more complex variants SHA-224/-256/-384/-512 were proposed.

## INTRODUCTION

The mathematical basis for the algorithms used in public key cryptosystems (RSA, Diffie–Hellman, discrete logarithms, elliptic curves, etc.) relies on some moderately deep concepts and results from number theory, which is covered in the specific chapters on these topics elsewhere in this handbook. Underlying the deep results in number theory, however, are some fundamentals that are almost, but perhaps not quite, obvious. Our purpose in this chapter is to present those parts of the theory of numbers necessary for an understanding of the more advanced material. We begin our discussion with a look at the ordinary integers. Central to work in number theory is the nature of arithmetic (addition, multiplication, and the like) modulo prime numbers. For some purposes, specifically, for example, in elliptic curves and in the advanced encryption standard of the National Institute of Standards and Technology (NIST), it is necessary to go beyond the integers to look at the polynomial arithmetic modulo irreducible polynomials that is the analog of ordinary arithmetic modulo prime integers. Fortunately, the results from arithmetic modulo prime integers carry over almost exactly to polynomial arithmetic, so we can treat this latter topic largely by analogy to more familiar material.

## REFERENCES

Most of this material can be found in any standard introductory text in number theory, such as the books by Hardy and Wright (1980), by Niven, Zuckerman, and Montgomery (1991), or by Rosen (2000). Although these references will be complete, they will also oversatisfy the needs of a reader interested only in cryptography. A detailed analysis of the computational complexity of algorithms in number theory can be found either in Bach and Shallit (1996) or in Cohen (1993). More condensed versions can be found as the introductory chapters in references on

cryptography by Buchmann (2001) or Koblitz (1987) or in the standard algorithms reference of Cormen, Leiserson, Rivest, and Stein (2003). For complexity and implementation issues of doing multiprecise arithmetic, there is still probably no better reference than Knuth (1998). The large book by Schneier (1996) presents a very brief introduction to and then relies on the material in this chapter. The standard reference on the large topic of finite fields is the book by Lidl and Niederreiter (1994). Further information can be found in Golomb (1982). Two background references on elliptic curves are Koblitz (1984) and Silverman and Tate (1992), although once again these cover much more material than is needed for this application. Two excellent references on elliptic curves in cryptography are the book by Menezes (1993) and the new book by Hankerson, Menezes, and Vanstone (2004). Further information on cryptography and on the elliptic curve recommendations of NIST can be found in their publications (Barker, 2000; NIST, 1999). Further information on the NIST AES can be found in Daemen and Rijmen (2001), from the Rijndael Web site (2003), or from NIST directly (NIST, 1998, 1999, 2000, 2001).

## DIVISIBILITY

Most of elementary number theory concerns the *integers*  $\mathbb{Z} = \{\dots, -3, -2, -1, 0, 1, 2, 3, \dots\}$ . Occasionally, we refer to the *rational numbers*  $\mathbb{Q} = \{a/b : a, b, \in \mathbb{Z}\}$ .

If  $a, b \in \mathbb{Z}$ , and  $b \neq 0$ , then the *integer part* of  $a/b$ , written  $[a/b]$ , also referred to as the *floor* of  $a/b$  and written  $\lfloor a/b \rfloor$ , is the integer  $c$  such that  $c \leq a/b < c + 1$ . The *ceiling* of  $a/b$ , written  $\lceil a/b \rceil$ , is the integer  $c$  such that  $c - 1 < a/b \leq c$ .

We present these definitions to clarify the notation for negative values. The integer part function “truncates toward negative infinity” in that, for example,

$$\lceil (-5)/4 \rceil = \lfloor 5/(-4) \rfloor = -2.$$

An integer  $b$  is *divisible* by an integer  $a$  if there exists an integer  $c$  such that  $b = ac$ . We say that  $a$  is a *divisor* of  $b$ .

**Notes**

- We write  $a|b$  or  $a \nmid b$ , read “ $a$  divides  $b$ ” or “ $a$  does not divide  $b$ ”, according as  $b$  is or is not divisible by  $a$ .
- We note that  $a|a$  always holds. If  $a|b$  and  $0 < a < b$ , then we say that  $a$  is a *proper divisor* of  $b$ .
- We note also that  $a|0$  holds for all integers  $a$  but that  $0|b$  never holds for any nonzero integer  $b$ . The only instance in which  $a|0$  would make sense would be in the expression  $0|0$ . By convention, we specifically exclude this relatively useless special case because permitting it would require the addition of extra qualifications on a large number of theorems.

**Theorem 110.1.** *The following hold for all integers:*

1. If  $a|b$ , then  $a|bc$  for any integer  $c$ .
2. If  $a|b$  and  $b|c$ , then  $a|c$ .
3. If  $a|b$ , then  $ac|bc$  for any integer  $c$ .
4. If  $a|b$  and  $b|a$ , then  $a = \pm b$ .
5. If  $a|b$  and  $a|c$ , then  $a|(bx + cy)$  for any integers  $x$  and  $y$ .
6. If  $a|b$ ,  $a > 0$ , and  $b > 0$ , then  $a \leq b$ .

*Proof.* The proofs of these follow immediately from the definition.

One of the basic results of school arithmetic is that division of two integers yields a remainder that is smaller than the divisor. This is formalized in the following theorem.

**Theorem 110.2. (The division algorithm).** *If  $a$  and  $b > 0$  are integers, then there exists a unique pair of integers  $q$  and  $r$  such that  $a = bq + r$  and  $0 \leq r < b$ .*

*Proof.* Among the values

$$\dots, a - 3b, a - 2b, a - b, a, a + b, a + 2b, a + 3b, \dots$$

there is a value  $r = a - qb$  that satisfies the required inequality. Indeed, taking negative numbers into account, if  $q = [a/b]$ , then  $q \leq a/b < q + 1$ , so  $bq \leq a < bq + b$  and thus  $0 \leq a - bq < b$ , as desired.

To prove uniqueness, we consider two such representations

$$a = bq_1 + r_1 = bq_2 + r_2$$

where we assume without loss of generality that  $q_1 > q_2$ , which implies that  $r_2 > r_1$ . From this we get

$$b(q_1 - q_2) = r_2 - r_1 > 0$$

so that  $b|(r_2 - r_1)$ . But this then implies that  $0 \leq b \leq r_2 - r_1 < r_2 < b$ , which is a contradiction.

We refer to  $q$  and  $r$  as computed by the division algorithm as the *quotient* and *remainder*, respectively.

Given integers  $a$  and  $b$ , we say that an integer  $c$  is a *common divisor* of  $a$  and  $b$  if  $c$  divides  $a$  and  $c$  divides  $b$ . If  $a$  and  $b$  are not both zero, then among the common divisors of  $a$  and  $b$  we will refer to the largest as the *greatest common divisor*, written  $\gcd(a, b)$ .

We remark that the *greatest common divisor* is sometimes referred to as the *highest common factor*.

We note that the  $\gcd$  is defined only for pairs of integers  $a, b$  not both of which are zero and that it is thus always positive.

In the case that  $\gcd(a, b) = 1$ , we say that  $a$  and  $b$  are *relatively prime* or *prime to one another*.

**Theorem 110.3.** *The  $\gcd$  of integers  $a$  and  $b$ ,  $g = \gcd(a, b)$ , is the least positive value of  $ax + by$  as  $x$  and  $y$  range over all integers.*

*Proof.* Among all the values of  $ax + by$  as  $x$  and  $y$  range over all integers, we choose the least positive value  $m = ax_0 + by_0$ , and we claim that this is  $g = \gcd(a, b)$ . Clearly, any common divisor, and especially the greatest common divisor  $g$ , must divide  $a$  and  $b$  and therefore  $m$ . If, then, we have that  $m|a$  and  $m|b$ , then  $g = \pm m$ , and because both  $m$  and  $g$  are positive by assumption, we have that  $g = m$ .

So let us assume that  $m \nmid a$ , for example, and therefore that  $a = qm + r$  with  $0 < r < m$ . But in that case we have  $0 < r = a - qm = a - q(ax_0 + by_0) = a(1 - qx_0) + by_0$ , which violates the choice of  $m$  as the *least* positive linear combination of  $a$  and  $b$ . We conclude that  $m|a$ . A similar argument shows that  $m|b$ , from which it follows that  $m = g$ .

**Theorem 110.4. (The Euclidean algorithm).** *If, given integers  $a$  and  $b$ , we make a repeated application of the division algorithm:*

$$\begin{aligned} b &= r_0, \\ a &= bq_1 + r_1, & 0 < r_1 < b \\ b &= r_1q_2 + r_2, & 0 < r_2 < r_1 \\ r_1 &= r_2q_3 + r_3, & 0 < r_3 < r_2 \\ &\dots \end{aligned} \tag{1}$$

*then the process must terminate with  $r_{j+1} = 0$  for some  $j$  and we have that  $r_j = \gcd(a, b)$ .*

*Proof.* It is useful for intuitive purposes to notice that the Euclidean algorithm is a recursive algorithm: if we use the division algorithm to determine  $q$  and  $r$  such that  $a = bq + r$  with  $0 \leq r < b$ , then

- either  $r = 0$  and  $b = \gcd(a, b)$
- or  $r \neq 0$  and  $\gcd(a, b) = \gcd(b, r)$ .

To prove the theorem, we observe that the process must terminate because the remainders  $r_i$  are positive and decreasing with every step.

We further note that when the process stops with  $r_{j+1} = 0$ , then  $r_j$  must be a divisor of  $a$  and  $b$  because we have the following:

$$\begin{aligned} r_{j-1} &= r_jq_{j+1} + 0 & \text{and hence } & r_j|r_{j-1}, \\ r_{j-2} &= r_{j-1}q_j + r_j & \text{and hence } & r_j|r_{j-2}, \end{aligned}$$

and so forth. Thus  $r_j$  is a common divisor of  $a$  and  $b$ . To see that  $r_j$  is the greatest common divisor  $g = \gcd(a, b)$ , we observe that  $g$  divides  $a$  and  $b$  and therefore divides  $r_1$ . Because  $g$  divides  $b$  and  $r_1$ , we have that  $g$  divides  $r_2$ , and so on, so that  $g$  must also divide  $r_j$ , from which we conclude that  $g = r_j$ .

**Theorem 110.5. (The extended Euclidean algorithm).** *The values  $x_0$  and  $y_0$  such that  $\gcd(a, b) = ax_0 + by_0$  can be obtained by eliminating the  $r_i$  from Eq. (1).*

*Proof.* We can write Eq. (1) as matrix equations, with each successive equation obtainable from the previous equation by the application of a simple matrix:

$$\begin{aligned} \begin{pmatrix} 0 & 1 \\ 1 & -q_1 \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} &= \begin{pmatrix} b \\ r_1 \end{pmatrix} \\ \begin{pmatrix} 0 & 1 \\ 1 & -q_2 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & -q_1 \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} &= \begin{pmatrix} r_1 \\ r_2 \end{pmatrix} \\ &\dots \\ \begin{pmatrix} 0 & 1 \\ 1 & -q_{j+1} \end{pmatrix} \dots \begin{pmatrix} 0 & 1 \\ 1 & -q_1 \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} &= \begin{pmatrix} r_j \\ r_{j+1} \end{pmatrix} = \begin{pmatrix} r_j \\ 0 \end{pmatrix} \end{aligned} \quad (2)$$

If we then compute the matrix product of the last line, we obtain the needed values  $x_0$  and  $y_0$ .

$$\begin{aligned} \begin{pmatrix} x_0 & y_0 \\ z & w \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} &= \begin{pmatrix} 0 & 1 \\ 1 & -q_{j+1} \end{pmatrix} \dots \begin{pmatrix} 0 & 1 \\ 1 & -q_1 \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} \\ &= \begin{pmatrix} r_j \\ r_{j+1} \end{pmatrix} = \begin{pmatrix} r_j \\ 0 \end{pmatrix} \end{aligned} \quad (3)$$

**Example**

We apply the Euclidean algorithm to the pair  $a = 261$ ,  $b = 48$ . We get the following:

$$\begin{aligned} 261 &= 48 \times 5 + 21, \\ 48 &= 21 \times 2 + 6, \\ 21 &= 6 \times 3 + 3, \\ 6 &= 3 \times 2 + 0, \end{aligned}$$

so the sequence  $q_1, q_2, q_3, q_4$  is 5, 2, 3, 2. The matrix product of Eq. (3) is as follows:

$$\begin{aligned} \begin{pmatrix} 7 & -38 \\ -16 & 87 \end{pmatrix} \begin{pmatrix} 261 \\ 47 \end{pmatrix} \\ = \begin{pmatrix} 0 & 1 \\ 1 & -2 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & -3 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & -2 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & -5 \end{pmatrix} \begin{pmatrix} 261 \\ 47 \end{pmatrix} &= \begin{pmatrix} 3 \\ 0 \end{pmatrix} \end{aligned}$$

from which we get the extended gcd as  $7 \times 261 - 38 \times 48 = 3$ .

**PRIME NUMBERS AND FACTORING**

We say that an integer  $p > 1$  is a *prime number* if there are no positive divisors of  $p$  other than 1 and  $p$ . If  $p$  is not prime, then it is a *composite number*.

**Theorem 110.6.** *The following hold:*

1. Every positive integer has a prime divisor.
2. If, for a prime  $p$ , we have  $p|ab$ , then either  $p|a$  or  $p|b$ .
3. If, for a prime  $p$ , we have  $p|\prod_{i=1}^n a_i$ , then  $p|a_i$  for some  $i$ .

*Proof.* Let  $a$  be a positive integer. Then  $a$  has at least the divisors 1 and  $a$ . If there are no other divisors, then  $a$  is prime and part (1) is proved. If  $a$  has other divisors, then let  $p$  be the least among them. If  $p$  is prime, then part (1) is proved. If  $p$  is not prime, then it has some divisor  $q \neq 1, p$ . But now we have  $1 < q < p < a$ , and because  $q|p$  and  $p|a$ , we must have  $q|a$ , contradicting the choice of  $p$  as the smallest divisor of  $a$ .

Now let  $ab$  be an integer that is divisible by a prime  $p$ , and let  $g_1 = \gcd(a, p)$  and  $g_2 = \gcd(b, p)$ . Because  $g_1$  and  $g_2$  are both divisors of  $p$ , and because the only divisors of  $p$  are 1 and  $p$ , we must have, say, that  $g_1 = 1$  and  $g_2 = p$ . This implies that  $p|b$ .

The proof of part (3) now follows by induction.

We now come to the main theorem of elementary number theory.

**Theorem 110.7. (The Fundamental Theorem of Arithmetic).** *Every positive integer  $a > 1$  can be factored into a product of primes, and the factoring is unique up to order.*

*Proof.* To prove the first part, we see that if  $a$  is prime, then it is a product of primes with only one factor in the product. If  $a$  is not prime, it must have a prime divisor  $a_1$  and an integer **cofactor**  $a_2 = a/a_1$ , both of which are positive and smaller than  $a$ . We can repeat the above argument on the factors  $a_1$  and  $a_2$ , but this process of splitting into factors can only go on for finitely many steps because the factors are all positive and smaller than  $a$ .

Now let us assume that we have  $a = \prod_{i=1}^n p_i = \prod_{j=1}^m q_j$  be two factorings of  $a$  into products of primes. Because  $p_1$  divides the first product, it must divide the second product, and therefore, it must divide  $q_j$  for some  $j$ . But  $q_j$  is prime, and therefore,  $p_i = q_j$ . We may now repeat this argument on  $a/p_1$ , and the argument must terminate with  $n = m$  and all the  $p_i$  matched up in a one-to-one fashion with a  $q_j$ .

**CONGRUENCES**

Given integers  $a, b$ , and  $m$ , we say that  $a$  is *congruent* to  $b$  modulo  $m$ , which we write as  $a \equiv b \pmod{m}$ , if the difference  $a - b$  is divisible by  $m$ . We refer to the integer  $m$  as the *modulus*. We note that divisibility, and thus the congruence relation, is independent of whether the modulus is positive or negative, so we usually restrict our attention to positive moduli  $m$ . By convention, a modulus  $m$  cannot be zero because that would require a divisibility condition  $0|(a - b)$  that we have earlier declared impermissible.

We also note that it seems all too commonplace to find incorrect terminology in use. Although we say and write that  $a$  is congruent to  $b$  modulo  $m$ , the arithmetic of congruences is referred to as *modular* arithmetic, not

(as is unfortunately often seen in publications in electrical engineering) modulo arithmetic.

Congruence arithmetic shares many properties with ordinary arithmetic, provided that we do not attempt arbitrary division.

**Theorem 110.8.** *Let  $a, b, c,$  and  $d$  be integers. Then*

1.  $a \equiv b \pmod{m}, b \equiv a \pmod{m},$  and  $a - b \equiv 0 \pmod{m}$  are equivalent statements.
2. If  $a \equiv b \pmod{m}$  and  $b \equiv c \pmod{m},$  then  $a \equiv c \pmod{m}.$
3. If  $a \equiv b \pmod{m}$  and  $c \equiv d \pmod{m},$  then  $a + c \equiv b + d \pmod{m}$  and  $ac \equiv bd \pmod{m}.$
4. If  $a \equiv b \pmod{m},$  then there exists an integer  $k$  such that  $a = b + km.$
5. If  $a \equiv b \pmod{m}$  and if  $f(n)$  is a polynomial in the variable  $n$  with integer coefficients, then  $f(a) \equiv f(b) \pmod{m}.$

As can be deduced from the theorem above, addition, subtraction, and multiplication with congruences is the same as for ordinary arithmetic. That division fails, however, can be seen from the following example. With conventional arithmetic, if we have  $ax = ay,$  for  $a \neq 0,$  then we can divide by  $a$  to obtain  $x = y.$  This fails in general in modular arithmetic. Consider  $a = 7, x = 17, y = 5,$  and modulus  $m = 21.$  Then certainly  $119 = 7 \times 17 \equiv 7 \times 5 \equiv 35 \pmod{21}.$  However, it is not true that  $17 \equiv 5 \pmod{21}.$  Because 7 divides 119, 35, and 21, we have only the weaker statement that  $17 \equiv 5 \pmod{3}.$

**Theorem 110.9.** *Let  $a, m, r,$  and  $s$  be integers. We have  $ar \equiv as \pmod{m}$  if and only if  $r \equiv s \pmod{m/\gcd(a, m)}.$  Specifically, if  $ar \equiv as \pmod{m}$  and  $\gcd(a, m) = 1,$  then  $r \equiv s \pmod{m}.$*

*Proof.* We have  $ar \equiv as \pmod{m}$  if and only if some integer  $k$  exists so that  $ar = as + km.$  If  $g = \gcd(a, m),$  then  $a = ga', m = gnt = g[m/\gcd(a, m)],$  and  $a'(r - s) = knl.$  Now, because  $\gcd(a', m') = 1,$  no prime dividing  $a'$  can divide  $m',$  and yet all the factors of  $a'$  must divide the right-hand side  $knl.$  We conclude that  $a' | k,$  so  $k' = k/a'$  is an integer and we have  $r - s = k'm',$  which is sufficient because of part (1) of the previous theorem.

If  $a \equiv b \pmod{m},$  then we say that  $b$  is a residue of  $a$  modulo  $m.$  The residue class of  $a$  modulo  $m$  is the set  $\bar{a} = \{n : n \equiv a \pmod{m}\} = \{a + \lambda m : \lambda \in \mathbb{Z}\}.$  A complete residue system  $R$  modulo  $m$  consists of the integers 0 through  $m - 1,$  so that every integer  $a$  is congruent modulo  $m$  to some residue  $r \in R$  and yet no members of  $R$  are congruent modulo  $m.$

The fundamental theorem on the solution of congruences is discussed next.

**Theorem 110.10.** *Given integers  $a, b,$  and  $m,$  the congruence*

$$ax \equiv b \pmod{m} \tag{4}$$

*is solvable for integers  $x$  if and only if  $\gcd(a, m) | b.$  If  $\gcd(a, m) | b$  and  $x_0$  is a solution, then all solutions of congruence (4) are given by  $x = x_0 + km,$  where  $k$  is any integer.*

*Proof.* If we have a solution  $x$  to the congruence, then we have an equality  $ax = b + km$  for some integer  $k.$  Clearly, then,  $\gcd(a, m)$  must divide  $b.$  Conversely, if  $\gcd(a, m) | b,$  then we can divide  $\gcd(a, m)$  from  $a, b,$  and  $m$  and reduce the problem to one of solving the congruence (4) in the case  $\gcd(a, m) = 1.$

In the simpler case of congruence (4) with  $\gcd(a, m) = 1,$  there must be integers  $t$  and  $u$  such that  $at - mu = 1.$  We can multiply by  $b$  to see that  $a(bt) - m(bu) = b,$  choose  $x_0 = bt$  as a solution to congruence (4), and then notice that the values  $x = bt + km$  for any integers  $k$  are an infinite set of solutions to (4) because we have  $a(x_0 + km) - m(bu + ak) = b.$

It remains only to show that these are the only solutions, and it suffices to deal with the case with  $\gcd(a, m) = 1.$  Assume, then, that we have two solutions,  $x_0$  and  $x_1,$  to (4) with  $\gcd(a, m) = 1.$  We then have  $ax_0 \equiv b \pmod{m}$  and  $ax_1 \equiv b \pmod{m};$  we subtract to get  $a(x_1 - x_0) \equiv 0 \pmod{m},$  which is equivalent to  $a(x_1 - x_0) = km$  for some integer  $k.$  Because  $a$  divides the left-hand side, it must divide the right-hand side, but because  $\gcd(a, m) = 1,$  we must have that  $a | k$  and thus that  $x_1 = x_0 + (k/a)m$  for some integer  $k/a,$  which is what we were trying to prove.

### Examples

Let us solve the following:

$$60x \equiv 21 \pmod{69}. \tag{5}$$

Because  $\gcd(60, 69) = 3,$  we divide through by 3 to get the equivalent congruence

$$20x \equiv 7 \pmod{23}. \tag{6}$$

The congruence

$$20x \equiv 1 \pmod{23}$$

has solutions, found using the extended Euclidean algorithm, of  $x = 15 + 23k$  for any  $k.$  The congruence (6) therefore has solutions  $x = 105 + 23(7k) = 13 + 23(7k + 4),$  or  $x \equiv 13 \pmod{23},$  and thus the congruence (5) has solutions  $x = 39 + 69(7k + 4),$  or  $x \equiv 16 \pmod{69}.$

To see an instance of a congruence with no solutions, consider the following:

$$60x \equiv 17 \pmod{69}.$$

To have solutions, we must have  $x$  such that  $60x - 17 = 69k$  for some integer  $k.$  But by rearranging terms this becomes  $60x - 69k = 17,$  with 3 dividing the left-hand side but not the right-hand side, which is impossible.

## GROUPS AND FIELDS DEFINED MOD PRIMES

Let  $S$  be a set on which a binary operation  $\oplus$  is defined. The binary operation is *closed* on  $S$  if, for every pair  $a, b \in S$ , we have  $a \oplus b \in S$ . The operation is *associative* if, for every triple  $a, b, c \in S$ , we have  $(a \oplus b) \oplus c = a \oplus (b \oplus c)$ . Given a set  $S$  together with a closed associative operation on  $S$ , we say that  $G = (S, \oplus)$  is a *group* if

- there exists an *identity* element  $e$  such that for all  $a \in S$ ,  $a \oplus e = e \oplus a = a$ ;
- for every element  $a \in S$  there exists an *inverse* element  $a'$  such that  $a \oplus a' = a' \oplus a = e$ .

We note that inverses are unique: if  $a'$  and  $a''$  are two elements for which

$$e = a \oplus a' = a \oplus a'',$$

then from  $e = a \oplus a'$  we get  $a'' = a'' \oplus (a \oplus a') = (a'' \oplus a) \oplus a' = e \oplus a' = a'$ .

A group  $G$  is said to be commutative or abelian if for every  $a, b \in G$  we have  $a \oplus b = b \oplus a$ .

A canonical example of a group, which happens to be an abelian group, are the integers  $(\mathbb{Z}, +)$  under ordinary addition, for which the identity is the number 0 and the inverse of  $a$  is  $-a$ .

The nonzero integers under multiplication do not form a group because there are no integers with multiplicative inverses except for  $\pm 1$ , but the nonzero rational numbers do form a group under multiplication. In this instance, the identity is the number 1, and the inverse of the nonzero rational number  $a/b$  is the rational number  $b/a$ .

A subgroup of a group  $G = (S, \oplus)$  is a pair  $G' = (S', \oplus)$  such that  $S' \subseteq S$  and  $G'$  is itself a group under  $\oplus$ . The set of even integers, for example, forms a subgroup of the group of integers under addition.

We say that a set  $S$  with two closed associative operations, written  $\oplus$  and  $\otimes$ , is a ring if  $S$  is an abelian group under  $\oplus$  and if  $\otimes$  distributes over  $\oplus$ . If the nonzero elements of  $S$  also form an abelian group under  $\otimes$ , then we say that  $S$  with its operations forms a field.

The canonical example of a ring is the set of integers under usual addition and multiplication, and the canonical example of a field is the set of rational numbers under usual addition and multiplication.

What we will now prove is central to the use of number theory for public key cryptography. We write  $\mathbb{Z}_{(\text{mod } n)}$  to denote the set of integers modulo an integer  $n$ . This is always a ring, and if  $n$  is a prime, the next theorem shows that it is also a finite field of  $n$  elements.

**Theorem 110.11.** *The set  $\mathbb{Z}_{(\text{mod } n)}$  of integers modulo a prime number  $p$  form a field under the usual operations of congruence arithmetic.*

*Proof.* Clearly, the integers modulo  $p$  under addition form an abelian group. The identity of the group under addition is the residue class congruent to 0 modulo  $p$ , and the inverse of any element  $a$  is just  $-a$ . Under multiplication, the identity must clearly be 1, and it

remains only to prove that any integer relatively prime to  $p$  has an inverse modulo  $p$ . This, however, is exactly the conclusion to be drawn from Theorem 110.10; for any  $a$ , the inverse is the residue  $b$  such that  $ab \equiv 1 \pmod{p}$ .

We note that  $\mathbb{Z}_{(\text{mod } n)}$  for a composite number  $n$  is never a field. The only integers modulo a composite  $n$  that have inverses modulo  $n$  are those that are relatively prime to  $n$ . A *reduced residue system* is a set  $S = \{s_i\}$  of residue classes modulo  $n$  for which

1. for all  $i$ ,  $\text{gcd}(s_i, n) \equiv 1 \pmod{n}$ ;
2. for any  $n \in \mathbb{Z}$ , there exists an  $s_i$  such that  $n \equiv s_i \pmod{n}$ ;
3. for no distinct subscripts  $i, j$  do we have  $s_i \equiv s_j \pmod{n}$ .

Modulo 21, for example, one reduced residue system is the set of residue classes  $\{1, 2, 4, 5, 8, 10, 11, 13, 16, 17, 19, 20\}$ . The integers  $3k$  and  $7k$ , for  $k$  any integer, are zero divisors. In ordinary arithmetic, if we have a product  $ab = 0$ , then one of  $a$  or  $b$  must be zero. Modulo a prime number, there are no nontrivial zero divisors, but modulo a composite number  $n$ , such as 21, the integers  $a$  that are not relatively prime to  $n$  but not congruent to zero modulo  $n$  have a nontrivial cofactor  $b$  such that  $ab \equiv 0 \pmod{n}$ . For example,  $3 \times 7 \equiv 0 \pmod{21}$  and  $6 \times 7 \equiv 0 \pmod{21}$ .

The Euler totient, also called the Euler phi function, is the function  $\phi(n)$  equal to the number of integers modulo  $n$  that are relatively prime to  $n$ . We adopt the convention that  $\phi(1) = 1$ . The first and most important property of the Euler function is that it is multiplicative; that is, that for relatively prime integers  $m$  and  $n$ , we have  $\phi(mn) = \phi(m)\phi(n)$ .

**Theorem 110.12.** *If  $m$  and  $n$  are integers for which  $\text{gcd}(m, n) = 1$ , then  $\phi(mn) = \phi(m)\phi(n)$ .*

*Proof.* Consider two complete sets of residue classes  $R_m = \{a_i : i = 1, \dots, \phi(m)\}$  and  $R_n = \{b_j : j = 1, \dots, \phi(n)\}$  of integers relatively prime to  $m$  and  $n$ , respectively. Let  $M$  and  $N$  be chosen so that  $Mm \equiv 1 \pmod{n}$  and  $Nn \equiv 1 \pmod{m}$ . We form the  $\phi(m)\phi(n)$  elements  $a_i n N + b_j m M$  and claim that these are distinct and that they form a complete set of residues modulo  $mn$ . They are distinct because if we had for two such elements the congruence  $a_i n N + b_{j_1} m M \equiv a_{i_2} n N + b_{j_2} m M \pmod{mn}$ , then we could reduce modulo  $m$  and modulo  $n$  to get  $a_{i_1} \equiv a_{i_2} \pmod{m}$  and  $b_{j_1} \equiv b_{j_2} \pmod{n}$ , which are contradictions. And if we choose any element  $c$  relatively prime to  $mn$ , then  $c$  reduced modulo  $m$  is prime to  $m$  and must be congruent to some  $a_i$ , and similarly for  $n$ , so that our system is complete.

**Theorem 110.13.** *If  $n > 1$  is an integer, and  $n = \prod_{i=1}^k p_i^{e_i}$  is the canonical factoring of  $n$  into a product of primes, then*

$$\phi(n) = \prod_{i=1}^k p_i^{e_i-1} (p_i - 1) = n \prod_{p|n} \frac{p-1}{p}.$$

*Proof.* By the multiplicativity of the Euler function, we need show only the following:

$$\phi(p^e) = p^{e-1}(p - 1)$$

for primes  $p$ , and the general formula will follow. To see this, we write each of the  $p^e$  integers 0 through  $p^e - 1$  base  $p$  as

$$k = a_{e-1} \times p^{e-1} + \dots + a_2 \times p^2 + a_1 \times p + a_0$$

with  $0 \leq a_i \leq p - 1$  for all  $i$ . We observe that the integers that are *not* prime to  $p^e$  are exactly those for which  $a_0 = 0$ . There are  $p^{e-1}$  of these, so there are  $p^e - p^{e-1} = p^{e-1}(p - 1)$  such integers that *are* prime to  $p^e$ , and the theorem is proved.

**Theorem 110.14.** For  $n \geq 1$  we have  $\sum_{d|n} \phi(d) = n$

*Proof.* We will prove this by induction on the number of distinct prime factors of  $n$ . For a prime power  $n = p^e$  we have  $\phi(p^e) = 1 + (p - 1) + p(p - 1) + \dots + p^e(p - 1)$ , which telescopes. If now we have  $\gcd(n, p) = 1$ , then

$$\begin{aligned} \sum_{d|np^e} \phi(d) &= \sum_{d|n} \phi(d) + \sum_{d|n} \phi(pd) + \dots + \sum_{d|n} \phi(p^e d) \\ &= 1 \times \sum_{d|n} \phi(d) + \phi(p) \times \sum_{d|n} \phi(d) + \dots + \phi(p^e) \\ &\quad \times \sum_{d|n} \phi(d) \\ &= n \times \sum_{d|p^e} \phi(d) = np^e. \end{aligned}$$

**Examples**

- For  $n = p$  a prime, we have  $\phi(p) = p - 1$  and  $\sum_{d|n} \phi(d) = 1 + (p - 1) = p = n$ , as required by Theorems 110.13 and 110.14.
- For  $n = p^e$  the power of a single prime, we have  $\phi(p) = p^{e-1}(p - 1)$  and  $\sum_{d|n} \phi(d) = 1 + (p - 1) = p = n$ , as required by Theorems 110.13 and 110.14.
- For  $n = pq$  the product of two primes, we have  $\phi(p) = p - 1$  and

$$\begin{aligned} \sum_{d|n} \phi(d) &= 1 + (p - 1) + p(p - 1) \\ &\quad + p^2(p - 1) + \dots + p^{e-1}(p - 1) \\ &= 1 + (p - 1) \frac{p^e - 1}{p - 1} = p^e = n. \end{aligned}$$

- For a more complicated  $n = 2^3 \times 3^2 \times 5 = 360$ , for example, we have

$$\begin{aligned} \phi(360) &= [2^2(2 - 1)][3(3 - 1)][1(5 - 1)] \\ &= 96 \\ &= 360 \left(\frac{2 - 1}{2}\right) \left(\frac{3 - 1}{3}\right) \left(\frac{5 - 1}{5}\right). \end{aligned}$$

A group  $G = (S, \oplus)$  is *cyclic* if there exists a *generating element*  $a$  such that repeated application of  $\oplus$  to  $a$  generates the entire set  $S$  as  $a, a \oplus a, a \oplus a \oplus a$ , and so forth. For

**Table 1** Index Function for the Prime 11

Exponent	1	2	3	4	5	6	7	8	9	10
Residue	2	4	8	5	10	9	7	3	6	1

example, both the integers and the integers modulo  $p$  are generated by 1 under ordinary addition.

What is crucial to the utility of number theory in public key cryptography is that, modulo a prime  $p$ , the group of integers formed by multiplication is also generated by a single element, which we refer to as a primitive root. For example, the integers modulo 11 are generated by repeated multiplication by the primitive root 2:

$$\begin{aligned} 2^1 &= 2 \times 1 && \equiv 2 \pmod{11}, \\ 2^2 &= 2 \times 2 && \equiv 4 \pmod{11}, \\ 2^3 &= 2 \times 4 && \equiv 8 \pmod{11}, \\ 2^4 &= 2 \times 8 && \equiv 16 \equiv 5 \pmod{11}, \\ 2^5 &= 2 \times 5 && \equiv 10 \equiv 10 \pmod{11}, \\ 2^6 &= 2 \times 10 && \equiv 20 \equiv 9 \pmod{11}, \\ 2^7 &= 2 \times 9 && \equiv 18 \equiv 7 \pmod{11}, \\ 2^8 &= 2 \times 7 && \equiv 14 \equiv 3 \pmod{11}, \\ 2^9 &= 2 \times 3 && \equiv 6 \pmod{11}, \\ 2^{10} &= 2 \times 6 && \equiv 12 \equiv 1 \pmod{11}. \end{aligned}$$

We can convert the multiplicative arithmetic modulo 11 into additive arithmetic in the exponents by using the exponents as discrete logarithms as in Table 1.

We note that discrete logarithms function for arithmetic modulo primes in the same way as do ordinary logarithms in that multiplication modulo a prime can be accomplished by adding discrete logarithms. For example, we have

$$8 \equiv 30 \equiv 5 \cdot 6 \equiv 2^4 \cdot 2^9 \equiv 2^{13} \equiv 2^3 \equiv 8 \pmod{11}.$$

With  $p = 11$  and  $\phi(p) = 10$ , we have one element of order 2, namely  $2^5 \equiv 10 \pmod{11}$  and four elements of order 5, namely  $2^2 \equiv 4 \pmod{11}$ ,  $2^4 \equiv 5 \pmod{11}$ ,  $2^6 \equiv 9 \pmod{11}$ , and  $2^8 \equiv 3 \pmod{11}$ . The multiplicative subgroup  $\{1, 4, 5, 9, 3\} = \{2^0, 2^2, 2^4, 2^6, 2^8\}$  generated by  $2^2 = 4$  is the same as the additive subgroup  $\{0, 2, 4, 6, 8\}$  of even exponents modulo 10. And there are no other subcycles modulo 11. The four elements whose exponents 1, 3, 7, 9 are relatively prime to 10 are all primitive roots modulo 11.

Before we can prove the next main theorem, we must first digress to continue the discussion of solutions of congruences. We have already observed that linear polynomials  $ax + b$  with coefficients taken from  $\mathbb{Z}_{(\text{mod } p)}$  have no solutions or unique solutions in the field  $\mathbb{Z}_{(\text{mod } p)}$ ; this is the meaning of Theorem 110.10.

In fact, we have the same strong theorem over finite fields that we have over the complex numbers.

**Theorem 110.15.** Let  $f(x) = a_n x^n + \dots + a_0$  be a polynomial of degree  $n$  and not identically zero with coefficients in  $\mathbb{Z}_{(\text{mod } p)}$ . Then  $f(n)$  has at most  $n$  distinct roots in  $\mathbb{Z}_{(\text{mod } p)}$ .

*Proof.* We prove this by induction on  $n$ . The case  $n = 1$  is Theorem 110.10.

We assume, then, that polynomials of degree  $n - 1$  or smaller have no more roots than the degree of the polynomial, and we let  $f(n)$  be a poly of degree  $n$  with coefficients in  $\mathbb{Z}_{(\text{mod } p)}$ . If  $f(n)$  has as many as  $n$  roots  $r_1, r_2, \dots, r_n$ , then we form the polynomial

$$g(n) = f(n) - a_n(x - r_1)(x - r_2) \cdots (x - r_n).$$

We have arranged for the  $x^n$  to disappear, so this is a polynomial of degree strictly smaller than  $n$ , but it has at least the  $n$  roots given explicitly above. This is contrary to our assumption unless the polynomial is identically zero when its coefficients are reduced modulo  $p$ . So  $g(n)$  is identically zero, which means that for all integers  $r$  we have the following:

$$f(n) \equiv a_n(x - r_1)(x - r_2) \cdots (x - r_n) \pmod{p}.$$

If there were an  $n + 1$ -st root  $r_{n+1}$  of  $f(n)$ , we would have the following:

$$f(r_{n+1}) \equiv a_n(r_{n+1} - r_1)(r_{n+1} - r_2) \cdots (r_{n+1} - r_n) \equiv 0 \pmod{p}.$$

We now utilize the fact that in a field there are no zero divisors in a field: if the product is zero modulo  $p$ , then one of the factors must be zero modulo  $p$ , which implies that we do not in fact have  $n + 1$  distinct roots of  $f(n)$ .

The fact that we are working in a field is crucial to the truth of the theorem above, not just to the method by which we have proved it. The polynomial  $x^2 + 3x + 2$ , for example, taken modulo the composite number 6, is only of degree two but has the four roots 1, 2, 4, 5.

The next three theorems provide the structure of the multiplicative group modulo primes.

**Theorem 110.16. (Fermat’s Little Theorem).** *If  $p$  is a prime, and  $a$  any integer with  $\text{gcd}(a, p) = 1$ , then  $a^{p-1} \equiv 1 \pmod{p}$ .*

We do not prove Fermat’s Little Theorem because it follows from the stronger and more general theorem of Euler.

**Theorem 110.17. (Euler’s Theorem).** *If  $a$  and  $m$  are integers with  $\text{gcd}(a, m) = 1$ , then  $a^{\phi(m)} \equiv 1 \pmod{m}$ .*

*Proof.* Consider a reduced residue system modulo  $m$ ,  $R_1 = \{r_1, \dots, r_{\phi(m)}\}$  and let  $a$  be a integer relatively prime to  $m$ . We claim that  $R_1$  is the same set, when reduced modulo  $m$ , as  $R_2 = \{ar_1, \dots, ar_{\phi(m)}\}$ . This is true because  $ar_i \equiv ar_j \pmod{m}$  implies that  $r_i \equiv r_j \pmod{m}$ .

We now observe the equality of the following products:

$$\prod_{i=1}^{\phi(m)} ar_i \equiv a^{\phi(m)} \prod_{i=1}^{\phi(m)} r_i \equiv \prod_{i=1}^{\phi(m)} r_i \pmod{m};$$

the first product is taken over the set  $R_2$  and the last is taken over the same set  $R_1$ .

Because these are a set of reduced residues, each is prime to  $m$  and we can divide out the product to get  $a^{\phi(m)} \equiv 1 \pmod{m}$ .

Fermat’s Little Theorem now follows as a special case of Euler’s Theorem in the case that  $m$  is a prime  $p$ .

**Theorem 110.18.** *The multiplicative group of integers modulo a prime  $p$  is cyclic and can be generated by a primitive root. The number of primitive roots modulo  $p$  is  $\phi(\phi(p))$ .*

*Proof.* We have already seen in the case of the prime 11 what it is that we wish to prove is always true, namely that we can work additively with the exponents of a single element that generates the full cycle of reduced residues.

We will say that an integer  $a$  has order  $e$  modulo  $p$  if  $a^e \equiv 1 \pmod{p}$  and  $a^f \not\equiv 1 \pmod{p}$  holds for no  $f$  smaller than  $e$ . The crucial fact we just proved in the previous theorem is that there are at most  $p - 1/e$  integers modulo  $p$  that have order  $e$  because all such are roots of the polynomial  $x^e \equiv 1 \pmod{p}$  and are not roots of  $x^f \equiv 1 \pmod{p}$  for any  $f$  smaller than  $e$ .

We first observe that if  $a$  has order  $e$ , then the powers  $a, a^2, \dots, a^e$  are all distinct modulo  $p$ . If they were not, and we had  $a^j \equiv a^k \pmod{p}$ , for  $0 < j < k \leq e, j \neq k$ , then we would have  $a^{k-j} \equiv 1 \pmod{p}$  but  $0 < k - j < e$ , contrary to our choice of  $e$ .

We next observe that the order  $e$  of any element must divide  $p - 1$ . Because we have  $a^e \equiv 1 \pmod{p}$  and  $a^{p-1} \equiv 1 \pmod{p}$ , we can conclude by doing arithmetic on the exponents that  $a^{\text{gcd}(e, p-1)} \equiv 1 \pmod{p}$ . But we cannot have  $\text{gcd}(e, p - 1) < e$  without violating our definition of  $e$  as the order of  $a$ . Hence  $e | (p - 1)$ .

If  $a$  is of order  $e$ , then  $a, a^2, \dots, a^{e-1}, a^e$  are distinct modulo  $p$  and are the solutions of  $x^e \equiv 1 \pmod{p}$ . The  $\phi(e)$  of these with exponents prime to  $e$  are actually of order  $e$  and not some smaller order. Thus for all divisors  $e$  of  $p - 1$  there are either  $\phi(e)$  residues or no residues of order  $e$ . If we let  $\psi(e)$  be the number of residues of order  $e$ , for  $e | (p - 1)$ , then clearly  $\psi(e) \leq \phi(e)$  and

$$\sum_{e|(p-1)} \psi(e) = p - 1.$$

By Theorem 110.14 we have

$$\sum_{e|(p-1)} \phi(e) = p - 1,$$

so in fact

$$\sum_{e|(p-1)} (\psi(e) - \phi(e)) = 0.$$

But each summand is less than or equal to zero and hence must be equal to zero. In particular, then,  $\psi(p - 1) = \phi(p - 1)$ . Because  $\psi(p - 1)$  is positive, so must be  $\phi(p - 1)$ , which means that a primitive root must exist.

Once we have verified the existence of an element  $g$  that generates the entire multiplicative cycle modulo  $p$ , it follows immediately by looking at the arithmetic with the

exponents that all the powers  $g^j$  for  $j$  prime to  $p - 1$  must also generate the complete cycle.

### THE CHINESE REMAINDER THEOREM

**Theorem 110.19.** *Let  $m_1, m_2, \dots, m_k$  be  $k$  integers that are relatively prime in pairs. Let  $a_1, a_2, \dots, a_k$  be any  $k$  integers. Then the congruences*

$$\begin{aligned} x &\equiv a_1 \pmod{m_1} \\ x &\equiv a_2 \pmod{m_2} \\ &\dots \\ x &\equiv a_k \pmod{m_k} \end{aligned}$$

have common solutions. All such solutions are congruent modulo  $m_1 m_2 \dots m_k$ .

*Proof.* We will provide two proofs of this theorem. First, we shall construct a solution explicitly. Let  $x_1 = a_1 + x_2 m_1$  for a variable  $x_2$ ; the values  $x_1$  certainly satisfy the first congruence. The second congruence now reads as follows:

$$\begin{aligned} a_1 + x_2 m_1 &\equiv a_2 \pmod{m_2} \\ x_2 m_1 &\equiv a_2 - a_1 \pmod{m_2}. \end{aligned}$$

The existence of  $b_1$  such that  $b_1 m_1 \equiv 1 \pmod{m_2}$  is guaranteed because the moduli are pairwise relatively prime. Thus,

$$x_2 \equiv b_1(a_2 - a_1) \pmod{m_2}$$

provides simultaneous solutions

$$x_1 = a_1 + m_1 b_1(a_2 - a_1) + x_3 m_1 m_2$$

of the first and second congruences, with  $x_3$  now the free variable. We continue one congruence at a time, and the conclusion is obvious.

Our second proof resembles Lagrange’s interpolation formula. Let  $M_j = \prod_{i \neq j} m_i$  for each  $j$ , and let  $b_j$  solve  $b_j M_j \equiv 1 \pmod{m_j}$ . Then the sum

$$a_1 b_1 M_1 + a_2 b_2 M_2 + \dots + a_k b_k M_k$$

is a simultaneous solution to the congruences.

In general, because the simultaneous solution is congruent modulo the product of the moduli, one would need multiple precision arithmetic to compute the solutions exactly. The first method of proof minimizes the need for multiprecision arithmetic, although the precision must grow with each congruence. The second method of creating the solution requires full precision throughout and is thus not as computationally efficient.

### POLYNOMIAL ARITHMETIC

Our goal in this chapter has been to provide a background in the number theory necessary to understand public key cryptography. Much of the necessary theory has to do with ordinary arithmetic, albeit with integers hundreds of bits in length. In one specific instance, however, that of elliptic curves used for cryptographic purposes, one must also be

prepared to deal with arithmetic in binary finite fields. The NIST has described several elliptic curves suitable for use in cryptography by those who wish to use elliptic curves for cryptography (NIST, 1999). Some of these curves are defined modulo large prime integers, while some of them are defined over binary finite fields.

The arithmetic of binary finite fields, using polynomials, is entirely analogous to ordinary integer arithmetic modulo primes. Instead of integers, we deal with polynomials whose coefficients are defined modulo 2, and instead of prime numbers we use “irreducible” polynomials. In a deeper abstract sense, both kinds of arithmetic are just arithmetic in finite fields, but we will for concreteness develop the theory by analogy with the more familiar ordinary integers.

### Polynomials

We will deal with *polynomials* in one variable,  $f(x) = a_n x^n + \dots + a_0$ ,  $a_n \neq 0$ , of degree  $\text{deg}(f) = n$ , whose coefficients  $a_i$  are integers taken modulo 2. The coefficient  $a_n \neq 0$  and the term  $a_n x^n$  are the *leading coefficient* and *leading term*, respectively, and the coefficient  $a_0$  is the *constant term*. When one shifts to polynomial arithmetic, one also usually introduces some new terminology, and we will refer to any finite field of  $k$  elements as the *Galois field*  $GF(k)$  of  $k$  elements, sometimes also written  $\mathbb{F}_k$ . One theorem that can be proved is that there is really only one finite field of  $k$  elements, so referring to “the” field is not incorrect. Thus, integer arithmetic modulo a prime  $p$  is arithmetic in the Galois field  $GF(p)$ , and we can refer to the polynomials as we have defined them here as polynomials *defined over*  $GF(2)$ , written  $GF(2)[x]$ .

We will, in this section, always mean “a polynomial in  $GF(2)[x]$ ” whenever we refer to “a polynomial.”

We note a few very simple (and convenient) facts about arithmetic in  $GF(2)[x]$ .

**Theorem 110.20.** *Let  $f(x)$ ,  $g(x)$ , and  $h(x)$  be polynomials in  $GF(2)[x]$ . Then the following are true:*

1. *The only constant polynomials are 0 and 1.*
2. *If  $f(x) = \sum_{i=0}^n a_i x^i$ ,  $g(x) = \sum_{i=0}^n b_i x^i$ , and  $h(x) = \sum_{i=0}^n c_i x^i = f(x) + g(x)$ , then  $c_i = \text{XOR}(a_i, b_i)$  for each  $i$ .*
3. *If  $f(x) = \sum_{i=0}^n a_i x^i$ , then  $f(x) = \sum_{i=0}^n a_i x^{2i}$ .*

*Proof.* The proofs of these follow from the definitions.

We note that arithmetic in polynomials modulo 2 is almost entirely analogous to the arithmetic in the integers. The two primary differences are the fact that the bit-level arithmetic is done with XORs and without carry bits (and is therefore much less complex at the bit level than ordinary arithmetic) and the fact that we bound the size of the operands with which we deal with the degree of the polynomial instead of with the magnitude of the integers. One other difference that is apparent with polynomials in  $GF(2)[x]$  is that “plus is the same as minus”: because  $+1 \equiv -1 \pmod{2}$ , we also have  $+x = -x$  in  $GF(2)[x]$ .

## Divisibility

We say that a polynomial  $f(x)$  is divisible by a polynomial  $g(x)$  if there exists a polynomial  $h(x)$  such that  $f(x) = g(x) \cdot h(x)$ . We say that  $g(x)$  is a *divisor* of  $f(x)$ . As in the case of integers, we note that the zero polynomial is divisible by any polynomial, and we adhere to the convention that we do not consider the case  $0|0$  that would be the only instance in which division by the zero polynomial would make sense. Given polynomials  $f(x)$  and  $g(x)$ , we say that a polynomial  $h(x)$  is a *common divisor* of  $f(x)$  and  $g(x)$  if  $h(x)$  divides  $f(x)$  and  $h(x)$  divides  $g(x)$ . If the polynomials  $f(x)$  and  $g(x)$  are not both zero, then among the common divisors of  $f(x)$  and  $g(x)$  we will refer to the divisor of largest degree as the *greatest common divisor*, written  $\gcd(f(x), g(x))$ .

**Remark:** Our universe of discourse is simplified by the fact that we are dealing with coefficients that are either 0 or 1. If we were dealing with coefficients modulo 3, for example, then there might be a legitimate need to deal with an ambiguity beyond just the degrees of the polynomials—both  $x^2$  and  $2x^2$  could be said to be divisors of  $x^3$  because we would have  $x^3 = (x) \times (x^2)$  and  $x^3 = (2x) \times (2x^2)$ . With coefficients defined only modulo 2, however, no such ambiguity exists; there is only one possible nonzero coefficient. The following theorem is the analog of Theorem 110.1. We note two differences between integers and polynomials under prime numbers and factoring, and groups and fields defined mod primes.

**Theorem 110.21.** *The following hold for all polynomials in  $GF(2)[x]$ :*

1. If  $f(x)|g(x)$ , then  $f(x)|g(x)h(x)$  for any polynomial  $h(x)$ .
2. If  $f(x)|g(x)$  and  $g(x)|h(x)$ , then  $f(x)|h(x)$ .
3. If  $f(x)|g(x)$ , then  $f(x)h(x)|g(x)h(x)$  for any polynomial  $h(x)$ .
4. If  $f(x)|g(x)$  and  $g(x)|f(x)$ , then  $f(x) = g(x)$ .
5. If  $f(x)|g(x)$  and  $f(x)|h(x)$ , then  $f(x)|(g(x)r(x) + h(x)s(x))$  for any polynomials  $r(x)$  and  $s(x)$ .
6. If  $f(x)|g(x)$ , then  $\deg(f(x)) \leq \deg(g(x))$ .

*Proof.* The proofs of these follow immediately from the definition.

**Theorem 110.22. (The polynomial division algorithm).** *If  $f(x)$  and  $g(x)$  are polynomials in  $GF(2)[x]$ , then there exists a unique pair of polynomials  $q(x)$  and  $r(x)$  such that  $f(x) = g(x)q(x) + r(x)$  and  $0 \leq \deg(r) < \deg(g)$ .*

*Proof.* Our earlier proof of the analogous Theorem 110.2 was largely existential. We will for the sake of variety construct the polynomials that prove this theorem.

In the case that  $\deg(f(x)) < \deg(g(x))$ , we set  $q(x) = 0$  and  $r(x) = f(x)$ .

In the case that  $\deg(f(x)) = \deg(g(x))$ , we set  $q(x) = 1$  and  $r(x) = f(x) + g(x) \equiv f(x) - g(x) \pmod{2}$ .

Finally, if we have  $\deg(f(x)) = n > \deg(g(x)) = m$ , we set  $q_1(x) = x^{n-m}$  and  $r_1(x) = f(x) + x^{n-m}g(x)$ , so that

$$f(x) = q_1(x) \cdot g(x) + r_1(x)$$

and  $\deg(r_1(x)) < \deg(g(x))$ . We repeat the above process with  $r_1(x)$  and  $g(x)$  replacing  $f(x)$  and  $g(x)$ , obtaining perhaps  $q_2(x) = x^{n'-m}$  and  $r_2(x)$  so that

$$\begin{aligned} f(x) &= q_1(x) \cdot g(x) + r_1(x) \\ &= q_1(x) \cdot g(x) + q_2(x) \cdot g(x) + r_2(x) \\ &= (q_1(x) + q_2(x)) \cdot g(x) + r_2(x) \end{aligned}$$

and so forth.

This terminates with  $q_k(x)$  so that

$$f(x) = \left( \sum_{i=1}^k q_i(x) \right) g(x) + r_k(x)$$

and  $0 \leq \deg(r_k(x)) < \deg(g(x))$ .

Uniqueness follows exactly as with the case of integers.

## Greatest Common Divisor

**Theorem 110.23. (The Euclidean algorithm).** *If, given polynomials  $f(x)$  and  $g(x)$  in  $GF(2)[x]$ , we make a repeated application of the division algorithm:*

$$\begin{aligned} f(x) &= g(x)q_1(x) + r_1(x), & 0 < \deg(r_1(x)) < \deg(g(x)) \\ g(x) &= r_1(x)q_2(x) + r_2(x), & 0 < \deg(r_2(x)) < \deg(r_1(x)) \\ r_1(x) &= r_2(x)q_3(x) + r_3(x), & 0 < \deg(r_3(x)) < \deg(r_2(x)) \\ &\dots & \dots \end{aligned} \tag{7}$$

*then the process must terminate with  $\deg(r_{j+1}(x)) = 0$  for some  $j$ , and we have that  $r_j(x) = \gcd(f(x), g(x))$ .*

*Proof.* The proof in the case of polynomials mimics almost exactly the earlier proof for integers.

**Theorem 110.24. (The extended Euclidean algorithm).** *The values  $r_0(x)$  and  $s_0(x)$  such that  $\gcd(f(x), g(x)) = f(x)r_0(x) + g(x)s_0(x)$  can be obtained by eliminating the  $r_i(x)$  from Eq. (7).*

*Proof.* Again, the proof for polynomials mimics the earlier proof for integers.

## Irreducible Polynomials

A polynomial  $f(x)$  in  $GF(2)[x]$  is called *irreducible* if it cannot be expressed as product  $f(x) = g(x)h(x)$  with  $g(x), h(x) \in GF(2)[x]$  and the degrees of  $g(x)$  and  $h(x)$  both smaller than that of  $f(x)$ .

As will be seen in the following theorems, the irreducible polynomials play a role in the formation of finite fields that is analogous to that of prime integers. Irreducible polynomials are normally defined in a manner slightly different from prime integers; instead of part (1) of Theorem 110.6, we have part (2) of the following analogous theorem.

**Theorem 110.25.** *The following hold:*

1. *The polynomial  $f(x)$  is irreducible in  $GF(2)[x]$  if and only if the only divisors of  $f(x)$  are itself and 1.*

2. Every polynomial of positive degree has an irreducible divisor.
3. If, for an irreducible polynomial  $f(x)$ , we have  $f(x) \mid \prod_{i=1}^n g_i(x)$ , then  $f(x) \mid g_i(x)$  for some  $i$ .

*Proof.* In essence, we mimic the proof for integers of Theorem 110.6, but we use the degree of the polynomial instead of the magnitude of the integer.

Let  $f(x)$  be an irreducible polynomial of positive degree and assume that  $g(x)$  is a divisor of least degree of  $f(x)$ . (We note in contrast to the integers that there are multiple polynomials of the same degree, and hence “a divisor” is correct and “the divisor” would be wrong.) Then we have  $f(x) = g(x)h(x)$  for some  $h(x)$  of degree at least 1. But this precisely contradicts the assumption that  $f(x)$  is an irreducible polynomial because we have both  $\deg(g(x)) < \deg(f(x))$  and  $\deg(h(x)) < \deg(f(x))$ , so neither  $f(x) \mid g(x)$  nor  $f(x) \mid h(x)$  can hold.

Conversely, let us assume that the only divisors of  $f(x)$  are itself and 1, and let  $f(x) \mid g(x)h(x)$  for two polynomials  $g(x)$  and  $h(x)$ . Let  $s(x) = \gcd(f(x), g(x))$ , and let us apply the extended Euclidean algorithm to get the following:

$$s(x) = f(x) \times u(x) + g(x) \times v(x). \tag{8}$$

We must by assumption have either  $s(x) = f(x)$  or  $s(x) = 1$ . In the former case we have  $f(x) \mid g(x)$ . In the latter case we multiply (8) by  $h(x)$  to get the following:

$$h(x) = f(x) \times u(x) \times h(x) + g(x) \times h(x) \times v(x),$$

from which we conclude that  $f(x) \mid h(x)$ , proving part 1.

To prove part 2, we observe that  $f(x)$  has a divisor of least degree  $g(x)$ . Because this divisor can have no divisors of smaller degree except 1, then this divisor must be irreducible.

Part 3 follows by induction.

**Theorem 110.26. (The fundamental theorem of arithmetic).** Every polynomial of positive degree  $f(x)$  can be factored into a product of irreducible polynomials, and the factoring is unique up to order.

*Proof.* Again, this proof mimics the proof for integers.

### Congruences

Given polynomials  $f(x)$ ,  $g(x)$ , and  $m(x)$ , we say that  $f(x)$  is congruent to  $g(x)$  modulo  $m(x)$ , which we write as  $f(x) \equiv g(x) \pmod{m(x)}$ , if the difference  $f(x) - g(x)$  is divisible by  $m(x)$ .

The basic results on congruences (Theorems 110.8, 110.9, and 110.10) carry over precisely for polynomials in  $GF(2)[x]$ , and their proofs are entirely similar. We also, by our definition of divisibility, have prevented the zero polynomial from being a modulus for congruences. We do not, however, need to prevent the nonzero polynomial of zero degree, namely 1, from being a modulus.

**Theorem 110.27.** Let  $a(x)$ ,  $b(x)$ ,  $c(x)$ ,  $d(x)$ ,  $r(x)$ , and  $s(x)$  be polynomials in  $GF(2)[x]$ . Then

1.  $a(x) \equiv b(x) \pmod{m(x)}$ ,  $b(x) \equiv a(x) \pmod{m(x)}$ , and  $a(x) - b(x) \equiv 0 \pmod{m(x)}$  are equivalent statements.
2. If  $a(x) \equiv b(x) \pmod{m(x)}$  and  $b(x) \equiv c(x) \pmod{m(x)}$ , then  $a(x) \equiv c(x) \pmod{m(x)}$ .
3. If  $a(x) \equiv b(x) \pmod{m(x)}$  and  $c(x) \equiv d(x) \pmod{m(x)}$ , then  $a(x) + c(x) \equiv b(x) + d(x) \pmod{m(x)}$  and  $a(x)c(x) \equiv b(x)d(x) \pmod{m(x)}$ .
4. If  $a(x) \equiv b(x) \pmod{m(x)}$ , then there exists a polynomial  $k(x)$  such that  $a(x) = b(x) + k(x)m(x)$ .

**Theorem 110.28.** Let  $a(x)$ ,  $m(x)$ ,  $r(x)$ , and  $s(x)$  be polynomials in  $GF(2)[x]$ . We have  $a(x)r(x) \equiv a(x)s(x) \pmod{m(x)}$  if and only if  $r(x) \equiv s(x) \pmod{m(x)/\gcd(a(x), m(x))}$ . Specifically, if  $a(x)r(x) \equiv a(x)s(x) \pmod{m(x)}$  and  $\gcd(a(x), m(x)) = 1$ , then  $r(x) \equiv s(x) \pmod{m(x)}$ .

**Theorem 110.29.** Given polynomials  $a(x)$ ,  $b(x)$ , and  $m(x)$  in  $GF(2)[x]$ , the congruence

$$a(x)r(x) \equiv b(x) \pmod{m(x)} \tag{9}$$

is solvable for polynomials  $r(x)$  if and only if  $\gcd(a(x), m(x)) \mid b(x)$ . If this is true, and  $r_0(x)$  is a solution, then all solutions are given by  $r(x) = r_0(x) + k(x)m(x)$ , where  $k(x)$  is any polynomial.

### Example

Let  $a(x) = x^4 + x^3 + x^2 + 1$ ,  $b(x) = x^2 + x$ , and  $m(x) = x^5 + x^4 + x + 1$ . We note that  $a(x) = (x + 1)(x^3 + x + 1)$ ,  $b(x) = x(x + 1)$ , and  $m(x) = (x + 1)^5$ , and that  $a(x)/(x + 1)$  is not divisible by  $x + 1$ . Thus,  $\gcd(a(x), m(x)) = x + 1$  and this divides  $b(x)$ . We reduce the congruence

$$(x^4 + x^3 + x^2 + 1) \times r(x) \equiv x^2 + x \pmod{(x^5 + x^4 + x + 1)} \tag{10}$$

to

$$(x^3 + x + 1) \times r(x) \equiv x \pmod{(x^4 + 1)}$$

by dividing by  $x + 1$ . If we follow the extended Euclidean algorithm for these polynomials, we have

$$\begin{aligned} x^4 + 1 &= (x^3 + x + 1) \times (x) + x^2 + x + 1, \\ x^3 + x + 1 &= (x^2 + x + 1) \times (x + 1) + x, \\ x^2 + x + 1 &= (x) \times (x + 1) + 1, \\ x &= 1 \times (x) + 0, \end{aligned}$$

so the sequence  $q_1, q_2, q_3, q_4$  is  $(x)$ ,  $(x + 1)$ ,  $(x + 1)$ ,  $(x)$ . The matrix product is as follows:

$$\begin{pmatrix} 0 & 1 \\ 1 & x \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & x + 1 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & x + 1 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & x \end{pmatrix} \begin{pmatrix} x^4 + 1 \\ x^3 + x + 1 \end{pmatrix} = \begin{pmatrix} x^2 & x^3 + x + 1 \\ x^3 + x + 1 & x^4 + 1 \end{pmatrix} \begin{pmatrix} x^4 + 1 \\ x^3 + x + 1 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$$

from which we get the extended gcd as follows:

$$(x^4 + 1)(x^2) + (x^3 + x + 1)(x^3 + x + 1) = 1.$$

We can choose  $r(x) = x(x^3 + x + 1) = x^4 + x^2 + x$ , and all solutions to Eq. (10) are given by the following:

$$r(x) = x^4 + x^2 + x + k(x)(x^5 + x^4 + x + 1),$$

where  $k(x)$  is any polynomial.

## Groups, Rings, and Fields Defined Modulo Polynomials

The basic structure of the integers modulo primes carries over to a basic structure of polynomials in  $GF(2)[x]$  modulo irreducible polynomials, but for fairly obvious reasons the arguments about the number of elements must change.

For a prime  $p$ , the number of nonzero residues modulo  $p$  is  $p - 1$ , and the residues modulo  $p$  form a field of  $p$  elements (counting the zero) with a cyclic multiplicative group generated by any primitive root. The residues modulo  $p$  have multiplicative orders dividing  $p - 1$ . Further, because the absolute values of two different primes are different, each prime defines a different field with a different number of elements.

Given a polynomial  $f(x)$  of degree  $d$ , then  $f(x)$  can be written as a string of 0 and 1 coefficients  $d + 1$  bits long, with the bit for the  $x^d$  term set. The  $2^d$  residues modulo  $f(x)$ ; that is, all the polynomials of degrees  $d - 1$  and lower, correspond to the  $d$ -bit sequences of 0s and 1s, and the number of residues is the same for all moduli of the same degree. Indeed, for each degree  $d$ , there is a unique field of  $2^d$  elements up to *isomorphism*, and this field can be obtained by considering polynomials modulo any irreducible polynomial of degree  $d$ .

## Primitive Polynomials and Shift Register Sequences

The structure of the finite fields defined by polynomials with coefficients 0 and 1 is described in depth in Lidl and Niederreiter (1994) and in Golomb (1982).

Let  $f(x)$  be a polynomial of degree  $d$ . If  $f(x)$  is irreducible, then the polynomials of  $GF(2)[x]$  form a field whose multiplicative group is cyclic, just like the field of integers modulo a prime integer. However, for computational reasons, we usually work not with the irreducible polynomials but with a more restrictive set of polynomials, the *primitive* polynomials.

Given a polynomial  $f(x)$  of degree  $d$  with constant term 1, the *order* of  $f(x)$ , written  $ord(f)$ , is the least integer  $e$  such that  $x^e \equiv 1 \pmod{f(x)}$ . A polynomial with constant term 0 can be written  $x^k g(x)$  for some integer  $k$ , and we say that the order of  $f(x)$  is the order of  $g(x)$ . A polynomial  $f(x)$  is called *primitive* if it has order  $e = 2^d - 1$ . The computational justification for our interest just in primitive and not in all irreducible polynomials is that being able to generate the multiplicative group with powers of  $x$  results in simpler electronic circuitry for the *shift register sequences* that are the coefficients of the residues (Golomb, 1982). Multiplication by  $x$  will be shown later to be simply a shift left followed possibly by an XOR; this is obviously simpler than multiplying by a polynomial having more than one nonzero coefficient.

**Table 2** Irreducible Polynomials of Small Degrees

Degree	Irreducible Polynomials
1	$x + 1$
2	$x^2 + x + 1$
3	$x^3 + x + 1$ $x^3 + x^2 + 1$
4	$x^4 + x + 1$ $x^4 + x^3 + 1$ $x^4 + x^3 + x^2 + x + 1$
5	$x^5 + 1$

The following theorems show that the notion of a primitive polynomial is well defined and that a primitive polynomial can always be found for any degree.

**Theorem 110.30.** *If  $f(x)$  is a polynomial of degree  $d$  and constant term 1, then the order of  $f(x)$  is finite and less than or equal to  $2^d - 1$ .*

*Proof.* Consider the sequence  $S = \{x, x^2, x^3, \dots\}$ . Taken modulo  $f(x)$ , this sequence becomes a sequence of polynomials in  $GF(2)[x]$  of degree less than or equal to  $d$ . None of these can be the zero polynomial: if a polynomial  $g(x)$  has degree  $\leq d$ , then  $xg(x)$  has constant term 0 but  $f(x)$  has constant term 1, so  $xg(x) \equiv 0 \pmod{f(x)}$  is impossible. There are  $2^d - 1$  such polynomials as elements of  $S$  reduced modulo  $f(x)$ , so eventually we run out of possibilities. Now if we have  $x^r \equiv x^s \pmod{f(x)}$ , then we have  $x^{r-s} \equiv 1 \pmod{f(x)}$ , because  $x$  and  $f(x)$  are relatively prime.

**Theorem 110.31.** *The order of any irreducible polynomial  $f(x)$  of degree  $d$  divides  $2^d - 1$ .*

**Theorem 110.32.** *For any degree  $d > 0$ , there exists a primitive polynomial of degree  $d$ .*

In fact, there are much stronger theorems that can be proved, but we will not prove them here. Theorem 110.32, however, is more than just the polynomial analog of the theorem that the integers modulo a prime integer form a cyclic group generated by a primitive root; it is the statement, in effect, that  $x$  can be taken to be that primitive root.

## Examples

**Irreducible Polynomials.** A small effort shows that the irreducible polynomials of degrees up through 5 are as presented in Table 2.

**Primitive Polynomials.** There are eight polynomials of degree 4 over  $GF(2)$  with constant term 1. With a small amount of trial and error, one can determine that many of them factor and are thus not irreducible. The factorings for the degree 4 polynomials are presented in Table 3.

We consider the sequence of powers of  $x$  modulo, for example,  $f(x) = x^4 + x + 1$ , and obtain Table 4.

Thus,  $x^4 + x + 1$  is not only irreducible but also primitive. One can similarly show that  $x^4 + x^3 + 1$  is primitive. This is an example of the following theorem that we will state but not prove.

**Theorem 110.33.** *Let  $f(x) = x^d + a_{d-1}x^{d-1} + \dots + a_1x + 1$  be a primitive polynomial. Then its reverse  $f'(x) = x^d + a_1x^{d-1} + \dots + a_{d-1}x + 1$  is also primitive.*

The polynomial  $x^4 + x^3 + x^2 + x + 1$  is irreducible, but it is not primitive. In fact, the multiplicative cyclic group is generated by  $x + 1$ , as shown in Table 5.

We note that the progression in Table 5 of  $1, x, x^2, x^3, x^3 + x^2 + x + 1, 1$  is the progression

$$\begin{aligned} (x + 1)^{12}, \\ (x + 1)^{24} &= (x + 1)^9, \\ (x + 1)^{36} &= (x + 1)^6, \\ (x + 1)^{48} &= (x + 1)^3, \\ (x + 1)^{60} &= 1. \end{aligned}$$

If we view the 0–1 coefficients as a sequence of bits, left to right in decreasing powers of  $x$ , so that the polynomial  $f(x) = x^4 + x + 1$  is represented as 1|0011, then the residues modulo  $f(x)$  can be written as four-bit sequences (with a temporary carry at the right), with  $x$  written as 0|0010. Multiplication by  $x$  is thus a shift left. If a 1 is shifted into the carry position, we XOR the pattern with 1|0011 to force the carry position back to zero. The elegant implementation in hardware is just that the bit shifted to the carry position is tapped and then always XORed (if it is a 0, this has no effect) with the lower bits as specified by the polynomial. Using this representation, Table 4 becomes Table 6.

**BIT COMPLEXITY**

There are two levels at which one might wish to analyze the time complexity of arithmetic and number-theoretic operations. For those whose interest is in software, the complexity of computation is normally measured in terms of the number of CPU instructions executed. Addition and subtraction instructions are far cheaper than multiplication, and division is normally so expensive that one avoids it if at all possible, so at the level of software and machine instructions one is usually counting multiplications to measure complexity. However, at the level of CPU

**Table 4** Powers of  $x$  Modulo  $x^4 + x + 1$

Power	Equivalent to	Reduces to
$x$	$\equiv x$	
$x^2$	$\equiv x^2$	
$x^3$	$\equiv x^3$	
$x^4$	$\equiv x^4$	$\equiv x + 1$
$x^5$	$\equiv x^2 + x$	
$x^6$	$\equiv x^3 + x^2$	
$x^7$	$\equiv x^4 + x^3$	$\equiv x^3 + x + 1$
$x^8$	$\equiv x^4 + x^2 + x$	$\equiv x^2 + 1$
$x^9$	$\equiv x^3 + x$	
$x^{10}$	$\equiv x^4 + x^2$	$\equiv x^2 + x + 1$
$x^{11}$	$\equiv x^3 + x^2 + x$	
$x^{12}$	$\equiv x^4 + x^3 + x^2$	$\equiv x^3 + x^2 + x + 1$
$x^{13}$	$\equiv x^4 + x^3 + x^2 + x$	$\equiv x^3 + x^2 + 1$
$x^{14}$	$\equiv x^4 + x^3 + x$	$\equiv x^3 + 1$
$x^{15}$	$\equiv x^4 + x$	$\equiv 1$

instructions, one usually is not concerned about the *bit-level* complexity; the cost of adding two 14-bit numbers on a 64-bit machine is usually the same as the cost of adding two 35-bit numbers.

Oddly enough, for purely theoretical purposes and for the very practical purposes of hardware design, one needs to consider the actual bit-level complexity of arithmetic. In general, a naive analysis of the complexity is sufficient for our purposes, if only because any reasonably complicated computation in number theory will require general purpose arithmetic, and general purpose arithmetic will not be able to make use of the clever tricks that might speed up arithmetic in special cases.

**Timing Costs of Arithmetic**

We measure the cost in time of arithmetic in terms of the number of bit operations needed. For example, to add two integers  $a = a_m a_{m-1} \dots a_1 a_0$  and  $b = b_n b_{n-1} \dots b_1 b_0$  of bit lengths  $m + 1$  and  $n + 1$ , respectively, where we assume  $m > n$ , the naive approach is the right-to-left ripple-carry schoolchild method that requires  $m + 1$  bit-adds (because  $m$  is assumed larger than  $n$ ). Multiplication requires  $(m + 1) \times (n + 1)$  bit-operations because there are that many products of bits  $a_i \times b_j$  that have to be added in to the running sum at the correct bit location.

**Table 3** Factorings for Degree 4 Polynomials

Polynomial	Factoring
$x^4 + 1$	$= (x + 1)^4$
$x^4 + x + 1$	Irreducible
$x^4 + x^2 + 1$	$= (x^2 + x + 1)^2$
$x^4 + x^3 + 1$	Irreducible
$x^4 + x^2 + x + 1$	$= (x + 1)(x^3 + x^2 + 1)$
$x^4 + x^3 + x + 1$	$= (x + 1)^2(x^2 + x + 1)$
$x^4 + x^3 + x^2 + 1$	$= (x + 1)(x^3 + x + 1)$
$x^4 + x^3 + x^2 + x + 1$	Irreducible

**Table 5** Powers of  $1 + x$  Modulo  $1 + x + x^2 + x^3 + x^4$

Powers	Equivalent to	Power	Equivalent to

$x^{13}$	1 1110	→ 1 1110	XOR	1 0011 = 0 1101
$x^{15}$	1 1010	→ 1 1010	XOR	1 0011 = 0 1001

Division is perhaps actually easier to analyze as a bit-level operation than with a higher radix. The extremely naive view of division as repeated subtraction is in fact exactly what is useful when analyzing the bit complexity. To produce the quotient and remainder  $q$  and  $r$  from input operands  $a$  and  $b$ , so that  $a = qb + r$ , it is necessary to perform as many as  $O(\lg a)$  subtractions. That this is logarithmic and not linear [that is,  $O(\lg a)$  and not  $O(q)$  subtractions] is because we can subtract not  $b$  from  $a$  but a subtrahend  $2^k \times b$  chosen to align with the leftmost nonzero bit of the minuend. In this way, each subtraction reduces by at least one the length in bits of the minuend. The cost of subtracting  $2^k \times b$  and not just  $b$  is lost in counting the costs of subtracting because we can initially align the bits of  $b$  with the leftmost and not the rightmost bit of  $a$  and then just shift right for each succeeding subtraction.

As stated, for general purpose arithmetic or for purposes other than purely theoretical analysis, one almost always is restricted to the naive complexity for arithmetic. Table 7, taken from Bach and Shallit (1996), presents in addition to the easily derived naive complexities the best-known asymptotic complexities for arithmetic, where the function  $\mu(m, n)$  is  $m(\lg n)(\lg \lg n)$  if  $m \geq n$  and  $n(\lg m)(\lg \lg m)$  otherwise.

For theoretical purposes, the asymptotic complexity at the bit level is no different from that at the software level of counting CPU instructions. The constants will change because of the aggregation of bits into words, but the inherent complexity will be the same.

**Table 7** Bit-Level Complexity of Arithmetic

Operation	Naive complexity	Best-known complexity
$a \pm b$	$\lg a + \lg b$	$O(\lg a + \lg b)$
$a \times b$	$(\lg a)(\lg b)$	$O(\mu(\lg a, \lg b))$
$a = qb + r$	$(\lg b)(\lg q)$	$O(\mu(\lg q, \lg b))$

### Worst Case of Greatest Common Divisor

A brief analysis of the greatest common divisor algorithm is illustrative of the nature of analysis of basic number-theoretic operations. We consider the Euclidean algorithm as the naive algorithm, and we observe that division is by far the most costly of the operations in the Euclidean algorithm.

**Theorem 110.34.** *The worst case of the naive Euclidean algorithm occurs with the computation of  $\gcd(F_{n+1}, F_n)$ , where  $F_{n+1}$  and  $F_n$  are consecutive Fibonacci numbers. Thus, the worst case of the naive Euclidean algorithm when given inputs  $A$  and  $B$  with  $1 \leq \lg A, \lg B \leq n$  is that  $n$  divisions are required.*

*Proof.* The Euclidean algorithm requires the maximal number of division steps in the event that the quotients are 1 at every step. This is exactly what happens when the inputs are consecutive Fibonacci numbers because the Fibonacci recurrence  $F_{n+1} = F_n + F_{n-1}$  is exactly the division algorithm  $F_{n+1} = 1 \times F_n + F_{n-1}$  with  $q = 1$  and  $r = F_{n-1}$ .

A more detailed analysis of the gcd, as given in Knuth (1998), shows that 41% of the quotients in the division step are 1, 16% of the quotients in the division step are 2, and 9% of the quotients in the division step are 3. This leads to an alternative gcd algorithm as follows: instead of dividing  $r_i$  by  $r_{i+1}$ , which is expensive, we subtract  $r_{i+1}$  from  $r_i$  as many as three times. If the values of  $r_i$  and  $r_{i+1}$  are known to be of the same number of bits, then 2/3 of the time we will be able to avoid the division at the cost of at most three subtractions. Although this algorithm is not necessarily suitable for operands longer than the register length of the CPU being used, it can be very effective for operands that fit into registers and on which single machine instructions can be used to perform the subtractions and tests (Buell, 1989).

### BIT COMPLEXITY FOR MULTIPRECISE ARITHMETIC

The usual analysis of the complexity of arithmetic assumes that the operands are simply strings of bits. In a real computer, however, operands are measured in terms of the number of words they require for their representation, and an addition of very short operands is no faster than addition of longer operands provided that all operands and results fit in a single CPU register. We refer to operands and arithmetic as *multiprecise* if the operands must be represented as multiword arrays. For the most part, it is only the constant that changes; the asymptotic analysis of arithmetic is not affected by word size or the overhead of handling arrays instead of single operands.

#### Complexity of Integer Arithmetic

The bit complexity for multiprecise arithmetic is not different from ordinary arithmetic. The issue in multiprecise arithmetic has thus usually been with software implementations. A detailed analysis exists in Knuth

(1998). Probably the most common software package in common use is the `gmp` library by Granlund (2001).

### Complexity of Polynomial Arithmetic

Virtually all the analysis for integer arithmetic, including multiprecision integer arithmetic, carries over for polynomial arithmetic in  $GF(2)[x]$ , with one major and crucial difference. Although the bit operation count is the same for polynomial arithmetic as for integers, there are no carries in polynomial arithmetic, so that the bit operations can be parallelized in hardware or vectorized in software.

### Montgomery Multiplication

Much of the use of number theory in computer security and in cryptography relies on multiplication of long-word-length objects (both integers and polynomials in finite fields  $GF(2^n)[x]$ ) modulo a *fixed* integer or polynomial modulus. A problem with this is that modular reduction is computationally expensive, costing roughly the same time as division. A clever technique for reducing the complexity of modular multiplication is because of Peter Montgomery (1985). This method has also been explored for implementation directly in hardware (Bajard, 1997; Eldridge, 1993). We remark that the Montgomery trick as presented below works *mutatis mutandis* for polynomial arithmetic.

The basic idea of Montgomery multiplication goes back to a standard trick that has been used for decades for arithmetic modulo Mersenne numbers. This trick is half the reason that the largest known prime numbers are usually Mersenne primes. (The other half is that a test exists that all prime numbers pass and most composite numbers fail. This test is useful in primality testing for eliminating most composites. If the numbers tested are generic numbers, then there are false positives that pass the test but are not prime. In the case of Mersenne numbers, however, the test is both “if and only if” in that all prime Mersenne numbers pass and all composite Mersenne numbers fail. The combination of a test that always works for Mersenne numbers coupled with the following trick for rapid computation modulo Mersenne numbers is why the largest known primes have usually been prime Mersenne numbers.)

Let  $M_n = 2^n - 1$  be the  $n$ -th Mersenne number, a number of  $n$  bits, and assume that we are doing arithmetic modulo  $M_n$ . The crucial operation is multiplication: if  $A$  and  $B$  are integers reduced modulo  $M_n$ , that is to say,  $n$ -bit numbers, then the product  $C = A \times B$  can be written as  $C = C_1 \times 2^n + C_0$ ;  $C_1$  and  $C_0$  are the digits of the product  $C$  written with radix  $2^n$ .

The computational trick is to observe the following:

$$\begin{aligned} C &= C_1 \times 2^n + C_0 \\ &= C_1 \times 2^n - C_1 + C_1 + C_0 \\ &= C_1 \times (2^n - 1) + C_1 + C_0 \\ &= C_1 \times M_n + C_1 + C_0 \\ &\equiv C_1 + C_0 \pmod{M_n}. \end{aligned}$$

For example, if  $n = 5$ , so  $2^n = 32$ , and if we let  $A = 17$  and  $B = 11$ , we have the following:

$$\begin{aligned} A \times B &= 17 \times 11 = 187 \\ &= 5(32) + 27 = 5(32) - 5 + 5 + 27 \\ &= 5(32 - 1) + 32. \end{aligned}$$

Modulo  $2^5 - 1 = 31$ , we have  $A \times B \equiv 32$ . On a binary computer, we split the 10-bit product 187 into its left half of  $0101_2 = 5_{10}$  and right half of  $1101_2 = 27_{10}$ , add the halves, and then subtract 31 from 32 (because in this case the addition of the halves generated a carry) to get the correct answer of 1 modulo 31.

In general, instead of having to *divide* by  $M_n$  to produce the remainder, we only need to add the left half of the product to the right half of the product. If there is a carry left, there is an additional subtraction. These costs are small, however, relative to the cost of naive modular reduction. The left half of a  $2n$ -bit number contains  $n$  bits, and we should expect on average that half of these would be 1. Reducing the  $2n$ -bit product modulo an  $n$ -bit modulus would naively require  $n$  subtractions. The cost of one  $n$ -bit addition followed some of the time with an  $n$ -bit subtraction is small by comparison.

The Montgomery algorithm is based on the technique for Mersenne numbers, and it works in essence by converting a modulus  $N$  with a complicated bit pattern into a modulus that is a power of 2. What would have been costly arithmetic operations become reductions modulo a power of 2 (choosing the bits of the right half of a double-length product) and divisions by a power of 2 (selecting the bits of the left half of a double-length product). The algorithm requires conversion of all numbers into a “Montgomery” representation, but if we have a great deal of arithmetic modulo a single fixed  $N$ , the one-time conversion into Montgomery representation prior to the arithmetic and the cost of converting back to ordinary representation afterward is more than compensated for by the elimination of expensive modular division operations.

Given a modulus  $N$ , we choose a suitable  $k$  to make  $R = 2^k > N$ . We assume that  $R$  and  $N$  are relatively prime (if not, we divide out the common factor and solve this problem, multiplying back by the common factor at the end). We can then solve for  $R'$  and  $N'$  such that  $RR' - NN' = 1$ .

What we now do is multiply all the constants and values of variables by  $R$ . Then, instead of doing arithmetic with integers  $a$  and  $b$ , say, we will be doing arithmetic with integers  $aR$  and  $bR$ . At the very end of the computation, we multiply any result by  $R'$  and reduce modulo  $N$ . Because  $RR' \equiv 1 \pmod{N}$ , we thus recover the result we would have if we had done the arithmetic in the usual number representation.

Addition and subtraction of the Montgomery-transformed numbers are fine, because

$$a + b = c \Leftrightarrow aR + bR = cR.$$

The problem is with multiplication:

$$aR \times bR = abR^2,$$

which means that we have an extra factor of  $R$ . What we need is a function to which we can pass the product  $abR^2$

and from which will be returned  $abR$ . We could do this by multiplying by  $R'$  and reducing modulo  $N$ , but that would be a multiplication modulo  $N$ , and it is exactly this that we are trying to avoid.

To convert a product  $T = abR^2$  into its Montgomery representation  $cR$ , we apply the functions

$$\begin{aligned} m &= (T \pmod{R}) \times N' \pmod{R} \\ t &= (T + mN)/R \end{aligned} \quad (11)$$

returning either  $t$  or  $t - N$ , whichever lies in the range 0 to  $N - 1$ .

We note the careful process of computing  $m$  and  $t$ . We begin with operands  $a$  and  $b$  each less than  $N$ , thus each less than  $R$ , thus each a  $k$ -bit number (we will call this “single-length”). We then convert to  $aR$  and  $bR$  modulo  $N$  as single-length operands. Then  $T$  is a double-length product of  $2k$  bits. Computing  $T \pmod{R}$  consists of taking the rightmost  $k$  bits, which is computationally cheap, and results in a single-length operand. The multiplication by  $N'$  really is a multiplication and results in a double-length product. Reduction mod  $R$  is once again the selection of the rightmost  $k$  bits to produce the single-length value  $m$ .

Computing  $mN$  requires a real multiplication. Adding the double-length  $T$  to the double-length  $mN$  is a genuine arithmetic operation, but it is inexpensive compared to the multiplications. Finally, division by  $R$  is merely shifting the sum right by  $k$  bits or else selecting the leftmost  $k$  bits. At the end, we may need one more genuine subtraction of  $N$ . The single modular reduction is accomplished at the cost of two multiplications, one or two addition/subtractions, and two bit shift/select operations. We note that the algebra has resulted in a value for  $T + mN$  that is zero modulo  $R$  that is, for which the rightmost  $k$  bits are zero.

### Example

Let  $N = 79$ , and instead of using a power of 2 for  $R$ , we use  $R = 100$  for readability. This would then be an efficient algorithm on a computer operating in decimal on words of two decimal digits in length. By analogy with the binary operations of a standard computer, we assume for this example that choosing the right two decimals (reduction modulo 100) of a four-decimal digit product and choosing the left two decimals (division by 100, discarding the remainder) are cheap when compared with actual division.

We find that  $64 \times 100 - 81 \times 79 = 1$ , so we have  $R = 100$ ,  $R' = 64$ ,  $N = 79$ ,  $N' = 81$ .

Let us assume we wish to multiply 61 and 5 modulo 79. To convert to Montgomery representation, we multiply both these numbers by  $R = 100$  and reduce modulo  $N = 79$ , using the standard expensive operations:  $61 \rightarrow 61 \times 100 \pmod{79} \equiv 17$  and  $5 \rightarrow 5 \times 100 \pmod{79} \equiv 26$ . In Montgomery representation, we multiply 17 times 26 to get  $T = 442$ . Modulo 79, we know that  $442 \equiv 6100 \times 500 \pmod{79}$ , but what we need to determine is the integer  $t$  that is the Montgomery representation for  $442/100 \pmod{79}$ .

We compute the following:

$$T \pmod{R} = 442 \pmod{100} \equiv 42$$

$$\begin{aligned} (T \pmod{R}) \times N' &= 42 \times 81 = 3402 \\ m &= ((T \pmod{R}) \times N') \pmod{R} \\ &= 3402 \pmod{100} \equiv 02 \\ T + mN &= 442 + 2 \times 79 = 600 \\ t &= (T + mN)/R = 600/100 = 6. \end{aligned}$$

We convert from Montgomery representation by multiplying  $t$  by  $R'$  modulo  $N$  to get  $6 \times 64 \pmod{79} \equiv 384 \pmod{79} \equiv 68$ . Algebraically, we have the following:

$$\begin{aligned} 61 &\rightarrow 61 \times 100 \pmod{79} \equiv 17 \\ 5 &\rightarrow 5 \times 100 \pmod{79} \equiv 26 \\ 68 &\rightarrow 68 \times 100 \pmod{79} \equiv 6 \end{aligned}$$

and the result of the Montgomery multiplication of  $17 \times 26$  is 6.

**Theorem 110.35.** *Montgomery multiplication, using Eq. (11), is correct. The cost of a single multiplication modulo  $N$  is approximately equal to the cost of three ordinary multiplications on integers of size equal to  $\lg N$ .*

*Proof.* We assume that value  $T$  is a product and hence is double length. Because we choose  $R > N$  but not too much bigger, the products can be taken to be double length (plus a constant addend) in  $R$ .

The first modular reduction simply converts  $T$  to a single-length number modulo  $R$ . Modulo  $R$ , we have that  $m = TN'$ . Thus,

$$mN \equiv TN'N \equiv -T \pmod{R}.$$

When we then take  $T + mN$ , we get an integer that is zero modulo  $R$ , and we can legitimately divide out the  $R$  and get an integer quotient for  $t$ .

Now the fact that we get the correct quotient comes from the fact that

$$tR = T + mN \equiv T \pmod{N}$$

so that, modulo  $N$ , we have  $t \equiv TR$ .

## INTRODUCTION

It is hard to place ourselves back in the mid-1970s, when conventional cryptography using a shared, secret key was the only type available—and the only type thought possible. Although effective at providing such functions as privacy and authentication, conventional cryptography has an inconvenient requirement. If one party wants to communicate with another party in a secure fashion, they have to somehow get a secret key to that other party before they can securely communicate. How can the parties (let us call them Alice and Bob) perform this key distribution, which must be done in a secure manner? Well, maybe Alice could encrypt the secret key before it is sent to Bob. What secret key will Alice and Bob use to encrypt this secret key? We are caught in an infinite series of requirements for a secure distribution channel for the secret key. We must somehow figure out how to get Bob a secret key, ideally over an otherwise insecure channel.

There are conventional cryptography solutions that get a secret key from Alice to Bob, but none of them are particularly convenient. Alice could send Bob a key in the postal mail or with a courier who has a handcuffed briefcase, but this precludes immediate, private communication between parties who have met spontaneously. Alice could send the secret key on an alternative electronic communication channel, such as e-mail or fax, but she is betting that an attacker will not be listening in on that channel. We could have a trusted third party, Trent, who shares a secret key with Alice and another secret key with Bob and uses these keys to encrypt a new secret key to be sent to and used by Alice and Bob. But how does Trent get his initial secret keys to Alice and Bob in the first place? Making sure a Trent is around whenever Alice wants to talk with a new person is not convenient. We really have to trust Trent, because if Trent is compromised, then the stolen keys can decrypt not only new communications between Alice and Bob but also any old encrypted communications that were saved. If  $N$  parties want to be able to securely communicate with each other, they will need a total of  $N \times (N - 1)/2$  secret keys, which can grow to be a very big number and an associated management

headache. This number can be reduced to  $N$  keys if we use more sophisticated protocols to get temporary (session) keys from Trent, but Trent must be there when we need him and must respond quickly.

The key distribution requirements for parties that want to communicate spontaneously is a fundamental disadvantage for conventional cryptography. But this was the only form of cryptography available until the mid-1970s, so people made it work the best they could. Most experts, at that time, said that doing better was a fundamentally unsolvable problem. Then a number of people made a significant series of discoveries that culminated in the invention of public key cryptography, so now we all can surf to a Web site where we had no previous contact and perform tasks such as entering our credit card numbers over a newly created secure communication channel.

Furthermore, some public key algorithms, such as RSA, can be used for both encryption (providing privacy) and also for a very different function—digital signature. A paper signature identifies the originator of a document in a way that both authenticates the originator (proves they are who they say they are) and provides nonrepudiation (does not allow the originator to deny that they are the originator). Clearly, there are flaws with the paper signature process, but in general it works fairly well. We would like to have an analogous capability for digital transmissions. Conventional cryptography can provide the authentication function, partially meeting the signature requirement. If Alice sends an encrypted message to Bob, and Bob can determine that it decrypts properly, then Bob knows it came from Alice because she is the only other entity with the secret key. But Alice can deny she sent a given message because Bob could have sent it to himself, because he too has the secret key. So, in this scenario using conventional cryptography, we have authentication but not nonrepudiation.

Some types of public key cryptography can provide nonrepudiation capability, which is a stronger notion than just authentication, via digital signature. If Alice signs a message with her private key (using techniques discussed later), then Bob can verify the signature with Alice's public

key. But now Alice cannot deny that she signed the message because she is the only one with her private key (unless she claims her private key was compromised). In this scenario, we have both authentication as well as the stronger notion of nonrepudiation, giving us digital signature.

Encryption alone provides privacy but not nonrepudiation. Digital signature alone provides nonrepudiation but not privacy. Encryption and digital signature can be combined to provide both characteristics. In this scenario, Alice and Bob each have two private and public key pairs, one for signing and one for encryption. It is a good practice to always sign a message before encrypting it, so we can always know the plaintext that we are signing. Alice can first sign a message with her private signing key and then encrypt that result with Bob's public encryption key. She sends this signed and encrypted message to Bob. Bob first decrypts the message with his private encryption key and then verifies the signature with Alice's public signing key. For best security, Alice and Bob should each have two different key pairs, one pair for encryption and the other pair for digital signature, to avoid certain attacks discussed later.

Public key cryptography, although a significant advance, has some shortcomings, such as performance and the need for revocation lists, and does not eliminate the need for conventional cryptography. In practice, systems protocols use a hybrid system of both conventional and public key cryptography.

The remainder of this chapter first reviews the breakthrough thought about public key cryptography in Ralph Merkle's puzzles and then looks at the knapsack algorithm, which was the first practical public key cryptosystem (now broken), and then the Diffie–Hellman key exchange algorithm, which is still used today, and a related public key cryptosystem called ElGamal. Finally, we examine the most popular and flexible public key cryptosystem, RSA, which can be used for both encryption and digital signature functions. We also look at some RSA implementation considerations and attacks.

Note that the algorithms and history discussed here are based on the public literature in cryptographic research. There is evidence that many of these ideas were previously discovered by the Communications Electronics Security Group (CESG) in Great Britain. See Levy (2001) and Singh (1999) for more details about this issue as well as some captivating accounts of the history of the invention, use, and politics surrounding public key cryptography.

Several references provide more detailed, yet broad, technical coverage of the topics in this chapter, such as a historical review by Diffie (1988); implementation considerations by Ferguson and Schneier (2003); a mathematics textbook by Garrett (2001); a mathematically oriented handbook by Menezes, Van Oorschot, and Vanstone (1996); a public key volume by Salomaa (1996); an applied handbook by Schneier (1995); and textbooks by Stallings (2003) and Stinson (2002).

## MERKLE'S PUZZLES

The first to make a dent in the problems fundamental to public key cryptography was Ralph Merkle (1978). As a

student, he wrote a paper for his computer security class describing a technique using puzzles to allow both Alice and Bob to obtain the same secret key by exchanging information over an insecure channel. Furthermore, an eavesdropping Eve, who monitors this insecure channel, cannot discover this secret key. Unfortunately, good communication of the idea between him and his professor did not occur, his professor did not recognize the value of his contribution, and Merkle dropped the course. He then wrote up his idea for publication, but it was rejected in the review process. Fortunately, he eventually found others who understood and enhanced the value of his initial contribution.

Here is Merkle's puzzle idea. If Alice wants to agree on a key with Bob, she first creates a large number of puzzles. A puzzle is a general term for something that can be solved with a large, but doable, amount of effort. Each puzzle contains a unique puzzle identifier and a key that is not visible until the puzzle is solved. Alice then sends these puzzles in random order to Bob. Bob picks one of these many puzzles at random and solves it, extracting the puzzle identifier and the key. Bob sends Alice the puzzle identifier and Alice looks up the corresponding key. Alice and Bob now both have a shared, secret key that they can use with conventional cryptography to exchange messages. Eve, our eavesdropper, is faced with the task of decrypting all the puzzles (or, on average, half of them) before the puzzle identifier that she sees passed from Bob to Alice has any meaning. As long as Alice and Bob finish using the key before Eve gets a chance to solve the puzzle that Bob chose, the communication is secure (unless Eve saves old encrypted messages, which she can now decrypt). Alice must generate a whole new series of puzzles before executing the protocol again or else Eve will eventually make enough progress to break all the puzzles.

Although the communication overhead for this scheme is too great to yield a practical solution, it represents the first rift in conventional wisdom that said that this was an impossible problem to solve. Merkle then worked with Martin Hellman and Whitfield Diffie after reading a draft paper by the two and finding they were thinking about the same issues. This work eventually led to the Merkle–Hellman knapsack algorithm (Merkle & Hellman, 1978), the first practical public key algorithm, which has now been broken, and the Diffie–Hellman key exchange algorithm (Diffie & Hellman, 1976b), which is still in use today. Later, Ron Rivest, Adi Shamir, and Len Adelman at MIT came up with another approach to public key cryptography and created the RSA algorithm (the initials of their last names) and the company by the same name (Rivest, Shamir, & Adelman, 1978). The RSA algorithm is the most widely used public key cryptography algorithm today and has the added advantage of providing digital signature functionality as well.

## ONE-WAY FUNCTIONS

All public key algorithms rely on the notion of a trapdoor one-way function. A one-way function is easy to compute in one direction but hard to compute in the reverse direction. The term *easy*, in a computational complexity sense, means it can be performed in polynomial time or better.

In addition, the terms *hard*, *computationally infeasible*, or *intractable* mean it takes more than polynomial time (i.e., an exponentially more difficult amount of time) to execute as the size of the input data increases. Note that this is related to the computational complexity notions of P and NP, but complexity theory generally deals with the worst case. In cryptography, the average case behavior is more important.

Hash algorithms take a long sequence of bits and map them to another fixed length and smaller sequence of bits. Many, but not all, hash algorithms have this one-way function characteristic. It is very easy to hash a long string of bits into a small hash representation, but it is computationally infeasible, given an arbitrary small hash representation, to come up with a string of bits that hash to this value. However, some hash algorithms, such as checksum (an XOR of all the bytes to produce a single byte), are easy in both directions, so do not qualify as one-way functions. Cryptographic hashes, such as MD5 (IETF, 1992) and SHA-1 (NIST, 2002), have the one-way property.

But unlike a plain one-way function, a trapdoor one-way function can be easy to compute in the reverse direction if you know a secret. If you know the secret trapdoor, the reverse function can be computed in polynomial, or P, time. If you do not know the secret, it is computationally infeasible to compute. It turns out that these functions are very difficult to find. But they are the key ingredient for public key cryptographic algorithms.

Let us formalize the concepts we have seen so far into the four properties that Diffie and Hellman (1976a) described as necessary for a public key cryptosystem. The first three are required and the fourth is optional:

1. Applying a decryption process  $D$  to a message  $M$  that has undergone an encryption process  $E$  yields the original message  $M$ :  $D[E(M)] = M$ .
2. Both  $E$  and  $D$  are easily computable from the same random source.
3. If  $E$  is revealed to the world, it gives no information about  $D$ .
4. The reverse of property 1 holds as well:  $E[D(M)] = M$ .

A function  $E$  that satisfies properties 1 through 3 is a trapdoor one-way function. Some algorithms that are based on functions that satisfy these three properties can be used directly for encryption (such as knapsack, ElGamal, and RSA). These are called *public key cryptosystems*. Other algorithms cannot directly be used for encryption but can allow two parties to agree on a common key that can subsequently be used for conventional encryption. These are called *public key distribution systems* (such as the Diffie–Hellman key exchange algorithm). A function that also satisfies property 4 is said to be reversible and is a public key cryptosystem that can be used for both encryption and digital signature (such as RSA).

## KNAPSACK ALGORITHM

The knapsack algorithm, created by Merkle and Hellman (1978), was the first practical public key cryptosystem algorithm and it can be used for both encryption and

(with modifications) digital signature, but it has been broken. All attempts to fix it have been unsuccessful, so it is not a practical algorithm today (although there has been renewed interest in the knapsack problem in a newer area called lattice-based cryptography). But it nicely provides the intuition about how trapdoor one-way functions work, so we begin with the knapsack problem.

The Merkle–Hellman knapsack algorithm is based on a mathematical problem called the *subset sum* problem, which is illustrated as follows. Assume we have a knapsack that can hold only a certain maximum weight of groceries and we have a table full of groceries of different weights. Our goal is to select just the right items from the table of groceries to exactly reach the maximum weight allowed by the knapsack.

### A Knapsack Algorithm Example

Assume that our table has five items that weigh 1, 3, 4, 6, and 10 pounds. Assume also that we have a knapsack that can hold a maximum of 21 pounds. With a little trial and error work, we find we can exactly fill the knapsack with the following items: 1, 4, 6, and 10. This seems like a simple problem, but when the number of items grows, the time it takes to find a solution grows exponentially, so this quickly grows from an easy problem to an impossibly difficult one. In computational complexity terms, it is an NP-complete problem.

But, there is a special kind of knapsack, called a *superincreasing knapsack*, which is trivial to solve. In a superincreasing knapsack, the items are not only in increasing order, but also each item weighs more than the sum of all the previous items in the list. For example, this is a superincreasing knapsack: 1, 3, 5, 10, and 20. Our original knapsack of 1, 3, 4, 6, and 10 is a nonsuperincreasing knapsack, because 4 is not greater than  $1 + 3$ .

Superincreasing knapsacks have the interesting property that makes finding a solution very simple. To do this, we go through the knapsack weights in reverse order and subtract them from the target weight. If the result is negative, we do not include this weight in the solution and go on to the next weight. If the result is positive, we include this weight in the solution and subtract this weight from current weight and go on to the next weight. The final result is 0 if we have a solution that exactly matches the starting weight. For example, with our superincreasing knapsack of 1, 3, 5, 10, 20 we can find the result that matches a total weight of 26 as follows:

$$\begin{aligned}
 26 - 20 &= 6 && \text{(positive, so use this weight)} \\
 6 - 10 &= -4 && \text{(negative, so skip this weight)} \\
 6 - 5 &= 1 && \text{(positive, so use this weight)} \\
 1 - 3 &= -2 && \text{(negative, so skip this weight)} \\
 1 - 1 &= 0 && \text{(zero, so use this weight and done)}
 \end{aligned}$$

So our solution is 20, 5, 1.

We need one more piece of information before we can use knapsacks for encryption. For every superincreasing knapsack, we can transform it into a nonsuperincreasing knapsack with the following transformation. We first pick a number  $m$  that is greater than the sum of all the knapsack items. We then find an  $n$  that is relatively prime (shares no

factors) to  $m$ . In this example, let us assume  $m = 41$  and  $n = 3$ . We then multiply every weight in the superincreasing knapsack by  $n$  and take the result mod  $m$ .

$$\begin{aligned} 1 \times 3 \bmod 41 &= 3 \\ 3 \times 3 \bmod 41 &= 9 \\ 5 \times 3 \bmod 41 &= 15 \\ 10 \times 3 \bmod 41 &= 30 \\ 20 \times 3 \bmod 41 &= 19 \end{aligned}$$

So the superincreasing knapsack 1, 3, 5, 10, 20 transforms to the nonsuperincreasing knapsack 3, 9, 15, 30, 19. We call the former knapsack the private key and the latter knapsack the public key. Let us assume these are owned by Bob. Bob keeps the private key private and gives the public key to anyone who needs it to encrypt a message for Bob.

Putting these pieces together, assume Alice wants to send the message 01011 10111 00011 to Bob. Alice first encodes each group of binary plaintext by mapping them against Bob's public key by adding up all the weights that have a 1 value (indicating that the weight is present).

$$\begin{aligned} 01011 &= 9 + 30 + 19 = 58 \\ 10111 &= 3 + 15 + 30 + 19 = 67 \\ 00011 &= 30 + 19 = 49 \end{aligned}$$

We then treat 58, 67, and 49 as the ciphertext and send it to Bob. Bob first calculates one more number: he must find the modular inverse of 3 mod 41, in other words,  $x$  where  $3 \times x \equiv 1 \pmod{41}$ . Using the extended Euclidean algorithm (Knuth, 1981), he finds  $x = 14$ . We can check this by seeing that  $(3 \times 14) \bmod 41 = 1$ .

Now, Bob multiplies each ciphertext value by  $x \bmod m$  as follows:

$$\begin{aligned} 58 \times 14 \bmod 41 &= 33 \\ 67 \times 14 \bmod 41 &= 36 \\ 49 \times 14 \bmod 41 &= 30 \end{aligned}$$

Finally, using his private key (the superincreasing knapsack), he finds these weights as the solution and converts them to binary by using a 1 for every weight present:

$$\begin{aligned} 33 &= 20 + 10 + 3 : 01011 \\ 36 &= 20 + 10 + 5 + 1 : 10111 \\ 30 &= 20 + 10 : 00011 \end{aligned}$$

So, Bob now knows the plaintext. An eavesdropping Eve would see only the ciphertext, the public key, and the non-superincreasing knapsack and so would be faced with solving a computationally infeasible problem.

Real world knapsacks need large values (on the order of 200 decimal digits) for many of the parameters. For more information on knapsack mathematics and implementation issues, see Garrett (2001) and Salomaa (1996). But not only has the original knapsack technique been broken, all known variants have also been broken (Odlyzko, 1990). So, this algorithm is no longer practical, but it remains important for its conceptual value.

## KEY ESTABLISHMENT TECHNIQUES

Before we explore the next algorithms, it is important to distinguish between several kinds of *key establishment* techniques (Menezes, Van Oorschot, & Vanstone, 1996). When public key cryptography is used for encryption, it is often for the purpose of getting Alice and Bob the same secret key, which no one else knows. Once both parties have this shared secret key, they can then use conventional cryptography (algorithms such as DES, DESede, AES) to encrypt their communications. This is desirable because conventional cryptographic algorithms, such as AES and DES, perform a few orders of magnitude faster than public key algorithms, such as RSA. This hybrid approach allows systems to optimize the key distribution benefits of public key cryptography with the performance of conventional cryptography. It turns out that there are two fundamental ways to accomplish the goal of establishing this secret key between the communicating parties, *key transport* and *key exchange*.

With key transport, Alice uses public key cryptography to encrypt another secret key that she generates and then delivers this encrypted secret key to Bob. Alice does this by encrypting the secret key with Bob's public key. When Bob receives this encrypted key, he decrypts it with his private key. Then, Alice and Bob communicate privately using conventional cryptography and this secret key.

Key exchange is a different technique that also results in Alice and Bob having a shared secret key. But, instead of Alice generating that secret key, encrypting it, and sending it to Bob (as in key transport), Alice and Bob exchange several numbers as part of a protocol. At the end of this protocol, Alice and Bob agree on the shared secret key. The magic here is that if an eavesdropper listens to all the traffic between Alice and Bob, he or she does not end up with the secret key!

Key transport tends to be more useful in applications where one party is not online. For example, with e-mail, we want to send a message without requiring the receiving party to be online to execute a protocol with us. Key exchange can be used when the other party is online, in applications such as instant messaging or secure telephone communication. Algorithms like knapsack, ElGamal, and RSA can be used for key transport. Algorithms such as Diffie-Hellman can be used for key exchange. All of them can be used for key establishment.

## DIFFIE-HELLMAN KEY EXCHANGE

The Diffie-Hellman key exchange algorithm (Diffie & Hellman, 1976b) was one of the first public key algorithms, and it is still in use today. Two parties exchange some information that results in both of them deriving the same value, which can be used as a key for subsequent use with a conventional cryptographic algorithm. Furthermore, an eavesdropping Eve can see all of the exchanged information but cannot derive the same key! It relies on the modular exponentiation, which is a computationally easy problem, and the discrete logarithm problem, which is an exponentially difficult problem. Modular exponentiation means finding the value of  $g^x \bmod n$  when all values are known. For example,  $3^4 \bmod 13 = 3$ . The inverse

problem, the discrete logarithm problem, asks for  $x$ , given  $b = g^x \bmod n$ . For example, solving for  $x$  in  $5 = 3^x \bmod 13$ . In this case, there is no solution for  $x$ . How about  $9 = 3^x \bmod 13$ ? In this case, there are multiple values of  $x$  (2, 5, 8, 11) where this holds true.

To have a unique solution, we must find a value for  $g$  that is a primitive root, or generator, of 13 (Garrett, 2001). A number  $g$  is a primitive root of 13 if all of its powers of  $g$  between 1 and 12 (done mod 13) generate all the values between 1 and 12. For example, with  $g = 2$  we obtain the following:

$$\begin{aligned} 2^1 \bmod 13 &= 2, \\ 2^2 \bmod 13 &= 4, \\ 2^3 \bmod 13 &= 8, \\ 2^4 \bmod 13 &= 3, \\ 2^5 \bmod 13 &= 6, \\ 2^6 \bmod 13 &= 12, \\ 2^7 \bmod 13 &= 11, \\ 2^8 \bmod 13 &= 9, \\ 2^9 \bmod 13 &= 5, \\ 2^{10} \bmod 13 &= 10, \\ 2^{11} \bmod 13 &= 7, \\ 2^{12} \bmod 13 &= 1. \end{aligned}$$

So 2 is a primitive root or generator of 13. The complete set of generators are  $\{2, 6, 7, 11\}$ . Knuth (1981) discusses the computation issue of finding generators. Picking the generator 7, for example, we know that  $9 = 7^x \bmod 13$  has the unique solution, found through trial and error, of  $x = 4$ . There are other algorithms for solving this discrete logarithm problem that are more efficient, but still exponential, such as Pollard's Rho algorithm or the even more efficient index calculus methods (Menezes, Van Oorschot, & Vanstone, 1996).

## A Diffie–Hellman Example

To start, either Alice or Bob picks a large, strong, prime number  $n$  (a method for doing this and the meaning of strong are discussed in a later section) and a value  $g$  that is a primitive root of  $n$ . These values are sent to the other party, and they can be seen by Eve. Alice and Bob each pick a large random number,  $a$  and  $b$ , which they keep private. Assume (keeping the numbers small and simple) that  $n = 23$ ,  $g = 11$ , Alice's private number is  $a = 30$ , and Bob's private number is  $b = 15$ :

1. Alice computes  $A = g^a \bmod n = 11^{30} \bmod 23 = 8$  and sends it to Bob.
2. Bob computes  $B = g^b \bmod n = 11^{15} \bmod 23 = 10$  and sends it to Alice.
3. Alice then computes  $k = B^a \bmod n = 10^{30} \bmod 23 = 2$ .
4. Bob then computes  $k = A^b \bmod n = 8^{15} \bmod 23 = 2$ .

So, Alice and Bob have derived the same key value, 2! Eve saw  $n$ ,  $g$ ,  $A$ , and  $B$ . For her to calculate the key as well, she would have to solve  $8 = 11^x \bmod 23$  or  $10 = 11^x \bmod 23$ . Both of these are discrete logarithm problems, which are exponentially difficult problems, meaning as the numbers get big enough, they are computationally infeasible to solve.

## Diffie–Hellman Attacks

Although Diffie–Hellman is considered secure today, there are a variety of attacks that lead to some implementation considerations, only briefly mentioned here. More details are discussed in Ferguson and Schneier (2003) and Garrett (2001).

The protocol as presented in the example is vulnerable to a man-in-the-middle attack (Stallings, 2003), where a malicious intruder, Mallory, can listen to and respond to the protocol messages from Alice and Bob in a way where Mallory can learn all the keys and Alice and Bob are not aware of this breach. Also, certain values passed as the prime number  $n$  or its primitive root  $g$  can cause weakness and should be checked as part of a higher level protocol. The prime number  $n$  should be on the order of 6800 bits long.

## ElGAMAL

The ElGamal public key cryptosystem created by Taher ElGamal (1985), like the Diffie–Hellman key exchange, is based on the discrete logarithm problem. But, unlike Diffie–Hellman key exchange, it can be used for encryption. Just as in Diffie–Hellman, the sender selects a large prime number  $n$  and  $g$ , a primitive root of  $n$ , and calculates a public key, which is sent to the receiver. The plaintext  $M$  has to be less than  $n$ . The sender also picks a random integer between 1 and  $n - 1$ , inclusive. Also, there are two ciphertexts created by the sender, one of which is used to represent the encrypted message key and the other that represents the encrypted message. The receiver uses the sender's public key to first recover the message key from the first ciphertext and then uses that message key to recover the plaintext message itself.

## An ElGamal Example

Let us assume, as in the previous Diffie–Hellman example (keeping the numbers small and simple) that  $n = 23$ ,  $g = 11$ , and Alice's private number is  $a = 30$ . Alice must also compute a random number  $k$  between 1 and  $n - 1$ , inclusive, for each encrypted block. We assume that  $k = 10$  for this block. Let us also assume that the plaintext message  $M = 13$ :

1. Alice computes  $A = g^a \bmod n = 11^{30} \bmod 23 = 8$  and sends it to Bob. This is her public key.
2. Alice computes  $K = A^k \bmod n = 8^{10} \bmod 23 = 3$ .
3. Alice computes a ciphertext  $C_1 = g^k \bmod n = 11^{10} \bmod 23 = 2$  and sends it to Bob.
4. Alice computes a ciphertext  $C_2 = K \times M \bmod n = 3 \times 13 \bmod 23 = 16$  and sends it to Bob.
5. Bob computes  $K = C_1^A \bmod n = 2^8 \bmod 23 = 3$ .
6. Bob computes the modular inverse,  $K^{-1}$ , of  $K$ . In other words, finding the value for  $x$  where  $3 \times x \equiv 1 \bmod 23$ .  $x = 8$ , using the extended Euclidean algorithm.
7. Bob then computes  $C_2 \times K^{-1} \bmod n = 16 \times 8 \bmod 23 = 13$ , the original plaintext message.

Note that in this algorithm, the size of the ciphertext is twice the size of the plaintext. Also, because of the random

$k$  value per message, we avoid having the same plaintext encrypting to the same ciphertext, thwarting dictionary attacks.

There is a form of the ElGamal algorithm that can be used for digital signature, but it is not a simple reversal of the encryption form of the algorithm. The ElGamal signature algorithm, with improvements by Schnorr, is the base for the U.S. government's Digital Signature Standard (DSS) (NIST, 1994). In DSS, the signature can be used only for digital signature and not encryption. This was a desirable property in the era when the U.S. government wanted to encourage the use of digital signatures for contract signing in international commerce but did not want to propagate the use of encryption, which could be used for criminal purposes.

## RSA

Although the seminal Diffie–Hellman article described the characteristics of a public key cryptosystem that can be used for both privacy (encryption) and nonrepudiation (digital signature), it did not describe an actual algorithm that had the essential properties. This motivated the MIT team of Rivest, Shamir, and Adleman to discover an algorithm with these properties. After many false starts, they finally arrived at the algorithm we know today as RSA. For this accomplishment, they were awarded the 2002 Turing Award, the Nobel Prize of computer science (2002 A. M. Turing Award Winners, 2004).

RSA was difficult to discover, but it is easy to describe. Quoting their article:

A message is encrypted by representing it as a number  $M$ , raising  $M$  to a publicly specified power  $e$ , and then taking the remainder when the result is divided by the publicly specified product,  $n$ , of two large secret prime numbers  $p$  and  $q$ . Decryption is similar; only a different, secret, power  $d$  is used, where  $e \times d \equiv 1 \pmod{(p-1) \times (q-1)}$ . The security of the system rests in part on the difficulty of factoring the published divisor,  $n$ .

### An RSA Example

First, we choose two random, large, prime numbers  $p$  and  $q$ . For the sake of a simple example, we keep the numbers simple, so let us say that  $p = 61$  and  $q = 71$ , both of which are prime. We then compute  $n = p \times q = 61 \times 71 = 4331$ . This is also known as the modulus. We discuss how to find large prime numbers in a later section.

We then compute something called the *Euler totient* of  $n$ , symbolized by  $\phi(n)$ . This is defined as the number of numbers less than  $n$  that are relatively prime to  $n$ . So  $\phi(12) = 4$  because the numbers  $\{1, 5, 7, 11\}$  are relatively prime to 12. Because all numbers less than a prime number are relatively prime to it (otherwise it would not be prime), the totient of a prime number is just 1 less than the number. So  $\phi(p) = p - 1 = 61 - 1 = 60$  and  $\phi(q) = q - 1 = 71 - 1 = 70$ . But, we want  $\phi(p \times q)$ , and it can be shown that this is equal to  $\phi(p) \times \phi(q)$ . So,

$$\phi(n) = \phi(4331) = \phi(61) \times \phi(71) = 60 \times 70 = 4200.$$

Now, we pick a random number  $e$  that is relatively prime to  $\phi(n)$ . Let us say that  $e$  is 1027. Then we find the corresponding  $d$ , which is the modular inverse of  $e \pmod{\phi(n)}$ . We can find  $d$  using the extended Euclidean algorithm as follows:

$$e \times d = 1 \pmod{\phi(4331)} \quad \text{or} \quad 1027 \times d = 1 \pmod{4200}, \quad \text{or} \\ d = 1963$$

The public key is  $\{e, n\}$  or  $\{1027, 4331\}$  and the private key is  $\{d, n\}$  or  $\{1963, 4331\}$ . Note that although each key is composed of more than just the modulus  $n$ , the RSA key size is conventionally stated as the size of just  $n$  in bits. Also, we must be sure to destroy  $p$  and  $q$ .

For this example, let us assume that Alice converts a plaintext message  $M$  into a series of decimal digits, such as 123, 456, and 789. Using Bob's public key, Alice computes the ciphertext  $C = M^{1027} \pmod{4331}$ . So  $123^{1027} \pmod{4331} = 62$ ,  $456^{1027} \pmod{4331} = 2167$ , and  $789^{1027} \pmod{4331} = 3197$ . Our ciphertext message is thus 62, 2167, 3197. Alice sends this ciphertext message to Bob.

Bob now needs to convert the ciphertext message to plaintext by using his private key. Bob computes the plaintext  $M = C^d \pmod{4331}$ . So  $62^{1963} \pmod{4331} = 123$ ,  $2167^{1963} \pmod{4331} = 456$ , and  $3197^{1963} \pmod{4331} = 789$ . The result is the original plaintext message 123, 456, 789.

### RSA Digital Signatures

As previously discussed, RSA is reversible, so it can be used both for encryption (privacy) and digital signature (nonrepudiation). A digital signature would proceed similarly, except Alice would sign a message with her private key using  $C = M^d \pmod{n}$  and Bob would verify the signature using Alice's public key using  $C^e \pmod{n}$ , which is  $(M^d \pmod{n})^e \pmod{n}$ , which is  $M^{de} \pmod{n}$ , which is back to  $M$ .

Although the digital signature could be applied to the entire message, in practice it is applied to a cryptographic hash, or message digest, of the message as both a performance improvement and integrity check. This message digest is usually generated using an algorithm such as MD5 or SHA-1 (Stallings, 2003) and acts like a one-way fingerprint for the message. So, Alice would first generate the message digest of the message  $MD(M)$  and sign it with her private key. She would then send the original message  $M$  and the signed message digest of  $M$  ( $M + D_{\text{Alice-Private}}[MD(M)]$ ) to Bob. Bob would then recalculate the message digest of  $M$  using the same hash algorithm and then apply Alice's public key to the signature portion of the message yielding  $MD(M)$ , which should be the same as the  $MD(M)$  that he just calculated if the signature verifies. More information about using RSA for digital signature can be found in Menezes, Van Oorschot, and Vanstone (1996).

### Generating Large Prime Numbers

As we have seen, the RSA algorithm requires that we generate two random, large, prime numbers  $p$  and  $q$ . Because a prime number is one that has no factors other than 1 and itself, it may seem that generating a prime number is as difficult as factoring a number, which is the exponentially hard problem that RSA is based on in the first place.

It turns out that there are several algorithms that can test whether a random candidate number is prime more efficiently than factoring.

First, how many prime numbers are there? The Prime Number Theorem, which says that the number of primes smaller than a given number  $n$  is about  $n/\ln(n)$ , gives us this insight (Garrett, 2001). We can use this theorem to estimate the density of prime numbers around a given number. For 1024-bit RSA keys,  $p$  and  $q$  are on the order of  $2^{512}$  each. So, about 1 of every  $2^{512}/[2^{512}/\ln(2^{512})]$  or 355 numbers in this vicinity are prime. One way to generate a prime number of this size is to just generate a random number and test whether it is prime, and this will take on average 355 attempts for keys of this size. We can skip even numbers and drop this average in half.

One algorithm for testing primality is the Miller–Rabin algorithm (Stallings, 2003). It is a nondeterministic algorithm, meaning that it determines that a number is prime with an uncertainty. The algorithm can be run multiple times to decrease this uncertainty, until it achieves an acceptable level of uncertainty. Recently, a deterministic algorithm for primality testing, known as AKS (Agrawal, Kayal, & Saxena, 2002) was discovered, but it is slower than Miller–Rabin.

Some authors and standards recommend or require that  $p$  and  $q$  are *strong* primes. This means that  $p - 1$  and  $p + 1$  are divisible by a large prime number. Although this helped thwart some factoring attacks, it does not help increase security with more recent factoring methods.

## RSA Attacks

Although RSA, with adequate key size, is considered secure today, there are a number of attacks that lead to some implementation considerations. In addition, if RSA is used improperly in security protocols, it can lead to vulnerabilities without breaking the RSA algorithm itself. This section gives just a few of the more common attacks and implementation considerations. For more details, see Boneh (1999), Ferguson and Schneier (2003), Garrett (2001), and Schneier (1995).

Fundamentally, a message  $M$  is encrypted via  $M^e \bmod n$ , so reverse this function and find  $M$ . This is known as taking the  $e$ th root mod  $n$  and is an apparently computationally hard problem (Garrett, 2001). However, this is not the only route to an attack against RSA.

An attacker can see  $e$  and  $n$ , because they form the public key, which is public. An attacker would like to get  $d$ , so they can either decrypt messages encrypted with  $e$ , or forge message signatures by signing them with  $d$ . One way to get  $d$  is to compute the modular inverse of  $e \bmod \phi(n)$ . But to get  $\phi(n)$ , we need to find  $p$  and  $q$ . This means we must factor  $n$  into its component primes  $p$  and  $q$ . But as  $n$  gets larger, this becomes exponentially more difficult. So the security of RSA is primarily based on the difficulty of factoring large numbers.

Table 1 (FactorWorld!, 2004) shows some history of factoring records, showing the decimal digit size, the year the factoring was completed, the amount of computing power required (expressed in millions of instructions per second-years) and the factoring algorithm used. MPQS stands for multiple polynomial quadratic sieve and GNFS

**Table 1** Decimal Digit Factoring Records

Decimal digits	Year	MIPS-years	Algorithm
116	1990	275	MPQS
120	1993	830	MPQS
129	1994	5000	MPQS
130	1996	1000	GNFS
140	1999	2000	GNFS
155	1999	8000	GNFS
158	2002	?	GNFS
160	2003	?	GNFS
174	2003	13200	GNFS

stands for general number field sieve. Note the efficiency gained with the new algorithm.

For comparison, Table 2 shows the decimal equivalent for a variety of RSA key sizes. Note, in general, the sizes of keys for public key cryptography are much larger and not comparable to the sizes of keys for conventional cryptography. The 512-bit key size is already vulnerable. Most applications today select a key size of 1024 bits. Some applications are beginning to use greater key sizes. Lenstra and Verheul (2001) predict that a key size of 2048 bits will remain secure until the year 2022. As in any use of cryptography, one should use a key size that not only is appropriate for current needs but that will also remain secure for the length of time the data must be secure. This means we must anticipate both improvements in computing power (as Moore’s law describes) and improvements in factoring algorithms. This can be as much an art as it is a science.

Another way of attacking RSA makes use of a plaintext–ciphertext pair. In this case, if an attacker knows  $M$  and the corresponding  $C$ , in addition to  $n$ , they can try to solve the equation  $C = M^e \bmod n$  for the encryption key or  $M = C^d \bmod n$  for the decryption key. But both of these problems are variations of the discrete logarithm problem, so we are back to another hard problem such as factoring, so this is infeasible as the numbers get large.

There are several other kinds of attacks that lead to some implementation considerations and constraints. For example, because of the *common modulus* attack one should never intentionally choose the same modulus, or  $n$ , for more than one user. At first, this might seem acceptable and desirable because it saves time as we do not have to generate another  $p$  and  $q$ . But if two users have the same  $n$ , then one of the users can use their own  $e$  and  $d$  along with  $n$  to find  $p$  and  $q$ . The user, with  $p$  and  $q$ , now takes the other user’s public key  $e$  and calculates his or her private key  $d$ .

**Table 2** RSA Key Size Decimal Equivalents

RSA key size	Decimal digits
512	155
1024	309
2048	617

There are numerous other implementation considerations. For example, the value for  $d$  should be larger than the square root of  $n$ , and the value for  $e$  is often selected to be 65537 to avoid some attacks. Also, as with any type of cryptography, good random number sources or pseudorandom number generation algorithms are critical.

### RSA Protocol Attacks

It is possible to use RSA in an incorrect way, which can lead to vulnerability, without actually breaking the algorithm itself. In general, these are known as *protocol attacks* (Kaufman, Perlman, & Speciner, 2002). One example arises when an attacker gets an RSA implementation to sign a carefully chosen number. This can occur in a challenge response protocol, where a challenger generates a numeric challenge, asks the challenged entity using RSA to sign the challenge with its private key, and then applies the challenged entity's public key to authenticate the entity. If an attacker can get an entity to sign a message  $M'$ , while the attacker's true agenda is to get the entity to sign a message  $M$ , they can generate a random number  $r$  and construct  $M' = r^e M \text{ mod } n$ . After the entity signs  $M'$  and returns it, the attacker takes the result and divides by  $r^e \text{ mod } n$  and gets the entity's signature on the original message  $M$ . This attack is called *blinding* (Boneh, 1999). A related attack is to have the entity sign two messages,  $M_1$  and  $M_2$ . They have inadvertently also signed  $M_3 = M_1 \times M_2 \text{ mod } n$ .

In another signing-based attack, a malicious Mallory gets Alice to decrypt some ciphertext by signing a message. Mallory generates a random number  $r$ , where  $r < n$ . Mallory sends  $y = (r^e \text{ mod } n) \times c \text{ mod } n$  to Alice, pretending it is a random number as part of a challenge/response authentication protocol, and Alice signs it with her private key  $d$ , giving  $u = y^d \text{ mod } n$  back to Mallory. Mallory then computes  $(r^{-1} \text{ mod } n) \times u \text{ mod } n$ , which is  $r^{-1} r^e r^d c^d \text{ mod } n$ , or  $c^d \text{ mod } n$ , which is just  $m$ , Alice's unencrypted message! This is one reason that the key pair used for digital signature should be distinct from the key pair used for encryption.

The RSA algorithm does not have a minimum block size, but if too small a block size is used, then an attacker can simply build a dictionary of all plaintext-ciphertext pairs. So, large block sizes are used in practice (usually the same size as the modulus). Short messages can be padded to meet this length. The standard PKCS1 is designed specifically for RSA to help do this padding in a way that resists attack (RSA Laboratories, 2001). Public key cryptosystems work best, in both a security and

performance sense, with small (but not too small) random-appearing data, such as secret keys and one-way hash functions.

## PROTECTING PUBLIC AND PRIVATE KEYS

The public key cryptographic algorithms we have discussed still leave open some higher level security considerations. First, as with any cryptographic application, the algorithm is only as good as the key protection. Private keys must be stored in ways that are inaccessible to attackers. Using passwords and passphrases that are weaker in entropy than the keys they protect defeats the intended security of the algorithm and is perhaps the biggest security weakness in systems that employ cryptography, public key or conventional. Other human-factor and systems issues are discussed in Schneier (2000).

We must also ensure that public keys purported to belong to an entity really do belong to them. We cannot always trust e-mail or public directory distributions of the public key. One common solution is to have a trusted third party, such as VeriSign, use their private key to sign a *digital certificate*, which contains an entity's public key and other identifying information. Then, users of that digital certificate can use the third party's public key (usually distributed with the operating system or browser) to validate the signature on the certificate. This authenticates that the public key really belongs to the entity.

There are several weaknesses with this approach to public key authentication, most notably with certificate revocation lists (CRLs) that must be checked (but usually are not) by applications to identify certificates that have been compromised. Gutman (2002) discusses these problems and potential solutions.

## CONCLUSION

Table 3 summarizes the algorithms referenced in this chapter and their characteristics. Elliptic curve cryptosystems, discussed in another chapter, are also a type of public key cryptosystem based on the ElGamal family. For Java implementations of many of the algorithms and supporting numeric calculations discussed in this chapter, see Bishop (2003).

Public key cryptography is an amazing invention. It has transformed many core security functions and practices and is present today in protocols and applications such as SSL/TLS, SSH, S/MIME, and PGP. Arguably, e-commerce

**Table 3** Public Key Algorithm Summary

	Public key cryptosystem	Public key distribution system	Encryption	Digital signature	Key establishment
<b>Knapsack</b>	X		X	X	X
<b>Diffie-Hellman</b>		X			X
<b>ElGamal</b>	X		X	X	X
<b>ElGamal signature &amp; DSS</b>				X	
<b>RSA</b>	X		X	X	X

would not be possible without this technology, because it relies on private, authenticated communication between two spontaneously interacting parties. So, we are now all free to connect to a Web site without any preexisting business relationship, and in a few mouse clicks can ensure we are privately sending our credit card number to an authenticated server to purchase a product. This technology has brought us a rich variety of computer applications, opened the doors for many mathematical developments, and raised many interesting privacy and political issues. Even more amazing, just over 25 years ago, most thought that this would not be technically possible.

## GLOSSARY

**Certificate Authority** A trusted third party that verifies public key owner identity and who then signs that public key with the certificate authority's private key, thereby authenticating that key and binding it to its owner.

**Certificate Revocation List** An online list, maintained by a certificate authority, which contains the serial numbers of all invalid certificates issued by that certificate authority.

**Diffie–Hellman** A public key distribution algorithm that leverages the discrete logarithm problem that is used for key agreement between two parties that have not previously exchanged secret information.

**Digital Certificate** The binding of a public key with the owner's identification and other fields, such as validity dates, that is digitally signed by a certification authority and validated with a public key, which is usually located in a browser or operating system. It is used to help prove that key owners are who they say they are.

**Digital Signature** The application of a private key to a message (or more typically to the message digest of a message) via a cryptographic algorithm to yield a signed message so that a receiver can apply the corresponding public key to the signed message via a cryptographic algorithm to yield the original message or message digest. This verifies that the message could only have been originally signed by the sender, providing both source authentication and the even stronger notion of nonrepudiation.

**Discrete Logarithm Problem** Given  $b = g^x \pmod n$ , find  $x$ .

**ElGamal** A public key cryptosystem that leverages the discrete logarithm problem, like the Diffie–Hellman algorithm, but unlike Diffie–Hellman, can be used directly to encrypt a message. Another part of this algorithm provides digital signature function.

**Hash Algorithm** A function that take a long sequence of bits and maps them to another, fixed length and smaller, sequence of bits.

**Key Agreement** Two (or more) parties exchange some data that results in both parties deriving a common key, in a way in which an eavesdropper cannot do so (as in the Diffie–Hellman algorithm). This common key can subsequently be used with a conventional cryptographic algorithm for private communication.

**Key Transport** One party creates a key and securely sends it to the other party using a previously

established conventional key or using a public key algorithm like RSA.

**Knapsack** A public key cryptosystem that leverages the subset sum problem. This algorithm is now considered insecure.

**Miller–Rabin Algorithm** A nondeterministic algorithm that determines whether a number is prime with a degree of uncertainty.

**Nonrepudiation** Not allowing denial that an action was performed. An example is the use of a digital signature to allow a person to sign a message with a private key, which also means they cannot deny it was signed by them because only they know that private key.

**One-Way Function** A function that is easy to compute in one direction but hard to compute in the reverse direction.

**Public Key Cryptography** A cryptographic technique that uses both secret and corresponding public information that, depending on the specific algorithm, provides message privacy via encryption, nonrepudiation via digital signature, or key exchange to parties that have not previously exchanged secret information.

**Public Key Cryptosystem** A system that uses two related keys, a private key that must be kept secret and a public key that must be known to all message senders, that provide for encryption with the public key and decryption with the private key, providing message privacy.

**RSA** A public key cryptosystem that can also be used for digital signature that leverages the problem of factoring large numbers into their component prime numbers.

## INTRODUCTION

Elliptic curves were first introduced into cryptography by Miller (1986) and Koblitz (1987). In recent years they have gained widespread interest because of their shorter key size compared to systems such as RSA, their superior efficiency in certain situations, and the smaller bandwidth that they require. These advantages are becoming more compelling as time progresses because of the increased use of smaller and smaller mobile computing devices with associated bandwidth and computational constraints.

However, probably the main driving force behind interest in elliptic curve based cryptography (ECC) is that as time progresses one needs to increase ECC key sizes more slowly than one needs to increase RSA key sizes. This is because the best known attacks against ECC are exponential in nature, whereas we already know that integer factorization has subexponential solutions.

In this chapter we aim to introduce the basics of elliptic curve cryptography. However, the literature is vast and we can only really touch on most subjects; more details can be found in the large number of books on the subject, such as Blake, Seroussi, and Smart (1999), Blake, Seroussi, and Smart (2004), and Washington (2003). We start by introducing the group law, which is the tool that allows one to convert traditional schemes such as Diffie–Hellman key exchange and ElGamal encryption into the elliptic curve setting. We then progress to explaining implementation issues, such as how one selects parameters and implements algorithms to ensure that elliptic curve-based systems run as fast as possible. Following this, we then go on to discuss the elliptic curve discrete logarithm problem (EC-DLP) on which the security results are based. In this section we also discuss how one generates secure elliptic curves, a procedure that is analogous to generating “safe” prime numbers in the traditional ElGamal system. After these sections, which introduce the mathematical foundations, we then begin to touch the surface of the large number of cryptographic protocols, which can be implemented using elliptic curves, concentrating on those most widely deployed. Then we discuss issues related to secure

implementation on trusted tokens such as smart cards. Elliptic curves are particularly suited to smart cards, for the reasons mentioned above, but smart cards are vulnerable to so-called side-channel attacks and hence one needs to implement procedures that minimize leaked information.

Before ending this introduction it is worthwhile for the reader new to elliptic curves to understand that although their use in cryptography is relatively recent, they have in fact been studied in mathematics for many years. Indeed they form the testing ground for many conjectures and programs that aim to unify various areas of mathematics.

The chord-tangent process we discuss under Group Law was certainly known to Newton and Fermat. Indeed, the doubling algorithm is a special case of Fermat’s method of ascent. The link with ellipses, and hence the name elliptic curve, comes via a route in the applied mathematics of the 19th century. In solving certain differential equations, which arise naturally in nature, one is led to the use of so-called elliptic functions. Whereas the traditional circular functions of sin and cos are related to properties of a circle and are periodic, that is:

$$\sin(z) = \sin(z + 2\pi) = \sin(z + 4\pi) = \dots = \sin(z + n2\pi),$$

elliptic functions are related to the properties of ellipses and are doubly periodic, as complex functions, that is:

$$\Psi(z) = \Psi(z + n_1\omega_1 + n_2\omega_2), \quad \text{for } n_1, n_2 \in \mathbb{Z}.$$

Elliptic functions are considered the next class of functions after the elementary ones of sin, cos, sinh, and so on. In fact they are the result of the following integral:

$$\Psi(z) = \int_{-\infty}^z \frac{dx}{\sqrt{f(x)}},$$

where  $f(x)$  is a cubic function. In general, such integrals cannot be expressed in terms of the elementary functions, hence the need to introduce a new class, which are called

elliptic functions. An elliptic function is related to the function  $\sqrt{f(x)}$ , where  $f(x)$  is a cubic polynomial, that is, to the following curve:

$$y^2 = f(x),$$

which is why such curves are called elliptic curves. The addition law, described under Group Law, is equivalent to the composition law for elliptic integrals used by in the study of some differential equations.

The study of diophantine equations of the following form:

$$y^2 = \text{cubic over } \mathbb{Z}, \quad (1)$$

was started in earnest in the early 20th century. It was soon noticed that the group law made these curves a useful testing ground for problems and conjectures in number theory, in particular as elliptic curves essentially formed the most interesting class of one-dimensional number theoretic objects.

In 1929 Siegel (1966) showed that the set of integral solutions to Eq. (1) was finite. Siegel's proof was not algorithmic and it was not until 1970 that Baker and Coates (1970) provided a proof of this result that allowed one to find the solutions.

In 1922 Mordell (1922) showed that the set of rational solutions to Eq. (1) forms an abelian group of finite rank. Mordell's proof used a technique that meant it was not always possible to compute the rank of the group or the generators. In the late 1950s Birch and Swinnerton-Dyer (1963, 1965), in one of the first major machine computations in number theory, produced a conjecture that related the obstruction to Mordell's proof being algorithmic with the value of a certain function called an L-function. At about the same time Shimura, Taniyama (and later Weil) came up with a conjecture that related this L-function to an object in complex function theory called a modular form. As the 1960s progressed people found links between various areas of mathematics in this way, as they tried to prove the conjectures of Birch and Swinnerton-Dyer and Shimura-Taniyama-Weil. In 1986 Frey (1986) conjectured a link, made more precise by Serre and then proved by Ribet (1990), between Fermat's Last Theorem and elliptic curves that meant that if someone proved the Shimura-Taniyama-Weil conjecture then they could prove Fermat's Last Theorem. Finally in 1995 Wiles (1995) proved the conjecture of Shimura-Taniyama-Weil and so Fermat's Last Theorem was proved.

Elliptic curves have also been used in areas of computational number theory relevant to traditional factoring-based public key cryptography. In 1987 Lenstra (1987) generalized Pollard's (1974)  $p - 1$  factoring method to the elliptic curve setting in much the same way as Miller and Koblitz generalized ElGamal public key systems to the elliptic curve setting. The resulting factoring method of Lenstra, called the elliptic curve method (ECM), is the most successful factoring algorithm for 100 decimal digit numbers in the sense that it will factor efficiently more 100 digit numbers than any other algorithm. However, it is particularly unsuited to the factoring of RSA style numbers that are the product of two primes of roughly

the same size. Despite this drawback ECM is often used as a subprocedure in processing the output of the sieving stage in algorithms to factor RSA style numbers.

Elliptic curves also play a crucial role in the primality testing method of Goldwasser and Kilian (1986). This technique, usually called the elliptic curve primality proving method (ECPP), produces a very short primality certificate. Although it is not a deterministic primality testing algorithm, such as the recent breakthrough of Agrawal, Kayal, and Saxena (2003), the fact that it produces a simple certificate makes it a very useful procedure when you want to guarantee that you are using prime numbers.

As one can see, elliptic curves have had a great influence on mathematics and have been studied for many years. Many of the techniques developed for purely intellectual curiosity have been applied in practical situations in cryptography. Indeed, we shall see the names of Frey, Pollard, and Weil coming up later when we discuss the EC-DLP.

## GROUP LAW

For cryptographic purposes we are interested only in elliptic curves defined over finite fields. We first need to select a finite field  $K$ ; in practice this is usually either a field of characteristic two  $K = \mathbb{F}_{2^p}$  or a field of large prime characteristic  $K = \mathbb{F}_p$ . The size of  $2^p$  or  $p$  is closely related to the size of the final ECC key, as we shall see later, and so one should ensure that the size of the finite field is at least 160 bits long.

An elliptic curve over  $K$  is then defined as a nonsingular cubic curve over the field  $K$ . Various simplifications can be applied, which boil down to the fact that a curve can be written either as

$$E : Y^2 = X^3 + aX + b, \quad \text{in large prime characteristic}$$

or as

$$E : Y^2 + XY = X^3 + aX^2 + b, \quad \text{in characteristic two.}$$

The set of points on the curve  $E(K)$  is then defined to be the set of all pairs  $(x, y) \in K \times K$  that satisfy the equation, plus a special point  $\mathcal{O}$  called the point at infinity. The point  $\mathcal{O}$  is considered to lie infinitely far up the  $y$ -axis.

By a theorem of Hasse it is known that

$$\#K + 1 - 2\sqrt{\#K} \leq \#E(K) \leq \#K + 1 + 2\sqrt{\#K}.$$

Hence, the number of points on the curve is very closely related to the size of the underlying finite field.

The set  $E(K)$  is in fact a finite abelian group, that is, we can add points to each other to form other points in such a way that the resulting addition law is associative, commutative, has an identity (the point at infinity  $\mathcal{O}$ ), and for which every point has an additive inverse. Given such a finite abelian group we can then transfer traditional discrete logarithm based cryptographic protocols to the elliptic curve setting.

There are two equivalent ways to define the group law on an elliptic curve. The first is a geometric way, which, although intuitively easy, is hard to use in practice and

makes more immediate sense for curves defined over the real numbers. This geometric definition can be made to be rigorous for finite fields, one just needs to be careful as to how one defines tangent, and so on. The second approach to defining the group law is to use formulae. These equations are very easy to use in practice, yet do not convey much intuition. We therefore opt to give both definitions.

### Geometric Definition of the Group Law

We assume for this section that the curve is given by an equation of the following form:

$$Y^2 = \text{cubic in } X.$$

However, a similar geometric definition works in other cases, one just needs to change the process of “reflecting in the  $X$ -axis” mentioned below.

Let  $P$  and  $Q$  be two distinct points on  $E$ , both defined over  $K$ . The straight line joining  $P$  and  $Q$ , called a chord, must intersect the curve at one further point, say  $R$ , because we are intersecting a straight line with a curve of degree three. The point  $R$  will also be defined over  $K$  because the line, the curve, and the points  $P$  and  $Q$  are themselves all defined over  $K$ . If we then reflect  $R$  in the  $X$ -axis we obtain another rational point which we shall call  $P + Q$  (see Figure 1 for a visualization over the real numbers).

Note, if one point  $Q$  is the point at infinity then the curve joining  $\mathcal{O}$  with  $P$  intersects the curve at a point with the same  $x$  coordinate as  $P$ , but which has  $y$  coordinate equal to minus the  $y$  coordinate of  $P$ . If we then reflect this point in the  $x$  axis we return to the point  $P$ . Hence,

$$P + \mathcal{O} = \mathcal{O} + P = P.$$

In a similar way one can see that we have the following:

$$(x, y) + (x, -y) = \mathcal{O}$$

and so if  $P = (x, y)$  then  $-P = (x, -y)$ .

The above definition is symmetric in the starting points  $P$  and  $Q$ , hence the resulting operation obviously satisfies

Figure 1: Adding two points on an elliptic curve.

the following:

$$P + Q = Q + P$$

and so the operation is commutative. Showing the above addition law is also associative in that for all  $P, Q$ , and  $R$  we have the following:

$$(P + Q) + R = (P + Q) + R,$$

is a little more involved, see Cassels (1991).

To add  $P$  to itself, usually called doubling  $P$ , we take the tangent to the curve at  $P$ . Such a line must intersect the cubic curve in exactly one other point, which we denote by  $R$ . Again we reflect the point  $R$  in the  $x$ - axis to obtain a point that we call  $[2]P = P + P$  (see Figure 2).

Note, that if the tangent to the point is vertical, it “intersects” the curve at the point at infinity and  $P + P = \mathcal{O}$  (i.e.,  $P$  is a point of order 2).

### Algebraic Formulation of the Group Law

We now present the group law by formulae on points. Using a little algebra one can show that the following formulae are what one would obtain from applying the geometric definitions above. We divide into two cases, that of large prime characteristic and that of characteristic two. Although other cases are possible, we limit ourselves to these two because they are the cases of most interest to cryptographers.

$$K = \mathbb{F}_p$$

The formulae for the group law in characteristic  $p > 3$ , where the curve is of the form

$$Y^2 = X^3 + aX + b$$

are given by, for  $P_i = (x_i, y_i)$ ,  $-P_1 = (x_1, -y_1)$ . If

$$P_3 = (x_3, y_3) = P_1 + P_2 \neq \mathcal{O},$$

Figure 2: Doubling a point on an elliptic curve.

then  $x_3$  and  $y_3$  are given by the formulae

$$\begin{aligned} x_3 &= \lambda^2 - x_1 - x_2, \\ y_3 &= (x_1 - x_3)\lambda - y_1. \end{aligned}$$

where if  $x_1 \neq x_2$  we set

$$\lambda = \frac{y_2 - y_1}{x_2 - x_1},$$

and when  $x_1 = x_2, y_1 \neq 0$  we set

$$\lambda = \frac{3x_1^2 + a}{2y_1}.$$

Two points sum to  $\mathcal{O}$  if  $x_1 = x_2$  and  $y_1 = -y_2$ , hence as a special case we have, if  $(x, 0) \in E(K)$  that  $2(x, 0) = \mathcal{O}$ .

$K = \mathbb{F}_{2^n}$

The formulae for the group law in characteristic two, with a curve of the form,

$$Y^2 + XY = X^3 + a_2X^2 + a_6$$

are given by, for  $P_i = (x_i, y_i), -P_1 = (x_1, y_1 + x_1)$ . If

$$P_3 = (x_3, y_3) = P_1 + P_2 \neq \mathcal{O},$$

then  $x_3$  and  $y_3$  are given by the formulae

$$\begin{aligned} x_3 &= \lambda^2 + \lambda + a_2 + x_1 + x_2, \\ y_3 &= (\lambda + 1)x_3 + \mu \\ &= (x_1 + x_3)\lambda + x_3 + y_1, \end{aligned}$$

where if  $x_1 \neq x_2$  we set

$$\lambda = \frac{y_2 + y_1}{x_2 + x_1}, \quad \mu = \frac{y_1x_2 + y_2x_1}{x_2 + x_1}$$

and when  $x_1 = x_2 \neq 0$  we set

$$\lambda = \frac{x_1^2 + y_1}{x_1}, \quad \mu = x_1^2.$$

Two points sum to  $\mathcal{O}$  if  $x_1 = x_2$  and  $y_2 = y_1 + x_1$ , hence as a special case if  $(0, y) \in E(K)$  then  $2(0, y) = \mathcal{O}$ .

### Projective Coordinates

For positive integers  $k$  we write

$$[k]P = \underbrace{P + P + \dots + P}_{k \text{ times}}.$$

This is extended to all integers  $k \in \mathbb{Z}$  using the inverse  $-P$  of a point. A lot of division operations in the field  $K$  are required if  $[k]P$  is computed using the standard coordinate system above, where one uses two field elements to represent a point. However, division is a very expensive operation that leads one to introduce a different coordinate system where one can implement the addition formulae above but without the need for expensive divisions. In

this section we introduce such a system, called projective coordinates, but for the sake of space we focus only on large prime characteristic  $p$ . However, a similar situation occurs in characteristic two.

To get some feeling for the operations in affine coordinates, so one can see the advantage of projective coordinates later, we now examine the operations defined above. In large prime characteristic, we can see that when  $P_1 \neq P_2$ , then the computation of  $P_1 + P_2$  requires one inversion and three multiplications in  $K$ ; we ignore additions in  $K$  because they are relatively cheap. We denote this computational cost by  $1I + 3M$ , where  $I$  and  $M$  denote, respectively, the cost of field inversion and multiplication. When  $P_1 = P_2$ , the cost of the point doubling operation can be seen to be  $1I + 4M$ .

The standard projective coordinates used in cryptography, often called Jacobian or weighted projective coordinates, represent an affine point  $(x, y)$  by a triple  $(X, Y, Z)$  on the following curve:

$$Y^2 = X^3 + aXZ^4 + bZ^6.$$

To map between the two coordinate systems we use the following:

$$(X, Y, Z) \longleftrightarrow (X/Z^2, Y/Z^3).$$

Notice, that many projective points correspond to a single affine point, a fact which is useful in some side-channel defences we mention later. The point at infinity  $\mathcal{O}$  is represented by the triple  $(1, 1, 0)$ .

The following sequence of operations computes the sum  $P_3 = (X_3, Y_3, Z_3)$  of two points  $P_1 = (X_1, Y_1, Z_1)$  and  $P_2 = (X_2, Y_2, Z_2)$  in projective coordinates, assuming  $P_1, P_2 \neq \mathcal{O}$  and  $P_1 \neq \pm P_2$ :

$$\begin{aligned} \lambda_1 &= X_1Z_2^2, & \lambda_2 &= X_2Z_1^2, & \lambda_3 &= \lambda_1 - \lambda_2, \\ \lambda_4 &= Y_1Z_2^3, & \lambda_5 &= Y_2Z_1^3, & \lambda_6 &= \lambda_4 - \lambda_5, \\ \lambda_7 &= \lambda_1 + \lambda_2, & \lambda_8 &= \lambda_4 + \lambda_5, & Z_3 &= Z_1Z_2\lambda_3, \\ X_3 &= \lambda_6^2 - \lambda_7\lambda_3^2, & \lambda_9 &= \lambda_7\lambda_3^2 - 2X_3, & Y_3 &= (\lambda_9\lambda_6 - \lambda_8\lambda_3^3)/2. \end{aligned}$$

Assuming division by 2 is performed by multiplication of a precomputed constant and multiplication by 2 is for free, one can then see that the cost of a point addition is given by  $16M$ , which will be faster than using affine coordinates when

$$16M < 1I + 3M$$

(i.e. when an inversion is slower than 13 multiplications). An important case is when one point, say  $P_1$ , is given in affine coordinates and the other one in projective coordinates (i.e. we have  $Z_1 = 1$ ). This requires only 11 multiplications and so this ‘‘mixed’’ addition will be faster than a purely affine addition when a single inversion is slower than 8 multiplications.

We still need to consider point doubling in projective coordinates, that will turn out to be the operation that dominates the execution of cryptographic applications.

The formulae for doubling are given by the following:

$$\lambda_1 = 3X_1^2 + aZ_1^4, \quad Z_3 = 2Y_1Z_1, \quad \lambda_2 = 4X_1Y_1^2, \\ X_3 = \lambda_1^2 - 2\lambda_2, \quad \lambda_3 = 8Y_1^4, \quad Y_3 = \lambda_1(\lambda_2 - X_3) - \lambda_3.$$

This has a cost of  $10M$ , which reduces to  $8M$  when one selects curves such that  $a = -3$  as one often does. Hence, with this optimization the cost of a projective doubling is faster than an affine one when

$$8M < 1I + 4M$$

(i.e. when an inversion is slower than four multiplications). Note, for almost all implementations of large prime characteristic fields a field inversion will always take longer than four field multiplications.

### Point Multiplication

As already mentioned the operation on which elliptic curve cryptography is built is the operation that takes an integer  $k$  and a point  $P$  and computes the point multiple as follows:

$$Q = [k]P = P + P + \dots + P.$$

This is, for suitably chosen curves, a function that is believed to be hard to invert. The value  $k$  is called the (elliptic curve) discrete logarithm of  $Q$  with respect to the base  $P$ .

Point multiplication in elliptic curves is a special case of the general problem of exponentiation in an abelian group. Hence, all of the prior work on such algorithms for use in traditional discrete logarithm based cryptosystems can be applied in the elliptic curve setting. However, one has some advantages that can be exploited in the elliptic curve situation. For example, elliptic curve subtraction comes for essentially the same cost as addition, so we can use signed representations for the multiplier  $k$ .

### The Binary Method

The simplest algorithm for point multiplication is the binary method, which relies on the binary representation of the number  $k$ . This comes in two variants; the right-to-left variant processes the bits of  $k$  from the least significant bit to the most significant bit, the left-to-right variant processes the bits in the reverse order. To understand both variants consider the multiplier  $k$  given by the following:

$$k = \sum_{j=0}^{\ell-1} k_j 2^j \quad k_j \in \{0, 1\},$$

where  $\ell$  is the bit-length of  $k$ .

The right-to-left variant works as follows:

```

T ← P.
Q ← O.
For j = 0 to ℓ - 1 do.
    If kj = 1 then Q ← Q + T.
    T ← [2]T.
Return Q.
```

The left-to-right variant works in the following manner:

```

Q ← O.
For j = ℓ - 1 to 0 by -1 do.
    Q ← [2]Q.
    If kj = 1 then Q ← Q + P.
Return Q.
```

Both methods are often referred to as the double-and-add algorithm, because the inner workings of each loop consist of always doubling a point and a conditional addition. One should notice that the left-to-right variant does not use a temporary variable  $T$ , which is often useful in practical situations where memory is constrained. Also, because one only performs addition of the point  $P$ , in the step  $Q \leftarrow Q + P$ , one can perform a “mixed” addition by keeping  $Q$  in projective coordinates and  $P$  in affine coordinates. The left-to-right variant is also of theoretical importance because it is this variant which is generalized to the more efficient algorithms we shall see below.

Whichever variant one uses, the binary method always performs  $\ell - 1$  point doublings and on average  $\ell/2 - 1$  point additions. If we let  $D_A$ , resp.  $D_P$ , denote the number of affine, resp. projective, doublings performed and  $A_A$ , resp.  $A_M$ , denote the number of affine, resp. mixed, point additions performed, then the left-to-right binary method requires on average

$$\ell(A_M/2 + D_P)$$

operations.

### The $m$ -ary Method

The obvious generalization of the binary method is, instead of processing one bit of  $k$  at a time, to process  $r$  bits at a time. This results in the  $m$ -ary method, where  $m = 2^r$ , for some integer  $r \geq 1$ . In practice one would usually take  $r = 4$  or  $5$ . We first write  $k$  in its  $m$ -expansion as follows:

$$k = \sum_{j=0}^{d-1} k_j m^j, \quad \text{with } k_j \in \{0, 1, \dots, m-1\}$$

and we then precompute the multiples as follows:

$$P_i = [i]P \quad \text{for } i = 0, \dots, m-1.$$

So as to take advantage of mixed addition below, one often computes the  $P_i$  in affine form. The  $m$ -ary point multiplication algorithm is then given by the following:

```

Q ← O.
For j = d - 1 to 0 by -1 do.
    Q ← [m]Q. (This requires r doublings.)
    Q ← Q + Pkj.
Return Q.
```

It can be readily verified that the algorithm computes  $[k]P$ , following Horner’s rule:

$$[k]P = [m](\dots [m]([m]([k_{\ell-1}]P) + [k_{\ell-2}]P) + \dots) + [k_0]P$$

Assuming projective coordinates are used for  $Q$  and affine coordinates for the  $P_i$  then:

- The number of projective doublings in the main loop of the  $m$ -ary method is  $(d - 1)r$ .
- The number of mixed additions in the main loop is  $d - 1$ .
- The preprocessing requires  $m - 2 \approx 2^r$  affine additions.

However, for an  $\ell$ -bit number  $k$ , we have  $d \approx \ell/r$ , which means that the  $m$ -ary method requires approximately

$$2^r A_A + \ell(A_M/r + D_P)$$

operations. Hence, for the cost of a little preprocessing and some extra storage we have reduced the number of mixed additions that are needed to be performed when compared to the binary methods.

### Window Methods

The  $m$ -ary method above can be regarded as a special case of a *window* method, where bits of the multiplier  $k$  are processed in blocks (windows) of length  $r$ . We can, however, improve things by using a variable length window and assuming each processed window starts with a set bit in the right most location. We think of this as the left hand edge of each window is allowed to slide leftwards, until it meets a set bit, thus giving the method its name. We first encode our multiplier as follows:

$$k = \sum_{i=0}^{d-1} k_i 2^{e_i},$$

where  $e_i - e_{i-1} \geq r$  and

$$k_j \in \{1, 3, 5, \dots, 2^r - 1\}.$$

We then precompute

$$P_i = [i]P \quad \text{for } i \in \{1, 3, 5, \dots, 2^r - 1\}.$$

The value  $[k]P$  if computed via the algorithm

$$\begin{aligned} Q &\leftarrow P_{k_{d-1}}. \\ \text{For } i = d-2 \text{ to } 0 \text{ by } -1 \text{ do.} \\ & \quad Q \leftarrow [2^{e_{i+1}-e_i}]Q. \\ & \quad Q \leftarrow Q + P_{k_i}. \\ & \quad Q \leftarrow [2^{e_0}]Q. \\ \text{Return } Q. \end{aligned}$$

The analysis of this method is quite involved but essentially boils down to the fact that  $d \approx \ell/(r + 1)$ . Hence, again assuming projective values of  $Q$  and affine values for the stored  $P_i$ :

- The number of projective doublings is around  $\ell$
- The number of mixed additions in the main loop is  $\ell/(r + 1)$ .
- The preprocessing requires  $2^{r-1}$  affine additions.

In total we therefore need about

$$2^{r-1} A_A + \ell(A_M/(r + 1) + D_P)$$

operations. We therefore not only reduce the number of mixed additions, we also reduce the preprocessing and the amount of required storage.

### Signed Digit Representations

We mentioned earlier that point subtraction has virtually the same cost as point addition on an elliptic curve group. This means we could make use of representations of the multiplier  $k$  that use negative, as well as positive, values of the window values  $k_i$ . First consider representing  $k$  in the following form:

$$k = \sum_{j=0}^{d-1} s_j 2^j \quad \text{where } s_j \in \{-1, 0, 1\}.$$

Such a representation is called a (binary) *signed digit* representation. Clearly, such a representation includes the standard binary representation, and the signed digit representation is not unique, as we can see from the example of representing the integer 3,

$$3 = 1 + 2 = -1 + 4 = 1 - 2 + 4 = \dots$$

One can, however, always select a signed digit representation which is particularly sparse, in that it has no adjacent nonzero digits (i.e.  $s_j s_{j+1} = 0$  for all  $j \geq 0$ ). Such a representation is called a *nonadjacent form* (NAF).

Given a NAF for  $k$  one can then compute a point multiplication, in a left-to-right form, via the following:

$$\begin{aligned} Q &\leftarrow \mathcal{O}. \\ \text{For } j = d - 1 \text{ to } 0 \text{ by } -1 \text{ do.} \\ & \quad Q \leftarrow [2]Q. \\ & \quad \text{If } s_j = 1 \text{ then } Q \leftarrow Q + P. \\ & \quad \text{If } s_j = -1 \text{ then } Q \leftarrow Q - P. \\ \text{Return } Q. \end{aligned}$$

A NAF usually has fewer nonzero digits than a binary representation, indeed the expected weight is around  $\ell/3$ . We therefore require, again assuming a projective representation for  $Q$  and an affine representation for  $P$ , around

$$\ell(A_M/3 + D_P)$$

operations, which is not as efficient as our  $m$ -ary method for windows of size  $r = 3$  or our sliding window method for  $r = 2$ . However, one can achieve this improvement without the need for preprocessing and storage inherent in the window based methods.

### A Signed $m$ -ary Sliding Window Method

We can, however, combine the sliding window method with the signed digit method to obtain a new method which is often the method of choice for general elliptic curve point multiplications. We assume that the windows we will choose will be of length at least  $r$ , and we define

$$B = \{-2^{r-1} + 1, \dots, -1, 0, 1, \dots, 2^{r-1} - 1\}.$$

We then write the multiplier  $k$  as follows:

$$k = \sum_{i=0}^{d-1} k_i 2^{e_i} \quad \text{with } k_i \in B \setminus \{0\} \text{ and } e_i \in \mathbb{Z}_{\geq 0},$$

where  $e_{i+1} - e_i \geq r$  for all  $0 \leq i \leq d-2$ . We do not explain how such a representation is computed, but see Blake et al. (1991) for details.

Once we have produced such a representation for  $k$  the algorithm is similar to those seen before. We need to precompute as follows:

$$P_i = [i]P \quad \text{for } i \in B \cap \mathbb{Z}_{\geq 0}.$$

Hence, we compute and store  $2^{r-2}$  points, which is less than that needed for the unsigned sliding window method for the same sized windows. We then compute  $[k]P$  via the following algorithm:

```

Q ← P_{k_{d-1}}.
For i = d-2 to 0 by -1 do.
  Q ← [2^{e_{i+1}-e_i}]Q.
  If k_i > 0 then Q ← Q + P_{k_i}.
  Else Q ← Q - P_{-k_i}.
Q ← [2^{e_0}]Q.
Return Q.

```

The expected number of operations performed by this method is, given our standard assumptions,

$$2^{r-2}A_A + \ell(A_M/(r+1) + D_P).$$

Hence, the improvement comes mostly in the precomputation and storage.

The exact choice of which algorithm to use such as  $m$ -ary, signed window method, NAF or signed sliding windows depends on various machine dependent parameters such as available memory, the relative costs of projective, mixed and affine point additions, and so on. The literature contains a number of other variants for use in elliptic curve systems that we do not have space to cover, but the above algorithms are the main ones and should form a starting point for the reader's own investigations.

### Special Methods

The above methods are useful when one is presented with a general point  $P$  and one is asked to compute  $Q = [k]P$ . However, in many of the protocols we shall see later one needs to compute either  $Q = [k]P$  for a fixed value of  $P$  over a number of runs of a protocol or  $Q = [k_1]P_1 + [k_2]P_2$ , a so-called multiple-exponentiation.

We present here algorithms for these special situations but giving only the most basic variants. A close examination of the research literature will reveal a large number of possible variants and improvements.

We start by considering the case of the multiplication  $Q = [k]P$ , where  $P$  is fixed over a number of runs of a protocol, a so-called fixed base method. In this situation one could do some precomputation using  $P$ , which could be too expensive if only one multiplication was to be performed but which is cheap if one considers a number are to be done.

We assume a window size of  $r$  bits and precompute as follows:

$$P_i = [2^{ri}]P$$

for  $i = 0, \dots, d = \lceil \ell/r \rceil$ . If this is done in affine coordinates then this requires  $\ell D_A$  operations. Then on receiving a multiplier  $k$  one encodes it in base  $2^r$  as follows:

$$k = \sum_{i=0}^{d-1} k_i 2^{ri},$$

with  $k_i \in \{0, \dots, 2^r - 1\}$ . With this encoding one can perform the following algorithm:

```

Q ← O.
T ← O.
For j = 2^r - 1 to 0 by -1 do.
  For i = 0 to d - 1 do.
    If k_i = j then T ← T + P_i.
  Q ← Q + T.
Return Q.

```

For each value of  $k$  this requires

$$(2^r + \ell/r)A_M$$

operations. Hence, if we are performing  $s$  such point multiplications of the same point  $P$  then the above algorithm requires

$$\ell D_A + s(2^r + \ell/r)A_M$$

as opposed to

$$2^{r-2}A_A + s\ell(A_M/(r+1) + D_P)$$

for  $s$  applications of the signed sliding-window method.

We now turn to so called multiexponentiation, which really should be multimultiplication in the elliptic curve setting. The most elementary form of this is as follows, often called Shamir's trick, but actually because of Strauss. Suppose we wish to compute the following:

$$Q = [k_1]P_1 + [k_2]P_2.$$

We precompute

$$\begin{aligned} P_0 &= O, \\ P_1 &= [0]P_2 + [1]P_1 = P_1, \\ P_2 &= [1]P_2 + [0]P_1 = P_2, \\ P_3 &= [1]P_2 + [1]P_1 = P_1 + P_2. \end{aligned}$$

Then, given the two multipliers  $k_1$  and  $k_2$ , we write the binary representation of  $k_1$  and  $k_2$  in a  $2 \times \ell$  matrix, with the least significant bits in the rightmost column. We let  $C_i$  denote the integer value obtained by taking the integer given by the binary representation in the  $i$ -th column of

the matrix, where the top row is the least significant bit of  $C_i$ , and compute  $Q$  via the following:

```

 $Q \leftarrow \mathcal{O}.$ 
For  $i = 1$  to  $\ell$  do.
     $Q \leftarrow [2]Q.$ 
     $Q \leftarrow Q + P_{C_i}.$ 
Return  $Q.$ 
    
```

This requires  $\ell$  projective doublings and  $\ell$  mixed additions (i.e.,  $2\ell$  curve operations) and should be compared to the  $\approx 3\ell$  curve operations needed on average to perform two binary multiplications followed by a projective addition. Even if using the signed sliding window method, one would require roughly

$$2\ell(A_M/(r + 1) + D_P)$$

operations. Hence, even this naive method of multimultiplication is faster than the two signed sliding-window multiplications when

$$D_P > r A_M/(r + 1).$$

As we mentioned before, a typical cost is  $D_P \approx 8M$  and  $A_M \approx 11M$ . Hence, if one took window widths of  $r = 3$  in the signed sliding window method then the multimultiplication method would be faster. The exact choice of method depends on various implementation details, such as the ratio  $I/M$  and the available memory.

### Special Curves

There is a certain family of curves, which occurs quite frequently in elliptic curve cryptography, called the *Koblitz curves*. Originally this term was used for curves defined over a subfield  $k$  of  $K$ , where we consider the group of points over the larger field for cryptographic purposes. The reason for considering these curves was that they possess an endomorphism structure that allows an efficient implementation of the point multiplication algorithms.

Nowadays, especially in standards such as SEC (2000a, 2000b), the name *Koblitz curve* is used for any elliptic curve that possesses a special endomorphism structure that enables improvements to be made to the multiplication algorithms above.

There are two common classes of Koblitz curves:

1. The classical case of curves over  $\mathbb{F}_2$  (sometimes called anomalous binary curves or ABC curves), which are given by the following:

$$Y^2 + XY = X^3 + aX^2 + 1,$$

where  $a \in \{0, 1\}$ . These curves are defined over  $\mathbb{F}_2$  but we work in the group of points defined over the field  $\mathbb{F}_{2^n}$ .

2. The more recent case of Koblitz curves over a large prime field which have a suitable endomorphism.

We do not discuss these curves further in this article, but the interested reader is referred to the extensive literature on such curves.

## THE ELLIPTIC CURVE DISCRETE LOGARITHM PROBLEM

The elliptic curve discrete logarithm problem (or EC-DLP) is the problem of reversing the point multiplication algorithm performed in the last section, that is, given  $P, Q \in E(K)$  find the value of  $\lambda$ , if it exists, such that

$$Q = [\lambda]P.$$

For suitably chosen fields, curves and points this problem is believed to be computationally infeasible to solve. In the following we shall summarize the results in this area.

However, we should note that many elliptic curve based cryptographic protocols actually rely on weaker problems for their security, such as the elliptic curve Diffie–Hellman problem (EC-DHP) or the elliptic curve Decision Diffie–Hellman problem (EC-DDH).

The elliptic curve Diffie–Hellman problem is the problem of given  $P, Q, R$  such that

$$Q = [x]P \quad \text{and} \quad R = [y]P$$

to find the value  $S$  such that

$$S = [xy]P.$$

Clearly the EC-DHP is no harder a problem than than the EC-DLP because we can solve EC-DHP given an oracle to solve EC-DLP.

Given  $P, Q, R$ , and  $S$  such that

$$Q = [x]P, R = [y]P \quad \text{and} \quad S = [z]P,$$

the elliptic curve Decision Diffie–Hellman problem is the problem of determining whether  $z = x \times y \pmod{l}$ , where  $l$  is the order of the point  $P$ . Clearly, an oracle to solve EC-DHP can be used to solve EC-DDH, hence EC-DDH is the (potentially) easier problem.

In most cases it is believed that all three problems are very hard to solve, for suitably chosen parameters. However, we shall see later that there is one special class of curves for which there is a polynomial time algorithm to solve EC-DDH but only a subexponential algorithm to solve EC-DHP or EC-DLP.

### Known Generic Attacks

We start by considering generic attacks against the EC-DLP. The name *generic* refers to the fact that such attacks will apply in any finite abelian group and not just an elliptic curve group. What makes elliptic curves particularly attractive is that for well-chosen parameter sets the generic attacks are the best one can currently perform. In the following cases we assume we have a discrete logarithm problem given by the following:

$$Q = [\lambda]P,$$

where  $P$  and  $Q$  are given and the goal is to find  $\lambda$ .

**Exhaustive Search**

This is the most elementary attack. One simply performs the following algorithm

```

 $R \leftarrow \mathcal{O}$ .
For  $\mu = 0$  to  $l - 1$  do.
  If  $R = Q$  then output  $\mu$  and stop.
   $R \leftarrow R + P$ .
Output "No Solution".

```

This algorithm requires  $O(1)$  storage, but requires  $O(\#E(K))$  time in both the worst and average case.

**Pohlig–Hellman**

The discrete logarithm problem in a group  $G$  [for instance,  $G = E(K)$ ] is only as hard as the discrete logarithm problem in the largest subgroup of prime order in  $G$ . This observation is because of Pohlig and Hellman (1978), and their method works in an arbitrary finite abelian group.

To explain the Pohlig–Hellman algorithm, suppose we have a finite cyclic abelian group  $G$  whose order is given by the following:

$$N = \#G = \prod_{i=1}^t p_i^{e_i}.$$

The case of noncyclic groups may be handled analogously. We assume that the number  $N$  can be factored (this assumption is valid for the EC-DLP because group orders for elliptic curve cryptography are rather small compared to current factoring records).

Now suppose we are given two points  $P, Q \in G$  such that there exists an integer  $\lambda$  such that

$$Q = [\lambda]P.$$

Our aim is to find  $\lambda$  by first finding it modulo  $p_i^{e_i}$  and then using the Chinese remainder theorem to recover it modulo  $N$ .

We can map the discrete logarithm in  $G$  to a discrete logarithm in a cyclic subgroup of prime power order  $C_{p^e}$  using the following map:

$$\phi_p : \begin{cases} G & \rightarrow & C_{p^e} \\ R & \mapsto & [N/p^e]R \end{cases}$$

The map  $\phi_p$  is a group homomorphism so if we have  $Q = [\lambda]P$  in  $\langle P \rangle$  then we will have  $\phi_p(Q) = [\lambda]\phi_p(P)$  in  $C_{p^e}$ . But the discrete logarithm in  $C_{p^e}$  would only be determined modulo  $p^e$ . This gives the following algorithm:

```

Write  $N = \#G = \prod_{i=1}^t p_i^{e_i}$ .
For  $i = 1$  to  $t$  do.
   $Q_p \leftarrow [N/p_i^{e_i}]Q$ .
   $P_p \leftarrow [N/p_i^{e_i}]P$ .
  Find  $\lambda_i \in \mathbb{Z}/p_i^{e_i}\mathbb{Z}$  such that  $Q_p = [\lambda_i]P_p$ .
Using the Chinese remainder theorem find  $\lambda$ 
such that  $\lambda = \lambda_i \pmod{p_i^{e_i}}$ .

```

The only problem is that we have not shown how to perform the step of solving the EC-DLP in a subgroup of

prime power order. We reduce this to the problem of solving EC-DLPs in subgroups of prime order as follows.

Suppose  $P$  and  $Q$  are of prime power order  $p^e$  such that

$$Q = [\lambda]P.$$

Clearly  $\lambda$  is defined only modulo  $p^e$  and we can write

$$\lambda = \lambda_0 + \lambda_1 p + \cdots + \lambda_{e-1} p^{e-1}.$$

We find  $\lambda_0, \lambda_1, \dots$  in turn, using the following procedure.

```

 $\lambda' \leftarrow 0$ .
For  $t = 0$  to  $e - 1$  do.
   $Q' \leftarrow Q - [\lambda']P$ .
   $P' \leftarrow [p^t]P$ .
   $Q'' \leftarrow [p^{e-t-1}]Q'$ .
   $P'' \leftarrow [p^{e-t-1}]P'$ .
  Find  $\lambda_t \in \mathbb{Z}/p\mathbb{Z}$  such that  $Q'' = [\lambda_t]P''$ .
   $\lambda' \leftarrow \lambda' + p^t \lambda_t$ .
Output  $\lambda'$ .

```

Note in the above algorithm that at the start of each loop we have, for some integer  $\lambda''$ ,

$$\lambda = \lambda' + p^t \lambda''.$$

The points  $P'$  and  $Q'$  are defined to be of order  $p^{e-t}$  such that

$$Q' = [\lambda'']P'.$$

Hence,  $P''$  and  $Q''$  are of order  $p$  and are related by the following:

$$Q'' = [\lambda_t]P''.$$

All the steps in the above two subprocedures of the Pohlig–Hellman algorithm are very simple. The main difficulty therefore is in solving the EC-DLP in the cyclic subgroups of prime order. It therefore follows that the difficulty of the EC-DLP depends on the largest prime factor of the order of the group, say  $l$ . For efficiency we prefer that the subgroup of order  $l$  contains a large proportion of all the points on the curve. Hence, it is common to take an elliptic curve  $E$  over a finite field  $K$  such that

$$\#E(K) = N = h \times l,$$

where  $l$  is a large prime and  $h$  is very small, typically  $h = 1, 2$ , or  $4$ . We shall now assume that elliptic curves have been chosen to satisfy this constraint.

**Baby-Step/Giant-Step**

In our above discussion of the Pohlig–Hellman algorithm we assumed we had an algorithm to solve the discrete logarithm problem in cyclic groups of prime order. We shall now describe a general method of solving such problems that is more efficient than exhaustive search. This method

is because of Shanks and is called the baby-step/giant-step method. Once again this is a generic method that applies to any cyclic finite abelian group.

Again we fix notation as follows. We have a public cyclic subgroup  $G = \langle P \rangle$  of some elliptic curve group  $E(K)$ , which we can now assume to have prime order  $l$ . We are also given a point  $Q \in G$  and are asked to find the value of  $\lambda$  modulo  $l$  such that

$$Q = [\lambda]P.$$

We assume there is some fixed encoding of the elements of  $G$ , so in particular it is easy to store, sort, and search a list of elements of  $G$ .

The principle behind the baby-step/giant-step method is a standard divide and conquer approach found in many areas of computer science. We first write the following:

$$\lambda = \lambda_0 + \lambda_1 \lceil \sqrt{l} \rceil.$$

Because  $\lambda \leq l$  we have that  $0 \leq \lambda_0, \lambda_1 < \lceil \sqrt{l} \rceil$ . The goal is then to find  $\lambda_0$  and  $\lambda_1$ .

In the first stage of the baby-step/giant-step method we compute the baby steps as follows:

$$P_0 \leftarrow \mathcal{O}.$$

For  $i = 0$  to  $\lceil \sqrt{l} \rceil$  do.

Store  $(P_i, i)$  in a hash table  $T$  indexed by the first entry in the pair.

$$P_{i+1} \leftarrow P_i + P.$$

Output  $T$ .

To compute and store the baby-steps clearly requires  $O(\lceil \sqrt{l} \rceil)$  time, and a similar amount of storage. We now perform the second stage involving the giant-steps:

$$P' \leftarrow \lceil \lceil \sqrt{l} \rceil \rceil P.$$

$$j \leftarrow 0.$$

$$Q' \leftarrow Q.$$

While  $(Q', i) \notin T$  for some  $i$  do.

$$j \leftarrow j + 1.$$

$$Q' \leftarrow Q' - P'.$$

$$\text{Output } i + j \lceil \sqrt{l} \rceil.$$

When this second stage terminates, which is guaranteed to happen after at most  $\lceil \sqrt{l} \rceil$  steps, it outputs the discrete logarithm of  $Q$  with respect to  $P$ . To see this notice that on termination of the while loop we have  $Q' = Q - [j]P'$  and there is a  $(P_i, i) \in T$  such that  $P_i = Q'$ . When such a match occurs we have the following:

$$[i]P = Q - [j \lceil \sqrt{l} \rceil]P,$$

and so  $\lambda_0 = i$  and  $\lambda_1 = j$ , that is,

$$[i + j \lceil \sqrt{l} \rceil]P = Q.$$

Notice that the time to compute the giant-steps is at most  $O(\sqrt{l})$ . Hence, the overall time and space complexity of

the baby-step/giant-step method is  $O(\sqrt{l})$ . This complexity is for both the worst and average cases of running the algorithm.

It is known, see Shoup (1997), that the baby-step/giant-step method is the fastest possible method for solving the discrete logarithm problem in a “black box” or ‘generic’ group. A black box group is a group modeled in such a way that the representations of group elements provides no structure. Of course in any particular group there may be a special purpose algorithm that works faster. The fact that for general elliptic curves the baby-step/giant-step method is the most efficient algorithm known for the EC-DLP has led some people to model elliptic curves as black box groups in security proofs.

In conclusion, combining the baby-step/giant-step method with the Pohlig–Hellman algorithm, if we wish a discrete logarithm problem in a group  $G$  to be as difficult as a work effort of  $2^{80}$  operations, then we need the group  $G$  to have a prime order subgroup of order at least  $2^{160}$ .

This means that for elliptic curve cryptography we select a curve such that

$$\#E(K) = N = h \times l,$$

where

$$l > 2^{160}.$$

### Pollard Methods

The trouble with the baby-step/giant-step method is that, although its run time is bounded by  $O(\sqrt{l})$ , it also requires  $O(\sqrt{l})$  space. This space requirement makes the algorithm infeasible in practice. Hence, it is desirable to reduce the large space requirement while still obtaining a time complexity of  $O(\sqrt{l})$ . Pollard achieved this (1978), but the method only has an expected running time rather than an absolute bound on the running time. The resulting algorithm is therefore of the “Las Vegas” type.

The methods for reducing the space complexity all make use of random walks, and a number of techniques exist in the literature almost all of which are because of Pollard (such as the rho, lambda, and kangaroo methods).

These algorithms were all developed for serial computers. In real life when one uses random walk-based techniques to solve discrete logarithm problems one uses a parallel version because of van Oorschot and Wiener (1994), using so-called distinguished points, which is easy to distribute over the Internet.

In 1997 Certicom announced a series of elliptic curve challenges, and the ones that have been successfully solved have all been done using the parallel Pollard method with distinguished points. At the time of writing the largest EC-DLPs attempted have been a curve over a binary field with group order of a 97-bit prime, a Koblitz curve with group order a 108-bit prime and a curve over a field of large prime characteristic with group order a 109-bit prime. The computational power needed to solve the 109-bit challenge utilized around 10,000 PCs running 24 hr a day for 549 days, and as such was greater than the effort needed to factor a 512-bit RSA modulus.

In January 2003 NIST, the U.S. National Institute for Standards and Technologies, issued its recommendations

on key establishment schemes (2003). In this document it presented the recommendations for various key sizes, which we give in the table below for both ECC-based systems and systems based on traditional discrete logarithms in a finite field  $\mathbb{F}_p^*$ . We assume the elliptic curve  $E$  has group order

$$\#E(K) = h \cdot l,$$

where  $l$  is a prime. We also assume for the finite field setting that the prime  $p$  satisfies  $p - 1 = t \cdot q$  where  $q$  is a prime, one then considers protocols defined in a subgroup of order  $q$  of the finite field  $\mathbb{F}_p^*$ . The first row gives the equivalent block cipher strength.

Group	Bits of security	80	112	128	129	256
$E(K)$	$\log_2(l) \geq$	160	224	256	384	512
	$\log_2(h) \leq$	16	16	16	16	16
$\mathbb{F}_p^*$	$\log_2(q) \geq$	160	224	256	384	512
	$\log_2(p) \geq$	1024	2048	3072	8192	15360

Note that the size of  $p$  in finite field systems is usually comparable to the size of the modulus in an RSA system. Hence, the above says that to obtain the same security as a 256-bit block cipher one would require an elliptic curve size of around 512 bits or an RSA modulus of around 15360 bits.

In 2001 Lenstra and Verheul (2001) published a careful analysis comparing the best known algorithms for RSA factorization, traditional discrete logarithms, and elliptic curve discrete logarithms. Their analysis came up with the following comparisons where  $N$  is an RSA modulus

Bits of security	80	109
$\log_2(l) \geq$	165	206
$\log_2(q) \geq$	142	193
$\log_2(p) \geq$	1184	3392
$\log_2(N) \geq$	1513	4047

Although different from the NIST comparisons, the two works show that as time progresses and traditional public key algorithm key sizes increase, the benefit of ECC becomes more pronounced.

### Known Special Attacks

We now consider attacks that apply to certain special classes of elliptic curves.

#### Weil Pairing and Tate Pairing Attacks

Menezes, Okamoto, and Vanstone (1993) were the first to show that the EC-DLP may be transformed into a discrete logarithm problem in a finite field. Their method used the Weil pairing. This method was generalized by Frey and Rück (1994) using the Tate pairing. We recall the Frey-Rück attack here.

Let  $K = \mathbb{F}_q$  and let  $P$  and  $Q$  be points in  $E(K)$  of order  $l$ . Suppose that  $l$  is coprime to  $q$ . Let  $k$  be a positive integer such that the field  $\mathbb{F}_{q^k}$  contains the  $l$ th roots of unity [in

other words,  $l|(q^k - 1)$  and  $k$  is the order of  $q$  in  $\mathbb{Z}_l^*$ ]. We use the following notation, where  $G = E(\mathbb{F}_{q^k})$  as follows:

$$\begin{aligned} G[l] &= \{P \in G : [l]P = \mathcal{O}\}, \\ lG &= \{[l]P : P \in G\}, \\ (\mathbb{F}_{q^k}^*)^l &= \{\alpha^l : \alpha \in \mathbb{F}_{q^k}^*\}. \end{aligned}$$

The Tate pairing is a mapping

$$\langle \cdot, \cdot \rangle : G[l] \times G/lG \rightarrow \mathbb{F}_{q^k}^*/(\mathbb{F}_{q^k}^*)^l,$$

which satisfies the following properties:

1. (Well defined)  $\langle \mathcal{O}, Q \rangle \in (\mathbb{F}_{q^k}^*)^l$  for all  $Q \in G$  and  $\langle P, Q \rangle \in (\mathbb{F}_{q^k}^*)^l$  for all  $P \in G[l]$  and all  $Q \in lG$ .
2. (Nondegeneracy) For each point  $P \in G[l] - \{\mathcal{O}\}$  there is some point  $Q \in G$  such that  $\langle P, Q \rangle \notin (\mathbb{F}_{q^k}^*)^l$ .
3. (Bilinearity) For any integer  $n$ ,  $\langle [n]P, Q \rangle \equiv \langle P, [n]Q \rangle \equiv \langle P, Q \rangle^n$  modulo  $l$ -th powers in  $\mathbb{F}_{q^k}^*$ .

The Tate pairing is used to attack the EC-DLP in the following way:

$$\begin{aligned} &\text{Choose } R \in_R E(\mathbb{F}_{q^k}) \text{ until } \langle P, R \rangle \notin (\mathbb{F}_{q^k}^*)^l. \\ &\zeta_1 \leftarrow \langle P, R \rangle. \\ &\zeta_2 \leftarrow \langle Q, R \rangle. \\ &\eta_1 \leftarrow \zeta_1^{(q^k-1)/l}. \\ &\eta_2 \leftarrow \zeta_2^{(q^k-1)/l}. \\ &\text{Find } \lambda \text{ such that } \zeta_2 = \zeta_1^\lambda. \end{aligned}$$

Note that the index calculus algorithms for solving the discrete logarithm problem in  $\mathbb{F}_{q^k}^*$  have subexponential complexity in terms of the field size  $q^k$  (their performance is comparable with integer factorization algorithms). Because the original problem is in a group of size  $q$  it is necessary that the subexponential complexity in terms of  $q^k$  be smaller than the complexity  $O(\sqrt{q})$  of the Pollard methods. Hence, this strategy is practical only when  $k$  is relatively small.

It is known that supersingular curves are vulnerable to the Frey-Rück attack (because the value  $k$  is always less than or equal to 6). There are also nonsupersingular curves that are vulnerable to this attack (e.g., curves of trace two over  $\mathbb{F}_q$ ). Hence, one should always choose elliptic curves such that

$$l \nmid q^k - 1$$

for all “small” values of  $k$  (e.g.,  $k \leq 30$ ). This test will eliminate all supersingular curves and curves of trace two, plus a few others. We emphasize that this test is trivial to perform and that the probability of a random nonsupersingular curve failing this test is negligible.

In practice one uses a slightly modified pairing, called the modified Tate pairing,

$$\langle \cdot, \cdot \rangle : G[l] \times G[l] \rightarrow \mathbb{F}_{q^k}^*/(\mathbb{F}_{q^k}^*)^l,$$

which is well-defined and bilinear and satisfies  $\langle G, G \rangle \neq 1$  for all  $G \neq \mathcal{O}$ . The use of a modified pairing slightly

simplifies the above attack and allows some interesting other applications to which we now turn.

Curves with small values of  $k$ , such as supersingular elliptic curves, are cryptographically interesting because they are an example of a group for which the best known algorithm to solve the Diffie–Hellman problem runs in subexponential time but for which there is a polynomial time algorithm to solve the Decision–Diffie–Hellman problem. Suppose we are given  $P = [a]G$ ,  $Q = [b]G$ , and  $R = [c]G$ , and we are asked to determine if  $ab \equiv c \pmod{l}$ , this is the Decision–Diffie–Hellman problem. Using the (modified) Tate pairing, which can be computed in polynomial time when  $k$  is small, we only need to check that

$$\begin{aligned} \langle R, G \rangle &= \langle [c]G, G \rangle = \langle G, G \rangle^c \\ &= \langle G, G \rangle^{ab} = \langle [a]G, [b]G \rangle \\ &= \langle P, Q \rangle. \end{aligned}$$

The Tate pairing has now become interesting in a constructive sense because of various new applications. The first constructive applications were pairing based key agreement and signature schemes by Sakai, Ohgishi, and Kasahara (2000) and a tripartite Diffie–Hellman key agreement protocol of Joux (2000). However, the most interesting application was the development of an identity-based encryption scheme by Boneh and Franklin (2001).

### The Anomalous Curves Attack

An elliptic curve  $E$  defined over a prime field  $\mathbb{F}_p$  is said to be anomalous if it has exactly  $p$  points. In 1997 several researchers independently announced related methods to reduce the discrete logarithm problem on an anomalous elliptic curve  $E/\mathbb{F}_p$  to the discrete logarithm problem in the additive group  $\mathbb{Z}/p\mathbb{Z}$  of the integers modulo  $p$ . Smart (1999) posted an announcement on the internet briefly describing a method to solve this problem. At the same time a preprint appeared by Satoh and Araki (1998), which used identical methods. It then became known that Semaev (1998) had already submitted an article on this topic, and that Rück (1999) had generalized this method to deal with Abelian varieties.

The  $p$ -adic version of the method essentially uses the  $p$ -adic filtration of a lift of the elliptic curve to the  $p$ -adic numbers. The  $p$ -adic elliptic logarithm is then used to solve the EC-DLP. The fact that the method applies only to anomalous curves is because one requires  $p = l$  so as to kill off the higher groups in the  $p$ -adic filtration.

We note that anomalous curves  $E/\mathbb{F}_p$  are very rare. There is approximately  $1/(4\sqrt{p})$  chance of a random curve being anomalous. Also, this phenomenon has no impact for the case of elliptic curves over fields of small characteristic. In the case of large odd characteristic one should always have

$$l \neq p.$$

We emphasize that this test is trivial to perform and that the probability of a random nonsupersingular curve failing this test is negligible.

### Weil Descent

The technique of Weil descent to solve the EC-DLP was first proposed by Frey (1998). This strategy was detailed further by Galbraith and Smart (1999). These early ideas were initially sketchy, giving the basic approach, but were unable to solve the EC-DLP for specific curves. Then the work of Gaudry, Hess, and Smart (2002) provided techniques and efficient algorithms that would allow certain curves to be attacked in practice. The precise approach followed in the work of Gaudry, Hess, and Smart is now called the GHS attack, but it should not be confused with the general Weil descent methodology, which could be made to apply to other curves.

The basic method applies to elliptic curves over field extensions of the form  $\mathbb{F}_{q^n}$ , where  $q$  is a prime or prime power and  $n > 1$ . The principle is to transform the EC-DLP from  $E(\mathbb{F}_{q^n})$  to a discrete logarithm problem on the Jacobian of a curve  $C$  over  $\mathbb{F}_q$ . Because subexponential algorithms exist for the discrete logarithm problem in high genus curves, this gives a possible method of attack against the EC-DLP.

In the basic GHS attack  $q$  is a Power of 2 and the curve  $C$  is a hyperelliptic curve. Menezes and Qu (2001) analyzed the GHS attack for cryptographically interesting cases and demonstrated that it did not apply to the case when  $q = 2$  and  $n$  is prime. However, this did not preclude fields of the form  $\mathbb{F}_{2^{155}}$ , because 155 is composite, which could be approached using the GHS attack. Such fields are interesting because they allow fast computations and are used in certain standards.

In 2001 Smart examined the GHS attack for elliptic curves with respect to the field extension  $\mathbb{F}_{2^{155}}/\mathbb{F}_{2^{31}}$  and concluded that such a technique was unlikely to work for any curve defined over  $\mathbb{F}_{2^{155}}$ . Jacobson, Menezes, and Stein (2001) also examined the field  $\mathbb{F}_{2^{155}}$ , this time using the GHS attack down to the subfield  $\mathbb{F}_{2^5}$ . They concluded that such a strategy could be used in practice to attack around  $2^{33}$  isomorphism classes of elliptic curves defined over  $\mathbb{F}_{2^{155}}$ . Because there are about  $2^{156}$  isomorphism classes of elliptic curves defined over  $\mathbb{F}_{2^{155}}$ , the probability of finding one where the GHS attack is applicable is negligible.

In 2002 Galbraith, Hess, and Smart extended the GHS approach via the use of isogenies. They were able to extend the attack to a much larger range of curves, but were still unable to attack all curves over the field  $\mathbb{F}_{2^{155}}$ . In 2003 Hess extended the approach still further by using different forms of Artin-Schreier extensions. Although the number of curves that can be attacked using the new method is much larger than the original GHS attack, one is still unable to apply the methodology to all curves over the field  $\mathbb{F}_{2^{155}}$ .

To avoid any possible security issues related to the GHS and the Weil descent methodology one can always take elliptic curves defined either over a large prime field of odd characteristic or curves over a field of order  $2^p$ , where  $p$  is a prime.

### Domain Parameter Generation

In using an elliptic curve system one needs to choose an elliptic curve. Taking all the above into consideration, the

current security recommendations imply that choosing a curve should be done in the following manner

- Choose a finite field  $K = \mathbb{F}_q$  of order  $q = 2^p$  or  $q = p$ , where  $p$  is a prime such that  $q \geq 2^{160}$ .
- Choose an elliptic curve  $E$  over  $K$  and compute  $N = \#E(K)$ . Write  $N = h \cdot l$ , where  $l$  is a prime.
- Reject the curve if  $h > 65536$  or  $l < 2^{160}$ .
- Reject if  $q = p = l$ .
- Reject if  $q^k \equiv 1 \pmod{l}$  for some  $k \leq 30$ .

The only difficult part of this procedure is Step 2, where one is asked to compute  $\#E(K)$ . Traditionally this was a difficult problem, but because of the polynomial time algorithm of Schoof (1985) it can at least be solved in principle in polynomial time. In the 1980s and early 1990s improvements were made to the basic Schoof algorithm, mainly by Elkies and Atkin, to produce a reasonably fast algorithm to compute  $\#E(K)$  in the two cases of interest, namely characteristic two and large prime characteristic.

The method of Schoof–Elkies–Atkin is called an  $l$ -adic method in that it works by computing the value of  $\#E(K)$  modulo  $l$  for lots of small primes  $l$  and then combines this information using the Chinese remainder theorem to obtain the correct value of  $N$ .

In 2000 another method was proposed by Satoh (2000) for the case of curves defined over fields of small characteristic  $p$ , in this  $p$ -adic approach one lifts the curve to the  $p$ -adic numbers and then computes the value of  $N$  modulo a suitably high power of  $p$ . The method of Satoh, as improved by Skjernaas, Vercauteren, Harley, and Mestre, is now the method of choice for fields of characteristic two.

Although algorithms to compute the number of points on an elliptic curve over a finite field are now common, one very rarely needs them. Various standards bodies, for example NIST, ANSI, and SECG, specify a set of curves that have already been generated. This allows implementors to work with only a finite set and so improve both efficiency and interoperability. This restriction, to using in practice a small set of curves, is not known to introduce any security weaknesses.

## PROTOCOLS

We now turn our attention to precisely which protocols one uses in elliptic curve cryptography. Although virtually any traditional discrete logarithm-based protocol can be converted into the elliptic curve setting, the three most important protocols are the elliptic curve variant of DSA (EC-DSA), the elliptic curve variant of Diffie–Hellman key agreement (EC-DH), and the elliptic curve variant of (a secure version of) ElGamal encryption (EC-IES). Hence, in this section we limit ourselves to discussing these three protocols only.

To specify elliptic curve protocols one requires a set of domain parameters, which consists of a finite field  $K = \mathbb{F}_q$ , an elliptic curve  $E$  over  $K$ , such that the group order  $N = h \cdot l$  is known with  $l$  a large prime. One of course assumes that the curve is “secure” in that the discrete logarithm problem in the subgroup of order  $l$  is hard. Finally, one also requires a fixed base point  $G$  of order  $l$ .

## EC-DSA

The elliptic curve variant of the digital signature algorithm, or EC-DSA, allows the owner of a private key  $x \in \mathbb{F}_l^*$  to digitally sign a message  $m$  such that anybody who knows the corresponding public key  $Y = [x]G$  is able to verify the signature on the message.

We let  $x\text{-coord}(T)$  denote the function that takes the  $x$  coordinate of the point  $T$  and then interprets its binary representation (in some standardized form) as an integer. When the field  $\mathbb{F}_q$  is of large prime characteristic then we simply interpret the value of  $x(T) \in \mathbb{F}_q$  as an integer. However, when  $q = 2^p$  this requires both parties to agree on some standardized way of representing elements of  $\mathbb{F}_q$ . Almost all standards use the same representation so in practice this is no problem.

The signing algorithm for EC-DSA is as follows, where we let  $H$  denote a cryptographic hash function from messages of arbitrary length to elements of  $\mathbb{F}_l^*$ .

```

Choose  $k \leftarrow \{1, \dots, l-1\}$ .
 $T \leftarrow [k]G$ .
 $r \leftarrow x\text{-coord}(T) \pmod{l}$ .
If  $r = 0$  then return to the beginning.
 $e \leftarrow H(m)$ .
 $s \leftarrow (e + xr)/k \pmod{l}$ .
If  $s = 0$  then return the beginning.
Output  $(r, s)$ .

```

Note, that the signing algorithm always performs a point multiplication on the base point  $G$  only. Hence, if memory allows this can be made very efficient using one of the fixed base multiplication routines.

Given a message  $m$ , a signature  $(r, s)$ , and a public key  $Y = [x]G$ , we verify the signature as follows:

```

Reject if  $r, s \notin \{1, \dots, l-1\}$ .
 $e \leftarrow H(m)$ .
 $u_1 \leftarrow e/s \pmod{l}, u_2 \leftarrow r/s \pmod{l}$ .
 $T \leftarrow [u_1]G + [u_2]Y$ .
Accept if and only if  $r = x\text{-coord}(T) \pmod{l}$ .

```

Note in the verification step we perform a simultaneous multiplication, for which we can use Shamir’s trick, or we can use a special fixed base algorithm to compute  $[u_1]G$  and a more general algorithm to compute  $[u_2]Y$  followed by a point addition.

Like most efficient digital signature algorithms, very little can be proved about the security of EC-DSA in the standard model of computation. In fact even if we accept the random oracle model one still is unable to prove the security of EC-DSA. However, if one assumes the generic group model as a way of modeling the elliptic curve group then a proof of security has been given by Brown (2002). In this proof it is shown that any attacker against EC-DSA, in the sense of an active attacker trying to form an existential forgery, must break the hash function  $H$  to be able to perform a successful attack on EC-DSA. However, one should note that the generic group model assumption is controversial; see Stern, Pointcheval, Malone-Lee,

and Smart (2002) for an example of a criticism of this approach.

## Key Agreement

The first application of asymmetric cryptography was the protocol of Diffie and Hellman for two parties to agree a secret key over a public unsecured channel. However, one should note that one needs to combine the Diffie–Hellman protocol with (at least) authentication to obtain a secure key agreement protocol.

The elliptic curve variant of the Diffie–Hellman protocol consists of two parties, usually denoted Alice and Bob, deciding on two private ephemeral keys. Alice generates the private ephemeral key  $a$  and computes the corresponding public ephemeral key  $P_A = [a]G$ , which she sends to Bob. Bob generates the private ephemeral key  $b$  and sends to Alice the public ephemeral key  $P_B = [b]G$ . Alice can then compute the shared secret as follows:

$$K = [a]P_B = [ab]G,$$

whereas Bob computes the same shared secret as

$$K = [b]P_A = [ab]G.$$

On the assumption that the elliptic curve Diffie–Hellman problem is hard, then an eavesdropper is unable to compute  $K$  given  $P_A$  and  $P_B$ .

Various improvements/choices can be made on the basic protocol. One can add authentication by the use of each party digitally signing its message flow, or one can add key confirmation. Because, in the authenticated version the long-term static public keys are used only to authenticate the message flows the protocol is easily seen to be forward secure, a property that traditional SSL-like RSA key transport does not possess. If one party, say Bob, is offline then Alice could take Bob’s static public key as his ephemeral public key; however, this would come at the expense of forward secrecy.

There is a protocol by Law, Menezes, Qu, Vanstone, and Solinas (2003), called MQV, which using the same message flows as the basic unauthenticated Diffie–Hellman protocol allows one to obtain an authentic key agreement scheme. This protocol is especially suited if bandwidth is constrained.

## EC-IES

To use elliptic curves as a public key encryption scheme one adapts the basic ElGamal scheme. The changes from the basic ElGamal scheme are to ensure semantic security against adaptive chosen ciphertext attacks. The resulting scheme, EC-IES, was proved secure by Abdalla, Bellare, and Rogaway (2000).

To encrypt one makes use of a message authentication code (MAC), which one should think of as a keyed hash function and a symmetric cipher  $E_k(m)$ . In addition use is made of a key derivation function  $KD(T, l)$ , which takes a small key  $T$  and expands it to a key (or keys) of length  $l$  for use by a MAC or symmetric cipher.

Given message  $m$  and public key  $Y = [x]G$  we produce the ciphertext  $(U, c, r)$  via the algorithm

$$U \leftarrow [k]G.$$

$$T \leftarrow [k]Y.$$

$$(k_1 \| k_2) \leftarrow KD(T, l).$$

Encrypt the message,  $c \leftarrow E_{k_1}(m)$ .

Compute the MAC on the ciphertext,  $r \leftarrow \text{MAC}_{k_2}(c)$ .

Output  $(U, c, r)$ .

Each element of the ciphertext  $(U, c, r)$  is important

- $U$  is needed to agree the ephemeral Diffie–Hellman key  $T$ .
- $c$  is the actual encryption of the message.
- $r$  is used to avoid adaptive chosen ciphertext attacks.

Decryption of  $(U, c, r)$  to recover the message  $m$  via the private key  $x$  is performed via the sequence of steps.

$$T \leftarrow [x]U.$$

$$(k_1 \| k_2) \leftarrow KD(T, l).$$

Decrypt the message  $m \leftarrow D_{k_1}(c)$ .

If  $r \neq \text{MAC}_{k_2}(c)$  then output “Invalid Ciphertext”.

Output  $m$ .

Assuming the MAC and symmetric cipher meet some basic security properties, the above scheme is secure under an interactive hashed version of the DDH assumption (see Abdalla et al., 2002, for precise details of the exact assumption needed).

If one does not like the interactive hash DDH assumption then one can also prove security assuming the key derivation function is perfect and assuming the Gap-Diffie–Hellman problem is hard. This later problem is the problem of solving EC-DHP assuming one has an oracle to solve the EC-DDH.

For further details of the security proofs for EC-IES one should consult (Dent,). There are also a number of issues related to EC-IES related to various choices made by standards bodies. Some of these choices have very slightly weakened the security results provable for EC-IES.

## DEFENCES AGAINST SIDE CHANNEL ATTACKS

Because elliptic curve cryptosystems are often used in potentially hostile environments their implementation is susceptible to side channel attacks such as those based on timing, power, or EM radiation. Such attacks were first introduced into the cryptographic community by Kocher, Jaffe, and Jun (1999).

It has proved possible, by examining the power trace, for example, to determine the operations performed by an algorithm. For example the sequence of double and add operations used in the point multiplication algorithm can be captured because the two operations are often distinguishable from different power traces. Such an attack is called simple power analysis (SPA). A more powerful attack, called differential power analysis (DPA), is when

the adversary runs many runs of the protocol with different data and then uses statistical correlations between the side channel data (e.g., the power traces) to determine the secret key.

The need to provide defences against these attacks has resulted in a large amount of literature over the past few years within the elliptic curve community (e.g., see any of the proceedings of the CHES conference). The essential idea to defend against SPA is to stop the attacker being able to distinguish between double and additions or to decorrelate the observable operations from the private key. For defences against DPA one tries to randomise the data in such a way as to remove any statistical correlations in the side channel data.

### Simple Power Analysis

If one uses the left-to-right binary exponentiation algorithm mentioned earlier then on observing the sequence of operations

$$D, A, D, A, D, D, A, D, D, D, A, \dots$$

we know that the binary representation of the secret multiplier will be

$$1, 1, 0, 1, 0, 0, 1, \dots$$

One way of stopping such attacks is to create exponentiation algorithms for which, even if you know the order of point additions and doublings, one cannot obtain the secret multiplier.

The problem with the left-to-right binary method is that each addition occurs only when a bit of the secret key is set. Hence, a possible defence is to always perform an addition no matter what the bit of the key is. Such an algorithm was given by Coron (1999):

```

Q ← O.
For j from ℓ - 1 to 0 by -1 do
  T[0] ← [2]Q.
  T[1] ← T[0] + P.
  Q ← T[kj].
Return Q.

```

This defence can be generalized to produce more efficient algorithms, we refer the reader to the extensive literature for more details (see Joye, for a survey).

Another defence against SPA is to make the side channel information from a point addition and the side channel information from a point doubling to be indistinguishable. An early idea of doing this was to add dummy operations into the procedures for addition and doubling. A more fundamental approach was proposed by Liardet and Smart (2001), who suggested using group law formulae that were the same for addition and doubling. This was first presented in the case of elliptic curves in Jacobi form and was quickly extended to Hessian form curves (Joye and Quisquater, 2001) and finally to curves in standard form by Brier and Joye (2002).

### Differential Power Analysis

The above defences do not defend against differential power analysis. In a differential attack the attack is essentially using correlations between the differences in the power trace created by the exact data being computed rather than the operations themselves. Hence, none of the above defences will protect against differential attacks because on every protocol run they operate on the same data.

There are a number of possible defences against differential power attacks on elliptic curves, but the most elegant and simple one is to use randomized projective coordinates. This randomizes the data in the following way. Suppose we are given an affine point  $P = (x, y)$  on the curve and are asked to compute  $Q = [k]P$ . We assume we are given a point multiplication algorithm that is secure against SPA and that operates on points in Jacobian projective coordinates. The randomized projective coordinates method then works as follows:

```

r ← K*.
P' = (XP, YP, ZP) = (xr2, yr3, r).
Q' = (XQ, YQ, ZQ) ← [k]P'.
Q ← (XQ/ZQ2, YQ/ZQ3).
Output Q.

```

Again we refer the reader to the Joye survey for further details of various defences.

### CONCLUSION

Elliptic curves are of interest to cryptographers because they provide public key encryption in an efficient manner. The key size required to match a given level of symmetric cipher security is smaller compared to traditional systems such as those based on factoring or traditional discrete logarithms. The reduced key size means one requires less bandwidth or computational resources to implement an elliptic curve based system. In addition new applications such as identity based cryptography are enabled by elliptic curves in a way that is impossible with traditional public key constructions.

## INTRODUCTION

Adi Shamir, co-inventor of the first public key cryptosystem (RSA), introduced the notion of identity-based cryptography (IBC) in 1984 as a way to simplify public key infrastructure (PKI) (Shamir, 1985). (See Chapter 57 of this *Handbook* for a review of public key infrastructure.) His idea, at a high level, is simple and elegant: if public keys did not need to be *distributed*—if, instead, all public keys in the system were somehow known to all users—then much of the infrastructure needed to support public key cryptography (e.g., public key directories) would be unnecessary. For example, if a user’s public key is its *identity* in some standardized format—e.g., an e-mail address—then a message sender needs only the user’s e-mail address to e-mail the user an encrypted message; no separate mechanism is needed to distribute public keys.

## High-Level Description of IBC

Since Shamir introduced this idea, cryptographers have discovered a wide variety of identity-based cryptosystems, but they share some common characteristics. Although user *public* keys can be any specified bit-string, user *private* keys are generated by a trusted third party, typically called a *private key generator* (PKG). Specifically, if the PKG’s public/private key pair is  $(P_{\text{PKG}}, S_{\text{PKG}})$  and a user’s public “identity” string is ID, then the PKG generates the user’s identity-based private key  $C_{\text{ID}}$  as a function of  $S_{\text{PKG}}$  and ID. To handle the possibility of revocation, the PKG typically includes the date (or some other time period) as part of the user’s ID so that user private keys naturally expire; it issues new periodic private keys only to users that are currently legitimate. In the case of identity-based encryption (IBE), encryption and decryption typically proceed as follows:

- Encryption: Sender uses  $(P_{\text{PKG}}, \text{ID}, m)$  to compute  $c$ , a ciphertext for message  $m$  under the identity ID.
- Decryption: Recipient uses  $(C_{\text{ID}}, c)$  to recover  $m$ .

For identity-based signing (IBS), the algorithms are as follows:

- Signing: Signer uses  $(C_{\text{ID}}, m)$  to compute Sig, a signature on message  $m$ .
- Verification: Verifier uses  $(P_{\text{PKG}}, \text{ID}, m)$  to verify Sig.

Notice that, as advertised, the IBE sender (or IBS verifier) does not need to fetch a separate public key for the IBE recipient (or IBS signer). Although it is true that the identity-based sender (or verifier) still needs to obtain the PKG’s *public key*, it is arguably much easier to distribute a few PKG public keys than (numerous) traditional user public keys (e.g., in some cases, it may even be a viable option to “embed” a PKG’s public key in applications or user devices). By removing the need to distribute user public keys (and certificates), IBC can enable a key (and certificate) management system with much less infrastructure than traditional PKI.

IBC covers much more than just IBE and IBS. Other types of cryptosystems that have identity-based versions include key agreement, signcryption (i.e., signer efficiently signs and encrypts a message), blind signatures (i.e., signer blindly signs an unknown message), undeniable signatures (i.e., legitimate signature is verifiable only with signer’s help, but signer cannot repudiate it), and ring signatures (i.e., signer signs anonymously as a member of an ad hoc group). In addition to briefly examining identity-based ring signatures later on, this chapter focuses primarily on IBE and IBS (especially IBE), their advantages and disadvantages, their closest alternatives, and some extensions.

It is important to emphasize that IBC has no significant advantages over traditional public key cryptography (PKC) in all contexts. In particular, IBC is not particularly advantageous when key and certificate distribution are already not a problem (e.g., in highly interactive protocols where one party could simply transmit its public and certificate to another party). In fact, this includes IBS, because a traditional public key signer can simply transmit its public key and certificate to a verifier along with its signature. (However, we hasten to add that IBS schemes still may have some performance advantages—in particular, because IBS users do not need to generate keys and because in IBS there is no separate public key or certificate to transmit, leading to a possible bandwidth reduction.)

Identity-based cryptography's advantage is perhaps clearest in the setting of noninteractive encryption (e.g., the sending of an encrypted email message), where the communication is initiated not by the owner of the public key and certificate, but by a sender that would otherwise (in a traditional public key encryption scheme) have to proactively fetch the recipient's public key and certificate before encrypting. Here, IBC reduces the load not only on senders but also on the trusted authority (the PKG) and its associated infrastructure, because no mechanism is needed to distribute public keys and certificates to encrypters. Identity-based cryptography has clear advantages in other contexts, as well (e.g., for ring signatures). We discuss these advantages in more detail later.

Identity-based cryptosystems can also have some disadvantages. In particular, the fact that the PKG generates the private keys of all of its users effectively gives the PKG *private key escrow* (i.e., the PKG can perform any private key operation that its users can, and therefore can, for example, decrypt its users' IBE-encrypted messages or forge its users' identity-based signatures). This disadvantage is particularly substantial for IBE, because a PKG can *passively* decrypt its clients' messages, whereas a certification authority (CA) in a PKI needs to mount an *active* attack. Another disadvantage is that the PKG must use *secure channels* to distribute the identity-based private keys, but this turns out to be a less serious problem. We compare identity-based cryptography with public key cryptography in the next section, focusing in more detail on these advantages and disadvantages.

## The Development of Practical Identity-Based Schemes

Although the high-level “blueprint” for identity-based encryption and signature schemes is quite simple, this does not imply that constructing *concrete* identity-based cryptosystems is an easy task. Shamir (1985) provided the first IBS scheme in his initial article on IBC. The two most well-known IBS schemes are Fiat–Shamir (1986) and Guillou–Quisquater (1988), the latter of which we review later.

Constructing IBE schemes proved to be a much more difficult problem. Although there were some early efforts (e.g., by Maurer & Yacobi, 1991), versions of the first truly practical IBE scheme, which use “pairings” over elliptic curves or abelian varieties, were discovered independently by Sakai, Ohgishi, and Kasahara (2001) and

Boneh and Franklin (2001). Boneh and Franklin provided the more rigorous treatment, proving that the scheme, when combined with the Fujisaki–Okamoto transform, is secure in the “random oracle model” against adaptive chosen ciphertext attack assuming the hardness of the so-called “Bilinear Diffie–Hellman” problem. Cocks (2001) discovered a very different IBE scheme in 2001 based on the hardness of the quadratic residuosity problem modulo a number of unknown factorization, but this scheme has attracted much less attention because it suffers from significant ciphertext expansion (i.e., the ciphertext is many times longer than the plaintext). We review Cocks's scheme and the Boneh–Franklin scheme in later sections of this chapter.

## More Than Just Identities

Identity-based cryptography is useful for more than just managing identities and simplifying PKI. In particular, the bit-string “ID” (as used in the high-level description of IBC) is not limited to containing someone's “identity”; it can contain any specified information.

For example, consider a scenario in which Bob performs the role of a PKG, generating a PKG public key  $P_{\text{Bob}}$  and issuing identity-based decryption keys to himself by setting ID to be a *date*; then Alice encrypts to Bob by applying an IBE scheme to  $(P_{\text{Bob}}, \text{ID} = \text{date}, m)$ , as discussed in Boneh and Franklin (2001). Why is this arrangement useful? Suppose that Bob is going on a vacation, and he would like to use his laptop to decrypt his messages during this period, but he is concerned that his laptop may be stolen, compromising his private key. To address this problem, Bob can download a batch of “date-based” decryption keys to his laptop; if his laptop is stolen, the compromise is limited to the dates of his vacation. The “master” private key—the one he uses in his role as PKG—remains secure on his home computer.

Generally speaking, ID can be any sort of “Incidental Data” that an authorizer—in its capacity as a PKG—may (or may not) “sign” by issuing the corresponding decryption key. When we view IBE from this broader perspective, we see that by encrypting a message with ID and an authorizer's public key, an encrypter makes a recipient's ability to decrypt contingent on the recipient's acquisition of the authorizer's signature (in the form of an identity-based decryption key) on ID. In this sense, a more appropriate name for identity-based encryption might be “signature-contingent decryption.” One can imagine a variety of scenarios, beyond the ordinary IBE scenario, where a content encrypter may want to make decryption (by one or more recipients) contingent on a release signed by a trusted authority. We discuss some of these scenarios toward the end of the chapter.

## IBC VERSUS PUBLIC KEY CRYPTOGRAPHY

In this section, we discuss the advantages and disadvantages of identity-based cryptography relative to public key cryptography. As we explain, the differences between identity-based *signing* and public key *signing* (PKS) are not very significant; so we focus our comparison

primarily on the trade-offs between identity-based encryption and public key encryption (PKE), which are more interesting. We also discuss “ring signatures” as another exemplary setting in which the advantages of IBC are compelling. Finally, we analyze some common objections to and misconceptions about identity-based cryptography.

### Points of Comparison

Before delving into advantages and disadvantages, let us establish a “mapping” between the fundamental components of IBC and PKI-supported PKC that will allow us to compare them, focusing on the encryption case.

First, consider a traditional PKE scheme: after Bob creates a public/private key pair  $(P_{Bob}, S_{Bob})$ , Alice uses  $(P_{Bob}, m)$  to compute a ciphertext  $c$  for her message  $m$ , and Bob uses  $(S_{Bob}, c)$  to recover  $m$ . This traditional PKE scheme suffers from a key authentication problem: How does Alice know that the value of  $P_{Bob}$  that she has obtained is really Bob’s public key rather than an impostor’s? The essential purpose of PKI is to solve this key authentication problem. Typically, a PKI includes a certification authority (CA), which publishes its own public key  $P_{CA}$  and then performs several functions. First, the CA registers Bob and gathers information about him, including his public key  $P_{Bob}$ . If satisfied, the CA signs this information with its private signing key  $S_{CA}$ , thereby generating a “public key certificate”  $C_{Bob}$  on  $P_{Bob}$  for Bob. Thereafter, the CA may use an “infrastructure” to distribute  $P_{Bob}$  and  $C_{Bob}$  to people such as Alice, who must obtain and verify Bob’s certificate before sending an encrypted message to Bob. Because Bob’s public key may eventually become invalid (e.g., if his private key is compromised), the CA may also need to deploy infrastructure to distribute “certificate status” information to people such as Alice, so that they can check that Bob’s certificate has not been revoked.

In an IBE scheme, a CA is replaced by a private key generator (PKG), which publishes its public key  $P_{PKG}$ ,

and then performs somewhat analogous functions. Like a CA, the PKG registers Bob and gathers his identifying information  $ID_{Bob}$ , but Bob does not generate and send a public key  $(P_{Bob})$  in an IBE scheme. If satisfied, the PKG “signs”  $ID_{Bob}$  using its private key  $S_{PKG}$ , thereby generating an identity-based decryption key  $C_{Bob}$  for Bob. The PKG must send  $C_{Bob}$  to Bob over a secure channel, because it is Bob’s only secret. Alice uses  $(P_{PKG}, ID_{Bob}, m)$  to compute a ciphertext  $c$  for her message  $m$ , and Bob uses  $(C_{Bob}, c)$  to recover  $m$ . IBE is convenient from Alice’s perspective, because she does not need to obtain and verify a certificate for Bob; rather, she knows that Bob (or an impostor) will be unable to decrypt her message unless he received the necessary identity-based decryption key  $(C_{Bob})$  from the PKG (in effect, an *implicit certificate*). IBE is also convenient from the PKG’s perspective, because the PKG does *not* need to deploy infrastructure to distribute Bob’s public key to people such as Alice; rather, assuming Alice knows  $P_{PKG}$  and  $ID_{Bob}$ , she already has all the information she needs to encrypt. The PKG can address the “revocation” issue by including time periods of sufficient granularity into  $ID_{Bob}$  and issuing new private keys to Bob at the beginning of each time period; Alice incorporates the current time period as part of  $ID_{Bob}$  when encrypting. PKI often uses a period-based approach to revocation as well (e.g., periodic issuance of CRLs); to ease comparison, we focus primarily on this type of PKI.

To summarize, the PKG plays a role analogous to that of a CA in a PKI. An identity-based decryption key is analogous to a certificate, but it is sent over a secure channel to the specific client (Bob) rather than being sent over a public channel to various third parties (like Alice). Instead of verifying Bob’s CA-issued certificate explicitly (as she would in a PKI), Alice “verifies” Bob’s PKG-issued identity-based decryption key implicitly by generating a ciphertext that cannot be decrypted without it. Unlike the encryption key in a PKE scheme, Bob’s identity-based encryption key is “transparent”; it is an identity that need not be separately *distributed or obtained*.

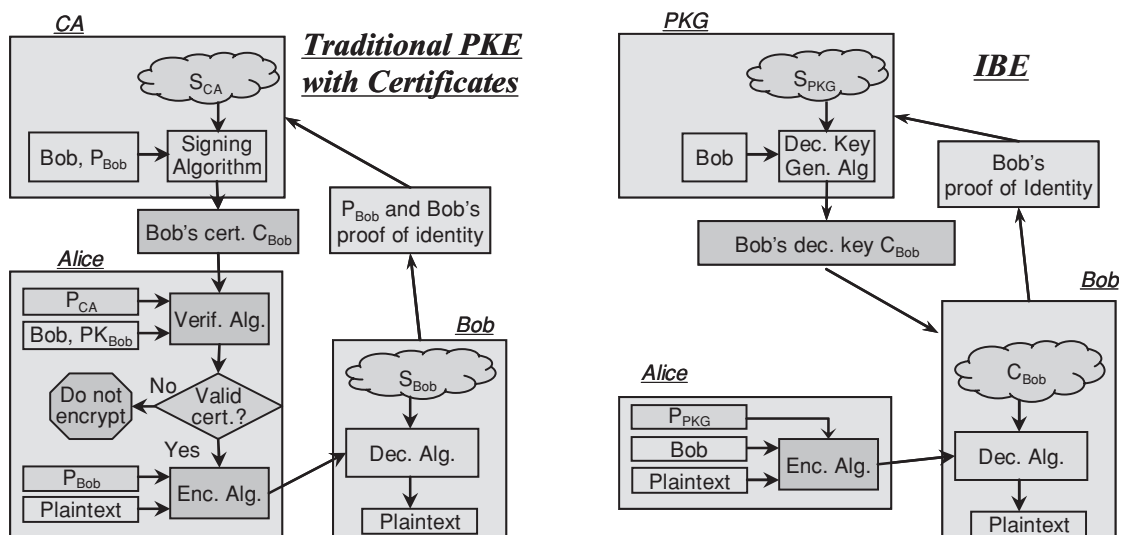

Figure 1: Comparison of PKI-supported PKE with IBE.

## Advantages of IBC

The main advantage of IBE is that, unlike PKI-supported PKE, the sender does not need to obtain the recipient's public key and (periodic) certificate, via some mechanism, before sending an encrypted message. In PKI-supported PKE, the sender may obtain this information either from a server within the system's infrastructure or from the recipient itself. (Note: Fig. 1 omits the latter option for simplicity.) However, both of these options impose undesirable interaction and delay on the encrypter before it can send its message. Each option also has additional problems. Specifically, obtaining the information directly from the recipient may not be viable in high-latency applications (e.g., e-mail), and obtaining it from the system requires that the system always be online and have considerable infrastructure. (Conversely, the advantages of IBE become less compelling when such an infrastructure is not considered burdensome or in highly interactive applications where the recipient can simply relay its public key and certificate to the sender.)

Let us consider a typical PKI in detail, to better understand how IBE simplifies things. In a typical PKI, it is not the recipient's responsibility to distribute its own public key and fresh certificate; instead, the sender should be able to acquire the recipient's public key and certificate status from the CA or its servers. Thus, the CA must deploy infrastructure that can respond to *third-party queries*—i.e., queries by one party (which may not even be a client of the CA) regarding the public key or certificate of a different party (a client of the CA). Such third-party queries are difficult to handle for several reasons. First, because these queries can come from anywhere and concern any client, every server in the system must always be online and able to ascertain the certificate status of every client in the system. Contrast this with IBE, in which *the PKG does not need to respond to third-party queries*; it needs only to distribute (using a “push” model, if desired) the private keys of the clients that it serves. Second, third-party queries multiply the query processing costs of the CA and/or its servers. For example, if each client's certificate status is queried 10 times per day, then the system must process  $10N$  queries (where  $N$  is the number of clients) rather than distributing just  $N$  daily identity-based private keys to clients. Finally, there is a business model and security consideration: if the CA must respond to queries from nonclients, it has less control over its costs and becomes more susceptible to denial of service (DoS) attacks. In short, by eliminating the need to deal with third-party queries, IBE can significantly reduce the costs and infrastructure needed to support encryption. Overall, IBE can be significantly more convenient both for encrypters and for the trusted authority.

A further advantage of IBE over PKI-supported PKE is that IBE is arguably more likely to propagate itself than PKI, whose adoption has been disappointingly slow. Using IBE, Alice can send Bob a message encrypted Bob's public key (his identity) even before Bob obtains his private key from the PKG; thus, Alice encourages Bob to adopt IBE. Conversely, PKI propagation is not as “viral;” instead, Bob must adopt PKI and generate a public key before

he can receive an encrypted message. In short, uptake of PKI technology for encryption can only be initiated by the intended recipient of a message, whereas uptake of IBE technology can be initiated also by the sender.

The advantages of IBS over PKS are less compelling. In fact, although some specific IBS schemes (e.g., the Guillou–Quisquater scheme, described later on) may have efficiency advantages, they *do not* have significant infrastructural advantages over traditional public key signing (PKS) schemes. The reason is that distributing public keys and certificates is much easier for PKS schemes than for PKE schemes: a PKS signer can simply distribute this information to the third-party verifier itself, sending its public key and certificate to the verifier along with its signature.

In terms of efficiency, however, IBS does allow users to avoid the expense to key generation. Also, IBS schemes may sometime have bandwidth advantages over PKS schemes—because an IBS signature may consume fewer bits than the combination of a PKS signature, PKS public key, and PKS certificate—but this may not always be the case. Besides, a similar bandwidth advantage can be achieved using other methods—for example, Boneh, Gentry, Lynn, and Shacham (2003) describe how multiple signatures, such as a PKS signature and PKS certificate—can sometimes be compressed into a single, short “aggregate” signature. In short, IBC greatly simplifies the management of encryption keys but performs little better than traditional PKI in managing basic signing keys (though it may have some efficiency advantages). (See Bellare, Namprempre, & Neven, 2004, for a comprehensive analysis and taxonomy of IBS schemes.)

IBC's infrastructural advantages are not limited to the encryption context, however; for example, another setting in which IBC has infrastructural advantages—that is, in which IBC removes the need for an infrastructure to distribute public keys and certificates—is *ring signatures*. In a conventional *public key* ring signature scheme, a signer  $A_i$  with public/secret key pair  $(P_i, S_i)$ , who belongs to an arbitrary “ring” of users  $R = (A_1, \dots, A_t)$  with public keys  $(P_1, \dots, P_t)$ , can use  $S_i$  and  $(P_1, \dots, P_t)$  to generate a “ring signature”  $\text{Sig}$  on a message  $m$  that will convince a verifier that *some* member of  $R$  signed  $m$ ; however, the verifier—which is given  $m$ ,  $\text{Sig}$ ,  $(P_1, \dots, P_t)$ , and possibly the  $t$  certificates for the  $t$  public keys—will not be able to determine *which* member generated the signature. This allows  $A_i$  to sign  $m$  *anonymously* as a member of the ring  $R$ . However, for ring signing to be truly anonymous, it is not reasonable for  $A_i$  to request the other ring members' public keys (and certificates) from the ring members directly, because the ring members potentially could break the anonymity of a ring signature by comparing their logs concerning who has made such requests. Thus, public keys must be distributed indirectly, though an *infrastructure*.

For *identity-based* ring signatures, the only information  $A_i$  needs about the other ring members is their identities;  $A_i$  does not need to separately obtain their public keys (since public keys are identities). Consequently, by making ring signatures identity-based, and assuming the PKG does not disclose the clients for which it has issued private keys, we can preserve anonymity while eliminating the

need for a public key distribution infrastructure. Moreover, identity-based ring signing is more convenient for the sender (i.e., the signer), who does not need to fetch other parties' public keys. Finally, identity-based ring signing, unlike conventional ring signing, allows the actual signer to include users in its ring even if those users do not yet have private keys. (Notice how these advantages—elimination of infrastructure, convenience for the sender, and usability of public keys before private keys are generated—parallel those of IBE.)

## Disadvantages of IBC

The primary disadvantage of IBC—and particularly of IBE—is private key *escrow* (i.e., the ability of the PKG to perform any private key operation, such as decrypting an IBE-encrypted message) that one of its clients can perform. Of course, escrow has advantages in some contexts. For example, giving private key escrow to law enforcement officials enables easier monitoring of suspected criminals. Also, within an enterprise, escrow allows a company to decrypt documents encrypted by an employee that has lost his decryption key or left the company. However, in many contexts, escrow will be completely undesirable.

How serious is escrow as a disadvantage relative to public key cryptography? Once again, the considerations are different for signing than for encryption. Unfortunately, for IBE, it is *unavoidable* that the PKG can *passively* decrypt its clients' messages, given IBE's basic premise that any specified string can act as a user's public key even if the user did not generate the string itself. To see why, notice that Bob cannot generate his own private key; if he could, then so could anyone else with equal computational power, because Bob is assumed to have no "privileged" knowledge about his identity string. So, Bob's private key must be generated by a third party (or a federation or "threshold" of third parties)—call it a "PKG"—as a function of Bob's string and information that is known only to the PKG—call it the PKG's private key. (See Boneh & Franklin, 2001 and Lee et al., 2004, for information regarding using multiple parties in the key-issuing process.) Because the only privileged information that Bob uses to decrypt comes from the PKG, the PKG can also decrypt. In PKI-supported PKE, the CA cannot mount this type of passive attack (though it can actively generate a fraudulent certificate for a "fake" key and relay it to a sender, hoping that the sender will encrypt with the fake key).

Escrow is not a significant disadvantage for IBS relative to PKS, because PKS suffers from an analogous problem—namely a CA can forge a user's signature by generating a "fake" public/private key pair, computing a certificate binding the fake public key to the user's identity, and then signing a given message with the fake private key. Clearly, neither public key signature schemes nor identity-based signature schemes are invulnerable to an active attack by the only "trusted" party in the system. Similarly, one can easily construct other types of identity-based cryptosystems that limit the PKG to active attacks—for example, a Diffie–Hellman key exchange authenticated

using IBS—thereby minimizing the disadvantage of escrow; however, in such cases, one should closely examine whether the identity-based scheme has any significant advantage over its traditional public key-based counterpart.

Another disadvantage of identity-based cryptography is that, if a PKG has a large clientele, private key generation can become computationally expensive. Suppose that the current date is included as part of client's public ID. Then, the PKG must generate a new private key for every client every day. Contrast this with a CA that issues a certificate revocation list (CRL) update every day. Most likely, the CRL update will require considerably less *computation*, because it needs to include only the small percentage of clients revoked on that day (though, as mentioned, the *communication* and *infrastructure* necessary for a CRL-based PKI may be much greater, because of third-party queries). To some extent, the computational problem of generating clients' daily private keys can be overcome by using *hierarchical* IBE, in which a root PKG offloads private key generation to lower level PKGs in much the same way as a root CA offloads certification to a hierarchy of CAs. We discuss hierarchical IBE later in this chapter.

## Common Objections to IBC

Here, we list some other possible objections to identity-based cryptography and analyze them in detail. To avoid confusion, we focus exclusively on the encryption case.

*Objection: Private Key Distribution Is Problematic:* Before Bob gets his identity-based private key, he must have a secure channel with his PKG. This predicament seems to pose a "chicken-and-egg" problem: how can Bob secure a channel before receiving his private key? In reality, the setup phase of IBE is no more problematic than the setup phase of PKI. To allow the PKG to transmit his identity-based private key securely during the setup phase, Bob can simply generate an ordinary public/private key pair and give the PKG a public key  $P_{\text{Bob}}$  during the registration process, just as he would when registering with a CA. In either case, the PKG/CA needs to confirm that  $P_{\text{Bob}}$  is Bob's public key; this separate "chicken-and-egg" problem may be accomplished "out-of-band"—for example, by having Bob register in person. Thereafter, the PKG can use  $P_{\text{Bob}}$  to encrypt each of Bob's periodic identity-based private keys, until the PKG is notified that  $P_{\text{Bob}}$  is invalid (while analogously, in a PKI, the CA may periodically affirm its certification of  $P_{\text{Bob}}$ , until otherwise notified). Using such a temporary public key does not eliminate the advantages of IBE, because it is needed only for private key transmission; it does not need to be distributed to, or obtained by, third parties (such as Alice). (We note that private key distribution could obviously be handled in different ways; the above approach merely simplifies the comparison to traditional PKI.)

*Objection: Key Revocation Is Problematic:* Suppose Bob's identity-based private key is compromised. Does Bob then need to change his identity? If Alice wants to encrypt a message to Bob, how does she find out that Bob's key is no longer valid, given that the main advantage of

IBE is that the encrypter should not need to obtain extraneous information about the recipient beforehand? In short, handling key revocation in IBE seems problematic. However, the solution (which was noted earlier) is simple: just embed a time period  $t$  in Bob's encryption key  $ID_{Bob,t}$ . The PKG sends Bob a new private key at the beginning of each time period (as long as his status remains valid), and it publishes its "schedule" of time periods as part of its public key  $P_{PKG}$ . Alice uses  $(P_{PKG}, ID_{Bob,t}, M)$  to encrypt  $M$  for Bob, knowing that Bob (or an impostor) cannot decrypt unless his decryption key is up to date. Revocation is not immediate—the granularity of revocation depends on the length of the time periods—but other common revocation solutions [such as certificate revocation lists (CRLs)] are also typically periodic. Online certificate status protocol (OCSP) and "mediated IBE" offer immediate revocation, but they have some disadvantages (discussed below).

*Objection: The PKG Is a Vulnerability:* A PKG can passively decrypt all client messages (because it has private key escrow); an attacker that compromises the PKG can do the same. Conversely, an attacker who compromises a CA cannot decrypt client messages unless an active attack is mounted (by giving Alice a "fake" certified public key for Bob). So, the consequences of a PKG compromise are more severe. However, the *probability* of a PKG compromise is arguably less than that of a CA compromise for certain PKI implementations, such as OCSP. In OCSP, the CA must always be online to respond to a certificate status queries by generating a fresh signature on the certificate's current status. If the OCSP CA is centralized, it becomes highly vulnerable to DoS attacks; if it is distributed and each server has its own secret key, then compromising any server compromises the entire system. A PKG's private key, which only needs to be used periodically, can (arguably) be more safely insulated. (Of course, again, OCSP has the advantage of offering immediate certificate revocation.)

*Objection: IBE Does Not Really Eliminate Nonclient Queries:* Suppose that Alice wants to encrypt to Bob, but that she is not a client of Bob's PKG; before encrypting, she must acquire the public key of Bob's PKG, perhaps by querying the PKG itself. However, the public key of Bob's PKG—which may include a "cryptographic" key, as well as "non-cryptographic" information, such as how a client's identity should be formatted to construct his public key, the PKG's schedule of time periods, and so on—is essentially static; thus, Alice's request for the PKG's public key is not a nonclient query requiring an *individualized* response. After obtaining its public key, Alice needs no further information from Bob's PKG to encrypt to Bob (because she can presumably obtain Bob's identity through alternative means).

*Objection: Pervasive Computing Makes IBE Obsolete:* One of the main advantages of IBE is that it allows Alice to encrypt to Bob without needing to interact with Bob or the CA to obtain Bob's public key and certificate status. This advantage is more pronounced when such interaction would be a burden—for example, when it would make the transaction slower, more expensive, or less reliable. However, if "pervasive computing" becomes sufficiently efficient, inexpensive, robust, and "pervasive," eliminating

interaction becomes less of an advantage. In this situation, IBE indeed begins to lose its advantage over PKE. In short, IBE is less of a win for highly interactive transactions, or when a suitable distribution infrastructure is already deployed.

## ALTERNATIVES TO IBE

We have already discussed one alternative to IBE: PKE supported by a PKI. Here, we discuss four other alternatives: Kerberos, mediated IBE, certificate-based encryption, and domain-based IBE.

### IBE versus Kerberos

Kerberos is an authentication and key establishment protocol that uses only symmetric (secret key) cryptography. The protocol employs a trusted authority, called a key distribution center (KDC), that already shares pairwise secret keys with other parties in the system. When one party (say, Alice) wants to establish a shared secret key with a second party (Bob), Alice contacts the KDC. The KDC generates a session key  $K_{AB}$  for Alice and Bob to share and (to oversimplify things a bit) encrypts  $K_{AB}$  under the respective secret keys  $K_{KA}$  and  $K_{KB}$  that it shares with Alice and Bob, sending the two ciphertexts to Alice. In her first message to Bob, Alice relays the encryption of  $K_{AB}$  under  $K_{KB}$ ; thereafter, Alice and Bob can use  $K_{AB}$  to encrypt and authenticate their communications.

Kerberos and IBE are similar in the sense that, in both, the trusted authority has "key escrow" because it generates all secret keys. However, the KDC must always be online to generate keys on demand. Moreover, the KDC generates potentially many more keys than a PKG—one for each *pair* of correspondents. Conversely, a KDC can generate symmetric keys quickly; a PKG needs much more computation to derive an identity-based decryption key.

There are also trade-offs from Alice's perspective. In IBE, Alice does not need to contact the trusted authority at all after obtaining its public key; she can encrypt to any of the PKG's clients during any time period without the PKG's assistance. In Kerberos, Alice must (at a minimum) contact the KDC every time she wants to communicate with someone new. She may need to contact the KDC even more frequently if she does not cache session keys that she receives from the KDC (which would consume memory), or if the session keys are valid for short time periods. Also, Alice's interaction with the KDC in Kerberos causes additional delay and bandwidth consumption and may make the protocol less reliable. Conversely, in Kerberos, Alice can find out immediately if Bob has been revoked; in IBE, Alice can only assume that Bob has been revoked if he does not respond appropriately (implicitly indicating that he cannot decrypt her message).

### IBE versus Mediated IBE

Mediated IBE—introduced by Ding and Tsudik (2003)—is similar to IBE in that Alice needs only Bob's identity and the public key of Bob's PKG to encrypt. The essential difference is in how decryption is performed. In mediated IBE, the PKG splits the decryption key for Bob's

identity between Bob and an entity called a “semitrusted mediator” (SEM). Bob must cooperate with his SEM every time he wants to decrypt a message; Bob cannot decrypt alone (nor can the SEM). The advantage of this arrangement over IBE is that it permits instant (as opposed to periodic) revocation; if Bob loses his decryption privileges, the SEM simply refuses to help him decrypt. The disadvantage of mediated IBE is that it’s not very scalable; because an SEM must cooperate in every decryption operation and must store a partial decryption key for each of its clients, mediated IBE is perhaps best suited to “enterprise” settings in which the clientele is small. As in IBE, the PKG has private key escrow.

Libert and Quisquater (2003b) and Baek and Zheng (2004) describe how a concrete mediated IBE scheme can be derived from the Boneh–Franklin IBE scheme; the latter proves that the resulting scheme is chosen ciphertext secure.

In comparing mediated IBE with IBE, one question to consider is whether revocation really needs to be immediate. For enterprise settings, where a fired employee can cause significant damage if its privileges are not revoked promptly, the answer may be yes. For other settings, such as when a client wants to revoke its key after it realizes that it left its wireless device on the train *several hours ago*, immediate revocation may be overkill—that is, it may be a less significant consideration than mediated IBE’s performance disadvantages (particularly its lack of scalability).

Also, in some contexts, mediated IBE may have few advantages over the following simple reencryption approach: Alice encrypts her message under the PKG’s public key, and (if Bob is entitled) the PKG decrypts and then reencrypts under Bob’s key. In both approaches, Alice needs only the PKG’s public key and Bob’s identity, whereas the PKG has private key escrow. The main difference is that, in mediated IBE, the PKG delegates partial decryption to an SEM rather than performing it itself. For a small clientele, where it may not make sense to have more than one SEM, delegation may not offer much advantage.

### IBE versus Certificate-Based Encryption and Certificateless PKE

Certificate-based encryption (CBE), proposed by Gentry (2003), and certificateless PKE (CL-PKE), subsequently proposed by Al-Riyami and Paterson (2003), are designed to preserve some of the advantages of IBE while eliminating private key escrow.

In CBE, Bob generates his own public/private key pair ( $P_{Bob}, S_{Bob}$ ), as in a regular PKI. Also, Bob obtains his certificate from his CA as he would in a regular PKI: he gives the CA  $P_{Bob}$  and his proof of identity, and the CA returns its digital signature on  $(Bob, P_{Bob}, time_t)$  or something similar. The difference from PKI is that Bob’s certificate  $C_{Bob,t}$  also functions as a secondary decryption key, as in IBE. This “super-functional” certificate, which can be viewed as an identity-based decryption key on the identity  $(Bob, P_{Bob}, time_t)$ , allows the CA to simplify its infrastructure, as explained below.

To encrypt to Bob, Alice must know  $P_{Bob}$  and  $P_{CA}$ , as in a regular PKI. However, she does *not* need to obtain and verify Bob’s certificate  $C_{Bob,t}$  before encrypting to him. Instead, to oversimplify a bit, Alice doubly encrypts her message—once with  $P_{Bob}$  using standard PKE and once with the identity  $(Bob, P_{Bob}, time_t)$  using an IBE scheme. To decrypt, Bob needs two decryption keys:  $S_{Bob}$  and  $C_{Bob,t}$ . Although Alice does not verify explicitly that Bob has an up-to-date certificate  $C_{Bob,t}$ , she verifies it implicitly by generating a ciphertext that cannot be decrypted without it. (Conversely, Alice is certainly welcome to obtain and verify  $C_{Bob,t}$  explicitly before encrypting, if she desires.)

Because Alice must obtain  $P_{Bob}$  before encrypting to Bob anyway, it may not seem like much of an advantage that she does not need to obtain  $C_{Bob,t}$  (see Fig. 2). However, notice that  $P_{Bob}$  is *long-lived* information (i.e., Bob will probably change his public key only rarely, perhaps once per year). Conversely, Bob’s certificate status information should be *fresh* (e.g., updated daily or hourly); indeed, the frequency of certificate status updates determines the time granularity of revocation. Thus, from

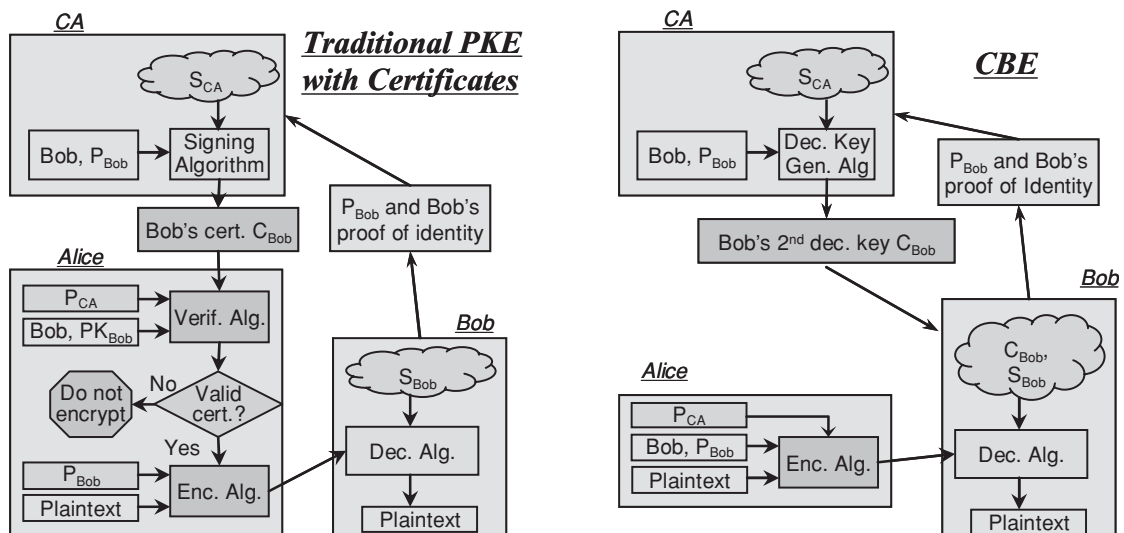

Figure 2: Comparison of PKI-supported PKE with CBE.

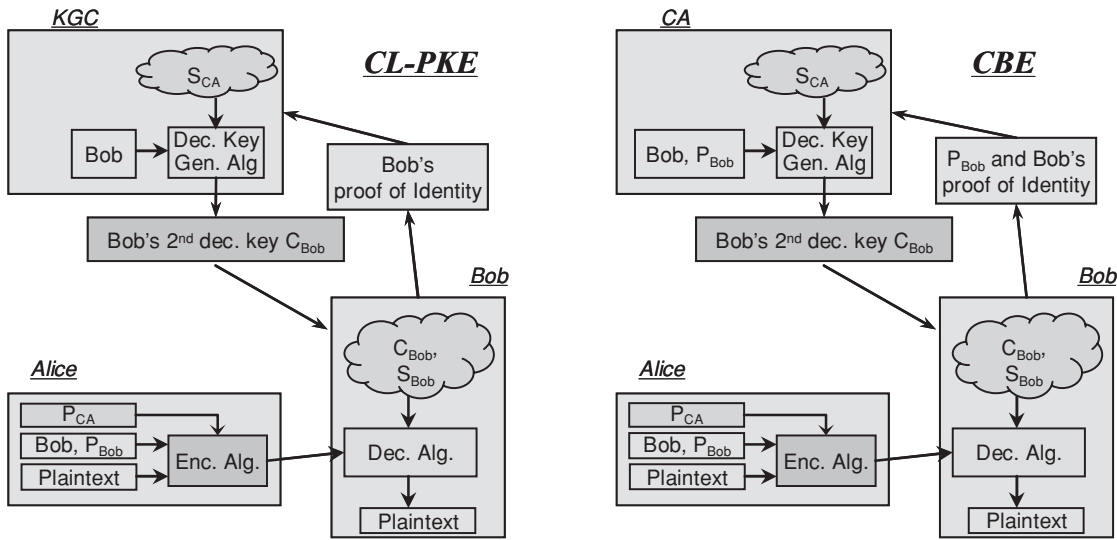

Figure 3: Comparison of CL-PKE with CBE.

Alice’s perspective, CBE is more convenient than PKI-supported PKE. In CBE, Alice needs only to obtain new information about Bob when he changes his public key; in PKI-supported PKE, she must obtain new information about him for each new time period that she encrypts to him.

Similarly, CBE is more convenient than PKI-supported PKE from the CA’s perspective. The CA does not need to set up infrastructure to distribute fresh certificate status information to third parties. Instead, like a PKG in IBE, the CA only needs to distribute certificates (i.e., identity-based decryption keys) to its clients, using a “push” model if desired. Overall, CBE allows a CA to enjoy many of the same infrastructural advantages as a PKG in IBE (discussed under “Advantages of IBE”), including reduced costs and infrastructure, a more sensible business model, and decreased susceptibility to DoS attacks.

Compared to IBE, CBE has the disadvantage that Bob’s public key must be obtained and distributed. The main advantage of CBE is that, unlike the PKG in IBE, the CA in CBE does not have escrow; it cannot decrypt Alice’s message to Bob because it does not know  $S_{Bob}$ . This is important from a privacy perspective. Also, because the CA does not have escrow, an attacker that compromises the CA cannot immediately decrypt messages sent to the CA’s clients; thus, the consequences of a CA compromise in CBE are less severe than those of a PKG compromise in IBE. A final advantage is that, unlike an identity-based decryption key in IBE, the CA can send  $C_{Bob}$  to Bob over an insecure channel, because nobody can decrypt his messages without  $S_{Bob}$ . Gentry (2003) also provides a concrete CBE scheme that is a relatively straightforward and efficient adaptation of the Boneh–Franklin IBE scheme and describes how a CBE CA can arrange its clients in a hierarchical fashion to improve its efficiency and scalability.

CL-PKE, proposed by Al-Riyami and Paterson (2003), is quite similar to CBE (see Fig. 3). The main difference is that the trusted authority, which is called a key generation center (KGC) in their scheme, “signs” only

Bob’s identity to generate  $C_{Bob}$  (which they call a “partial private key”). The main advantage of this arrangement is that Bob can use multiple public keys with the same identity without needing to get multiple values of  $C_{Bob}$  from the KGC. A disadvantage is that the KGC must send  $C_{Bob}$  via a secure channel, because otherwise Bob’s identity could be usurped. As a corollary,  $C_{Bob}$  cannot also serve as a certificate that Alice has the option of explicitly verifying.

Al-Riyami and Paterson also provide certificateless signature and key agreement schemes, but the advantages of “certificateless PKC” are greatest in the encryption context (for reasons similar to those discussed in connection with IBC). Yun and Lee (2004) provide generic constructions of certificateless encryption and signature schemes. Kang, Park, and Hahn (2004) provide a certificate-based signature (CBS) designed to be compatible (in particular, it uses the same parameters) with Gentry’s CBE scheme.

### IBE versus Domain-Based IBE

Two papers—Chen, Harrison, Moss, Soldera, and Smart (2002) and Smetters and Durfee (2003)—suggest using hybrid PKI/IBE approach in which companies or domains have public keys that must be distributed and obtained, but these companies or domains use an IBE scheme to generate private keys for their employees or clients. To encrypt to Bob, Alice must obtain Bob’s identity and the public key of Bob’s company; a CA must distribute the public key of Bob’s company to third parties.

As one would expect, the advantages and disadvantages of this hybrid approach, which we call domain-based IBE (DBIBE), lie in between those of PKI and IBE. DBIBE probably reduces the number of public keys relative to traditional PKI, but probably not so much that it becomes practical for users or applications to store these public keys locally. Thus, some infrastructure may be necessary to distribute public keys and certificates.

Unlike in IBE and CBE, the CA in DBIBE must distribute fresh certificate status information concerning the domain-based public keys to third parties for each time

period. Thus, if Alice encrypts to the same person during different time periods using DBIBE, she can use the same domain-based public key, but she must recheck this public key's certificate status; this check is unnecessary in IBE and CBE. Conversely, if Alice encrypts to different people in the same domain during the same time period, Alice need not obtain new information when using IBE or DBIBE; in CBE, she must obtain the second person's public key.

Relative to an IBE scheme managed by a "global" PKG, DBIBE mitigates the key escrow problem somewhat; DBIBE PKGs have escrow only over clients in their respective domains. Relative to CBE, such domain-based escrow may be a disadvantage in some contexts [though it may be acceptable (or even desirable) in others—e.g., where a company may wish to have access to its employee's e-mails].

## THE GUILLOU–QUISQUATER IBS SCHEME

At last, we describe some concrete IBC schemes. Although the advantages of IBS over PKS are not as significant as the advantages of IBE over PKE, this section describes an IBS scheme by Guillou and Quisquater (1988) that has some efficiency advantages over the widely used RSA PKS scheme, while achieving essentially identical security (in the random oracle model); although verifying a Guillou–Quisquater (GQ) signature takes longer than verifying a (low-public-exponent) RSA signature, GQ signature generation is faster. (As mentioned above, Shamir, 1985, described the first concrete IBS scheme in his initial article proposing the notion of IBC.)

The GQ signature scheme is as follows.

*Setup:* The PKG picks two large (e.g., 512-bit) primes  $p$  and  $q$  and sets  $n = pq$ . It also picks two cryptographic hash functions  $H_1: \{0, 1\}^* \rightarrow Z/nZ$  (from arbitrary length bit-strings to integers modulo  $n$ ) and  $H_2: \{0, 1\}^* \rightarrow [0, 2^k - 1]$ , where  $k$  bits is a suitable hash output size (e.g., 160 bits for SHA-1). Finally, it picks a prime number  $e > 2^k$  that is relatively prime to  $\varphi(n) = (p-1)(q-1)$  and computes  $d$  such that  $ed \equiv 1 \pmod{\varphi(n)}$ . The PKG keeps the values  $(p, q, d)$  secret; its public key includes  $(n, e, H_1, H_2)$  and possibly other information, such as the PKG's "schedule" for issuing private keys to its clients.

*Private Key Generation:* Given Bob's identity string  $ID_{\text{Bob}} \in \{0, 1\}^*$ , the PKG sets  $s_{\text{Bob}} \equiv (H_1(ID_{\text{Bob}}))^d \pmod{n}$ . It sends  $s_{\text{Bob}}$  to Bob via a secure channel.

*Signing:* To sign the message  $m$ , Bob:

- Generates a random number  $r \in Z/nZ$  with uniform distribution
- Computes  $R = r^e \pmod{n}$  and sets  $c = H_2(m \| R)$
- Computes  $S = rs_{\text{Bob}}^c \pmod{n}$  and sends the signature  $(S, c)$  to Alice

*Verification:* Alice computes  $R' = S^e / (H_1(ID_{\text{Bob}}))^c \pmod{n}$  and confirms that  $c = H_2(m \| R')$ .

In the GQ IBS scheme, Alice does not need to obtain an individual public key for Bob; instead, she needs only his PKG's public key and his identity  $ID_{\text{Bob}}$ . Also, for a

1024-bit modulus  $n$ , the signature in GQ is about  $1024 + 160 = 1184$  bits for typical parameters, much shorter than the combination of an RSA signature, RSA public key and RSA public key certificate, which may be  $3 \times 1024 = 3072$  bits overall. GQ's signing and verification time are each dominated by two exponentiations, with exponents about  $k$  bits apiece. Conversely, the RSA PKS scheme may use a small public exponent (e.g.,  $e = 3$ ), allowing very fast verification; however, signing exponent is typically very long (e.g., 1024 bits), making signature generation slower than in GQ.

## COCKS'S IDENTITY-BASED ENCRYPTION SCHEME

Cocks's IBE scheme (2001) is fairly lightweight computationally, but it involves significant ciphertext expansion (i.e., the length of the ciphertext is many times the length of the plaintext). For this reason, and because pairings have turned out to be a remarkably versatile cryptographic tool, the Boneh–Franklin IBE scheme has received much more attention. However, we review Cocks's scheme for completeness.

*Setup:* The PKG picks two large (e.g., 512-bit) primes  $p$  and  $q$  satisfying  $p \equiv q \equiv 3 \pmod{4}$  and sets  $n = pq$ . It also picks a cryptographic hash function  $H: \{0, 1\}^* \rightarrow Z/nZ$ . The PKG keeps the values  $(p, q)$  secret; its public key includes  $(n, H)$  and possibly other information, such as the PKG's "schedule" for issuing private keys to its clients.

*Private Key Generation:* Given Bob's identity string  $ID_{\text{Bob}} \in \{0, 1\}^*$ , the PKG determines the smallest  $i$  such that the Jacobi symbol of  $a_i = H(i, ID_{\text{Bob}})$  modulo  $n$  is 1:

$$\left(\frac{a_i}{n}\right) = 1.$$

The PKG computes Bob's private key as  $r_i = a_i^{(n+5-p-q)/8} \pmod{n}$ , which satisfies either  $r_i^2 \equiv a_i \pmod{n}$  or  $r_i^2 \equiv -a_i \pmod{n}$ , as described in (Cocks, 2001).

*Encryption:* To encrypt to Bob using  $n$  and  $ID_{\text{Bob}}$ , Alice first generates Bob's encryption key  $a_i$ . (Notice that she can compute the Jacobi symbol of  $a_i$  modulo  $n$  without knowledge of  $n$ 's factorization.) Alice does not know whether Bob's private key is a modular square root of  $a_i$  or  $-a_i$ ; thus, she must, in effect, generate two ciphertexts, the first of which she generates as follows. Alice generates a symmetric key  $k$  and encrypts the plaintext message  $m$  with it. She encrypts each bit of the symmetric key separately. To send a bit  $b \in \{-1, 1\}$  of the symmetric key, she picks a random  $t \in Z/nZ$  such that

$$\left(\frac{t}{n}\right) = b,$$

and sends the ciphertext  $c \equiv t + a_i/t \pmod{n}$ .

*Decryption:* To recover  $b$  from  $c$ , Bob computes  $c + 2r_i \equiv t + 2r_i + a_i/t \equiv t(1 + r_i/t)^2 \pmod{n}$  and then computes the following:

$$\left(\frac{c + 2r_i}{n}\right) = \left(\frac{t}{n}\right) = b.$$

The two Jacobi symbols are identical because, modulo  $n$ ,  $c + 2r_i$  equals  $t$  times a quadratic residue. Bob must also perform the encryption procedure for  $-a_i$ , choosing a different random value of  $t$ . Once the complete symmetric key  $k$  is obtained, Bob can decrypt the plaintext message  $m$ .

In terms of performance, about  $2 \times 128 \times \log n \approx 262144$  ciphertext bits are needed to encrypt a 128-bits AES key; thus, the communication complexity of Cocks's scheme is quite high. Bob needs to perform the decryption procedure only once for each bit of the symmetric key, depending on whether  $r_i$  is a modular square root of  $a_i$  or  $-a_i$ ; because each decryption involves only a fast Jacobi symbol computation, Cocks's scheme is quite practical in terms of computation.

Although Cocks's scheme has significant performance disadvantages relative to Boneh–Franklin, it has the advantage that its security is based on the quadratic residuosity problem (an old, well-established hard problem in cryptography), whereas the security of Boneh–Franklin is based on the comparatively new and less-studied “Bilinear Diffie–Hellman” problem. The quadratic residuosity problem is as follows: given a modulus  $n$  of unknown factorization and a number  $a$  whose Jacobi symbol modulo  $n$  is 1, decide whether there exists some  $x \in \mathbb{Z}/n\mathbb{Z}$  such that  $x^2 \equiv a \pmod{n}$  (i.e., whether  $a$  is a quadratic residue). Currently, the fastest known general algorithm for deciding quadratic residuosity, when  $n$  and  $a$  are generated as above, involves first factoring  $n$ .

Cocks proves the semantic security of his scheme assuming the hardness of the quadratic residuosity problem. When Cocks's IBE scheme is used in combination with certain transforms, such as that described in (Fujisaki & Okamoto, 1999), the resulting hybrid encryption scheme can be proven secure against chosen-ciphertext attacks in the random oracle model. (We discuss the Fujisaki–Okamoto transform more explicitly in connection with the Boneh–Franklin IBE scheme.)

## IDENTIFY-BASED ENCRYPTION USING PAIRINGS

In 2001, Boneh and Franklin discovered a very practical IBE scheme that uses a mapping over elliptic curves (and, more generally, over abelian varieties) called a “pairing”; they also rigorously proved its security (in the “Random Oracle Model”) against chosen-ciphertext attacks under the assumption that a certain number-theoretic problem, called the “Bilinear Diffie–Hellman Problem,” is “hard” to solve. (Sakai, Ohgishi, & Kasahara, 2001, informally presented a similar pairing-based IBE scheme without chosen ciphertext security.)

Before discussing the Boneh–Franklin IBE scheme in detail, we provide some background on the relevant mathematical properties of pairings and discuss previous uses of pairings in cryptography.

### Mathematical Background (on Pairings)

A “pairing”  $\hat{e}: G_1 \times G_1 \rightarrow G_2$  is a mapping that takes two elements of a first cyclic algebraic group of order  $q$  and maps them to an element of a second cyclic algebraic group, also of order  $q$ . Modified Weil and Tate pairings

(e.g., as described in Joux, 2000; Boneh & Franklin, 2001; or Barreto, Kim, Lynn, & Scott, 2002)—seem to be particularly useful for cryptography. They map two elements of a  $q$ -order subgroup of an elliptic curve or abelian variety  $E(F_{p^k})$  to an element in a  $q$ -order subgroup of a finite field  $F_{p^{\ell}}$  (for some integer  $\ell \geq 1$ , which depends on the particular curve or variety). For convenience, we call a pairing “useful” if it also has the following desirable properties:

- *Bilinearity*:  $\hat{e}(aQ, bR) = \hat{e}(Q, R)^{ab}$  for all  $Q, R \in G_1$  and all  $a, b \in \mathbb{Z}$ .
- *Nondegeneracy*: The map does not send all pairs in  $G_1 \times G_1$  to the identity in  $G_2$ .
- *Computability*: An efficient algorithm exists to compute  $\hat{e}(Q, R)$  for any  $Q, R \in G_1$ .

For certain curves and varieties (e.g., *supersingular* ones), modified Weil and Tate pairings are useful pairings.

Below, we review some cryptographic uses of pairings. See Barreto (2004) for a comprehensive list of references related to pairing-based cryptography. For information on the implementation and performance of pairing-based cryptography, see Barreto, Kim, Lynn, and Scott (2002). Because pairing-based cryptography is relatively new, however, do not be surprised to see performance enhancements subsequent to the publication of this *Handbook*.

### Previous Uses of Pairings in Cryptography

The first significant use of useful pairings in cryptography was destructive—namely to cryptanalyze (or “break”) cryptosystems that use supersingular elliptic curves. The security of elliptic curve cryptosystems often relies on the hardness of the elliptic curve discrete logarithm (DL) problem:

*Discrete Logarithm (DL) Problem*: Given  $P \in G_1$  and  $aP$  (for unknown randomly chosen  $a \in \mathbb{Z}/q\mathbb{Z}$ ), compute  $a$ .

For certain elliptic curves, the DL problem is believed to be much harder than the DL problem for finite fields; this is basically why elliptic curve variants of common cryptosystems (e.g., Diffie–Hellman and ElGamal) can use smaller keys, making them faster and more efficient. However, Menezes, Okamoto, and Vanstone (1993) demonstrated that, because the Weil (and Tate) pairing  $\hat{e}: G_1 \times G_1 \rightarrow G_2$  is efficiently computable when  $G_1$  is a *supersingular* elliptic curve group (and  $G_2$  is a subgroup inside a finite field), pairings allow the supersingular elliptic curve DL problem to be reduced to the finite field DL problem. Specifically, given  $(P, aP)$ , one can efficiently compute  $g = \hat{e}(P, P)$  and  $g_a = \hat{e}(P, aP)$  and then use a subexponential index-calculus algorithms to compute the discrete logarithm of  $g_a$  with respect to  $g$  within the finite field.

Sakai, Ohgishi, and Kasahara (1999) and Joux (2000) were the first to discover significant *constructive* applications of pairings in cryptography. Joux proposed a scheme for “tripartite Diffie–Hellman”—that is, a one-round key agreement scheme analogous to Diffie–Hellman in which three (rather than just two) parties derive a shared secret. In this scheme, each of the three

parties—say, Alice, Bob, and Carol—chooses a random value in  $Z/qZ$ —say,  $a, b$ , and  $c$ . Alice sends  $aP$  to Bob and Carol; similarly, Bob and Carol transmit  $bP$  and  $cP$ . At this point, each of the three parties can compute  $s = \hat{e}(P, P)^{abc}$ , their shared secret; for example, Alice—who knows  $a, bP$ , and  $cP$ —can compute  $s$  as  $\hat{e}(bP, cP)^a$ .

Sakai, Ohgishi, and Kasahara proposed, among other things, a *noninteractive* two-party key agreement protocol (Sakai, Ohgishi, & Kasahara, 2000). In their protocol, a trusted third party, which we call a PKG, generates a private key  $s \in Z/qZ$  and publishes  $P, sP$ , as well as other relevant information (e.g., hash functions and key update schedules). Alice and Bob have public keys  $P_A, P_B \in G_1$ . These public keys may be identity based—for example, one may set  $P_A = H(\text{ID}_A)$ , where  $\text{ID}_A$  is Alice’s identity string, and  $H: \{0, 1\} \rightarrow G_1$  is a specified cryptographic hash function. After Alice and Bob receive their private keys— $sP_A$  and  $sP_B$ , respectively—from the PKG, they may each compute their shared secret  $\hat{e}(P_A, P_B)^s$  non-interactively; for example, Alice computes this value as  $\hat{e}(sP_A, P_B)$ .

Both of these early pairing-based cryptosystems rely on the hardness of the following problem.

**Bilinear Diffie–Hellman (BDH) Problem:** Given a randomly chosen  $P \in G_1$ , as well as  $aP, bP$ , and  $cP$  (for unknown randomly chosen  $a, b, c \in Z/qZ$ ), compute  $\hat{e}(P, P)^{abc}$ .

The BDH problem is analogous to the well-known Diffie–Hellman (DH) problem, which (over the group  $G_1$ ) is defined as follows.

**Diffie–Hellman (DH) Problem:** Given a randomly chosen  $P \in G_1$ , as well as  $aP, bP$  (for unknown randomly chosen  $a, b \in Z/qZ$ ), compute  $abP$ .

Notice that, for the BDH problem to be hard, it must be hard to solve the DH problem over both  $G_1$  and  $G_2$ . If the DH problem over  $G_1$  is easy, one can efficiently compute  $abP$  from  $aP$  and  $bP$  and then compute  $\hat{e}(P, P)^{abc} = \hat{e}(abP, cP)$ . If the DH problem over  $G_2$  is easy, one can efficiently compute  $\hat{e}(P, P)^{abc}$  from  $\hat{e}(P, P)^{ab}$  and  $\hat{e}(P, P)^c$ , after computing  $\hat{e}(P, P)^{ab} = \hat{e}(aP, bP)$  and  $\hat{e}(P, P)^c = \hat{e}(P, cP)$ .

The Boneh–Franklin IBE scheme, which we now describe, also relies on the hardness of the BDH problem.

## The Boneh–Franklin IBE Scheme

**Setup:** The PKG generates groups  $G_1$  and  $G_2$  of prime order  $q$  with a useful pairing  $\hat{e}: G_1 \times G_1 \rightarrow G_2$ , an arbitrary generator  $P$  of the group  $G_1$ , and two cryptographic hash functions  $H_1: \{0, 1\}^* \rightarrow G_1$  and  $H_2: G_2 \rightarrow \{0, 1\}^k$ . (The message space for the IBE scheme will be  $\{0, 1\}^k$ , the set of  $k$ -bit strings.) The PKG then picks random  $s \in Z/qZ$ , keeping this value secret. Its public key includes  $(G_1, G_2, \hat{e}, P, sP, H_1, H_2)$  and possibly other information, such as the PKG’s “schedule” for issuing private keys to its clients.

**Private Key Generation:** Given Bob’s identity string  $\text{ID}_{\text{Bob}} \in \{0, 1\}^*$ , the PKG computes Bob’s private key as  $sP_{\text{Bob}}$ , where  $P_{\text{Bob}} = H_1(\text{ID}_{\text{Bob}})$ .

**Encryption:** To encrypt a  $k$ -bit message  $m$  to Bob using  $\text{ID}_{\text{Bob}}$  and the PKG’s public key, Alice computes  $P_{\text{Bob}} = H_1(\text{ID}_{\text{Bob}})$ , generates random  $r \in Z/qZ$ , and computes the ciphertext  $c = [rP, m \oplus H_2(g^r)]$ , where  $g = \hat{e}(sP, P_{\text{Bob}}) \in G_2$ .

**Decryption:** To decrypt  $c = [U, v]$ , Bob computes,  $v \oplus H_2(\hat{e}(U, sP_{\text{Bob}}))$ , which should equal  $m$ .

The above scheme is provably secure (in the random oracle model) against chosen-plaintext attacks assuming the BDH problem is hard, but it is not secure against adversaries capable of adaptive chosen-ciphertext attack. However, one can get a chosen-ciphertext secure scheme by applying the Fujisaki–Okamoto transform, as follows. The PKG includes two additional cryptographic hash functions  $H_3: \{0, 1\}^{k+k_0} \rightarrow Z/qZ$  and  $H_4: \{0, 1\}^{k_0} \rightarrow \{0, 1\}^{k_{\text{sym}}}$  within its public key, where  $k_0$  is the length of a random string  $\sigma$  (e.g., 160 bits) used in the modified encryption procedure and  $k_{\text{sym}}$  is the length of a random key for a symmetric encryption scheme  $E$  (e.g., 128 bits for AES), also used in the modified encryption procedure. Also,  $H_2$  is modified slightly so that its output is  $k_\sigma$  bits. Then, modified encryption and decryption proceed as follows.

**Encryption:** To encrypt message  $m$  to Bob using  $\text{ID}_{\text{Bob}}$  and the PKG’s public key, Alice computes  $P_{\text{Bob}} = H_1(\text{ID}_{\text{Bob}})$ , generates random  $\sigma \in \{0, 1\}^{k_0}$  and computes  $r = H_3(m \parallel \sigma)$ . She sets the ciphertext to be  $m = [rP, \sigma \oplus H_2(g^r), E_{H_4(\sigma)}(m)]$ , where  $g = \hat{e}(sP, P_{\text{Bob}}) \in G_2$ .

**Decryption:** To decrypt  $c = [U, v, w]$ , Bob sets  $\sigma' = v \oplus H_2(\hat{e}(U, sP_{\text{Bob}}))$ , sets  $m' = E_{H_4(\sigma')}^{-1}(w)$ , and sets  $r' = H_3(m' \parallel \sigma')$ . Bob checks that  $U = r'P$ ; if not, the decryption process fails. If so, Bob concludes that  $m'$  is the plaintext.

## Pairing-Based IBE Without Random Oracles

Recently, Boneh and Boyen (2004) proposed a pairing-based IBE scheme that is provably secure *without random oracles* against adaptive chosen-ciphertext attacks, assuming the following problem is hard:

**Decision Bilinear Diffie–Hellman (Decision BDH) Problem:** Let  $S_0$  be the set of tuples  $(P, aP, bP, cP, g^d)$ , where  $P \in G_1; a, b, c \in Z/qZ; g = \hat{e}(P, P)$  and  $d = abc \pmod{q}$ . Let  $S_1$  be the set of tuples  $(P, aP, bP, cP, g^d)$  without the restriction on  $d$ . Suppose that a tuple  $(P, aP, bP, cP, g^d)$  is selected by choosing  $k \in \{0, 1\}$  uniformly and drawing a tuple uniformly from  $S_k$ . Given the tuple, decide whether  $k$  equals 0 or 1.

The Decision BDH problem is hard if it is computationally infeasible to decide correctly with probability nonnegligibly more than  $1/2$ . The scheme presented below has only semantic security (not chosen-ciphertext security); chosen-ciphertext security can be achieved through a transform by Canetti, Halevi, and Katz (2004). The scheme is described in a way that incorporates and generalizes a simplification by Waters (2004) that improves the efficiency of the Boneh–Boyen scheme.

**Setup:** The PKG generates  $G_1, G_2, \hat{e}$ , and  $P$  as before. For some integer  $d$  (Waters implicitly sets  $d = 161$ ), the PKG also generates random  $(P_0, \dots, P_d) \in G_1$ . Finally, it

picks a random  $s \in Z/qZ$  and stores  $sP_0$  as its secret key. It publishes the key  $(G_1, G_2, \hat{e}, P, sP, P_0, P_1, \dots, P_d, V, \theta)$ , where  $V$  is the description of a set of  $d$ -dimensional integer vectors and  $\theta: \{0, 1\}^* \rightarrow V$  is a (collision-resistant) mapping of user identity strings to vectors in  $V$ . [Waters implicitly sets,  $V = \{(z_1, \dots, z_d) : z_1 = 1; \forall 2 \leq i \leq d, z_i \in \{0, 1\}\}$ , and suggests a collision-resistant hash function (such as SHA-1) to map identities to 160-bit strings  $(z_2, \dots, z_{161})$ .] The PKG also may publish other information, such as its “schedule” for issuing private keys to its clients.

*Private Key Generation:* Given Bob’s identity string  $ID_{Bob} \in \{0, 1\}^*$ , the PKG computes  $(z_1, \dots, z_d) = \theta(ID_{Bob}) \in V$ . The PKG then generates a random  $t \in Z/qZ$ , and sets Bob’s private key  $(S_{Bob}, T_{Bob})$  according to  $S_{Bob} = sP_0 + tP_{Bob}$  and  $T_{Bob} = tP$ , where  $P_{Bob} = z_1P_1 + \dots + z_dP_d$ .

*Encryption:* To encrypt  $m \in G_2$ , Alice computes  $(z_1, \dots, z_d) = \theta(ID_{Bob})$  and  $P_{Bob} = z_1P_1 + \dots + z_dP_d$ . She generates a random  $r \in Z/qZ$ , and sends the ciphertext  $c = [rP, rP_{Bob}, m \cdot g^r]$ , where  $g = \hat{e}(sP, P_0) \in G_2$ .

*Decryption:* To decrypt  $c = [U, U_{Bob}, v]$ , Bob computes  $v \cdot \frac{e(T_{Bob}, U_{Bob})}{e(S_{Bob}, U)}$ , which should equal  $m$ .

Using Waters’s parameters, the PKG’s public key is unfortunately quite large, because it includes of 164 elements of  $G_1$ . Although the details are omitted here, it turns out that one can use substantially smaller values of  $d$  (e.g.,  $d = 5$ ) while maintaining provable security if one allows the integers  $z_i$  to vary within a larger range than  $[0, 1]$  (e.g., within  $[0, 2^{160/(d-1)} - 1]$ ). This allows the PKG’s public key to be substantially smaller. Either way, encryption and decryption are reasonably efficient, taking only about twice as much time as in Boneh–Franklin, even though Boneh–Franklin is known to be secure only in the random oracle model.

## HIERARCHICAL IDENTITY-BASED ENCRYPTION

IBE lifts the public key and certificate management problem from the client level to the PKG level; to encrypt to Bob, Alice needs to obtain a public key (and possibly a public key certificate) only for Bob’s PKG, not for Bob. This advantage of IBE is maximized when there are very few PKGs in the system. In this case, after Alice obtains and stores the public keys of these PKGs, she (ideally) need not fetch anyone’s public key ever again.

However, a disadvantage of IBE is that private key generation can become computationally expensive for the PKG if it has a large clientele; particularly, if its chosen time granularity of key updates (and, hence, its time granularity of key “revocation”) is very small. Of course, one way to solve this problem (and keep fine time granularity) is to have many PKGs, each with a clientele of manageable size, but this solution does not maximize the abovementioned advantage of IBE; if there are many PKGs, Alice may need to obtain many public keys.

In traditional PKI, this problem is addressed by having a hierarchy of certification authorities. In a hierarchical PKI, Bob is certified by a CA, which (in turn) is certified by another CA, and so on, up to a “root” CA; the result is a “certificate chain” connecting Bob to his root CA. Before encrypting to Bob, Alice must obtain Bob’s certificate

chain, along with his public key and the public keys of the intermediate CAs in his certificate chain. As long as Alice knows the public key of Bob’s root CA beforehand, Alice can verify that Bob’s public key and those of the intermediate CAs have been properly certified; she can then encrypt to Bob. From a CA’s perspective, hierarchical PKI allows a CA to delegate its certificate generation to “lower level” CAs. This delegation is doubly advantageous; not only does it allow a CA to reduce its workload, but it also gives the task of checking the correctness of Bob’s claimed identity information to a lower level CA that probably has a closer relationship with Bob.

To get the advantages of hierarchical PKI, but without the need to distribute and obtain certificate chains, Horwitz and Lynn (2002) introduced the notion of “hierarchical IBE”; they also described a hierarchical IBE scheme that is practical only for a two-level hierarchy. In hierarchical IBE, Bob’s private key is generated by his *parent* PKG after it receives its private key from Bob’s grandparent PKG, and so on, up to a “root” PKG. For example, if Bob’s e-mail address is Bob@cs.univ.edu, then his corresponding “ID-tuple” is (edu,univ,cs,Bob), and his private key is generated by his computer science department [which has ID-tuple (edu,univ,cs)] after it receives its private key from the university. Alice can encrypt to Bob if she knows his identity [e.g., (edu,univ,cs,Bob)] and the public key of his *root* PKG. She does not need the public key of Bob’s parent PKG; indeed, neither Bob nor any of his “ancestor” PKGs below the root has any public keys or certificates at all. Hierarchical IBE also enjoys the double advantage of delegable private key generation: local identity checking and better scalability. Once it gets its own private key, Bob’s parent PKG (e.g., his computer science department, which probably has a close relationship with him) can generate Bob’s private key without any interaction with higher level PKGs (thereby enhancing scalability).

A disadvantage of hierarchical IBE is that Bob’s ancestors in the hierarchy have escrow (i.e., they can decrypt ciphertexts directed to Bob). This escrow problem is unavoidable (just as it is to nonhierarchical IBE); it is inevitably the case that the federation of entities that generates Bob’s private key (the set of Bob’s ancestors, in this case) will be able to decrypt Bob’s mail. However, in some cases, one can limit escrow to a subset of Bob’s ancestors. For example, Gentry and Silverberg (2002) describe a hierarchical IBE scheme in which Bob’s ancestors do not have escrow if they are higher in the hierarchy than Alice’s and Bob’s lowest level common ancestor. For example, if Alice and Bob are in the same computer science department, the computer science department has escrow, but the university and higher level ancestors do not.

Another disadvantage of hierarchical IBE is that it might be difficult for the various entities in the hierarchy to coordinate their key update schedules. Like public keys, key update schedules need to be obtained; thus, they should ideally be included in the root PKG’s public key, which is the only public key in the system. In this case, the root PKG’s public key will become very large if lower level PKGs are permitted to have different key update schedules; conversely, limiting the lower level PKGs to a “global” key update schedule reduces flexibility.

Below, we describe a concrete hierarchical IBE scheme, from Gentry and Silverberg (2002), that efficiently enables a hierarchy with an arbitrary number of levels. Although the Gentry–Silverberg scheme devolves into the Boneh–Franklin scheme when the hierarchy is only one level, hierarchical IBE is not merely a recursive application of IBE; instead, private key generation must be holistically integrated from top to bottom in the hierarchy. The Gentry–Silverberg hierarchical IBE scheme is as follows.

*Root PKG Setup:* The root PKG sets up like a PKG in Boneh–Franklin.

*Private Key Generation:* Let  $E_t$  be an entity with ID-tuple  $(ID_1, \dots, ID_t)$ , where  $(ID_1, \dots, ID_i)$  is the ID-tuple of  $E_t$ 's ancestor at level  $i$ . Then, to generate  $E_t$ 's private key,  $E_t$ 's parent:

- Computes  $P_t = H_1(ID_1, \dots, ID_t) \in G_1$ ;
- Generates random  $s_{t-1} \in Z/qZ$ , and sets  $Q_{t-1} = s_{t-1}P$ ;
- Sets  $S_t = S_{t-1} + s_{t-1}P_t$ , where  $S_{t-1} \in G_1$  is part of  $E_t$ 's parent's private key;
- Sends  $(S_t, Q_1, \dots, Q_{t-1})$  to  $E_t$  as  $E_t$ 's private key.

As “base” values for this recursion,  $S_0 = 0$  and  $s_0 = s$  (the root PKG's secret). An intermediate PKG at level  $i > 0$  can generate  $s_i$  randomly for each of its clients, or keep it fixed.

*Encryption:* To encrypt a  $k$ -bit message  $m$  to  $E_t$  using  $(ID_1, \dots, ID_t)$  and the root PKG's public key, Alice computes  $P_i = H_1(ID_1, \dots, ID_i) \in G_1$  for  $1 \leq i \leq t$ , generates random  $r \in Z/qZ$ , and computes the ciphertext  $c = [rP, rP_2, \dots, rP_t, m \oplus H_2(g^r)]$ , where  $g = \hat{e}(sP, P_1) \in G_2$ .

*Decryption:* To decrypt  $c = [U, U_2, \dots, U_t, v]$ ,  $E_t$  computes

$$v \oplus H_2 \left( \frac{e(U, S_t)}{\prod_{i=2}^t e(Q_{i-1}, U_i)} \right),$$

which should equal  $m$ .

As with Boneh–Franklin, the Fujisaki–Okamoto transform can be applied to the above hierarchical IBE scheme to make it secure (in the random oracle model) against adaptive chosen-ciphertext attacks, assuming the hardness of the BDH problem. Also, as noted by Boneh and Boyen (2004) and Waters (2004), one can construct a HIBE scheme that is provably secure without random oracles under the Decision BDH assumption by straightforwardly extending the techniques used for the nonhierarchical case.

As noted by Gentry and Silverberg (2002), when we take advantage of the observation (a recurring theme in this chapter) that an identity-based private key can also be viewed as the PKG's signature on that identity, the above secure HIBE scheme leads directly to a secure hierarchical IBS (HIBS) scheme, as follows. Root PKG setup and private key generation are the same as above. Then, to sign  $m$ , entity  $E_{t-1}$  generates a signature that looks like a private key on the tuple  $(ID_1, \dots, ID_{t-1}, m)$ —that is,  $E_{t-1}$ :

- Computes  $P_m = H_1(ID_1, \dots, ID_{t-1}, m) \in G_1$
- Generates random  $s_{t-1} \in Z/qZ$ , and sets  $Q_{t-1} = s_{t-1}P$

- Sets  $S_m = S_{t-1} + s_{t-1}P_m$ , where  $S_{t-1} \in G_1$  is part of  $E_{t-1}$ 's private key
- Sends  $(S_m, Q_1, \dots, Q_{t-1})$  as its signature on  $m$

The only proviso is that if one wants to treat private key generation and signing as distinct procedures, one should ensure that the message space (i.e., possible values of  $m$ ) does not overlap with the identity space (i.e., possible values of  $ID_t$ )—for example, by appending a different prefix to  $m$  than to  $ID_t$  before applying  $H_1$ . To verify  $E_{t-1}$ 's signature on  $m$ , confirm the following:

$$e(S_m, P) = e(sP, P_1)e(Q_{t-1}, P_m) \prod_{i=2}^t e(Q_{i-1}, P_i),$$

where  $P_m = H_1(ID_1, \dots, ID_{t-1}, m)$  and  $P_i = H_1(ID_1, \dots, ID_i)$  for  $1 \leq i \leq t - 1$ .

The security of the HIBS scheme follows immediately from the security of the HIBE scheme, because an attacker that can generate a HIBS forgery can generate a HIBE private key to which it is not entitled. However, HIBS can be proven secure in the random oracle model under a weaker assumption than the hardness of BDH—namely the hardness DH in  $G_1$  (cf. Bellare et al., 2004, and Libert & Quisquater, 2004).

## MORE THAN JUST IDENTITIES: EXTENDING IDENTITY-BASED CRYPTOGRAPHY

Not surprisingly, the techniques that enable IBE (especially pairings) are useful for more than just managing identities. Barreto (2004) has collected numerous references on the uses of pairings in cryptography, covering everything from fast pairing computation algorithms, to pairing-based functions that are verifiably random, to public key multicast encryption, to schemes that allow limited third-party searches on encrypted data. In this section, we briefly survey a few other pairing-based protocols, especially those that can properly be considered applications or extensions of IBC.

### Signature-Contingent Decryption

As mentioned under Introduction, IBE allows an encrypter to generate a ciphertext that is indecipherable until a specified authorizer signs some specified incidental data ID. Thus, one may view IBE as enabling “signature-contingent decryption” or “authorized decryption.” We have already seen one example of a “signature” being used as a decryption key—namely CBE; in CBE, the “signature” is a certificate issued by a CA. This subsection mentions some other applications of the “signature-contingent decryption” concept, beyond the usual context of simplifying PKI.

### Policy Enforcement and Controlling Workflow

Casassa Mont, Pearson, and Bramhall (2003) describe how IBE enables the creation of “sticky policies.” In their scenario, the incidental data ID is the “policy” that the encrypter trusts that the authorizer will enforce before it

issues the decryption key. As an example, they mention a DRM scenario: a content provider may encrypt its content such that a recipient device can decrypt it only if an authorizer confirms that the recipient's device has a compliant trusted platform. Using IBE, one can ensure that the encrypter's policy "sticks" to the encrypted content—that is, the authorizer must be aware of the policy before it can "sign" the policy by issuing the decryption key needed to recover the content.

Casassa Mont and Bramhall (2003) describe how IBE can be used to address the "late binding" problem, where it is not known beforehand exactly who will be the person filling a particular role. Using IBE, an encrypter can specify the role of a would-be decrypter; later, if the authorizer determines that a recipient satisfies that role, it "certifies" the recipient by giving it the appropriate decryption key, allowing the recipient to decrypt. Thus, IBE simplifies role-based access control.

### Public Key Encryption with Keyword Search

Consider the following scenario. Bob has an e-mail account with a service provider that he does not completely trust, but he wants to enable his service provider to sort his e-mail to some extent, even if his e-mail is encrypted. For example, Bob may want his service provider to route all encrypted e-mails containing an encryption of the keyword "Project X" into a special folder, without the service provider learning anything beyond the fact that these e-mails contain this common plaintext term. Independently, two recent articles—Waters, Balfanz, Durfee, and Smetters (2004) and Boneh, Di Crescenzo, Ostrovsky, and Persiano (2004)—construct "searchable public key encryption" (SPKE) schemes by building on the Boneh–Franklin IBE scheme. Waters et al. focus on the application of constructing an encrypted but searchable audit log; the log encrypts its entries in such a way that an "audit escrow agent" can enable less trusted "investigators" to search the log for specified keywords.

Essentially, the approach they use for constructing a SPKE scheme from the Boneh–Franklin IBE scheme is as follows. Alice creates a (preferably short) list of keywords that her message contains. For each keyword  $W$ , she uses an IBE scheme that encrypts  $k$ -bit messages to encrypt  $0^k$  (the string consisting of  $k$  zeros), using Bob's public key as the PKG's public key and using the keyword  $W$  itself as the identity. She appends the list of IBE ciphertexts to her encrypted message. If Bob wants to enable his service provider to distinguish which messages contain  $W$ , he behaves like a PKG and gives the service provider the identity-based decryption key (under his public key) for "identity"  $W$ , thereby effectively "signing" the keyword that can be searched. Then, the service provider can determine whether Alice included  $W$  in her list of keywords simply by attempting to decrypt each IBE ciphertext with the decryption key for the identity  $W$ ; if one of the ciphertexts decrypts to  $0^k$ ,  $W$  is in Alice's list (with high probability).

Boneh et al. show that IBE is actually necessary for the existence of searchable public key encryption (SPKE) schemes and suggests that the converse may be false. An IBE scheme can readily be used to construct a SPKE scheme only if the IBE scheme has "public key privacy;"

for example, given an IBE ciphertext  $c$  that is the encryption of  $0^k$  under identity  $W_1$  or identity  $W_2$ , it should be hard to distinguish which is the case. Without such public key privacy, the service provider (and other parties) could extract more information about Bob's e-mails than he wishes to permit. Although the Boneh–Franklin IBE scheme is public key private, Cocks's IBE scheme is not (see Boneh et al., 2004).

### Miscellaneous Applications

Next, we mention miscellaneous other extensions of IBC. These include using pairings to achieve key-insulated, forward-secure, and intrusion-resilient encryption, fuzzy IBE, secret handshakes, and simplified IPSec.

#### Key-Insulated, Intrusion-Resilient, and Forward-Secure Encryption

In a key-insulated, intrusion-resilient, or forward-secure encryption (or signature) scheme, a user may retain some measure of security even if its private key is compromised. In a key-insulated or intrusion-resilient scheme, the idea is that the user maintains two "modules" (e.g., a laptop and a phone). Although the user maintains a fixed *public* key, the two modules interact at the beginning of each time period to generate the time period's *private* key, which the second module can use to perform private key operations (e.g., decryption or signing). A scheme is called *key-insulated* (Dodis, Katz, Xu, & Yung, 2002) if an adversary that is given access to all of the second module's secrets for one or more time periods (e.g., when the adversary steals the user's phone) still cannot compromise the scheme's security for other time periods. Constructing a key-insulated cryptosystem from an identity-based cryptosystem is trivial: in time period  $t$ , the first module [which acts as a PKG with key pair  $(P_{\text{PKG}}, S_{\text{PKG}})$ ] gives the second module the private key for identity " $t$ "; then, taking key-insulated encryption as an example, the sender encrypts its message using  $P_{\text{PKG}}$  and  $t$ . (Unfortunately, unlike IBC, key insulation requires a private and authenticated channel to exist between the two modules *even after all secrets on the second module are compromised*; perhaps, in some circumstances, this difficult requirement could be met using a physical link.)

*Strong key insulation and intrusion resilience* offer even stronger security guarantees. A strongly key-insulated scheme is not only key-insulated but also retains its security against adversaries that compromise the first module but not the second. Bellare and Palacio (2002) construct a strongly key-insulated encryption scheme by starting with the trivial key-insulated encryption scheme derived from Boneh–Franklin and then splitting the PKG's secret key between the first and second modules. An intrusion-resilient scheme retains its security as long as the adversary does not compromise both modules in the same time period. Dodis, Franklin, Katz, Miyaji, and Yung (2003) describe an encryption scheme that achieves intrusion resilience (roughly speaking) by splitting the PKG's functionality between the two modules, which then proactively update their shares of the PKG's secret at the beginning of each time period. Like key-insulated schemes,

strongly key-insulated and intrusion-resilient schemes suffer from the problematic secure channel requirement described above. The scheme of Dodis et al. also incorporates a technique to achieve forward security.

In a forward-secure scheme, a user maintains a fixed public key, but it evolves its private key forward in such a way that, if its private key for time period  $t$  is compromised, the attacker still cannot perform private key operations for time periods  $t - 1$  or earlier. (However, all future time periods are compromised, because the attacker can now also evolve the private key forward.) Thus, although the user needs only one module, it obtains a weaker security guarantee than key insulation. Canetti, Halevi, and Katz (2003) constructed the first non-trivial forward-secure encryption scheme by adapting the HIBE scheme of Gentry and Silverberg (2002). At a high level, their idea is to arrange the time periods (for convenience, assume there are  $2^k$  of them) from left to right as leaves in a binary tree, associate a HIBE identity tuple to each node (including interior nodes) in the tree depending on the node's position in the hierarchy, and have the user evolve its periodic private key by traversing the tree from left to right while generating (using the Gentry-Silverberg private key generation procedure) and caching the appropriate node private keys. To encrypt a message to Bob, Alice treats Bob's public key as if it were the public key of a root PKG in a HIBE scheme, expresses the time period as if it were a  $k$ -element ID-tuple, and then applies HIBE.

### Fuzzy Identity-Based Encryption

For IBC to be practical, identity strings must be chosen in a systematic way that ensures (at least with high probability) the uniqueness of each identity. Traditional identities, such as names (e.g., John Smith), do not satisfy this criterion, although one could mitigate this problem by adding more information to the name-space (e.g., place of residence) or making it hierarchical. This chapter has used e-mail addresses as a running example of a name-space offering uniqueness, but one may prefer to use identity strings that are more closely and reliably tied to actual people. One option is to use biometrics, such as fingerprints or voice prints (or some combination), to construct globally unique personal identifiers. Unfortunately, the measured value of a biometric tends to vary each time the biometric is sampled.

To use biometrics as identities in IBC, a couple of solutions have been proposed. One is to treat the sampled biometric as a corrupted codeword in an error-correcting code. The PKG gives the user the identity-based private key corresponding to the codeword closest to the scanned value of its biometric. To encrypt to the user, a sender might first scan the user's the biometric and then encrypt using the closest codeword (which is hopefully the same as it was in the PKG's scan). Sahai and Waters (2004) propose a different approach, called "fuzzy IBE," that modifies Boneh-Franklin to allow a user to decrypt even if its decryption key corresponds to an identity  $ID$  that is different from the identity  $ID'$  that the sender uses to encrypt, as long as  $ID$  and  $ID'$  are sufficiently close under some metric, such as Hamming distance.

### Secret Handshakes

Balfanz et al., (2003) describe a "secret handshake" scheme, which is also based on the Sakai-Ohgishi-Kasahara noninteractive key agreement protocol. If Alice believes Bob is a member of group B, and Bob believes Alice is a member of group A, their scheme allows Alice and Bob to confirm the correctness of these memberships; if either membership is incorrect, neither party learns which groups the other party *actually* belongs to.

### Streamlined IPSec

Appenzeller and Lynn (2002) note that IPSec can be dramatically simplified by replacing an approach based on traditional public key cryptography with an approach that uses the Sakai-Ohgishi-Kasahara (2000) noninteractive key agreement protocol. Their modified version of IPSec simplifies key management, requires no notion of "sessions," needs no per-host state, and has minimal bandwidth overhead. A disadvantage is that, to use the noninteractive key agreement protocol, the parties must share a PKG.

Smetters and Durfee (2003) propose a less radical change to IPSec—namely using domain-based IBC (discussed above as an alternative to IBE). Unlike Appenzeller-Lynn, this approach permits the use of multiple PKGs (one for each domain). It also has the advantage over PKI of raising the problem of key and certificate management from the user level to the domain level.

## CONCLUSIONS AND FURTHER READING

With the development of practical IBE schemes in 2001, IBC has been an especially active and exciting research area over the past few years, and likely will continue to be for the foreseeable future. Given that IBC is a rapidly moving target, the strategy of this chapter has been (1) to give newcomers to IBC a good high-level intuition for the advantages and disadvantages of, and alternatives to, IBC in general (and thereby to enable practitioners to consider IBC's usefulness in various settings) and (2) to provide concrete and useful details regarding IBE and IBS (especially IBE) as illustrative examples. We hope that the intuition, at least, has enduring value.

By necessity, much was omitted. For example, many other types of identity-based cryptosystems (e.g., identity-based signcryption, blind signatures, undeniable signatures, and key agreement) were not covered. Also, even for IBE and IBS, some technical material (e.g., an optimized algorithm for computing the Tate pairing of two points on an elliptic curve) was left out. These are areas of current research. The reader interested in current IBC research can find a wealth of information through the International Association for Cryptologic Research (IACR), whose homepage lists major cryptology conferences and links to the Cryptology ePrint Archive, where cryptologists often post recent research results.

Many chapters on topics related or relevant to IBC can be found in this *Handbook*. For example, there are infrastructurally oriented chapters on PKI, key management, and identity management. There are also more

algorithmically oriented chapters on the basics of encryption, public key algorithms, number theory, and elliptic curves.

## GLOSSARY

**Certificate** A digital signature generated by a trusted authority (often called a CA) that signs a public key and an identifier.

**Certificate-Based Encryption** Encryption scheme in which a personal secret key and a certificate are needed to decrypt.

**Certificateless Public Key Encryption** Encryption scheme in which a personal secret key and an identity-based secret key are needed to decrypt.

**Certification Authority** A trusted authority that issues certificate (or certificate status information).

**Certificate Revocation List** A list of certificates revoked before their anticipated expiration dates, which is signed by a Certification Authority.

**Domain-Based Identity-Based Encryption** Encryption scheme in which each domain has a PKG that publishes its public key and that issues identity-based decryption keys to clients in its domain.

**Forward-Secure Encryption** Encryption scheme in which a user evolves its private key forward such that, if it is compromised, previous time periods remain secure.

**Hierarchical IBE** IBE scheme in which the sender encrypts using an ordered (e.g., hierarchical) sequence of strings (e.g., an identity-tuple) and the public key of a PKG.

**Identity-Based Cryptography** The study of, or the collection of, cryptosystems in which any arbitrary string can serve as an identity-based public key, and an identity-based private key is generated using an identity-based public key and a PKG's secret key.

**Identity-Based Encryption** Encryption scheme within IBC, in which a sender encrypts using an identity-based public key and a PKG's public key.

**Internet Protocol Security** A set of security protocols developed by the Internet Engineering Task Force.

**Intrusion-Resilient Encryption** Encryption scheme using two modules that provides some security unless both modules are compromised in the same time period.

**Kerberos** An authentication and key agreement protocol using symmetric cryptography.

**Key-Insulated Encryption** Encryption scheme using two modules that provides some security unless the first module is compromised.

**Mediated IBE** Encryption scheme in which a user must collaborate with a semi-trusted mediator to decrypt.

**(Useful) Pairing** A non-degenerate efficiently-computable bilinear map that maps two elements of a first group to an element of a second group.

**Private Key Escrow** Ability of a PKG to perform any identity-based private key operations that its clients can.

**Private Key Generator** A trusted authority that uses its secret key to compute identity-based private keys corresponding to identity-based public keys.

**Public Key Encryption** A cryptographic protocol that uses two keys — a public key known to everyone (the public) and a private or secret key known only to the recipient (private party) of the message.

**Public Key Infrastructure** Infrastructure needed to distribute public keys and certificates (or certificate status information).

**Random Oracle Model** A false but useful heuristic employed in proofs of security, in which a cryptographic hash function is treated as if it is an oracle that, on a given input, outputs a consistent random response.

**RSA** A public key encryption and signature scheme.

**Third-Party Query** A query by one party requesting another party's public key public key or certificate (or certificate status information).

## INTRODUCTION: WHAT IS A PROTOCOL?

Here is a protocol we have all known since we were children: two children get one cake and need to share it in a way that they both agree to. It would easily create unfairness if one of them cuts the cake and then selects a piece. Instead, one child cuts the cake, then the other one gets to select a piece, and then the child who cut the cake gets the remaining piece.

One can think of a protocol as a step-by-step recipe for one or more chefs to cook a particular dish and make sure that nobody makes a mistake. More generally, a protocol is a sequence of steps taken by one or more participants wanting to achieve some goal. Often, and as above, it is important to construct the protocol in a way that makes the different participants behave in the wanted way; in the example above, this corresponds to cutting the cake into two equally large pieces. In the case of only one participant, of course, this does not apply, as if he or she were to cheat, he or she would simply cheat him- or herself.

In this chapter, we cover the fundamentals of how to design and understand a protocol, starting with understanding the problem to be solved, including the threat that an attacker poses. Therefore, given that the emphasis is on understanding how to design rather than what is being used, we do not survey common protocols, such as secure sockets layer, Internet security protocol, and so on. Instead, we give examples of useful cryptographic building blocks and some protocols that use these building blocks.

## CLASSIFYING PROTOCOLS WITH RESPECT TO THE ADVERSARY

When one designs a protocol, it is important to understand what could go wrong if somebody were to cheat. First, it is important to think of who could cheat. The cake-cutting protocol is well designed so not much can go

wrong (if we exclude cheating such as grabbing the whole cake and running away with it instead of cutting it). Conversely, if the person who cuts also got to choose first, it is easy to see how he or she could cheat: by cutting two very different-sized pieces and then selecting the largest. So in the general situation where two people want to fairly share a cake, it makes sense to think of these two people as possible cheaters, or adversaries, when considering whether the protocol one has designed is secure.

To see that there may be other types of adversaries, let us consider another type of protocol. Assume that there are two people and that one of these people wants to send a message to the other to suggest a meeting place for their upcoming rendezvous. Of course, the sender could cheat by writing down another place than the one where he or she wants to meet, but even though this is a form of cheating, it does not seem like a very appealing thing to do. Conversely, if a person working in the post office is very curious, he or she may want to get access to the letter and open it to learn the meeting place. This seems like a more reasonable type of cheating for this scenario. Therefore, this type of protocol should be designed to protect against some third party, but we may not have to worry about one of the principal participants cheating the other. One approach to avoid the “post office attack” might be to send several numbered messages, one for each letter of the meeting place, letting the intended recipient piece together the message from the many numbered messages received. At least, this would make it a little harder for the adversary we consider, as he or she would have to get access to a large portion of the numbered messages to be able to know what the meeting place is with a good probability.

Of course, if the two parties have access to some form of encryption, and have already exchanged keys, there would be much better approaches to secure the exchange of information. However, if the two parties have not agreed on what keys to use for the encryption and authentication, they need to do so first. The adversary may want to eavesdrop on this process, or even replace some of the messages

going back and forth during this phase, with the goal of learning or replacing the keys the two main parties will use. At the same time, one of the two participants may want to trick the other into using a particular key, perhaps with some known weakness in. This could allow the cheater to leak some secret information that the other sent to him or her, and then claim that he or she did not, but rather that some unknown attacker intercepted the encrypted messages and managed to break the weak key. If it then could be shown that the key used really turned out to be weak, then this would hold the cheater free from responsibility. This example shows that several types of adversaries may coexist at the same time: both protocol participants and unknown third parties. It also suggests that protocol design could be rather complex, given all the bizarre ways of cheating that might exist.

For protocols involving two or more participants, it is important to determine all reasonable ways in which these could attempt to cheat and design the protocol in a way that allows the detection of or avoids any such cheating. A protocol is *secure* against a given type of adversary if this adversary cannot cause an incorrect output to be produced by the protocol without this being detected by the other protocol participants. Therefore, to make meaningful statements about the security of a protocol, it is important first to specify exactly what the adversary is able to do and what his or her goals might be.

A protocol can be thought of as a “recipe” to compute some information. Many protocols require interaction between the parties who hold the inputs that we want to compute the output from, but interestingly, this is not a requirement. In fact, a very common protocol, the Diffie–Hellman key exchange, requires no interaction at all. Given that this is a very straightforward protocol, it is well suited as a first real example of a cryptographic protocol.

We will assume that everybody who potentially wants to use the protocol knows the protocol and also knows some common system parameters. One of such parameters is a large prime value, which is often denoted  $p$ . Another value is what is referred to as a generator and is denoted  $g$ . We do not describe exactly how this is selected here but instead refer to the chapter on key establishment for more details. Each party selects a secret key. We refer to Alice’s secret value as  $x_A$ , to Bob’s as  $x_B$ , Cindy’s as  $x_C$ , and so on. Each party computes a corresponding public key, as the value  $g$  raised to the secret key, modulo  $p$ . Thus,  $y_A = g^{x_A} \pmod{p}$ , and  $y_B = g^{x_B} \pmod{p}$ . If two parties, say Alice and Bob, wish to establish a shared key, then Alice will take Bob’s public key  $y_B$  and raise to her own secret key  $x_A$ , whereas Bob will take Alice’s public key  $y_A$  and raise to his own secret key  $x_B$ . Given how  $y_A$  and  $y_B$  are defined, we will have  $y_B^{x_A} = (g^{x_B})^{x_A} = (g^{x_A})^{x_B} = y_A^{x_B}$  and therefore these two parties will have the same value. Now, the important thing is that they are the only two who can do this. Although Cindy, for example, has both  $y_A$  and  $y_B$ , she cannot compute the shared key that Alice and Bob computed given these values; she needs one of their secret keys for this.

Now, before we start looking at more complex protocols, it is important to first develop an understanding of what we hope to achieve when designing a given protocol. To do this, we need to start by understanding

what we want to prevent from happening. In other words, we need to understand what types of attacks our protocol is likely to have to withstand.

## UNDERSTANDING THE ADVERSARY

### What Are the Goals of the Adversary?

In many situations, it is likely to assume that it is not the goal of the cheating adversary to cause an arbitrary incorrect output to be produced by the protocol. Rather, he or she may have some particular goal, such as getting a bigger piece of cake, learning the secret messages, or being able to leak secret information without being held responsible. The first thing we must understand before starting to design a protocol is what the likely adversary will want to achieve.

For example, if we are designing a system that allows users to download and watch movies for a fee, we should naturally be concerned that an adversary will want to watch movies without paying or give others access to watch movies, whether for free or for a charge. We may also be concerned about privacy: to protect against an adversary who wants to determine who watches what movies. Conversely, we are likely to be less concerned about the location of a given subscriber, as long as the above security requirements are satisfied. Now, consider instead another example in which we want to design a system that allows legitimate users to access a corporate database. Here, we may require that nobody accesses the database from outside the office to make sure that employees are not forced to download sensitive documents by an outside kidnapper, so here location might matter. Privacy is likely to not matter much: if anybody within the company wishes to determine who downloads what files, that is probably okay. But just as in the movie download case, it is obvious that we want to make sure that only registered users get to download information. We do not want a visitor to the building to have access rights to the database. This shows us two situations that on the surface are very similar in one respect: protecting access to some resource. Given the big differences in adversarial goals, the protocols for the two situations are likely to be very different, though.

It is often reasonable to assume that the adversary is *rational* (i.e., he or she will only do things that benefit him or her), whereas a *malicious* attacker may do things even if they hurt him or her, as long as he or she reaches his or her goals. For example, a cell phone user may want to cheat (and send incorrect messages to a base station, for example) if this will lower the monthly bill and get him or her better coverage and service. He or she is not likely to cheat in this way if it makes it impossible for him or her to place phone calls, because he or she is rational. Conversely, a terrorist might want his or her cellular phone to send incorrect messages to base stations, no matter whether he or she can place phone calls, if this incorrect information were to cause the base station to drop connections of other users. This is because this second adversary is malicious.

One can even have many adversaries, each with different goals and abilities, and have different security

guarantees against each one of them. We give an example of that below.

### What Can the Adversary Do—And Not Do?

It is important to specify what an adversary is able to do to reach his or her goals. It is a common assumption that the adversary has some computational limitations. For example, it is commonly assumed that the adversary cannot factor large integers of certain forms (this is what the RSA signature and encryption techniques rely on). The reason people feel comfortable making this assumption is that nobody so far has specified a method that does factor large integers, and many people have tried.

In other situations, people may make no particular assumptions on the computational abilities of the adversary. In other words, even though nobody is known to have the ability to factor large numbers, one would assume that *the adversary* knows it (but won't tell anybody else). Clearly, such an adversary is more powerful than an adversary who cannot factor large numbers, and therefore, a protocol that is secure against this more powerful adversary is more secure than one that is only secure against an adversary who cannot factor. Of course, it may be difficult to design a protocol that is of the more secure kind or such a protocol may need expensive hardware to be run or may be very inefficient for the intended participants. It is therefore not always beneficial to offer the absolutely highest level of security at any cost but rather to offer the best level of security for a reasonable threat. This threat, of course, corresponds to the believed abilities of the adversary.

Let's consider the case of setup boxes for satellite TV. They may use some protocol that makes it difficult to clone them or make it difficult to watch a program by a person who has not paid his or her subscription to the service. We all know that it is not impossible to cheat in such systems, though. It may be expensive to reverse engineer the hardware and figure out what the protocol is, which acts as a deterrent of cheating. Conversely, once somebody has learned this, he or she could tell lots of other people or plainly build fake setup boxes en masse. If there is a way for the service provider to change the protocol occasionally, in a way that is automatically updated by "legal" decoders, that would then make illegal decoders less valuable and make it more difficult for the adversary to sell these. Similarly, if there would be a way to detect if a given decoder is legal or not—without physical access to it—that may allow the service provider to know the extent to which service is stolen and perhaps even who the adversary is. That, again, would make it less attractive to cheat. Although the service providers would clearly love to be able to produce a protocol that is secure against any adversary, such a method is not known to exist. Therefore, the question becomes: how much security can we obtain at a reasonable cost?

### WHAT SHOULD A PROTOCOL DO—AND NOT DO?

Before designing a protocol for a given situation, it is crucial to consider all the things that the protocol should do

to protect against the adversary. For example, it may be important for information to be encrypted so that the adversary cannot eavesdrop on it and learn secret information. Similarly, it may be important for protocol participants to be able to verify from whom a particular message originated and possibly to prove this to other participants. To end up with a good protocol, all of these requirements should be kept in mind when the protocol is designed. This is better than trying to add security features to an already existing protocol, as doing that is likely to complicate the protocol and the security analysis of the same.

It is also important to consider what the protocol should *not* do. For example, many wireless protocols attach a short tag to each message that is being broadcast, where this tag tells each recipient whether the message was intended for him or her. Many protocols also use a tag that specifies from whom the message was sent, allowing easy responses. Both of these types of tags are practical to make the protocol efficient (participants would not have to bother with messages that are not intended for them!) but also have drawbacks. Namely, it is possible for an eavesdropping adversary to determine who is communicating with whom—simply by monitoring the radio traffic! This may be contrary to the privacy wishes of the participants.

Another example showing that it is important to consider what protocols should not do—to potentially avoid this when designing them—can be found in the context of anonymous payment schemes. Payment schemes such as those proposed by Chaum (1983) or Brands (1994) have the nice feature that they allow users to spend money in a way that is not traceable by the bank or anybody else for that matter. However, it also allows criminals to do the same, of course, and if a criminal can force an honest user to withdraw money and pass it on to the criminal (in a blackmail attack, for example) then the funds are still impossible to trace: for the bank, for the legitimate user, and anybody else. That means that this type of crime may be encouraged, as the protocol allows for abuse of the privacy, and without any means of tracing or blocking the use of money that has been stolen in this manner.

Therefore, we must consider all possible types of attacks against a protocol, and make sure that the protocol itself does not give rise to new types of attacks—whether this attack benefits from too little privacy (as in the wireless example) or too much (as in the payment example.) This could be very challenging.

### COMMON BUILDING BLOCKS

Although each setting and adversary may require a unique protocol to reach the wanted goal, there are many common building blocks that can be used by different protocols. We review some of these here and then describe how these can be used in various settings.

#### Proving Without Leaking: The Zero-Knowledge Protocol

A protocol is *zero knowledge* if it allows one participant (the prover) to convince another participant (the verifier) that some statement is true but without having to give

out information that allows the verifier to know why the statement is true or to convince somebody else of this fact. To make this a little less abstract, consider a prover who wants to convince a verifier that he or she knows the secret key corresponding to a particular public key. Doing this would in effect prove that he or she is the person associated with the public key (assuming the secret key has not been compromised). Although the prover could simply send over the secret key to the verifier, allowing the verifier to check that it corresponds to the given public key, this would not be such a smart approach, as now, because the verifier would also know the secret key. It would be better if the prover can convince the verifier that he or she knows the secret key without giving any information at all—short of the fact that the prover knows the secret key.

There are many ways for a prover to convince a verifier that he or she knows the secret key without automatically leaking the same. For example, he or she could let the verifier select a random value, encrypt this with the prover's public key, and send this ciphertext to the prover. The prover would then decrypt the ciphertext, obtaining the random value, and send this to the verifier. The verifier would know that only he or she knew the random number and so the prover must have been able to decrypt the ciphertext! However, this is not zero knowledge: it leaks one piece of information to the verifier, namely a plaintext. The reason is that the verifier could cheat by not selecting a random plaintext and encrypting it, but instead send over a ciphertext that he or she would like to know the plaintext to. The prover would decrypt the ciphertext he or she received and send back the resulting plaintext, not knowing that the verifier did not already know this. This could be used by a cheating verifier to learn the plaintext to any ciphertext corresponding to the prover's public key, which could be disastrous for the prover.

A modification of the above protocol is as follows:

1. The verifier selects a random plaintext, call this  $R$ . He or she encrypts this with the prover's public key, obtaining a ciphertext  $C$ . He or she sends  $C$  to the prover.
2. The prover decrypts  $C$ , obtaining a value  $r$  (that should be equal to  $R$ ). However, he or she does not send  $r$  to the verifier. Instead, he or she concatenates a portion of random bits to  $r$ , and encrypts the resulting value with his or her own public key (the public key of the prover). Call this new ciphertext  $c$ . He or she sends  $c$  to the verifier. Note that the verifier cannot decrypt  $c$ , so he or she cannot obtain  $r$  (or any portion thereof) from it.
3. The verifier sends  $R$  to the prover. The prover compares this to  $r$ . If they are the same, he or she knows that the verifier knew the plaintext corresponding to  $C$ . If not, then he or she knows that the verifier was trying to cheat, in which case he or she will abort the execution of the protocol.
4. The prover sends  $r$  and the random bits used to pad it, allowing the verifier to check that if he or she encrypts this, he or she would obtain  $c$  (which is the value that the prover sent him in step 2) and that  $r$  equals  $R$  (which means that the prover must know the secret key that allows him or her to decrypt). If both of these conditions hold, the verifier knows that the prover must know the secret key, but he or she does not learn anything else.

In the above protocol, the encryption technique used to encrypt  $r$  is referred to as a *commitment*. It can be seen as a form of encryption where one cannot decrypt or even replicate the ciphertext from its input plaintext unless the *entire* input is known—plaintext *and* random bits.

Why does this work? Because the verifier does not know the random bits used by the prover, he or she cannot obtain  $r$  without disclosing  $R$ . More specifically, he or she cannot verify whether the response he or she gets in step two is correct: he or she must continue by performing step 3 of the protocol. This allows the prover, in turn, to verify that the verifier did not cheat (by not knowing the plaintext of  $C$ ). Finally, step 4 allows the verifier to check that the prover did not cheat (by performing the protocol without knowing the secret key needed for decryption of  $C$ ).

The way one shows that the protocol is zero knowledge is by showing that the verifier could have produced the entire transcript of the protocol on his or her own, without the involvement of the prover. This can be done as follows: The verifier picks a random value  $R$  and encrypts this as in step 1, obtaining the ciphertext  $C$ . This is the information of step 1 of the protocol. Then, he or she sets  $r = R$  and selects a random bit sequence to pad  $r$  with. He or she encrypts the padded value using the prover's public key, obtaining  $c$ . This is the information of step 2 of the protocol. He or she then produces the information of step 3 of the protocol. This is simply the value  $R$ , which he or she knows. Finally, he or she produces the information of step 4 of the protocol, namely the value  $r$  and the random bits appended to it. He or she knows these, of course, because he or she produced them by him- or herself. Now, the verifier has produced a complete transcript, which a third party cannot tell apart from a "real" transcript.

If the third party cannot tell a real transcript from a "faked" (or simulated) transcript, then one cannot leak any more information than the other. We know that the simulated transcript cannot leak any information about the secret key, simply because the verifier does not know this value (so how could the transcript he or she produces depend on this value?). Then, we must conclude that the real transcript also does not leak any information about the secret key. This is what we wanted to prove: that the protocol is zero knowledge.

But why does the real protocol manage to convince the verifier that he or she could have produced the transcript on his or her own? That is a valid question. The answer is simply that the real protocol convinces the verifier that the prover knows the secret key because the verifier knows that only he or she knows the plaintext  $R$  and that he or she is not trying to con him- or herself into believing that the prover knows how to produce this value from the resulting ciphertext  $C$ . In contrast, the third party does not know this: he or she sees the entire transcript, not knowing who knows  $R$  and who does not.

Another type of zero-knowledge protocol is the cut-and-choose protocol. This works using the same basic principles used by two people trying to share a cake in a fair way: there are two (or more) possible questions a verifier may ask. The prover prepares the answers to these and sends commitments to each answer. The verifier then selects what question to ask, and the prover has to "open up" the corresponding commitment. If he or she refuses to do so, or the answer it contains is incorrect, then the verifier

rejects the proof. Otherwise, the verifier trusts the proof with some probability. The prover and verifier may repeat the above many times, until the verifier is convinced enough that the prover is not cheating. The protocol is designed such that knowing one of the answers does not give away the secret the prover claims to know, but knowing more than one would give away at least some portion of the secret. However, each round of the proof uses different randomness to make the exact questions and answers somewhat different from before, and so, the verifier will never learn two “matching” answers (and will therefore not learn the secret). We will give more concrete examples of this method later.

## Proving Correct Exponentiation

In many situations, one protocol participant has a secret key, which is often a value  $x$  for which another value  $y = g^x$  (modulo some known very large integer  $p$ ) is known. Some other protocol participant may provide him or her with a value  $m$  and want him or her to compute  $s = m^x$  (modulo  $p$ ). But given  $s$  and  $y$ , this second participant will not be able to verify whether  $s$  was correctly computed because he or she does not know the value  $x$ . Therefore, the first participant has to act as a prover and convince the second participant (the verifier) that the correct exponent was used. There are many possible protocols to do this, we show one such from David Chaum (1991).

1. The verifier selects two random numbers,  $a$  and  $b$ , and computes  $q = g^a n^b$  (modulo  $p$ ). He or she sends this value  $q$  to the prover but does not reveal  $a$  or  $b$ . To simplify the notation, we do not write out the “modulo  $p$ ” onwards.
2. The prover computes  $w = q^x$ . Note that this is equal to  $g^{ax} n^{bx} = g^{xa} n^{xb} = y^a s^b$ . He does not send this value to the verifier (as this would allow the verifier to cheat by sending an arbitrary value  $q$  and have  $q^x$  computed!). Instead, he or she commits to  $w$  and sends this commitment, call it  $c$ , to the verifier.
3. The verifier receives  $c$  and then reveals  $a$  and  $b$  to the prover.
4. The prover verifies that  $q = g^a n^b$ . If it is not, then he or she halts the protocol. Otherwise, he or she sends  $w$  to the verifier.
5. The verifier checks whether  $w = y^a s^b$ . If it does, then he or she accepts the proof, knowing that the prover could not have computed this quantity in step 2 (when he or she did not know  $a$  and  $b$ ) without knowledge of  $x$ . If the equality does not hold, then he or she knows that the prover must have cheated.

## Proving Correct Encryption/Reencryption

A common crypto system is El Gamal encryption. It works as follows: there is a secret key,  $x$ , that is only known by the owner of the corresponding public key  $y = g^x$ . A message  $m$  is encrypted by selecting a random value  $e$  and computing the pair  $(y^e m, g^e)$ . Call this pair  $(A, B)$ , where  $A$  is the quantity  $y^e m$  and  $B$  is the quantity  $g^e$ . Note that encryption can be done by anybody because it uses only public information. However, only the owner of the secret key can decrypt, which is done by computing  $A/B^x = y^e m / (g^e)^x = y^e m / (g^x)^e = y^e m / y^e = m$ .

In many cases, a protocol participant has some message  $m$  that needs to be encrypted as above and needs to convince a verifier that it is indeed encrypted correctly. This corresponds to proving that he or she used the same exponent  $e$  for the first and the second term. We may use the protocol for correct exponentiation to accomplish this task. More specifically, we can consider the quantity  $B$  as a public key corresponding to a secret key  $e$  known only by the prover. Then, the prover would show that the quantity  $A/m$  (for a known message  $m$ ) equals  $y$  raised to the same exponent  $e$ —the “secret key.” If you look at the protocol for proving correct exponentiation, you will see that this is sufficient for the verifier to be convinced that the prover performed a correct exponentiation and, therefore, a correct encryption of the known value  $m$ .

Another common method is what is referred to as reencryption. Here, a first participant receives an El Gamal ciphertext  $(A, B)$ . He or she may not know the secret key to decrypt and may not know what message the pair corresponds to. He or she still wishes to produce a new and independent-looking ciphertext that corresponds to the same secret key and the same message. What he or she does is as follows: chooses a random value  $e'$  (which is not related to the value  $e$  above.) He or she then computes  $y^{e'}$  and  $g^{e'}$ , and then  $(A y^{e'}, B g^{e'})$ . Note that because  $(A, B)$  equals  $(y^e m, g^e)$  for some unknown value  $e$ , the new pair must equal  $(y^{e+e'} m, g^{e+e'})$ . Since we could rename  $e+e'$  as  $e''$ , we see that this new pair, let us call it  $(A', B')$  is an encryption of the same message  $m$  as  $(A, B)$  is. Note again that  $m$  does not need to be known for this to be performed. We will demonstrate useful applications for this onwards.

Now, say that a verifier may want to know that the reencryption was performed correctly, that is, that  $(A, B)$  corresponds to the same (potentially unknown) plaintext  $m$  as  $(A', B')$  does. Again, this corresponds to showing that the factors multiplied in to  $(A, B)$  to obtain  $(A', B')$  were correctly formed. If we divide  $A'$  by  $A$ , and  $B'$  by  $B$ , we receive these. The prover will show that they use the same exponent, just as we did for correct encryption: by using one of them as a public key, and prove that the other one is consistently formed, using the protocol for correct exponentiation.

## Proving Equivalence

There are two types of common equivalence proofs: a first type allows a prover to convince a verifier that the plaintexts of two different ciphertexts equal each other. The second type of equivalence test allows two players, each holding a secret value, to compare these two values to see if they are the same—of course, without revealing any other information about the values to each other. We describe how this can be performed next and later show uses of these techniques.

First, let us therefore consider how a prover can show that the plaintexts of two ciphertexts are the same. We again use El Gamal encryption and call the ciphertexts  $(A, B)$  and  $(A', B')$ . We assume for now that they are constructed using the same public key; this is not a necessary requirement but simplifies the protocol. Recall that  $(A, B) = (y^e m, g^e)$  and  $(A', B') = (y^{e'} m', g^{e'})$  for some values  $e, e', m, m'$ .

Both prover and verifier can compute  $(A/A', B/B') = (y^{e-e'} m/m', g^{e-e'})$ . If the plaintexts are equal to each other, this means that this quantity equals  $(y^{e''}, g^{e''})$  for some value  $e''$ . If the prover knows  $e$  and  $e'$ , then he or she will also know  $e''$  and will be able to prove to the verifier that the “divided pair” is of the expected format, using the same techniques as shown before. Conversely, if the prover does not know both  $e$  and  $e'$ , but does know  $x$  (where  $y = g^x$ ), then he or she still can prove the relation. Namely that the divided pair is of the form  $((g^{e''})^x, g^{e''})$ , again using the same technique.

In the second variant of the comparison problem, the two protocol participants each have a value and want to compare these two values. They want to learn only whether the values are equal. This problem is referred to as the “socialist millionaires’ problem” and was proposed by Jakobsson and Yung (1996). The reason for this is that there is another, more famous problem in which the two participants each have a value (representing their riches) and wish to compare these (to learn who is the wealthiest). The socialist millionaires wish to know only if they are equally wealthy. There are many possible protocols to let the two participants compare their values. We consider one with a similar structure to the protocols we have introduced—this is introduced to simplify the understanding of the protocol, but it should be noted that there are more efficient techniques.

We call the two participants  $P_1$  and  $P_2$ , as they are both provers in a sense.  $P_1$  has a value  $m_1$ , and  $P_2$  has a value  $m_2$ . Furthermore,  $P_1$  has a secret key  $x_1$  and a corresponding public key  $y_1 = g^{x_1}$ ;  $P_2$  has a secret key  $x_2$  and a corresponding public key  $y_2 = g^{x_2}$ , both using the same modulo  $p$ . Now, let  $y = y_1 y_2$ . This corresponds to a secret key  $x = x_1 + x_2$ , which is not known by either part on its own. The comparison protocol is as follows:

1. Both participants encrypt their value ( $m_1$  and  $m_2$ ) using the public key  $y$  and El Gamal encryption. This results in ciphertexts  $(A_1, B_1)$  and  $(A_2, B_2)$ . They send these ciphertexts to each other.
2. Both participants compute  $(A, B) = (A_1/A_2, B_1/B_2)$ . Note that this is an encryption of the value 1 if and only if  $m_1 = m_2$ .
3.  $P_1$  selects a random number  $r_1$ , and  $P_2$  selects a random number  $r_2$ . They both keep their respective value secret.
4.  $P_1$  computes  $(A', B') = (A_1^{r_1}, B_1^{r_1})$  and sends  $(A', B')$  to  $P_2$ . He or she proves to  $P_2$  that the exponentiation of  $A$  uses the same exponent as the exponentiation of  $B$ . This can be done using the protocol for correct exponentiation that we have shown before.
5.  $P_2$  computes  $(A'', B'') = (A_2^{r_2}, B_2^{r_2})$  and sends  $(A'', B'')$  to  $P_1$ . He or she proves to  $P_1$  that the exponentiation of  $A'$  uses the same exponent as the exponentiation of  $B''$ .
6.  $P_1$  partially decrypts the ciphertext by computing  $B''^{x_1}$ , sending this quantity to  $P_2$ . He or she also proves that he or she performed the correct exponentiation with respect to his or her public key.  $P_2$  further decrypts the ciphertext by computing  $(B''^{x_1})^{x_2}$  and proving this to be done correctly. If the plaintext equals 1, then the participants conclude that  $m_1 = m_2$ .

Note that  $(A'', B'')$  was an encryption of  $(m_1/m_2)^{r_1+r_2}$ . This equals 1 if and only if  $m_1 = m_2$ . Otherwise it is a random

value, and because neither participant knows both  $r_1$  and  $r_2$ , they will not be able to say something about the other participant’s secret value ( $m_1$  or  $m_2$ ) from this quantity.

You may ask yourself what the benefit of steps 3–5 is. To see this, assume that we always would set  $r_1$  and  $r_2$  to 1. Then, at least participant  $P_2$  would learn  $m_1/m_2$  in step 6. Because he already knows  $m_2$ , he would in fact learn  $m_1$ . This is not possible in the above protocol.

## Secret Sharing and Proactive Secret Sharing

In section 5.4, we saw an example of a secret sharing scheme. The public key  $y$  corresponded to a secret key that was not known by either participant but rather was the sum of their individual shares. The secret shares, in other words, were  $x_1$  and  $x_2$ , and the public key was  $y = g^{x_1+x_2}$ . This is referred to as a two-of-two secret sharing scheme. This means that there are two shares, and to reconstitute the secret key (or perform any function computation using it, such as the decryption performed in the section, “Proving Equivalence”), one needs both of those. In short, we write a two-of-two secret sharing scheme as a (2,2) secret sharing scheme. It is clear that using the same method, one can create a (3,3) or (4,4) secret sharing scheme or an  $(n,n)$  secret sharing scheme, where  $n$  is the number of shares.

Another type of secret sharing scheme does not require all shares to be used to reconstitute the secret. A  $(k,n)$  secret sharing scheme—pronounced a  $k$ -of- $n$  secret sharing scheme—has the property that only  $k$  of the  $n$  shares are needed. For example, if  $k = 2$  and  $n = 3$ , we only need two of three shares, and any two will work. The construction of such a secret sharing scheme follows a very simple and elegant principle, which we illustrate for the (2,3) case. Consider a line that intersects the  $y$  axis is some point  $(x,y) = (0,y_0)$ . Call  $y_0$  the secret to be shared. Let  $(x_1,y_1)$ ,  $(x_2,y_2)$ , and  $(x_3,y_3)$  be three points on the line. We call these the secret shares. If you know one of secret shares alone, you cannot say anything about where the line intersects the  $y$  axis (i.e., you cannot compute the secret). However, if you know two of the shares—any two!—that allows you to extrapolate the line to determine the intersection with the  $y$  axis, and therefore the secret. So there are three secret shares, and any two of them are sufficient to compute the secret. At the same time, one is not enough. We can easily expand this to a (2,4) scheme by producing another point  $(x_4,y_4)$  on the line: it is still the case that any two of the secret shares can be used to compute the secret. Now, a line is a degree-1 polynomial. If we instead of a line use a degree-2 polynomial, it is not sufficient to know two secret shares (points on the curve) to compute the secret (the intersection with the  $y$  axis.) However, three shares is enough. In general, we need  $k + 1$  shares to determine where a curve intersects the  $y$  axis if the curve is a degree- $k$  polynomial. This corresponds to a  $(k+1,n)$  secret sharing scheme. In our setting, all the points on the curve are represented by integers, and all arithmetic is modulo some integer as well; to perform the extrapolation in such a situation, one uses a LaGrange interpolation, which is covered in more detail in another chapter. The secret sharing scheme we have explained was invented by Shamir (1979) and is referred to as *Shamir secret sharing*.

Secret sharing can be used in many ways to enhance security. One of the most common ways is to distribute

a secret key, such as the signing key for a certification authority (CA), so that an intruder who gains temporary access to one of the machines of the CA cannot learn the secret signing key. Instead, if the signing key is distributed between some  $n$  machines, and  $k$  out of these shares are necessary to reconstitute the key, the attacker would have to gain access to at least  $k$  of the machines. This, of course, is much more difficult than gaining access to only one machine. The primary reason why we do not set  $k = n$  (which would require all shares to be present to compute the secret) is to avoid problems associated with temporary failures of some of the servers. For example, in a (2,3) secret sharing scheme, one can perform all the computation as long as only one of the servers does not respond. This gives security against attacks in which a small number of machines are targeted and brought down to prevent correct execution of the protocol.

As described above, a benefit of using a secret sharing scheme is to defend against an attacker that compromises a small number of machines. A proactive secret sharing scheme defends against a more aggressive attack, namely one in which the attacker gains access to some small number of machines during a first time period, some other machines during a second time interval, and yet some other machines in a third interval. It is assumed that the attacker is detected and “kicked out” from machines at the end of each time interval, and so he or she compromises only a given maximum number of machines at any point in time. When he or she compromises a machine, he or she copies all its information and sends it to some central site of his or hers. This site then obtains lots of shares over time. In fact, after the attacker has compromised all machines, it will have received shares from all of these.

To avoid that the secret can be reconstituted by the attacker after performing an attack of this kind, all the shares are “rerandomized” at the end of each time interval, but without affecting what point the new curve intersects the  $y$  axis in. This can be done by adding a curve to the old curve. The curve we add to it will intersect the  $y$  axis in (0,0) and will have the same degree as the first curve but otherwise be randomly selected. This creates a new curve that intersects the  $y$  axis in the same point as the old curve but where each share will be new and independent of the old shares. Therefore, as long as the attacker does not compromise  $k$  shares during any one point in time, he or she will not benefit from old shares he or she has obtained—they will not be on the same curve as newer shares will. This is referred to as *proactive secret sharing* and was introduced by Herzberg, Jarecki, Krawczyk, and Yung (1995).

## Hash Functions, Signatures, and Message Authentication Codes

We now briefly describe hash functions, digital signatures, and message authentication codes (MACs). These three building blocks are described in much more detail in other chapters; we only briefly review them here for the convenience of the reader, given that some of the protocols we describe later use these constructions.

A hash function is a function that takes an arbitrarily long input and produces a fixed-length and relatively short output. The output is typically 128 bits (as for MD5)

or 160 bits (as for SHA-1). It is not possible to compute what could have been the input given an output value, and it is not possible to find two input values that produce the same output value. These collisions exist, as can be seen from the fact that the inputs can be of any length and, therefore, that there are more input values than output values. Still, given the construction of the hash function, it is computationally infeasible to find such collisions. Similarly, given an output, it is infeasible to find an input that would have generated this output. Hash functions are covered in much more detail in other chapters of this book, and we refer the interested reader to these.

A digital signature  $s$  on a message  $m$  is a value that can be produced only by somebody with knowledge of a particular secret key—the secret key of the signer. Once produced, the value  $s$  can be verified (relative to  $m$ ) without knowledge of the secret key—the corresponding public key suffices. An example of a signature scheme using the same computational structures as we have used above is the *Schnorr signature*, named after its inventor, Claus-Peter Schnorr. There, a signer has a secret key  $x$  in an interval between 0 and  $q$  for some large prime number  $q$  and a corresponding public key  $y = g^x$  modulo  $p$ . For details on the choice of the parameters  $p$  and  $q$ , we refer to the article by Schnorr (1991) and subsequent chapters in this book.

A signature is generated by selecting a temporary secret key,  $k$ , and computing  $r = g^k$ , which can be thought of as a temporary public key. Then,  $s$  is set to  $s = xe + k$  modulo  $q$ , where  $e = h(m, r)$ . Here,  $h$  is a hash function, and  $m$  is the message to be signed. The pair  $(r, s)$  constitutes the signature on  $m$ .

To verify a triple  $(m, r, s)$ , a verifier will check if  $g^s = y^e r$ , where  $e$  is computed as  $e = h(m, r)$ . Note that if the signature was correctly computed, then  $g^s = g^{xe+k} = g^{xe} g^k = y^e r$ . This is exactly what is verified. Variations of these equations exist and can be shown to be equivalent.

A MAC can be thought of as a digital signature, where the same key is used to produce and verify a “signature.” This, of course, means that a MAC cannot be used to sign a contract, as anybody who can verify it could also have produced it. Conversely, MACs can be used between two participants who share a key, for these to be able to authenticate messages they send to each other. An eavesdropper will not be able to forge MACs because he or she does not know the key that is used. A MAC function can be implemented by using a hash function, in which case it is referred to as a HMAC. This is done by hashing the input to the MAC function along with the key of the MAC function, both to produce the MAC value and to verify it. For more details, we refer to the publication by Bellare, Canetti, and Krawczyk (1996) in which the concept was proposed.

## SOME CRYPTOGRAPHIC PROTOCOLS Payments, Micropayments, and Applications

Cryptographically secure payment schemes can be produced in many different ways. Two of the most popular are based on a digital signature or on hash functions alone. We review the principles of these.

A payment scheme can be based on a digital signature scheme. One solution is for a user to select a secret key and public key, and then perform a withdrawal from a bank by getting a bank signature on the public key along with

a denomination. The user's secret and public key are used only for this withdrawal, and so each withdrawal uses new and random keys. Conversely, the keys used for signing are the same for every withdrawal—they are the keys of the bank. A bank signature on the message “ $y, \$1$ ” corresponds to a withdrawal of \$1, where one needs the secret key associated with  $y$  to spend the funds. The user spends the funds (or parts thereof) by signing a message that states the amount. In other words, to spend 55 cents of the above dollar, he or she will sign a message saying “55 cents” using the secret key corresponding to  $y$ . The recipient of the money will verify the signatures (both that of the user and that of the bank on the public key of the user). He may later deposit the funds with a bank. This bank will then verify the signatures as well, and also verify that the user who withdrew the funds have not issued payments in excess of the withdrawn value. If this holds, then the bank credits the account specified by the participant performing the deposit.

The above payment scheme is best suited for payments that are not very small—55 cents may in fact be in the small range in view of the amount of work that has to be performed to verify the signatures, and so on. A scheme with smaller computational overhead is as follows:

The user selects a random value  $r_n$  and computes  $r_{n-1} = h(r_n)$ , where  $h$  is a hash function. He or she, then iteratively computes  $r_i = h(r_{i+1})$  for  $0 < i < n$ . This results in a “hash chain” of length  $n + 1$  (i.e., one with a known endpoint and  $n$  values that are preimages to the endpoint. Let us assume that  $n = 100$ ).

The user then obtains a bank signature on the end value  $r_1$ , and the value of the withdrawal, say \$1. He or she does not show the bank any of the other values of the chain.

To pay a recipient, the user gives him or her the preimage to  $r_1$  (i.e., the value  $r_2$ ). The recipient can verify whether this is correct by computing  $h(r_2)$  and comparing this to  $r_1$ . This corresponds to a payment of 1 cent, because all  $n = 100$  values together are worth \$1. To pay another cent, the user will reveal the value  $r_3$ , which can be verified by hashing it, and compare the result to the known value  $r_2$ . To pay 2 cents after that, he or she gives  $r_5$ . The recipient then applies the hash function twice and compares it to the last known value on the chain. The recipient can deposit a sequence of payments by sending the last one to the bank. The bank can then hash it the appropriate number of times and compare the result to  $r_1$  (or the last deposited value on the chain). If they agree, then the bank credits the participant who performed the deposit with the corresponding amount. This scheme is referred to as PayWord and was proposed by Rivest and Shamir (1996).

In PayWord, the user will know that nobody can steal his or her money by forging payments on his or her behalf. This is so because nobody can find hash preimages to the values that are public, given the assumption on the hash function. In the above, we assume that the user stores all the values  $r_1 \dots r_n$ . This is, in fact, not necessary: he or she can instead store only  $r_n$  and then compute the wanted value from this by applying a hash function the appropriate number of times. Note that he or she cannot compute a value  $r_2$  from  $r_1$ , or  $r_3$  from  $r_2$ , and so on, as this requires inverting the hash function. Whereas storing a long chain may be expensive in terms of storage, computing

consecutive preimages of a long chain will be computationally demanding. A solution that minimizes both of these costs was suggested by Coppersmith and Jakobsson. That construction is also a good example of a protocol that only involves only one participant—the participant who needs to generate the sequence of hashed values.

## Achieving Privacy and Privacy Control

### Payments Patterns

In the payment schemes described above, there is no privacy from the bank. In other words, if the bank issuing the funds also receives the deposit, it will know exactly where the user in question spent his or her money. This is so because it will know to what merchant account it was later deposited. At the same time, the bank will know who withdrew the funds—at least by a pseudonym—because the withdrawal needs to be done from an account, and the account holder needs to prove that he or she has access rights to it. Although pseudonyms can be helpful in hiding the real identity of the user, there are ways in which a pseudonym can be associated with the real identity. For example, anybody paying his or her phone bill is with a big likelihood revealing this link, because people typically pay their *own* phone bills and not that of others, and the phone number is associated with a name. Similarly, having anything shipped to your address will reveal the link. To offer a better degree of privacy for payment schemes, several solutions have been proposed.

One such solution uses what is called “blind signatures.” A blind signature can be generated only by somebody who has the secret signing key. After it has been generated, it can be “unblinded” by the party who requested it. The result of the unblinding is a valid signature, but one that cannot be related to the blind signature. To the signer, a particular unblinded signature will be equally likely to correspond to the actual request during which it was generated as to another request. We do not describe how to generate blind signatures here but instead refer the interested reader to other chapters of this book and to the article by Chaum (1983), in which the concept was first proposed.

Using blind signatures, one can get perfect privacy. The user would identify him- or herself to withdraw money from his or her account and would then blind the message to be signed. This would be sent to the bank, who would debit the bank account and generate the blind signature. This would be unblinded by the user, who later can spend the money in the same way as described before. When the money gets deposited with the bank, the bank can verify the validity of the signature, but cannot determine from what withdrawal it stems.

One concern with the above proposal is that because the user specifies the message, he or she then blinds it. He or she could ask the bank to withdraw just a dollar from his or her account, but let the message state that the digital signature corresponds to \$100—or any amount for that matter. This would enable him to spend up to that amount while having only \$1 debited from his account. Of course, this is not very appealing to the bank. To avoid this, the bank could use different public and secret keys to sign messages. It would use one key pair for \$1 withdrawals,

one for \$5 withdrawals, one for \$50, and so on. To withdraw \$56, one would withdraw one of each of the above types or some other combination that adds up to the correct amount. Then, the value would not be part of the message; only the public key associated with the funds would. The user can state whatever message he or she wishes—this corresponds to the public key used only for spending the money, and if he or she “cheats” by using the “wrong” message, then he or she simply prevents him- or herself from spending the money.

Another, much more serious, concern is that a criminal would force an honest user to withdraw money from his or her account in a way that is blinded both from the bank and the honest user—but not to the attacker! That can be done simply by having the attacker prepare the message and the blinded version and then forwarding this to the honest user, who would (under threat) request to make a withdrawal, send the blinded message, and forward the resulting blinded signature to the attacker. The attacker would then unblind it and later be able to spend the money in a way that cannot be traced back to him or her or the attack. Many proposals have been made to avoid this type of threat; some of these are described by von Solms and Naccache (1992) and Jakobsson and Yung (1996).

### Traffic Analysis

Encryption is used to prevent an eavesdropper from determining what two communicating parties say to each other. In many situations, though, it may not matter so much what people say as the fact that they are communicating. For example, if one person repeatedly communicates with a known criminal; this very fact is enough to suspect that he or she is also criminal—reading the plaintext messages may confirm this, but is not necessary to establish a suspicion. In this case, the “eavesdropper” may be law enforcement. The technique of determining who is communicating with whom is referred to as *traffic analysis*. There are other cases where the party attempting to do traffic analysis is on the other side of the law. Examples of this relate to finding out what electronic votes were cast by whom, determining what Web pages people browse, and determining purchase patterns. There are several ways of preventing traffic analysis by making it impossible for an eavesdropper to do any better than guessing when it comes to who originated a given message or what message a given person sent. We review some of these techniques next.

### The Chaumian Mix

A mix network is run by a series of servers, each of which takes a collection of ciphertexts as input, reorders these and decrypts them, and output this new collection of items. These items are also ciphertexts, unless the process of decrypting, permuting, and forwarding has completed. They are given to the next server, who again permutes them and decrypts them. For each server, the order of the appearance of the items changes—the latter because the removal of one layer of encryption. This way, an eavesdropper who sees all input items and all output items will not be able to determine their correspondence. That is, unless he or she corrupts the server that performed the operation on them—if he or she does, then he or she will know

the exact relation between them. However, because there are many servers that each operate on the collections of items, an attacker would need to corrupt all of them to determine the correspondence between inputs and outputs.

To take a little bit more detailed look at this technique, we assume that all messages to be sent are encrypted many times; first with a first public key and then with a second, a third, and so on up to an  $n$ th public key. The last public key used for encryption belongs to the first server in the line, the second to the last key belongs to the second server, and so on. Therefore, the last layer of encryption to be added is removed first and then the second to last. The last server in the mix network owns the first public key used, and he or she outputs the original message. Of course, and as described above, the servers also randomly reorder all items as they forward them.

Let us see how this can be used. Say that there are some large numbers of voters. Each voter specifies what candidate he or she wants to vote for and then encrypts this message. He or she then encrypts the resulting ciphertext and then encrypts *that* ciphertext and so on. In the end, each voter has an item that has been encrypted some specific number of times, say  $n$  times. Everybody encrypts their votes the same number of times, and this number is of course known by everybody. The public keys used for encryption correspond—in reverse order—to the public keys of the servers of the mix network. These multiply encrypted votes are then given to the first server, who permutes, decrypts, and sends the results to the second server and so on. In the end, the  $n$ th server outputs a collection of plaintext messages: these are the votes! Here, it is not possible to determine who voted for whom.

This type of mix network is sometimes referred to as a Chaumian mix, after the researcher who first proposed the idea, David Chaum (1981).

### Reencryption Mixes

One drawback of a Chaumian mix is that each time an item is encrypted, it typically grows a little, and so the multiply encrypted message may become somewhat large. This is because one needs to attach a random pad before each encryption, or otherwise one could determine what inputs to the mix network corresponds to what outputs simply by encrypting the outputs. Another drawback is that all the public keys of the mix servers have to be used in the right order. If one of the servers is down or refuses to collaborate, then the mixing cannot complete unless its secret decryption key is collectively known by some other set of servers (i.e., it is *shared*, as was described before). However, probably the biggest drawback is that one server may decide to remove any number of items and replace them with items of a similar format. That way, he or she can encrypt the names of candidates he or she favors and replace the same number of (arbitrarily selected) ciphertexts with these. He or she would then decrypt, permute, and forward, and nobody would know about the replacement, assuming he or she added the appropriate number of “encryption layers” to the new votes. Of course, although this attack cannot be detected, people may suspect that it took place if all the votes are for one candidate, so the attacker would replace only a sufficient number of votes to swing the election in favor of his or her preferred candidate.

All of these problems can be addressed using what is sometimes referred to as a reencryption mix. In a reencryption mix, the inputs are only encrypted once; that is, there are not multiple layers of encryption. However, there is not one server who knows the corresponding secret key—this is shared between many servers. Also, instead of *decrypting* the input items, they perform *reencryption* (as described before). After all the servers have permuted and reencrypted, the resulting list of outputs are still ciphertexts: they have not been decrypted. They would then be decrypted by some set of servers, potentially the same set, but without the need for any permutation. The decryption would be performed in several steps, as the secret keys for decryption would be shared between several servers, possibly using a proactive secret sharing scheme as described above. The decryption process would be done similarly to how we showed in the last protocol in the section, “Proving Equivalence.” One can see that the size of the input ciphertexts does not depend on the number of servers.

Note that the above approach does not address the problem with replacement of ciphertexts. Therefore, as servers reencrypt and permute the ciphertexts, they also have to prove equivalence between all input items and all output items, using a proof of correct exponentiation or reencryption. We have shown before how to do that to one given ciphertext. Here, the problem is a little bit more complex because the server needs to avoid showing the correspondence between input items and output items—otherwise there will be no protection against traffic analysis.

Many ways of doing this have been proposed. One of the conceptually simpler versions is that each server shows how some fraction of all inputs were operated on to produce the corresponding outputs. The correspondence between these items are therefore revealed, but not that of the remaining items. All the other servers together select what items a given server should “open up.” That means that a server will not know beforehand what items will be audited and, therefore, he or she will be caught with a big probability if he or she tries to modify a large number of items. For example, in an election with 1 million voters, he or she can change exactly one vote and get a way with it with probability 50% (if half of all items are audited). He or she can cheat on 2 items with probability 25%, and on 10 items with probability less than 1 in a 1,000. Similarly, he or she can cheat on 20 items with a probability less than 1 in a million. This provides a very high degree of assurance that the election results are correct, given that it is likely to be necessary to corrupt much more than 20 votes to swing a standard election with a million voters. This scheme was proposed by Jakobsson, Juels, and Rivest (2002), and more details are provided in their article, along with a more detailed analysis of the failure probabilities. There are other, more complicated, solutions that make it impossible to replace even one of the ciphertexts without being detected (see, for example, the scheme by Abe, 1999).

### Crowds

An alternative to mix networks is a system referred to as “crowds,” a concept proposed by Reiter and Rubin (1998). You can think of that as a group of participants that want

to protect each other’s privacy. When one of them wants to send a message somewhere, he or she instead sends it to one of the members of the group. This member either sends it to its destination or passes it on to another group member. This third group member, in turn, sends it to either its destination or to a fourth group member and so on. The group members that messages are forwarded to are chosen randomly. This way, an outside observer will not know where a given message originated: it could be from anybody in the group. Similarly, group members would not know either, as they may get the message either from the originator or from somebody who just passed it on. Clearly, the size of the group impacts the degree of privacy offered by this solution in the same way as the number of messages input to a mix network affects the privacy of each message. If there are only two group members in crowds, an outsider would be able to guess who the originator is with 50% probability, and there would be no “internal” hiding of the origin within the group. However, for reasonably large groups (or crowds) of participants, the privacy is reasonable. Depending on the application this is used for, encryption or reencryption techniques may be used in conjunction with the above idea. It may not be practical for an election because it requires all group members (voters) to be available for each other, but it does suit applications such as Web browsing.

### Fair Exchange

A fair exchange is a technique that allows two participants to exchange information in a manner that prevents one of them from cheating the other in a way that gets the cheater the information he or she wanted but leaves his or her victim without the information he or she expected. An example situation is where two participants want to sign a contract simultaneously. Neither participant wants the other to be able to walk away with a signed contract before he or she also has one. Another possible application is the exchange of (digital) money: one participant has a certain number of electronic dollar coins and the other a matching number of electronic yen coins. They want to exchange these for each another in a way that prevents either party from not fulfilling his or her part of the deal. In fact, this situation is technically very similar to the contract exchange example, because both an electronic coin and a contract typically would use a digital signature to authenticate its authenticity. The problem therefore often becomes one of exchanging digital signatures in a way that prevents one party from getting the other’s signature without sending over his or her own.

The simplest solution to this problem is to involve a trusted third party who will receive both signatures, verify their correctness, and then send them out to their recipients at the same time. Sometimes, though, it is not reasonable to expect the existence of such a trusted third party, and other solutions are preferable. Another type of solution does involve a trusted third party, but only if something goes wrong. The main structure of such a protocol is as follows:

1. Participant A encrypts his or her signature  $s_A$  and a description of what he or she wants in return, using

the trustee's public key. He or she sends the resulting ciphertext to participant B.

2. Participant B sends his or her signature  $s_B$  to participant A.
3. Participant A sends his or her signature  $s_A$  to participant B.

Now, if participant A refuses to perform the third step, then participant B will send the ciphertext to the trusted party, along with  $s_B$ . The trusted party will decrypt the ciphertext and verify that  $s_B$  is the signature A wants in exchange. He or she will then send  $s_A$  to B and  $s_B$  to A.

In reality, the protocol is a bit more complicated. Namely one has to protect against A's cheating by producing a ciphertext on some useless information. Then he or she would stop intentionally at the end of the second step, successfully having cheated participant B. Therefore, A has to prove to B that the ciphertext "contains" the correct plaintext—but without revealing the exact contents of the ciphertext. (Doing so would allow B to cheat.) For more details on how this could be done, please see a detailed description in the article by Asokan, Shoup, and Waidner (1998).

## Broadcast Authentication

In many situations, there is a small number of senders who wants to transmit data to a large number of recipients. The recipients want to know that the data are authentic, that is, that the data were indeed sent by the claimed sender.

One could use digital signatures for this purpose and let each sender digitally sign each message that he or she sends. However, digital signatures are relatively expensive to produce and verify, and the typical verifier in this kind of setting may not have a lot of computational power. Conversely, one may use MACs to authenticate each message. This is considerably less expensive because it uses only a symmetric cryptography operation as opposed to a asymmetric (or public key) operation. However, because each message is to be received by a very large number of participants, it is not convenient to attach one MAC for each recipient to each message. At the same time, one cannot send the same MAC to many recipients interested in verifying its correctness. The reason is that whoever can verify a MAC can also produce it. Giving the verification key to many recipients would therefore allow one cheating receiver to potentially impersonate the sender and make other recipients believe that fake messages were authentic.

A solution to the above problem is the TESLA protocol, introduced by Perrig, Canetti, Tygar, and Song (2002). In this, a large number of symmetric keys are produced as follows: first, an "end point" key is selected at random. Then, a one-way function (such as a hash) of this key is computed, and the result is a second key. A third key is produced by hashing the second key and so on. In this way, some  $n$  keys are produced. (This is therefore the same structure as is used in PayWord, as previously described.) This is all done by the participant who will later want to authenticate his or her messages. The last key to be produced, we may call this  $k_n$ , is made public.

To authenticate a first message, the sender uses key  $k_{n-1}$  to compute the MAC. He or she sends the message and the MAC to everybody, but nobody can verify it. Then, some time later, he or she sends the key  $k_{n-1}$  to everybody. Now, they can verify the MAC. They also verify that this key is correct by hashing it and comparing the result to key  $k_n$ . The next time the sender wishes to transmit an authenticated message, he or she uses key  $k_{n-2}$  to MAC it and later transmits this key as well. More specifically, each time interval (of, say, 5 s) is associated with one key used for MAC-ing. In this interval, the key two time intervals back is revealed (two steps as opposed to one to avoid synchronization problems). Because everybody will know the release schedule, nobody will accept an authentication that uses a key that has already been released. This is important, of course, because potentially anybody knows this key.

To do this, the sender can have stored all the keys in the sequence, which is referred to as a hash chain. Alternatively, he or she can store only one value: the one that was used to generate all the others. Then, when he or she needs a specific key, he or she would compute this from the "original" key by applying a hash function the appropriate number of times. The first approach has the drawback of requiring a potentially very large amount of storage, if the chain is long. The latter will force the sender to perform a lot of computation for each key he or she wishes to compute. This is so because he or she will have to compute keys in the reverse order they were initially produced, and hash functions are believed not to be invertible. Thus, he or she has to perform all the steps from the original key each time. If he or she stores some fraction of keys in between, he or she increases the storage by that number. In the end, the product of the amount of storage and the number of hash function computations remains more or less the same. An approach that avoids both the excessive computational requirements and the excessive storage requirements was described by Coppersmith and Jakobsson (2003). This way, TESLA remains highly efficient even for very long chains.

## GLOSSARY

**Adversary** When designing a cryptographic protocol, we need to consider the ways in which it potentially can be abused. A common technique is to consider how one or more protocol participants, all controlled by one adversary, can cause the incorrect computation to be performed.

**Authentication** A way for one protocol participant to convince another of his or her identity. Typically, this is linked to a message sent between these two participants, in which case we say that this message is authenticated. There are authentication schemes that are symmetric (e.g., MACs), and there are those that are asymmetric (e.g., digital signatures.)

**Ciphertext** The data conveying an encrypted message.

**Decryption** The process of obtaining a readable message (a *plaintext*) from an encrypted transformation of the message (a *ciphertext*).

**Diffie–Hellman** A public key cryptosystem used to exchange a secret (symmetric) key.

**El Gamal** An encryption technique (named after its inventor) often used in mix networks.

**Encryption** The process of rendering a message (a *plaintext*) into a data string (a *ciphertext*) with the aim of transmitting it privately in a potentially hostile environment.

**Fair Exchange** A cryptographic technique to protect two or more protocol participants against each other's potential misbehavior, thereby ensuring that each participant obtains the information he or she expects at the end of the protocol execution.

**Key** A short data string parameterizing the operations within a cipher or cryptosystem, and whose distribution determines relationships of privacy and integrity among communicating parties.

**Key Pair** The combination of a public and private key.

**Malicious** An adversary may perform actions that hurt others even if they do not benefit him- or herself.

**Mix Network** An anonymity construction built from a series of mix servers, each of which perform some reordering and reencryption/encryption/decryption of input ciphertexts before passing the resulting ciphertexts on to the next mix server.

**Plaintext** A message in readable form, prior to encryption or subsequent to successful decryption.

**Private Key** In an asymmetric or public key cryptosystem, the key that a communicating party holds privately and uses for decryption or completion of a key exchange.

**Public Key** In an asymmetric or public key cryptosystem, the key that a communicating party disseminates publicly. In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and Diffie–Hellman are examples of public key systems. *Public key* is synonymous with *asymmetric*.

**Reencryption** The process of generating a new ciphertext from an old ciphertext in a way that the two ciphertexts correspond to the same plaintext but look different. Here, different typically means that one cannot determine whether they correspond to the same plaintext without decrypting both.

**RSA** A public key cryptosystem in very wide use today, as in the SSL (secure sockets layer) protocol. RSA can also be used to create and verify digital signatures.

**Secret Sharing** A way to partition information so that a small portion of the pieces does not reveal the information in question, whereas a sufficiently large portion does. This required number of pieces is referred to as the threshold of the secret sharing scheme.

**Symmetric** A type of cryptographic system in which communicating parties employ shared secret keys. The term is also used to refer to the keys employed in such a system.

**Traffic Analysis** Determining who is communicating with whom. Often this type of analysis reveals plenty of information about the relationships between protocol participants, even to a party who cannot determine what plaintext messages are sent between the communicating parties.

**Zero Knowledge** A way of performing a cryptographic proof, guaranteeing that no secret information is leaked to the verifier of the proof. This is often proven by demonstrating a simulator of the proof; this is an algorithm that produces transcripts that cannot be distinguished from real protocol transcripts when inspected by a third party.

## FURTHER READING

The reader interested in more detailed treatment of the topics discussed here need go no further than this handbook. Subsequent chapters offer details on most aspects of cryptography. However, for the reader interested in other reading material, we recommend two introductory books on the field of cryptology, namely *Applied Cryptography* (Schneier, 1996) and the online compendium *Frequently Asked Questions About Today's Cryptography* (RSA Laboratories, 2004). Both describe common protocols, along with what these are intended to be used for. In addition, the reader interested in specific details in the protocols described in this chapter is recommended to look at the articles listed in the bibliography, many of which are relatively accessible to nonexperts.

## INTRODUCTION

Quantum cryptography is the name under which are commonly known those techniques that make use of the laws of quantum mechanics to prevent the unauthorized access to secret information. The most celebrated of such protocols, whose description is the main scope of this section, is quantum key distribution, undoubtedly the most successful quantum information processing protocol from the technological viewpoint. Quantum key distribution is a scheme that allows two remote parties to share a common secret random string of bits even in the presence of an adverse party who tries to eavesdrop. As discussed shortly, it solves the problem of secure distribution of private cryptographic keys by allowing the detection of any eavesdropping.

Quantum key distribution is historically the first quantum information processing protocol. Some of the ideas behind it were implicitly suggested by Stefan Wiesner, who proposed “quantum tokens which cannot be forged,” later published in Wiesner (1983). The first quantum cryptographic protocol, however, was put forward in 1984 by Charles Bennett and Gilles Brassard (Bennett & Brassard, 1984). In this protocol, the ingredients used to guarantee security are the use of single quanta to encode bits, the Heisenberg uncertainty principle, which implies the impossibility of knowing the polarization of a single photon along two different polarization axes, and the quantum no-cloning theorem (i.e., the impossibility of making a faithful copy of a single unknown quantum state; Wootters & Zurek, 1982). It is indeed the disturbance introduced by any eavesdropping on the signal used to encode the key bits that makes possible the detection of any intrusion. The use of a further ingredient, namely quantum entanglement, was first proposed by Ekert in 1991. Entanglement is the property of quantum systems composed of two or more subsystems to show stronger nonlocal correlation between its subsystems than compatible with the laws of classical physics. Although entanglement is not essential for the implementation of quantum cryptographic schemes its use allows new strategies for the detection of unwanted eavesdropping. Since the publication of the above seminal articles the field has reached an astonishing degree of sophistication in a very short time. Great progress has been made on both the theoretical side, with

very detailed analysis of eavesdropping strategies and of security criteria on both the two original protocols as well as on their several variations, and on the experimental side, with several preindustrial prototypes for the secure distribution of cryptographic keys in local networks of optical fibers of nearly 100 km. In the following pages, we describe the basic concepts and techniques of quantum key distribution for a readership with no previous knowledge of quantum mechanics and suggest the essential reading for further, more detailed, study.

The typical scenario of all quantum key distribution protocols is the following: two remote parties, traditionally called Alice and Bob, want to establish a secret random binary string to be later used as private cryptographic key. They have at their disposal a private quantum channel and a public classical channel. The private quantum channel is used to exchange a sequence of single quanta. Because of the properties of quantum systems any attempt to intercept and measure such quanta will modify their state. The public classical channel is used to exchange information and can be passively eavesdropped. The fact that eavesdropping on the public channel cannot be detected does not compromise the security of the protocol, as shown shortly. It is important, however, that the public channel must be authenticated (i.e. at some stage Alice and Bob must acknowledge each other as the legitimate parties). A malicious eavesdropper, traditionally called Eve in the literature, may “cut” the public channel pretending to be Bob with Alice and Alice with Bob. If such a man-in-the-middle attack were successful Eve would have two keys, one in common with Alice and the other in common with Bob. To prevent this Alice and Bob use an authentication procedure requiring the use of a previously shared short secret key. This may seem a sort of catch-22 situation in which a key is needed to establish a key. The situation is slightly different. It is true that Alice and Bob must initially share a short secret classical key, but this is needed only once. Indeed at the end of a successful quantum distribution session Alice and Bob share a key much longer than the one used for authentication and they can agree to keep a short part of it for authentication in a subsequent session. In this sense, quantum key distribution is a process of cryptographic key growth.

## PUBLIC VERSUS PRIVATE KEY CRYPTOSYSTEMS

Cryptography is the art of concealing information in transit. In the typical scenario, the sender, Alice, wants to send a secret message, from now on called plaintext, to a legitimate receiver, Bob. To this goal Alice encrypts the plaintext into a cyphertext by mean of an encryption algorithm with the help of some secret additional information, called key. The cyphertext must be unintelligible to any unauthorized party and only Bob, who shares the key with Alice, should be able to recover the plaintext from the cyphertext by mean of a decryption algorithm.

Present-day cryptographic protocols can be divided into two categories: private key and public key cryptosystem. The basic idea behind public key cryptosystems, known also as asymmetric cryptosystems, is that the key used to encrypt the message need not be the same one used to decrypt it. One such protocol is RSA. The security of public key cryptosystem relies on the existence of problems that are difficult to solve—such as factoring large numbers—unless some additional information is available.

The security of public key cryptosystems is acceptable for most purposes. As their security is based on the unproved computational complexity of some problems (e.g., it is not known if no classical algorithm can solve the factoring problem in polynomial time), the degree of privacy they provide is acceptable when the time required to decrypt the cyphertext is longer than the time over which the information it contains is sensitive or when the value of the resources needed to decrypt the message is bigger than the value of the information gained. Furthermore, a quantum algorithm—the Shor algorithm—is known to solve the factoring problem in polynomial time. Although it is not yet foreseeable a date by which the first quantum computer will be on our desks, this is a potential danger when highly secret information must be protected.

Private key cryptosystems are used when Alice and Bob want to exchange highly sensitive information whose secrecy must be above doubt. In such cryptosystems, the keys used in the encryption and in the decryption algorithms are the same. The algorithms themselves are public and the security is guaranteed by the secrecy of the key. A description of the Vernam cipher or one time pad illustrates the idea. In this cryptosystem the plaintext is converted into a binary string. The key is also a (secret) random binary string and the encryption algorithm consists in the sum modulo two of the plaintext and the key. The decryption algorithm consists again in a sum modulo two of the cyphertext and the key. Because the sum modulo 2 is associative and the sum of any string with itself is identically zero, it is clear that the decryption algorithm gives back the plaintext. Three requirements are strictly necessary to guarantee security of the one time pad: the key must be (1) a truly random string of length equal to the plaintext, (2) used only once, and (3) secret.

If the above requirements are met then, as shown by Shannon (1946), the information gained by Eve when she intercepts the cyphertext is zero. This can be easily understood by noting that the XOR of any binary string with a random binary string of equal length is itself random. If

the key is not random, or if it is used more than once, then some periodicity in the statistical properties of the cyphertext may appear, thus revealing some information about the key. If, for instance, the key is used twice, then Eve, by doing the XOR of two intercepted cyphertexts, can eliminate the key and obtain the XOR of two plaintexts, which is no longer random and contains valuable information. The above description of classical cryptosystems is a rather simple one and is aimed simply to setting the scenario for quantum cryptosystems. A more detailed description of classical cryptosystems can be found in other sections of the present *Handbook*, in particular in the chapters on encryption basics, symmetric key encryption, public key infrastructures, and data encryption standard.

It is clear that the difficult point in the implementation of public key cryptosystems is the key distribution. At some stage, before transmitting their secret messages, Alice and Bob must agree on a common secret key. In most circumstances, they exchange the key by means of a trustworthy courier. This procedure, however, is not without drawbacks. For instance, there is no guarantee that Eve has not read the key while it is being exchanged. Quantum key distribution provides a solution precisely to the key distribution problem, guaranteeing secrecy though the laws of quantum mechanics.

## THE PHOTON POLARIZATION AND THE RULES OF QUANTUM MECHANICS

To introduce the principles and language of quantum mechanics used in quantum cryptographic protocols, we analyze the properties of the photon polarization. This choice is justified not only by the fact that the photon polarization is an excellent case study to introduce all the basic concepts of quantum mechanics but also by the fact that indeed quantum optical systems are the technology used to experimentally implement quantum key distribution.

### Classical Polarization

In classical physics monochromatic light is an electromagnetic wave, characterized by an oscillating electric field perpendicular to the direction of propagation of the wave. The light polarization is the plane of oscillation of this electric field (see Figure 1). Linearly polarized light is characterized by a fixed plane of oscillation.

In Figure 2a and 2b a vertically and a horizontally polarized waves are pictorially shown. Because of the superposition principle, more general polarization states can be obtained by suitably superimposing vertically and horizontally polarized waves. For instance, the sum of a vertical and a horizontal wave of equal amplitude gives rise to a wave polarized at  $+45^\circ$  if the two waves are in phase or  $-45^\circ$  if their phase is opposite (Figure 2c and 2d). Circularly polarized waves (Figure 2e and 2f), in which the direction of the electric field rotates, are obtained by superimposing two orthogonal linearly polarized waves of equal amplitude with a phase difference of  $\pi/2$ , which means that the horizontal wave reaches its maximum when the amplitude of the vertical one has zero

**Figure 1:** The polarization of an electromagnetic wave is the direction of oscillation of the electric field. Above is shown a vertically polarized monochromatic plane wave at a given time  $t$ . The wave propagates in the positive  $z$  direction, whereas the electric field  $E$  oscillates sinusoidally in the  $x$  direction.

amplitude and vice versa. The most general polarization state, obtained by the superposition of two orthogonally polarized waves of arbitrary amplitude and phase difference is elliptical. The light emitted by common thermal sources, such as the sun or incandescence lamps, is unpolarized (i.e., its polarization is not fixed but fluctuates over time scales of a few nanoseconds).

A polarizer is an optical device made from a material with anisotropic absorbing properties. When a light beam crosses a polarizer with polarization axis  $n$  all the electric field perpendicular to the direction  $n$  is absorbed, whereas the field in the direction parallel to  $n$  crosses the polarizer entirely undisturbed. Consider now a light beam crossing two polarizers in sequence, with polarization axis  $a$  and  $b$ , respectively. The light emerging from the first polarizer is polarized along the  $a$  direction, whereas the light emerging from the second one is polarized along the  $b$  axis. If the angle between the  $a$  and  $b$  axis is  $\theta_{ab}$ , the amplitude of the field transmitted by polarizer  $b$  is a factor  $\cos\theta_{ab}$

**Figure 2:** Various polarizations can be obtained by superimposing vertically (a) and horizontally (b) polarized waves. Superposing two waves of equal amplitude with a  $0$  or  $\pi$  phase difference produces a linearly polarized wave along the  $45^\circ$  (c) or  $-45^\circ$  (d) direction. Analogously a left circular (e) or right circular (f) polarization is obtained by superimposing a vertical and a horizontal wave of equal amplitude with a phase difference of  $\pi/2$  or  $-\pi/2$  respectively.

**Figure 3:** An unpolarized light beam shines on a first polarizer  $a$ . The light emerging from the polarizer is polarized along the polarizer axis—the vertical axis in the case of polarizer  $a$ . If a second polarizer  $b$  is inserted, the light intensity transmitted by  $b$  is a factor  $\cos^2\theta_{ab}$  less intense than the light transmitted by  $a$ .

smaller than the amplitude of the light transmitted by the first polarizer  $a$ . As the light intensity is proportional to the square of the electromagnetic field, we immediately obtain Malus’s law:  $I_T = I_0 \cos^2 \theta$  (i.e., the intensity  $I_T$  of the light transmitted by a polarizer is equal to the incident intensity  $I_0$  diminished by a factor  $\cos^2\theta$ , where  $\theta$  is the angle between the polarization of the incident light and the polarizer axis).

Another interesting device is the beam splitter (BS). A light beam entering a BS is split into a transmitted and a reflected beam. Because of the conservation of energy, the sum of the transmitted and reflected intensities is equal to the intensity of the incident beam. Of particular interest is the 50% BS, in which the transmitted and reflected beams have equal intensity.

Finally, a polarizing beam splitter (PBS) is a beam splitter that reflects or transmits light depending on the polarization of the incident light. If the polarization of the incoming light is parallel to the PBS axis, the beam is transmitted, whereas if it is polarized in its orthogonal direction, it is reflected. In general, if  $\theta$  is the angle between the polarization of the incoming light beam and the PBS axis  $n$ , the transmitted beam has an intensity  $I_T = I_0 \cos^2 \theta$  and is polarized along  $n$ , whereas the reflected light has an intensity  $I_R = I_0 \sin^2 \theta$  and is polarized along the direction perpendicular to  $n$ .

### Quantum Polarization

In quantum terms, a light beam is described, crudely speaking, as a beam of indivisible massless particles called photons, all traveling at the speed of light  $c$  and with energy proportional to the frequency of the field. Here the term *particle* is not to suggest a material point but rather a quantum of energy. The intensity of the field is proportional to the number of photons in the beam. Each photon is characterized by its own polarization. A polarized light beam is one in which all photons have the same polarization, whereas in an unpolarized beam, the polarization of each photon is fixed in time but randomly distributed.

Photons polarized along a given axis cross undisturbed a polarizer with the same polarization axis, whereas they are absorbed by a polarizer with orthogonal polarization

**Figure 4:** A polarizing beam splitter (PBS) with vertical axis is shown. In such a device a vertically polarized light beam is transmitted (a), whereas a horizontally polarized light beam is reflected (b). If a light beam with intensity  $I$ , polarized at an angle  $\theta$  with respect to the vertical direction, is shone on the PBS, a vertically polarized fraction with intensity  $I \cos^2 \theta$  is transmitted, whereas a horizontally polarized fraction with intensity  $I \sin^2 \theta$  is reflected. At a single photon level, this means that each photon of the beam is either reflected (c) with probability  $\sin^2 \theta$  or transmitted (d) with probability  $\cos^2 \theta$ . Note that in both cases the polarization of the incident photon, originally at an angle  $\theta$ , changes abruptly, becoming either vertical if transmitted or horizontal if reflected. This is an example of projective quantum measurement.

axis. When a beam of  $N_0$  photons polarized along axis  $a$  crosses a polarizer with axis  $b$ , a fraction  $N_T = N_0 \cos^2 \theta_{ab}$  of photons are transmitted, whereas all the others are absorbed. This is nothing but Malus's law, once the intensity is expressed in terms of photon number. Note that because photons are indivisible quanta, each photon is either transmitted or absorbed. The probability that a photon is transmitted is equal to  $\cos^2 \theta_{ab}$ ; however, the transmitted photon is no longer polarized in the  $a$  direction but in the  $b$  direction.

Similarly, a BS does not “split” photons; they are either reflected or transmitted and the conservation of energy becomes simply a conservation of photon number. Finally, when a beam of  $N_0$  photons polarized along axis  $a$  enters a PBS with axis  $b$ , a fraction  $N_T = N_0 \cos^2 \theta_{ab}$  of photons is transmitted, whereas a fraction  $N_R = N_0 \sin^2 \theta_{ab}$  is reflected. All transmitted photons are polarized along  $b$ , whereas all reflected photons are polarized in the direction orthogonal to  $b$ , as can easily be verified by placing a polarizer with axis along  $b$  in the path of the transmitted beam or with axis in the direction perpendicular to  $b$  in the path of the reflected beam.

A PBS can be viewed as a measurement device for photon polarization. Suppose that the beam is so weak that only a single photon at a time crosses a PBS with a photodetector at each output arm, as depicted in Figure 4. Each time a photon arrives either one or the other photodetector clicks, never both at the same time. When it clicks always the same photodetector, say  $D_0$ , it means that each photon is polarized in the direction parallel to the PBS axis. When it clicks always  $D_1$ , then all the photons

are polarized in the direction orthogonal to the PBS axis. When photons are polarized in any other direction it is not possible to predict which detector will click but only to assign the probability of each detector to click. From what we have said above, it should be clear that it is not possible to determine the polarization of a single photon—a beam with a large number of identical photons is needed to make a statistical analysis of the measurement results.

We now introduce the mathematical formalism needed to describe the quantum properties of photon polarization. To start with let us choose two linear orthogonal polarization axes and call them vertical and horizontal. The state of a single vertically polarized photon is labeled by the symbol  $|V\rangle$ ; the state of a single horizontally polarized photon is labeled by  $|H\rangle$ . The general state of a single photon with polarization  $A$  is described by two complex numbers  $\alpha_V, \alpha_H$  and is written in the so-called Dirac notation, as  $|A\rangle = \alpha_V |V\rangle + \alpha_H |H\rangle$ . The quantities  $\alpha_V, \alpha_H$  are called probability amplitudes because the probability that if we measure the photon polarization in the vertical/horizontal direction we obtain a positive answer (i.e., a click in the corresponding detector) that is equal respectively to  $|\alpha_V|^2; |\alpha_H|^2$ . Since either one of the two detectors will click, we must clearly have  $|\alpha_V|^2 + |\alpha_H|^2 = 1$ . In mathematical terms, therefore, the state of a quantum system, in our case the state of the photon polarization, is described by a complex vector of unit length. Any two orthogonal polarizations form a basis in terms of which the photon polarization state can be expressed. The choice of basis depends on which polarization measurement is made on the photon. For instance, linearly polarized photons along one of the two diagonal axes can be written respectively as follows:

$$|45^\circ\rangle = (|H\rangle + |V\rangle)/\sqrt{2};$$

$$|-45^\circ\rangle = (|H\rangle - |V\rangle)/\sqrt{2}$$

and vice versa

$$|H\rangle = (|45^\circ\rangle + |-45^\circ\rangle)/\sqrt{2};$$

$$|V\rangle = (|45^\circ\rangle - |-45^\circ\rangle)/\sqrt{2}.$$

From now on, we label  $\{|H\rangle; |V\rangle\}$  as the (+) basis, whereas we label  $\{|45^\circ\rangle; |-45^\circ\rangle\}$  as the (x) basis. It should be clear from the above discussion that, if we measure  $|H\rangle$  in the (+) basis, we will obtain always the answer  $H$ , whereas if we measure it in the (x) basis, we obtain randomly, with equal probability,  $45^\circ$  or  $-45^\circ$ .

To conclude this section, we introduce the concept of inner product. Given two state vectors  $|A\rangle = \alpha_V |V\rangle + \alpha_H |H\rangle, |B\rangle = \beta_V |V\rangle + \beta_H |H\rangle$  the inner product  $\langle A|B\rangle$  is defined as  $\langle A|B\rangle = \beta_V \alpha_V^* + \beta_H \alpha_H^*$ . Physically  $|\langle A|B\rangle|^2$  is the probability that state  $|A\rangle$  will pass the test for being in state  $|B\rangle$ . There exist linear operators  $U$  such that if all the state vectors are transformed by  $U$ , all the inner products are unaffected (for real three-dimensional vectors, any rotation operator has this effect). Such operators are called unitary. The time evolution of any closed quantum system (i.e., in the absence of dissipation) is represented by a unitary operator.

**Figure 5:** Experimental scheme of BB'84 quantum key distribution protocol. A laser emits a sequence of dim single-photon pulses. By means of a Pockels cell (PC), Alice changes randomly the photon polarization of the photons that are sent to Bob, typically via an optical fiber. Bob chooses randomly his measurement basis by means of a second PC and a PBS.

### NONORTHOGONAL STATES QUANTUM KEY DISTRIBUTION PROTOCOLS

We have now all the ingredients to introduce the first quantum key distribution protocol, known as BB'84, after Bennett and Brassard who proposed it in 1984 (Bennett & Brassard, 1984). Here is the scenario: Alice wants to send a secret string to Bob by means of a sequence of polarized photons. To this end, she could use the following coding scheme:

$$0 \rightarrow |V\rangle; 1 \rightarrow |H\rangle,$$

choose randomly between 0 and 1, and send the correspondingly polarized photon to Bob (see Figure 5).

Bob receives the photon and measures its polarization. He can do it without errors, provided he knows in advance which polarization basis Alice has used, by means of a PBS and two photodetectors, as shown in Figure 4. If the axis of Bob's PBS is vertical then whenever he detects a transmitted photon, he knows that Alice has sent a 0, and whenever he measures a reflected photon he knows that Alice has sent a 1. The reader can easily find the weakness of the above scheme. A malicious eavesdropper, Eve, could intercept the photon, measure it, and resend a photon correspondingly polarized to Bob. There would be no way for Alice and Bob to detect the presence of Eve and therefore the above scheme would be totally insecure.

However, as first shown by Bennett and Brassard, the introduction of additional randomness into the protocol is enough to make it secure. Indeed it is enough for Alice not to encode her random bits always on the same basis but to switch randomly between the  $\{|H\rangle; |V\rangle\}$  (+) basis and the  $\{|45^\circ\rangle; |-45^\circ\rangle\}$  (x) basis. The protocol works as follows: Alice chooses a random string of bits and encodes

them choosing randomly between the (+) and the (x) basis. In other words, the qubits are coded as follows:

$$0 \rightarrow |45^\circ\rangle; 1 \rightarrow |-45^\circ\rangle,$$

OR

$$0 \rightarrow |V\rangle; 1 \rightarrow |H\rangle,$$

according to the randomly chosen basis. The photons are then sent through a private quantum channel to Bob, who measures them. However, now Bob does not know which basis was randomly chosen by Alice and therefore he can only choose randomly how to align the PBS of his measuring apparatus. Half of the times his measurement basis will coincide with the basis chosen by Alice. In this case, the result of his measurement will coincide with the bit sent by Alice. Whenever Bob's measurement basis differs from Alice's, however, the results of his measurements are entirely uncorrelated with the bits sent by Alice. At this stage of the protocol, in the absence of Eve, Alice and Bob share two strings whose bits have a 50% chance of being correlated. To discard the uncorrelated bits, Alice announces on a public classical channel the basis used to encode her bits. Bob then announces publicly in which instances his measurement basis coincides with Alice's but keeps secret the result of the measurement. In the absence of Eve, at this stage of the protocol Alice and Bob share a secret random string of bits, known as sifted key. An example of possible sequence is shown in Figure 6.

Let us turn our attention now to the consequences of the presence of Eve. The simplest eavesdropping strategy, known as the intercept-and-resend strategy, consists in intercepting the photons Alice sends to Bob, to measure their polarization and then to resend to Bob a photon with the same measured polarization. Since Eve, like Bob, does not know which basis was randomly chosen by Alice to polarize her photons, she can only make a random choice of measurement basis. She has a 50% chance of measuring in the right basis, in which case Bob receives from Eve a photon with the same polarization originally chosen by Alice and therefore cannot detect Eve's presence. With a 50% chance, however, Eve's basis choice is wrong, in which case the result of her measurement has no correlation whatsoever with the polarization of Alice's photon. The consequences of this are twofold. First of all Eve gains no knowledge from her measurement. Furthermore, her measurement modifies irreversibly the state of Alice's photon and therefore even when Bob measures it

Alice's basis	+	+	×	+	×	+	×	+	+	+	×	+	×	×
Alice's bits	1	0	0	1	1	0	0	0	1	0	0	1	0	1
Alice's photons	H	V	45°	H	-45°	V	45°	V	H	V	45°	H	45°	-45°
Bob's basis	+	×	×	+	+	×	×	×	+	×	×	+	+	×
Bob's bits	1	0	0	1	0	1	0	1	1	1	0	1	0	1
Same basis?	Yes	No	Yes	Yes	No	No	Yes	No	Yes	No	Yes	Yes	No	Yes
Sifted key	1		0	1			0		1		0	1		1

**Figure 6:** An example of sequence of steps leading to the sifted key in the BB'84 protocol. Note that in this example we have assumed no eavesdropping. The presence of Eve would introduce discrepancies between Alice and Bob sifted keys.

in the correct basis his resulting bit is uncorrelated with Alice's. Suppose, for instance, that Alice sends a vertically polarized photon (i.e., a 0) and that Eve measures it in the ( $\times$ ) basis, obtaining as a result the polarization  $-45^\circ$  (i.e., a 1). The best Eve can do is to send to Bob a photon with the same polarization she measured. If he measures in the (+) basis (i.e., the same used by Alice), then the chances of obtaining 0 and 1 are the same. This suggests the following strategy to detect Eve's presence: Alice and Bob select a random subset of their sifted key and compare the values of such bits over the public channel. In the absence of any eavesdropping, all the values of Alice and Bob bits should coincide. If, however, Eve has intercepted the photons sent over the private quantum channel, there is a 25% chance that the value of each such bit differs. If Alice and Bob compare a substring of length  $n$  the probability that Eve is not detected is equal to  $(3/4)^n$ , which, for sufficiently large  $n$  is basically negligible. Eve could reduce her chance to be detected by intercepting only a subset of the photons exchanged between Alice and Bob; this, however, also reduces her knowledge about the final key. In general, the more the information gained by Eve the more the noise she introduces over the private quantum channel (i.e., the more Alice's and Bob's raw keys will differ). Indeed from both the conceptual and the practical viewpoints eavesdropping and environmental noise at the quantum level are the same thing and therefore, to be on the safe side, any noise should be attributed to eavesdropping. Once Alice and Bob have detected Eve's presence they must estimate the amount of information she has gained on the key (i.e., the error rate she has introduced in the sifted key), known as QBER, for quantum bit error rate, and compare it with a security threshold (we discuss later how such a threshold can be established). If the QBER is below the security threshold, it is possible for Alice and Bob to distill a private key by means of a discussion over the public channel. Such part of the protocol is entirely classical and we only briefly describe it. If, however, the QBER is above threshold, then Alice and Bob must restart the protocol.

Here in summary are the steps of the BB'84 protocol:

Alice

- Chooses a random sequence of polarization basis, either (+) or ( $\times$ ).
- Chooses a random binary string. Such bits are encoded as  $0 \rightarrow V$  or  $+45^\circ$ ,  $1 \rightarrow H$  or  $-45^\circ$  polarized photons, according to the random choice of basis made above.
- The photons are sent to Bob via a quantum private channel.

Bob

- Chooses a random sequence of polarization basis, either (+) or ( $\times$ ).
- Measures the polarization of the photons sent by Alice according to the above choice of basis.

At the end of this stage Alice and Bob share a string of random bits called a raw key. The two raw keys differ

because in 50% of cases they used a different a basis to randomly prepare/measure the photons.

Alice

- Announces on the public classical channel the basis used to polarize her photons but keeps secret the bits sent.

Bob

- Announces on the public channel which of his measurements were made in the same basis.

Alice and Bob.

- Discard all bits of their string whenever their basis disagree.

At the end of this stage Alice and Bob share a binary string known as a sifted key. In the absence of noise and eavesdropping their sifted keys should coincide.

Alice and Bob

- Select a substring of the sifted key, compare them over the public channel and make a statistical estimate the QBER (i.e., estimate the percentage of bits which disagree in their strings. Such substrings, used for a statistical estimate, are discarded.).
- Compare the QBER with the security threshold. If the noise is below threshold they correct the errors in their key obtaining the so called reconciled key.
- Distill a shorter secret key, the private key, out of the reconciled key.
- If the QBER is above threshold, they restart the protocol at some later stage.

The sequence of steps listed above is basically common, apart from minor details, to all quantum key distribution protocols.

The careful reader has probably noticed some redundancy in the above protocol. Indeed, the random use of two different polarization bases, i.e., of four states belonging to two nonorthogonal bases, is not necessary. Security can be obtained with the use of just two nonorthogonal polarization states, as shown by Bennett in 1992. In this protocol, Alice encodes her random bits on two nonorthogonal states, for example:

$$\begin{aligned} 0 &\rightarrow |V\rangle \\ 1 &\rightarrow \cos\theta|V\rangle + \sin\theta|H\rangle. \end{aligned}$$

Since these two states are not orthogonal, neither Bob nor Eve can, with a single measurement, determine the polarization of the photon. Bob's goal is not to maximize his mutual information of Alice's string, which is a statistical quantity, but to be sure that the bit value he detects is the same Alice has sent. To this purpose he performs what is known as positive operator value measure (POVM). The polarization measurement process using a PBS is an example of what is known in physics

as projective measurement (or VonNeumann measurement). The reason for such a name is nearly obvious: the polarization of a photon that has crossed a polarizer is always along the polarizer's axis (i.e., it is projected on the polarization basis of the polarizer whatever the original polarization of the photon). The number of outcomes of a projective measurement is equal to the number of basis states—two orthogonal polarizations in the case of photons. In a POVM the number of possible outcomes is increased by making a joint projective measurement on the original system and an auxiliary system called ancilla. A mathematical description of POVM is entirely outside the scope of the present review. The interested reader can find a thorough description of POVMs in Peres (1993) and in Nielsen and Chuang (2000). For the present discussion, it will be enough to say that for the Bennett'92 protocol it is possible to devise a POVM with three possible outcomes: 0, 1, and? (i.e., either Bob knows with certainty the bit value sent by Alice or he knows nothing about it). Here are the steps of the Bennett'92 protocol:

- Alice sends a random sequence of photons polarized in one of two nonorthogonal polarizations on a private quantum channel.
- Bob measures the photons with a POVM with outcomes 0,1,?
- Bob announces on the public channel which bits have not been identified (i.e., outcomes?).
- Alice discards from his string such bits.

At this stage Alice and Bob share a sifted key. The remaining steps leading to the secret private key are the same as in the BB'84 protocol. Again the presence of Eve is identified as nonzero error rate on the sifted key.

We should also briefly mention the existence of other quantum key distribution protocols that make use of a larger set of nonorthogonal states, such as the six-states protocol (Bruss, 1998). They do not differ conceptually from the protocols described so far, the only difference being in the details of their practical implementation and of eavesdropping detection.

Let us turn our attention to the security threshold. Once the sifted key has been established Alice, Bob and Eve have each a—generally different—random binary string. Let's call such strings  $X, Y, Z$ , respectively, and  $P(X, Y, Z)$  their joint probability distribution. Under which condition such joint probability distribution can be established will be discussed in the next section. Alice and Bob can establish a secret key, using error correction and privacy amplification, if and only if  $I(X, Y) \geq \text{Max} \{I(X, Z); I(Y, Z)\}$ , where  $I(X, Y)$  denotes the mutual information between the random variables  $X, Y$  (Csiszár & Koerner, 1978). In other words, the requirement to establish a cryptographic key is that the information shared between Alice and Bob must be higher than the information Eve has on either Alice's or Bob's strings. The problem is that Alice and Bob must estimate  $P(X, Y, Z)$  from the knowledge of  $X, Y$  (i.e., from the marginal distribution  $P(X, Y)$  only). This requires a detailed analysis of the optimal eavesdropping strategies on the given

quantum key distribution protocol. Such analysis is rather complex and requires realistic assumptions about what Eve can do on the specific quantum channel used. Some aspects of quantum eavesdropping are described later.

The procedure, by which Alice and Bob can establish a key, once they have estimated that the QBER is below the security threshold, consists, as mentioned, of two steps. The first is error correction, at the end of which Alice and Bob share the reconciled key. According to Shannon's theorem, if the error rate is  $e$ , the number of bits that Alice and Bob must somehow make public to correct all errors in a string of length  $n$  is at least equal to  $n[e \log_2 e + (1 - e) \log_2 (1 - e)]$ . The Shannon theorem is nonconstructive and therefore provides no explicit recipe to design such error correcting codes. Some codes with efficiency very close to the Shannon limit have been proposed: for a short discussion, see the review chapter on quantum cryptography contained in Bowmeester, Ekert, and Zeilinger (2000) and the review article by Gisin, Ribordy, Tittel, and Zbinden (2002).

The error correcting protocol discussion over the public channel will in general disclose to Eve some additional information about the reconciled key. To eliminate virtually all information Eve has on the reconciled key, Alice and Bob make use of a privacy amplification protocol. This protocol is again entirely classical and therefore here we simply illustrate the basic idea. Suppose that the probability that Eve's bit is the same as the reconciled key is  $p = \frac{1}{2} (1 + \epsilon)$ . For  $\epsilon = 0$  Eve has no knowledge of the key as this amounts to choosing randomly her bit value. Assume now that Alice and Bob extract a shorter key by taking the parity bit of two consecutive bits, therefore halving the length of their reconciled key. The probability that each of Eve's bits now coincides with the corresponding one of this shorter key is reduced to  $p' = \frac{1}{2} (1 + \epsilon^2)$ . It is not necessary to actually sacrifice every second bit as more efficient privacy amplification protocols have been developed (Bennett, Brassard, & Maurer, 1995).

What has been described above is a particular case of what is known as secret key agreement by public discussion (see Maurer, 1993). In this framework two important techniques should be briefly mentioned, namely advantage distillation and quantum privacy amplification. Advantage distillation (Maurer, 1993; Maurer & Wolf, 1999) is a classical protocol that allows Alice and Bob to share a secret key even if they start from a disadvantageous situation (i.e., when the information Eve has on Bob's or Alice's string is larger than the mutual information between Alice and Bob). The basic idea is that before starting the error correction and privacy amplification Alice and Bob distill, by means of two way communications (i.e., by means of feedback), a string on which Eve's information is smaller than their mutual information. Quantum privacy amplification (Deutsch et al., 1996) is a quantum protocol that can be used in entanglement based quantum key distribution, which is described below. The interesting point is that the QBER above which advantage distillation or quantum privacy amplification make possible the establishment of a secret key is the same, as shown by Gisin and Wolf (1999).

## QUANTUM EAVESDROPPING

A correct estimation of the security threshold requires a detailed analysis of all the possible eavesdropping strategies on the private quantum channel used in a given quantum key distribution protocol. Alice and Bob, given their QBER, must estimate the information Eve has on their bit strings. The assumption is that Eve does not suffer of any technological limitation. In other words, to prove unconditional security one has to assume that the adverse party has at its disposal perfect technology. It must be said straight away that, although a complete theory of quantum eavesdropping is still missing, the field has reached a very high degree of sophistication and is rapidly becoming an area of research by itself. Here we simply illustrate some basic strategies and their limitations. In eavesdropping analysis, one considers various classes of eavesdropping strategies of increasing generality. The simplest and more realistic of such classes is the one of individual attacks, called also incoherent attacks. For such attacks, Eve lets each of the photons in transit interact with a separate probe system that is then individually measured. The interesting feature of this strategy, as illustrated in the previous section is that a joint probability distribution can be assigned for Alice, Eve, and Bob measurement outcomes. The simplest incoherent eavesdropping attack, namely the intercept-and-resend strategy, or opaque eavesdropping, has already been illustrated for the BB'84 protocol. For such strategy the only way by which Eve could reduce the chance of being detected is by reducing the number of photons intercepted and measured. This, however, will reduce also her knowledge on the sifted key. A factor that could reduce the chance to detect Eve's intrusion is the presence of more than one photon in the signal sent by Alice to Bob. The experimental realization of true single photon sources is very challenging. In the simplest experimental implementation, Alice uses faint pulses containing an average of about 0.1 photons. Since photons are indivisible quanta, an average of 0.1 photons simply means that most pulses contain no photons, some contain a single photon, and few pulses contain two or more photons. In this case, Eve could send the signal through a beam splitter, obtaining, sometimes, two single photon pulses. This allows Eve either to keep one of the photons for her measurement and send the other to Bob (who could not detect Eve's interception as his photon has not been measured on its way) or to perform a measurement on both single photon signals, increasing the amount of information gained from bits sent by Alice. Therefore, the use of sources that are as much as possible true single photon sources is of great importance.

The reader may wonder why Eve does not simply try to build a device able to make multiple copies of the photons sent by Alice. This would allow her to send the signal to Bob without modifying it and to perform her measurement on the photon "clones." One of the "oddities" of quantum mechanics that prevents this simple strategy is that an unknown quantum state cannot be faithfully copied, a fundamental fact known as "no-cloning theorem," first discussed by Wootters and Zurek (1982). In our specific discussion, this means that, if we are given a photon in an unknown polarization state, we cannot build

any device able to produce for us two photons with the same such polarization. The theorem is straightforward to prove. Suppose we are given a vertically polarized photon and a device able to accept it as input and to produce two vertically polarized photons as output. The action of such device is described by a linear unitary operator as follows:

$$|V\rangle|\text{blank}\rangle \rightarrow |V\rangle|V\rangle,$$

where  $|\text{blank}\rangle$  is a given fixed initial state of our device. Suppose also that the same apparatus can copy also a horizontally polarized photon:

$$|H\rangle|\text{blank}\rangle \rightarrow |H\rangle|H\rangle.$$

An apparatus able to do the above copying operation is perfectly feasible. Assume, however, that the input state is the arbitrary state  $|A\rangle = \alpha_V|V\rangle + \alpha_H|H\rangle$ ; by linearity we have the following:

$$\begin{aligned} (\alpha_V|V\rangle + \alpha_H|H\rangle)|\text{blank}\rangle &\rightarrow (\alpha_V|V\rangle|V\rangle + \alpha_H|H\rangle|H\rangle) \\ &\neq (\alpha_V|V\rangle + \alpha_H|H\rangle)(\alpha_V|V\rangle + \alpha_H|H\rangle), \end{aligned}$$

which shows how it is impossible to clone a photon in an unknown polarization state.

Much recent research in quantum information theory has investigated so-called approximate cloning (i.e., the design of machines able to clone), with the maximum possible fidelity, of states belonging to a given set. Although their description falls well outside the scope of this brief review their importance in the framework of eavesdropping strategies in quantum key distribution must be stressed. The important point is that approximate cloning modifies the state of the original signal and that, in general, the more the information of the original state is contained in Eve's copy, the more the original signal is disturbed. To see that Eve cannot make a copy of the original signal without modifying it, consider the following eavesdropping attack on the Bennet'92 protocol. Suppose Alice uses two states,  $|s_0\rangle, |s_1\rangle$ , to encode her bits and that Eve has built a machine  $M$  that makes copies of the signal states as follows:

$$\begin{aligned} |s_0\rangle|\text{blank}\rangle &\rightarrow |s_0\rangle|m_0\rangle, \\ |s_1\rangle|\text{blank}\rangle &\rightarrow |s_1\rangle|m_1\rangle, \end{aligned}$$

where, as before,  $|\text{blank}\rangle$  is a standard initial state of the machine. As the evolution of a quantum machine is described by a unitary operator, which preserves the inner product, we must have  $\langle s_1|s_0\rangle\langle\text{blank}|\text{blank}\rangle = \langle s_1|s_0\rangle\langle m_1|m_0\rangle$ . Because  $\langle\text{blank}|\text{blank}\rangle = 1$  this means that  $\langle s_1|s_0\rangle = \langle s_1|s_0\rangle\langle m_1|m_0\rangle$ . Note, however, that the signal states are nonorthogonal (i.e.,  $\langle s_1|s_0\rangle \neq 0$ ), so the above condition can be satisfied only when  $\langle m_1|m_0\rangle = 1$ . This, however, implies that Eve does not have any information on the signal states. Whenever  $\langle m_1|m_0\rangle \neq 0$  the signal states are modified; that is:

$$\begin{aligned} |s_0\rangle|\text{blank}\rangle &\rightarrow |s'_0\rangle|m_0\rangle, \\ |s_1\rangle|\text{blank}\rangle &\rightarrow |s'_1\rangle, |m_1\rangle, \end{aligned}$$

with  $\langle s_1 | s_0 \rangle \neq \langle s'_1 | s'_0 \rangle$ . This change in the direction of the signal change causes a change in the statistics of Bob's measurements outcomes, revealing Eve's presence. We stress again that in individual attack strategies described above the photons are intercepted and somehow measured individually. For the BB84 protocol, it can be shown (see Gisin et al., 2002) that, for QBER below 15%, a secret key immune against any individual attack can be established by means of error correction and privacy amplification. For QBER between 15% and 25%, the use of the advantage distillation protocol is necessary. However, such protocols are much less efficient than just error correction and privacy amplification.

To conclude this section, we mention the existence of more general classes of eavesdropping strategies known as coherent attack. In the most general coherent strategy, known also as joint attack, several photons are probed coherently and Eve performs a joint measurement on the probe after Alice and Bob have ended their public discussion. An intermediate class is that of collective attack, in which the photons are probed individually but the probes are measured collectively at the end of the public discussion. These strategies require that Eve can store coherently the probe states to delay as much as possible their measurement. We do not discuss such strategies here because on the one hand they are much less realistic than individual attack, whereas on the other hand, a complete theory of coherent eavesdropping is still missing. For a review of the state of the art see Gisin et al. (2002).

## ENTANGLEMENT-BASED QUANTUM KEY DISTRIBUTION PROTOCOL

In 1991 Ekert proposed a new protocol in which a new quantum ingredient was introduced to guarantee the security of quantum key distribution: entanglement. To illustrate the concept of entanglement, which, as said in the introduction, is the property of quantum systems to show stronger nonlocal correlations than any classical system, consider the following two photons state:

$$|\psi\rangle = (|V\rangle_A |H\rangle_B - |H\rangle_A |V\rangle_B) \sqrt{1/2},$$

where the subscripts A and B mean that the first and second photon of the pair are in Alice's and Bob's hands, respectively (see Figure 7).

Suppose that Alice measures the polarization of her photon in the (+) basis and obtains as a result V. This will immediately modify the state of Bob's photon, which will instantaneously collapse into state  $|H\rangle$ . Analogously if Alice's measurement result is  $|H\rangle$ , then Bob's photon will collapse into state  $|V\rangle$ . In other words, as a result of her measurement in the (+) basis Alice can obtain, with equal probability, the result V or H; however, once her measurement is performed she can predict with certainty the outcome of Bob's measurement, provided he measures in the (+) basis as well. This kind of correlations could be explained in classical terms. Suppose, however, that Alice measures her photon in the (×) basis. The outcome of her measurement can be, with equal probability,  $\pm 45^\circ$ . The astonishing fact is that Alice's outcome will again

determine Bob's. To see this it is enough to notice that given any two orthogonal polarizations  $N, N_\perp$  the state  $|\psi\rangle$  can be written as follows:

$$|\psi\rangle = (|N\rangle_A |N_\perp\rangle_B - |N_\perp\rangle_A |N\rangle_B) \sqrt{1/2}$$

and therefore Alice's and Bob's measurements outcome will always be correlated provided they use the same basis, whatever this is. No classical theory can explain such strong correlations.

It is straightforward to see how entanglement can be used to implement a quantum key distribution protocol. Since Alice's measurement on her photon can be seen as a random preparation of Bob's photon, the first steps of BB'84 protocol can be modified as follows: Alice and Bob choose randomly to measure their photons in the (+) or in the (×) basis. When they choose the same basis, which for random choice happens with 50% chance, the outcomes of their measurements are perfectly (anti-) correlated: when they measure in the (+), such outcomes will be, with equal probability, either Alice H Bob V or Alice V Bob H. When they both measure in the (×) basis, the possible equiprobable outcomes will be either Alice  $+45^\circ$  Bob  $-45^\circ$  or Alice  $-45^\circ$  Bob  $+45^\circ$ . Note that these outcomes are truly random, as they are determined by the laws of quantum mechanics. When Alice and Bob choose a different basis, the outcomes of their measurements will be two uncorrelated random bits.

The remaining discussion over the public channel leading to the sifted key and the detection of the possible presence of Eve is the same as in the BB'84 protocol. Entanglement, however, makes possible more sophisticated strategies to detect the presence of Eve. Such strategies were initially developed in the study of the foundations of quantum mechanics. The basic idea is that entanglement between Alice and Bob is destroyed by any measurement made by Eve and that any residual correlation between Alice and Bob measurements can, in this case, be accounted for by the laws of classical physics. Classical correlations can be statistically distinguished from quantum ones. A set of inequalities that would be satisfied by the statistical properties of a suitable set of measurement on two separate subsystems if these were classically correlated but would be violated by quantum correlated (entangled) systems have been proven by J. S. Bell (Bell, 1987). In

**Figure 7:** A source emits pairs polarization entangled photon. The first photon of the pair is sent to Alice, the second to Bob. By means of two Pockels cells and two PBS, they make random polarization measurement on their photons.

the Ekert'91 protocol Alice and Bob make their measurement along three polarization directions randomly chosen from a suitable set. This will be the step leading to the raw key. In the following public discussion, Alice and Bob announce their measurement bases. When the bases chosen by Alice and Bob are the same, their results should be perfectly correlated. The instances in which they have performed their measurements in different bases are not discarded but used to make a statistical test. If the data statistics violate a particular form of Bell inequality, then entanglement has not been disrupted by Eve and the key distribution session can continue with the reconciliation step, otherwise the degree of security must be estimated before proceeding with reconciliation. As already mentioned, quantum privacy amplification (Deutsch et al., 1996) allows one to distill a shorter string of entangled qubits out of the set disrupted by Eve. The basic idea is that Eve acquires information on the key bits by entangling her measurement apparatus with the entangled photons exchanged between Alice and Bob. However, entanglement is a "monogamous" quantity: the more Eve gets entangled with Alice and Bob, the lesser these two are entangled each other. The quantum privacy amplification protocol allows Alice and Bob to increase their mutual entanglement on a subset of their initial set of entangled pair of photons, therefore reducing virtually to zero their entanglement with Eve. However, the resources needed for such protocol are the same needed for quantum computation and therefore it is not discussed here.

## SUGGESTIONS FOR FURTHER READING

This chapter simply touches the surface of the broad research now going on in quantum cryptography. In particular, we have emphasized the theoretical aspects of the topic while basically ignoring the experimental aspects. Furthermore, we have not discussed more specialized aspects of the field, such as quantum bit commitment, as they are at present less well established than quantum key distribution. We therefore conclude this chapter with some suggestion for further reading. The list is by no means complete and reflects the writer's tastes and interests. The first published popular article on quantum cryptography is Bennett, Brassard, and Ekert (1992), still a pleasant starting point. Other review articles, from gentle to more formal, can be found in Macchiavello, Palma, and Zeilinger (2001); see also LoMonaco (1998), Luetkenhaus (1999), Gisin and Brunner (2003), and the review chapter on quantum cryptography contained in Bowmeester et al. (2000). At present the most complete review article on the subject is that by Gisin et al. (2002), a very thorough presentation of all theoretical and experimental aspects of quantum key distribution, aimed to a readership with a reasonable familiarity with basic quantum mechanics and quantum optics. In this chapter, I have not discussed quantum cryptographic protocols based on continuous variables (see, for instance, Hillery, 2003; Grosshans et al., 2003). This choice is because of the fact that their description, although not adding conceptually anything to the above introductory overview, would require the use

of the language of quantum optics. This is well outside the aims of a tutorial review. To the reader interested in fundamentals of quantum mechanics, we suggest the classic lectures by Richard Feynman (1963). Quantum cryptography is often described within the broader context of quantum computation and quantum information theory. The classical reference book in the field is Nielsen and Chuang (2000). More introductory lecture notes are available on the Web; in particular, we suggest the lecture notes by Preskill and by Mermin. The latter in particular are aimed at a computer science readership with no prior knowledge of quantum mechanics.

## GLOSSARY

- Asymmetric** In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are, respectively, referred to as public and private. RSA and D-H are examples of asymmetric systems. *Asymmetric* is synonymous with *public key*.
- Beam Splitter** An optical device that partly reflects and partly transmits a light beam.
- Ciphertext** The data conveying an encrypted message.
- Cloning** The process of making an approximate copy of an unknown quantum state.
- Cryptanalysis** The science of analyzing weaknesses in cryptographic systems.
- Cryptography** The science of constructing mathematical systems for securing data.
- Cryptology** The combination of the complementary sciences of cryptography and cryptanalysis.
- Cryptosystem** A complete system of encryption and decryption, typically used to describe a public key cryptographic system.
- Decryption** The process of obtaining a readable message (a *plaintext*) from an encrypted transformation of the message (a *ciphertext*).
- Eavesdropping** The act of interception of the cyphertext and of its decryption by and adverse party.
- Encryption** The process of rendering a message (a *plaintext*) into a data string (a *ciphertext*) with the aim of transmitting it privately in a potentially hostile environment.
- Entanglement** The property of quantum systems composed by two or more subsystems to show stronger nonlocal correlation between its subsystems than compatible with the laws of classical physics.
- Key** A short data string parameterizing the operations within a cipher or cryptosystem, and whose distribution determines relationships of privacy and integrity among communicating parties.
- Key Distribution** A protocol for the distribution of cryptographic keys.
- Photo Detector** An optical device that measures the presence of a photon in a beam by absorbing it.
- Photon** An energy quantum of the electromagnetic field. One of the properties of photon is its polarization.
- Plaintext** A message in readable form prior to encryption or subsequent to successful decryption.
- Polarization** The plane of oscillation of the electric field of an electromagnetic wave.

**Polarizer** An optical device made from a material with anisotropic-absorbing properties. When a light beam crosses a polarizer with polarization axis  $n$ , all the electric field perpendicular to the direction  $n$  is absorbed, while the field in the direction parallel to  $n$  crosses the polarizer entirely undisturbed.

**Polarizing Beam Splitter** A beam splitter that reflects or transmits light depending on the polarization of the incident light. If the polarization of the incoming light is parallel to the PBS axis the beam is transmitted while if it is polarized in its orthogonal direction it is reflected.

**Private Key** In an asymmetric or public-key cryptosystem, the key that a communicating party holds privately and uses for decryption or completion of a key exchange.

**Public Key** In an asymmetric or public-key cryptosystem, the key that a communicating party disseminates publicly. In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and D-H are examples of public key systems. *Public key* is synonymous with *asymmetric*.

**Symmetric** A type of cryptographic system in which communicating parties employ shared secret keys. The term is also used to refer to the keys employed in such a system.

## INTRODUCTION

In cryptographic context, 40, 56, 64, 80, 90, 112, 128, 155, 160, 192, 256, 384, 512, 768, 1024, 1536, 2048, and 4096 are examples of key lengths. What they mean and how they are and should be selected is the subject of this chapter.

Key lengths indicate the number of bits contained in a certain cryptographic key or related arithmetic structure. They are a measure for the security that may be attained. To the uninitiated, however, the relation between key lengths and security is confusing. To illustrate, key lengths 80, 160, and 1024, though quite different, may imply comparable security when 80 is the key length for a symmetric encryption method, 160 a hash length, and 1024 the bit length of an RSA modulus. Part of this correspondence follows immediately from the well-known "fact" that symmetric encryption with  $B$ -bit keys and

$2B$ -bit cryptographic hashes offer the "same" security. But the correspondence with 1024-bit RSA is quite a different story that allows many variations. In the sequel, an attempt is made to view this and other key length issues from all reasonable perspectives.

Key lengths are often powers of 2 or small multiples thereof. This is not for any mathematical or security reason. It is simply because data is usually most conveniently processed and stored in chunks of 8 bits (bytes), 32 bits (words), 64 bits (blocks), and so on.

## Symmetric Encryption and Cryptographic Hashing

Ideally, the long-term prospects of the relationship between key length and security should be well understood when key length decisions are made. In the case of symmetric encryption and cryptographic hashing methods,

the decision is facilitated for most users by the following three facts:

1. There is broad consensus which symmetric key lengths and cryptographic hash sizes are “conservative” (i.e., have good prospects to offer very long term security).
2. Nowadays, for symmetric cryptosystems and cryptographic hash functions most default choices available on the marketplace are conservative.
3. The performance of symmetric cryptosystems and cryptographic hash functions is barely, if at all, affected by the key length choice.

Thus, for symmetric encryption and cryptographic hashing it suffices to make a reasonably well informed conservative choice.

## Asymmetric Cryptosystems

As hinted at above, there is much less agreement about conservative choices for asymmetric cryptosystems such as RSA. Furthermore, for these cryptosystems the performance *does* deteriorate with increasing key lengths. Even if a consensual conservative choice could be made, it may not be a choice that is practically feasible. In practice most users of asymmetric cryptosystems follow the recommendations of the vendor community. But there is no guarantee that the vendor community always has sufficient business incentive to comply with the recommendations of the standards bodies or that the latter fully understand all relevant issues. The larger context is the overall cost/benefit picture and the fact that in all practical circumstances there are more pressing areas than key sizes to which industry is giving a higher priority when addressing security concerns. However, those issues are not addressed in this chapter. The main purpose of the present chapter is to offer unbiased advice to the more prudent users of asymmetric cryptosystems to help decide which of the available options may be adequate for their purposes.

## Security in Practice

The security that corresponds to a key length choice for a cryptographic protocol measures the largest effort, that is, in principle, needed to attack the cryptosystem incorporating that protocol. The key length itself yields an upper bound for the security, namely the effort required for exhaustive key search. Cryptosystems are usually most efficiently attacked by exploiting other than cryptographic key-related weaknesses. Examples are imperfections in the underlying protocol, the implementation, the environment, or the users. Selecting appropriate key lengths may therefore be regarded as an academic exercise. It should be kept in mind, however, that inadequate key length choices do affect the security of a cryptosystem. In the remainder of this chapter, security-affecting issues other than key lengths are discussed no further.

## Overview

This chapter is organized as follows. The section titled Security Level introduces the concept of security level and contains the general background for the remainder

of the chapter. Key lengths for symmetric cryptosystems are discussed under Symmetric Cryptosystems and cryptographic hash function sizes under Cryptographic Hash Functions. An overview of asymmetric methods is given under Asymmetric Methods, which leads to the discussion of factoring based cryptosystems under Factoring-Based Cryptosystems and of discrete logarithm based cryptosystems under Discrete Logarithm-Based Cryptosystems. The reader who is not familiar with common cryptographic concepts such as symmetric and asymmetric cryptosystems may look them up in other chapters of this handbook.

In the sequel,  $\log x$  denotes the natural logarithm of  $x$  and  $\log_b x$  denotes the base  $b$  logarithm of  $x$ . As customary,  $\exp(x) = e^x$ .

## SECURITY LEVEL

### Generic Attacks

For symmetric cryptosystems, *generic attacks* are defined as attacks where the key has to be recovered from a known (plaintext, ciphertext) pair. Plaintext and ciphertext in case of block ciphers may consist of a number of blocks that is not too large. In the cryptographic literature such attacks are referred to as known plaintext attacks. It is assumed that the input pair uniquely determines the key or that correctness of the key can independently be verified. Refer to Brazier (2000) for a discussion of the latter point. For asymmetric cryptosystems generic attacks are defined as attacks where the private key has to be found given the public key.

Generic attacks exclude attacks where the attacker has access to any other data that can be generated only by means of the unknown key, such as in differential and linear cryptanalysis of block ciphers. In this chapter only generic attacks are considered because it is generally believed that they most closely correspond to real-life situations. Furthermore, given the cost of an attack effort as used in this chapter and as defined below, for most popular block ciphers generic attacks are the ones that are believed to have the lowest cost (cf. M. J. Wiener, personal communication, 2004; see Symmetric Cryptosystems for an exception).

### Security Level

If a symmetric cryptosystem with  $\lambda$ -bit keys does not allow a generic attack that requires less effort than exhaustive key search, then it is traditionally said to have *security level*  $\lambda$ . Exhaustive key search for  $\lambda$ -bit keys may be expected to involve  $2^{\lambda-1}$  different keys, with in the worst case up to  $2^{\lambda}$  keys. In general, a cryptographic system offers security level  $\lambda$  if a successful generic attack can be expected to require effort approximately  $2^{\lambda-1}$ . How an attack effort is measured is explained in the next paragraph.

### The Cost of an Attack Effort

A security level explicitly refers to an attack effort and not to the time that may be needed to realize it. All attacks discussed in this chapter are fully parallelizable in the following way. Assume an attack can be realized in  $d$  days by a device that costs  $c$  dollars. Then, for any reasonable  $w$ ,

the attack can be realized in  $d/w$  days by a device costing  $cw$  dollars. As first suggested in this context in Bernstein (2001), this implies that an appropriate way to measure an attack effort is obtained by multiplying the time required by the equipment cost; see also Lenstra, Shamir, Tomlinson, and Tromer (2002) and Wiener (2005) where this measure is referred to as the *throughput cost* and *full cost*, respectively. Below it is simply referred to as the *cost* of an attack effort and it will be measured in *dollardays*: the attack effort suggested above would cost  $dc$  dollardays. Exhaustive key search is an example of a fully parallelizable attack, because the search space can be arbitrarily divided over any number of processors that can work independently on the search range assigned to them.

This cost allows to leave unspecified if and how an attack effort is parallelized or distributed—all one has to do is make sure that full parallelization of an attack is possible. Note that this does not take into account large-scale (and possibly surreptitious) Internet-based calculations. For cryptographically relevant key lengths, however, effective attacks require such a huge computational effort that they will not go unnoticed when mounted using some type of Internet worm.

### Relation Between Security Level and Security

To determine whether a cryptographic system offers adequate security or protection, it is not immediately useful to tie the definition of security level to symmetric cryptosystem key lengths. In the first place, the amount of time and money required to realize an attack effort decreases over time because computers become faster and cheaper. Thus, the amount of protection offered by a certain fixed security level is constantly eroded. A related point is that cryptanalytic progress over time may affect the security level of a cryptographic system not by lowering the cost to realize a certain attack but by proposing an improved attack method. Furthermore, the definition of security level involves an unspecified constant of proportionality—vaguely indicated by the “approximately  $2^{\lambda-1}$ ”—and thus its meaning may vary from system to system. And finally, “adequate protection” is a vague term whose interpretation depends on the application one has in mind and is even then still subjective. In the remainder of this section, these issues affecting the relation between security levels and security are addressed, which allows selection of key lengths corresponding to any amount of protection one feels comfortable with.

### Modeling the Relation

Although a cryptosystem’s security level may not be indicative of its effectiveness, security levels allow comparison of the security offered by cryptosystems. Assuming identical constants of proportionality and environments, a cryptosystem of security level  $\lambda + \mu$  may be expected to be  $2^\mu$  times harder to attack, and thus be  $2^\mu$  times more secure, than a cryptosystem of security level  $\lambda$ . Once it has been agreed that a certain security level offers an adequate amount of protection in a certain known (past) environment, twice the protection can be achieved in that environment by incrementing the security level by one (assuming other characteristics of the cryptosystem involved

are not affected by the change). And, more in general, an  $x$  times higher amount of protection follows, in that same environment, by adding  $\log_2 x$  to the security level. If, additionally, the effect of changes in the environment is modeled, then a more general correspondence can be derived between security levels and amount of protection for any (future) environment. As indicated above, these environmental changes come in two flavors: changes in the computational environment that affect the amount of protection by lowering the cost at which the same attack can be realized but that leave the security level itself unchanged and changes in the cryptanalytic environment that allow a different type of attack thereby lowering the security level. The presentation below heavily relies on Lenstra and Verheul (2000) where this approach was first proposed.

### Defining Adequate Protection

The data encryption standard (DES) is a symmetric cryptosystem with 56-bit keys, published in 1977 by the U.S. Department of Commerce (National Bureau of Standards, 1997) and was brought up for reaffirmation, like other Federal Information Processings Standards (FIPS), once every 5 years. There was some skepticism about the security level of the DES. But despite extensive cryptanalysis no better generic attack than exhaustive key search has been found and the security level is generally believed to be 56.

Because the DES was widely adopted, there must have been broad consensus that in 1982, the first year the DES would come up for review, it offered an adequate amount of protection for commercial applications. For that reason, and for the purposes of this chapter, *adequate protection* is defined as the security offered in 1982 by the DES. Disregarding the effect of the constant of proportionality, this is synonymous with *security level 56 in 1982*. In the remainder of this section, it is discussed what security level can be expected to offer adequate protection until the year of one’s choice. It is left to the reader to determine how the definition of adequate protection compares to one’s own security requirements and, if desired, to change the default choice made above. The paragraphs below may be helpful for this purpose.

### The Cost of Breaking the DES

To put the definition of adequate protection in a different light, in 1980 it was estimated that, in 1980 money and technology, an exhaustive key search attack against the DES would require on average 2 days on a device that would cost approximately U.S.\$50 million to build. The design underlying this estimate is fully parallelizable as defined above: in 1980 the DES could be broken in approximately 100M dollardays. The cost does *not* include the one time overhead for the detailed design specifications.

### Modeling the Effect of Changes in the Computational Environment

Technical progress had a profound effect on the security of the DES. In 1993 a DES key search engine was proposed that would require about 150K dollardays, down from the 100M dollardays required by the 1980 design (Wiener,

1993). And in 1998 a parallel hardware device was built for U.S.\$130K, including design overhead, and used to crack the DES in a matter of days (Electronic Frontier Foundation, 1998; Kocher, 1999). Thus, though security level 56 may have offered adequate protection for commercial applications in 1982, this is no longer the case in 2004.

The effect of changes in the computational environment is modeled using Moore's law. Traditionally, it says that the computing power per chip doubles every 18 months. To make Moore's law less technology dependent the following variant is adopted for this chapter:

**Moore's law:** The cost of any fixed attack effort drops by a factor 2 every 18 months.

This can be seen to be in reasonable correspondence with the various DES cracking devices referred to above. It follows that the 100M dollardays cost of the 1980 DES cracker would be reduced to 40M dollardays in 1982, because  $40 \approx 100/2^{24/18}$ .

Obviously, all estimates of this sort based on Moore's law have to be taken with a grain of salt and interpreted appropriately: the approximate values and growth rates matter, not the precise figures. General agreement on Moore's law, however, is impossible to achieve. As formulated above, it is an acceptable compromise between those who argue that this rate of progress cannot be sustained, and those who find it prudent to expect more rapid progress or that, based on economies of scale arguments, an even stronger version of Moore's law would apply when highly parallel devices are taken into account (cf. P. C. Kocher, personal communication, September 1999). Another argument in favor of more rapid progress is that cost according to the definition used in this chapter includes both time and the price of memory: speed may increase—traditionally the only effect taken into account in Moore's law—whereas simultaneously the price of memory may drop, combined with the fact that for asymmetric cryptosystem cryptanalysis larger memories may allow closer to optimal parameter selection and thereby make computations much more time efficient (cf. Lenstra et al., 2003 and Factoring-Based Cryptosystems). But arguing against it is the observation that memory speeds often lag behind, thereby affecting or possibly canceling the effect of processor speedups. Overall the choice made in this chapter must be seen as a compromise that attempts to take all processor speed and memory issues into account.

### The Cost of Adequate Protection

Adequate protection was defined as the security offered by the DES in 1982. The cost to break the DES in 1982 is estimated as 40M dollardays. This leads to the following equivalent and more generally applicable definition of adequate protection. Irrespective of the speed or type of the cryptosystem, a cryptosystem is said to offer adequate protection until a given year if the cost of a successful attack measured in that year—and thus using the buying power of the dollar in that year—can be expected to be approximately 40M dollardays. See below how to change the cost figure corresponding to adequate protection from 40M to  $x * 40M$  if 40M is felt to be inadequate ( $x > 1$ ) or

overkill ( $0 < x < 1$ ) or if the effect of inflation is not adequately taken into account by Moore's law. For reasonable values of  $x$ , the effect of the resulting corrections is mostly negligible because only the approximate values matter.

For asymmetric cryptosystems based on the factoring problem or the general problem of computing discrete logarithms in multiplicative groups of finite fields the 40M dollardays cost measure will be used to determine adequate protection. For other asymmetric cryptosystems based on the discrete logarithm problem, symmetric cryptosystems, and cryptographic hash functions one can instead use the approach based on security levels combined with Moore's law. To allow comparison with DES security levels, the effect of the constant of proportionality must be taken into account, at least in principle. Below it is shown how this is done.

### The Effect of Moore's Law

It follows from Moore's law that to maintain the same amount of protection once every 18 months the security level should be incremented by 1, assuming the speed is not affected. Thus, assuming the same speed as the DES, a symmetric cryptosystem of security level  $56 + 10 = 66$  would offer adequate protection in 1997, because  $1997 - 1982 = 15$  years covers 10 periods of 18 months. Under the same assumption, security levels 76 and 86 should be adequate until 2012 and 2027, respectively.

More in general, a symmetric cryptosystem of speed comparable to the DES would offer adequate protection until the year  $y = 1982 + 15x$  if its security level is  $\lambda = 56 + 10x$ . Given a security level  $\lambda$ , the year  $y(\lambda)$  until which it offers adequate protection is thus calculated as follows:

$$y(\lambda) = 1982 + \frac{3(\lambda - 56)}{2}. \quad (1)$$

Conversely, given a year  $y$ , the security level  $\lambda(y)$  that offers adequate protection until year  $y$  is as follows:

$$\lambda(y) = 56 + \frac{2(y - 1982)}{3}. \quad (2)$$

Although this may be a reasonable model that leads to a useful computational tool, it would stretch the imagination to use it beyond, say, the year 2050. But it is, for instance, not unreasonable to conclude that the widely used security level  $\lambda = 80$  offers adequate protection until the year

$$y(80) = 1982 + \frac{3(80 - 56)}{2} = 2018$$

[cf. Eq. (1)].

### The Effect of the Constant of Proportionality

If a symmetric cryptosystem is  $s > 0$  times faster than the DES, exhaustive key search and thus generic attacks are  $s$  times faster as well. To compensate for  $s \neq 1$  without changing the year,  $\log_2 s$  should in principle be added to the security level; or if the security level should be left unchanged,  $1.5 \log_2 s$  must be subtracted from the year.

Ciphers faster than the DES ( $s > 1$ ) require a higher security level or the same security level does not last as long. But for slower ciphers ( $s < 1$ ) a lower security level suffices or the same security level lasts longer.

In theory, this correction based on the speed compared with the DES takes care of the unspecified constant of proportionality mentioned above. In practice, however, this correction should not be used. Not only is  $|\log_2 s|$  typically small but also making such corrections would lead to a misleading sense of precision contradictory to the way these estimates should be interpreted.

### Alternative Definitions of Adequate Protection

Defining adequate protection as the security offered by security level 56 in 1982 may be a reasonable compromise. But it is a subjective choice. If “security level 56 in year  $Y$ ” better reflects one’s feelings, then one should replace in the sequel all occurrences of 1982 by  $Y$ . Furthermore, in the “40M dollardays cost” associated with adequate protection, the 40 must be divided by  $2^{2(Y-1982)/3}$ . For instance, if the DES was still felt to offer adequate protection in the year 1990, replace 1982 by 1990 throughout, and 40M by 1M, because  $2^{2(1990-1982)/3} \approx 40$ .

Similarly, if one is more comfortable with interpretation of cost figures and finds the “40M dollardays” inappropriate, replace the 40 in the sequel by  $x * 40$  for any  $x \neq 1$  of one’s choice. As a consequence, all occurrences of the year 1982 must be replaced by  $1982 - 1.5 \log_2 x$ .

### Modeling the Effect of Changes in Cryptanalytic Capabilities

Moore’s law may act as a self-fulfilling prophecy by influencing and controlling the development of the steady stream of improvements required to sustain it. There is no similar mechanism controlling the rate of cryptanalytic progress.

Moore’s law affects all cryptosystems across the board in the same way by lowering the cost of attacks (cf. discussion of Moore’s law under Security Level). However, cryptanalytic progress usually affects the security level of one particular type of cryptosystem while leaving that of others untouched. An advance in factoring does not affect the security level of symmetric cryptosystems, and a newly found peculiarity in the design of an  $S$ -box used by some symmetric cryptosystem has no effect on the security level of RSA or of symmetric cryptosystems using nonaffected designs. Furthermore, the overall effect of cryptanalytic progress may vary from system to system. When a new weakness in a symmetric cryptosystem or cryptographic hash function is discovered, it may be possible to modify or simply retire it because relatively small modifications often render new attacks useless and, if not, there are enough equivalent alternative cryptosystems and functions to choose from. In the asymmetric case, the situation is different. The luxury of a quick switch to an alternative cryptosystem can generally not be afforded because there are not that many different equivalent schemes. As a result, adapting key lengths may be the only option to compensate for the effects of a new cryptanalytic insight such

as a new algorithm to solve the mathematical problem underlying an asymmetric cryptosystem.

There are cryptographic applications, however, where system modification or retirement and key length adaptations are not feasible, and where adequate protection must be maintained for an extended period of time, even in the presence of cryptanalytic progress discovered after the application was put to use. For instance, in long-term confidential data storage in an infrastructure that lacks appropriate physical protection, the fixed stored data must remain undecipherable as long as the confidentiality must last. With the present state of the art of cryptology disasters can always happen, and adequate long-term protection cannot be fully guaranteed. Barring disastrous cryptanalytic progress, however, proper application of suitably modeled cryptanalytic progress leads to an acceptable practical solution for long-term protection as well.

It remains to model cryptanalytic progress. A priori it is unclear how this should be done. However, because there is no reason to expect significant changes in the global research community that is interested in cryptanalysis, it is assumed that the rate of cryptanalytic progress in the future is the same as it was since cryptography became more of a mainstream public domain activity. Because past cryptanalytic progress varied considerably between different cryptographic systems, a specific cryptanalytic progress model is defined for each of the various cryptosystems. The details of each model are described in the relevant sections below.

## SYMMETRIC CRYPTOSYSTEMS

Symmetric cryptosystems are encryption methods where sender and receiver share a key for encryption and decryption, respectively. Examples are block and stream ciphers. There is a great variety of such cryptosystems, but only a few of them are generally accepted and widely used. The popular block ciphers, with the exception of the original DES, can be expected to offer adequate protection (cf. Security Level) for the foreseeable future. If adequate protection until the year 2018 is desired the key generation method should use at least 80 random bits. With 90 random bits adequate protection until at least 2030 may be expected. Thus, from a pragmatic point of view, key length selection for block ciphers is hardly an issue as long as one sticks to widely used modern schemes. In this section, some issues are discussed concerning security levels and key lengths for a number of popular block ciphers.

Stream ciphers are more problematic. They are not considered here for a variety of reasons. Often their design is proprietary or their usage subject to licensing restrictions. Their cryptanalysis is too much in a state of flux and their security level influenced by the way they are used. For instance, the strong version A5/1 of a stream cipher used in the European cellphone industry can trivially be broken (Biryukov, Shamir, & Wagner, 2001) a similar application of the stream cipher RC4 was found to be completely insecure (Fluhrer, Mantin, & Shamir, 2001), and the stream cipher SEAL has been revised several times (Handschuh & Gilbert, 1997). Finally, all six stream ciphers submitted to the NESSIE initiative (New

**Table 1** Common Block Ciphers

Name	Key Length	Block Length	Security Level
DES	56	64	56
Two key triple DES	112	64	112
Three key triple DES	168	64	123
DESX	120	64	120
IDEA	128	64	128
AES-128	128	128	128
AES-192	192	128	192
AES-256	256	128	256

European Schemes for Signatures, Integrity, and Encryption [NESSIE], 2000–2003.) were found to be too weak and none was selected, illustrating the apparent difficulty of designing stream ciphers.

## Block Ciphers

Table 1 lists some common block ciphers along with their key length choices, block lengths, and the most up-to-date information about their security levels under generic attacks. The list is for illustrative purposes only and is not, nor is it meant to be, exhaustive. In- or exclusion of a cipher in no means indicates the author's support for that cipher or lack thereof. Although other types of attacks such as differential and linear cryptanalysis are not considered to determine the security level (cf. Security Level), the more recent block ciphers are designed to have strong resistance against those attacks as well.

Typically, key lengths of block ciphers are not variable parameters, so for a fixed block cipher iterated application is the only way to increase its security level. Double encryption using two independent keys is widely believed to add little to the security level (cf. Wiener, 2004) and is therefore not considered in Table 1. Triple encryption, however, has significant effect on the security level, as shown for the DES in Table 1. It turned out to be a convenient way to boost security by repeated application of an available cipher when replacement by a stronger one is not an option. Usually the middle encryption is a decryption operation for easy compatibility with the original single encryption. The two key variant uses the same key for the first and last iteration, but a different for the middle decryption iteration, whereas the three key variant uses three independent keys for the three iterations.

For triple-DES the security levels in Table 1 are based on the analysis in Wiener (2004). For two key triple-DES the security level of 112 assumes that the known plaintext consists of at most  $2^{12}$  blocks; for instance, with  $2^{30}$  known plaintext blocks the security level would be only about 100 (cf. M. J. Wiener, personal communication, 2004). Also, under a different attack model, where an unlimited number of chosen plaintexts is allowed, the security level drops even sharper, namely from 112 to about 75 (cf. M. J. Wiener, personal communication, 2004). For DESX (cf. Kilian & Rogaway, 1996) and IDEA (cf. Biham, Dunkelman, Furman, & Mor, 2004) the security levels are based on the fact that even after many years no effective cryptanalysis has been published, as far as generic attacks

are concerned. For the advanced encryption standard (AES), they may be based on wishful thinking because at the time of writing of this chapter the AES has been scrutinized for only a few years. But this is combined with the expectation (based on the sudden replacement of SHA by SHA-1, see Cryptographic Hash Functions) that if anytime soon something serious affecting the AES would be found, a modification would be introduced. Table 1 shows that, other than for legacy reasons and if the security level is the only criterion, there is in principle no reason to settle for a cipher that offers a security level lower than its key length.

## Performance Considerations

As indicated under Security Level, a proper interpretation and comparison of the security levels in Table 1 in principle requires knowledge of the relative speeds of the various block ciphers. It is also mentioned, however, that this type of “overprecision” has no practical relevance. This is illustrated here.

According to Eq. (1) under Security Level, security level  $\lambda$  offers adequate protection until the year  $y(\lambda) = 1982 + 3(\lambda - 56)/2$ , disregarding the effect caused by the speed relative to the DES. A block cipher of security level  $\lambda \geq 128$  leads to an uncorrected year estimate of  $y(128) = 2090$  and beyond. Proper interpretation of this result is that security level 128 should suffice for, say, the next 3 decades and probably even longer. Incorporation of the effect of the speed compared with the DES has no effect. For instance, IDEA and the DES have comparable hardware performance, but in software, IDEA is approximately twice faster (i.e.,  $s = 2$  in the notation presented under Security Level). So, in principle it would be “correct” and may be even believed to be prudent to subtract  $1.5 \log_2 2 = 1.5$  from the year 2090, as set forth under Security Level. But the practical conclusion that IDEA should offer adequate security for the foreseeable future remains untouched by this correction. The same practical conclusion would be reached for block ciphers of security level 128 that would be a million times faster or slower than the DES.

## Other Considerations

Another issue with block ciphers is their block length. With  $b$  bit blocks, and under reasonable assumptions regarding randomness of the inputs and the cipher's output behavior, a duplicate output block may be expected after about  $2^{b/2}$  blocks have been encrypted. A duplicate generated with the same key may facilitate cryptanalysis and should be avoided.

When  $b = 64$ , this implies that the key should be refreshed well before  $2^{32}$  blocks of 64 bits (i.e., 32 GB) have been encrypted—say after 10 gigabytes. When  $b = 128$ , the likelihood is negligible that duplicate blocks are encountered for any realistic amount of data properly encrypted with the same key.

## Symmetric Key Lengths That Offer Adequate Protection

With the exception of the DES, all ciphers listed in Table 1 offer adequate protection with respect to generic attacks at least until the year 2030: even the weakest among

them, two key triple-DES, may be expected to offer adequate security until 2066 because, according to Eq. (1),  $y(112) = 1982 + 3(112 - 56)/2 = 2066$ . Correction for the performance degradation compared with the DES (by  $-\log_2 1/3$  resulting in  $y(112) = 2067.5$  because  $s$  would be  $1/3$ ) is meaningless because the precision suggested by the original calculation is overzealous already: the model is nowhere near precise enough to draw conclusions up to a specific year, let alone half a year, and certainly not if it is more than 50 years in the future.

Given the virtual lack of cryptanalytic progress with respect to generic attacks and assuming current cryptanalytic trends persist (i.e., that cryptanalysis remains relatively ineffective), the ciphers of security level  $\geq 128$  can be expected to offer adequate protection for any conceivable commercial application, including long-term data storage, and as long as anyone can reasonably predict. Thus, most ciphers from Table 1 with the exception of the DES can safely be recommended, as long as the amount of data that will be encrypted with a single key is limited. If the latter cannot be guaranteed, the AES should be used.

In Blaze et al. (1996), which dates back from 1996, it is recommended that for adequate protection for the next 20 years (i.e., until the year 2016) keys in newly deployed symmetric cryptosystems should be at least 90 bits long. According to the estimates presented here, security level  $\lambda = 90$  would offer adequate security until the year  $y(90) = 1982 + 3(90 - 56)/2 = 2033$  and security level  $\lambda(2016) = 56 + 2(2016 - 1982)/3 = 78\frac{2}{3}$  would suffice until the year  $y = 2016$  (cf. Eqs. [1] and [2]). Thus, the recommendation of Blaze et al. (1996) is conservative and can be followed without hesitation.

It may seem wasteful to use a key length such as 128 that leads to a security level that is so much larger than necessary. As far as the speed of symmetric cryptosystems is concerned, this is not an issue because key sizes have no major impact on their speed. If the “overlong” key is problematic because of other concerns such as cost of key exchange or storage, a sufficiently shortened but still adequately long version may be used and padded with a fixed sequence of bits known as *salt* (cf. Schneier, 1996). If used, salt should be applied with great care. For instance, in case of triple-DES care must be taken that it does not reduce the encryption to double encryption, thereby effectively almost halving the length of the already shortened key (cf. Wiener, 2004). Because algorithms are generally designed assuming the entire key is secret, as a general practice it is recommended to derive the actual key from the shortened version and the salt by hashing or a similar mixing operation.

## CRYPTOGRAPHIC HASH FUNCTIONS

Given an input consisting of an arbitrary sequence of bits, a cryptographic hash function efficiently produces a fixed length output, the *hash* of the input. In this section  $H$  denotes the bit length of the hash. The output is intended as a “fingerprint” of the input in data integrity and authentication applications. Therefore, cryptographic hash functions must have a number of properties that make them suitable for these applications. In the first place given any output value for which the corresponding input

is unknown, it must be computationally infeasible to find any input that hashes to that output. Second, for a known (input/output) pair, it must be computationally infeasible to find another input that hashes to the same output. Although these two properties suffice for many applications (cf. Bellare & Rogaway, 1997) it is common to assume a stronger version of the last property, namely that it must be computationally infeasible to find two distinct inputs that hash to the same output. This last requirement is often referred to as *collision resistance*.

The issue at discussion here are the requirements on  $H$  without which a cryptographic hash function cannot have the desired properties (i.e., the length requirements that must be met irrespective of any of the other properties of the hash function). Obviously, satisfying the requirements on  $H$  does not guarantee proper design of the hash function, it is just a necessary first step.

Assume that the output of a hash function behaves as a uniformly distributed random  $H$  bit value. It follows from the first two requirements that  $H$  must be chosen such that it is computationally infeasible to perform  $2^H$  applications of the hash function (for random inputs). Thus, to achieve security level  $\lambda$  and to satisfy the first two requirements, it must be the case that  $H \geq \lambda$ .

The collision resistance requirement, however, has more severe consequences for  $H$ . If values are drawn at random from a set of cardinality  $C$ , then the expected number of draws before an element is drawn twice (a so-called collision) is approximately  $1.25\sqrt{C}$ . This fact is commonly known as the *birthday paradox*. It follows that if the hash is computed of different randomly selected inputs, a duplicate output can be expected after about  $1.25 * 2^{H/2}$  attempts. This birthday paradox attack is fully parallelizable with cost, as defined under Security Level essentially proportional to  $2^{H/2}$  (cf. Wiener, 2004). To achieve security level  $\lambda$  and to satisfy the third requirement, it must therefore be the case that  $H \geq 2\lambda$ .

The search for a collision as described above is commonly known as a *collision attack*. Resistance against exhaustive key search and collision attacks play comparable roles in the contexts of symmetric cryptosystems and cryptographic hash functions, respectively: well-designed symmetric cryptosystems do not allow generic attacks faster than exhaustive key search, and well-designed cryptographic hash functions do not allow discovery faster than by collision attacks of a distinct pair of inputs with identical outputs.

## Cryptographic Hash Functions

Table 2 lists some common hash functions along with their output lengths and the most up-to-date information

**Table 2** Common Cryptographic Hash Functions

Name	H	Security Level
RIPEMD-160	160	80
SHA-1	160	80
SHA-256	256	128
SHA-384	384	192
SHA-512	512	256

about their security levels under collision attacks (cf. Federal Information Processing Standard 180-2, 2000).

## Cryptanalytic Developments

Well-known precursors of the cryptographic hash functions in Table 2 are MD4, MD5, and RIPEMD-128, all with  $H = 128$ , and SHA, with  $H = 160$ . Significant deficiencies were found in their design. MD4 is considered to be broken, and it is widely suspected that the security levels of MD5 and RIPEMD-128 are both lower than 64. Furthermore, a sufficiently serious problem was found in SHA to replace it by SHA-1. For a discussion of these developments, see Chabaud and Joux (1998), Dobbertin, Bosselaers, and Preneel (1996), and Bosselaers (2004).

The results of those cryptanalytic findings were incorporated in the design of the cryptographic hash functions in Table 2. That is no guarantee that those functions do not allow faster attacks than collision attacks. But it indicates that the functions from Table 2 were designed with a great deal of care and that an unanticipated new weakness most likely requires new cryptanalytic insights. Given how infrequently such insights occur, it is reasonable at this point to assume that the security levels in Table 2 are accurate for the foreseeable future. This should be combined with a conservative choice of cryptographic hash function and, where possible, application of the methods from Bellare and Rogaway (1997) to design one's protocols in such a way that the cryptographic hash function does not have to be collision resistant (i.e., does not have to meet the third requirement). If the latter is properly done it effectively doubles the security level.

## Performance Considerations

Whether a cryptographic hash function of hash length  $H$  offers adequate protection until a certain year, as defined under Security Level, in principle depends on the relative speed of the hash function compared to the DES. With inputs of comparable length, the speed of all common cryptographic hash functions is comparable to the speed of common block ciphers, such as the DES. Thus, the effect of incorporating the speed is negligible to begin with. Furthermore, as argued under Symmetric Cryptosystems, for the larger  $H$  values the effect is best neglected anyhow because it would lead to inappropriately precise interpretation of inherently imprecise figures.

## Cryptographic Hash Lengths That Offer Adequate Protection

In combination with the findings under Security Level and Symmetric Cryptosystems, it follows that cryptographic hash functions with  $2\lambda$ -bit hash values offer adequate protection until the year  $y(\lambda) = 1982 + 3(\lambda - 56)/2$  (cf. Eq. [1]). More in particular, the above cryptographic hash functions with  $H = 160$ , assuming they remain unbroken, may be expected to offer adequate protection until the year  $y(160/2) = 2018$ . All functions listed in Table 2 can be expected to offer adequate protection at least until the year 2030, very conservatively estimated, under the proviso that the functions with 160-bit hash values

are used in combination with the methods from Bellare and Rogaway (1997). As a rule of thumb, hash lengths must be chosen to be twice longer than symmetric key lengths.

## ASYMMETRIC METHODS

### Private Key and Public Key

In asymmetric cryptosystems each user, say  $A$ , has its own pair of keys:  $A$ 's private key  $s_A$  and the corresponding public key  $p_A$ . Typically, the public key  $p_A$  can be used by any party to encrypt information intended for user  $A$ , which can then be decrypted by  $A$  using  $s_A$ . Alternatively,  $A$  may use  $s_A$  to digitally sign documents, and any party can use  $p_A$  to verify the resulting digital signatures. For some cryptosystems, a single private/public key pair allows both en-/decryption and digital signatures, but great care has to be taken when doing so (cf. Davida, 1982; Desmedt & Odlyzko, 2003; Haber & Pinkas, 2001).

### Performance Deterioration

For symmetric cryptosystems and cryptographic hash functions the number of realistic alternatives is fairly limited, and their speed hardly depends on the key or hash length one settles for. For asymmetric cryptosystems, the situation is different. There the performance of both the public operation (encryption or signature verification) and the private one (decryption or signature generation) deteriorates markedly, and possibly to different degrees, as the security level increases. Therefore, for asymmetric cryptosystems it is more important than for symmetric cryptosystems and cryptographic hash functions to determine the smallest key length that still offers the right amount of protection, thereby balancing security and performance requirements.

## The Design of Asymmetric Cryptosystems

The design of all common symmetric cryptosystems and cryptographic hash functions is mostly based on a combination of hard-to-define ingredients such as experience, avoidance of common errors, incorporation of the latest cryptanalytic insights, taste, sound judgment, and luck. As argued in Landau (2004), the design of the AES is a first attempt to a more scientific, less artful approach to block cipher design. All common asymmetric cryptosystems, conversely, are based on a well-defined mathematical problem, if at all possible combined with a proof that solving the latter is equivalent to breaking the cryptosystem. The security of an asymmetric cryptosystem is then based on the hope and belief that the mathematical problem does not allow an efficient solution. Sometimes that hope turns out to be ill founded. For instance, the once popular trapdoor knapsack public key cryptosystems (cf. Merkle & Hellman, 1978) were found to be susceptible to attacks using lattice basis reduction. Efficient lattice basis reduction methods thus meant the end for trapdoor knapsack asymmetric cryptosystems. Refer to Nguyen and Stern (2001) for the extensive literature on these and related subjects.

## Factoring and Discrete Logarithms

The two mathematical problems underlying the popular and by now “classical” asymmetric cryptosystems are integer factorization and computing discrete logarithms, as described below. Both these problems have been the subject of active research during the past few decades. Also, the cryptographic protocols they are embedded in have been widely studied, in various cases resulting in provable equivalence of breaking the protocol and solving the mathematical problem. Despite occasional jumps because of theoretical advances, it turned out that the practical implications of the solution methods for the mathematical problems underlying asymmetric cryptosystems so far always displayed a smooth pattern without jumps or unwelcome “surprises.” The assumption that this same smooth pattern persists allows reasonably well-founded analyses of key lengths required for adequate protection in the future. These analyses are presented in the subsequent sections.

It should be understood, however, that a clearly discernable and well-established past pattern in practical cryptanalytic progress is no guarantee that the future pattern will be the same or that there will not be any surprising breakthroughs with immediate practical consequences. With the present state of the art there is no hard proof of the security of any of the popular asymmetric cryptosystems, simply because there are no proofs yet of the difficulty of any of the underlying mathematical problems: the only evidence of their difficulty is our failure to solve them. This is independent of any proofs of equivalence between a cryptosystem and its underlying mathematical problem. To refer to this provable equivalence as “provable security,” as common in the cryptographic literature, may be misleading, because what it actually means is “provable equivalence to a problem of unproved hardness.”

Roughly speaking, all common asymmetric cryptosystems are based on one of the following two problems, or a variation thereof:

**Integer factorization.** Given a composite integer  $n > 0$ , find integers  $u > 1$  and  $v > 1$  such that  $n = uv$ .

In RSA, the most common factoring based asymmetric cryptosystem, a user’s public key contains the integer  $n$ , the corresponding private key contains (information equivalent to)  $u$  and  $v$ , and  $n$  is unique per user.

**Discrete logarithm.** Given an element  $g$  of a multiplicatively written group  $G$  and an element  $h$  in the subgroup  $\langle g \rangle$  generated by  $g$ , find an integer  $k$  such that  $g^k = h$ . The smallest nonnegative such  $k$  is referred to as the discrete logarithm of  $h$  with respect to  $g$  and denoted  $\log_g h$ .

For additively written groups, one would look for an integer  $k$  such that  $kg = h$ . The smallest nonnegative such  $k$  is again referred to as  $\log_g h$ .

In discrete logarithm-based asymmetric cryptosystems, a user’s public key contains  $g$  and  $h$  and the corresponding private key contains  $\log_g h$ . Different users may share the same  $g$  but use different  $h$ ’s.

The *traditional* discrete logarithm problem refers to the case where  $G$  is chosen as the multiplicative group  $(\mathbf{F}_{p^\ell})^*$

of a finite field  $\mathbf{F}_{p^\ell}$  of cardinality  $p^\ell$ , for some prime  $p$  and positive integer  $\ell$ .

Instances of these problems can easily be generated that are suitable for cryptographic applications and generally believed to be hard to solve. In the sections below, it is discussed how to do this in such a way that the corresponding cryptosystems offer adequate protection until a specified year, as defined under Security Level. This has certain consequences for the size of the integer  $n$  and its factors, for the cardinality  $\#(g)$  of the subgroup  $\langle g \rangle$ , and for the cardinality  $p^\ell - 1$  of the group  $G = (\mathbf{F}_{p^\ell})^*$  if the traditional discrete logarithm problem is used. Intuitively this is rather obvious, because small integers are easy to factor, small factors are easy to find, and discrete logarithms are easy to calculate if  $\#(g)$  is small. The requirements on  $n$  and its factors are discussed under Factoring-Based Cryptosystems and the same is done for  $g$  both for the case  $G = (\mathbf{F}_{p^\ell})^*$  and for more general groups  $G$  under Discrete Logarithm-Based Cryptosystems.

## Other Asymmetric Cryptosystems

There are quite a few asymmetric cryptosystems that are based on different mathematical problems than the currently popular ones mentioned above, but that have not yet gained general acceptance. The reason for the latter is related to the underlying mathematical problem, the cryptographic protocol it is embedded in, or a combination of these issues. There may be skepticism about the difficulty of the mathematical problem because it has not been studied long enough. Or the effectiveness of solution methods may be hard to judge or in a constant state of flux, making it difficult to recommend secure parameter choices. Also, cryptographic protocols that are provably equivalent to the mathematical problem may still be lacking, or the cryptosystem may simply be too impractical. Asymmetric cryptosystems that have any of these shortcomings are discussed no further in this chapter. Examples are the recently proposed lattice-based cryptosystems (cf. Nguyen & Stern, 2001), such as NTRU in Ajtai and Dwork (1997), Goldreich, Goldwasser, and Halevi (1997), and, in particular, Hoffstein, Pipher, and Silverman (1998) (even though it was not originally designed as a lattice-based cryptosystem). Although NTRU looks promising because of frequent protocol design tweaks, the dust has not settled yet and it is too early for a fair security assessment. The reader is recommended to consult the recent cryptology literature to find the latest updates on asymmetric cryptosystems that are not treated here.

## FACTORIZING-BASED CRYPTOSYSTEMS

There are several types of asymmetric cryptosystems that rely for their security on the hardness of the integer factorization problem: if the integer factorization problem can be solved for a certain composite integer referred to as the *modulus*  $n$ , then the cryptosystem using that  $n$  can be broken. Thus, factoring the modulus suffices to break the cryptosystem. In this section, we discuss how  $n$  should be selected in such a way that the integer factorization problem for  $n$  offers adequate protection until a year of

one's choice. It should be kept in mind, however, that for most common factoring-based cryptosystems (such as RSA) it has, in general, not been proved that factoring the modulus is also necessary to break them, although cryptosystems equivalent to factoring do exist. An example is Rabin's signature scheme (cf. Rabin, 1979).

## Main Variants

The way the modulus is constructed depends on the factoring-based cryptosystem one uses. In the most common factoring-based cryptosystems, the modulus is the product of two primes of approximately the same size (cf. Rivest, Shamir, & Adleman, 1983). A variation, RSA multiprime (cf. Rivest, Shamir, & Adleman, 1983), improves the efficiency of the private operations by allowing more than two factors of approximately equal size in the modulus. Less common variants are RSA for paranoids (Shamir, 1995), where the private operations are performed modulo the smallest prime factor of the modulus, and variants where the modulus contains repeated factors. Requirements on the size of the modulus and its factors are discussed below. For any of the variants moduli can be constructed efficiently because primes of any practical size can be generated quickly.

## Trial Division

The conceptually most straightforward way to factor a composite integer  $n$  is by trying if  $n$  is divisible by 2, 3, 5, 7, 11, 13, ..., successively trying all primes until the smallest proper divisor is found. This process is known as *trial division*. It remains the method of choice of amateur factorizers. For that reason a detailed explanation of the cryptanalytic ineffectiveness of trial division is provided.

For randomly selected composites without known properties, and therefore not stemming from cryptographic applications, trial division is often a very efficient way to find a factor because for random composites the smallest factor can be expected to be small: half of the random composites are even, so the first trial division attempt will be successful in 50% of the cases, one-third of the remaining (odd) numbers is divisible by 3 and so on. It is very easy, however, to construct composites for which trial division is totally ineffective. This can be seen as follows.

According to the *prime number theorem* the number of primes up to  $x$  is proportional to  $x/\log x$ . This means that to find the smallest prime factor  $p$  of  $n$  using trial division on the order of  $p/\log p$  smaller primes have to be tested before  $p$  is found. Because the cost of each attempt is at least proportional to the logarithm of the number tested and because the primes  $\leq p$  can be generated in time proportional to  $p$ , the overall computational effort to find the prime factor  $p$  of  $n$  is proportional to  $p$ . Thus, if  $n$  is constructed as the product of two, say,  $b$ -digit primes, the computational effort to factor  $n$  using trial division is on the order of  $10^b$ , which can be parallelized in any way one sees fit by distributing ranges of candidate factors. Even for moderate  $b$  such as 50 a computational effort of this magnitude is out of reach, also if any realistic level of parallelism is applied. Furthermore, there are other factoring methods that would factor such  $n$  much

faster. These other methods also allow arbitrary, but even much simpler, parallelization.

Another consequence of the prime number theorem is that the number of  $b$ -digit primes outnumbers the number of smaller primes. Thus, it does not help much, as often proposed, to exclude from the search in the example the primes having fewer than  $b$  digits thereby limiting the trial divisions to  $b$ -digit primes. This counting argument needs to be refined if binary as opposed to decimal length is used—amateur factorizers, however, are usually bit challenged and prefer decimal notation.

## Exponential Time Factoring Algorithms

In the worst case, where  $n$  has two factors of approximately equal size, the computational effort to factor  $n$  using trial division is proportional to  $\sqrt{n} = n^{1/2} = \exp((\log n)/2)$ . With a constant multiple of the input length  $\log_2 n$  in the exponent, it follows that trial division is an *exponential time algorithm*. There are exponential time factoring algorithms that are much faster than trial division. For instance, Pollard's rho method (Pollard, 1978) can be expected to find the smallest  $p$  dividing  $n$  after a computational effort that is not proportional to  $p$  but to  $\sqrt{p}$  (i.e., proportional to  $n^{1/2}$  in the worst case  $p \approx \sqrt{n}$ ).

If exponential time algorithms were the fastest factoring algorithms, it would be possible to select moduli  $n$  in such a way that  $\log_2 n$  is proportional to the desired security level: if Pollard's rho would be the best factoring algorithm, then  $4\lambda$ -bit moduli would offer security level  $\lambda$ . Unfortunately, for cryptographic applications of factoring-based asymmetric cryptosystems, exponential-time algorithms are by no means the best that can be done for factoring. As indicated above, much faster factoring algorithms exist. As a consequence, the required modulus bit length grows much faster than a linear function of the desired security level. In particular, modulus sizes grow much faster than symmetric cryptosystem key sizes and cryptographic hash function sizes.

## Polynomial Time Factoring Algorithms

On the opposite side of the spectrum from exponential-time algorithms are the *polynomial time algorithms*: a polynomial time factoring algorithm would require computational effort proportional to at most  $(\log n)^c$ , for some constant  $c$ . Although a polynomial time factoring algorithm has been published in Shor, 1994, it requires a not-yet-existing type of computer, a so-called quantum computer, to run it on. If the engineering problems of building a large enough quantum computer can be solved, factoring may be done in polynomial time, which will most likely mean the end for factoring-based asymmetric cryptosystems. Even a very modest prototype quantum device whose factoring capabilities would be non-trivial but well below those of an ordinary PC, for instance a device that would be able to factor a 128-bit RSA modulus in half an hour, would suffice to shake our confidence in the practical difficulty of integer factorization. Most popular number theory based asymmetric cryptosystems would be affected to the same dramatic extent. The effect on symmetric cryptosystems and cryptographic hash functions would be less significant.

Alternatively, development of a polynomial time factoring algorithm that would run on a traditional computer, a possibility that cannot yet provably be excluded, would have the same consequence. Even if the method has complexity  $O((\log n)^{12})$  and will not be a practical threat, its mere existence would be devastating for most current asymmetric cryptosystems—irrespective of future improvements and eventual practical applicability of the method.

At this point, there is not sufficient reason to suspect that practical polynomial time factoring is a realistic prospect. The possibility of practical polynomial time factoring is therefore not included in the analysis below.

What can realistically be done, however, is something that lies between exponential time and polynomial time factoring. These so-called subexponential time factoring algorithms are further discussed below.

### Subexponential Time Factoring Algorithms

The computational effort required for an exponential time factoring algorithm is bounded from above by a constant positive power of

$$n = \exp(\log n).$$

For a polynomial time method the required computational effort would be bounded from above by a constant power of

$$\log n = \exp(\log \log n).$$

To express the computational effort of algorithms that are faster than exponential time but not as fast as polynomial time, both possibilities are captured in a single formula in the following way. Let

$$L[n, r, \alpha] = \exp(\alpha(\log n)^r (\log \log n)^{1-r}).$$

Exponential time is characterized by  $r = 1$ , polynomial time by  $r = 0$ , and everything in between (i.e.,  $0 < r < 1$ ) is referred to as *subexponential time* (with, in all cases,  $\alpha$  a positive constant).

There are many factoring algorithms for which the computational effort is expected to be  $L[n, 1/2, 1 + o(1)]$  for  $n \rightarrow \infty$  (i.e., asymptotically for  $n$  to infinity, the value of  $\alpha$  approaches 1). For most of these algorithms the analysis is based on heuristic arguments, for some it can rigorously be proved. Note that, on the scale from  $r = 0$  to  $r = 1$  suggested above,  $L[n, 1/2, 1 + o(1)]$  (i.e.,  $r = 1/2$ ) is halfway between exponential time and polynomial time—this is just a curiosity of this parameterization and should be taken with a grain of salt. One example is the quadratic sieve factoring algorithm (QS), which can heuristically be expected to factor  $n$ , irrespective of any properties its factors may have, for a computational effort that behaves as  $L[n, 1/2, 1 + o(1)]$  for  $n \rightarrow \infty$  (cf. Pomerance, 1983). Another example is the elliptic curve method (ECM), which can heuristically be expected to find a factor  $p$  of  $n$  for a computational effort  $(\log n)^2 L[p, 1/2, \sqrt{2} + o(1)]$  (cf. Lenstra, 1987); in the worst case  $p \approx \sqrt{n}$  this becomes  $L[n, 1/2, 1 + o(1)]$ .

### Number Field Sieve

Because so many quite different methods all share essentially the same expected computational effort  $L[n, 1/2, 1 + o(1)]$ , this was suspected by some to be the “ultimate” complexity of factoring, although the author is unfortunately not aware of any published conjectures. In 1988 these cryptographic dreams were shattered by John Pollard’s invention of a new factoring algorithm (cf. Lenstra & Lenstra, 1993). The blow was, however, softened considerably by credible-looking evidence that the new method would become practical only beyond key sizes that were then employed in practice. Even though as a result of Pollard’s invention long-term expectations suddenly changed significantly, the practical impact turned out to fit smoothly on the anticipated crypt-analytic curve. The credible-looking evidence later turned out to be wrong—if the new algorithm had immediately been as effective as it turned out to be, its practical impact would have been alarming, too.

The original version of the new factoring algorithm, now referred to as the *special number field sieve* (SNFS), was intended to factor the ninth Fermat number  $F_9 = 2^{2^9} + 1$ , a number that was indeed completely factored in 1990 (Lenstra, Lenstra, Manasse, & Pollard, 1993). The SNFS can be applied to numbers that allow a particularly “nice” polynomial representation, such as  $F_9$ . Based on heuristic arguments the expected computational effort is  $L[n, 1/3, 1.526 + o(1)]$ . The generalized version, now referred to as the *number field sieve* (NFS), factors any number  $n$  for a (heuristic) expected computational effort  $L[n, 1/3, 1.923 + o(1)]$  (cf. Lenstra & Lenstra, 1993), which was later improved to  $L[n, 1/3, 1.902 + o(1)]$  (cf. Coppersmith, 1993).

On the scale from exponential time ( $r = 1$ ) to polynomial time ( $r = 0$ ) the NFS represents substantial progress from the halfway point ( $r = 1/2$ ) in the direction of polynomial time algorithms. Because the invention of the NFS no progress affecting the current best  $r = 1/3$  value has been published (with the exception of  $r = 0$  for quantum computers).

### The Cost of the NFS

Let the cost function be as defined under Security Level, that is, the product of time (or, equivalently, computational effort) and equipment cost. The NFS has two major stages, the relation collection stage and the matrix stage. As shown in Bernstein (2001) and Lenstra et al. (2002), the cost of the NFS depends on the way the relation collection stage is carried out. If a memory-intensive approach based on sieving is used the overall NFS cost behaves as  $L[n, 1/3, 2.852 + o(1)]$  for  $n \rightarrow \infty$ . An ECM-based approach is asymptotically considerably less costly: just  $L[n, 1/3, 1.976 + o(1)]$  if the matrix step is done on a mesh of processors and  $L[n, 1/3, 2.080 + o(1)]$  if the matrix is done using more traditional methods, and both for  $n \rightarrow \infty$ .

### NFS Results

Compared with the older  $L[n, 1/2, 1 + o(1)]$  methods, the NFS is conceptually complicated and, originally, suffered

from rather large  $o(1)$  values. Therefore, it was believed by some that the NFS had only theoretical but no practical value (cf. Dagstuhl Seminar 9226, 1992). However, a lot of progress has been made to improve the method, thereby lowering the  $o(1)$ s. As a result the NFS eventually surpassed the older methods also from a practical point of view. At the time of writing of this chapter, the NFS is the method of choice for actual large-scale distributed factorization experiments (cf. Cavallar et al., 2000; J. Franke, personal communication, 2004) and special purpose factoring hardware design proposals such as TWINKLE and TWIRL (cf. Lenstra & Shamir, 2000; Shamir & Tromer, 2003; Shamir, 1999). The following results have been obtained using the sieving-based approach:

- **Software implementation:** a 576-bit modulus has been factored using the NFS in about 12 years of computing time on a 1-GHz Pentium III processor (J. Franke, personal communication, 2004). In reality the attack made use of the full parallelizability of the main part of the attack: it was done on  $m$  processors in  $12/m$  years of computing time per processor, for some large  $m$ . Assuming the essential parts of a single 1-GHz Pentium III processor can be obtained for, say, U.S.\$100, a software attack on a 576-bit RSA modulus would cost less than 0.5M dollardays.
- **Special purpose hardware design proposal:** using 90-nm VLSI technology, it can be expected that factorization of a 1024-bit modulus takes at most one year using TWIRL, a special purpose hardware device that takes at most U.S.\$1 million to build (Lenstra et al., 2003). It follows that in 2004, at the time of writing this chapter, the cost of an attack on a 1024-bit RSA modulus using dedicated hardware can be estimated as at most 400M dollardays.

The earlier 130-nm version of the same device has a cost that is 10 times as high. The relatively large cost reduction is because of the fact that the larger memory of the later 90-nm design allowed much better parameter choices and thus led to a more than proportional speedup. This is an example of the effect that was noted in the discussion of Moore's law under Security Level. This remark is solely meant to explain why the 90-nm data point is so much better than the previous 130-nm one, it does not influence Moore's law or the way it will be used for asymmetric crypto systems,

Actually, these results refer to just the relation collection step, in practice the most cumbersome stage of the NFS factoring process. The other major stage, the matrix step, although in theory equally costly, is in practice negligible compared to the relation collection stage (cf. Bernstein, 2001; Lenstra et al., 2002).

Using  $L[n, 1/3, \dots]$ -based estimates (as shown below) it can be seen that dedicated hardware is substantially more cost-effective than a software implementation. This implies that the hardware estimates lead to larger, more conservative RSA moduli. The estimates below are therefore based on the hardware figures.

## Extrapolation to Other Modulus Lengths

The 400M dollardays cost to factor 1024-bit moduli in the year 2004 is combined with the asymptotic cost estimates for NFS to estimate the cost of factoring  $b$ -bit moduli in 2004 as follows:

$$\frac{L[2^b, 1/3, \alpha]}{L[2^{1024}, 1/3, \alpha]} \times 400\text{M dollardays},$$

with  $\alpha = 2.852 + o(1)$ . For the sake of simplicity—and because no better alternative is available—it is assumed that upon substitution the two  $o(1)$ s cancel. From a theoretical point of view, this assumption is hardly acceptable, but for limited range approximations the results of this compromise approach have been satisfactory, so far. Although the 400M dollardays for 1024-bit moduli is based on the sieving-based approach, the author found that rough estimates for the ECM-based approach are not that much different. Therefore, one may alternatively replace 2.852 by 1.976 or 2.080 in the above estimate. For key length estimate purposes,  $\alpha = 1.976 + o(1)$  is a more prudent choice than the other two choices because  $\alpha = 1.976 + o(1)$  results in lower factoring costs and therefore larger and more conservative choices for key lengths achieving adequate protection.

As an example, 1248-bit moduli are roughly expected to be between

$$\frac{L[2^{1248}, 1/3, 1.976]}{L[2^{1024}, 1/3, 1.976]} \approx 250,$$

and

$$\frac{L[2^{1248}, 1/3, 2.852]}{L[2^{1024}, 1/3, 2.852]} \approx 3000$$

times costlier to factor than 1024-bit ones. Similarly, 1536-bit moduli are between 137K and 26M times costlier and 2048-bit moduli are at least 2 billion times costlier to factor than 1024-bit ones.

These extrapolation arguments are mostly useful to get a quick first impression of the cost of breaking a certain modulus size. If a more accurate estimate is needed, the much more cumbersome approach from Lenstra et al. (2003) can be used.

## Cryptanalytic Developments

During the past 3 to 4 decades, there has been a steady stream of developments in integer factorization algorithms. The practical performance of the best-existing algorithms such as the NFS and the ECM is still constantly fine-tuned and improved. This smooth progress is, less frequently, combined with more substantial advances such as, most importantly, the invention of an entirely new method or, less dramatic but often with important practical consequences, better ways to handle certain steps of existing methods. It is reasonable to assume that the trend as observed so far will continue for the years to come.

Combining the occasional jumps and the regular smooth progress, the effect of cryptanalytic progress on the difficulty of the integer factorization problem turns

out to be very similar to Moore's law: overall, and on the same equipment, the cost of factoring drops by a factor 2 every 18 months. According to Moore's traditional law as formulated under Security Level, the equipment cost also drops by a factor 2 every 18 months. These two effects, cryptanalytic progress and hardware advances, have in the past been independent and it is reasonable to assume that they will remain to be so. As a result of the combination of these two independent effects, the decrease in the cost of factoring is modeled in the following way:

**Double Moore factoring law:** The cost of factoring any fixed modulus drops by a factor 2 every 9 months.

As an example, in 2.5 years it can be expected that the cost of factoring a 1024-bit modulus is reduced to the following:

$$\frac{400\text{M}}{2^{2.5 \times 12/9}} \approx 40\text{M dollar days.}$$

Similarly, over a period of 6 years it is expected that the factoring cost drops by a factor  $2^{6 \times 12/9} = 256$ . Thus, it would be conservative to expect that factoring a 1248-bit modulus in 2010 would cost about the same as a 1024-bit modulus in 2004.

Note that the double Moore factoring law consists of equal technology and algorithmic components. If one argues that because of economies of scale and high parallelism a double Moore law already applies to the technology component alone (cf. P. C. Kocher, personal communication, September 1999), then one should consider a triple instead of double Moore factoring law. This is not done here.

### Small Factors

In regular RSA, the modulus is chosen as the product of two primes of approximately equal sizes. Asymptotically, and for all regular RSA moduli commonly in use, the most efficient published method to factor such moduli is the NFS. As cited above, there are at least two variants of RSA where the modulus  $n$  may have one (RSA for paranoid) or more (RSA multiprime) prime factors that are substantially smaller than  $\sqrt{n}$ . Currently, the asymptotically fastest method to find small factors, if there are any, is the ECM. Therefore, care must be taken to select the factors in such a way that finding them using the ECM can be expected to be at least as hard as factoring  $n$  using the NFS. The reader is referred to Lenstra (2001) for a further discussion of this point.

### RSA Modulus Lengths That Offer Adequate Protection

According to the definition discussed under Security Level, an RSA modulus offers adequate protection until year  $y$  if the factorization cost in that year can be expected to be at least 40M dollar days. Thus, 1024-bit RSA moduli offer adequate protection for 2.5 more years from the year 2004, when this chapter was written. More in general, by combining the above extrapolation to other modulus lengths with the double Moore factoring law it can be determined—to the best of the current knowledge—if a  $b$ -bit RSA modulus offers adequate protection until the year  $y$ : it does if

$$\frac{L(2^b, 1/3, \alpha)}{L(2^{1024}, 1/3, \alpha)} \times 400 \geq 40 \times 2^{4(y-2004)/3},$$

where, again,  $\alpha = 1.976$  leads to a conservative, relatively large  $b$  value and  $\alpha = 2.852$  to a less prudent smaller one. All estimates are conservative in the sense that the base-point of the extrapolation is the cost of an attack on a 1024-bit modulus using the dedicated hardware described in Shamir and Tromer (2003) as analyzed in Lenstra et al. (2003).

Table 3 lists the resulting RSA modulus bit lengths for both choices for  $\alpha$  and for several years, and Table 4 lists the years until which several common RSA modulus bit lengths offer adequate protection, again for both  $\alpha$ -values. For each year  $y$  in the two tables the security level  $\lambda(y) = 56 + 2(y - 1982)/3$  that offers adequate protection until year  $y$ , rounded upward to the nearest integer, is given between parentheses (cf. Eq. [2]). Note that  $\lambda(y)$  corresponds to the minimally required symmetric key length in year  $y$ .

It follows from the tables that 2048-bit RSA moduli offer adequate protection at least until the year 2030, and even until 2040 if one is less prudent and confident that ECM-based factoring devices will not be able to outperform the sieving-based approach before the year 2040.

Although this type of estimate is the best that can be done at this point, it should be understood that actual factoring capabilities may follow an entirely different pattern. Any prediction more than a few decades away about security levels is wishful thinking. The figures in the tables should be properly interpreted, namely as today's best estimates that may have to be revised tomorrow. Anyone using factoring based asymmetric cryptosystems should constantly monitor and stay ahead of the developments in the research community.

**Table 3** Minimal RSA Modulus Bit Lengths for Adequate Protection Until a Given Year

Year $y$ ( $\lambda(y)$ )	(Optimistic) Bit Length for $\alpha = 2.852$	(Conservative) Bit Length for $\alpha = 1.976$
2010 (75)	1112	1153
2020 (82)	1387	1569
2030 (88)	1698	2064
2040 (95)	2048	2645
2050 (102)	2439	3314

**Table 4** Years Until Which Common RSA Modulus Bit Lengths Offer Adequate Protection

Modulus Bit Length	(Conservative) Year $y_c$ for $\alpha = 1.976 (\lambda(y_c))$	(Optimistic) Year $y_o$ for $\alpha = 2.852 (\lambda(y_o))$
1024	2006 (72)	2006 (72)
1280	2014 (78)	2017 (80)
1536	2020 (82)	2025 (85)
2048	2030 (88)	2040 (95)
3072	2046 (99)	2065 (112)
4096	2060 (108)	2085 (125)
8192	2100 (135)	2142 (163)

## DISCRETE LOGARITHM-BASED CRYPTOSYSTEMS

Let  $g \neq 1$  belong to some group  $G$  and let  $h \neq 1$  be an element of the subgroup  $\langle g \rangle$  of  $G$  generated by  $g$ . It is assumed that the order  $\#\langle g \rangle$  of  $g$  is known, but the order of  $h$  is unspecified. The cryptographic application of the generator  $g$  imposes a representation for each element of  $\langle g \rangle$ . Given these representations the group operation and inversion can be performed efficiently. Using multiplicative notation for the group operation the element  $g^k$  can for any  $k$  be computed in  $O(\log |k|)$  group operations plus a single inversion if  $k < 0$ . Conversely, because of the cryptographic application,  $g$  and  $G$  must be chosen such that the “reverse” problem of computing  $\log_g h$  offers adequate protection until a year of one’s choice. The resulting requirements on  $g$  and  $G$  are discussed in this section.

The discrete logarithm problem can be solved either in the subgroup  $\langle g \rangle$  directly or in the group  $G$  in which  $\langle g \rangle$  is embedded. For adequate protection, it must be infeasible to solve the problem using either approach. Of particular practical interest is the traditional discrete logarithm problem where  $G = (\mathbf{F}_{p^\ell})^*$ .

### Unsuitable Groups

There are groups in which discrete logarithms are not hard to compute. An example is the additive group of integers modulo a positive integer, where computing discrete logarithms is equivalent to modular division. Obviously, such groups must be avoided in cryptographic applications. Unfortunately, this is not always as easy as it sounds. There are examples of groups where at first sight the discrete logarithm problem looks hard, but where, after closer scrutiny by the research community, the problem turned out to be easier than expected. For instance, a certain type of elliptic curve based groups as proposed for cryptographic applications in Miyaji (1993) was shown to allow trivial discrete logarithm computation in Satoh and Araki (1998), Semaev (1998), and Smart (1999). Interestingly, these groups were offered as an alternative to another class of elliptic curve based groups where the discrete logarithm problem allowed an undesirable reduction to the traditional case  $G = (\mathbf{F}_{p^\ell})^*$  (cf. Frey & Rück, 1994; Menezes, Okamoto, & Vanstone, 1993).

Accidents of this sort are impossible to avoid. But, as a general advice, cryptographic application of newly proposed groups should be postponed until the mathematical

and cryptanalytic communities have scrutinized the proposed groups and failed to “break” them. In the sequel, it is implicitly assumed that the groups in question do not allow other attacks than the ones described below. If  $G = (\mathbf{F}_{p^\ell})^*$ , discrete logarithms in  $G$  can be calculated using a method that is similar to the NFS algorithm for integer factorization discussed under Factoring-Based Cryptosystems. Roughly speaking, computing discrete logarithms in  $(\mathbf{F}_{p^\ell})^*$  is about as hard as factoring an integer  $n$  with  $\log n \approx \log p^\ell$  using the NFS. Thus, to achieve adequate protection until a given year the size requirements on  $n$  as presented under Factoring-Based Cryptosystems imply the same size requirements on  $p^\ell$ .

This is a rough estimate in the sense that it somewhat underestimates the difficulty of computing discrete logarithms in  $(\mathbf{F}_{p^\ell})^*$  and thereby overestimates the  $p^\ell$  values that would suffice for adequate protection. An often encountered argument is that the matrix step (cf. Factoring-Based Cryptosystems) as required for the discrete logarithm version of the NFS, is much harder than the one for the regular factoring NFS. It is true that the matrices, assuming comparable dimensions, are harder to deal with. But, in the first place, compared with factoring the cost will not increase by more than a factor  $(\log \#\langle g \rangle)^2$ , which is, relatively speaking, only a minor effect. In the second place, the actual cost of the relation collection stage (cf. Factoring-Based Cryptosystems) may still far outweigh the matrix step cost, further diminishing the effect of the more expensive matrix step on the overall cost of the computation. Given the granularity of finite field sizes that are available in practice, there is no practical need for more precise estimates.

### Reduction to Prime Order Subgroup

Because of the Pohlig–Hellman algorithm, the problem of computing  $\log_g h$  can efficiently be reduced to the problem of computing  $\log_g h$  modulo each of the prime divisors of  $\#\langle g \rangle$  and their powers (cf. Pohlig & Hellman, 1978). Therefore, and because the complete factorization of  $\#\langle g \rangle$  may be unknown and hard to find (cf. Factoring-Based Cryptosystems), it is assumed that  $\#\langle g \rangle$  has at least one prime divisor that satisfies the size requirements specified further below and, if applicable, the structural requirements set forth in the next paragraphs. For convenience of presentation and without loss of generality, it is assumed that  $\#\langle g \rangle$  itself is prime, implying that the order of  $h$ , the element whose discrete logarithm is sought, equals the same

prime. If  $G = (\mathbf{F}_{p^\ell})^*$  with  $\ell \geq 2$ , this prime  $\#(g)$  must be carefully chosen, as shown in the next paragraphs.

### The Discrete Logarithm Problem in a Subgroup of $G = (\mathbf{F}_{p^\ell})^*$

The generator  $g$  belongs to  $G = (\mathbf{F}_{p^\ell})^*$  and thus has (prime) order dividing  $p^\ell - 1$ . For  $\ell > 1$ , however, the number  $p^\ell - 1$  has factors that should be avoided in the sense that if  $\#(g)$  divides such a factor, the difficulty of the discrete logarithm problem in  $\langle g \rangle$  may be affected:  $g$  must be chosen such that  $\#(g)$  does not divide  $p^d - 1$  for any  $d$  less than and dividing  $\ell$ . This is explained below. Readers not interested in the justification of the choice of  $\#(g)$  can skip to its size requirements.

### Justification of Choice of Subgroup of $(\mathbf{F}_{p^\ell})^*$

For each positive integer  $d$  dividing  $\ell$  the finite field  $\mathbf{F}_{p^\ell}$  has a subfield  $\mathbf{F}_{p^d}$  and the multiplicative group  $G = (\mathbf{F}_{p^\ell})^*$  has a subgroup  $(\mathbf{F}_{p^d})^*$  of order  $p^d - 1$  dividing  $p^\ell - 1$ . If the order  $\#(g)$  of  $g$  divides  $p^d - 1$  for a  $d$  less than and dividing  $\ell$ , then  $g$  belongs to the true subgroup  $(\mathbf{F}_{p^d})^*$  of the multiplicative group  $G = (\mathbf{F}_{p^\ell})^*$  of the finite field  $(\mathbf{F}_{p^\ell})$ , and thereby  $g$  belongs to the true subfield  $\mathbf{F}_{p^d}$  of  $\mathbf{F}_{p^\ell}$ . Representations of such subfield elements of  $\mathbf{F}_{p^\ell}$  can efficiently be mapped back and forth to direct representations in the finite field  $\mathbf{F}_{p^d}$  itself. As a result, the discrete logarithm problem in  $\langle g \rangle$  can be solved in the true subfield  $\mathbf{F}_{p^d}$ , which is a substantially easier problem than in the “large” field  $\mathbf{F}_{p^\ell}$ : in the notation presented under Factoring-Based Cryptosystems it reduces the cost of computing discrete logarithms from  $L[p^\ell, 1/3, \alpha]$  to  $L[p^d, 1/3, \alpha]$ , for some constant  $\alpha > 0$ .

It follows that  $g$  should be chosen in such a way that its order  $\#(g)$  does not divide  $p^d - 1$  for any  $d$  less than and dividing  $\ell$ . This is achieved as follows. The  $d$ th cyclotomic polynomial  $\Phi_d(X)$  is recursively defined by the following:

$$X^d - 1 = \prod_{t \text{ dividing } d} \Phi_t(X).$$

For instance,  $\Phi_1(X) = X - 1$ ,  $\Phi_2(X) = X^2 - 1/X - 1 = X + 1$ ,  $\Phi_3(X) = X^3 - 1/X - 1 = X^2 + X + 1$ , and so on. Thus,  $g$  must be chosen in such a way that  $\#(g)$  divides  $p^\ell - 1$  but does not divide  $\Phi_d(p)$  for a  $d$  less than and dividing  $\ell$ . This condition is satisfied if  $g$  is chosen so that  $\#(g)$  is a prime divisor larger than  $\ell$  of  $\Phi_\ell(p)$ , the “last” cyclotomic factor of  $p^\ell - 1$  (cf. Lenstra, 1997). For instance, if  $\ell = 2$  the order  $\#(g)$  of  $g$  must be chosen as a sufficiently large prime divisor of  $\Phi_2(p) = p + 1$ ; and of

$$\Phi_6(p) = \frac{p^6 - 1}{(p - 1)(p + 1)(p^2 + p + 1)} = p^2 - p + 1$$

if  $\ell = 6$ .

### Size Requirements

Under the general representation assumptions specified at the beginning of this section (and avoiding unsuitable groups), the best methods to solve the discrete logarithm problem in  $\langle g \rangle$  require approximately  $\sqrt{\#(g)}$

group operations. There are essentially two methods that achieve this operation count, Shanks’s baby-step/giant-step method (Knuth, 1998, Exercise 5.17) and Pollard’s rho method (Pollard, 1978). Shanks’s method requires a substantial amount of memory. This implies that the cost of an attack effort (as defined under Security Level) by means of Shanks’s methods is much larger than  $\sqrt{\#(g)}$ : according to Wiener (2004) it is approximately  $(\#(g))^{2/3}$ .

Pollard’s rho method requires just a constant amount of memory when run on a single processor. Although this implies an attack effort cost of approximately  $\sqrt{\#(g)}$ , an attack of this sort does not have any practical significance because the original algorithm imposes a long serial computation that cannot be parallelized. However, a variation of Pollard’s rho method allows efficient parallelization with the same cost (cf. Pollard, 1978). Therefore, both from a theoretical as practical point of view, the cost of Pollard rho based attack effort is approximately  $\sqrt{\#(g)}$ .

It follows that the discrete logarithm problem in an order  $\#(g)$  subgroup  $g$  offers security level approximately  $\log_2 \sqrt{\#(g)} = \frac{1}{2} \log_2 \#(g)$ . To decide whether a certain discrete logarithm security level offers adequate protection as defined in Section 2, the relative speed of the group operation compared to the DES must in principle be taken into account. Because in any standard application the DES will be at least as fast as the group operation, and considerably faster if  $g \in (\mathbf{F}_{p^\ell})^*$ , neglecting this effect will only increase the level of protection offered by the discrete logarithm based cryptosystem.

### Cryptanalytic Developments

Concerning cryptanalytic methods that directly attack the subgroup discrete logarithm problem, the most recent substantial cryptanalytic development was the parallelization of Pollard’s rho method, as referred to above. This influenced the practical significance of a Pollard rho based attack, but had no theoretical effect on the cost. As far as the choice of the subgroup size  $\#(g)$  is concerned, it is therefore reasonable to assume that for the foreseeable future the cost of subgroup attack efforts will not be different from the current cost of  $\sqrt{\#(g)}$  group operations. This cost corresponds to the provable lower bound for the computation of discrete logarithms in generic groups (cf. Nechaev, 1994; Shoup, 1997).

There has been a steady stream of improvements to the NFS method for factoring that may have comparable effects on the version of the NFS that applies to the computation of discrete logarithms in  $(\mathbf{F}_{p^\ell})^*$ . As under Factoring-Based Cryptosystems it is reasonable to assume that in the foreseeable future there will not be major variations in the rate of cryptanalytic progress observed over the last few decades.

### Choices of $\#(g)$ and $p^\ell$ That Offer Adequate Protection

Summarizing the above conditions on  $g$ , it is assumed that  $g$  is chosen in such a way that  $\#(g)$  is prime so that the discrete logarithm problem in  $\langle g \rangle$  cannot be reduced to a discrete logarithm problem in a smaller group (of order a proper divisor of  $\#(g)$ ). Furthermore, if  $g \in (\mathbf{F}_{p^\ell})^*$

it is assumed that  $\#(g)$  is a prime divisor larger than  $\ell$  of  $\Phi_\ell(p)$  to make sure that  $g$  cannot be embedded in a smaller multiplicative group  $(\mathbf{F}_{p^\ell})^*$  for some  $d < \ell$ .

Under these restrictions,  $g$  must be chosen such that the discrete logarithm problem in  $(g)$  offers adequate protection until the year of one's choice. Combining the attack effort cost of  $\sqrt{\#(g)}$  with Moore's law it follows that a subgroup of prime order  $\#(g)$  offers adequate protection until the year

$$y \left( \frac{1}{2} \log_2 \#(g) \right) = 1982 + \frac{3 \left( \frac{1}{2} \log_2 \#(g) - 56 \right)}{2}$$

[cf. Eq. (1)]. This "double growth" compared with symmetric key lengths leads to the same rule of thumb as given at the end of Cryptographic Hash Functions for hash function lengths. Because the collision attack presented under Cryptographic Hash Functions and Pollard's rho-based attack here are both based on the same birthday paradox technique, this is hardly a surprise.

If  $g \in (\mathbf{F}_{p^\ell})^*$  adequate protection until year  $y$  also requires to select  $p^\ell$  in such a way that

$$\frac{L(p^\ell, 1/3, \alpha)}{L(2^{1024}, 1/3, \alpha)} \times 400 \geq 40 \cdot 2^{4(y-2004)/3},$$

with  $\alpha$  either 1.976 (prudent) or 2.852 (optimistic) as under Factoring-Based Cryptosystems. This is the same requirement as on regular RSA moduli.

It follows that the U.S. government's digital signature algorithm (DSA), standardized in FIPS Publication 186 (cf. Federal Information Processing Standard 186, 1994), with  $\#(g) \approx 2^{160}$  offers adequate protection against subgroup attacks until the year

$$y \left( \frac{1}{2} \log_2 \#(g) \right) \approx y \left( \frac{1}{2} \log_2 2^{160} \right) = y(80) = 2018.$$

But the fact that the DSA prescribes usage of  $g \in (\mathbf{F}_{p^\ell})^*$  with  $\log_2 p \leq 1024$  undermines the security level and implies that the DSA offers adequate protection only until 2006 (cf. Table 4). FIPS Publication 186 is currently being revised to support larger key sizes for the DSA. ECDSA (cf. Johnson & Menezes, 1999) does not suffer from an embedding in a finite field and is believed to offer adequate protection until 2018 when 160-bit prime order subgroups are used.

## CONCLUSION

To summarize, adequate protection was defined as the security offered in 1982 by the DES. It was argued that a cryptosystem offers adequate protection until a given year if the cost of a successful attack in that year is at least 40M dollardays: a computation that lasts  $x$  days on possibly parallelized or distributed equipment that costs 40/ $x$  million dollars to build (for any reasonable  $x$ ).

Given this definition and using conservative dedicated hardware cost estimates, for the most common cryptographic systems the following general key length recommendations can be made:

- **Symmetric cryptosystems:** A symmetric cryptosystem with  $(56 + b)$ -bit keys and no known weaknesses offers adequate security until year  $1982 + y$  only if  $3b \geq 2y$ .
- **Cryptographic hash functions:** A cryptographic hash function of bit-length  $112 + b$  and without known weaknesses offers adequate security until year  $1982 + y$  only if  $3b \geq 4y$ .
- **Factoring-based asymmetric cryptosystems:** Refer to Table 3 for modulus bit lengths that should offer adequate protection until year  $2000 + 10i$  for  $0 < i \leq 5$ . Refer to Table 4 for the year until which several common modulus bit lengths can be expected to offer adequate protection.
- **Discrete logarithm-based asymmetric cryptosystems:** A subgroup  $(g)$  offers adequate security until year  $1982 + y$  only if

$$3 \left( \frac{1}{2} \log_2 \#(g) - 56 \right) \geq 2y.$$

If  $g \in (\mathbf{F}_{p^\ell})^*$ , then  $\log_2 p^\ell$  must satisfy the same requirements as modulus bit lengths for factoring based asymmetric cryptosystems. Furthermore, stay away from newly proposed groups.

Finally, it was shown how the definition of adequate protection can be tuned to one's own perception of security and how this changes the key length recommendations.

## ACKNOWLEDGMENT

This chapter benefited greatly from enlightening e-mails from Michael Wiener and insightful and detailed comments and suggestions by anonymous reviewers. The first version of this chapter was written while the author was employed by Citigroup, N.A.

## GLOSSARY

**AES (Advanced Encryption Standard)** A block cipher with 128-bit blocks and keys of 128, 192, or 256 bits, successor of the DES.

**DES (Data Encryption Standard)** A block cipher with 64-bit blocks and keys of effectively 56 bits, replaced in favor of the AES.

**DESX (Data Encryption Standard XORed)** Strengthened version of the DES where the input plaintext is bitwise XORed with 64 bits of additional key material before encryption with DES and the output is also bitwise XORed with another 64 bits of key material.

**DSA (Digital Signature Algorithm)** A standardized digital signature algorithm that relies for its security on the hardness of computing discrete logarithms in 160-bit prime order subgroups of the multiplicative group of a 512 to 1024-bit prime field.

**ECDSA (Elliptic Curve Digital Signature Algorithm)** As DSA, except that the multiplicative group is replaced by the group of point of an appropriately chosen elliptic curve.

**ECM (Elliptic Curve Method)** An integer factorization method that makes use of elliptic curves.

- FIPS (Federal Information Processing Standards)** Standards and guidelines that are developed by the USA National Institute of Standards and Technology (NIST) for Federal computer systems and approved by the USA Secretary of Commerce.
- GHz (Gigahertz)** A unit of alternating current or electromagnetic wave frequency equal to one thousand million hertz.
- IDEA (International Data Encryption Algorithm)** A block cipher with 64-bit blocks and 128-bit keys.
- MD (Message Digest)** A digital fingerprint serving as a compact representative image of an input string of arbitrary length.
- NESSIE (New European Schemes for Signature, Integrity, and Encryption)** A European project to put forward a portfolio of strong cryptographic primitives that has been obtained after an open call and been evaluated using a transparent and open process.
- NFS (Number Field Sieve)** An integer factoring algorithm that makes use of algebraic number fields and sieving.
- QS (Quadratic Sieve)** An integer-factoring algorithm that makes use of quadratic polynomials and sieving.
- RACE (Research and Development in Advanced Communications Technologies in Europe)** A European program for the preparation and promotion of an integrated broadband communication system in Europe.
- RC4 (Ron's Cipher 4)** A propriety stream cipher with variable key size.
- RIPEMD (RACE Integrity Primitives Evaluation Message Digest)** A 160-bit cryptographic hash function.
- RSA (Rivest Shamir Adleman)** A public key cryptosystem that relies for its security on the hardness of the integer factorization problem.
- SEAL (Software-Optimized Encryption Algorithm)** A binary additive stream cipher with 160-bit keys, designed for efficient software implementation on 32-bit processors.
- SHA (Secure Hash Algorithm)** A 160-bit cryptographic hash function.
- TWINKLE (The Weizmann Institute New Key Location Engine)** A proposed special purpose optoelectronic device for the factorization of integers.
- TWIRL (The Weizmann Institute Relation Locator)** A proposed special purpose pipelined hardware device for the factorization of integers.
- XOR (Exclusive or)** A function of two bits that produces zero if the two inputs bits are identical and that produces one if the two input bits are different.

## INTRODUCTION

Cryptography plays a fundamental role in information security to provide confidentiality, authentication, and data integrity, even authorization. The most critical element in any cryptographic system is (cryptographic) *key*, and *key management* is the most important and difficult issue in cryptosystems. The security of a cryptosystem relies on secrecy of the keys and not on the secrecy of the encryption/decryption algorithms. Selection of keys with large size precludes the attempt of determining a key by brute force (see the chapter for key length in this book). Thus, breaking a cryptosystem comes to try to break the key management scheme.

Key management refers to generation, distribution, updating, and revocation of keys. *Key generation* is generally implemented by a (pseudo)-random number generator (with proper seeds) to enforce that the keys generated will be uniformly distributed in the key space, thus preventing attackers from guessing (Bishop, 2003). The issue of who is responsible for generating the key is dependent on cryptosystems/key management schemes (as discussed for each of key management schemes in the following sections). *Key distribution* refers to securely distributing a pregenerated key to corresponding communicating parties over insecure channels. Different key distribution schemes have been proposed and are discussed in the following sections. In some schemes, the key generation is accomplished by the participation of all communicating parties and the generated key contains the shares of all parties and is computed by each of the parties, thus there is no further need for distributing the key. In this case, key generation and key distribution become one task, called *key agreement*. The combination of key generation and key distribution is also called *key establishment*

(Boyd & Mathuria, 2003). *Key updating* refers to changing/regenerating and redistributing the key. Whether there is a need for key updating or how to perform key updating depends on security systems and is discussed in the following sections. *Key revocation* refers to destroying the key. One way is to discard/remove the key from its storage after its usage. Another way is to set an expiration date for a key and to treat the key as invalid once the key expires.

Key management can be typically classified as secret key management for two-party communication, public key management (certificate) (they are for secret key cryptosystems and public key cryptosystems respectively), and group key management for secure multiparty (group) communication. It is well known that the biggest problem with secret key cryptosystems is how to distribute securely the shared secret key to two communicating parties ahead of data communication. Unless the two parties meet face to face and tell each other their shared secret key, any other way of distributing the shared secret key, such as by e-mail, phone, or postal mail, may result in the interception/disclosure of the shared secret key during its transmission. Another problem with secret key cryptosystems is the large number of keys ([i.e.,  $n(n-1)/2$ ]). Suppose there are  $n$  people in a related communication setting such that any two people may communicate. Each individual needs  $n-1$  keys, one with each of other  $n-1$  people. The total number of keys needed in this setting is  $n(n-1)/2$ . When  $n$  is large, it is a problem. Several secret key management schemes for two-party communication have been proposed and they are discussed under Secret Key Management for Two-Party Communication. The invention of public key cryptosystems aims to eliminate the key distribution completely because the public key of an individual will be made public and the private key is just

kept secret to the individual. However, the following problem arises: when someone, say, Bob, obtains the public key of an individual, say, Alice, from her personal home page, her e-mail, or a public key dictionary, how can Bob be assured that the public key Bob received is really Alice's and not a masquerader's? It is very possible that Alice's public key was modified/replaced during its storage or transmission (which is generally not secured). The solution for binding an individual's public key with its identity is *public key certificates* and *trusted certificate authority*, which are discussed under "Public Key Certificate."

In contrast to two-party communication, *secure group communication* (SGC) involves multiple (more than two) parties. SGC is becoming increasingly important because broad critical applications, such as teleconferencing, multipartner military action, and cyberforensics in critical fields, such as government, military, and law enforcement, resort to SGC to provide confidentiality and integrity. Other typical SGC applications include collaborative work, telemedicine, distributed interactive simulations, interactive games, and grid computing. As in two-party communication, the confidentiality of group communication is achieved by encrypting group messages with a shared secret, which is called *group key*. Only the group members can access the group key and thus are able to decrypt the messages. Therefore, the first issue facing SGC is *group key management*. The main difficulty for group key management is *group dynamics*. Unlike in two-party communication where the communication will terminate if either party leaves or stops the communication, the group communication continues even when the members join or leave the group communication dynamically. Whenever members join and/or leave the group, the group key needs to be changed to guarantee *backward secrecy* and *forward secrecy*. Backward secrecy means that when a member joins a group, the group key needs to be changed so that the new member cannot obtain the old group keys to decrypt previous messages (in case he or she has intercepted and stored such earlier messages). Forward secrecy means that whenever a member leaves a group, the group key needs to be changed so that the ex-member does not possess the current group key; otherwise, he or she would be able to decrypt future group messages. Because group dynamics is a typical behavior of group communication, key updating (also called rekeying) is a typical feature of group key management. There has been considerable research on group key management and the book *Secure Group Communication over Data Networks* (Zou, Ramamurthy, & Magliveras, 2004) provides a comprehensive survey of SGC and group key management. Group Key Management for Secure Group Communication gives a brief introduction of group key management so that readers could sense the flavor of group key management for SGC.

## SECRET KEY MANAGEMENT FOR TWO-PARTY COMMUNICATION

Two-party key management refers to the situation where there are two people communicating and the key management procedure involves sharing keys between them.

Typically, there are three classes of key management schemes for two-party communication: public key cryptosystems, Diffie–Hellman key exchange, and trusted central authority. They are discussed in this section.

### Secret Key Establishment With Public Key Cryptosystems

Assume two users, Alice and Bob, wish to communicate using a secret key. Let  $P_B$  and  $S_B$  be Bob's public key and private key respectively. Let us further assume that Alice wishes to start the communication with Bob. Alice would generate an ephemeral session key  $k$  and then encrypt it under Bob's public key and send it across. This way only Bob (who holds the corresponding private key) would be able to decrypt the message to obtain the secret key. The steps are depicted below.

Alice to Bob:

$$y = \{k\}_{P_B}.$$

Bob:

$$k = \{y\}_{S_B}.$$

Thus, Alice and Bob obtain a common secret key that they can use for secure communication.

It is worth pointing out that the public key cryptosystems is much slower than the secret key cryptosystems, thus the public key cryptosystem is generally used to encrypt and distribute a secret key (which is short) and the secret key cryptosystem to encrypt and transmit data messages (of random length). This kind of combination between secret key encryption and public key encryption results in an efficient yet secure scheme, called *hybrid encryption*. Here is an example. Suppose Alice wants to send messages to Bob securely. Alice first generates a secret session key SK, encrypts a message  $m$  with SK (by a secret key encryption algorithm), encrypts SK with Bob's public key (by a public key encryption algorithm), and transmits both the encrypted message and the encrypted session key to Bob. After receiving the transmission, Bob first decrypts the session key (with his private key) and then decrypts the message with the session key. The advantages of hybrid encryption are obvious. The (long) messages of random lengths are encrypted using a secret key encryption algorithm, which is efficient. The session key is encrypted by a public key encryption algorithm and can be securely transmitted to the receiver over insecure channels. Compared to messages, a session key is very short. Thus the public key encryption of the session key will not be an efficiency problem.

### Secret Key Establishment With a Diffie–Hellman Key Agreement

In 1976, Diffie and Hellman proposed an elegant protocol for two parties to achieve a shared secret key over an insecure channel. This is the well known Diffie–Hellman key exchange/agreement protocol (Diffie & Hellman, 1976). The protocol is based on discrete logarithm problem (DLP). The DLP problem and Diffie–Hellman key exchange are discussed below.

Figure 1: Diffie–Hellman key agreement.

Suppose  $n$  is a positive integer.  $\mathbb{Z}_n^*$  is defined as the set of numbers in  $\mathbb{Z}_n$  that are relatively prime to  $n$ , that is,  $\mathbb{Z}_n^* = \{a \mid 1 \leq a \leq n-1 \text{ and } \gcd(n, a) = 1\}$ . Let  $p$  be a large prime and  $\alpha \in \mathbb{Z}_p^*$  a primitive element (i.e., generator) of  $\mathbb{Z}_p^*$  ( $= \{1, 2, \dots, np-1\}$ ). Given  $a \in [0, p-2]$ , computing  $\beta \equiv \alpha^a \pmod p$  is efficient, but the reverse is not. The related DLP can be stated as follows: given any  $\beta \in \mathbb{Z}_p^*$ , find the unique integer  $a$ ,  $0 \leq a \leq p-2$  such that  $\alpha^a \equiv \beta \pmod p$ . We denote the integer  $a$  by  $\log_{\alpha} \beta$ .

The Diffie–Hellman key agreement protocol can be described as follows. Suppose  $p$  is a large prime and  $g$  is a generator of  $\mathbb{Z}_p^*$  such that the DLP problem in  $\mathbb{Z}_p^*$  is intractable. Both  $p$  and  $g$  are publicly known. Suppose two members, Alice and Bob, want to establish a shared secret. Alice selects a random number  $a \in [1, p-2]$ , computes  $p_a = g^a \pmod p$ , and sends  $p_a$  to Bob over the insecure channel. Similarly, Bob selects a random number  $b \in [1, p-2]$ , computes  $p_b = g^b \pmod p$ , and sends  $p_b$  to Alice. As a result, each of Alice and Bob is able to compute the shared secret key  $SK = (p_b)^a = g^{ab} = (p_a)^b \pmod p$  (see Figure 1). However, any other individual cannot compute  $SK$  even if he or she intercepts the public components  $p_a$  and  $p_b$  and can compute  $g^{a+b}$ .  $a$  (or  $b$ ) is called the Diffie–Hellman private share or simply private share of Alice (or Bob), and  $p_a \pmod p$  (or  $p_b \pmod p$ ) the Diffie–Hellman disguised public share or simply public share of Alice (or Bob). We call the derived secret key  $SK = g^{ab} \pmod p$  a DH key.

It is worth pointing out that the DH key agreement method should never be used in the basic form described here, as it is vulnerable to a man-in-the-middle attack (see “The man-in-the-middle Attack in Diffie–Hellman Key Exchange”). Furthermore, in practice, the derived DH key is rarely used as a secret key but rather as a (long term) shared secret that enters into the computation of the (short term) session keys (see key utilization).

## Secret Key Establishment With a Trusted Central Authority

As mentioned in the introduction, one problem with secret key cryptosystems is  $n(n-1)/2$  keys for a group of  $n$  people. A solution to the problem is using a trusted central authority. Suppose there is a trusted central authority Trent and every individual has one unique shared secret key with Trent. For example, Alice has a shared secret key with Trent  $K_{AT}$  and Bob has a shared secret key  $K_{BT}$ . Whenever Alice and Bob want to communicate, the following steps show a typical scenario to establish a shared secret key (called session key and just used in one communica-

tion session) between them:

Alice  $\rightarrow$  Trent:  $\{A, B\}_{K_{AT}}$ .  
 Trent  $\rightarrow$  Alice:  $\{k_{AB}, \{A, k_{AB}\}_{K_{BT}}\}_{K_{AT}}$ .  
 Alice  $\rightarrow$  Bob:  $\{A, k_{AB}\}_{K_{BT}}$ .

Alice wants to talk to Bob and sends a message encrypted with key  $K_{AT}$  to Trent. Then Trent selects a random number as session key  $K_{AB}$  and sends an encrypted message back to Alice. The message contains the session key along with a ticket  $\{A, k_{AB}\}_{K_{BT}}$  and was encrypted with  $K_{AT}$ . Finally, Alice sends the ticket to Bob. As a result, Alice and Bob obtain a shared secret key  $k_{AB}$ . Kerberos (Kohl & Neuman, 1993; Steiner, Neuman, & Schiller, 1988) is an example of this kind of system.

## PUBLIC KEY MANAGEMENT

Public key cryptosystems are based on the existence of a key pair for each user. Every user in the system has a public key and a corresponding private key. To transmit a message securely, it is encrypted with the recipient’s public key. The recipients uses its private key to decrypt the message. Because the private key is never required to be transmitted to or shared with other individuals, the need for sharing secret information is eliminated. The major issue in public key management essentially changes to one of authentication: how to verify the authenticity of the public key.

Public key cryptosystems have become very popular for transmitting of information securely over the Internet. The reason for the popularity is the security offered and the fact that they are relatively simple to use. The major disadvantage with public key cryptosystems is that they are relatively a lot slower than the secret key cryptosystems. As a result, in practice usually a hybrid scheme is used. Still the issue of authentication of the public key still remains. Public key management is implemented through the concept of a *public key infrastructure* (PKI) (Brands, 2000; Choudhary, Bhatnagar, & Hague, 2002; Lloyd & Sams, 1999; Nash, Duane, Joseph, & Brink, 2001), which consists of *public key certificate* and *certificate authority*.

We discuss these concepts below.

### Public Key Certificate

Public key certificates can be thought of as digital documents that bind a public key to an individual or an entity. An analogy could be a notary seal that binds a person’s identity to the signature in a way that is verified by the notary. The notary could be thought of as a trusted third party. Certificates help in the verification of claims that a certain public key indeed belongs to a specific individual. This helps in providing authentication of users and also helps avoid attacks where someone could impersonate a valid user.

A basic certificate contains the public key and the name of the owner. Generally, it also includes an expiration date, which would help in revocation of the keys. Additionally, the certificate might also include the name of the certifying authority, the serial number and other information.

The most commonly and widely accepted standard in public key certificate is the X.509 standard. It is an International Telecommunication Union standard for defining digital certificates, will be discussed later in this section.

## Certificate Authority

A certificate authority (CA) is a third-party organization that vouches for the authenticity of the public keys belonging to subjects or other certification authorities. The certification authority is responsible for issuing and managing digital certificates of authenticity, which are electronic records that a user holds the private key corresponding to the public key enclosed. The CA usually has some kind of agreement with a financial institution (also known as *registration authority* (RA)), which provides the CA with the necessary information used to confirm a user's identity.

The major roles of a CA are as follows:

- Issues public/private keys to those users who do not wish to generate their own keys
- Issues certificates to users that carry its signature; the signature ensures that it is impossible for anyone to modify the contents of the certificate without being noticed
- Publishes the user's certificates
- Manages the published certificates
- Issues information regarding revocation of certificates in the form of certificate revocation lists

The CA acts as the central agent for trust in the PKI. As long as the users can trust the CA, they can be assured about the distribution, management, and revocation of public keys in the system. The signed digital certificates issued by the CA give the users the required trust for the authenticity and integrity of the public keys contained in them.

The registration authority is responsible for the identification and authentication of the certificate subscribers. It records and verifies all the information regarding the users that the CA needs to issue a certificate. The RA does not issue or sign any certificate on its own. It acts as an intermediary between the CA and users.

The RA is a place where users must go to verify their identity and apply for a certificate. The verification can be done in a number of ways. For example, any valid identity card that the user hold could be one of the ways to authenticate the user's identity. The functions of a RA are listed below.

- Accept user request for the issuance of a certificate
- Validate the user
- Send the request to the CA
- Receive the processed and signed certificate from the CA
- Send the certificate to the correct user

## Hierarchical Certificate Authorities

With the rapid increase in the number of users on the Internet over the past few years, it has practically become

infeasible for a single certification authority to be able to handle the needs of certificates for all the users. As a result, multiple CAs exist over the Internet, VeriSign, and Thawte being some examples. Most of the CAs exist in noncooperative domains, such as financial, health, and business. When two users share the same CA, they are assumed to know its public key. But in cases where they do not get their certificates from the same CA, a hierarchy of the CAs is required. A certification hierarchy provides scalability and ease of administration.

The hierarchical CA model was proposed in late 1980s and was initially employed in the privacy enhanced mail standard. In the hierarchical CA model, the trust between CAs flows from the root. It uses certificates linking members of the hierarchy to validate other CAs. The root CA is trusted by all users. Also known as the root authority, it has a self-signed certificate. The child CAs of the root CA are known as subordinate certification authorities. Each CA in the hierarchy has certificates for clients (forward) and for parents (backward). These certificates might contain the certification for the client (user) or may contain certificates that certify other CAs. Each intermediate node trusts the certificates issued by its parents. It can be considered as a big tree like structure where the end user is placed at the leaf node. The validity for the leaf's certificate is verified by tracking backward from its certifier, to other certifiers, until a trusted root certificate is found.

Figure 2 explains how the hierarchical trust model works. In the figure, CA  $\ll U \gg$  implies the certificate issued by the certification authority for U. Note that U could be an end user ( $U_1, U_2,$  and  $U_3$ ) or other CAs (B,C,D,E,F). When a user wants to obtain and/or verify the certificate (of another user), the certificate chain is used to trace the authenticity of certificates. For example, when  $U_3$  hope to verify  $U_1$ 's certificate,  $U_3$  follows  $E \ll C \gg C \ll B \gg B \ll D \gg D \ll U_1 \gg$ .

## Revocation of Public Key Certificate

Certificate revocation is a process by which the binding between the identity and the public key is made invalid. Although certificates have a period of validity, they can be revoked before expiry. There can be a number of reasons

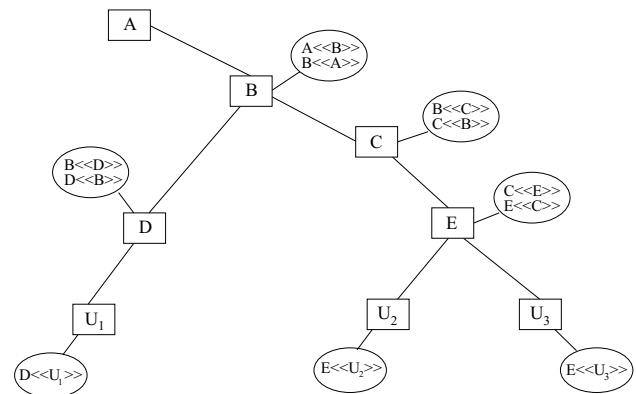

Figure 2: Certificate authority hierarchy.

why key revocation could be invoked, some of which are mentioned below:

- The private key of the user is compromised.
- CA's certificate is compromised.
- The CA may no longer certify the user.

There are many approaches to certificate revocation. We discuss a few of them here.

- Certificate revocation lists: a CRL contains outdated or compromised certificates from a certificate authority. The CA generates such lists periodically and publishes them to a directory. The CRL contains the serial number and date of issue for every compromised key that has a valid expiration date. The major advantage of using such a scheme is that it is very simple. The trouble with CRLs is the fact that it requires that the CA or some other source of CRLs to be online at all times. Without access to a recent CRL, the user would not be able to know if the certificate is valid. Another issue comes with the frequency with which the CRLs are released by the CA. If the CRLs are issued infrequently, then the amount of time vulnerable to compromise increases. Conversely, issuing the CRLs frequently reduces the vulnerability period but increases the network traffic generated.
- Online Certificate Status Protocol (OCSP): an alternative to CRLs is based on online validation services that currently leverage RFC 2560—the online certificate status protocol (Myers, Ankney, Malpani, Galperin, & Adams, 1999). The protocol requires the user to contact an online server about whether a certificate is valid. The answer obtained from the server is digitally signed.
- Certificate revocation tree: based on the Merkle hash trees, the certificate revocation tree (CRT) was proposed in 1998 (Merkle, 1989). The scheme allows a user to attain a short proof of validity for a certificate based on its serial number. The serial numbers of the revoked certificates are stored as leaves. A Merkle hash tree is later constructed with the leaves, the root of which is signed by the CA. It takes  $O(\log n)$  time for a proof that a given serial number is not in the leaves. The tree changes with each new certificate revocation.

## X.509 Certificate Standard

A public key infrastructure uses certificates to provide authentication. With the widespread use of PKIs all across the globe, certain standards had to be laid to ensure global compatibility between the certificates. The X.509 is a PKI standard that is accepted worldwide [RFC 2510 (Adams & Farrell, 1999) and RFC 2459 (Housley, Ford, Polk, & Solo, 1999)]. It defines the standards for the format of the certificates, what information goes in them and the way the CRLs are implemented.

X.509 assumes a strict hierarchical system of certificate authorities for issuing certificates. It describes a model for cross-certification of certificates from multiple CAs. It supports a number of protocols such as Privacy Enhance Email (PEM), Secure Hyper Text Transfer Protocol (S-HTTP), and SSL for providing security to the privileged information stored in the certificates. In addition to the

CAs signature, a X.509 certificate consists of the following information:

- Version: describes the version of the certificate that has been issued
- Serial number: each certificate is issued a unique identifier by the CA that is called the serial number
- Signature algorithm identifier: an identifier for the algorithm that the CA uses to sign the certificate
- Issuer name: specifies the name of the CA who issued the certificate
- Validity period: signifies the time for which the certificate is valid; it has the date of issue and also the date when the certificate expires
- Subject (user) name: the name of the user with whom the public key is identified
- Subject public key information: this field has the public key of the user along with the algorithm with which the key is used

There have been three versions of X.509 that have come out to date, with version 3 being the latest. The first two versions were developed primarily to be used for interorganizational operations. These versions had several structural restrictions with regard to the policy association and the utility of these certificates was restricted. X.509 version 3 introduced the concept of *extensions* in 1996. Extensions provide methods for associating additional attributes with users and the public keys. It provides organizations with the option of adding additional information such as employee id apart from their common name. X.509 version 3 allows for private extensions that can be used to carry information unique to communities. Each extension in a certificate can be classified as critical or noncritical. If a system that uses certificates with extensions encounters a critical extension that it does not recognize, it rejects it. Conversely, a noncritical extension could be ignored. Some of the extensions of X.509 version 3 are discussed below:

- Alternate name: an alternate name refers to a name that identifies a user in an organization. It can be an e-mail address or an employee id. The advantage of using such alternate names in the X.509 certificates is that it helps to identify the user entity without referring to the X.500 directory.
- Subject directory attributes: this extension allows for the certificate to contain attribute values for the user entity in addition to its name.
- Certification path constraints

We know certificates have a validity period associated with them but they may have to be revoked prior to their expiry date for a number of reasons discussed above. X.509 standard defines a method for certificate revocation wherein the CA periodically issues a CRL. We know that the CRL consists of a list of the revoked certificates and is freely available in a public directory.

## Public Key Infrastructure

Public key infrastructure refers to the framework and services that provide for the generation, production,

management, and accounting of public key certificates. The PKI encompasses certificate management and registration functions. The PKI is a coherent structure of CAs. Most of the PKIs adopt the hierarchical structure discussed above. The main functions of a PKI are as follows:

- Authentication: implies that the sender is he or she claims to be
- Confidentiality: implies that the information is readable only by the intended receiver
- Integrity: implies that the receiver is able to confirm (through the use of) certificates that the message has not been modified during transmit
- Nonrepudiation: implies that the sender/receiver cannot disavow what he or she has done

A PKI brings the required trust from the physical world into the electronic world with the use of public key certificates and certification authorities. Based on the number of CAs in an arrangement, a PKI can be classified as one of the three types.

1. Single CA architecture: the most basic of the architecture, it consists of a single CA that issues the certificates and CRLs to all the users. All users in the system use the certificates issued by this central CA. The major advantage of such a system is that it is simple to deploy and certificate revocation becomes easy. Scalability becomes a major hurdling issue in the use of such kind of system. Although the single CA scheme is very suitable for a small enterprise, for a big firm, the single CA would not be able to serve all the users.
2. Enterprise CA architecture: the scalability factor leads us to design a decentralized framework of CAs for enterprises with large number of users. This requires the distribution of operations of certificate issuing, management and revocation of a single CA to multiple CAs. The ways in which these CAs are organized in the PKI leads to the following two models of enterprise CA architecture:
  - Hierarchical PKI architecture: the hierarchical PKI architecture is the most common PKI and is deployed by many organizations. Unlike the single CA architecture, here a number of CAs coexist and provide the PKI service. The system consists of a root CA and its subordinates. More about the architecture and functioning can be found in the section on hierarchical certification authorities.
  - Mesh architecture: in the mesh architecture multiple CAs exist in a peer-to-peer model. Each CA is an independent entity and there is no superior-subordinate relationships among the CAs. Each CA is a trusted entity and because the CAs can issue certificates to one another, they share a bidirectional relationship. Because in a mesh PKI, all CAs need to cross certify each other, it becomes quite complex than the corresponding hierarchical model. The advantage that is gained is because of the fact that multiple trust paths exist and the certification path from a user's certificate to a trust point is nondeterministic.
3. Hybrid CA architecture: the need for a hybrid CA architecture comes in when two organizations having

different public key infrastructures need to interact among themselves. A hybrid CA architecture allows organizations with different PKIs to interact and interoperate with each other in a trusted environment.

## GROUP KEY MANAGEMENT FOR SECURE GROUP COMMUNICATION

Secure group communication refers to that scenario of group communication in which the members of a group can communicate with one another in a way that outsiders (any user who is not a member of the group) cannot glean any information even when they are able to intercept the messages. Secure group communication has been an active area of research because of the need to maintain privacy and integrity in group oriented applications.

Based on the mechanism employed by the group members to obtain the common shared key, the group key management schemes for SGC can be broadly classified into three main classes: centralized key distribution, decentralized key management, and distributed (Contributory) key agreement. The book (Zou et al., 2004) offers a comprehensive overview of group key management and here we just highlight the main ideas of these schemes.

### Centralized Key Distribution

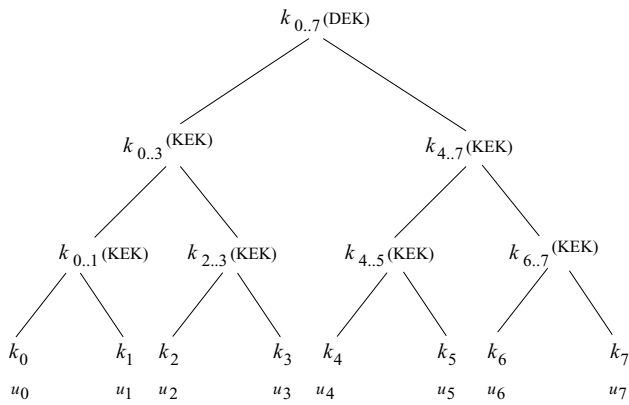

Most of the early key management schemes proposed for SGC had the notion of a trusted central authority, which is responsible for the generation and distribution of the group key. The central entity is also known as group controller or key distribution center (KDC). Assume that there is a secure channel between the central entity and each of the members. The central entity generates the group key and distributes it to each of the members via the secure channel between them.

The naive group key management scheme works as follows. Whenever a member joins, the group controller generates a new group key, encrypts the new key with the old key, and multicasts to the group. At the same time, the group controller also sends the new key to the joining member via the secure channel between the joining member and the group controller. Whenever a member leaves, the group controller generates a new group key and sends the key to each of the remaining members one by one. The naive scheme is, of course, unscalable for the member leaving operation. An elegant scheme, called key tree, was proposed, which treats the join operation and leave operation in the same way and is discussed next.

It is worth pointing out that being responsible for the generation and distribution of the group key, the group controller is obviously a single point of failure. The entire group would be affected if the security of the group controller is compromised. It also becomes a performance bottleneck in situations where the group controller also performs the task of rekeying the keys on membership change.

### Key Tree Based Scheme

The key tree based scheme is a powerful group key management scheme and was developed independently by several research groups (Caronni, Waldvogel, Sun, &

**Figure 3:** Key tree based scheme: each group user is assigned the keys from its leaf to the root.

Plattner, 1998; Noubir, 1998; Wallner, Harder, & Agee, 1998; Wong, Gouda, & Lam, 1998). In this scheme, the group users and keys are organized in the form of a logical tree with the view of reducing the number of messages required for rekeying (see Figure 3). Each node in the tree is assigned a key and each group user is placed at a leaf node of the tree. Each group user is assigned keys along the path from its leaf to the root. For example,  $u_3$  is assigned the keys  $k_{2..3}$ ,  $k_{0..3}$ ,  $k_{0..7}$ . Leaf keys are owned by individual users and shared between the group controller and each of group users. The internal keys are shared by subsets of group users are used to encrypt other keys, and called key encryption keys (KEK). The root key is shared by all of the group users and is utilized as the group key for encrypting data message and thus, it is also called data encryption key (DEK). (Note: it is a common practice that the root key is not used directly as the group key but used to derive the group key.) When a group user leaves, all the keys the leaving user knows (i.e., all the nodes from the parent of the leaving user to the root) need to be changed. Every changed key is then encrypted by its two child keys and broadcast to the group. When a user joins the group, a similar procedure applies after the user is authenticated. The group controller decides where the user is to be placed in the tree and determines the keys for the joining user (i.e., the ones from the root to the new user's leaf). The group controller sends the new user's leaf key to the new user securely (it is assumed that there is a secure channel between the group controller and each of the group users). The the group controller changes these keys, encrypts them with its two child keys, and broadcasts them to the group. Suppose  $n$  is the group size and the key tree is a balanced binary tree, then the maximum number of keys held by any user at any given time is  $\log_2(n) + 1$ . The number of keys that need to be changed for a join or leave is of the order of  $O(\log(n))$  and so is the number of rekeying messages.

### Decentralized Key Management

The decentralized approach involves splitting up a large group into small subgroups with a view of distributing the load of key management to different levels in the system. The approach minimizes the concentration of work at any centralized place and also helps in providing better fault

tolerance. A typical decentralized scheme is IOLUS and is discussed below.

### IOLUS

Mittra proposed a framework for scalable secure multicasting (Mittra, 1997). The scheme splits a large group into small subgroups. Each of such subgroups is managed by a *group security agent* (GSA). The security of the system is managed at different levels that can be viewed as a hierarchy. The GSA at the highest level is also called a *group security controller* (GSC). GSC may control the division of subgroups and the selection of GSAs. Each of the subgroups have different independent keys for communication. A GSA will have not only its own subgroup key but also its parental subgroup key. In this way, when a GSA receives a message from one subgroup (encrypted with the subgroup key), it can decrypt the message, encrypt the message with the key of the other subgroup, and send to the other subgroup. This independence of the keys has an advantage that member join and leave can now be treated locally. The system tends to be scalable and the fault tolerance is also improved because of the absence of a central controller. Despite being scalable and fault tolerant, IOLUS suffers from the increased communication costs during actual data exchanges. This happens because of the fact that the message gets encrypted and decrypted several times when it is sent from a user in one subgroup to another. The GSA may possibly become a performance bottleneck. Figure 4 shows an example. When a member from subgroup  $S_4$  sends a message  $M$  encrypted with key  $K_4$ , the GSI between  $S_1$  and  $S_4$  will decrypt  $M$  and reencrypt  $M$  with key  $K_1$ . All the members in subgroup  $S_1$  can recover  $M$ . The GSI between  $S_1$  and  $S_5$  will reencrypt  $M$  with  $K_5$  and thus the members in  $S_5$  will recover  $M$ . Similarly, the GSI between  $S_0$  and  $S_1$  will reencrypt  $M$  with  $K_0$ , so all members in  $S_0$  will recover  $M$ . At this stage, the message will continue to be transmitted to other subgroups  $S_2$  and  $S_3$  and finally to  $S_6, \dots, S_9$ .

### Distributed (Contributory) Key Agreement

Distributed key agreement schemes involve an equal participation by all the members of a group toward key management. Each member provides its share toward the shared key. The group key is a function of all the shares provided by the users. Being contributory in nature, each user should be aware of the other users in the group to make sure the protocol is robust. A few of the distributed key agreement protocols have been proposed in the literature and we discuss the Burmester and Desmedt protocol below.

#### Burmester and Desmedt Protocol

Burmester and Desmedt proposed a contributory key agreement scheme in 1995 (Burmester & Desmedt, 1995, 1996). The protocol involves two rounds of broadcast per user and hence a total of  $2n$  broadcast messages. The protocol is explained below.

Suppose that  $p$  (a large prime) and  $g$  (a generator of  $\mathbb{Z}_p^*$ ) are the public components and the group size is  $n$ . Let the members in the group be  $m_0, m_1, m_2, \dots, m_{n-1}$  and the members are treated cyclically. The following steps are performed to obtain the common shared secret:

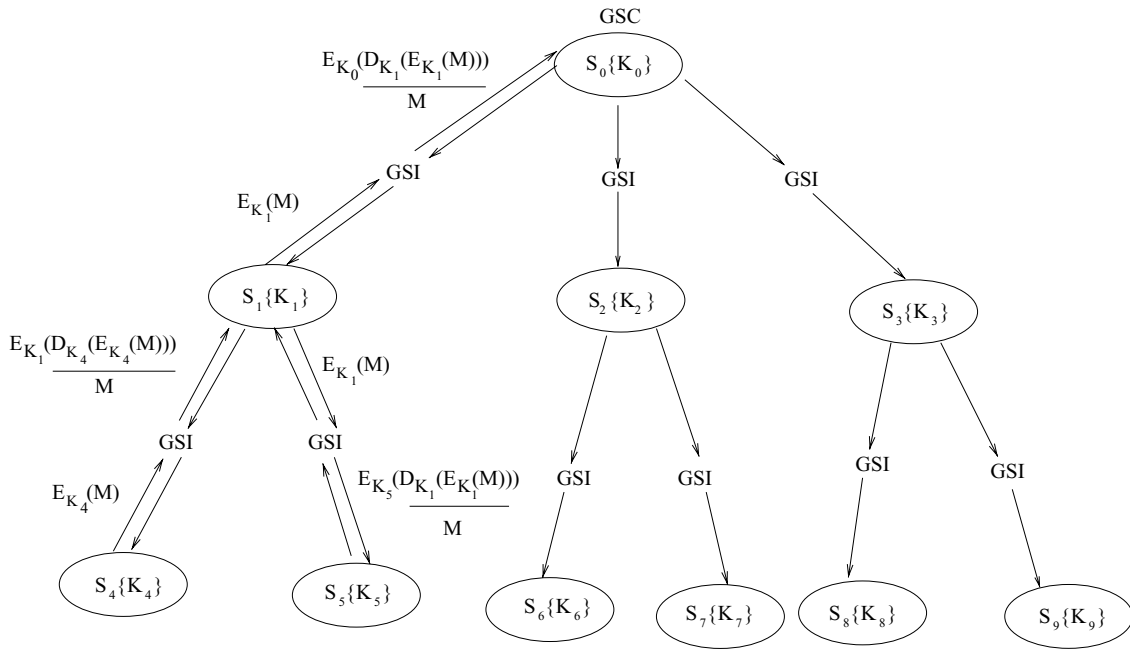

Figure 4: Subgroups and GSAs in Iolus scheme.

- Step 1 Every member  $m_i$  generates a random exponent  $s_i$  and broadcasts  $b_i = g^{s_i}$  ( $b$  stands for blinded secret). This is the first round of broadcast.
- Step 2 Every member  $m_i$  then computes and broadcasts  $X_i = (b_{i+1}/b_{i-1})^{s_i}$ . This is the second round of broadcast.
- Step 3 Every member  $m_i$  can now obtain the shared key by computing  $K_i = b_{i-1}^{s_i} \times X_i^{n-1} \times X_{i+1}^{n-2} \dots X_{i-2} \text{ mod } p$ .

The group key so obtained is  $K = g^{s_0 s_1 + s_1 s_2 + \dots + s_{n-2} s_{n-1} + s_{n-1} s_0}$ .

### AUTHENTICATED KEY MANAGEMENT

As discussed above, security functions (such as encryption algorithms and MAC algorithms) are public and the security of a system depends on the secrecy of keys. Thus the attacker targets breaking keys, in particular key management schemes. One common attack is the *man-in-the-middle* attack in the sense that the attacker sits in the middle of two communicating parties and cheats both parties but the two parties have no sense that an attacker is in the middle who is capturing all the communications. This kind of attacks is most dangerous yet hidden. To defend against the man-in-the-middle attack, there is a need for mutual authentication during the key management process (Boyd & Mathuria, 2003). Two scenarios are discussed below.

#### The Man-in-the-Middle Attack in Diffie-Hellman Key Exchange

The Diffie-Hellman key agreement is a wonderful protocol but it suffers from the man-in-the-middle attack. As shown in Figure 5, when Alice and Bob are conducting key exchange and data communication, Carol is sitting in between secretly. The exchanged values  $p_a = g^a \text{ mod } p$  and  $p_b = g^b \text{ mod } p$  are replaced with  $p_c = g^c \text{ mod } p$  by Carol. The key computed by Alice (or Bob) becomes  $g^{ac} \text{ mod } p$  (or  $g^{bc} \text{ mod } p$ ) and is mistaken to be the secret key shared

between Alice and Bob. When Alice transmits messages that were encrypted with  $g^{ac} \text{ mod } p$  and directed to Bob, Carol intercepts the messages, decrypts them, reencrypts them using  $g^{bc} \text{ mod } p$ , and sends them to Bob. As a result, Carol obtains all the messages in cleartext form, whereas Alice and Bob are totally unaware that their communications have been compromised.

To defend against the man-in-the-middle attack, authentication should be involved in the key exchange procedure, called authenticated Diffie-Hellman (Kaufman, Perlman, & Speciner, 2002). In this setting, Alice and Bob know some sort of secret in advance with which they can conduct mutual authentication. This shared secret can be used to prove that it was they who generated the Diffie-Hellman public shares. The proof can be performed in the following ways:

- Encrypt the Diffie-Hellman public shares using the shared secret and transmit the encrypted shares
- Encrypt the Diffie-Hellman public shares with each other's public key, that is, authentication using public key encryption
- Sign the Diffie-Hellman (public) share and send the share, the participants' signature, and their public key

Figure 5: Man-in-the-middle attack in Diffie-Hellman key exchange.

certificate, that is, authentication using public key signature.

Another way to defend against the man-in-the-middle attack in the Diffie–Hellman key exchange is using published Diffie–Hellman shares (Kaufman et al., 2002). In this scenario, every individual has a publicly known, permanent, unforgeable, public share, which can be achieved using public share certificates, as public key certificates do.

### The Man-in-the-Middle Attack in Public Key Cryptosystems

Public key cryptosystems can also suffer from the man-in-the-middle attack. For example, when Alice is transmitting the public key  $P_A$  to Bob (or Bob is retrieving Alice's  $P_A$  from Alice's personal home page or a public key directory), an attacker, Carol, intercepts the transmission and replaces  $P_A$  with her own public key  $P_C$ . Bob will mistake  $P_C$  as Alice's public key,  $P_A$ , encrypt messages with  $P_C$ , and send them to Alice. Carol intercepts the messages, decrypts them using her private key, reencrypts them with  $P_A$ , and sends the reencrypted messages to Alice. This is caused by separation of an individual's identity and its public key. The problem can be solved by public key certificates that bind a public key with its owner (see "Public Key Certificate"). Public key certificates are in fact an authentication method via certificate authority.

## KEY UTILIZATION

There are different kinds of keys that can be utilized in different security functions.

### Secret Key

A secret key is a shared secret between two communicating parties. A secret key is primarily used for encryption/decryption in a secret key cryptosystem. In this case, the secret key is both the *encryption key* and the *decryption key*.

A secret key can also be used for user authentication, an example of which is the following. Suppose  $K_{AB}$  is a secret key shared by Alice and Bob and Bob wants to authenticate Alice before data communication. Bob initiates the authentication by sending a challenge (a nonce  $R$ ) for Alice to respond. Bob then checks the response (decrypts it using  $K_{AB}$  and compares it with  $R$ ) and verifies that it is really Bob in the other end. The challenge/response procedure is as follows:

```
Bob → Alice: R           //Bob sends a nonce (i.e., a random value)
Alice → Bob: {R + 1}KAB //Alice responds with R + 1 encrypted by KAB.
```

Finally, a secret key can also be used for data integrity such as computing message authentication code (MAC). In this case, the secret key can also be called an MAC key. The sender computes the MAC for a message, sends the MAC along with the message. The receiver recomputes the MAC after receiving the message, and compares the computed MAC with the received MAC. If matched, the message was intact, otherwise, the message was modified during its transmission.

### Public Key and Private Key

A public key is an individual's key in a public key cryptosystem and is made public, whereas a private key is an individual's key in a public key cryptosystem and must be kept secret to the individual itself. The public key is used for encryption of messages and thus is the encryption key, whereas the private key is used for decryption and thus is the decryption key. As discussed previously, because of the high computation cost, the public key is generally used to encrypt a secret key before data communication. The public key and private key can also be used in digital signature: Alice signs a message using her private key (so signature key) and then anybody else (to say, Bob) can verify Alice's signature using her public key (so verification key). If the verification succeeds, then both the message and the message sender are authenticated (i.e., the message is intact during its transmission and the message sender is indeed Alice). Similar to the secret key based user authentication, the private key and public key can be used for user authentication in a challenge–response manner. Suppose Alice's public key is  $P_A$  and private key  $S_A$  and Bob wants to authenticate Alice. In this case, the private key  $S_A$  is used by Alice for encryption and thus an encryption key and the public key  $P_A$  is used for decryption by Bob and thus a decryption key. The challenge and response procedure is as follows:

```
Bob → Alice: R           //Bob sends a nonce (i.e., a random value)
Alice → Bob: {R + 1}SA //Alice responds with R + 1 encrypted by SA.
```

### Key Granularity and Derivation

A common practice is that one key is just used for one purpose, thus making it harder for an attacker to compromise keys. For example, when confidentiality is required, a secret key is used for encryption (as well as decryption) or a public key and its corresponding private key are used for encryption and decryption. For data integrity, an independent MAC key (different from the encryption/decryption key) is used for computing MAC. For authentication using digital signature, a new pair of public and private keys, which is different from the pair of public and private keys used for encryption and decryption, are generated for signature generation and verification.

In most implementations of secure communication systems, two participants first establish a shared secret, called a master key, and then, derive other keys from the master key. For example, in SSL, six different keys are derived from the master key with three in each direction: encryption key, initialization vector, and MAC key.

Another good practice is separating a long term secret key from short-term session keys. Once two communicating parties establish a long-term shared secret key via some methods, the long-term key is used to generate/encrypt/distribute short-term session keys for different communication sessions and the short-term session keys are used for the encryption of data in sessions. There are several reasons for doing this. First, if data are encrypted with different keys, instead of a single key, the likelihood of an attacker being able to break the ciphertext/key will be reduced (Bishop, 2003). Second, the replay

attacks will be less effective (Bishop, 2003). Finally, the compromise of one session key will only cause the encrypted data in this session to be revealed. Furthermore, even though the long term secret key is compromised, the previous communications data can be still protected because the data was encrypted with the session keys, unless the transmissions of session keys were also captured and stored, resulting in the session keys being discovered.

## KEY STORAGE, RECOVERY, AND ESCROW

As discussed above, there are mainly three kinds of keys: secret key, public key, and private key. The issue with public key is to protect the key's integrity. Public key certificate will suffice. Conversely, the issue with secret key (for secret key cryptosystems) and the private key (for public key cryptosystems) is to protect their confidentiality (Bishop, 2003).

People may protect keys' confidentiality by remembering them or writing them on a notebook. The first method is painful because the key can be quite large. Furthermore, memorization may be lost. The second method is not reliable because the notebook may be destroyed or stolen. Therefore, key storage is a serious issue. One simple choice is to put the key in a file (or a key database) and protect the file by some access control mechanism. However, access control mechanisms can often be defeated (Bishop, 2003). Another attempt is encrypting the key file with a new key. This will result in the same problem: how to store the new key. Furthermore, the key is entered to decrypt the file, the key and file contents will reside in memory at some point, which provides a chance for an attacker to eavesdrop the key. The attacker can also record the keystrokes used to decrypt the file and replay them at a later time, thus compromising the key (Bishop, 2003). One feasible alternative is to manufacture the key onto physical devices such as ROM or smart cards. To encrypt or decrypt a message, the smart card is inserted into a computer and the key is read from the smart card into a computer register, used for encrypting the message, and then discarded, thus the key will never be exposed at any point. The main problem with the smart card solution is that the smart cards may be lost or stolen. One remedy is to split the key into two pieces (such as  $\text{key} = \text{key1} \oplus \text{key2}$ ) and to put each piece into an independent device.

Now matter how careful a person is, there is a possibility that the key was lost. Once a key is lost, there is a need to recover the key. For (careless) individuals, it is advisable for you to keep your key in a safe place. In case your key is misplaced or lost, you can retrieve a copy of your key rather than conceding that all your important data (encrypted with your key) are irretrievably lost (Kaufman et al., 2002). As discussed above, storing all users' keys unencrypted somewhere is a big security risk and storing the users' keys in a key database encrypted with a key  $K$  needs to expose  $K$  to the database server. This would mean that all the keys are exposed to anyone who has access right to the server. The feasible and secure way is to have a trusted third party store and recover keys.

*Key escrow* is a key recovery system in which a third party can recover the key (Bishop, 2003). Key escrow is primarily applied to legal and law enforcement settings. The objective of a key escrow system is to provide encryption of data traffic such that the properly authorized third parties can obtain the traffic encryption keys (Menezes, Oorschot, & Vanstone, 1996). This grants the authorized third parties the capability to decrypt the traffic if needed (Menezes et al., 1996). A key escrow system contains three components (Bishop, 2003): (1) the user security component, performing encryption/decryption and supporting the next component; (2) the key escrow component, managing key storage and utilization of recovery keys; and (3) the data recovery component, performing data recovery. There are five desirable properties for a key escrow system (Bishop, 2003): (1) independence on the encryption algorithm; (2) complete protection of users' privacy and data confidentiality unless the escrowed keys are used; (3) requirement of legal/business process mapping into the key exchange protocol, thus preventing users from bypassing the escrow system; (4) requirement of authenticating all participating parties; (5) requirement of the escrowed key's valid time being exactly matched with the message's observable time.

Currently, there are two typical key escrow systems (Bishop, 2003): Clipper Chip and the Yaksha escrow system. Clipper Chip is the U.S. government's escrowed encryption standard (EES) and Yaksha is based on RSA cryptosystem and utilizes a central escrow server.

## CONCLUSION

This chapter discussed key management issues and techniques for three different settings: secret key management, public key management, and group key management. Key management deals with the issues as key generation, key distribution/key agreement, key updating, and key revocation. Secret key management can be based on public key cryptosystems, Diffie-Hellman key exchange, or a trusted central authority. Public key management mainly deals with preventing forgery/replacement of a public key and utilizes public key certificates and certificate authority to bind the identity of an individual with its public key. Group key management can be centralized, decentralized, or distributed. The article also discussed relevant issues such as authenticated key management, key utilization, key storage, and key escrow.

## ACKNOWLEDGMENT

We thank anonymous reviewers for their constructive suggestions.

## GLOSSARY

**Certificate Authority** A third-party organization that vouches for the authenticity of the public keys belonging to subjects.

**Certificate Revocation** A process by which the binding between the identity and the public key is made invalid.

**(Digital) Signature** A value computed for a message based on a user's private key such that a recipient of

the message can verify, based on the public key of the user, that the message is really from the user.

**Key Agreement** One class of key management methods, by which the shared secret key is agreed upon by all participants and contains the shares of all participants.

**Key Escrow** A key recovery system in which a third party can recover the key.

**Key Management** The technique to deal with generation, distribution, updating, and revocation of keys.

**Message Authentication Code** An authenticator that is a hash function of both the data to be authenticated and a secret key. In other words, MAC is a keyed hash function. It is also referred to as a cryptographic checksum.

**Public Key Certificate** Binding of a public key with the identity of its owner, signed by a trusted certificate authority. It is used to obtain the authentic public key of a user or verify the authenticity of a claimed public key by a user.

**Public Key Infrastructure** The framework and services that provide for the generation, production, management, and accounting of public key certificates.

**Secure Group Communication** A scenario of group communication in which the members of a group can communicate with one another in a way that outsiders (any user who is not a member of the group) cannot glean any information even when they are able to intercept the messages.

## INTRODUCTION

Since the early 1990s, one of the global buzzwords (or, rather, buzz-letters) has been “e,” short for *electronic*, which signifies almost everything connected with (inter-)networking. The ubiquity of “e” is caused by the global penetration of the Internet and, in many places of the world, by easier availability of Internet-based services, compared to the traditional services. Numerous e-processes are already taking place, starting from e-banking and ending with (in some countries) e-government. This had led to the situation where one wants to “e-ize” most of the processes and services that can be found in a modern society. After all, moving to the e-services helps one to cut down costs and save time. Additionally, it makes it possible for more and more people to become a part of the global society and to benefit from its services.

Not surprisingly, also “e-izing” (nationwide or local) elections promises to give measurable benefits. The very basic idea of the elections is to give every citizen of a country (or some other political unit) an equal right when deciding about the future of their country. To guarantee equal rights, it is essential to achieve a high voter turnout. As the most extreme case, let us look at an imaginary political system that has only two parties in an election where “the winner takes all.” If only 51% of the voters vote and the winning party collects 51% of the participating votes, the resulting government does not necessarily represent the majority of the citizens.

This is exactly where e-voting could help: it is at least one's hope that when voting is made more convenient, considerably more voters will turn out. And what could be more convenient than voting at your own home by using your own personal computer? Or your laptop when traveling—or even your mobile phone when you do not have access to the Internet? Moreover, if votes are submitted electronically, vote counting could be almost instantaneous—in the contemporary world, quick

vote counting is unfortunately an important issue. And last but not least, e-voting could make it cheaper and easier to organize elections.

But, alas, convenience is not everything. Traditional voting booths have been designed to prevent vote coercion. But how can coercion be prevented when a user votes from home? How can that voter's computer functions be correctly ascertained (no viruses, Trojan horses, or keyboard sniffers)? How can that voting center's computer functions be correctly ascertained (e.g., denial of service attacks and insider attacks)? Asking from a voter's—who may not know anything about how a computer or the Internet works—point of view, can one guarantee the correctness and robustness of the elections? And what about privacy? Can one protect the voter against coercers?

The answer is “partially, yes.” Under some feasible *cryptographic* assumptions, privacy can be protected, although the voter still needs to trust his or her *voting platform* (e.g., a computer or a mobile phone) and other pieces of hardware that are not under his or her own control. (But see also Further Research Topics). If, additionally, special hardware is used, one can design coercion-free elections. The use of secure cryptographic protocols together with fault-tolerant, well-organized, sufficiently duplicated, and constantly verified voting infrastructure *might* also guarantee robustness. The necessary cryptography is already out there, together with a developing understanding of what are (at least some of) the specific requirements on the infrastructure and on the voters. Real understanding cannot come before people have gone through many trials and errors that result from electronic elections with significant, nonduplicated, and nonreputable outcomes. It is our feeling that these real-life requirements will never be satisfied, even if some new breakthrough in cryptography makes some of the requirements obsolete.

Before going further, some warnings. e-voting means at least two quite different things: *Internet voting* (voting over the Internet, as discussed above, by using a personal

computer or mobile device with the possible help of minimal additional specialized hardware) or *kiosk voting* (voting in some fixed location, such as a library or kiosk, by using special hardware). Kiosk voting also includes the current practice of some countries to use electronic or mechanical devices—such as optical scans—in the voting stations. Kiosk voting can be easier to organize—there is no question about the untrusted operating system on the voter’s computer, for example—but it does not allow for convenient “anywhere voting.” (However, note that a diligent user can analyze software, running on his or her computer, whereas software, running in a kiosk is most likely going to be nonaccessible.) Still, kiosk voting might increase the voter turnout—and definitely decreases vote counting time. In this survey, by e-voting we refer primarily to Internet voting. All the protocols that we present can also be used in the case of kiosk voting, although some of their features might be overkill. Conversely, even in the case of kiosk voting, the current cryptographic solutions—even if used 100% correctly, which is rarely the case—are not yet completely satisfying.

In this chapter, we are going to present in detail several (under appropriate definitions) secure and (relatively) efficient cryptographic e-voting protocols. We discuss the level of security achieved by the described protocols and also their efficiency. We stop on the requirements on the infrastructure that seem to be necessary for the state of the art cryptographic e-voting protocols to fulfill their promise. Finally, we outline some important open questions and further research directions.

**Notation.** Let  $cands$  be the number of candidates, somehow enumerated by integers from 0 to  $cands - 1$ . Let  $V = (V_1, \dots, V_{voters})$  be the set of eligible voters. Let  $V' \subseteq V$  be the set of eligible voters who turned up and voted. Let  $v_i$  be the vote as cast by  $V_i$ ; we assume  $v_i = \perp$  if  $V_i$  did not vote. Let  $\mu$  be the concrete voting mechanism that is being used.

## VOTING: GENERAL OVERVIEW

During an election of, for example, a national or local government, voters cast votes to a number of candidates. After the voting phase, the winning candidate(s) are computed from the set of votes. There are many game theoretically sound (or just validated by practice) *voting mechanisms* for the latter part. Next, we briefly summarize some of the well-known voting mechanisms (in all cases, the candidate with the most points wins). As in the rest of the chapter we assume that there are voters (voters) and candidates ( $cands$ ). In all four cases, every voter outputs an ordered list of  $cands$  candidates.

1. **Plurality:** A candidate receives 1 point for every voter that ranks it first. (Here, it is sufficient for the voter to output only the top choice.)
2. **Borda:** For each voter, a candidate receives  $cands - 1$  points if it is the voter’s top choice,  $cands - 2$  if it is the second choice,  $\dots$ , 0 if it is the last.
3. **Single transferable vote (STV):** The winner determination process proceeds in rounds. In each round, a

candidate’s score is the number of voters that rank it highest among the remaining candidates, and the candidate with the lowest score drops out. The last remaining candidate wins. (A vote transfers from its top remaining candidate to the next highest remaining candidate when the former drops out.)

4. **Maximin:** A candidate’s score in a pairwise election is the number of voters that prefer it over the opponent. A candidate’s number of points is the lowest score it gets in any pairwise election.

If a mechanism  $\mu$  is used, let  $\mu(v_1, \dots, v_{voters})$  be the result of the election given votes  $v_i$ .

Exactly how the voting process is organized depends largely on the individual country and sometimes also on the individual county or even the village. However, an election tends to have at least the following phases, where the specifics of every phase may vary wildly:

- **Voter registration:** All/most of the/some of the citizens are automatically registered as voters. The rest must register themselves as eligible voters.
- **Voting:** During a few preannounced days, every registered voter can cast his or her vote. At some a priori known time moment, the voting phase will be over. Voting period may depend on the individual tallier. (Thus, this model includes absentee voting.)
- **Tallying:** After the end of voting phases, talliers count their tallies that are then mixed together to obtain the final result. (This phase depends heavily on the voting mechanism, the size of the country, etc.)

In practice, plurality and Borda elections are somewhat easier to organize than STV and Maximin because in them only the total count of points for every candidate is needed for every candidate. This total count can just be incremented as more and more votes from different voting stations become counted. This also means that when there are many talliers (e.g., corresponding to different counties) different subtallies can just be added up.

## E-VOTING: GENERAL SETTING

Different countries implement elections in different ways to comply and cope with their own traditions, definition of democracy, size of the country, and so on. E-voting must take all such considerations into account and thus, just to make e-voting understandable to the voters, at least at first, e-voting must largely mimic conventional voting. In particular, e-voting should have a registration phase, a voting phase, and a tallying phase. Only later, when voters have become used to the e-voting, could one change the election process to better suit the specifics of e-voting.

Thus, we think of e-voting as just a method to make voting more convenient by enabling both the voters and the talliers to use technology to speed up their part of the process. Maybe later changes caused by e-voting will cause a revolution in the voting process—and thus in the whole society. Currently, the change offered by e-voting is (or at least, in our opinion, should be) rather evolutionary.

How would (evolutionary) e-voting look like in an ideal world? First, the voters enter their votes to the

voting platform (e.g., a computer). Then, the votes get transmitted to a central machine (the *tallying platform*) that computes the winner by using a fixed voting mechanism. Finally, the talliers output the name of the winner (or winners) with other auxiliary information that may be necessary (e.g., the number of votes of every candidate). In such an ideal world, all parts of the system function correctly. In particular, ideal e-voting has two important properties:

1. **Correctness:** The output of the elections is  $\mu(v_1, \dots, v_{\text{voters}})$ . That is, the election outputs a correct result, meaning that only the votes of legitimate voters count.
2. **Privacy:** During the election, nobody will gain new information about any of  $v_i$ -s—except what follows from  $\mu(v_1, \dots, v_{\text{voters}})$  and their own private inputs. This includes the next subgoals: (a) voter's preferences remain private, (b) voting is coercion free (even if you choose so, you are not able to later prove your vote), and (c) independence (voter should know his or her vote).

All mentioned subgoals correspond to the necessity of avoiding certain attacks. For example, imagine a simple voting protocol where every voter sends its encrypted vote to the tallier. Bob, a huge fan of a singer named Alice, just copies her encrypted vote and enters this to the voting platform. Or may be, Bob is able to manipulate the ciphertext so that his vote is the opposite of Alice's vote. This does not violate Alice's privacy (only under very special circumstances, Bob gains any information about Alice's vote!) but it creates undesirable situations where voters vote as their idol does—or as their hated one does not. This means that Bob must know his vote.

Next, we give the definition of a secure electronic voting protocol. The definition is not fully formal because, in practice, it is not clear what is meant by “security.” Moreover, some of the electronic voting protocols, presented in the following sections, do not satisfy the ideal security definition.

Assume that we have a fixed voting mechanism  $\mu$ , such as Plurality or Borda. Let  $\Phi_\mu$  be the function that, given votes of participating voters, computes some intermediate result that is necessary for finding the winner. For example,  $\Phi_{\text{Plurality}}(v_1, \dots, v_{\text{voters}})$  is usually a function that returns a vector  $(w_1, \dots, w_{\text{cands}}, w_\perp)$ , where  $w_i = \#\{j : v_j = i\}$  is the number of voters  $V_j$  that voted for the  $i$ th candidate. It is possible to define  $\Phi_{\text{Plurality}}(v_1, \dots, v_{\text{voters}}) = w$ , where  $w$  is the name of the winner. However, such solutions are not usually considered in the case of paper ballot voting, because the privacy of losing candidates is usually hard to implement. The concrete definition depends on the voting traditions of an individual country. For example, if the number of seats in the parliament is proportional to the number of votes every party achieves, the full vector  $(v_1, \dots, v_{\text{voters}})$  must be revealed.

As in a conventional election, an e-voting protocol consists also of the registration phase, the voting phase, and the vote counting phase. In the registration phase, the legitimate voters obtain the right to participate in e-voting. How this is done depends heavily on the

traditions and technological infrastructure. For example, in some countries, the voters may be able to register by using their ID cards. This is largely a political issue, and we will just assume that legitimate voters will be able to vote and obtain necessary information (such as the public keys of the authorities) in an authenticated manner.

In the voting and tallying phase, we make a comparison with the “ideal world.” In the ideal world e-voting protocol, the trusted third party  $\mathcal{T}$  keeps a database of votes. Every voter  $V_i$  casts a vote  $v_i$  that may be equal to  $\perp$ . The third party  $\mathcal{T}$  stores the vote in her database. (A voter might be able to vote several times, but then only the result of the last vote counts.) After the end of the voting phase,  $\mathcal{T}$  computes  $\psi = \Phi_\mu(v_1, \dots, v_{\text{voters}})$ . In the tallying phase, the value  $\psi$  is published. The tallier  $\mathcal{A}$  finds the winner(s) of the election, based on  $\psi$ , by using rules, induced by the mechanism  $\mu$ . (This part of the election is repeatable and verifiable by everybody.)

It is required that at the end of the protocol, the participants should have no information about the private inputs and outputs of their partners, except for what can be deduced from their own private inputs and outputs. In particular,  $V_i$  has no information about the value of  $v_j$  for  $j \neq i$ , and  $\mathcal{A}$  has no information about the value of  $v_i$  for any  $i$ , except what they can deduce from their own private inputs and outputs. In practice, it usually means that it is required that the voting center gets to know how many voters voted for every candidate but not how did every single voter vote.

In an ideal world, exactly three types of attacks are possible (Goldreich, 2004): a party can (a) refuse to participate in the protocol, (b) substitute his or her private input to the trusted third party with a different value, or (c) abort the protocol prematurely. In our case, attack (c) is irrelevant, because  $V_i$  has no output in the voting phase and  $\mathcal{T}$  has no output in the tallying phase. (Attack [c] models the case when the first party halts the protocol after receiving his private output but before the second party has enough information to compute her output.)

Therefore, in an ideal world e-voting protocol, we cannot protect against a participant, who (a) refuses to participate in voting (*nonparticipation attack*) or (b) enters a vote that differs from his or her preference (may correspond to vote manipulation). No other attacks should be possible. Neither (a) nor (b) is traditionally considered an attack in the context of voting. The argument here is game theoretical and the solutions must be proposed by mechanism design (and politics!) instead of cryptography: namely a nonmanipulable mechanism (e.g., the algorithm with what the election winner is determined from all the collected votes) must be designed so that answering against one's true preference (or nonparticipation) would not give more beneficial results to the respondent than the truthful answer.

Conversely, as we stated, no other attacks should be allowed. This requirement is very strict, so we explain why it is necessary in the voting context. Clearly, one must protect the privacy of voters: it is required that in democracy, one should be able to vote according to his or her true preferences. There are many cases where nonprivate voting could damage the interests of the individual voter (starting from a quarrel with his or her significant other

and ending with the possibility of getting discriminated by the new government, against whom one just voted).

It is also necessary to protect the privacy of  $\mathcal{A}$ , although the reason here is more subtle. Namely if  $V_i$  obtains any additional information about  $\psi$  before the end of the elections, he or she might halt the protocol or change his or her vote. This might always happen because by a classical result of voting theory, all nondictatorial voting mechanisms can be manipulated (Gibbard, 1973; Satterthwaite, 1973). As an easy example, a voter can decide to vote for his or her second preference, when the first preference has no chance to win. (Halting the e-voting protocol while having no information on  $\psi$  is equivalent to the nonparticipation attack.) The third requirement on the protocol, of course, is that  $\mathcal{A}$  either halts or receives  $\Phi_\mu(v_1, \dots, v_{\text{voters}})$ .

In a real-world implementation, we want to replace  $\mathcal{T}$  by a cryptographic protocol  $\Pi = (V_1, \dots, V_{\text{voters}}; \mathcal{A})$  between  $V_i$  and  $\mathcal{A}$ . This protocol  $(V_1, \dots, V_{\text{voters}}; \mathcal{A})$  is assumed to be “indistinguishable” from the ideal-world protocol, that is, with a high probability, it must be secure against all attacks except (a) and (b). “Secure” means that the privacy of  $V_i$  (resp.  $\mathcal{A}$ ) must be protected if  $V_i$  (resp.  $\mathcal{A}$ ) follows the protocol and that  $\mathcal{A}$  either halts or receives the value  $\Phi_\mu(v_1, \dots, v_{\text{voters}})$ . Note that in particular this means that all messages between voters and  $\mathcal{A}$  must be authenticated by say using digital signatures.

Ideally, the security of the voters should be information theoretical (that is, even an omnipotent adversary should not be able to violate the privacy of voters), whereas the security of tallier  $\mathcal{A}$  can be computational (that is, a computationally bounded adversary should not be able to force  $\mathcal{A}$  to accept an output that is not equal to  $\Psi_\mu(v_1, \dots, v_{\text{voters}})$ ). This is because the voters, if they cheat, must do it online, whereas the adversary has all the eternity to violate voters’s privacy. However, it is much easier to design e-voting with computational voter security. In particular, all protocols that are described in the next sections provide only computational voter privacy.

In a majority of existing secure e-voting protocols, every participant proves in zero knowledge (Goldwasser, Micali, & Rackoff, 1989) that he or she behaved correctly. (Sometimes, it is sufficient to have weaker guarantees, e.g., to present witness indistinguishable proofs.) Every voter must be able to verify the correctness of the zero-knowledge proofs and thus can verify that his or her vote was counted. In this case, one talks about *voter-verifiable (or voter-verified) electronic elections*. If the zero-knowledge correctness proofs are not only verifiable by the designated verifier but for everybody, including the casual observers, one talks about *universally verifiable electronic elections*. In practice, it is important that electronic (including both Internet and kiosk) elections were universally verifiable. Without universal verifiability, there is no hope of having any reliable “vote recounting” in the case of overvoting or undervoting, and no hope of correcting the errors in current kiosk voting. See, for example, (Verified Voting Foundation, 2004) for a high-profile campaign for universal verifiability.

Finally, note that the security requirements of e-voting schemes are different from the requirements of say electronic banking. One could assume that e-banking is at

least to some extent reliable, because in the case of cheating, bank would get out of business. However, the sitting government will get out of business when it loses the election and, moreover, has means to influence operators of e-voting systems. This is one of the reasons why universal verifiability is a must in the case of e-voting.

## CRYPTOGRAPHIC PRELIMINARIES

A public key cryptosystem is a triple  $\Pi = (\text{Gen}, \text{Enc}, \text{Dec})$  where  $\text{Gen}$  is the key generation algorithm that generates a private/public key pair  $(sk, pk)$ ,  $\text{Enc}$  is the encryption algorithm, and  $\text{Dec}$  is the decryption algorithm. For a fixed  $\Pi$  and public key  $pk$ , we denote the corresponding plaintext space by  $P = P(\Pi, pk)$ , randomness space by  $R = R(\Pi, pk)$ , and ciphertext space by  $C = C(\Pi, pk)$ . Denote the encryption of a message  $m \in P$  as  $\text{Enc}_{pk}(m; r)$ , where  $pk$  is the used public key and  $r \in R$  is the used random coin. Throughout this chapter, let  $\kappa$  denote the security parameter.

### IND-CPA Secure Homomorphic Cryptosystems

Define

$$\text{Adv}_{\Pi, \kappa}^{\text{pkcsem}}(\mathcal{A}) := |\Pr[(sk, pk) \leftarrow \text{Gen}(1^\kappa), (m_0, m_1) \leftarrow A(1^\kappa, pk), b \leftarrow_r \{0, 1\}, r \leftarrow_r R : A(1^\kappa, m_0, m_1, pk, \text{Enc}_{pk}(m_b; r)) = b] - \frac{1}{2}|.$$

We say that  $\Pi$  is *IND-CPA secure* if  $\text{Adv}_{\Pi, \kappa}^{\text{pkcsem}}(\mathcal{A})$  is negligible in  $\kappa$  for any probabilistic polynomial time machine  $\mathcal{A}$ . That is,  $\Pi$  is IND-CPA secure if it is difficult for a polynomially bounded adversary to distinguish between random encryptions of two elements chosen by him- or herself.

Assume that the  $C$  (resp.  $P$ ) is a group with group operation  $\cdot$  (resp.  $+$ ). Assume that  $R$  is a groupoid with groupoid operation  $\circ$ .  $\Pi$  is *homomorphic* when  $\text{Enc}_{pk}(m_1; r_1) \text{Enc}_{pk}(m_2; r_2) = \text{Enc}_{pk}(m_1 + m_2; r_1 \circ r_2)$  for any valid public key  $pk$ , plaintexts  $m_i$ , and random coins  $r_i$ .

The first well-known IND-CPA secure homomorphic cryptosystem ElGamal was proposed by El Gamal (1984). In the conventional ElGamal, one fixes two large primes  $p$  and  $q$ , s.t.  $q \mid (p-1)$ , and let  $G_q$  be the unique subgroup of  $\mathbb{Z}_p^*$  of order  $q$ . Let  $g$  be a generator of  $G_q$ . Private key is a random element  $sk \leftarrow_r \mathbb{Z}_q$ . The corresponding public key is  $h \leftarrow g^{sk}$ . Encryption is defined as  $\text{Enc}_{pk}(m; r) := (g^r; mh^r)$ . A ciphertext  $(c, d)$  can be decrypted by  $m \leftarrow d/c^{sk} = mh^r/g^{skr}$ . Because  $\text{Enc}_{pk}(m_1; r_1) \text{Enc}_{pk}(m_2; r_2) = \text{Enc}_{pk}(m_1 m_2; r_1 + r_2)$ ,  $P$  is the multiplicative group  $(G_q, \cdot)$ . ElGamal is IND-CPA secure under the decisional Diffie–Hellman assumption (Tsionis & Yung, 1998).

In several e-voting protocols, one needs an additively homomorphic cryptosystem, that is, where  $P = (\mathbb{Z}_n, +)$  for some (possibly key dependent)  $n$ . One can modify ElGamal to behave like an additively homomorphic cryptosystem by defining  $\text{Enc}_{pk}(m; r) := (g^r; g^m h^r)$ , but in this case decryption is feasible only when  $m$  is known to belong to some relatively small set (e.g.,  $m \in \{0, 1\}$ ).

Paillier's cryptosystem Paillier (Paillier, 1999) is the first well-known IND-CPA secure additively homomorphic cryptosystem. Its IND-CPA security is based on the decisional composite residuosity assumption (Paillier, 1999). Paillier's cryptosystem was extended by Damgård and Jurik to allow encryption of large messages (Damgård & Jurik, 2001). In the Damgård–Jurik cryptosystem DJ01,  $n = pq$  is the public key and its factorization  $(p, q)$  is the secret key. One sets  $\text{Enc}_{\text{pk}}(m; r) := (1 + n)^{m_r} \text{mod } n^{s+1}$ , where  $s \geq 1$  can be freely chosen after  $n$  is generated. Here,  $m \in \mathbb{Z}_n$  and  $r \leftarrow_r \mathbb{Z}_n^*$ . (In practice,  $r \leftarrow_r \mathbb{Z}_n$  suffices.) For decrypting, one first computes  $\text{Enc}_{\text{pk}}(m; r)^{(p-1)(q-1)} = (1 + n)^{m(p-1)(q-1)} r^{\varphi(r^s)} \text{mod } n^{s+1} = (1 + n)^{m(p-1)(q-1)} \text{mod } n^{s+1}$  and recovers  $m$  from that by using an algorithm from Damgård and Jurik (2001).

Another similar cryptosystem, DJ03, was proposed by Damgård and Jurik in 2003 (Damgård & Jurik, 2003). DJ03 is slower and has longer ciphertexts than DJ01, and its IND-CPA security is based on both the decisional Diffie–Hellman and the decisional composite residuosity assumptions being true. Conversely, it has a simpler threshold version than DJ01.

## Threshold Homomorphic Cryptosystems

The goal of a threshold cryptosystem  $\Pi = (\text{Gen}, \text{Enc}, \text{Dec})$  is to make it possible to share the private key among a set of receivers, so that only authorized sets of servers can decrypt messages. As always, Gen is the key generation algorithm, Enc is the encryption algorithm, and Dec is the decryption algorithm. In the case of a threshold cryptosystem, the key is generated jointly by all participants so that everybody knows the public key pk, and all servers will have shares of the private key sk. Decryption is done by an authorized set of servers without explicitly reconstructing the private key. Conversely, encryption algorithm is mostly used by outsiders who might not know that decryption is done in a threshold manner.

Next we describe the *threshold ElGamal Cryptosystem*, mostly because of its simplicity. A description of the more complicated threshold DJ01 and DJ03 cryptosystems can be found from Damgård and Jurik (2001, 2003). Let Gen be a subgroup of  $\mathbb{Z}_p^*$  of order  $q$ , where  $q$  and  $p$  are large primes. To generate a secret key  $s \in \mathbb{Z}_p$ , every server  $\text{Server}_j$  generates a share  $s_j$  as in Shamir's secret sharing scheme (Shamir, 1979). That is,  $s_j = f(j)$  for some polynomial  $f$  that is unknown to any single server. There exists exactly one polynomial  $f$  of degree  $k$  such that  $s_j = f(j)$  for  $j \in \{1, \dots, k\}$ . Server  $j$  commits to her share  $s_j$  by publishing the value  $h_j \leftarrow g^{s_j}$ . As in Shamir's secret sharing scheme, the secret  $s$  is equal to  $s = f(0)$ .

By the Lagrange interpolation formula, given  $k$  points  $(x_i, y_i)$ , s.t.  $y_i = f(x_i)$ ,  $i = 1, \dots, k$ ,  $f(x) = \sum_{i=1}^k y_i \prod_{j=1, j \neq i}^k (x - x_j)/(x_i - x_j) \pmod{p}$  (here,  $x_j = j$  and  $y_j = s_j$ ) and thus  $s = f(0) = \sum_{i=1}^k c_i s_i \pmod{p}$ , where  $c_j := \prod_{i=1, i \neq j}^k -j/(i - j) \pmod{p}$ .

Therefore,  $g^s$  can be computed as  $\prod_{i \in X} h_i^{c_i}$  from the public values  $h_i$  only, where  $X$  is any subset of  $k$  authorities. Then,  $h = g^s$  is announced as the public key. No collection of  $<k$  servers learns  $s$ , but note that  $s$  is only computationally hidden (w.r.t. the discrete logarithm problem).

To decrypt  $(x, y) = (g^r, mh^r)$ , the servers  $\text{Server}_j$  perform the following steps: (a) each  $\text{Server}_j$  broadcasts  $w_j = x^{s_j}$  and proves in zero-knowledge that  $\log_g h_j = \log_x w_j$ ; (b) let  $X$  be any subset of  $k$  authorities who passed the zero-knowledge proof. The plaintext can be recovered by  $X$  as  $m' \leftarrow y / \prod_{j \in X} w_j^{c_j}$ . Really,  $w_j^{c_j} = x^{c_j s_j} = g^{r c_j s_j}$ , thus  $m' = m g^{r s} / \prod g^{r c_j s_j} = m$ .

## How to Prove Equality of Discrete Logarithms?

Chaum and Pedersen (1992) proposed the following protocol, where  $A$  proves that  $x = g^\mu \wedge y = h^\mu$  for some  $\mu$ : (a) prover generates a random  $r \leftarrow_r \mathbb{Z}_q$  and sends  $(a, b) \leftarrow (g^r, h^r)$  to verifier; (b) verifier sends a random  $e \leftarrow_r \{0, 1\}^t$ ,  $t \geq 80$ , to prover; (c) prover sends  $z = r + \mu e \text{mod } q$  to verifier; and (d) verifier checks that  $g^z = ax^e$  and  $h^z = by^e$ .

## Commitment Schemes

A commitment scheme is a function  $C : X \times R \rightarrow Y$  from the plaintext space  $X$  and random coin space  $R$  to the commitment space  $Y$ . A commitment scheme  $C$  is (a) *statistically hiding* if the commitment  $y = C(m; r)$  leaks a statistically insignificant amount of information about the plaintext  $m$  and the coin  $r$  and (b) *computationally binding* if, given commitment  $y = C(m; r)$  to some element  $r$  from the plaintext space, it is hard to find  $m' \in P$ ,  $m' \neq m$  and an  $r'$ , s.t.  $y = C(m'; r')$ . For the best-known commitment schemes (e.g., Pedersen 1991), the plaintext space is equal to  $\mathbb{Z}_n$  for some  $n$ . Therefore,  $C(m; r) = C(m + n; r)$  and such commitment schemes are not binding over the integers.

Fujisaki and Okamoto (1999) proposed an *integer commitment scheme* that is binding over the integers. Their scheme was later improved by Damgård and Fujisaki (2002). The Damgård–Fujisaki integer commitment scheme is computationally binding and statistically hiding, given some reasonable cryptographic assumptions. Moreover, one can construct a very efficient honest-verifier statistical zero-knowledge (HVSZK) argument of knowledge that given three commitments  $c_1$ ,  $c_2$ , and  $c_3$ , the prover knows such integers  $\mu_1$  and  $\mu_2$  and corresponding random coins  $\rho_1$ ,  $\rho_2$ , and  $\rho_3$ , that  $c_1 = C(\mu_1; \rho_1)$ ,  $c_2 = C(\mu_2; \rho_2)$ , and  $c_3 = C(\mu_1 \mu_2; \rho_3)$ .

The homomorphic property of integer commitment schemes together with the efficient HVSZK argument of knowledge for the multiplicative relation can be used to construct efficient HVSZK arguments of knowledge of type  $c_1 = C(\mu_1; \rho_1) \wedge \dots \wedge c_n = C(\mu_n; \rho_n) \wedge c_{i+1} = C(\mu_{i+1}; \rho_{i+1}) \wedge \mu_{i+1} = p(\mu_1, \dots, \mu_n)$ , where  $p$  is an arbitrary polynomial  $p \in \mathbb{Z}[X_1, \dots, X_n]$ . Lipmaa (2003) proposed a uniform methodology for constructing efficient HVSZK arguments of knowledge for a relatively large class  $\mathcal{D}$  of languages; it is conjectured but not known that  $\mathcal{D} = \mathcal{NP}$ . Given a statistically hiding and computationally binding integer commitment scheme with efficient HVSZK arguments of knowledge for additive and multiplicative relations, one can argue in HVSZK that she knows an auxiliary (suitably chosen) witness  $\omega$ , such that  $\mathfrak{R}_S(\mu; \omega) = 0$ , where  $\mathfrak{R}_S$  is the representing polynomial of

$S$  (Matiyasevich, 1993; Lipmaa, 2003). In particular, this results in an subquadratic-length *Diophantine argument system* for all languages from the class  $L_2$  of bounded arithmetic.

The *range argument*  $y = C(\mu; \rho) \wedge \mu \in [L, H]$  has an HVSZK argument of knowledge with linear length  $\Theta(|\mu|)\kappa$  (Lipmaa, 2003). It is based on the famous theorem of Lagrange that every nonnegative integer  $\mu$  can be represented as  $\omega_1^2 + \dots + \omega_4^2$  for some integers  $\omega_i$ . The corresponding values  $\omega_i$  can be computed efficiently (Lipmaa, 2003). (See Groth, 2004, for a slight refinement.)

## Efficient RAIE

In the next, we need an honest-verifier zero-knowledge proof of knowledge that the prover has encrypted a value of form  $\text{voters}^j$  where  $j \in [0, \text{cands} - 1]$  for some publicly known constants  $\text{voters}$  and  $\text{cands}$ . This is called a *range argument in exponents* (RAIE). The currently most efficient honest verifier computational zero-knowledge (HVCZK) RAIE was proposed by Lipmaa, Asokan, and Niemi (2002). The resulting RAIE has communication  $\Theta(\max(k, \text{cands} \log \text{voters}) \cdot \log \text{cands}) = \Theta(\text{cands} \cdot \log \text{voters} \cdot \log \text{cands})$ . For RAIE, one can use another function  $a^{\llbracket i \rrbracket}$  instead of the exponentiation  $a^i$  (Lipmaa, 2003). The function  $a^{\llbracket i \rrbracket}$  is defined as follows. All nonnegative integral solutions  $(x, y)$  of the equation  $x^2 - axy - y^2 = 1$  are equal to either  $(a^{\llbracket i+1 \rrbracket}, a^{\llbracket i \rrbracket})$  or  $(a^{\llbracket i \rrbracket}, a^{\llbracket i+1 \rrbracket})$ ,  $i \geq 0$ , where  $a^{\llbracket i \rrbracket}$  can be computed by using the next recurrent identities (Matiyasevich, 1993):  $a^{\llbracket 0 \rrbracket} := 0$ ,  $a^{\llbracket 1 \rrbracket} := 1$ , and  $a^{\llbracket i+2 \rrbracket} := aa^{\llbracket i+1 \rrbracket} - a^{\llbracket i \rrbracket}$  for  $i \geq 0$ . Thus,  $\{a^{\llbracket i \rrbracket}\}_{i \in \mathbb{N}}$  is a Lucas sequence. When  $a > 2$  and  $i > 0$  then  $(a - 1)^i \leq a^{\llbracket i+1 \rrbracket} \leq a^i$ . Also,  $a^{\llbracket i \rrbracket}$  can be computed almost as efficiently as  $a^i$ .

## Bulletin Board

A bulletin board is a public broadcast channel with memory where a players write information that any party can read. See, for example, Cramer, Gennaro, and Schoenmakers (1997).

## HOMOMORPHIC E-VOTING SCHEMES

Assume that the election uses the Plurality mechanism. (Implementing other mechanisms by using the next approach is also possible, although much more cumbersome.) Then, secure e-voting can be achieved as follows by using a secure homomorphic threshold cryptosystem  $\Pi = (\text{Gen}, \text{Enc}, \text{Dec})$  (Cramer, Gennaro, & Schoenmakers, 1997; Damgård & Jurik, 2001): Let  $a$  be the upper limit to the number of voters. Let  $\tau \geq 1$ . There is  $2\tau + 1$  servers that share a public key  $\text{pk}$  and a private key  $\text{sk}$  so that everybody can encrypt a message by using  $\text{pk}$ , but only  $\geq \tau + 1$  collaborating servers can jointly decrypt the ciphertext. Assume  $v_i \in [0, \text{cands} - 1]$  corresponds to the preferred candidate. The  $i$ th voter encrypts  $\text{voters}^{v_i}$  by using the key  $\text{pk}$  and sends it to the servers. The servers collect all ciphertexts and return receipts to the voters. The list of all encrypted votes is written on the bulletin board. After the end of the election, the servers multiply all ciphertexts, getting  $y = \text{Enc}_{\text{pk}}(\sum_i \text{voters}^{v_i}) = \text{Enc}_{\text{pk}}(\sum \alpha_j \text{voters}^j)$ , where

$\alpha_j$  is the number of voters who voted for the candidate  $j$ . Thus, the servers can jointly decrypt  $y$ , and then compute the coefficients  $\alpha_j$ . The value  $y$  together with the vector  $(\alpha_1, \dots, \alpha_{\text{cands}})$  is published.

Next, we will look into the details of this generic *homomorphic e-voting* protocol.

## Guaranteeing Correctness

To guarantee the correctness of this protocol, all voters must prove or argue in zero knowledge that they encrypted a value of form  $a^j$ , where  $j \in [0, \text{cands} - 1]$ . This corresponds to the RAIE. The function  $a^{\llbracket i \rrbracket}$  is exactly as suitable as  $a^i$  to be used as the encoding function that the voters use in the homomorphic e-voting scheme (Lipmaa, 2003). Because  $(a^{\llbracket i \rrbracket})^2 - aa^{\llbracket i \rrbracket}a^{\llbracket i+1 \rrbracket} - (a^{\llbracket i+1 \rrbracket})^2 = 1$ , there is a  $\Theta(\text{cands} \log \text{voters})$ -bit HVSZK argument of knowledge to prove that a voter voted correctly. Lipmaa, Asokan, and Niemi (2002) proposed an alternative RAIE that is also based on the methodology from (Lipmaa, 2003). Instead of the function  $\text{voters}^i$  (or  $\text{voters}^{\llbracket i \rrbracket}$ ), it uses the function  $b^i$ , where  $b$  is the least prime  $b \geq \text{voters}$ . Because  $\text{voters}$  is fixed a priori and publicly known,  $b$  can be computed before the electronic voting starts. This RAIE is approximately as efficient as the RAIE based on the Lucas sequences: the arguer must argue that the committed value  $\mu$  is such that  $b^L \leq \mu$  and  $\mu \mid b^H$ . As later shown in (Damgård, Groth, & Salomonsen, 2002), one can simplify the argument even more by assuming that  $b = p^2$  for a prime  $p$ : then one has to argue the knowledge of an  $\omega$ , for which  $(\omega \mid p^{H-L}) \wedge (\omega^2 p^{2L} = \mu)$ . The RAIE is the single most communication-consuming subprotocol of the homomorphic voting scheme. Therefore, the use of HVSZK arguments results in a  $\Theta(\log \text{cands})$ -fold decrease of total communication.

Server's correctness can be verified by every voter by multiplying all the votes on the bulletin board, checking that their own votes are there, that the product is equal to  $y$ , and, finally, that  $\sum \alpha_j \text{voters}^j$  is a correct decryption of  $y$  (by verifying another zero-knowledge proof).

## Multicandidate Voting

The homomorphic e-voting scheme is especially efficient when used together with the additive variant of ElGamal. However, this is true only when  $\text{voters}^{\text{cands}}$  is relatively small: the decryption results in  $g^{\sum \alpha_j \text{voters}^j}$ , from which  $\sum \alpha_j \text{voters}^j \in [0, \text{voters}^{\text{cands}} - 1]$  can be found by solving the restricted discrete logarithm problem. The realistic value of  $\text{voters}$  is in  $\{1, \dots, 10^8\}$ , depending on the elections. In the two-candidate case, when  $\text{cands} = 2$ , and assuming that  $\text{voters} = 10^7$ ,  $\text{voters}^{\text{cands}} \leq 10^{14} \leq 2^{47}$ . Finding the corresponding discrete logarithm can be done in time  $O(\sqrt{\text{voters}^{\text{cands}}}) \leq 2^{24}$ , which is still realistic in most of the cases. However, for  $\text{cands} > 3$ , we must look at alternatives to ElGamal.

The DJ01 cryptosystem can serve as a natural alternative. By using DJ01, the servers directly recover  $\sum \alpha_j \text{voters}^j$ , and thus the costly discrete logarithm computation can be avoided. Moreover, values up to say  $\text{voters}^{\text{cands}} \approx 2^{4096}$  (this corresponds to say  $\text{voters} \leq 10^8$  and  $\text{cands} \leq 150$ ) can be tolerated without significant

performance loss. Conversely, the threshold DJ01 cryptosystem is slower and less convenient than the threshold ElGamal cryptosystem. Some compromise is offered by the DJ03 cryptosystem. However, at this moment, the choice of existing IND-CPA secure homomorphic cryptosystems is not completely satisfying.

The currently most efficient multicandidate homomorphic voting protocol is described in Damgård, Groth, and Salomonsen (2002).

## VERIFIABLE SHUFFLE-BASED E-VOTING SCHEMES

In the verifiable shuffle-based approach (initiated by Chaum, 1981), every voter encrypts his or her vote  $v_i$  by using a public key cryptosystem  $\Pi = (\text{Gen}, \text{Enc}, \text{Dec})$  that must be IND-CPA secure, allow certain efficient zero-knowledge proofs of knowledge and be reblindable. Reblindability means that there must exist a function  $\text{blind}$ , such that for every ciphertext  $c$ ,  $\text{blind}_{\text{pk}}(c; R) = \text{Enc}_{\text{pk}}(\text{Dec}_{\text{sk}}(c); R)$  as distributions, where  $R$  is the domain of random coins of  $\Pi$ . Clearly, every homomorphic cryptosystem is reblindable because then one can define  $\text{blind}_{\text{pk}}(c; r) := c \cdot \text{Enc}_{\text{pk}}(0; r)$ .

In this approach, the encrypted votes,  $c_{0i} = \text{Enc}_{\text{pk}}(v_i; r_i)$  are posted on the bulletin board together with the zero-knowledge proof of knowledge that  $\text{Dec}_{\text{sk}}(c_{0i})$  corresponds to a valid candidate. This zero-knowledge proof of knowledge may not be necessary and can be replaced by a potentially simpler proof of knowledge that the voter knows  $\text{Dec}_{\text{sk}}(c_{0i})$ . At the end of the voting phase, the values  $c_{0i}$  will be mixed by  $\ell$ ,  $\ell > 1$ , *mix-servers*  $\text{MixServer}_1, \dots, \text{MixServer}_\ell$ . The  $j$ th mix-server  $\text{MixServer}_j$  receives a list of voters encrypted votes  $(c_{j-1,1}, \dots, c_{j-1,\text{voters}})$ ,  $c_{j-1,i} = \text{Enc}_{\text{pk}}(v_{\chi_{j-1}(i)}; r'_{j-1,i})$ , where  $\chi_{j-1}$  is some permutation and  $r'_{j-1,i}$  is some random number. She then randomly reblinds all ciphertexts and permutes them. That is, she generates a random permutation  $\pi_j$  and for every  $i \in [1, \text{voters}]$  she creates a random blinding factor  $r''_{ji}$ . She defines the following:

$$c_{ji} := \text{blind}_{\text{pk}}(c_{j-1,\pi_j^{-1}(i)}; r''_{ji}) \quad (1)$$

and writes  $(c_{j1}, \dots, c_{j\text{voters}})$  on the bulletin board. This must be accompanied by a proof of correctness that for some permutation  $\pi_j$  and for some random  $r''_{ji}$ , holds.

Every mix-server must verify the proofs of knowledge up to her round. At the end of  $\ell$  rounds, all servers (and voters) must verify the correctness of all proofs of knowledge on the board. After that, everybody can be sure that  $(c_{\ell 1}, \dots, c_{\ell \text{voters}})$  is an encryption of some permutation of  $(v_1, \dots, v_{\text{voters}})$ . Thus, the only thing left is to decrypt the ciphertext tuple. This can be done in a threshold manner, assuming that  $\frac{1}{2}\ell + 1$  servers have to collaborate to decrypt this tuple. At the end of this section we describe some alternative possibilities.

How can we prove efficiently that Eq. (1) is true for some  $\pi_j$  and  $\{r''_{ji}\}_i$ ? Next, we give a brief description of two existing verifiable shuffle protocols. (See Neff, 2001, for the third.)

## Furukawa-Sako Protocol

Represent the permutation  $\pi_j$  by the permutation matrix  $M^i$ , with  $M_{ab}^i = 1$  if  $\pi_j(a) = b$  and  $M_{ab}^i = 0$  otherwise. A nice way of using this matrix representation to achieve efficient zero-knowledge proofs is described in Furukawa and Sako (2001) and Furukawa (2004). It is based on the next fact (Furukawa, 2004): Let  $\delta_{ij}$  be 1 if  $i = j$  and 0 otherwise. Let  $\delta_{ijk}$  be 1 if  $i = j = k$  and 0 otherwise. Let  $q$  be a large prime. An voters  $\times$  voters matrix  $M$  is a permutation matrix if

$$\sum_h M_{hi} M_{hj} = \delta_{ij} \quad (2)$$

and

$$\sum_h M_{hi} M_{hj} M_{hk} = \delta_{ijk}. \quad (3)$$

Thus, instead of Eq. (1), one could prove that  $c_{ji} = \text{blind}(\prod_{i=1}^{\text{voters}} c_{j-1,i}^{M_{ji}^i}; r''_{ji})$  and that Eqs. (2) and (3) are true.

Equation (2) can be verified by defining  $s_i = \sum_{j=1}^{\text{voters}} M_{ij} e_j$ , for  $e_j$  chosen randomly by the verifier, and then checking that  $\sum_{i=1}^{\text{voters}} s_i^2 = \sum_{i=1}^{\text{voters}} e_i^2$ . Because of Eq. (2),  $s_i^2 = \sum_{j=1}^{\text{voters}} M_{ij} M_{ik} e_j e_k = \sum_{\chi(i)} e_{\chi(i)}^2$  and  $\sum_{i=1}^{\text{voters}} s_i^2 = \sum_{i=1}^{\text{voters}} e_{\chi(i)}^2 = \sum_{i=1}^{\text{voters}} e_i^2$ . Analogously, Eq. (3) is verified by checking that  $(\sum M_{ij} e_j)^3 = \sum e_i^3$ . Some more care has to be taken to achieve complete security (Furukawa, 2004; Furukawa & Sako, 2004).

In this approach, the prover must make approximately 8 voters exponentiations, and the verifier must make approximately 10 voters exponentiations. When  $|p| = 1024$  and  $|q| = 160$ , it takes about 5280 voters bits to communicate the proof of knowledge.

## Groth's Verifiable Shuffle

An alternative, somewhat more efficient, verifiable shuffle was proposed by Groth (2003). It assumes the use of an IND-CPA secure homomorphic cryptosystem  $\Pi$  (e.g., ElGamal, Paillier, or DJ01) and a compatible homomorphic commitment scheme. In this verifiable shuffle, the prover first commits to the shuffle. The verifier picks a vector of random integers, and the prover proves that the scalar product of this vector and the vector of encrypted votes is preserved after the shuffling. In more details, Groth's verifiable shuffle is as follows:

- Prover: For  $j \in \{1, \dots, \text{voters}\}$ , commit to  $C_{1,i} \leftarrow C_{\text{pk}}(\pi(j); r_{2,j})$ . Send  $C_{1,i}$ , together with a proof of correct shuffle, to the verifier.
- Verifier: For  $j \in \{1, \dots, \text{voters}\}$ , generate a random  $t_j$  and send  $t_j$  to the prover.
- Prover: For  $j \in \{1, \dots, \text{voters}\}$ :  $C_{2,i} \leftarrow C_{\text{pk}}(t_{\pi(j)}; r_{tj})$ . Send  $\{C_{1,i}\}_i$ , together with a proof of correct shuffle and that this shuffle was the same as on step 1, to the verifier.
- Prover proves in zero knowledge that  $\text{Dec}_{\text{sk}}(\prod c_{ji}^{t_{\pi(i)}}) = \text{Dec}_{\text{sk}}(\prod c_{j-1,i}^{t_i})$

The three first proofs of knowledge can be executed jointly by proving that for a random  $\lambda$ , chosen by the verifier,  $\{C_{1,i} C_{2,i}^\lambda\}$  commits to  $\{i + \lambda t_i\}$ . The proof that  $\{c_i\}$  commits to  $\{m_i\}$  can be done as follows: Prover sets  $c_m = C_{\text{pk}}(m; 0)$ ,

for  $m$  generated by the verifier, and proves that the multiplication of the contents of  $c_1 c_m^{-1}, \dots, c_{\text{voters}} c_m^{-1}$  is equal to  $\prod_{i=1}^{\text{voters}} (m_i - m)$ . All (or at least a significant fraction) of the resulting voters zero-knowledge multiplication proofs can be done in parallel by using multicommitments.

In this approach, the prover must perform approximately 6 voters exponentiations, and the verifier must perform approximately 6 voters exponentiations. When  $|p| = 1024$  and  $|q| = 160$ , it takes about 1184 voters bits to communicate the proof of knowledge.

## Security Model and Strengthening

By using a verifiable shuffle-based scheme as described above, both the privacy of the voters and the correctness will hold if at least  $\tau + 1$ , where  $\ell = 2\tau + 1$ , servers are honest. It is, however, possible to achieve a better result. Assume that  $\Pi$  is the ElGamal cryptosystem and that every mix-server  $\text{MixServer}_j$  has additionally her own private key  $sk_j$  and public key  $h_j = g^{sk_j}$ . Every voter encrypts his vote  $v$  as

$$(a_0, b_0) \leftarrow (g^r; v \cdot (h_1 \cdot \dots \cdot h_\ell \cdot h)^r)$$

for  $r \leftarrow R$ . The first mix-server generates a random number  $r_1$  and computes the following:

$$(a_1, b_1) \leftarrow (a_0 \cdot g^{r_1}, b_0 \cdot a_0^{-sk_1} \cdot (h_2 \dots h_\ell \cdot h)^{r_1})$$

Then  $(a_1, b_1) = (g^{r+r_1}, v \cdot (h_2 \dots h_\ell \cdot h)^{r+r_1})$ , that is, the first mix-server has peeled off encryption by his own key. He will then shuffle the result and accompany it with a proof of correct reencryption and shuffling. This can be done efficiently (Furukawa, 2004), although the proof will not be zero-knowledge but “permutation hiding.” The second mix-server behaves analogously, by generating a random number  $r_2$ , and computing  $(a_2, b_2) = (g^{r+r_1+r_2}, v(h_3 \dots h_\ell \cdot h)^{r+r_1+r_2})$  and sending the results—in a shuffled form, accompanied with correctness proofs—to the third server. The last server outputs the set  $\{(g^{r+r_1+\dots+r_\ell}, v h^{r+r_1+\dots+r_\ell})\}$  of encrypted votes. After that,  $2t + 1$  servers collaborate to recover  $\{v\}$ . Here, the privacy of any voter is preserved if at least one of the mix-servers is honest. At least  $\tau + 1$  servers must be honest to recover  $\{v\}$  from the shuffle. (See Groth, 2004, for a different approach.)

## COMPARISON AND PRACTICAL CONSIDERATION

We briefly described two main approaches to cryptographic e-voting: one that is directly based on IND-CPA secure homomorphic encryption and the other based on verifiable shuffles. (We did not describe the third major approach, based on blind signatures, because of the lack of universal verifiability. There are also potentially other problems with this approach. See, e.g., Fujioka, Okamoto, & Ohta, 1992, for one possible blind-signature-based protocol.) Of these two approaches, the first one is more efficient, but the second one is more universal. The verifiable shuffle-based approach becomes more efficient when the number of candidates is large (in the hundreds), when there is a need to support write-ins or

different voting mechanisms (e.g., Borda). Moreover, in the verifiable shuffle-based e-voting, the voters do not have to perform zero-knowledge proofs of vote validity: it suffices to encrypt and sign the vote; invalid votes will be detected by servers anyhow. This is important in practice, since it decreases the complexity of software that needs to be installed in voters machines. Last and not least, the privacy of voters is guaranteed if at least one of the mix-servers is honest (given that the reencryption techniques are used), while the correctness of elections is guaranteed when at least the fraction of  $\frac{1}{2}$  of the servers is honest. This compares favorably to the homomorphic approach, where also the privacy depends on the threshold trust. This means, in particular, that in the case of verifiable shuffle-based solution, less servers could be used.

On the other hand, in the homomorphic e-voting protocols, the job of talliers is considerably simpler, and it is simpler to achieve universal verifiability. In the verifiable shuffle-based protocols, every mix-server has to perform  $C$  voters exponentiations (shuffle verification and correctness proof, reencryption, etc), where  $C \approx 20$  is a small constant. In the homomorphic protocols, the servers must just multiply the encryptions and then jointly decrypt the result. The verification of voter’s correctness proofs can be distributed among different servers so that every server verifies only a fraction of them. This means that it is likely that homomorphic protocols are faster at least by an order of the magnitude. However, one must first test this in practice. It is also likely that continuous research in both directions will result in even faster protocols. Only since 2002 have we started to see really efficient cryptographic protocols for e-voting [e.g., protocols used in homomorphic e-voting from Damgård & Jurik (2001), Damgård et al. (2002), Lipmaa (2003), and Lipmaa et al. (2002) and verifiable shuffle protocols from (Furukawa (2004), Furukawa & Sako (2001), Groth (2003), and Neff (2001)]. The recent breakthroughs in both directions are at least partially caused by the recently developed efficient IND-CPA secure homomorphic cryptosystems (Damgård & Jurik, 2001, 2003; Naccache & Stern, 1998; Okamoto & Uchiyama, 1998; Paillier, 1999) and the relatively new concept of integer commitment schemes (Damgård & Fujisaki, 2002; Fujisaki & Okamoto, 1999).

## FURTHER RESEARCH TOPICS

All described e-voting protocols have some flaws in common. Next, we outline some major problems in e-voting protocols and propose some initial solutions. An efficient solution to any of the following problems would be a major advance in the state of the art. Note that some of (or even, most of) the problems in e-voting cannot have cryptographic solutions, and we do not discuss them at all.

### Information-Theoretic Privacy for Voters

As mentioned before, ideally the privacy of voters should be information theoretical. However, all the described approaches only guarantee computational privacy. To somewhat improve the situation, one could use public key encryption with really high security parameter

(say, ElGamal in  $\mathbb{Z}_p$  with  $|p| = 4096$  and  $|q| = 256$ ). Many zero-knowledge proofs in a voting protocol can be done by using statistically hiding commitment schemes; because of statistical hiding, such proofs may be executed by using moderate security parameters. Alternatively, one could try to devise protocols that really are information theoretically secure (in a suitable trust model). At this moment the corresponding solutions are inefficient (Otsuka, 2004).

Alternatively, *real* information theoretical security can be obtained by using *cryptographic randomized response techniques (cryptographic RRTs)* (Ambainis, Jakobsson, & Lipmaa, 2004). Here, every voter randomizes his or her vote by using a publicly known probability; the result of randomization does not say anything about the real preference of the voter. If a large number of votes are “summed” together, one can obtain an unbiased estimate to the actual voting result with a very small error margin. Cryptographic RRT of Ambainis, Jakobsson, and Lipmaa (2004) should be used to guarantee that the voters randomise their votes correctly. Whether this solution is politically acceptable, is unclear. However, it seems to be currently the only efficient way to guarantee unconditional vote privacy.

## Eliminating the Random Oracle Assumption

Almost all e-voting protocols use honest-verifier zero-knowledge proofs (or arguments) of knowledge that are known to be intrinsically interactive in the standard model (i.e., without any assumptions of the existence of a random oracle or a common reference string). However, for universal verifiability, the correctness proofs must be noninteractive. Honest-verifier zero-knowledge proofs of knowledge are usually made noninteractive—in the random oracle model—by using the Fiat-Shamir heuristic (Fiat & Shamir, 1986) by first proving that the protocol is secure when using a random oracle and then the random oracle with a hash function such as SHA1. Unfortunately, it is known that there exist natural-looking protocols that are secure in the random oracle model but that cannot be instantiated with any function. There is no guarantee that this is not the case with the existing voting e-protocols.

The common reference string (CRS) model seems to be much more realistic, and in efficiency, protocols in the CRS model rival with the protocols in the random-oracle model. As a short example, Damgård (2001) has proposed the next general methodology of transforming three-round honest-verifier zero-knowledge proofs to noninteractive zero-knowledge proofs in the CRS model. Assume that all participants have an access to a trapdoor commitment public key of a central authority (e.g., the CA who is needed anyways). Then given a three-round honest-verifier zero-knowledge protocol with messages  $(a, e, z)$ , the prover will first transfer a trapdoor commitment to  $a$ , obtain  $e$ , and only then return  $(a, z)$ . (See Damgård, 2001, for a complete protocol.)

In electronic voting, we however need noninteractive zero knowledge. The current noninteractive zero-knowledge proofs in the CRS model are not that efficient, unless one wants to use nonstandard assumptions. For example, Groth (2004) proposes efficient noninteractive zero-knowledge proofs in the CRS model, where the

security assumption is that the concrete protocol is sound. It is an important open problem to design efficient non-interactive zero-knowledge proofs in the CRS model that rely only on standard computational assumptions.

Moreover, we think that the CRS model is almost realistic, but it would still be desirable to do without it. The implication of noninteractive witness-indistinguishable protocols, obtained by, say, derandomization (Barak, Ong, & Vadhan, 2003), to e-voting is something that must still be studied.

## Achieving Coercion Resistance

As noted before, an e-voting system should be secure against coercing (and vote buying). A lot of relevant cryptographic research has been focusing on verifiability; that is, making it impossible for a voter to prove that he or she obeyed the coercer. However, as noted in Juels and Jakobsson (2002), verifiability is insufficient. To be really coercion resistant, an e-voting protocol should additionally be secure against the randomization attack (coercer forces the voter to submit invalid vote), forced-abstention attack (coercer forces the voter to refrain from voting), and simulation attack (coercer buys the secret key of the voter and simulates the voter by using this key). Juels and Jakobsson proposed a *coercion-resistant e-voting protocol* (Juels & Jakobsson, 2002) that is secure against the mentioned attacks. However, their—yet formally unpublished—solution is not very efficient. It would be very important in practice to improve upon their protocol.

Finally, note that the next simple administrative procedure helps significantly. Allow parallel kiosk voting and Internet voting such that for voters who have voted both ways, only their kiosk vote will be counted. However, this solution has also clear drawbacks. First, ideally, one would like to organize e-voting without any kiosk voting at all, to decrease costs. Parallel voting would instead increase the costs. Second, an invalid or a closely guarded individual is not able to go to a kiosk polling station.

## Human-Oriented Verifiability

One huge problem with all described e-voting protocols is that they are hardly verifiable by an average Joe. To increase the trust in e-voting, it should be possible for every voter to verify that their own vote is counted correctly. There are yet no completely satisfying solutions to this problem. See Malkhi, Margo, and Pavlov (2002) and Chaum (2004) for some recent work in this direction and Damgård and Jurik (2002) for another approach that does not require trust in the equipment.

## ACKNOWLEDGMENTS

We thank anonymous referees for very useful comments. This work was partially supported by the Finnish Defence Forces Research Institute of Technology.

## GLOSSARY

**Electronic Voting** Paperless voting by using any electronic or mechanical voting.

**Homomorphic Public Key Cryptosystem** A public-key cryptosystem where group operations on ciphertexts result in group operations on plaintexts.

**Internet Voting** Voting over the Internet using personal computing devices.

**Kiosk Voting** Electronic voting in predestined locations (e.g., libraries and schools).

**Public Key Cryptosystem** A triple (Gen, Enc, Dec), where Gen is an efficient key generation algorithm that generates a public and a secret key, Enc is an efficient encryption algorithm that uses the public key, and Dec is an efficient decryption algorithm that uses the secret key.

**Universal Verifiability** An election is said to be universally verifiable if anybody, not only the voters, can verify that the election winner has been determined correctly.

**Verifiable Shuffle** A permutation of ciphertexts, such that nobody but the permuter can distinguish the used permutation, but anybody can verify that some permutation was used.

**Voting Mechanism** A rule to determine election winner from the votes of the voters.

## DEFINITION

We know that evidence is an offer or support of proof: the latent fingerprint, the bloodstains on the carpet, the smoking gun. How does digital evidence fit into this landscape? And what constitutes “digital evidence”?

### What Is Digital Evidence?

According to *Merriam-Webster's Dictionary of Law*, the word *evidence* means, “something that furnishes or tends to furnish proof.” In 1998, the Scientific Working Group on Digital Evidence defined the term *digital evidence* as “. . . any information of probative value that is either stored or transmitted in digital form.”

In plain English, and as tested and defined in various United States courts, digital evidence is an offer of proof generated, stored, or transmitted in electronic form. This proof could originate from sources such as a cell phone, a pager, a personal digital assistant (PDA), or a computer; basically, any device that can be used to transmit and store data in binary form. For example, text messages, e-mail, databases, or Web server logs.

### How Is Digital Evidence Used?

Digital evidence is useful in a court of law in criminal or civil cases ranging from cyberstalking to industrial espionage. However, given the high volume of legal actions filed in the United States, cases involving digital evidence are no different from those involving more traditional forms of evidence; they may never reach the trial phase. This in no way makes the handling or veracity of the evidence any less formal or important. In fact, the digital evidence you gather and analyze today may be used in a civil lawsuit years from now. For this reason, all digital evidence should be treated as if it were to come under legal scrutiny.

The most frequent uses of digital evidence tend to be policy or employment related, or related to breaches of security on corporate computer systems. Such cases may include employee misuse of company resources, such as

surfing Internet pornography sites from company workstations or illegally downloading or copying software. Security breaches could originate from external sources, such as an outsider who exploits a vulnerability to find a way into a company's private network. Or breaches could originate inside the company itself, for example, an employee attempting to gain entry into resources of sensitivity beyond their privilege level.

Careful isolation and examination of digital evidence is key in identifying whether suspected information security or criminal activity occurred and the extent of damages incurred. This is discussed in detail below.

## ADMISSIBILITY

The Federal Rules of Evidence provide guidance on the question of what constitutes admissible evidence, that is, evidence that may be presented in a court of law. Regardless of form, evidence is considered admissible if it is relevant, material, and competent. Accordingly, evidence is deemed relevant and material if it may make the fact in question more probable. The competency of evidence is based on precedents regarding its reliability.

Let us take a look at the standards as they pertain to digital evidence.

### United States Standards

Digital records as proof are offered under the Best Evidence Rule. The Federal Rules of Evidence, under section 1001, includes “electronic recording, or other form of data compilation,” in its definition of legally admissible “Writings and Recordings.”

Rule 1002 requires that the evidence be an “original,” which may pose a problem in that a true original of digital evidence is in binary form and therefore not humanly readable. Rule 1001(3) addresses this problem by stating in its definition of *original* the following: “If data are stored in a computer or similar device, any printout or other output readable by sight, shown to reflect the data accurately, is an ‘original.’”

The onus is on the presenter of the digital evidence to prove that the data are reflected accurately. Authenticating the evidence, accounting for the handling of the evidence, and providing assertions of the integrity of the evidence is of paramount importance.

Another method that digital records are successfully introduced as evidence is under the Federal Rules of Evidence's Hearsay Exception, Rule 803(6), which provides an exception to the inadmissibility of hearsay for business records (i.e., kept or generated in the regular course of business). According to the Department of Justice in their document "Searching and Seizing Computers and Obtaining Electronic Evidence in Criminal Investigations," "... the business record exception is the most common hearsay exception applied to computer records."

## International Standards

The British Standards Institution (BSI) has published a series of guidelines and procedural steps to, if not ensure, at the minimum heighten the probability of computer records as admissible evidence. The standards have gained international acceptance and cover the proper handling and storage of digital data from its creation to discovery in legal proceedings. The recurring theme is an audit trail or, more specifically, methods to provide accountability, authentication, and nonrepudiation of the records so as to be admissible as evidence.

These themes are similar to the United States' standards of proper care and handling of evidence under the Best Evidence Rule; authentication of the evidence, accountability for the handling of the evidence, and proving the integrity of the evidence before and after examination.

## PRESERVATION OF EVIDENCE

To present digital evidence, it must be examined. Before the examination, it must first be preserved. How the data are identified, collected, and handled is the single most important piece of information when presenting digital evidence. Remember, for the evidence to be deemed admissible, it must be shown as relevant and material. Any doubt that can be raised as to the integrity of the evidence and its handling could impact a showing of relevance.

Preserving digital evidence should be thought of as similar to preserving a crime scene; document everything, take photos, and thoroughly record as much information as possible regarding the state of the evidence at the time it was found. If the evidence is a running computer, volatile data are easily and irretrievably lost.

The following sections highlight key areas of preserving the scene to ensure the relevance and materiality of digital evidence.

### Chain of Custody

The prevailing rule in gathering, handling, and dealing with digital evidence is to document absolutely everything. Write down anything and everything that you see, do, or think from the moment the word "evidence" is first uttered.

One of the strongest documents in the investigator's cadre of notes and records is the chain of custody

document. An accurate reflection of evidence handling is essential to providing a testament to the integrity of the evidence, should the veracity of the evidence or its handling ever be called into question. The chain of custody documentation is the single most important record in the event that the evidence will be used in court. If the evidence is intended for use in an administrative, criminal, or civil action, the integrity of the evidence will be the first point of interrogation by an opposing party.

The chain of custody is a written record describing how the evidence was identified, collected, stored, and handled and by whom, when, and for what purpose. According to the RFC 3227, "Guidelines for Evidence Collection and Handling," the chain of custody should provide the following:

- Where, when, and by whom the evidence was discovered and collected
- Where, when, and by whom the evidence was examined and handled
- Who had possession of the evidence, how was it stored, and when
- When the evidence changed hands and when and how did the exchange occur (this category includes shipping)
- Physical description of the evidence (make and model, serial number, drive size, etc.)
- Hash values, if applicable/available (described under "Preserving Evidence Integrity" below)

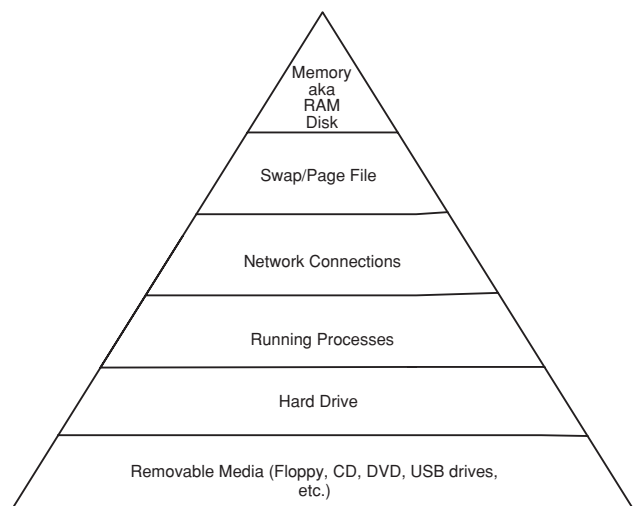

### Volatile versus Nonvolatile Evidence

Volatility of the evidence source is of prime consideration when collecting, securing, and examining digital evidence. The term *volatility*, in this context, means "subject to change." In other words, the integrity and availability of the evidence can be compromised easily and possibly destroyed.

Something as simple as shutting down the suspect device may jeopardize potentially valuable information residing in memory; half-finished or deleted files, opened files, e-mails or fragments of opened files and e-mails, passwords, user names, Web addresses or Web page fragments, and program fragments or characteristics are just a few of the items that may be found in an examination of the random access memory (RAM) space. Some malicious programs load and run entirely in memory space to avoid detection during a hard drive examination. All of this information is irretrievably lost when the host system is shut down or the power removed. Additionally, by removing power or shutting down a machine, information such as running processes, data residing in swap or page-file space, and network connection information are lost. Therefore, all of these information sources are regarded as volatile.

*Nonvolatile evidence* refers to data or information that, although still subject to change as far as date and time stamps, and associated user information, the data itself remain substantively intact, regardless of the power or connectivity status of the machine. This typically refers to the data residing on the hard drive or removable media such as floppy disks, compact discs (CDs), or

**Figure 1:** Order of evidence volatility.

digital video discs (DVDs) or the floppy, CD-ROM, and DVD drives themselves.

The generally accepted order of volatility, from most volatile evidence source to least, is as shown in Figure 1.

Validation and examination of volatile, as well as non-volatile, evidence helps “tell the story” with regard to the state of the evidence at the time of collection. In cases of memory-resident malicious code, it may contain the entire story, otherwise missed in an examination of only nonvolatile evidence.

## Evidence Handling Guidelines

Evidence gathering and preservation should be clearly documented for the sake of organization. The more consistent the approach to evidence collection, the more likely the evidence will stand tests to its credibility.

The first and foremost rule of evidence handling is to document absolutely everything. Whether the examiner maintains a log by hand or electronically, it is imperative that a “paper trail” be established and maintained, attesting to everything from the first point of contact between the examiner and the requestor of his or her services right up until the evidence is presented in court or destroyed. This is similar to the chain of custody but differs in that it should be a diary of the examination steps and procedures. Key elements of a handler’s log are as follows:

- Date
- Time
- Examiner’s name
- Examiner’s company name
- Detailed description of the evidence (i.e., hard drive, laptop, PDA, etc.) that includes model, make, serial number(s)
- Detail description of any and all actions. If the actions involve physical handling of the evidence, include details of what was handled, how, and why
- Date and time the action or activity concluded

- Date, time, and physical location where the examiner stored the evidence upon conclusion of handling, preferably in a locked, fireproof safe.

## Preserving Evidence Integrity

The value of evidence is earned only if its integrity survives challenge. You must be able to prove that the evidence is intact, in exactly the same state as it was found and collected. The popular method of offering such proof is a mathematical checksum, such as MD5 or SHA-1. A checksum operation calculates a unique “hash” value, which can serve as a sort of fingerprint. The hash value is represented by a 16-character hexadecimal value, calculated against the contents of a file or drive. Once an original hash is calculated, the hashing operation should produce the identical value every time against that same piece of evidence, so long as that evidence did not change. Even a minor change, such as opening a file on a Windows machine, may change the state of the evidence by altering its date and time stamp and, thus, reflect a new hash value at the next checksum operation identifying a change.

Any form of digital evidence can be hashed, including a volatile evidence dump file, a logical drive, a physical hard drive, or a digital camera’s memory card. Prior to collection of volatile evidence or physically removing a hard drive to be used as evidence from a computer, a checksum should be calculated against the hard drive to use as the litmus against tampering. This hash value should be noted in the chain of custody form.

Likewise, a checksum operation should be performed on the contents of a memory card, if the evidence in question is a digital photograph. The hash and the images can be burned to a CD to provide an assurance that any photographs introduced as evidence have not been tampered with or electronically altered. Some higher-end digital camera makers have built in a “watermarking” system on images to add an additional layer of integrity checking.

Volatile evidence can be collected onto a write-once/read-many format, such as a CD-ROM. To avoid making changes to the state of the hard drive, which itself may and probably will be considered evidence, volatile evidence should be collected using a trusted binary run from a CD or floppy disk. This method provides the least amount of interaction with the suspect host while still allowing an investigator(s) to collect the evidence. At the time the volatile evidence is written to the CD-R disk, a hash value should be calculated as the final step. Again, this hash should be noted on the chain of custody form as a characteristic of the volatile evidence collected.

Once nonvolatile evidence, such as a hard drive, is collected as evidence by physical removal, another process is needed to ensure the integrity of the original evidence. This process is a bit-level copy of the evidence drive. Using one of many tools, both freeware and commercial, a physical drive can be duplicated, bit for bit. This is superior to a copy operation in that the bit-level duplicate is absolutely identical to the original, whereas a copy is just that, with its own new date and time stamps and user and file statistics. Such a copy is immediately tainted by virtue of the fact that it is inherently unlike the original.

Again, this duplication process is proved by a checksum. The hash value of the bit-level duplicate should match that of the original. Both hashes should be noted in the chain of custody.

Finally, the examination of the evidence should only occur on the bit-level duplicate, never the original. The original evidence should be stored in a static-free container, in a tightly controlled environment, preferably locked in a safe that only one person controls. The storage of the original media should, again, be noted in the chain of custody.

### Examination Guidelines

As stated above, the examination of the evidence should be carried out only on the duplicate of the evidence. This protects the original evidence from any alterations. This also protects the examiner; if a change is accidentally made to the duplicate, that copy can be destroyed and another duplicate made.

The media on which the duplicate is made should be absolutely “clean,” in other words, new, unformatted disks. If the only medium available for an examination copy is a reused drive, the drive should be “wiped,” or written over using a disk wiping utility, several times over. As of this writing, the Department of Defense standard for writing over a used drive is to wipe it seven times. Wiping a used drive, or designating a new, unformatted drive, ensures that the bit-level duplicate will be free from leakage from previous data. Any such data leak would be easily identified by the hashing operation at the completion of the duplication process.

The duplicate should be treated as the original evidence in that any actions involving the examination copy should be noted in the chain of custody, including the examination itself. Tools used to examine the data should be noted, and those tools should involve as little interaction with the digital evidence as possible. Hardware write blockers should be employed at all times during an examination. Software write blockers are not always 100% effective, and an examiner wants as little room for doubt as possible as to the integrity of both the examination and the evidence. Remember, any changes to the examination duplicate will alter the hash value, thus creating a question as to the integrity of the examination and, potentially, the evidence itself.

Occasions may arise where the examination must be carried out on the original media. An example of this would be collection of the volatile memory or RAM disk. Even the act of acquiring the data in memory will change the contents as any action that appears on a monitor screen is recorded, albeit temporarily, in memory. In this instance, the examiner should checksum the resultant data as soon as possible after the data acquisition and then follow the above steps of duplication so as to preserve the state of the data. Additionally, every step in the collection process should be recorded in the examiner’s log, including key strokes. Some operating systems will record your interaction for you by default, such as the Linux bash history. Whenever possible, such logs of shell activities should be harvested along with the evidence and kept with the evidence, as well as included in the examiner’s log.

## PRESENTATION

Presenting digital evidence is easier than it sounds. First, the actual evidence is the preserved hard drive, handheld device, memory card, or a CD containing the volatile evidence collected. The actual pieces of a computer or other digital device are not glamorous, nor are they human-readable. The physical evidence is shown, but that’s not the end of the story. The examination records—the chain of custody, autogenerated reports (available in commercial forensic analysis software), printed logs, and so on—become stand-ins for the physical evidence. Recall that U.S. law supports human-readable records excerpted from digital media, discussed previously in this chapter.

As you may have already ascertained, the presentation is what the careful documenting of evidence handling is all about. The chain of custody, the checksum hashes, and the examiner’s report support the integrity of the evidence, the thoughtfulness of the care and handling of the evidence, and the results of the examination of the evidence. Key factors in sustaining the admissibility and relevance of digital evidence are validation, authentication, and non-repudiation.

### Validation

The chain of custody and evidence handling hash values may be presented as forms of validating that the evidence presented is unaltered. Each provides a layer of support that the evidence, as presented and examined, is in the same state as it was when it was originally identified, collected, duplicated, and examined. In other words, that the forensic process did not impact or alter the evidence in any way.

The chain of custody validates the integrity of the evidence by its detailed mapping of the handling of both the original evidence and any examination copies throughout the lifespan of the investigation.

The hash values, which should appear on the chain of custody document, may be highlighted to illustrate that the evidence’s “fingerprint” never changed during the course of collection and examination. Thus, it can be extrapolated that the evidence itself never changed.

### Authentication

Authenticating digital evidence is no different from any other form of evidence. Authentication is typically a human act, whereby one attests to the authenticity of the evidence. In simple terms, it is stating, “This is what I found, here’s where I found it, and this is what I did with it.” The investigator and/or examiner are the central players in the authentication process. Sworn affidavits, depositions, discovery responses, and expert testimony are legal methods of authenticating evidence that may involve the person who collected and/or examined the digital evidence at issue.

The chain of custody plays a role here, as well as in validation, by establishing who touched the evidence, when, how, and why. Again, these acts are supported by sworn statements by the person or people who appear on the log.

## Nonrepudiation

The term *nonrefudiation* means indisputable proof that evidence is what it claims to be. The proof must be complete, and it must be tamper proof. In the technical community, it is typically applied to discussions of digital certificates, which provide proof of origin or proof of receipt in transactions. In this discussion, nonrepudiation may be applied to the evidence itself. The act of locking away the original piece of equipment in evidence is an act to support nonrepudiation of the integrity of the evidence. The evidence is stored in a tamper-proof manner.

The examination copies of evidence can be encrypted by the examiner, which does not necessarily make evidence tamper proof, merely tamper resistant by anyone other than the holder of the encryption key. Encrypting working copies does add a level of control to support the investigator's authentication of their work. But encryption is not, in and of itself, nonrepudiable. It is up to the authentication and validation efforts to provide sufficient proof that the subsequent examination of the evidence did not tamper with the integrity of that evidence. File system time stamps on the encrypted file help support claims of nonrepudiation.

## RETENTION/DESTRUCTION

After collecting the evidence, how long should it be kept? When is it safe to dispose of the evidence and should it be disposed of properly?

Regulated industries must adhere to legal retention requirements such as Sarbanes-Oxley, discussed below. Nonregulated entities also have a duty to retain evidence, but requirements are usually triggered and spelled out by a court-issued protective order. Those entities not embroiled in litigation, however, should document historical records that have been destroyed—what was destroyed, when, how, why, and by whom. In other words, entities who dispose of historical data are well advised to be ready to present evidence as to why they do not have the evidence, should they ever be served with a discovery request or preservation request.

As a business matter, everyone should have a documented retention and destruction policy. Moreover, that policy should be reviewed on an annual basis for relevancy and compliance.

## Retention Guidelines

There are two reasons to retain digital evidence, regulatory compliance, or litigation. Businesses under the watchful eye of their respective state or federal government should be well versed in their duties. For instance, publicly held companies and their supporting industries are subject to the document retention guidelines under the Sarbanes-Oxley Act (SOX; 2002). SOX requires that documents, including digital records, be preserved for 7 years, under penalty of prison for no less than 10 years for company management and a hefty fine, up to \$5 million.

Those unaffected by industry regulation need to be concerned with record retention requirements if such records are, or are likely to be, the target of discovery motions in litigation. Failure to preserve data in this case is

referred to as “spoliation of evidence.” Evidence spoliation carries potentially severe sanctions, up to and including default judgment or criminal punishment, if the destruction of evidence is shown to be willful. In other words, if your company has been issued a discovery or preservation of data request and, subsequent to the receipt of that request, opposing counsel can show that records responsive to that request were destroyed. Negligent destruction of data, records that were destroyed by accident, typically carry less severe sanctions. The punishment could be monetary fines or attorney's fees.

To avoid evidence spoliation claims, record retention policies should be in place and routinely reviewed. Compliance audits should always be part of scheduled policy reviews.

## Destruction of Evidence

The nature of digital evidence, residing or written in digital form to magnetic media, makes disposal of some forms of evidence as difficult as recovering it was simple. Data that are “deleted” from a hard drive are not actually gone. Rather, it is simply designated as available space, the previous file system pointers to the data removed from the drive's file map. Once written to a magnetic surface, such as the platters of a hard drive, it is nearly impossible to actually physically remove. Therefore, there are two options to properly dispose of digital evidence: reusing or recycling the media, and physical destruction.

## Reuse/Recycling

The decision to reuse or recycle media on which sensitive data, such as that used as evidence, should be considered carefully. Some forms of media are economically more feasible to simply destroy. For example, CDs or DVDs are relatively inexpensive. If used to gather evidence that may be considered confidential or valuable, such as intellectual property, it is not worth the risk to reuse rewritable disks.

But what about hard drives? Large capacity drives can get expensive. Tape drives can also be costly. Both types of media are intended for reuse.

The question then becomes how to protect the data previously preserved. In other words, how to “destroy” the evidence without destroying the media. The answer is to overwrite the data. There are several programs available, both commercial and freeware, that write over the entire contents of a drive with random 0s and 1s, rendering the data unobtainable. This is more than merely reformatting. Reformatting a drive is similar to deleting in that it merely reassigns the available data surface. The data are still there and readable. Overwriting the entire disk assures that the data are obscured.

Overwriting, or disk wiping, is an operation that should be performed several times over to prevent any data leakage. Wipe utilities are typically configurable to allow the user to specify the number of overwriting operations. A minimum of three wipes is considered best practice, although the higher the number of overwrites, the better. As of this writing, the United States Department of Defense standard is to wipe a drive seven times before media is allowed to be reused.

### Media Destruction

The only truly safe way to dispose of data is to physically destroy the media on which it resides. This is relatively simple for floppy disks, CDs, DVDs, tapes, USB drives, and zip drives. Hard drives are bit more involved. Technically, unless each platter is completely shattered, someone somewhere can probably recover data from it. The methods to recover data get more expensive, the worse the condition of the drive, but it is still possible. Therefore, the only way to be absolutely certain that data on a hard drive are absolutely gone is to destroy it absolutely.

Incineration of the entire drive is one method. Opening up the hard drive and then removing and shattering each platter individually is another method. There are also media destruction and disposal services available, although contracting out such actions may be against your organization's data handling policy, depending on the sensitivity of the data residing on the media.

As with all aspects of digital data and evidence handling, media destruction should be carefully documented. Have a policy and procedure in place to ensure that the media are truly destroyed and that the evidence is truly irretrievable. In addition, close out your investigation or examination documentation with the date, time, manner, and identity of the actual person who destroyed the media.

### CONCLUSION

Digital evidence is similar to any other form of legal proof; it must withstand challenges to its integrity, its handling must be carefully tracked and documented, and it must be authenticated by the handler(s) and examiner(s). The fact that the evidence resides on or is generated by a digital device only means that a skilled digital forensics examiner should be involved in the handling process to ensure that any material facts may be properly preserved and introduced.

### GLOSSARY

**Admissible** Capable of being allowed or conceded.

**Authentication** To prove that an item of evidence is genuine for the purpose of establishing admissibility.

**Chain of Custody** Written record describing how the evidence was identified, collected, stored, handled, by whom, when, and for what purpose.

**Digital Evidence** Information of probative value stored or transmitted in electronic form.

**Media** Physical repository of electronically generated, stored, or transmitted data.

**Nonrepudiation** Ability to ensure that initiator, creator, or sender of digital information is unable to deny being the initiator, creator, or sender, or that the recipient of digital information is unable to deny being the recipient.

**Volatility** Subject to change.

## INTRODUCTION: DIGITAL INTELLECTUAL PROPERTY

Information is becoming widely available via global networks. These connected networks allow cross references among databases. The advent of multimedia allows different applications to mix sound, images, and video and interaction with a large amount of information (e.g., in e-business, distance learning, and human-machine interface). The industry is investing to deliver audio, still image, and video data in electronic form to customers, and broadcast televisions companies, major corporations, and photo archivers are converting their archive contents from analog to digital form. This movement from traditional media, such as paper documents, analog recordings, to digital media is due to the several advantages of digital media over the traditional media. Among these advantages are (Swanson, Kobayashi, & Tewfik, 1998; Tirkel et al., 1993):

- The quality of digital signals is higher than that of their corresponding analog signals. Traditional assets degrade in quality as time passes. Analog data require expensive systems to obtain high-quality copies, whereas digital data can be easily copied without loss of fidelity.
- Digital data (audio, still image, and video signals) can be easily transmitted over networks (e.g., the Internet). A large amount of multimedia data is now available to users all over the world. This expansion will continue at a rapid rate, especially with the widening availability of advanced multimedia services such as e-commerce, e-government, advertisement, interactive TV, digital libraries, and many others.
- Exact copies of digital data can be easily made. This is very useful but it also creates problems for the owner of valuable digital data like precious digital images. Replicas of a given piece of digital data cannot be distinguished and their origin cannot be confirmed. It is not easy to determine which piece is the original and which is the copy.

- It is possible to hide some information within digital data in such a way that data modifications are undetectable for the human senses.

## E-Commerce

Modern electronic commerce (e-commerce) is a new activity that is the direct result of a revolutionary information technology, digital data and the Internet. E-commerce is defined as the conduct of business transactions and trading over a common information systems (IS) platform such as the Web or Internet. The amount of information being offered to public access grows at an amazing rate with current and new technologies. Technology used in e-commerce is allowing new, more efficient ways of carrying out existing business, and this has had an impact not only on commercial enterprises but also on social life. The e-commerce potential has become a reality with the development of the World Wide Web (WWW) in the 1990s.

E-commerce can be divided into e-tailing, e-operations, and e-fulfillment; all supported by an e-strategy. E-tailing involves the presentation of the organization's selling wares (goods and services) in the form of electronic catalogs (e-catalogs). E-catalogs are an Internet version of the information presentation about the organization, its products, and so on. E-operations covers the core transactional processes for production of goods and delivery of services. E-fulfillment is an area within e-commerce, which still seems quite blurred. It complements e-tailing and e-operations as it covers a range of postretailing and operational issues. The core of e-fulfillment is payment systems, copyright protection of intellectual property, security (which includes privacy), and order management (i.e., supply chain, distribution, etc.). In essence, fulfillment is seen as the "fuel" to the growth and development of e-commerce.

The owners of copyright and related rights are granted a range of different rights to control or be remunerated for various types of uses of their property (e.g., still images, video, and audio). Among these is the right to exclude

others from reproducing the property without authorization. The development of digital technologies, permitting transmission of digital data over the Internet, has raised questions about how do these rights apply in the new environment? How can the digital intellectual property be made publicly available while guaranteeing ownership of the intellectual rights?

### Copyright Protection of Intellectual Property

An important factor that slows down the growth of multimedia networked services is that authors, publishers, and providers of multimedia data are reluctant to allow the distribution of their documents in a networked environment. This is because the ease of reproducing digital data in their exact original form is likely to encourage copyright violation, data misappropriation, and abuse. There is the problem of theft and distribution of intellectual property. Therefore, creators and distributors of digital data are actively seeking reliable solutions to the problems associated with copyright protection of multimedia data.

Moreover, the future development of networked multimedia systems, in particular on open networks such as the Internet, is conditioned by the development of efficient methods to protect data against unauthorized copying and redistribution of the material put on the network. This will guarantee that the owners' rights are protected and their assets are properly managed. Copyright protection of multimedia data has been accomplished by means of cryptography algorithms to provide control over data access and to make data unreadable to unauthorized users. However, encryption systems do not completely solve the problem because once encryption is removed there is no more control on the dissemination of data.

## DIGITAL WATERMARKING

The concept of digital watermarking arose while trying to solve problems related to the copyright of intellectual property in digital media. It is used as a means to identify the owner or distributor of digital data. Watermarking is the process of encoding hidden copyright information because it is possible today to hide information messages within digital audio, video, still images, and texts by taking into account the limitations of the human audio and visual systems.

### Digital Watermarking: What, Why, When, and How?

Digital watermarking has proved to be an efficient technique to protect intellectual property from illegal copying. It provides a means of embedding a message in a piece of digital data without destroying its value. Digital watermarking embeds a known message in a piece of digital data as a means of identifying the rightful owner of the data. These techniques can be used on many types of digital data, including still imagery, movies, and music. In this chapter, we focus on digital watermarking for images and in particular invisible watermarking.

### What Is Digital Watermarking?

A digital watermark is a signal permanently embedded into digital data (audio, still images, video, and text) that can be detected or extracted later by means of computing operations to make assertions about the data. The watermark is hidden in the host data in such a way that it is inseparable from the data and so that it is resistant to many operations that do not degrade the host document. Thus by means of watermarking, the work is still accessible but permanently marked.

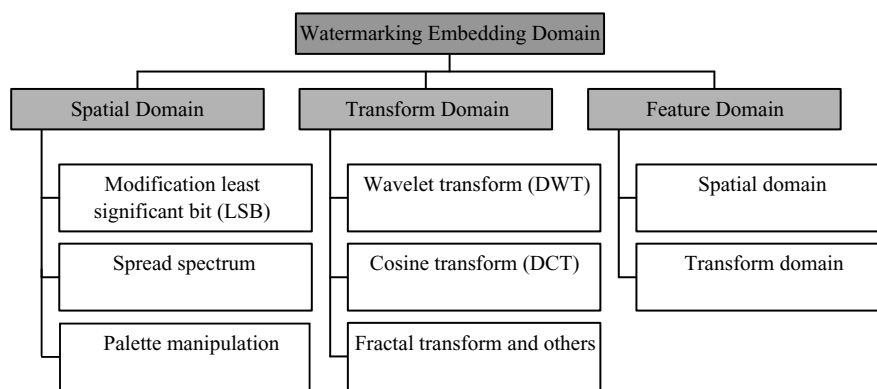

Conversely, watermarking is not like encryption. Watermarking does not restrict access to the data, whereas encryption has the aim of making messages unintelligible to any unauthorized persons who might intercept them. Once encrypted, data cannot be retrieved except by a reverse process called decryption. A watermark is designed to permanently reside in the host data. If the ownership of a digital work is in question, the information can be extracted to completely characterize/identify the owner.

### Why Digital Watermarking?

Digital watermarking is an enabling technology for e-commerce strategies: conditional and user specific access to services and resources. Digital watermarking offers several advantages. The details of a good digital watermarking algorithm can be made public knowledge. Digital watermarking provides the owner of a piece of digital data the means to mark the data invisibly. The mark could be used to serialize a piece of data as it is sold or used as a method to mark a valuable image. For example, this marking allows an owner to safely post an image for viewing, but legally provides an embedded copyright to prohibit others from posting the same image. Watermarks and attacks on watermarks are two sides of the same coin. The goal of both is to preserve the value of the digital data. However, the goal of a watermark is to be robust enough to resist attack but not at the expense of altering the value of the data being protected. Conversely, the goal of the attack is to remove the watermark without destroying the value of the protected data. The contents of the image can be marked without visible loss of value or dependence on specific formats. For example a bitmap (BMP) image can be compressed to a JPEG image. The result is an image that requires less storage space but cannot be distinguished from the original. Generally, a Joint Picture Experts Group (JPEG) compression level of 70% can be applied without humanly visible degradation. This property of digital images allows insertion of additional data in the image without altering the value of the image. The message is hidden in unused "visual space" in the image and stays below the human visible threshold for the image.

### When Did the Technique Originate?

The idea of hiding data in another media is very old as described in the case of steganography. Nevertheless, the term *digital watermarking* first appeared in 1993, when Tirkel et al. (1993) presented two techniques to hide data in images. These methods were based on modifications to the least significant bit (LSB) of the pixel values.

**Figure 1:** Classification of watermarking algorithms based on domain used for the watermarking embedding process.

### How Can We Build an Effective Watermarking Algorithm?

The following sections provide a detailed answer to this question. However, it is desired that watermarks survive image-processing manipulations such as rotation, scaling, image compression, and image enhancement. Taking advantage of the discrete wavelet transform properties and robust features extraction techniques is the new trends that are used in the recent digital image watermarking schemes. Robustness against geometrical transformation is essential because image-publishing applications often apply some kind of geometrical transformations to the image, and thus, an intellectual property ownership protection system should not be affected by these changes.

### Digital Watermarking Concept

In this section, we try to provide a theoretical background of watermarking. We focus mainly on digital images and the principles by which watermarks are implemented. We discuss the requirements needed for an effective watermarking system and show that the requirements are application dependent; however, some of them are common to most practical applications. The challenges facing researchers in this field are reviewed from viewpoint of the digital watermarking requirements. Swanson et al. (1998) sheds some light on this matter.

### Visible Versus Invisible Watermarks

Digital watermarking is divided into two main categories: visible and invisible. The idea behind the visible watermark is very simple. It is equivalent to stamping a watermark on paper, and for this reason is sometimes said to be digitally stamped. An example of visible watermarking is provided by television broadcasting channels, such as BBC, CNN, and TV5, whose logos are visibly superimposed on the corner of the TV picture frame. Invisible watermarking, conversely, is a far more complex process and concept. It is most often used to identify copyright data such as author, distributor, and source.

Though a lot of research has been conducted in the area of invisible watermarks, much less has been done for visible watermarks. Visible and invisible watermarks both serve to deter theft but they do so in very different ways.

Visible watermarks are especially useful for conveying an immediate claim of ownership (Mintzer, Braudaway, & Yeung, 1997). Their main advantage, in principle at least, is the virtually elimination of the commercial value of a document to a would-be thief, without lessening the document's utility for legitimate, authorized purposes. Invisible watermarks, conversely, are more of an aid in catching a thief than for discouraging theft in the first place (Mintzer et al., 1997; Swanson et al., 1998). This chapter focuses on the latter category, and the phrase *watermark* is taken to mean the invisible watermark, unless otherwise stated.

### Watermarking Classification

There are different classifications of invisible watermarking algorithms. The reason behind this is the enormous diversity of watermarking schemes. Watermarking approaches can be distinguished in terms of watermarking host signal (still images, video signal, audio signal, integrated circuit design), the availability of original signal during extraction (nonblind, semiblind, blind). Also, they can be categorized based on the domain used for watermarking embedding process, as shown in Figure 1. The Watermarking application is considered one of the criteria for watermarking classification. Figure 2 shows the subcategories based on watermarking applications.

### Digital Watermarking Application

The four main digital watermarking applications are

- Copyright protection
- Image authentication
- Data hiding
- Covert communication

Figure 2 shows the different applications of watermarking with some examples for each of these applications. Moreover, digital watermarking has been proposed for tracing images in the event of their illicit redistribution. The need for this has arisen because modern digital networks make large-scale dissemination simple and inexpensive. In the past, infringement of copyrighted documents was often limited by the unfeasibility of large-scale

Figure 2: Classification of watermarking technology based on applications.

photocopying and distribution. In principle, digital watermarking makes it possible to uniquely mark each image sold. If a purchaser then makes an illicit copy, the illegal duplication may be convincingly demonstrated (Swanson et al., 1998). Such discussion on watermarking applications leads us to explain the difference between robust and fragile watermarks.

**Robust Versus Fragile Watermarks.** Robust and fragile watermarks are also two categories of watermarking; it all depends on what you want to do with the watermark (application). A robust watermark is difficult to be removed from the object in which it is embedded in. It is used for ownership assertion (proof of ownership). The main properties of this kind of watermark are as follows:

- Robustness against all kinds of image distortion (difficult to remove)
- Does not have good localization properties
- Should distinguish malicious and nonmalicious modifications
- The watermark can be embedded using spread spectrum or frequency domain techniques
- Watermark pattern must be perceptually transparent
- Watermark depends on a secret key

Conversely, the fragile watermark, which is also known as a tamper-proof watermark, is easy to alter. Such watermarks are destroyed by data manipulation. It is used for content authentication (good for integrity checks). The main properties of this class of watermarking are as follows:

- Break easily (remove easily)
- Computationally cheap
- Good localization properties
- Too sensitive for redundant data
- Embedded in spatial domain

**Watermark Embedding**

Generally, watermarking systems for digital media involve two distinct stages: (1) watermark embedding to indicate copyright and (2) watermark detection to identify the owner (Swanson et al., 1998). Embedding a watermark requires three functional components: a watermark carrier, a watermark generator, and a carrier modifier.

A watermark carrier is a list of data elements, selected from the unwatermarked signal, which are modified during the encoding of a sequence of noiselike signals that form the watermark. The noise signals are generated pseudorandomly, based on secret keys, independent of the carrier. Ideally, the signal should have the maximum amplitude, which is still below the level of perceptibility. The carrier modifier adds the generated noise signals to the selected carrier. To balance the competing requirements for low perceptibility and robustness of the added watermark, the noise must be scaled and modulated according to the strength of the carrier (Swanson et al., 1998; Tirkel et al., 1993).

Embedding and detecting operations proceed as follows. Let  $I_{orig}$  denote the original multimedia signal (an image, an audio clip, or a video sequence) before watermarking. Let  $W$  denote the watermark, which the copyright owner wishes to embed, and  $I_{water}$  denote the signal with the embedded watermark. A block diagram representing a general watermarking scheme is shown in Figure 3. The watermark  $W$  is encoded into  $I_{orig}$  using an embedding function  $E$  as follows:

$$E(I_{orig}, W) = I_{water}. \tag{1}$$

(a) Watermarking embedding system

(b) Watermarking detecting system

Figure 3: Embedding and detecting systems of digital watermarking.

The embedding function makes small modifications to  $I_{orig}$  related to  $W$ . For example, if  $W = (w1, w2, \dots)$ , the embedding operation may involve adding or subtracting a small quantity  $a$  from each pixel or sample of  $I_{orig}$ . During the second stage of the watermarking system, the detecting function  $D$  uses knowledge of  $W$ , and possibly  $I_{orig}$ , to extract a sequence  $W'$  from the signal  $R$  undergoing testing:

$$D(R, I_{orig}) = W'. \tag{2}$$

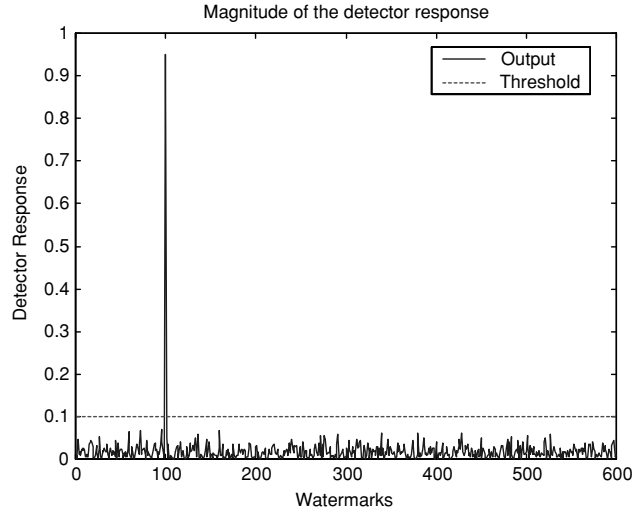

The signal  $R$  may be the watermarked signal  $I_{water}$ , it may be a distorted version of  $I_{water}$  resulting from attempts to remove the watermark, or it may be an unrelated signal. The extracted sequence  $W'$  is compared with the watermark  $W$  to determine whether  $R$  is watermarked. The comparison is usually based on a correlation measure,  $\rho$ , and a threshold,  $\lambda_0$ , used to make the binary decision ( $Z$ ) on whether the signal is watermarked. To check the similarity between  $W$ , the embedded watermark and the extracted one ( $W'$ ), the correlation measure between them can be found using the following expression:

$$\rho(W, W') = \frac{W \cdot W'}{\sqrt{W' \cdot W'}}, \tag{3}$$

where  $WW'$  is the scalar product between these two vectors. However, the decision function is

$$Z(W', W) = \begin{cases} 1, & \rho \geq \lambda_0 \\ 0 & \text{otherwise} \end{cases}, \tag{4}$$

where  $\rho$  is the value of the correlation and  $\lambda_0$  is a threshold. A 1 indicates that a watermark was detected, whereas a 0 indicates that a watermark was not detected. In other words, if  $W$  and  $W'$  are sufficiently correlated (greater than some threshold  $\lambda_0$ ), the signal  $R$  has been verified to contain the watermark, which confirms the author's ownership rights to the signal. Otherwise, the owner of the watermark  $W$  has no rights over the signal  $R$ . It is possible to derive the detection threshold  $\lambda_0$  analytically or empirically by examining the correlation of random sequences. Figure 4 shows the detection threshold of 600 random watermark sequences studied and only one watermark, which was originally inserted, has a significantly higher correlation output than the others. As an example

**Figure 4:** The detection threshold experimentally of 600 random watermark sequences studied; only one watermark, which was originally inserted, has a higher correlation output above others. Threshold is set to be 0.1 in this graph.

of an analytically defined threshold,  $\tau$  can be defined as follows:

$$\tau = \frac{\alpha}{3N_c} \sum_{n=1}^{N_c} |I_{water}(m, n)|, \tag{5}$$

where  $\alpha$  is the weighting factor and  $N_c$  is the number of coefficients that have been marked. The formula is applicable to square and nonsquare images (Voyatzis, Nikolaidis, & Pitas, 1998). One can even just select certain coefficients (based on a pseudorandom sequence or a human visual system [HVS] model). The choice of the threshold influences the false positive and false negative probability. Voyatzis et al. (1998) proposes some methods to compute predictable correlation thresholds and efficient watermark detection systems.

**A Watermarking Example**

A simple example of the basic watermarking process is described here. The example is very basic and meant to illustrate the main concept. The discrete cosine transform (DCT) is applied on the host image, which is represented by the first block (8 × 8 pixel) of the “trees” image shown in Figure 5. The block is given by the following:

$$B_1 = \begin{bmatrix} 0.7232 & 0.8245 & 0.6599 & 0.7232 & 0.6003 & 0.6122 & 0.6122 & 0.5880 \\ 0.7745 & 0.7745 & 0.7745 & 0.7025 & 0.7745 & 0.7025 & 0.7745 & 0.7025 \\ 0.7745 & 0.7745 & 0.7025 & 0.7745 & 0.7745 & 0.7025 & 0.7025 & 0.7025 \\ 0.7025 & 0.7025 & 0.7025 & 0.7025 & 0.7025 & 0.7745 & 0.7025 & 0.7025 \\ 0.7745 & 0.7025 & 0.7745 & 0.7025 & 0.7025 & 0.7025 & 0.7025 & 0.7025 \\ 0.7025 & 0.7025 & 0.7025 & 0.7745 & 0.7025 & 0.7745 & 0.7025 & 0.7025 \\ 0.7025 & 0.7745 & 0.7025 & 0.7025 & 0.7745 & 0.7025 & 0.7745 & 0.7025 \\ 0.7025 & 0.7025 & 0.7745 & 0.7745 & 0.7745 & 0.7025 & 0.7025 & 0.7025 \end{bmatrix}.$$

Figure 5: The "trees" image with its first  $8 \times 8$  block.

Applying DCT on  $B_1$ , results in  $DCT(B_1)$ :

$$DCT(B_1) = \begin{bmatrix} 5.7656 & 0.1162 & -0.0379 & 0.0161 & -0.0093 & -0.0032 & -0.0472 & -0.0070 \\ -0.0526 & 0.1157 & 0.0645 & 0.0104 & -0.0137 & -0.0114 & -0.0415 & -0.0336 \\ -0.0354 & 0.0739 & -0.0136 & -0.0410 & -0.0081 & -0.0187 & -0.0871 & 0.0063 \\ -0.0953 & 0.0436 & 0.0379 & -0.0090 & -0.0394 & 0.0182 & -0.0031 & -0.0589 \\ -0.1066 & 0.0500 & 0.0034 & -0.0355 & -0.0093 & 0.0147 & 0.0526 & -0.0278 \\ -0.0790 & -0.0064 & 0.0088 & 0.0240 & -0.0200 & -0.0361 & -0.0586 & -0.0731 \\ -0.0422 & 0.0366 & -0.0460 & -0.0150 & 0.0518 & 0.0141 & 0.0105 & -0.0980 \\ 0.0025 & 0.0697 & 0.0327 & -0.0140 & 0.0286 & -0.0084 & -0.0422 & 0.0329 \end{bmatrix}$$

Notice that most of the energy of the DCT of  $B_1$  is compact at the DC value (DC coefficient = 5.7656).

The watermark, which is a pseudorandom real number generated using a random number generator and a seed value (key), is given by the following:

$$W = \begin{bmatrix} 1.6505 & 0.2759 & -0.8579 & -1.6130 & -1.0693 & 0.2259 & -0.4570 & 0.7167 \\ 0.7922 & -0.6320 & 0.8350 & -0.3888 & 0.4993 & 0.2174 & -1.6095 & -0.9269 \\ 0.7319 & 0.7000 & 1.6191 & -0.0870 & 0.7859 & 0.1870 & -0.3633 & 2.5061 \\ 0.9424 & 0.8966 & -0.0246 & -1.4165 & 0.5422 & 0.1539 & -1.1958 & 0.0374 \\ 0.2059 & 1.8204 & 0.5224 & -0.9099 & -1.6061 & -0.7764 & -0.8054 & -1.0894 \\ -0.1303 & -0.3008 & 1.6732 & -1.1281 & -0.3946 & 0.8294 & -0.0007 & -0.7952 \\ 0.0509 & -1.7409 & 1.1233 & 0.3541 & 0.1994 & -0.0855 & 0.1278 & -0.6312 \\ -0.1033 & -1.7087 & 0.5532 & 0.2068 & 2.5359 & 1.7004 & -0.6811 & -0.7771 \end{bmatrix}$$

Applying DCT on  $W$  results in  $DCT(W)$  as shown below:

$$DCT(W) = \begin{bmatrix} 0.2390 & 1.5861 & 0.1714 & 0.7187 & -0.3163 & -1.0925 & 2.6675 & 1.3164 \\ 0.1255 & 0.8694 & 2.8606 & -0.2411 & 0.6162 & -1.1665 & -0.1335 & -0.8266 \\ 0.0217 & -1.4093 & -1.3448 & 1.3837 & 1.3513 & 1.0022 & 0.8743 & 0.3735 \\ -1.7482 & 0.8337 & 1.5394 & -0.0076 & -1.7946 & 1.1027 & -0.4434 & -0.5771 \\ -0.7653 & 0.5313 & 0.9799 & 1.2930 & -0.0309 & -0.9858 & -0.9079 & -0.8152 \\ 0.4222 & -0.9041 & 1.2626 & -0.0979 & 0.6200 & 0.1858 & -0.1021 & 0.1452 \\ 1.4724 & -1.1217 & 0.7449 & -0.2921 & -0.3144 & -0.7244 & 0.4119 & 0.0535 \\ 0.4453 & 0.0380 & 0.9942 & -1.5048 & 0.0656 & 0.4169 & -0.7046 & -0.5278 \end{bmatrix}$$

$B_1$  is watermarked with  $W$  as shown in the block diagram in Figure 6 according to the following formula:

$$f_w = f + \alpha \cdot w \cdot f, \quad (6)$$

where  $f$  is a DCT coefficient of the host signal ( $B_1$ ),  $w$  is a DCT coefficient of the watermark signal ( $W$ ), and  $\alpha$  is the watermarking energy, which is taken to be 0.1 ( $\alpha = 0.1$ ). The DC value of the host signal is not modified, thereby minimizing the distortion of the watermarked image. Therefore, the DC value will be kept un-watermarked.

The above equation can be rewritten in a matrix format as follows:

$$\text{DCT}(B_{1w}) = \begin{cases} \text{DCT}(B_1) + \alpha \cdot \text{DCT}(W) \cdot \text{DCT}(B_1) & \text{for all coefficient except DC value} \\ \text{DCT}(B_1) & \text{for DC value,} \end{cases} \quad (7)$$

where  $B_{1w}$  is the watermarked signal of  $B_1$ . The result after applying the above equation can be calculated as follows:

$$\text{DCT}(B_{1w}) = \begin{bmatrix} 5.7656 & 0.1346 & -0.0386 & 0.0172 & -0.0090 & -0.0028 & -0.0598 & -0.0079 \\ -0.0532 & 0.1258 & 0.0830 & 0.0101 & -0.0145 & -0.0101 & -0.0409 & -0.0308 \\ -0.0355 & 0.0635 & -0.0117 & -0.0467 & -0.0092 & -0.0206 & -0.0947 & 0.0066 \\ -0.0786 & 0.0472 & 0.0438 & -0.0090 & -0.0323 & 0.0202 & -0.0029 & -0.0555 \\ -0.0984 & 0.0527 & 0.0037 & -0.0400 & -0.0092 & 0.0132 & 0.0478 & -0.0255 \\ -0.0823 & -0.0058 & 0.0099 & 0.0238 & -0.0212 & -0.0368 & -0.0580 & -0.0742 \\ -0.0485 & 0.0325 & -0.0494 & -0.0146 & 0.0502 & 0.0131 & 0.0109 & -0.0985 \\ 0.0026 & 0.0700 & 0.0360 & -0.0119 & 0.0288 & -0.0088 & -0.0392 & 0.0312 \end{bmatrix}$$

Notice that the DC value of  $\text{DCT}(B_{1w})$  is the same as the DC value of  $\text{DCT}(B_1)$ . To construct the watermarked image, the inverse DCT of the above two-dimensional array is computed to give  $B_{1w}$  as follows:

$$B_{1w} = \begin{bmatrix} 0.7331 & 0.8361 & 0.6609 & 0.7228 & 0.5991 & 0.6026 & 0.6175 & 0.5922 \\ 0.7818 & 0.7809 & 0.7735 & 0.7011 & 0.7712 & 0.6955 & 0.7755 & 0.6998 \\ 0.7734 & 0.7746 & 0.6973 & 0.7682 & 0.7663 & 0.7002 & 0.6956 & 0.6920 \\ 0.7064 & 0.7093 & 0.7045 & 0.7037 & 0.7013 & 0.7692 & 0.6986 & 0.6933 \\ 0.7872 & 0.7100 & 0.7789 & 0.7081 & 0.7067 & 0.7012 & 0.7013 & 0.6996 \\ 0.7051 & 0.7032 & 0.7026 & 0.7801 & 0.7078 & 0.7741 & 0.7015 & 0.6978 \\ 0.7017 & 0.7765 & 0.7002 & 0.7067 & 0.7765 & 0.7026 & 0.7736 & 0.6992 \\ 0.6877 & 0.7048 & 0.7712 & 0.7800 & 0.7793 & 0.7001 & 0.7044 & 0.6974 \end{bmatrix}$$

It is easy to compare  $B_{1w}$  and  $B_1$  and see the very slight modification because of the watermark.

### Robust Watermarking Scheme Requirements

In this section, the requirements needed for an effective watermarking system are introduced. The requirements are application dependent, but some of them are common to most practical applications. One of the challenges for researchers in this field is that these requirements compete with each other. Such general requirements are listed below. Detailed discussions of them can be found in references (Ruanaidh, Dowling, & Roland, 1996; Voyatzis et al., 1998).

### Security

Effectiveness of a watermark algorithm cannot be based on the assumption that possible attackers do not know the embedding process that the watermark went through. The robustness of some commercial products is based on such an assumption. The point is that by making the technique very robust and making the embedding algorithm public, this actually reduces the computational complexity for the attacker to remove the watermark. Some of the techniques use the original nonmarked image in the extraction process. They use a secret key to generate the watermark for security purpose (Swanson et al., 1998).

### Invisibility

**Perceptual Invisibility.** Researchers have tried to hide the watermark in such a way that watermark is impossible to notice. However, this requirement conflicts with other requirements such as robustness, which is an important requirement when facing watermarking attacks. For this purpose, the characteristics of the HVS for images and the human auditory system (HAS) for audio signals are exploited in the watermark embedding process.

**Statistical Invisibility.** An unauthorized person should not detect the watermark by means of statistical methods. For example, the availability of a great number of digital

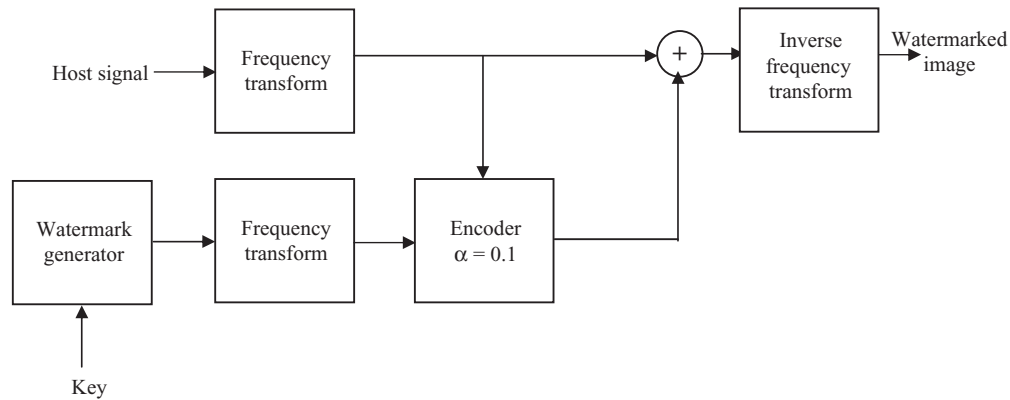

Figure 6: Basic block diagram of the watermarking process.

works watermarked with the same code should not allow the extraction of the embedded mark by applying statistically based attacks. A possible solution is to use a content dependent watermark (Voyatzis et al., 1998).

### Robustness

Digital images commonly are subject to many types of distortions, such as lossy compression, filtering, resizing, contrast enhancement, cropping, rotation, and so on. The mark should be detectable even after such distortions have occurred. Robustness against signal distortion is better achieved if the watermark is placed in perceptually significant parts of the image signal (Ruanaidh et al., 1996). For example, a watermark hidden among perceptually insignificant data is likely not to survive lossy compression. Moreover, resistance to geometric manipulations, such as translation, resizing, rotation, and cropping, is still an open issue. These geometric manipulations are still very common.

### Watermarking Extraction: False Negative/Positive Error Probability

Even in the absence of attacks or signal distortions, false negative error probability (the probability of failing to detect the embedded watermark) and of detecting a watermark when, in fact, one does not exist (false positive error probability), must be very small. Usually, statistically based algorithms have no problem in satisfying this requirement.

### Capacity Issue (Bit Rate)

The watermarking algorithm should embed a predefined number of hidden bits in the host signal that depends on the considered application. There is no general rule for this. However, in the image watermarking, the possibility of embedding into the image at least 300–400 bits should be guaranteed. In general, the number of bits, which can be hidden into data, is limited. Capacity issues were discussed by Servetto, Podilchuk, and Ramchandran (1998).

One can understand the challenge to researchers in this field because the above requirements compete with each other. The important test of a watermarking method would be that it is accepted and used on a large, commercial scale and that it stands up in a court of law. None

of the digital techniques have yet to meet all of these requirements. In fact the first three requirements (security, robustness, and invisibility) can form sort of a triangle (Figure 7), which means that if one is improved, the other two may be affected.

### Digital Watermarking Algorithms

Current watermarking techniques described in the literature can be grouped into three main classes. The first includes the transform domain methods, which embed the data by modulating the transform domain signal coefficients. The second class includes the spatial domain techniques, which embed the watermark by directly modifying the pixel values of the original image. The transform domain techniques have been found to have the best robustness, when the watermarked signals are tested after having been subjected to common signal distortions. The third class is the feature domain technique, which takes into account region, boundary, and object characteristics. Such watermarking methods may present additional advantages in terms of detection and recovery from geometric attacks, compared with previous approaches.

The algorithms in this survey are organized according to their embedding domain, as indicated in Figure 1. These are grouped into spatial domain techniques, transform domain techniques, and feature domain techniques. We highlight the main features of these techniques. The wavelet domain is the most efficient domain

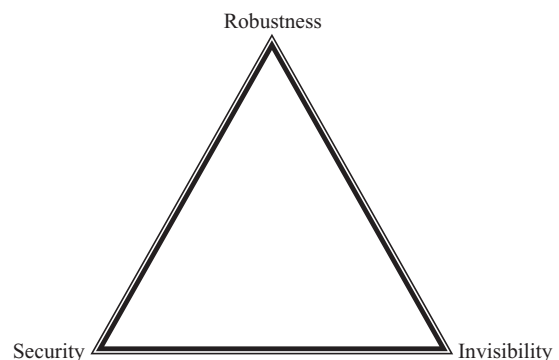

Figure 7: Digital watermarking requirements triangle.

for watermarking embedding so far. However, our review considers some other techniques, which serve the purpose of giving a broader picture of the existing watermarking algorithms. Some examples of spatial domain and fractal based techniques are reviewed as well.

### Spatial Domain Techniques

This section gives a brief introduction to the spatial domain technique. Many spatial techniques are based on adding fixed amplitude pseudonoise (PN) sequences to an image. In this case,  $E$  and  $D$ , as introduced earlier, are simply the addition and subtraction operators, respectively. Pseudonoise sequences are also used as the “spreading key” when considering the host media as the noise in a spread spectrum system, where the watermark is the transmitted message. In this case, the PN sequence is used to spread the data bits over the spectrum to hide the data. When applied to the spatial or temporal domains, this approach modifies the LSB of the host data. The invisibility of the watermark is achieved on the assumption that the LSB data are visually insignificant. The watermark is generally recovered using knowledge of the PN sequence (and perhaps other secret keys, like watermark location) and the statistical properties of the embedding process. Two LSB techniques are described in reference (Schyndel, Tirket, & Osborne, 1994).

### Transform Domain Techniques

Many transform-based watermarking techniques have been proposed. To embed a watermark, a transformation is first applied to the host data, and then modifications are made to the transform coefficients. The works presented in Ruanaidh et al. (1996), Servetto et al. (1998), Schyndel et al. (1994), Bors and Pitas (1996), Nikolaidis and Pitas (1996), and Pitas (1996) can be considered to be the pioneering efforts that utilize the transform domain for watermarking process. These articles were published at early

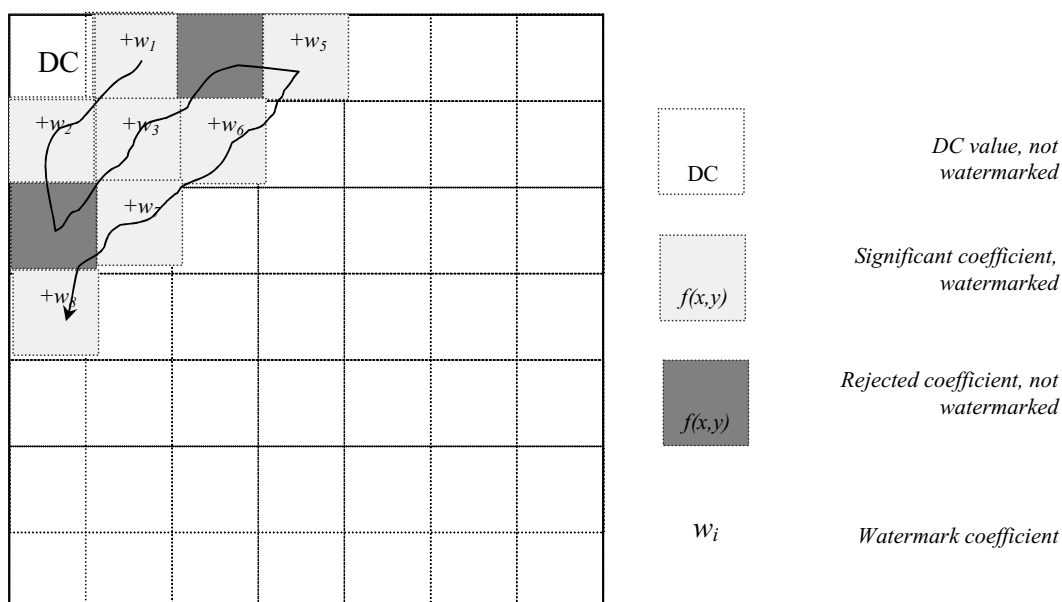

stages of development of watermarking algorithms, so they represent the basic framework for this research area. This section has three main parts, including discussions of wavelet-based watermarking, DCT-based watermarking, and fractal domain watermarking.

### Digital Watermarking Using Wavelet Decomposition.

Many articles have proposed to use the wavelet transform domain for watermarking because of a number of advantages that can be gained by using this approach. The works described in Wei, Qin, and Fu (1998), Zhu, Xiong, and Zhang (1998), Suahil and Obaidat (2001), and Suhail, Obaidat, Ipson, and Sadoun (2003) implement watermarking in the wavelet domain. As an example, a perceptually based technique for watermarking images is proposed in Wei et al. (1998). The watermark is inserted in the wavelet coefficients and its amplitudes are controlled so that the watermark noise does not exceed the just-noticeable difference of each wavelet coefficient. Meanwhile, the order of inserting watermark noise in the wavelet coefficients is the same as the order of the visual significance of the wavelet coefficients (Wei et al., 1998). The invisibility and the robustness of the digital watermark may be guaranteed.

### Discrete Cosine Transform-Based Digital Watermarking.

Several watermarking algorithms have been proposed to utilize the DCT. However, Cox, Kilian, Leighton, and Shamoon (1997) and the Koch and Zhao (1995) algorithms are the most well known DCT-based schemes. Cox et al. (1997) proposed the most well-known spread spectrum watermarking schemes. Figure 8 shows the block diagram of the Cox et al. algorithm. The image is first subjected to a global DCT, and then the 1,000 largest coefficients in the DCT domain are selected for watermarking. They used a Gaussian sequence of pseudorandom real numbers of length 1,000 as a watermark. This

**Figure 8:** Cox embedding process, which classifies DCT coefficients into significant and rejected coefficients.

approach achieves a good robustness against compression and other common signal processing attacks. This is a result of the selection perceptually significant transform domain coefficients. However, the algorithm is in a weak position against the invariability attack proposed by Craver, Memon, Yeo, and Yeung (1997). Also, the global DCT employed on the image is computationally expensive. The DCT has been applied also in many other watermarking algorithms (Suhail & Obaidat, 2003).

### Fractal Transform Based Digital Watermarking.

Though a lot of work has been done in the area of invisible watermarks using the DCT and the wavelet-based methods, relatively few references exist for invisible watermarks based on the fractal transform. The reason for this might be the computational cost of the fractal transform. Discussions of fractal watermarking methods are presented in Puate and Jordan (1996). Puate and Jordan (1996) used fractal compression analysis to embed a signature in an image. In fractal analysis, similar patterns are identified in an image and only a limited amount of binary code can be embedded using this method. Because fractal analysis is computationally intensive and some images do not have many large self-similar patterns, the techniques may not be suitable for general use.

### Feature Domain Techniques (Second-Generation Watermarking)

First-generation watermarking (1GW) methods have been mainly focused on applying the watermarking on the entire image/video domain. However, this approach is not compatible with novel approaches for still image and video compression. JPEG2000 and MPEG4/7 standards are the new techniques for image and video compression. They are region or object based, as can be seen in the compression process. Also, the 1GW algorithms proposed so far do not satisfy the watermarking requirements.

Second-generation watermarking (2GW) was developed to increase the robustness and invisibility and to overcome the weaknesses of 1GW. The 2GW methods take into account region, boundary, and object characteristics and give additional advantages in terms of detection and recovery from geometric attacks compared with first-generation methods. This is achieved by exploiting salient region or object features and characteristics of the image. Also, 2GW methods may be designed so that selective robustness to different classes of attacks is obtained. As a result, watermark flexibility will be improved considerably.

Kutter et al. used feature point extraction and the Voronoi diagram as an example to define region of interest (ROI) to be watermarked (Kutter, Bhattacharjee, & Ebrahimi, 1999). The feature extraction process is based on a decomposition of the image using Mexican hat wavelet mother, as shown in Figures 9 and 10. However, the stability of the method proposed depends on the feature points. These extracted features have the drawback that their location may change by some pixels because of attack or during the watermarking process. Changing the location of the extracted feature points will cause problems during the detecting process.

**Figure 9:** Mexican hat mother wavelet function for 1D.

From the literature review in this section, it is apparent that digital watermarking can be achieved by using transform techniques, embedding watermark data into the frequency domain representation of the host image or by directly embedding the watermark into the spatial domain data of the image. The review also shows there are several requirements that the embedding method has yet to satisfy. Creating robust watermarking methods is still a challenging research problem. These algorithms are robust against some attacks but not against most of them. As an example, they cannot withstand geometric attacks such as rotation or cropping. Also, some of the current methods are designed to suit only specific application, which limits their widespread use.

Moreover, there are some concerns in the existing algorithms associated with the watermark embedding domain. These concerns vary from system to system. Watermarking schemes that modify the LSB of the data using a fixed magnitude PN sequence are highly sensitive to signal processing operations and are easily corrupted. Some transform domain watermarking algorithms cannot survive most image processing operations and geometric manipulations. This will limit their use in large numbers of applications. Using fractal transforms, only a limited amount of binary code can be embedded. Because fractal analysis is computationally expensive, and some images do not have many large, self-similar patterns, fractal-based algorithms may not be suitable or practical for general use. Feature domain algorithms suffer from problems of stability of feature points if they are

**Figure 10:** The 2D Mexican hat mother wavelet function in spatial domain (left) and in transform domain (right).

exposed to an attack. For example, the method proposed in Kutter's work (Kutter et al., 1999) depends on the stability of extracted features whose locations may change by several pixels because of attack or because of the watermarking process. This will cause problems during the decoding process. Security is an issue facing most of the existing watermarking algorithms.

## STEGANOGRAPHY

Steganography is one of the fundamental ways by which data can be kept confidential. It is an effective method of hiding data that has been used throughout history. This section will give an introductory discussion of steganography: what it is, how it can be used, and how the steganographic implications can have on information security.

### What Is Steganography?

Steganography has been around since the times of ancient Rome. Steganography (also known as *steg* or *stego*) is the art of writing in cipher, or in characters, that are not intelligible except to persons who have the key; it is a type of cryptography (Johnson, 2004; Radcliff, 2003). In computer terms, steganography has evolved into the practice of hiding a message within a larger one in such a way that others cannot distinguish the presence or contents of the hidden message. Steganography has evolved into a digital strategy of hiding a file in some form of multimedia, such as an image, an audio file (such as a .wav or mp3), or even a video file.

However, image steganography is defined as hiding a secret message within an image in such a way that others cannot distinguish the presence or contents of the hidden message. For example, a message might be hidden within an image by changing the LSB to be the message bits. By embedding a secret message into a carrier image, a stego image is obtained. It is important that the stego image contains no easily detectable artifacts because of message embedding that could be detected by electronic surveillance.

### Steganographic History

Steganography appeared before cryptography (Kahn, 1967). Throughout history, people have hidden information by a multitude of methods and variations. For example, in ancient Rome and Greece, text was traditionally written on wax that was poured on top of stone tablets. If the sender of the information wanted to obscure the message—for purposes of military intelligence, for instance, they would use steganography: the wax would be scraped off and the message would be inscribed or written directly on the tablet. Wax would then be poured on top of the message, thereby obscuring not just its meaning, but its very existence (Johnson, 2004). Another ingenious method was to shave the head of a messenger and tattoo a message or image on the messenger's head. After the hair grew back, the message would be undetected until the head was shaved again.

Recent times have yielded more advanced techniques, such as the use of invisible ink, where messages are written using substances that subsequently disappear. The

hidden message is later revealed using heat or certain chemical reactions. Invisible inks offered a common form of invisible writing, especially during the early years of World War II. A seemingly innocent letter could contain a very different message written between the lines with invisible ink.

Other methods may employ routine correspondence, such as the application of pinpricks in the vicinity of particular letters to spell out a secret message. Advances in photography produced microfilms that were used to transmit messages via carrier pigeon. Further developments in this area improved film and lenses that provided the ability to reduce the size of secret messages to a printed period. Because of the advances in technology today, moving communications to electronic means, digital multimedia signals, typically audio, video, or still image, are being used as vehicles for steganographic communication.

### Steganography Applications

Like many information security tools, steganography can be used for a variety of reasons, some not so good. Steganography can be used to maintain the confidentiality of valuable information to protect the data from possible sabotage, theft, or unauthorized viewing such as in the case of military applications. Steganography can also be used as a way to make a substitute for a one-way hash value (where you take a variable length input and create a static length output string to verify that no changes have been made to the original variable length input) (Schneier, 1996). Further, steganography can be used to tag notes to online images (like Post-it notes attached to paper files) (Radcliff, 2003).

Unfortunately, steganography can also be used for illegitimate reasons. For instance, if someone was trying to steal data, they could conceal it in another file or files and send it out in an innocent looking e-mail or file transfer. Furthermore, persons with a hobby of saving pornography on their hard drives may choose to hide the evidence through the use of steganography. As was pointed out, it can be used as a means of covert communication. Of course, this can be both a legitimate and an illegitimate application.

### Steganography Tools

There are many good and different tools that are available for steganography. An important distinction that should be made among the tools available today is the difference between tools that do steganography and tools that do steganalysis, which is the method of detecting steganography and destroying the original message. Steganalysis focuses on this aspect, as opposed to simply discovering and decrypting the message, because this can be difficult to do unless the encryption keys are known. For more comprehensive discussion of steganography tools, see Johnson (2004).

### Algorithms and Systems

There are several different steganographic systems that can be used to embed hidden messages into JPEG images. The statistical distortion depends on the steganographic

system that inserted the message into the image. Because of this different distortions associated with the different systems, it is possible to identify the signatures left by each system and allow for the identification of which system was used. Three popular steganographic programs available on the Internet that hide information in JPEG images are JSteg, JSteg-Shell, JPHide, and OutGuess. All three of these examples use a form of least significant bit embedding and are detectable by using statistical analysis. LSB manipulation is a quick and easy way to hide information but is vulnerable to small changes resulting from image processing or lossy compression. Such compression is a key advantage that JPEG images have over other formats. High-color quality images can be stored in relatively small files using JPEG compression methods. JPEG files are well known for being efficient carriers of image information, often achieving compression gains of about 90%, according to simple comparisons of JPEGs. During compression, the steganographically hidden message delicately embedded usually within the LSBs of the color information is easily destroyed. A generally acceptable image quality is preserved when steganographically embedding a maximum of 15% of the cover image's file size. These file sizes limit the amount of message data in the average GIF to approximately 150 to 450 bytes and the average JPEG image to anywhere from 3 to 150 KB.

JPEG images use the discrete cosine transform to achieve compression that is called a lossy compression transform because the cosine values cannot be calculated exactly, and repeated calculations using limited precision numbers introduce rounding errors into the final result. Also, images can be processed with Fast Fourier and wavelet transformations (Xia, Boncelet, & Arce, 1997). Other image properties such as luminance can also be manipulated. Patchwork (Bender et al., 1996) and others use *redundant pattern encoding* or spread spectrum methods (Cox et al., 1997) to scatter hidden information throughout the cover images. These approaches may help protect against image processing such as cropping and rotating, and they hide information more thoroughly than by simple masking. They also support image manipulation more readily than tools that rely on LSB. In using redundant pattern encoding, you trade off message size against robustness. A small message may be painted many times. A large message may be inserted only once because it would occupy a greater portion of the image area.

Moreover, some techniques *encrypt and scatter* the hidden data throughout an image. Scattering the message makes it appear more like noise. Proponents of the approach assume that even if the message bits are extracted, they will be useless without the algorithm and stego-key to decode them. For example, the White Noise Storm tool and frequency hopping, which scatters message throughout the image, are based on spread spectrum (SS) technology. Instead of having channels of communication that are changed with fixed formula and passkey, White Noise Storm spreads eight channels within a random number generated the previous window size and data channel. Scattering and encryption helps protect against hidden message extraction but not against message destruction through image processing. A scattered message in the image's LSBs is still as vulnerable destruction from

lossy compression and image processing. Steganography's niche in security is to supplement cryptography, not replace it. If a hidden message is encrypted, it must also be decrypted if discovered to provide another layer of protection.

### Statistical Analysis

One of the more common tests that can reveal that an image has been modified by steganography is by determining that an image's statistical properties are different from the normal. Some tests just measure the entropy of the redundant data and are independent on the data format. It can be expected that images with hidden data will have higher entropy than those images without.

Simple tests are used to measure the correlation toward one. These tests are not able to decide automatically if an image contains a hidden message. One property of encrypted data is that the 1 and zero bit are equally likely. When using the method to LSB embed encrypted data into a GIF image that contains color two more often than color three, color two is changed more often to color three than the other way around. As a result, the difference in color frequency between two and three is reduced by the embedding. The  $\chi^2$ -test can be used to determine whether an image shows distortion from embedding hidden data. Because the test uses only the stego medium, the expected distribution for the  $\chi^2$ -test has to be computed from the image. The probability of embedding information into different parts of the image is computed. For an image that does not contain any hidden information, it is expected that the probability of embedded information is zero everywhere.

### Attacking Steganography

The only way to detect/attack steganography is to be actively looking into specific files or to get very lucky. Sometimes an actively enforced security policy can provide the answer. Detecting the movement and behavior of traffic on your network may also be helpful to attack steganography. However, network intrusion detection systems can help administrators to gain an understanding of normal traffic in and around the network and can thus assist in detecting any type of attack on the network. If the administrator is aware of this sort of anomalous activity, it may warrant further investigation.

Steganalysis is the comparison among the carrier (cover), stego image, and the hidden message. The various methods used to analyze stego images are termed attacks and include *stego-only*, where the attacker has access only to the stego image; *known cover*, where the attacker has access only to the carrier; *known message*, where the attacker has access only to the message; *chosen stego*, where the attacker has access to both the stego image and stego algorithm; and *chosen message*, where the attacker generates a stego image from a message using an algorithm, looking for signatures that will enable him to detect other stego images.

The stego-only attack is the most important attack against steganographic systems because it will occur most frequently in practice. In general, there are two mechanisms to attack steganography, which really are also

methods of detecting it. These are the visual attack and the statistical attack. The visual attack finds out the differences in the files that are encoded where it relies on the capabilities of the human visual system. However, the statistical attack is to compare the frequency distribution of the colors of a potential stego file with the theoretically expected frequency distribution for a stego file where it performs statistical tests on the stego file.

### The Stego-Only Visual Attack

The visual attack is a stego-only attack that exploits the assumption of most authors of steganography programs that the LSBs of a cover file are random. This is done by relying on a human to judge if an image presented by a filtering algorithm contains hidden data. The filtering algorithm removes the parts of the image that are covering the message. The output of the filtering algorithm is an image that consists only of the bits that potentially could have been used to embed data. The filtering of the potential stego image is dependent on the steganographic embedding function that is analyzed. This form of steganography borrows from spread spectrum techniques employed in radio communication, especially the embedding of information in the LSBs, whose values are essentially lost in the noise of the image.

### The Stego-Only Statistical Attack

Regarding visual attacks, statistical attacks exploit the fact that most steganography programs treat the LSBs of the cover file as random data and therefore assume that they can overwrite these bits with other random data (the encrypted secret message). However, in "A Survey of Steganography" by S. Hetzl past examples have proven that the LSBs of an image are not random (Hetzl, 2002). When a steganography program embeds a bit through overwriting the LSB of a pixel in the cover file, the color value of this pixel is changed to an adjacent color value in the palette, or in the RGB cube if the cover file is a true color image. The volume within the RGB cube represents all possible colors identified as a combination of red, green, and blue, each with intensity from 0 to 255. When overwriting the LSBs of all occurrences of one of these color values with a bit from the secret message, the frequencies of these two color values will essentially be the same. This happens because the data being embedded are encrypted and therefore equally distributed. The essence of the statistical attack is to measure how close to identical the color frequency distributions of the potential stego file are. This results in a measure for the probability that the analyzed file contains a hidden message. This statistical attack is implemented using a  $\chi^2$ -test. In successive steps, increasing areas of the potential stego file are analyzed, starting with the first percentage of data, then the first two percentages of data, and so on until 100% of the data have been analyzed.

LSB encoding is only one popular method of information hiding. Another method that is described as "frequency domain experimentation" is frequency domain encoding that inserts messages into images by working with two-dimensional Fast Fourier transform (2D FFT) of the carrier image (Schneier, 1996).

## Steganography and Security

Steganography is an effective means of hiding data, thereby protecting the data from unauthorized or unwanted viewing. But stego is simply one of many ways to protect the confidentiality of data. It is probably best used in conjunction with another data hiding method. When used in combination, these methods can all be part of a layered security approach. For example, encryption is one of the good complementary methods. Encryption is the process of passing data or plaintext through a series of mathematical operations that generate an alternate form of the original data known as ciphertext. The encrypted data can only be read by parties who have been given the necessary key to decrypt the ciphertext back into its original plaintext form. Encryption does not hide data, but it does make it difficult to read!

## CONCLUDING REMARKS

The term *information hiding* relates to both watermarking and steganography. There are three different aspects to an information hiding system that contend with one another: capacity, security, and robustness (Chen & Wornell, 2001). Capacity refers to the amount of information that can be hidden. Security refers to the inability of an eavesdropper to detect hidden information, and robustness refers to the amount of modification the cover medium can withstand before the hidden information is destroyed.

The differences between the watermarking and steganography are often questioned or debated. The underlying technology to implement both of them may be the same, but the objectives are different. In the watermarking technique, the object of the communication channel is the carrier. The embedded information (watermark) can be thought of as an attribute of the carrier as it conveys additional information about the carrier such as copyright, ownership, distribution, tamper detection, and so on. Many watermarking techniques require a certain amount of robustness to carrier distortion (an exception is fragile watermarks). The payload size (size of the embedded information) is typically small. However, from an attack point of view, a successful attack against a watermarking system is to make the watermark unreadable or unintelligible. However, discovery of the fact that a watermark exists is not necessarily considered an attack.

In the case of steganography, the object of the communication channel is the embedded information. The carrier is simply an envelope that should conceal the existence of the embedded message. The main goal of steganography is secretive communication. Most steganographic techniques are fairly fragile to carrier disruptions and the payload size is relatively large when compared with watermarks. An attack against a steganographic system is the detection that an embedded message exists. Another attack is similar to watermarking, which includes disruption of the communication channel.

The techniques employed to encode information in both watermarking and steganography may be similar; however, the primary differences are in the application of the embedded information and the relationship to the carrier.

## GLOSSARY

**Algorithm** A set of steps used to solve a problem or perform an operation.

**Compression** This is a process used to represent data with less data. This can be done by removing redundant information. Another technique is to represent the most frequently occurring datum in a data stream with a shorter datum.

**Contrast** The variation in brightness between the darkest and lightest regions of an image.

**Correlation** It is a measure of similarity between two signals. The degree of similarity is often expressed as a number between zero and one. One indicates a perfect match.

**Digital Watermarking** It is an identification code carrying information (an author's signature, a company logo, etc.) about the copyright owner, the creator of the work, the authorized consumer, and so on. It is permanently embedded into digital data to indicate copyright and provide a means for checking if the data have been modified.

**Discrete Cosine Transform** A transform used in many applications, including image compression. It breaks an image down into additive real sinusoidal components.

**E-Commerce** It is the conduct of business transactions and trading over a common information systems platform such as the Web or Internet.

**Fast Fourier Transform** An algorithm for computing the Fourier transform with fewer computations.

**Fourier Transform** A method of transforming image information from the spatial domain to the frequency domain.

**Fragile Watermark** Fragile watermarks are also known as tamper-proof watermarks. Such watermarks are destroyed by data manipulation.

**Frequency Domain** A representation of a signal according to its basic frequency components.

**Image Compression** The class of techniques used to reduce the amount of data necessary to represent an image.

**Image Enhancement** A class of techniques used as selective emphasis and suppression of information in an image. The ultimate goal is to increase the image's usefulness. Enhancements may include such operations as sharpening or contrast modification.

**Information Hiding** Information hiding deals with communication security, which comprises encryption and traffic security. Encryption protects the content during distribution over an open network such as the Internet. The traffic security pertains to concealing its sender, its receiver, or its very existence.

**Intensity** Amplitude or power of light.

**Invisible Watermarking** It refers to the embedded digital watermark that is nonseeable. It is hidden in the content. It can be detected by an authorized agency only. It is most often used to identify copyright data, such as author, distributor, and so on.

**JPEG** Joint Picture Experts Group. JPEG usually refers to the image compression standard developed by that group. This type of image compression can be either lossless or lossy, depending on the application.

**MPEG** Motion Picture Experts Group. It has developed an algorithm to compress video sequences. Typically, references to MPEG refer to the compression algorithm.

**MPEG-4** It is an International Standard Organization (ISO)/International Electromechanical Commission (IEC) standard (ISO / IEC 14496). It provides an audio-visual coding standard for very low bit rate channels. Such channels are found in the Internet and mobile applications.

**Noise** A random variation in signal value occurring during digitizing, transmission, or other processes in a digital system.

**Pixel** A picture element. An image is composed of many tiny dots. These dots are called pixels.

**RGB** The additive color space consisting of the primaries red, green, and blue. This color model is used in most computer graphics display hardware

**Scaling** The geometric process that enlarges or shrinks an image.

**Spatial Domain** The normal domain of image data intensity as a function of position.

**Steganography** It is a subdiscipline of information hiding. Here, secret information is hidden in an innocuous (harmless) message. Such an innocuous message is also known as cover message.

**Visible Watermarking** It is an extension of the concept of logos. Such watermarks are applicable to images only. These logos are inlaid into the image, but they are transparent. It is sometimes called digitally stamped. An example of visible watermarking is provided by television channels, such as CNN, BBC, and TV5, whose logos are visibly superimposed on the corner of the TV picture frame.

**Watermarking Invisibility** Imperceptibility requires that the marked data and the original data should be perceptually indistinguishable.

**Watermarking Robustness** Robustness refers to the fact that the embedded information should be reliably decodable after modifications of the marked data.

**Watermarking Security** Security here refers to the difficulty of extracting or removing the embedded watermark without knowledge of the secret key (or keys).

**Wavelet Transform** A transform that decomposes a signal into very simple basis functions.

## DIGITAL EVIDENCE AND DIGITAL FORENSICS

One of the by-products of the growth of information technology has been the proliferation of the “computer criminal.” Forensic evidence at a crime scene that once was limited to physical items and attributes (carpet fibers, tool marks), and biological matter (hair, blood, fingerprints) now often includes *digital evidence*. In 1999, the Scientific Working Group on Digital Evidence ([www.swgde.org](http://www.swgde.org)) defined digital evidence as:

*Information of probative value stored or transmitted in binary form.*

Examples of digital evidence would include common application files (word processing, spreadsheets, etc.), graphical files, audio and video recordings and files, server logs, and application executables.

Like other forensic disciplines, digital forensics has its origins in the legal system. Digital forensics can be described as a technical solution to what is principally a legal problem. This statement is true for all of the forensic sciences. As a result, the law has had an equal, if not greater, influence on the practice of digital forensics than has computer science or engineering. The admissibility of digital forensic processes and products is the ultimate goal.

Law enforcement’s view of digital forensics is driven by the premise that anything done to an item collected as evidence is subject to presentation in court. This simple fact has tremendous impact, not only on law enforcement’s view of digital forensics but also on the development and regulation of processes. Regardless of the scientific virtue of anything discovered, the value of these discoveries is constrained by the requirements of the legal system.

## Who Should Read This Chapter?

We wrote this chapter for semitechnically literate professionals at small or medium-sized law enforcement agencies (or businesses) who are involved in the processing of digital evidence. Agencies of this size make up the majority of law enforcement agencies in the United States.

From our many discussions with personnel from these agencies, we have found that the person most often placed in charge of digital forensics examinations was selected because they were the most technically literate person in the agency. It is atypical for these personnel to have degrees in IT-related fields (e.g., computer science, management information systems, or information technology) or years of experience in computer-related fields.

Furthermore, we did not assume that these agencies have access to digital forensics experts or that they have large budgets for training or technology, which is typical for the majority of small law enforcement agencies with which we are familiar. The descriptions and demonstrations in our chapter were written at a level that a semi-technically literate person should be able to follow without too much trouble. For the more technical demonstrations, interested readers may wish to refer to the resources listed in our reference section for more information. A very good source on the use of the Linux operating system in digital evidence cases, written specifically for law enforcement, is Grundy (2004). Readers should also refer to other chapters in this volume, including Computer Forensics Procedures and Methods, Forensic Computing, Forensic Analysis of Windows Systems, and Forensics Analysis of UNIX systems.

This chapter is not a step-by-step “how-to” guide but rather a primer to create an understanding of the challenges, combined with descriptions and pointers on what

is available, in terms of technologies and methods, to assist agencies in dealing with these challenges. Our reference section contains dozens of books and pointers that further elaborate on the solutions we describe in this chapter.

## Challenges to Law Enforcement

In this chapter, we provide an introduction to several challenges that agencies face during digital evidence investigations. We selected these challenges based on discussions with local, state, and national law enforcement agencies and our own personal experience. Because of space limitations, we have not included every conceivable problem that agencies may encounter. Rather we selected a subset of problems that have demonstrated an ability to hinder computer crime investigations. In fact some of the problems may not be widespread at the moment. For instance, encryption is used in a small percentage of digital evidence cases; however, when used it can greatly impede an investigation.

We present these challenges in the following order:

- Data obfuscation
  - Encryption
  - Steganography
- Forensic tool validation
- Forensic countermeasures
- Large quantities of evidence
- Diversity of digital devices and media

For each challenge we describe potential solutions for dealing with the problem. We begin this chapter with the most technical subject first, techniques for obfuscating (hiding) digital files.

## Data Obfuscation

Criminals who use computers to conduct illegal activities often attempt to hide the fruits of their crimes and often hide the very tools used in the commission of the crime (e.g., software tools). Hiding files on a computer can take on many forms, ranging from simply changing a file's three-letter extension to more technical methods such as file encryption and steganography. Each of these technologies has the potential to impede severely the recovery of digital evidence. We discuss encryption and steganography in turn below and describe potential methods of coping with each.

## Encryption

This section provides sufficient detail on encryption so that the semitechnical reader can understand the problems that may be encountered during digital forensic examinations involving encryption. Readers interested in more detailed information on encryption are urged to review chapters in Volume II, Part 3 of the Handbook of Information Security: Encryption Basics, Symmetric-Key Encryption, Hashes and Message Digests, and Public-Key Algorithms. We include several important resources on encryption at the end of this chapter.

In simple terms, encryption takes a digital artifact (text, picture, audio, video, etc.) and transforms it so that

it is unreadable. The transformation process requires a cipher—mathematical encryption algorithm—and a key. Frequently, the key is a password. The cipher takes the file and key and performs the necessary calculations to make the file unreadable. To decrypt requires reversing the transformation process so that the file is once again readable. This requires knowing which cipher was used, and most importantly, the key that was used in the transformation process.

Encryption is used legitimately and legally by business, industry, governments, military, and individuals, to ensure privacy of information by keeping it hidden from those not authorized to read the information. Unfortunately, it can also be used by criminals to hide the fruits of their crimes.

There are two major classes of encryption algorithms: symmetric (or secret key), and *asymmetric* (or public key). Symmetric key algorithms use a single key for encryption and decryption. Asymmetric key encryption algorithms use two keys: a public key and a *private* key. The public key is freely shared and is used by senders to encrypt a message that is meant for the recipient only.

Assuming the encryption works as intended, the encrypted message can only be decrypted with the recipient's private key. Often the keys are interchangeable; that is, if the public key encrypts the message, the private key can decrypt it, and if the private key encrypts a message, the public key can decrypt it. Although keys are often interchangeable, this is not required for asymmetric encryption. The private key may also be used in digital signatures as a means of authenticating the source of a message. A "digital signature" encrypted with the sender's private key may be attached to a message. Any message recipient can prove the message is authentic by decrypting the signature using the sender's public key, assuming the sender's private key has not been compromised.

A symmetric cipher (i.e., mathematical formula or algorithm) combines the password and the message and encrypts them into "ciphertext," essentially an unreadable scrambled message. To "decipher" the message (i.e., recover the text) requires knowledge of the cipher.

With public key algorithms, a separate mathematical function is used to create the public/private key pair. The private key is protected by encrypting it with a symmetric key cipher and a password. Knowledge of the encryption algorithm and the password used to encrypt the private key is required to recover the text.

Symmetric and public key algorithms are not directly comparable because the process underlying the encryption cipher differs dramatically. The current U.S. government standard for symmetric encryption is the Advanced Encryption Standard, which has key lengths of 128, 192, or 256 bits. In contrast, public key algorithms such as the RSA public key algorithm use keys containing 1024, 2048, or 4096 bits. The longer the key length, the more secure the encrypted message is for both symmetric and asymmetric encryption. As of 2004, symmetric key lengths of 128 bits or more are considered secure, as are public key lengths of 1024 bits or more.

Public key encryption is a slow process compared with symmetric key encryption because more computation is required. Because of this, a third form of encryption is

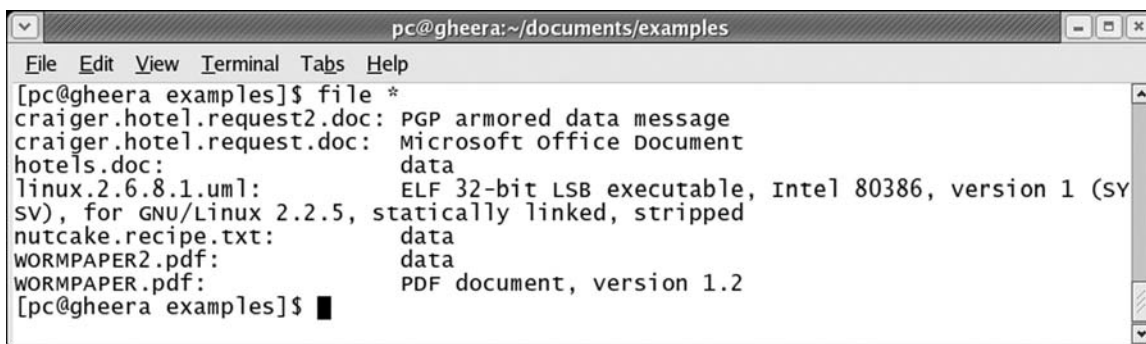

Figure 1: UNIX file command run against several files.

sometimes used. This form of encryption is a hybrid technique that combines symmetric and public key encryption. Examples include PGP (Pretty Good Privacy, <http://www.pgpi.org>) and its open source counterpart, GPG (GNU Privacy Guard, <http://www.gnupg.org>). These hybrid algorithms create randomly generated session keys that are used to encrypt messages with a symmetric cipher (DES, Triple-DES, CAST, AES, etc.). The session key is then encrypted with a public key, and the encrypted session key is sent, with the encrypted message to the recipient of the message. The recipient uses his or her private key to decrypt the encrypted session key, which may then be used to decrypt the message. Hybrid methods are attractive because they combine the best of both symmetric and public key encryption algorithms. As an additional measure of security, the recipient's private key is encrypted with a symmetric cipher and requires a password to decrypt. This extra layer of encryption of the private key provides an added layer of security.

### What Information Can Be Encrypted?

Suspects can encrypt any digital files, from an individual file to an entire hard drive. Regardless of what data is encrypted, it is necessary to know both the cipher used for encryption and the password in order to decrypt the ciphertext.

### Individual File Encryption

Before investigators can decrypt and analyze encrypted information, the encrypted files must be detected and identified for further analysis. Many digital forensic tools can determine whether a file has been encrypted by evaluating the file's header information. Header information is digital information contained within the beginning of a file that indicates the file type. Unfortunately, this method

only works if the file headers have not been modified and whether the file has a recognizable header.

There is no single, simple, 100 percent accurate way of determining whether an individual file is encrypted, or whether the file merely resembles an encrypted file. In the following example, four of the files in the directory (Figure 1) are encrypted:

- request2.doc: GPG Public-key ASCII encrypted
- football.sch GPG Public-key binary encrypted
- WORMPAPER2.pdf GPG Symmetric key encrypted file
- shoppinglist.txt PGP Symmetric key encrypted file

Additionally, the file hotels.doc is a compressed—using zip compression—file whose header information was removed. When the header information is removed from a file, applications can no longer correctly determine the file type. It also means that the file is corrupted and most likely cannot be opened by the application that created it.

We ran the UNIX file command against all of the files in this directory. The file command reads a file's header information and compares it against a known list of headers to determine the type of file. As Figure 1 demonstrates, the file command contains enough information to conclude that request2.doc is as an encrypted file of type PGP armored. For the remaining encrypted files, however, the headers do not contain enough information to determine the type of file by using the file command.

We replicated this experiment using the same files and a commercial forensics tool. As Figure 2 demonstrates, we achieved the same results (under the column "File Type").

It is impossible to determine whether a file is encrypted merely by "eyeballing" its contents. As Figures 3–5

File Name	File Type	Ext	Full Path
WORMPAPER.pdf	Acrobat Portable Document Format (P...	pdf	final\NO NAME-FAT12\WORMPAPER.pdf
request.doc	Microsoft Word 97 Document	doc	final\NO NAME-FAT12\request.doc
request2.doc	PGP Encrypted Message	doc	final\NO NAME-FAT12\request2.doc
shoppinglist.txt	Plain Text Document	txt	final\NO NAME-FAT12\shoppinglist.txt
football.sch	Unknown File Type	sch	final\NO NAME-FAT12\football.sch
WORMPAPER2.pdf	Unknown File Type	pdf	final\NO NAME-FAT12\WORMPAPER2.pdf

Figure 2: Results for commercial forensic toolkit.

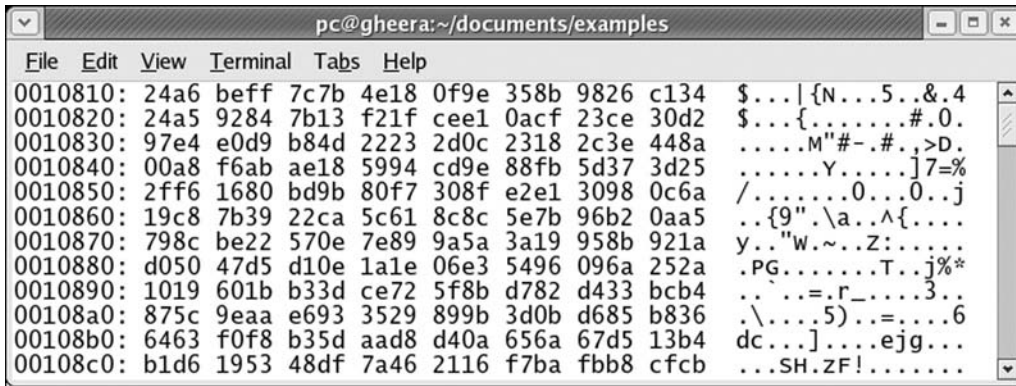

Figure 3: Symmetric cipher encrypted file.

demonstrate, the contents of an encrypted file may appear very similar to other files such as binary executables and compressed files (e.g., zipped files). To demonstrate, we created a symmetric key encrypted file (Figure 3), a compressed file (Figure 4), and a binary executable (Figure 5). Clearly, there are no visually identifiable differences that allow an investigator to determine the type of file through a mere visual examination.

File System-Level Encryption

There exist several applications that can encrypt a volume (partition) or even an entire hard drive. These applications are available for several operating systems, including Windows, Linux, and Macintosh. These applications work the same as individual file encryption, using a cipher and a key to encrypt data.

Some of these applications can leave visible clues that a suspect is running hard drive encryption. For instance, we found that several Windows-based encryption applications display their icon in the Window's taskbar. Figure 6 shows the icon displayed—floppy disk with yellow key underneath—for the BestCrypt encryption application (www.jetico.com). (There is no guarantee that a volume or disk encryption application will place its icon in the Window's taskbar. Therefore, lack of an icon does not guarantee that the file system is not encrypted. An investigator can be certain a file system or disk is encrypted if the investigator attempts to access files and is presented with dialog box requesting a password for file access.)

When the user attempts to access a file on an unmounted encrypted file system, the encryption program will ask the user for the password. If the user does not have the correct password, the encrypted file system remains unmounted and the files cannot be accessed. However, if the encrypted file system is mounted, then the files can be accessed. (Mounting a file system makes the files on the media accessible to the operating system and applications.)

Windows Encrypted File System (EFS)

The Windows 2000, XP, and 2003 Server operating systems have the capability of encrypting volumes using Microsoft's Encrypted File System (EFS). EFS is a hybrid method that uses a symmetric algorithm for data encryption and a public-key for protecting the symmetric key. Access to the public key is protected via a password. While Windows 2000 defaults to 56-bit Digital Encryption Standard (DES), XP and 2003 Server defaults to the Advanced Encryption Standard (AES) with a 256-bit key, a much more secure cipher than either 56-bit DES or 3DES.

EFS supports third-party data recovery through the concept of a Data Recovery Agent (DRA). A DRA is a designated authority—most often a security or network administrator but could be anyone—whose private key is used to protect the data in addition to the primary's public key (i.e., the original data owner's public key).

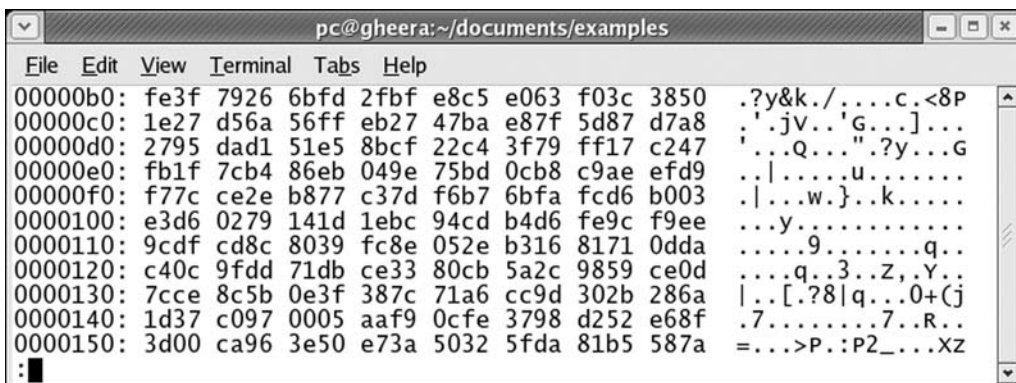

Figure 4: Compressed file with modified header.

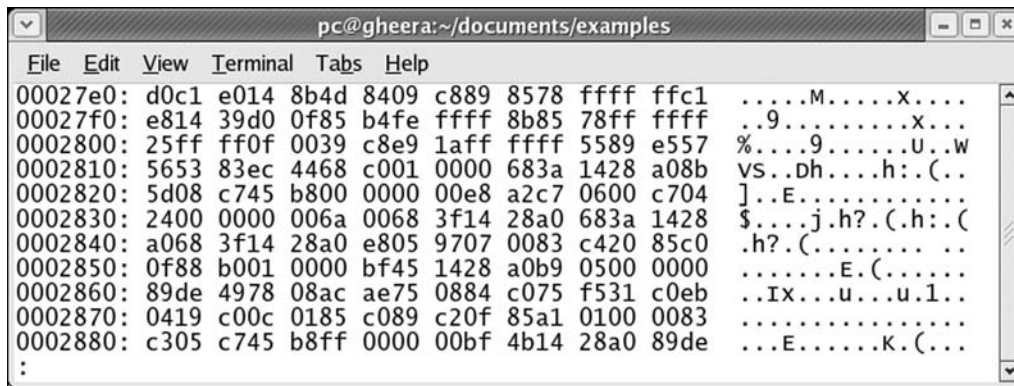

Figure 5: Binary executable without header.

Consequently, in a networked environment data recovery of an EFS encrypted partition is very possible as long as someone has been designated as a third-party DRA. If a DRA does not exist, then the only person capable of decrypting the data is the primary owner. Should this be the case, other methods are required to gain access to the public key's password. Some of these methods are described in a later section.

### How to Determine Whether Files Are Encrypted

How does one determine whether a file is encrypted? Unfortunately, this sometimes requires trial-and-error attempts to decrypt the files, using a variety of encryption applications. This is demonstrated below with GPG and PGP encryption applications.

An investigator should run a forensic application that uses header information against all files on a hard drive first to determine whether any files are obviously encrypted. As demonstrated previously, accurately determining the type of file can be hit-or-miss depending on what type of encryption is used. If an investigator has on good authority that the suspect is known to use encryption, then some trial-and-error involving attempts to decrypt the files with a variety of encryption applications may be necessary.

Below we demonstrate this with GPG and PGP encryption applications. (Some applications append their own three letter extension when encrypting files, such as .gpg or .pgp. A user can remove the extension to remove that clue.)

Figure 7 demonstrates a trial-and-error attempt to decrypt files using GPG. Figure 8 demonstrates this process using PGP. The total experimental results are presented in Table 1.

Table 1 indicates how PGP and GPG performed in determining whether or not a file was encrypted. The Ys under the "GPG" and "PGP" headings indicate that the application correctly determined whether the file

was encrypted. For this simple example, the applications were 100% accurate. GPG and PGP correctly determined that files encrypted with the other applications were encrypted, as well as determining whether the cipher used for encryption was a symmetric or public key cipher.

Real-world situations are much more complex than this example; however, this simple demonstration shows the type of experiments one might have to conduct in order to determine which files, if any, are encrypted.

### Breaking Encryption

Several techniques that can be used to recover digital evidence are described. Each of these methods relies on recovering the password used for encryption.

### Asking the Suspect and Social Engineering

The simplest and easiest method of overcoming encryption is to ask the suspect for the password(s). This technique can be very effective, particularly if it is used immediately after law enforcement serves a search warrant on the suspect. This is the time when suspects may be psychologically weak, confused, or frightened, and are therefore more psychologically amenable to answering questions. We know of numerous examples of suspects who openly shared passwords, and other relevant information, upon being served with a search warrant.

Another approach that relies on psychology is "social engineering." Social engineering is a term commonly used to describe how computer criminals gather information by tricking people (e.g., secretaries, network administrators, help-desk personnel, regular users, etc.), into divulging information necessary to break into a computer. In social engineering, the investigator attempts to use knowledge of the suspect to obtain the password, either by direct inquiry or by educated guessing based on information provided by the suspect. For example, suspects can often be induced to reveal private information about them that can be used to guess passwords. For example, often words such as pet's names, children's names, and football team names are used as passwords. The effectiveness of social engineering is highly dependent on the interpersonal skills and insight of the investigator. Examination of the suspect's home and other details about their life can also be useful in searching for information relevant to the suspect's passwords.

Figure 7: Attempting to decrypt files with GPG.

If a suspect refuses to divulge his or her passwords, three other options are available. One is to use “password cracking” software. A second method is to search the suspect’s computer, in the hope that the suspect’s password is located somewhere on the computer. Finally, investigators may attempt to recover passwords from other accounts used by the suspect, in the hope that the suspect has used the same password on more than one account. Each of these methods is described.

## Automated Tools: Password Crackers

Password cracking is a term that implies an automated method of guessing passwords. There are three commonly employed modes of password guessing: (a) heuristic or rule-based attacks, (b) dictionary attacks, and (c) brute force attacks. These are described in order of the complexity and amount of time it typically takes to perform the attack.

### Rule-Based Attacks

Rule-based attacks make use of numerous rules of thumb that users often follow when creating passwords. Rule-based attacks can be based on information retrieved through social engineering, as mentioned earlier. The reason these attacks are so effective is that human behavior is often predictable: users often create passwords that are meaningful to themselves personally because these passwords are easy to remember. Examples include birthdays, anniversaries, names of children, simple keyboard combinations ('qwerty,' 'abc123,' etc.), names of pets, and commonly used passwords such as the word "password" or the username.

Organizational password policies often mandate that users create passwords composed of upper- and lowercase letters, numbers, and special characters in order to increase the difficulty of guessing passwords. Despite these policies, some users create password combinations that follow a formula that is guessable. For instance, a username followed by a number or special character, such as 'lmcbride1,' or 'lmcbride!' are common.

A rule-based attack generates passwords using a defined set of characters. Thus, guesses for a username 'lmcbride' might include: lmcbride1, lmcbride2, lmcbride3...lmcbride\*, lmcbride/, and so on. Rule-based attacks work remarkably well because passwords that are created from a truly random set of characters are very difficult to remember. When passwords are difficult to remember, users often write their passwords down, and these passwords may be located through other procedures.

### Dictionary Attack

A *dictionary attack* uses a list of words from a dictionary as the basis for guessing passwords. If the suspect uses a word contained in the dictionary, it will be guessed fairly quickly, no matter how long the word: "Antidisestablishmentarianism" will be guessed more quickly than "cat" because it comes prior to it in a dictionary. Depending on the size of the dictionary and the speed of the computer, in many cases, a dictionary attack may run through all the words in the dictionary in less than a minute.

Dozens of dictionaries can be downloaded from the Internet, including specialized dictionaries containing names of cartoon characters, sports teams, or mythical or fictional characters from TV shows, movies, or literature. Dictionaries are also available in multiple languages. We suggest that law enforcement agencies download several

sets of dictionaries, including some of the largest dictionaries available, and use all of these dictionaries before moving to the more time-consuming brute force attack.

### Brute Force Attack

The most time-consuming type of password attack is the brute force attack. A brute force attack looks at combinational possible combinations of letters, numbers, and special characters, and uses them in guessing the password. A password eight characters in length that uses upper- and lowercase letters (52), numbers (10), and special characters (32), means there are  $94^8$  or 6,095,689,385,410,816 possible combinations. Brute force attacks on passwords more than eight characters in length are generally unfeasible. Use brute force attacks as a last resort only.

### Passwords on Disk

Accessdata's Password Recovery Toolkit (PRTK) is a commercial password cracker ([www.accessdata.com](http://www.accessdata.com)) that works for many encryption problems. PRTK has a very interesting password cracking methods that works in concert with Accessdata's Forensic Toolkit (FTK). This method is based on the fact that the user's password may appear somewhere on the suspect's hard drive. For instance, the suspect may have included the password in a document, or an ill-behaved encryption application placed the password in RAM, and was subsequently written to a swap or hibernation file. FTK will extract and index every word on a hard drive and output this list to a text file, which can be then imported into PRTK and used as a dictionary. If the password appears anywhere on the hard drive, in allocated, unallocated, or slack space, then the PTK will break the password.

### Break Other Accounts

Humans are creatures of habit, as they saying goes. Most users employ the same password for many different accounts: Why remember 10 passwords for 10 accounts when I only have to remember one! A careful user may use multiple passwords, but to reduce cognitive load, select passwords that fall into a category that is meaningful to the user, for instance, characters from Star Trek, a pet's name, and so on. It may be useful for an agency to attempt to (legally) break passwords for other accounts to which the suspect has access to determine whether the suspect uses a guessable pattern, for example, ckirk!, mspollo!, msulu! (i.e., Star Trek characters).

### Commercial and Freeware Tools

There are commercial and freeware tools that perform password cracking. There are several free password crackers that are very good and widely used, including John the Ripper ([www.openwall.com](http://www.openwall.com)) and Crack (<ftp.cerias.purdue.edu/pub/tools/unix/pwdutils/crack>). One of the best-known and efficient applications is L0phtCrack, a commercial tool from @stake ([atstake.com](http://atstake.com)). Password dictionaries may be found at several locations on the Internet and are easily located by using Google to search for “password cracking dictionary.”

### Steganography

*Steganography* is a term that means “covered writing.” Steganographic algorithms take the bits that comprise a message and embed these bits within another file. The most common example is hiding text within a graphical image, which is demonstrated below.

There are several steganographic algorithms. One of the more common uses the least significant bit of a byte from the file to be hidden; exchanging that bit with the least significant bit from a byte within the cover medium, or file the data is to be hidden in. On average, no more than 50 percent of the bits from the cover medium (also called the receptacle image) are changed in this process. Because they are the least significant bits, very little of the receptacle will display an obvious change.

For example, in order to hide the letter A, we first convert it to the ASCII character 65 in decimal, or 1000001 in binary form. We need eight bytes of data to hide the

ASCII value of “A.” If we have the following eight bytes of data, inserting the ASCII character A will yield:

```
1110101 → 1110101
1101101 → 1101100
1001100 → 1001100
0110110 → 0110110
0010111 → 0010110
0101000 → 0101000
0000001 → 0000001
```

Here we have hidden the character A, which in this case only required changing two of the least significant bits in the 8 bytes of data we selected. We can of course recover the hidden text by stripping the least significant bit from each byte and piecing them back together.

### Steganographic Demonstration

Various steganographic algorithms and programs will hide digital data within almost any other form of digital data. Evidence can be hidden in audio files, various types of graphical images, text files, and other files in Figure 9. We illustrate hiding the text from the Declaration of Independence (9629 characters, a lengthy document) within a NASA graphic image.

This is a large image, 1280 × 1024 pixels, therefore, we are hiding a large document; therefore, we need a large number of bits in which to exchange the bits to be hidden. The example below uses the freeware steganographic program Outguess to hide the text of the Declaration of Independence and save the new file as “hidden.jpg.”

Figure 9: Original Image—Buzz.jpg.

A password was also used to make it more difficult to extract the contents of the file.

```
# outguess -k 'password' -d dofi.txt buzz.jpg hidden.jpg
Reading buzz.jpg...

122: 36796(49.6%) [49.6%], bias 34630(0.94), saved: 35, total: 13.80%
135: 36922(49.8%) [49.8%], bias 34458(0.93), saved: 19, total: 13.85%
164: 36678(49.4%) [49.5%], bias 34136(0.93), saved: 49, total: 13.76%
164, 70814: Embedding data: 74152 in 266613
Bits embedded: 74184, changed: 36678(49.4%) [49.5%], bias: 34136, tot:
266499, skip: 192315
Foiling statistics: corrections: 12996, failed: 494, offset: 118.798470
+- 250.581476
Total bits changed: 70814 (change 36678 + bias 34136)
Storing bitmap into data...
Writing hidden.jpg...
```

Note that there is some loss of information because of the transposition of bits, which causes degradation in the quality of the image. However, this is typically not

discernible to the human eye. Figure 10 shows the resulting image, which contains the hidden text.

Figure 10: Stegoed Image: hidden.jpg.

To demonstrate that the files are distinct, we calculate the MD5 cryptographic hash of each file:

```
# sha1sum buzz.jpg hidden.jpg
f131e22ca580183d9767f91379074d9d1ec43029  buzz.jpg
75a6fed4bf9e929b096b6ac65e830e902c53bec4  hidden.jpg
```

Note that the two cryptographic hashes of the original and hidden file are different, indicating that the two files have distinct content.

In order to recover the hidden text from the graphic file it is necessary to know the application that was used to hide the image because different applications may use different algorithms to hide data.

If someone attempts to extract the hidden content but does not know the password, the extraction process essentially fails. Below is an example of results obtained when an incorrect password is used.

```
# outguess -k 'mypassword' -r hidden.jpg declaration.txt
Reading hidden.jpg...
Extracting usable bits: 266613 bits
Steg retrieve: seed: 51622, len: 63321
Extracted datalen is too long: 63321 > 33327
```

### File Recovery

We recover the steganographic content by supplying the correct password.

```
# outguess -k 'password' -r hidden.jpg declaration.txt
Reading hidden.jpg...
Extracting usable bits: 266613 bits
Steg retrieve: seed: 164, len: 9269
```

We successfully recovered our text. The length of the text is 9269 bytes (characters), which is the same number of bytes that was contained within the original document. We can determine whether anything has changed in the recovered file by calculating a cryptographic hash of the file and comparing it to the hash of the original file.

```
# sha1sum declaration.txt dofi.txt
ca2c56c043d7da0fea8ae31891bcff0d289034ca  declaration.txt
ca2c56c043d7da0fea8ae31891bcff0d289034ca  dofi.txt
```

As is obvious from the hashes, the recovered file is identical to the original file.

### Coping with Steganography

A major problem for law enforcement with respect to steganography is that the information is “hidden in plain sight.” A document can be embedded in an MP3 file or a graphical image, and if the MP3 is played or the graphical image is viewed by an investigator, it will not be obvious that information is hidden within the medium. A Web page may contain dozens or hundreds of graphic images, any of which may or may not contain an embedded message. It is impossible to determine through visual examination whether a graphic file contains vital evidence embedded as hidden data.

---

The best clue that a suspect has used steganography is often provided by a search for steganography tools on a suspect’s computer. If steganographic tools or applications are located, the next task is to determine which files contain embedded information. The first and best option is to ask the suspect at the outset which files contain hidden information. If the suspect refuses to divulge that information, there are two options. First is to use automated tools that can detect, albeit imperfectly, hidden information. Second is to conduct trial-and-error experimentation as described in the prior section on encryption.

---

---

Several automated tools are available to evaluate the frequency of bits within a file to determine whether the file has embedded steganographic information. Stegdetect ([www.outguess.com](http://www.outguess.com)) is a freeware application that calculates statistics on a graphic as a means of determining whether an image contains hidden information.

---

The listing below demonstrates the use of Stegdetect to determine if steganographic content is present in several files:

```
# Stegdetect *.jpg
testimg.jpg : jphide(***)
testimgp.jpg : jphide(***)
testorig.jpg : jphide(***)
testprog.jpg : jphide(***)
travel.jpg : negative
```

In the listing above, we used Stegdetect to determine that four of the five files contain steganographic contents, and it includes the name of the application that was most likely used to hide the content. In this example, JPhide,

a popular Windows-based steganography program, was identified. Stegdetect correctly identified the files that contain steganographic content, as well correctly determining that travel.jpg did not contain any embedded information.

Various other tools are available that use similar calculations to determine whether a file has hidden information. We have found that these tools are not foolproof; they can miss files with embedded information.

### Manual Methods of Determining Steganographic Content

A suspect may leave clues as to files with steganographic content. For instance, in the presence of steganography programs, one should conduct a visual search for all graphical files. Two graphical files that appear to be the same visually but have different cryptographic hashes may be evidence of embedded information. The graphic file with the latest creation or modified date and time is more likely to the file with embedded content.

Steganography programs often use a password to increase the difficulty of extracting the hidden content. As discussed in the section on encryption, there are several avenues one can pursue for recovering passwords. The first and easiest is simply to ask the suspect for any passwords he or she uses. It may come as a surprise how often suspects freely provides passwords when asked.

## DIGITAL FORENSIC TOOL VALIDATION

Digital forensic techniques and tools, as with all other forensic disciplines, must meet basic evidentiary and scientific standards to be allowed as evidence in legal proceedings. The requirements for the admissibility of scientific evidence and expert opinion were outlined in the precedent setting U.S. Supreme Court decision in the case of *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, 509 U.S. 579 (1993). In order to be admissible, evidence or opinion derived from scientific or technical activities must come from methods that are proven to be “scientifically valid.” Scientifically valid techniques are capable of being proven correct through empirical testing. In practice, this means that the tools and techniques used in digital forensics must be validated and that crime laboratories, including digital forensic labs, should be accredited or otherwise proven to meet such scientific standards. Obviously strict and accurate validation testing of new forensic tools is required if the results from such applications are to be acceptable as evidence in criminal cases.

In the United States, the American Society for Crime Lab Directors/Lab Accreditation Board (ASCLD/LAB: [www.ascl-d-lab.org](http://www.ascl-d-lab.org)) is the official body that accredits crime labs. The board has developed numerous standards relating to establishing the validity and acceptability of forensic techniques, tools, and accreditation of individual crime labs. ASCLD/LABs criteria for accreditation consist of standards covering crime lab management and operations, personnel, and physical plant. Each standard is labeled as desirable, important, or essential, depending on its importance and requirement for meeting ASCLD/LAB specifications. Labs seeking accreditation must meet 100% of the essential criteria, 75% of the important criteria, and 50% of desirable criteria.

With respect to forensic tools and techniques, ASCLD/LAB standard 1.4.2.6 addresses the required scientific validation of procedures used in crime labs:

1.4.2.6 ARE NEW TECHNICAL PROCEDURES SCIENTIFICALLY VALIDATED BEFORE BEING USED IN CASEWORK AND IS THE VALIDATION DOCUMENTATION AVAILABLE FOR REVIEW?

Standard 1.4.2.6 is an essential standard, indicating the importance of scientific validation of tools and techniques. In the context of digital forensics labs, this standard requires that software (and hardware) must be validated prior to its use in examinations.

In the context of digital evidence, the Scientific Working Group for Digital Evidence (SWGDE) defines the term validation as “An evaluation to determine if a tool, technique or procedure functions correctly and as intended” (SWGDE, p. 2). Software validation has long been an important component of software design and development. However, it plays a crucial role in digital forensics because the potential consequence of denying a defendant’s constitutional rights to life and liberty:

Validation testing is critical to the outcome of the entire examination process. Validation, based on sound scientific principles, is required to demonstrate that examination tools (hardware and software), techniques and procedures are suitable for their intended purpose. Tools, techniques and procedures should be validated prior to initial use in digital forensic processes. Failure to implement a validation program can have detrimental effects. (SWGDE, p. 2)

### Validation Testing Challenges

The National Institute for Standards and Technology’s (NIST) Computer Forensics Tool Testing (CFTT: [www.cftt.nist.gov](http://www.cftt.nist.gov)) division is one government entity that formally tests computer forensics software. CFTT performs extremely rigorous scientific tests to validate software tools used in digital forensic examinations. CFTT has and continues to perform testing on numerous computer forensic software applications and has identified various problems that have been addressed by the software vendors. Unfortunately, the ability of one organization to examine all forensic software products and their variations is limited because of the sheer magnitude of the task. For example, software should be revalidated when either a major new release occurs or when a patch or update is released to add features or correct previously existing problems. Such retesting is called regression testing. In addition, revalidation should occur when significant changes are made to the operating system on which the software will run. Updates to operating systems have the potential to change the operation of software that was previously found to work correctly on an earlier version of the operating system. Most people have experiences from attempting to run software under an operating system change that was guaranteed to be “backward compatible” that will make this requirement self-evident.

As mentioned previously, the forensic community cannot rely on a single certifying body to test and evaluate all

forensic software, as the sheer pace of change and number of software products is overwhelming. In addition, software tools written by forensic examiners that are not commercial products, often provide additional functionality examiners find useful. Such software, unless it is widely distributed and used, will not rise to the attention of major validation organizations. Consequently, the onus of validation testing is placed on individual examiners who often have no training in software validation testing. Validation is thus often an ad hoc measure that suffices for the moment. Care must be taken in such testing to insure that sufficient scientific rigor is applied to prevent the invalidation of the tool and the evidence it produces.

## Validation Testing Approaches

There are various ways to validate a forensic software tool, some of which are more rigorous than others. The most rigorous involves both testing and a detailed examination of the source code, called a code walkthrough. As its name implies, code walkthroughs require that the actual source code is available and also requires programmers, software engineers, and managers with technical expertise. In addition to knowledge of software coding techniques and languages, expertise must also include detailed understanding of the task being performed, in this case forensic examination of computer files and hardware (e.g., hard drives). Code walkthroughs may take months or even years to conduct on large software applications. Obviously, such testing will not be possible for all applications of interest.

From the standpoint of a forensic investigator, there is a more practical and informal approach, black-box testing. This is where much validation of digital forensic software occurs due to both the complexity and time required for code reviews and due to the fact that commercial companies are usually unwilling to share source code (which is rightly considered valuable proprietary intellectual property). Black-box testing is an attractive alternative because it does not require programming and software engineering expertise or source code, while allowing the testing of software in a less expensive and quicker fashion. It does, however, require that the testing be designed by personnel with domain knowledge of digital forensics and computer hardware/software standards (i.e., understanding of the processes to be tested). In black-box testing, the software is treated without regard for its internals (code), only the ability of the tool to function correctly and as intended is evaluated. The software code is treated as a “black box” the internal functioning of which is unknown.

Black-box testing of forensic tools can be accomplished in several ways. One way is to exercise a tool's capability against a known standard. For instance, say that we wish to test the keyword search capability of hypothetical Tool A. To do this, we need a known sample (e.g., a hard drive) that contains known and defined instances of the text for which we will search. Tool A's search function is tested by searching our known sample for instances of the keyword. In this example, we search for the term “coke\_buddy” on the hard drive as in previous examples. For completeness and fidelity to the real world, our known instances must include the keyword in common formats such as 16-bit UNICODE and 7-bit ASCII, as both formats are used by

the operating system to store data on the hard drive. We then use Tool A to perform a search for the keyword and record the results.

Another accepted method of black-box testing is to compare the validation results between more than one tool that performs the same function (i.e., Tools A, B, and C). This method is useful when we do not have a known sample to test, that is, we do not have a validated reference data source. This approach can provide particularly strong evidence of validation if one or more of the tools (A, B, or C) have been validated previously.

This approach allows us to perform validation testing in the absence of a known sample, unlike the testing procedure above that requires the contents of the test data to be known *a priori*. If we run the search and all three tools return the same results, then we have supporting evidence that the software functions as intended. This result is strongest when Tools B and C have both been validated, and Tool A returned the same results. The claim is weaker if the only one of the other tools has been validated. If none of the other tools have been validated, the confidence is the weakest, although the fact three tools created by three separate programming teams returned the same results can be interpreted as triangulating on the results. Care must be taken, however, to exercise the tools over their full range of user selectable parameters and against a number of different data sets or test samples. While one or two tests may show excellent results, there can always be situations where the tool will fail that are unusual enough to have not been tested or addressed by the designers. Some peculiar combination of set-up parameters, operating criteria, or type of files being searched may reveal a hidden error that, while rarely occurring, is sufficient to invalidate the tool.

## Test Samples

Selecting or creating test samples is one of the most challenging aspects of validation testing. The test sample should consist of a number of heterogeneous examples that replicate conditions that will be found in the real world. In addition to common types of data, the test samples must include boundary cases. These boundary cases are conditions or examples of things the tool must be capable of detecting even if they are very uncommonly found in most situations. If the tool correctly reports the results from real-world examples as well as boundary cases, then we can say with some authority that the software functions as expected.

A test sample for validation testing would ideally be a sample prepared by the tester containing a complete set of variables and data to thoroughly exercise the application under test. The advantage of running the tool against a known sample is that the results are known *a priori* given that the examiner knows what exists on the source media. The disadvantage is that time and effort to create the known sample, which can be extensive, and the potential lack of knowledge about the range of variables that can exist. When preparing a hard disk for testing a tool for text searching, for example, both common formats (16-bit UNICODE and 7-bit ASCII) must be included. If the preparer of the test sample does not know about or forgets to include 16-bit UNICODE examples in the sample, the sample will not exercise the tool sufficiently to

evaluate its performance. In the creation of test samples for computer forensic applications, this requires that the sample be developed by experts with extensive knowledge of both computer hardware and operating system standards. Such expertise is required to ensure that the test sample does not overlook important conditions or data which would hamper the validation tests thoroughness.

As mentioned previously, it is not always possible to generate a complete and thorough test sample, and in such a case a variety of real-world data sets may be used. A sufficient number of diverse data sets must be used to adequately test the application. Selection should be made from a number of possible operating systems and including a variety of different data types produced by a number of different applications. Careful selection of such data sets can produce a test sample sufficiently varied to give confidence in the validation testing performed. One option is to use test samples consisting of data from previous forensic examinations where the results of the examination are already known. This is preferable to an unknown test sample, and is much less time consuming and difficult than deliberately generating a new test sample. Test samples derived from previous, extensive forensic examinations have the advantage of being known samples; that is, the examiner has a good idea of what exists on the disk, higher confidence coming from the most thorough of previous investigations. Regardless of how the test sample is selected, care must be taken to ensure the samples exercise the boundary conditions.

## Analysis of Results

In the Daubert decision, the court found that in evaluating a scientific technique, known or potential rates of error, and error type should be considered. Two error types are of particular interest, Type I and Type II errors. Type I errors occur when a tool or process falsely identifies a positive result when none is present (i.e., a false positive). Type II errors occur when a tool or process does not identify results that are actually there (i.e., a false negative). Identification of what type of error is present is of particular importance due to the legal implications of using such results in a court proceeding. Therefore, if the forensic tool does not function as intended and returns erroneous results, it is important to identify the type of error that occurred.

Returning to our example involving the search for the keyword “coke\_buddy,” we know that our sample hard drive contains instances of our keyword as we prepared the test drive. Tool A’s performance is evaluated by comparing the tools search results with our expected results. The tool should find all known instances of the keyword, if Tool A’s search function works as expected. Table 2 shows the result of a test where Tool A found all instances of the keyword.

**Table 2** Search Results for Tool A

Format	Location (byte offset)	Found
UNICODE	14432	Y
ASCII	212178	Y
ASCII	242966	Y
UNICODE	7663911	Y

In this example, Tool A has passed the test by detecting all instances of the keyword and not returning any errors. If, for example, the test results had turned out as in Table 3.

**Table 3** Search Results for Tool B

Format	Location (byte offset)	Found
UNICODE	14432	N
ASCII	212178	Y
ASCII	242966	Y
UNICODE	7663911	N

In this instance, Tool A did not find the keyword when present in UNICODE format. This is a Type II error, the return of a false negative. If, for example, the test sample hard drive only contained the keyword in ASCII format, and we recorded the following results in Table 4 below:

**Table 4** Search Results for Tool C

Format	Location (byte offset)	Found
UNICODE	N/A	Y
ASCII	212178	Y
ASCII	242966	Y
UNICODE	N/A	Y

In this example, Tool A falsely identified the keyword as being present in a case where it was not and is an example of a Type I error, a false positive.

Of course there are other combinations of results that can occur, such as if the tool misidentifies the contents of the drive, identifying a UNICODE instance as an ASCII instance. The larger the number of different types of data to be identified, the more convoluted the results can become. The larger the number of test samples, or the larger the number of relevant data in the test sample, the higher the confidence in the results of the test.

In an actual tool validation, we would have included several more stringent tests, including keywords that overlapped contiguous sectors and keywords that overlapped noncontiguous (fragmented) sectors. These two circumstances are typically considered two of the most strenuous tests for a search tool.

In the case of a test failure, it is important to determine, if possible, why the tool did not function as intended. In the example where the tool failed to identify the UNICODE keyword, it could be that the keyword crossed noncontiguous cluster boundaries, that is, part of the keyword was situated in one cluster, and the remaining part was in another cluster that was not contiguous with the first (which occurs due to file fragmentation). In this instance one would continue testing to determine whether any other situations caused a failure to report the correct results. A single failure does not necessarily discredit the use of the software in its entirety. The failure needs to be interpreted in light of the remaining test results. Regardless of the outcome, validation testing requires extensive and thorough documentation, identifying all test conditions, variables used, hardware and associated software used in

the test, and all test results. In the case of test failures, the results and conditions that resulted in the error should be especially well documented, and the examiner may wish to consider contacting the company or individual that created the software and inform them of the anomaly.

A tool doesn't have to meet 100% success to be validated. There are cases where it may be impossible, for various reasons, to achieve perfect results. For instance, the ability of a password cracker to break encryption is determined by many factors, one of which is time (every password is crackable, given enough time). Therefore, in some cases, a more realistic goal of less than 100% results may be used.

## Summary

As can be seen, while there are numerous methods by which validation testing may be performed, all of them require careful thought, preparation, and documentation to test the application as completely as possible. Documentation is one of the most important activities in validation testing, as it allows others to both understand and to repeat the examiners experiments. Replication of experimental results by other examiners is one of the foremost requirements for acceptance of scientific testing.

## FORENSIC COUNTERMEASURES

Our population as a whole is becoming more computer literate, and so are criminals. Criminals who use computers to conduct illegal endeavors are learning techniques that allow them to cover traces of these criminal acts. The term "forensic countermeasures" and "anti-forensics" have been used to describe the techniques performed on digital media in order to reduce the likelihood that digital evidence will be recovered. Forensic countermeasures include a collection of disparate techniques, such as encryption and steganography (covered previously), file compression, media formatting, file wiping, and even wholesale destruction of media. Criminals may combine these techniques for added effect, for instance, encrypting a document and then wiping the original file from the media. In this section, we will concentrate on the topic of file wiping as forensic countermeasure primarily because several commercially available applications advertise the ability to remove all traces of evidence from magnetic media.

Although forensic countermeasures can be used in criminal endeavors, there are legitimate and legal uses of these techniques. For example, disposing of old computer hardware and media can be problematic because residual sensitive information can remain on media. We are not making a value judgment regarding the uses of these techniques but rather are merely describing what we know to be true with regard to computer criminal behavior.

## File Wiping

A number of commercially available tools promise to remove all traces of "evidence" on a computer. These tools, and their freeware cousins, write a series of characters, 1's, 0's, or random characters over a file several times. This overwriting technique eliminates law enforcement's opportunity to recover the file's contents because the contents have been overwritten, destroying all previously written data. This file-overwriting technique is commonly

referred to as "wiping" a file. Although these wiped files may be recovered using special techniques such as magnetic force microscopy, the tools required are expensive enough that only the best-funded agencies have access to such equipment.

The following Linux command line will write a series of zeros over every sector on a floppy disk:

```
# dd if=/dev/zero of=/dev/fd0
```

This command will wipe not only the file contents but also the file system areas (master boot record, FAT, and root directory entry), as well as the unaddressable space at the end of the disk (i.e., disk space that cannot be used by the file system).

Several companies advertise their products' ability to purge unwanted files (evidence) from magnetic media (floppy disks, hard drive, etc.) We have tested several of these applications in our lab, and none appear to work perfectly without some investigation, and trial-and-error experimentation. Some of these tools are simple command line tools that do a respectable job of overwriting files but fail to wipe the directory entries that contain information such as file names, attributes, date and times, and file size.

Many GUI-based tools are extensively configurable. When we ran these tools with the default settings, we were able to recover some information that we surmised would have been wiped. This may be a serious problem for those using GUI-based tools: users must understand something about where "trace" evidence is located on a computer and understand how to correctly configure the tool in order to completely remove trace evidence. Learning how to configure software correctly usually entails reading a manual that is written from a technical point of view that may be difficult to understand for the average user. It also entails technical computer knowledge about where such information is likely located on the disk. Most criminal suspects are like other computer users in that they are averse to reading technical manuals, relatively uneducated about the intricate technical details of computers, and quite happy to work with a tool's default settings.

A second reason that wiping a file may not remove all traces of the file is that the operating system or many applications may save a file to several different locations on media. From the user's viewpoint, a single copy of the file seems to exist on the computer; however, there may be several complete copies of the file and several dozen parts of the file scattered throughout the hard drive. Users are unaware of the existence of these "extra" copies. In order to remove all remnants of a file users must know where these remnants may remain on a computer, as well as how to configure a tool correctly to wipe these areas. Below we describe several places from which evidence may be recovered. These include: (a) RAM, (b) swap file, (c) hibernation file, and (d) unallocated space.

## Trace Evidence in RAM

When a user opens the file in an application, the contents of a file are transferred into RAM. The file's contents may remain in RAM until the file has been closed and memory used by the file is required by the operating system. This is an important reason not to simply pull the plug on a suspect's computer, as doing so may destroy critical evidence.

To demonstrate how evidence may remain in RAM even after a file has been wiped from a hard drive, we performed a simple experiment. First, we opened an old version of this chapter in a word processor, then closed the file, and used a wiping tool to remove the copy of the chapter from the hard drive. Next, we used the utility *dd* to write the contents of RAM to a hard drive (see listing below). “*dd*” is a general-purpose UNIX utility that can copy files and is useful for creating forensic images. (We used a copy of *dd* that was modified to be able to access RAM and compiled to run under Windows operating system.)

```
C:\>dd if=\\.\PhysicalMemory bs=4k conv=noerror of=e:\RAM.img
Forensic Acquisition Utilities, 1, 0, 0, 1035
dd, 3, 16, 2, 1035
Copyright (C) 2002-2004 George M. Garner Jr.
```

```
Command Line: dd if=\\.\PhysicalMemory bs=4k conv=noerror of=e:\RAM.img
Based on original version developed by Paul Rubin, David MacKenzie, and Stuart Kemp
Microsoft Windows: Version 5.1 (Build 2600.Professional Service Pack 2)
```

```
19/01/2005 16:53:52 (UTC)
19/01/2005 11:53:52 (local time)
```

```
Current User: TIGER\pc
Total physical memory reported: 1047472 KB
Copying physical memory...
Physical memory in the range 0x00002000-0x00002000 could not be read.
Physical memory in the range 0x00124000-0x00163000 could not be read.
C:\WINDOWS\system32\dd.exe:
    Stopped reading physical memory:
```

```
The parameter is incorrect.
The parameter is incorrect.
```

```
Output e:\ram.img (1073082368 bytes)
261983+0 records in
261983+0 records out
```

The “*if=\\.\PhysicalMemory*” specifies *dd* to read from RAM, with a block size of 4096 bytes (*bs=4096*), and to write 0’s to the file if part of RAM cannot be read (*conv=noerror*). We are writing the contents of RAM to a file called *RAM.img* on a shared drive on a different computer so as not to taint our suspect’s computer.

After creating an image of RAM (*RAM.img*), we can perform a keyword search on the contents to determine whether any of portions of our chapter remained in RAM even after we closed our file. We first extracted the human readable text from *RAM.img*, and then performed our search for the keyword “*coke.buddy*,” which appears several times in this chapter. The listing below demonstrates that we found a large part of our chapter in RAM, even after wiping the file from the hard drive. Our keyword is in bold.

A forensics examiner can access the contents of unallocated space by either:

- making a forensic image of the media and performing a physical analysis on the image,
- or booting the suspect’s computer with a bootable forensic disk and performing a physical analysis at the device level. The latter is typically performed with a Linux bootable disk. Figure 13 shows

a search of the physical hard drive for the term ***coke.buddy***. Because we are accessing the physical hard drive, we are searching both allocated and unallocated space. This means that our search will normally find instances of the keywords in deleted files as well as in active files; however, because we previously wiped our copy of the chapter from our hard drive, our keyword search should only return results from unallocated space.

Because RAM is volatile, it is important to create an image of the contents of RAM post haste if it is suspected that evidence resides therein. The likelihood of the operating system overwriting a file in RAM increases as time passes. First responders should process the most volatile evidence first, including RAM, followed by less volatile evidence such as floppy disks, CD and DVDs.

Creating a forensic image of RAM involves working with a live system. The very fact that investigators work with a live system means that he or she is changing the suspect media, which is contradictory to good computer forensics practice. However, in some circumstances (e.g., evidence in RAM), the investigator must work outside the scope of these general rules in order to pursue the evidence. Forensic procedures for working with live systems are not as “hard and fast” as those for working on media that has been powered down and may depend heavily on the individual circumstances of the investigation/case.

## Trace Evidence in the Swap and Hibernation Files

When a computer’s RAM is full and the operating system must allocate memory for an application, the operating

system makes room in RAM by writing out part of its contents to a temporary scratchpad called a “swap file.” A swap file is simply dedicated space on a hard drive whose contents are temporary and overwritten as needed. Under Windows operating systems, swap files are usually located in the root directory. These files are named pagefile.sys in the most current versions of Windows operating systems (Windows NT, 2000, XP, and 2003) and win386.swp in older versions of Windows (3/3.1, 95, 98, and ME). Under Linux and UNIX systems, a single partition is devoted to the swap file and is usually labeled /swap. The swap file is essentially a scratchpad to hold data temporarily, and its contents are overwritten frequently.

Hibernation files are usually found on laptop computers, as opposed to on workstations or servers. The hibernation file holds the contents of RAM when the laptop is placed in hibernation mode. When a laptop is put into hibernation mode, the operating system writes out the contents of RAM to the hard drive and then puts the computer into a suspended state. When the laptop is “awakened,” the previous contents of RAM are transferred back into RAM from the hibernation file, thus restoring the state of the computer.

Below we illustrate the procedure for searching for a file with the keyword “coke\_buddy” in the hibernation file. The swap and hibernation files are locked while the operating system is running and therefore cannot be easily accessed under a live system. The safest way to access these files is by powering off the computer and rebooting using a forensic-capable boot disk such as Knoppix (<http://www.knoppix.com>) or FIRE (Forensic Incident Response Environment, (<http://www.sourceforge.net/projects/biatchux>)).

```
# strings /mnt/hdal/hiberfil.sys
| grep -ian -C 5 `coke_buddy`
```

Hibernation files contain both binary and human-readable text. We run the *hiberfil.sys* file through the UNIX *strings* command to recover the human readable text, and pipe the results to the UNIX *grep* command, a powerful search utility. The flags “-ian” indicate that we want a case insensitive search (-i), to treat the input as text (-a), and display line number associated with the results (-n). The flag “-C 5” indicates that we want five lines of ‘context’ both before and after each hit. The listing below shows that our keyword was found in the hibernation file.

```
# strings /mnt/hdal/hiberfil.sys
| grep -ian -C 3 `coke_buddy`
1048197-x
1048198-knowX
1048199-ard dri
1048200 : coke_buddy
1048201- UNICodeE fo
1048202-rmat; howeverJ
1048203-to deter
```

An examiner can search swap and hibernation files for a particular type of file, such as a graphics file, by searching for the headers and footers associated with the particular type of file. For example, a JPEG graphic file begins with the hex expression “D8 FF D8” in the header and ends

with “FF D9.” An examiner could recover a JPEG file by extracting the content between the header and footer. (See Craiger [2005] in this volume to see how to accomplish this with the UNIX *dd* command.)

## Trace Evidence in Unallocated Space

Hard-drive space can be partitioned into two primary types of space: allocated and unallocated space. Allocated space holds active files, that is, files that can be accessed by the file system and operating system. These files contain a pointer in the file system’s “table of contents” (for example, a FAT root directory, an NTFS master file table, or UNIX EXT2 superblock). When a user deletes a file, the operating system marks the file’s entry in the table of contents as reusable. Thereafter, the contents of the deleted file are in unallocated space (i.e., space not reserved for a file). Although the information is still on the disk, the contents of unallocated space are not directly accessible by the normal computer user.

Removal software writes a series of characters over a file, making it difficult to recover its contents; however, many software applications will leave trace evidence; that is, they may leave all or part of the contents of the file that are separate from the location of the original file with which a user (suspect) worked. For example, when a suspect modifies a file, many applications write copies of the file to the hard drive. These copies, called temporary files, are intended to help applications recover the file’s contents when there is an abnormal termination of the application or operating system.

Within Microsoft Word, each time a document is saved through the key combination [CTRL-S], the application writes a temporary file to the hard drive. Figure 11 shows temporary files that were written to the hard drive while we were modifying this chapter. The fact that an application writes a temporary copy of the file to the hard drive is not obvious to the average computer user. For many applications, temporary files are written to the /TEMP or /TMP directory under Windows, although the location where the temporary files are written is customizable by a technically knowledgeable computer user.

When the user closes a file, the application silently removes the temporary files from the hard drive. The temporary files’ contents, however, will remain in unallocated space until overwritten.

A forensics examiner can access the contents of unallocated space by either (a) making a forensic image of the media and performing a physical analysis on the image or (b) booting the suspect’s computer with a bootable forensic disk and performing a physical analysis at the device level. The latter is typically performed with a Linux bootable disk.

Figure 12 shows a search of the physical hard drive for the term ‘coke\_buddy.’ Because we are accessing the physical hard drive, we are searching both allocated and unallocated space. This means that our search will normally find instances of the keywords in deleted files as well as in active files; however, because we previously “wiped” our copy of the chapter from our hard drive, our keyword search should only return results from unallocated space.

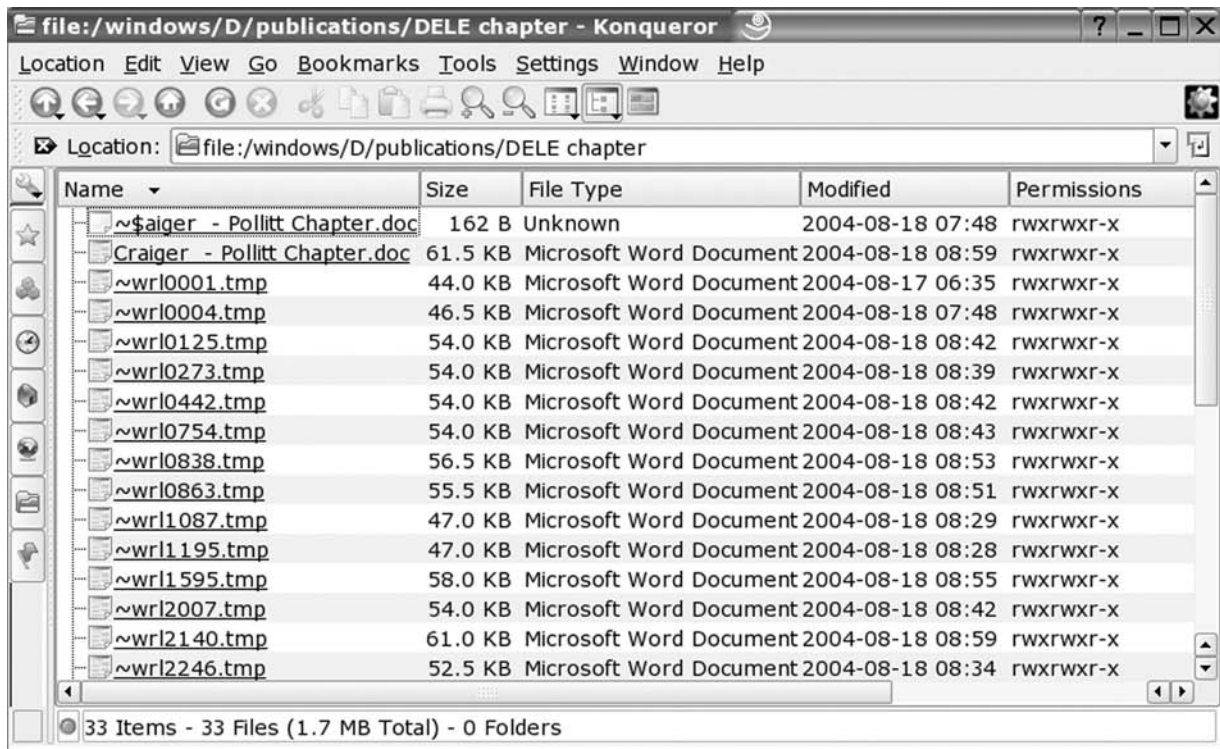

Figure 11: Temporary files.

We must access the entire physical partition to search for keywords in unallocated space. If we mount the partition, we will only be able to access files in allocated space. We access the entire physical partition through Linux' device file `/dev/hda1`. (See Craiger, 2005, this volume for more information on Linux file systems.). `/dev/hda1` corresponds to the first partition of the first IDE hard drive, which contains our Windows operating system. We use the `dd` command to read the file, piping it through the `strings` command to extract human-readable strings. We use `grep` to search through the all the strings on our physical partition.

Figure 12 shows the first three instances of our keyword. From this we can conclude that at least one document contained this keyword.

Thus far, we have only searched for the keyword in 7-bit ASCII format, the default for the `grep` utility. Any instance of our keyword in any other format, such as 16-bit UNICODE, will not be found. We must conduct another search and specify that `grep` search for UNICODE (16-bit little endian) instances of our keyword, which we specify with the flags `-el`. The results appear in the listing below: On our 37 GB hard drive, there were 50 occurrences of the term 'coke\_buddy' in UNICODE format.

Where did all of these occurrences of our keyword come from? The simple answer is from the temporary files. Again, the contents of these files will remain on the media until overwritten, or until the user runs a file wiping software to wipe the contents of unallocated space.

## Summary

This section demonstrates that forensic countermeasures such as file wiping may or may not have the intended effect of removing all traces of a file. The less technically sophisticated the user, the less likely it is that they fully understand the file system and operating system characteristics necessary to configure file-wiping software to perform correctly. On the other hand, technically sophisticated users often have the knowledge to remove all traces of a file; thus, it is helpful to obtain background information on the user's technical sophistication before performing a forensic examination.

Many evidence-elimination tools provide the capability to wipe swap files, hibernation files, and unallocated space. In this instance, the techniques described will not be effective. Nevertheless, the forensic examiner should thoroughly analyze all of the files described when working with evidence on which evidence removal software may have been used.

```
# dd if=/dev/hda1 | strings -e l | grep -ic `coke_buddy`
71683856+0 records in
50
71683856+0 records in
36702134272 bytes transferred in 1163.48693 seconds (3154494 bytes/sec)
```

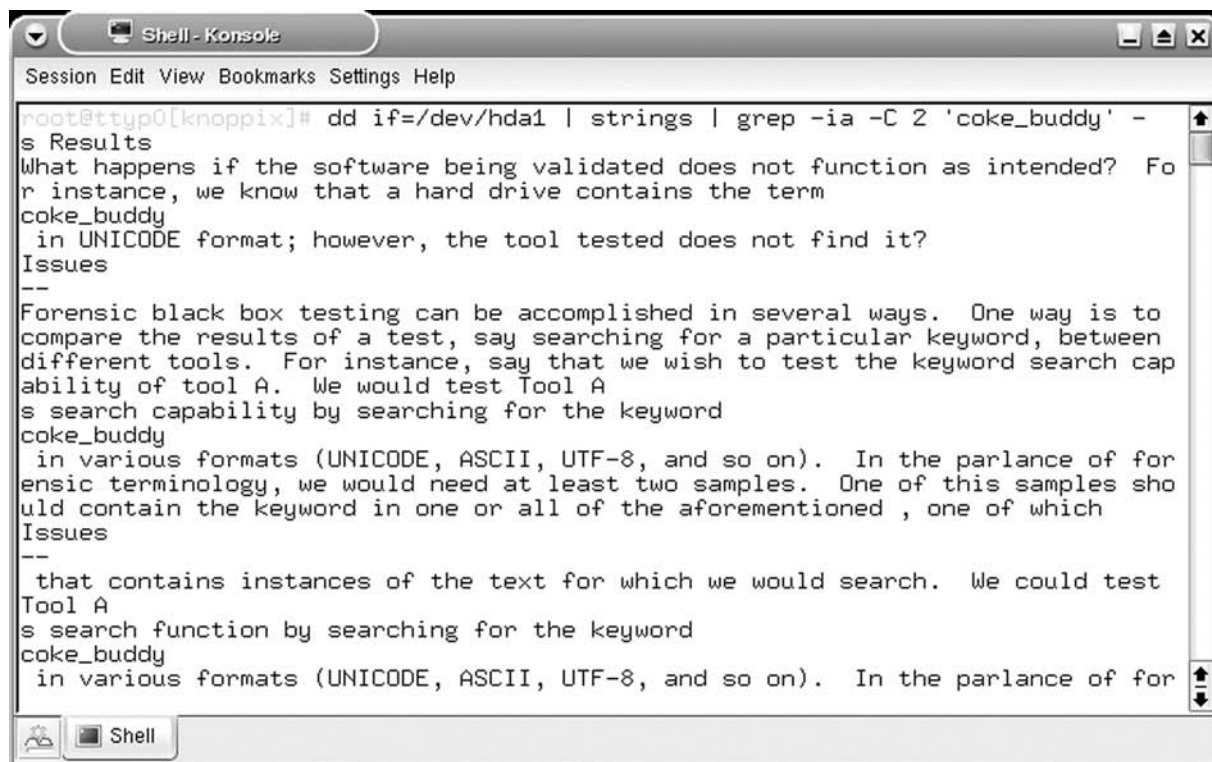

Figure 12: Keyword search results on physical partition.

## DIGITAL EVIDENCE: GROWING IN VOLUME AND DIVERSITY

The amount of evidence that exists in digital form is growing rapidly. This growth is demonstrated in Table 5, which was presented by the Federal Bureau of Investigation at the 14th INTERPOL Forensic Science Symposium:

Table 5 Digital Evidence Growth

FBI CART Examinations	
Caseload:	
	FY '99 - 2084 cases
	FY '00 - 3591 cases
	FY '01 - 5166 cases
	FY '02 - 5924 cases
	FY '03 - 6546 cases
Data Burden:	
	FY '99 - 17 terabytes
	FY '00 - 39 terabytes
	FY '01 - 119 terabytes
	FY '02 - 358 terabytes
	FY '03 - 782 terabytes

Source: FBI Computer Analysis & Response Team (CART)

The Computer Analysis Response Team (CART) is the FBI's computer forensic unit and is primarily responsible for conducting forensic examinations of all types of digital

hardware and media. The data above represents two metrics of the unit's activity. A "case," as used in this chart, represents a submission of evidence to the unit. A case may be a single floppy disk or several hundred computers and a multi-terabyte database. The data burden represents the total capacity of digital media examined by CART. Because the FBI is somewhat unique as a law enforcement agency, its broad jurisdiction makes it useful as an indicator of investigative activity.

While the number of cases increased threefold in the past three years, the volume of data increased by 46 times during the same period! This is a staggering number, given that it is many times the volume of data in the Library of Congress, the largest library on Earth (Jesdanan, 2004). Given the declining prices of digital storage media and the corresponding increases in sales of storage devices, the volume of digital information that investigators must deal with is likely to continue its meteoric increase.

CNET News published a report on March 5, 2004, which described the over \$12 billion business growing at a rate of more than 5%, while the cost per megabyte of storage fell by 30%. ([http://news.com.com/2100-1015\\_3-5170267.html?tag=fd\\_nbs.ent](http://news.com.com/2100-1015_3-5170267.html?tag=fd_nbs.ent)). This tremendous increase in data presents a number of problems for law enforcement.

Traditionally, law enforcement has seized all storage media, duplicated it, and then conducted their examination of the data on the duplicated copy. One of the first steps in the examination process is to recover latent data such as deleted files, hidden data and fragments from unallocated file space. This process is called *data recovery*

and requires processing every byte of any given piece of media. Compounding these problems are the practices of providing the defendant with a copy of the data and retaining the data for the length of the defendant's sentence.

If this methodology continues, the growing amounts and types of digital media will push budgets, processing capability and physical storage space to their limits. Compounding these problems are the practices of providing the defendant with a copy of the data and retaining the data for the length of the defendant's sentence.

## Consequences for Law Enforcement

As Table 5 shows, the number of FBI cases has tripled in just 5 years. This is the result of the increased presence of digital devices at crime scenes combined with a heightened awareness of digital evidence by investigators. The FBI has indicated that digital evidence has spread from a few types of investigations, such as hacking and child pornography, to virtually every investigative classification, including fraud, extortion, homicide, identity theft, and so on.

With this increasing prevalence of digital evidence, it is likely that a majority of all criminal investigations will involve digital evidence, and in fact, we may have already reached this point. The chief executive of the British Library estimated in 2002, that each year 250 megabytes of information was created for each person on the planet (<http://www.researchinformation.info/rispring03data.html>). The growth of digital evidence causes three related problems. First, anyone involved in conducting criminal investigation will need to be able to recognize digital evidence. While this may seem fairly straightforward, it is not. As we will discuss later in this chapter that there is a growing diversity of digital tools and toys that can hold digital evidence, and it will not always be obvious to an investigator that these small digital objects may hold the key to a crime.

The second problem is that investigators must seize and process this evidence. Again, while this may seem straightforward for a single computer with an 80 GB hard drive, the problem is much more complicated by what law enforcement now encountering: Crime scenes with several networked computers each of which may contain a 200+ GB hard drives, and several hundred DVDs. The average 40 hour forensic examination for an 80 GB hard drive will soon require several months (or years) to process all of the digital evidence from new crime scenes. The implications in terms of increased budgets for law enforcement personnel, training, hardware, and software are clear.

Finally, the ubiquity of digital evidence will require that every agency will require access to digital forensic examination services. No longer will the small law enforcement agency be able to send their digital evidence to state or federal agencies because these agencies will be overwhelmed with their own case work. Smaller law enforcement agencies must find ways of coping with this requirement.

## Solutions for Data Reduction

A simple solution to these problems is not evident, but several factors may reduce the impact of data expansion.

The most obvious is that only the specific data needed to prove guilt or innocence need be seized. Seized evidence can be further processed to reduce the amount of data which must be examined and analyzed. Forensic examiners call this data reduction.

There are a number of approaches to data reduction, each of which has advantages and weaknesses. Some of these techniques involve eliminating information based upon factors such as where the data is found in the file system, the type of data, the header information, and whether the file matches a database of known digital signatures. Once the data has been reduced on the basis of its intrinsic characteristics, it can more efficiently be searched for the content of the data.

A method currently used for data reduction involves performing a hash analysis against digital evidence. A cryptographic one-way hash (or "hash" for short) is essentially a digital fingerprint: a very large number that uniquely identifies the content of a digital file. Figure 13 displays the hashes for several files. On the left are the names of the files, and on the right, under the heading "Hash" are the 128-bit (MD5) hashes. A hash is uniquely determined by the contents of a file. Therefore, two files with different name but the exact same contents will produce the same hash. This is demonstrated in Figure 13 as "orlando.txt" is a copy of "forensic.pdf," but simply renamed. Note that they result in the same hash.

After hashing the file "CET4932.doc" we added a single space and then attempted to verify the file. As Figure 13 shows an error was generated, indicating the contents of the file have changed.

The larger the number of bits produced by a cryptographic hash algorithm, the smaller the likelihood of a collision. A collision occurs when two files with different contents result in the same hash. Even with the 128-bit MD5 hash the likelihood of a collision are astronomically small, although some researchers have been able to demonstrate the possibility. In practice we have never observed a collision. Nevertheless, to further reduce the possibility of collisions NIST developed the SHA-1 (secure hash algorithm revision 1) hash algorithm that comes in 160-, 192, and 256-bit versions. The difference in the amount of time required to calculate an MD5 versus SHA-1 is negligible with fast computers, consequently, we suggest using the 160-bit SHA-1 as a minimum.

NIST produces a set of hash sets called the National Software Reference Library that contains hashes for approximately 7 million files as of 2004 ([www.nslr.nist.gov](http://www.nslr.nist.gov)). Files in a hash set typically fall into one of two categories. *Known* files are known to be "ok," and can typically be ignored, such as system files such as win.exe, explore.exe, etc. *Notable* files are suspicious files that are flagged for further scrutiny; files that have been identified as illegal or inappropriate, such as hacking tools, pictures of child pornography, and so on. A hash analysis automates the process of distinguishing between files that can be ignored while identifying the files known to be of possible evidentiary value. Once the known files have been identified then these files can be filtered. Filtering out the known files may reduce the number of files the investigator must evaluate by half or more. NSRL contains MD5 as well as SHA-1 hashes for each file.

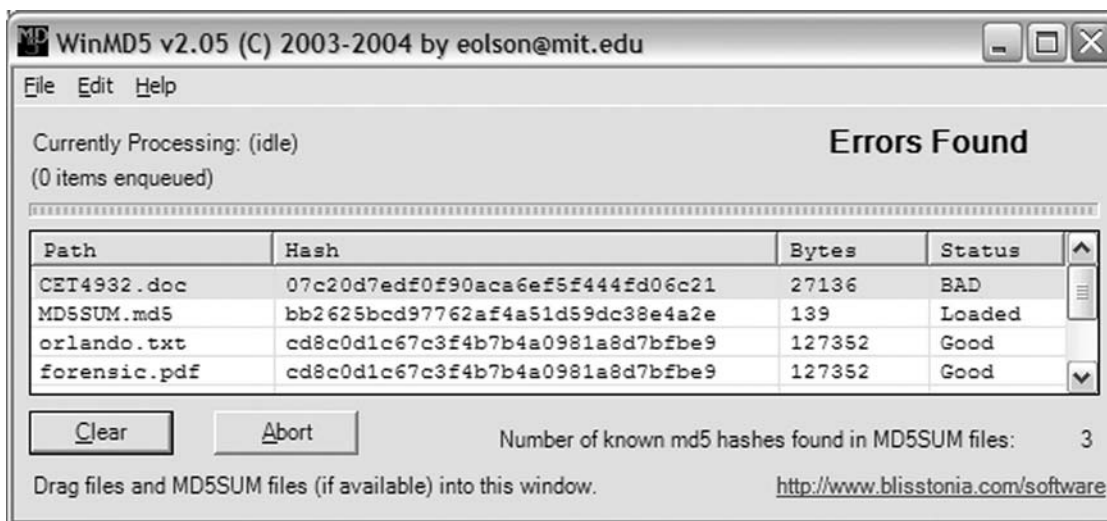

Figure 13: MD5 Cryptographic one-way hashes.

Once the data reduction process has been completed, individual data objects could be digitally signed to ensure reliability, and only contentious objects retained for court purposes. An additional approach is to make these data objects available virtually to reduce the number of physical copies needed for review and testimony.

### Using Technology to Cope

The FBI's Regional Computer Forensic Laboratory in Dallas, Texas, developed a number of innovative techniques in order to deal with the massive amounts of data seized as a result of the September 11, 2001, attacks.

One of the first techniques was to utilize commercially available network attached storage devices (NAS). At first, these devices were used to store file system images from multiple computers that were being imaged simultaneously. It did not take long to realize that the bandwidth of these devices was not up to the task, and imaging took longer than with dedicated devices. Another technique was to use these NAS devices as repository for logical copies of multiple computers. In this way, a single examination process such as a string search could be performed against multiple evidence items simultaneously. Since the processing was being done by examiner workstations that were connected over a network, bandwidth was still an issue. Another issue was that the NAS's internal operating systems did not always deal with file modification times, access times, and creation (MAC) times in a way consistent with the operating system used in the original evidence. This presented some serious issues with analytical reliability.

The primary problems with this approach can be categorized as either bandwidth issues or data reliability issues.

Despite these issues, the use of mass storage was crucial to the rapid analysis of the 9-11 data and showed tremendous promise for future improvements in forensic examination techniques. To solve the bandwidth problem, the RCFL developed the use of fibre channel architecture to connect the examination and imaging machines to the mass storage device. Utilizing this technology, bandwidth

was increased from network speeds to hardware speeds. This went a long way toward speeding up the process, but in order to allow multiple examiners to use this system concurrently, it required very expensive fibre channel switches and huge quantities of storage. To support up to 24 examiners simultaneously while processing terabytes of data, few other options existed.

The mass storage solution developed by the RCFL utilized a commercially available Storage Attached Network solution (SAN). This solution not only allowed for on-the-fly configuration of virtual drives, rapid access and redundancy but also for central management and backup. The combination of the two technologies has proven to be revolutionary.

An additional benefit to the SAN/fibre channel solution has been the ability to create virtual drives for investigator/attorney review. A drive containing the examination product can be created on the SAN, permissions can be set to prevent write access, and the drive made available over a network, where access is controlled and logged. The review of examination results over a network was pioneered by the Colorado Regional Computer Forensic Laboratory, and was further refined by the Dallas laboratory.

One might well ask why we should be interested in this very high-end process that is far more expensive than many organizations can afford. Experience has shown that the problems faced by very large Federal entities such as the FBI, IRS, and Department of Defense push the envelope of technology. The solutions developed by these organizations often can be adapted, in less expensive ways, to other organizations. Because today's "bleeding edge" technology becomes tomorrow's everyday tools, it is useful to recognize the lessons being learned every day by these large agencies. History has shown that the problems faced by these agencies tend to migrate downward and become problems for smaller organizations.

### The Explosion of Diverse Digital Media

Volume of data is not the only growing challenge facing forensic investigators. The increasing diversity of storage objects and data formats can also present formidable

problems to law enforcement. These challenges include recognizing new media, obtaining technology to read new objects and formats, and developing the expertise to forensically examine each new format.

Technology product life cycles are short, but criminal investigations and prosecutions often take a number of years. Likewise, law enforcement training cycles are usually measured in years. As a result, investigators and forensic examiners must have the training and equipment to deal with several generations of technology.

As this chapter is being written, the epitaph for floppy disks is also being written (Niesse, 2004); however, there are likely millions of floppy disks sitting in evidence rooms around the world that investigators will need to access and examine for years to come. Likewise, large amounts of data storage are being added to an increasing variety of everyday objects. This presents an increase in the number of sites in which probative evidence may be found and often leads to multiple redundant sources of the same data. Because redundant/related evidence may be present in multiple locations such as desktop computers, laptop computers, phones, and PDAs, there are advantages to adopting a "case-focused" examination of all collected evidence, as opposed to a "media-centric" examination in which each piece of media is examined separately.

Along with the proliferation of devices incorporating digital storage capacity, the variety of storage formats has increased. An example of this is found in the portable music devices that contain miniature hard drives and flash memory. While sharing a common purpose, each supports a variety of storage formats, many of which are proprietary.

From a forensic perspective, the examiner needs to understand each of these formats and must have hardware and software capable of examining each type. The challenges presented by the growing myriad of digital devices are only exacerbated by the fact that these devices now hold a quantity of information that would have unimaginable only a few years ago.

While it may be obvious that a desktop computer's hard drive, laptop, CD, or floppy disk might hold evidence, there may be sources of digital evidence that may be overlooked by the first responder who has not been trained to identify digital devices. Common place devices that now hold digital files are ubiquitous. A new version of the Swiss army knife includes a USB data storage that can hold 256MB of digital files. Similarly, there are several watches and pens that hold 256MB of digital files. It is not clear from simple observation that these simple, common devices have a dual purpose.

The simplest and most cost-effective solution for the problem of recognizing digital storage devices is continual, mandatory training. First responders and investigators must be trained to perform a thorough investigation of all elements at a crime scene, not matter how innocuous a device might seem. Our preferred solution to this problem would be a set of courses developed and maintained by, or overseen by, a federal agency and provided in an online format such as a series of Web-based training courses. Law enforcement budgets have always been tight. Online courses would obviate the need for travel which is always costly.

The growth in size and diversity of data storage is a continuing problem that will not likely disappear soon. The challenges associated with this growth are likely to become more even problematic over time, as digital data becomes more ingrained into the fabric of everyday life. These challenges will necessitate organizational, training, financial, and operational evolution if law enforcement is to provide competent and timely service in the coming years.

## A LAW ENFORCEMENT VIEW OF THE FUTURE OF DIGITAL EVIDENCE

The volume and pervasiveness of digital evidence will force law enforcement to adapt in a wide variety of ways. The current volume overwhelms the currently deployed resources, as volume increases substantial new resources will be needed. Additional people with significantly higher levels of education and training will be required to manage and process the growing amounts of digital evidence. New hardware and software tools will be needed to more efficiently process the increased volume of evidence. But the increase in pervasiveness will affect a much broader range of issues in law enforcement.

Today, digital evidence is collected in only a fraction of cases. As more of our lives are spent and recorded online, law enforcement will have to provide for the collection and preservation of digital evidence in virtually every case. As more and more of law enforcement's activities are digitized, from computer-aided dispatch systems, digital booking systems, and even digital video cameras in patrol cars, policies and procedures will need to be adapted to ensure the integrity of these evidentiary records. In fact, the volume of internally and externally generated information will require agencies to not merely automate but rather to develop specialized law enforcement enterprise architectures. While law enforcement has been evolving from "high touch" to "high tech," that transition must go from bureaucratic sloth to Internet time.

The hardware and software tools used by law enforcement practitioners will have to evolve along with the available technology or rather beyond it. Keeping up with current technology trends is essentially impossible. Technology diffusion in society can take years, and law enforcement, being conservative in nature, is typically slow to embrace the latest and greatest in technology. Although public agencies may not be able to "get ahead of the curve," the creative use of cutting edge technologies can provide significant leverage. For instance, there is a growing trend, exemplified at the Dallas Regional Computer Forensic Labs, to the use of aggregated storage coupled with very fast input/output channels to create storage area networks (SANs). This is an example of leveraging human and technical resources in ways that individual agencies cannot.

Forensic software will have to evolve as well. Currently, virtually all of the forensic software focuses on the documentation and data recovery aspects of the examination. What few tools, such as filters for header information or text string search tools, are in use are designed with the notion of answering the question: "Is it there?" rather

than “What do we know about the information contained in this digital evidence.” Consequently, more research is needed that assists law enforcement deal with the deluge of information they are facing. One of the current research trends is to use data mining techniques to assist law enforcement in identifying evidence from terabytes of data. Data mining uses statistical, clustering, or artificial intelligence techniques to reduce large volumes of data to a manageable size, by identifying patterns among the individual data elements.

Another change that will significantly impact law enforcement is the increase of network-connected devices. As our phones, computers, entertainment devices, and household appliances become connected, we will have many more sources of digital evidence to integrate into a given investigation. Further, networked communications, which has expanded from text e-mail into video, audio, and rich-text forms easily and quickly sent and received from a wide variety of devices, will require the largely “static” evidence focus to expand substantially into the dynamic collection of data in transit. This change will have both technical and legal implications. Law enforcement’s technical capability to collect, preserve, process, and analyze intercepted dynamic data is generally primitive and very labor intensive. New tools and processes will have to be developed if the large proportion of data is transient. The current legal schema for collecting communications evidence, despite being updated in 2001 with the USA Patriot Act, essentially is modeled on a 1960’s notion of communication. The Patriot Act’s mechanics are so onerous that it is used only in situations which can justify the huge overhead of the application process, the live monitoring and minimization, court reporting and notice requirements. If this process is not streamlined, then a very high proportion of the available evidence will not be collected.

## GLOSSARY

- Code walkthrough** analysis of source code by programmers and managers for quality assurance purposes.
- Data recovery** Finding latent information and restoring its context.
- Data reduction** Eliminating data that is not significant.
- Digital evidence** Information of probative value stored or transmitted in digital form.
- Duplicate digital evidence** An accurate digital reproduction of all data objects contained on an original physical item (see forensic image).
- Forensic image** An exact, bit-for-bit copy of media.
- Hash** Also known as a message digest, cryptographic hash, or one-way hash. A hash is a hex value, typically 128- or 160-bit, that is unique to the contents of a file.
- MD5 hash** A 128-bit cryptographic hash algorithm created Ron Rivest of MIT.
- Metadata** A file’s metadata consists of all information about the file excluding its contents: file name, size, MAC times, starting cluster, permissions, attributes, etc.

**Original data evidence** Physical items and the data objects associated with such items at the time of acquisition or seizure.

**Physical evidence** Items on which data objects of information may be stored and/or through which data objects are transferred.

**Regression testing** Testing performed to find bugs in software applications or modules after new code is added.

**SHA-1 hash** the Secure Hash Algorithm version 1, a 160-bit cryptographic hash developed by the National Institute for Science and Technology.

**Unallocated space** the clusters not in use by a file. Where deleted files reside.

## INTRODUCTION AND FOUNDATIONS OF COMPUTER FORENSICS

In this section, we present the main concepts, background information, and foundations of computer forensics.

### Definition

In 2001, computer forensics was defined as “the use of scientifically derived and proved methods toward the preservation, collection, validation, identification, analysis, interpretation, documentation, and presentation of digital evidence derived from digital sources for the purpose of facilitation or furthering the reconstruction of events found to be criminal, or helping to anticipate unauthorized actions shown to be disrupted to planned operations” (Digital Forensics Research Workshop, 2001). Computers can be used to steal private information, tarnish the reputation of organizations or individuals, rob money, or even brag about the technical capabilities of attackers. Moreover, cyberattackers can use technology to exchange electronic messages to coordinate their actions or to hide prohibited secret information.

The core of digital forensics is to gather evidence and to analyze it to apprehend attackers. To build a strong link between the evidence and the attacker, the investigator should possess sufficient skills. Also, he or she must have enough knowledge about the legal framework or the internal security policies, depending on the nature of the digital crime.

### Computer Forensic Process

Despite the abundant research activity related to digital forensic models, the tasks constituting the forensic

process have not been standardized yet. Many of the proposed guidelines are specific to several technologies or systems and are not yet open enough to be applied to various kinds of digital attacks. For example, the model proposed by Farmer and Venema (1999), which forms the kernel of the well-known Coroner's Toolkit is specific to UNIX systems. In 2001, the U.S. Department of Justice (DoJ) presented a four-step model (National Institute of Justice, 2001), including “collection, examination, analysis, and reporting.” In 2001, the Digital Forensics Research Workshop introduced three extra phases (“identification,” “preservation,” and “decision”) making the framework more appropriate to computer forensics. In fact, the DoJ model does not take into account some particular characteristics of this field. Identification, for instance, becomes more complex in the case of digital forensics because of the huge volume of available data that may need to be analyzed. This model was then enhanced by Reith, Carr, and Gunsh (2002), who added some ideas derived from traditional FBI forensics procedures (FBI, 2002). Recently, Rowlingson (2004) proposed a 10-step process that guarantees evidence readiness (i.e., the evidence is accessible when it is required to support a legal process) (Tan, 2001). These approaches are, in essence, similar. The slight differences between them reside in several details. Effectively, the computer forensic process should be flask to support most of the concrete cases. For instance, the identification step should not be performed if the digital evidence is used as an alibi.

In the following, the most important steps that are shared by the aforementioned models are discussed. More precisely, evidence collection, preservation, and analysis, as well as intention inference, will be focused on.

The first task is to locate and identify useful evidence. To this end, the investigator should seize the various hardware that may contain relevant information. Unfortunately, this is not always possible to perform. Meanwhile, computers, hard disks, or CD-ROMs can be seized; local area networks (LANs) and communications infrastructures, which can hold key elements, are difficult or even impossible to seize for evidence purposes. Moreover, the complexity of evidence collection depends heavily on the cleverness of the attacker. For instance, the use of encryption scrubbing tools makes evidence harder to reach.

Once gathered, the evidence has to be correctly maintained to prevent it from being totally or partially lost. In fact, the attacker may try to get back the hardware evidence to avoid being caught. He or she can also delete or alter digital information that constitutes a proof against him or her. Thus, evidence integrity is a key factor that should be considered to guarantee admissibility if needed (Stephenson, 2003).

The two last steps are crucial to have a sound interpretation of the collected information. The time, techniques, or location of attack's source, to name just a few, are elements that can help the forensic analyst in his or her task. Just like traditional crimes, profiles can be built to characterize criminals. Evidence analysis and suspect intention inference are so close that they could be merged in the same step. Their separation comes from the fact that different skills are needed for different tasks. Evidence analysis involves a deep context-specific scientific knowledge, whereas behavior modeling can be used through the use of traditional techniques.

A key feature of digital forensics is that the quantity of gathered information can be so big that it becomes hard to analyze. For example, visualizing the content of five megabytes of electronic documents or log files could not be done manually. To this end, various automated tools can assist investigators to accelerate the search of digital evidence or to conduct an inference-based reasoning to analyze the attack. These topics are more thoroughly discussed below.

It is noteworthy to point out that the cost estimation, which is of great importance, was somewhat absent from the cited forensic models even though Wolfe-Wilson and Wolfe (2003) established several links between the forensic activity and the business continuity plan or the incident response plan. Before beginning to conduct the investigation, the criminologists should quantify the estimated cost of the process in terms of effort, money, and time. Adding this phase has two benefits. First, it helps investigators decide whether it is beneficial to conduct the investigation. Second, it constitutes a reliable basis to schedule the various activities so that a maximum level of efficiency is reached.

## Computer Evidence Requirements

To recognize digital evidence as legal proof to indict or to discharge a suspect, it has to conform to several requirements. In particular, the evidence should not be altered, and examination results should be accurate, verifiable, and repeatable. However, the most crucial requirement an investigation should fulfill is authenticity, that is, to

demonstrate that a given (hardware or software) piece of evidence is effectively related to the suspect. For example, to link data on a computer to individuals, the investigator can use access control logs, cryptographic-based authentication, or biometric features. Conversely, to prove malicious network activity, he or she can rely on IP addresses, passwords, or digital certificates. A reoccurring problem at this stage is to consider the case where an alibi is investigated. In fact, the reliability of the evidence, especially time and location, is the main issue to prove in such cases. Another issue is that pieces of evidence should be admissible, meaning that they should be acceptable legally. This assumes that the investigator must be aware of the legal framework.
